The anti-DNA antibodies are the most highly associated autoantibodies in lupus nephritis. The pathogenicity of anti-DNA antibodies in this setting is suggested by three separate observations: (1) anti-DNA levels tend to correlate with the relative activity of lupus nephritis,[80–82] (2) the anti-DNA antibody can be isolated from the glomeruli of the affected kidneys,[83] and (3) nephritis can be induced in normal mice by administration of monoclonal anti-DNA antibodies.[84] Lupus nephritis can be present in the absence of anti-DNA, a finding suggesting additional or alternative mediators.

Immune complexes of SLE can activate the classic complement pathway. Therefore, the detection of the consumption of complement may also be useful in supporting the diagnosis of lupus nephritis. Hypocomplementemia, both low C3 and C4, is found at presentation in more than three-fourths of patients with SLE and is more common with lupus nephritis.[84,85] Because of the activation of the classic complement pathway in SLE, serum C4 is often used as an index of the inflammatory state and disease activity in lupus nephritis. Successful treatment of SLE typically results in improvement in C4 and C3. However, in patients with a genetic C4 deficiency, complement C4 remains persistently decreased. Along with positive autoimmune serologic findings, patients with lupus nephritis have a varying degree of renal dysfunction. Alternatively, renal dysfunction may be minimal or even absent in lupus nephritis.

The most useful laboratory studies to support the diagnosis of nephritis in a patient with SLE includes the urinary sediment urine protein to creatinine ratio from a first morning specimen, serum creatinine, and renal biopsy. The renal biopsy findings are used to define the class of lupus nephritis and also drive the choice of immunosuppressive therapy in a given patient. Additional laboratory evaluation includes a complete and differential blood cell count to screen for anemia, thrombocytopenia, and leukopenia because pancytopenia or suppression of individual cell lines can be seen on presentation of uncontrolled SLE. Serum albumin is often used to define the impact of proteinuria further. The ratio of serum

albumin to globulin is generally reversed in SLE (normal, 2:1) because of the presence of hyperglobulinemia resulting from high serum levels of multispectrum antibodies in these patients.

Diffuse lupus glomerulonephritis (class IV) is seen in 20% to 50% of all children presenting with SLE who undergo renal biopsy,[86] with a higher incidence in African-American and Hispanic children. In the Glomerular Disease Collaborative Network patient registry, with a predominantly African-American patient group, 54% of children and adolescents who underwent biopsy for diagnosis and classification of lupus nephritis had diffuse lupus glomerulonephritis (class IV).

Just as the overall systemic disease may wax and wane, and involve new systems, lupus nephritis may recur, or it may change to a different pathologic class over time. Relapse of renal disease after treatment of lupus nephritis may be identified by the laboratory evaluation of urinalysis, the degree of proteinuria, the presence of hypoalbuminemia, and the rise in serum creatinine (Table 26.7) in these patients.

KEY POINT

Renal pathologic features of lupus nephritis can change over time.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for a patient suspected of having SLE nephritis can be narrowed based on the presence or absence of other clinical and laboratory findings. HSP can manifest with joint pain, systemic symptoms, nephritis, and a purpuric rash. HSP is, however, characterized by an absence of significant ANAs. Furthermore, the renal biopsy results in HSP demonstrate a dominant IgA staining pattern on immunofluorescence that is not seen in SLE.

Peri-infectious syndromes may also masquerade as SLE, especially if both nephritis and arthritis are clinically present. Unfortunately, the ANA test result may also be positive in this setting, thus complicating the picture. If the kidney biopsy findings are inconclusive, and the history of a

preceding infection is convincing, the presumed infection is treated and the patient is observed. Close follow-up is warranted, and the aggressive immunosuppressive regimen required for proliferative lupus nephritis lesions is reserved for patients with a confirmed diagnosis.

ANA positivity can be seen in other rheumatologic diseases that may involve the kidney, particularly in mixed connective tissue disease and rheumatoid arthritis (RA). The diagnosis of RA may be established by radiologic evaluation of the affected joints, which may show erosions and deforming arthritis. Therefore, a presentation with renal disease, a positive ANA test result, and deforming arthritis is suggestive of RA. Finally, thrombotic thrombocytopenia purpura (TTP), which may occur in the setting of SLE, can lead to significant renal disease with symptoms of oligoanuria, acute renal failure, hemolytic anemia, and thrombocytopenia, far exceeding those expected with the classic lupus nephritis lesion. An assessment of the ADAMTS13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13) level should be sufficient to differentiate this disease from SLE. Because TTP does not respond to the therapy used to treat lupus nephritis, it is crucial that this disorder is identified and treated appropriately.

TREATMENT STRATEGIES

To date, there are no randomized controlled trials or comprehensive cohort studies to suggest the optimal treatment for children with lupus nephritis. Therapy for pediatric lupus nephritis is based on the histologic classification of

---

KEY POINTS

- Treatment for lupus nephritis is based on the renal biopsy pathologic findings.
- Class I and II lupus may respond to corticosteroids and management of extrarenal manifestations of SLE.
- Proliferative lupus nephritis (class III and IV) requires escalation of immunotherapy regimen.

Table 26.7 Laboratory parameters used to identify uncontrolled systemic lupus erythematosus nephritis relapse.

Relapse		
Mild	Moderate	Severe
Hematuria increasing. RBC casts may be present	Increasing serum creatinine (within 30% of baseline)	Serum creatinine increasing ≥ 30% over baseline
Sterile Pyuria. WBC casts may be present	Proteinuria increasing up to 2 fold from baseline and UPC < 5 g/g	Proteinuria increasing and UPC ≥ 5 g/g

the renal lesion and the results of clinical trials conducted in adults with lupus nephritis. It remains unclear whether a given lesion on a pediatric biopsy equates to that seen on an adult biopsy and whether the findings in adult trials can be generalized to children. However, the standard of care at present involves the use of those drugs that were found to be successful in adult trials. Given this situation, determining the optimal balance between potential benefits and adverse side effects continues to be a priority in the treatment and future research of the pediatric patient with lupus nephritis.

CLASS I AND II LUPUS NEPHRITIS

Minimizing the inflammatory state with the use of immunosuppressive drugs remains the primary therapeutic modality in the treatment of SLE and lupus nephritis. In addition, patients with all classes of lupus nephritis may benefit from supportive measures such as adequate nutrition, optimal blood pressure control, and diuretics for edema. ISN classes I and II occur less frequently in patients who have undergone biopsy. (see Table 26.4).

In general, treatment for class I is directed at the treatment of the SLE extrarenal manifestations. Treatment of class II lupus nephritis is guided by the degree of proteinuria. Corticosteroid treatment alone may be effective in reducing urine protein to less than 3 g/day. If corticosteroids are ineffective, or if there is a relapse of urine protein with an attempt to reduce or wean from steroid treatment, it is reasonable to consider calcineurin inhibitor therapy for patients with class II lupus. The risk of long-term immune suppression when there is no clear evidence that class I and II lesions have long-term renal health import must be considered. Careful surveillance is required to ensure that if transformation to a more severe kidney lesion occurs, the lesion can be identified and treated in a timely fashion.

CLASS III AND IV LUPUS NEPHRITIS

Clinical trials data indicate that corticosteroids alone are not effective for inducing remission in patients with actively proliferative lupus nephritis. Corticosteroids are more appropriately combined with at least one other immunosuppressant agent in this setting. Patients with focal proliferative glomerulonephritis (class III) or diffuse proliferative lupus nephritis (class IV) are at the greatest risk of progression to end-stage renal disease (ESRD) if the nephritis is left uncontrolled.[9,11,87] These two clinicopathologic subgroups of lupus nephritis are best treated with another immunosuppressive, in addition to corticosteroids. Additional indicators for aggressive immunotherapy for class III lupus nephritis are (1) elevated creatinine level at the time of renal biopsy, (2) severe nephritic syndrome, (3) the presence of crescent formation in the biopsy specimen, (4) severe tubulointerstitial disease, and (5) evidence of vasculitis.[88]

In general, immunosuppression treatment regimens are separated into two phases: (1) induction, a time of maximal immune suppression exposure; and (2) maintenance, when immune suppression can be reduced, with the goal to limit side effects yet maintain renal remission. The ideal second agent and the length of treatment with additional immunosuppressants continue to evolve.

Cyclophosphamide

The initial National Institutes of Health (NIH) regimen, which included 2 years of cyclophosphamide exposure combined with corticosteroids, improved renal survival and set the stage for future regimens.[89–97] Unfortunately, this regimen is also associated with significantly higher morbidity in patients. The NIH lupus nephritis treatment regimen (2001 version) involved induction with intravenous methylprednisolone, 1 g/m^2 of body surface area, administered as a monthly bolus for at least 12 months, and it could be extended to 36 months.[9] Intravenous cyclophosphamide was given in a dose of 1000 mg/m^2 of body surface area, as a monthly bolus for 6 consecutive months, and then once every 3 months for at least 24 additional months. Patients failing to respond after 1 year could be considered for recycling of therapy. Recycling was limited to no more than twice.

Because of side effects associated with high-dose cyclophosphamide use in the NIH regimen, the Euro-Lupus Nephritis Trials (ELNT) compared the efficacy of low-dose intravenous cyclophosphamide with the standard high-dose NIH regimen.[96,97] All adult patients received three daily 750-mg intravenous methylprednisolone pulses, followed by oral glucocorticoid therapy at an initial dose of 0.5 mg equivalent prednisolone/kg/day for 4 weeks. After 4 weeks, glucocorticoids were tapered by 2.5 mg prednisolone every 2 weeks. The high-dose cyclophosphamide group received eight intravenous cyclophosphamide (Cytoxan) pulses within a year, given as six monthly pulses followed by two quarterly pulses. The initial cyclophosphamide dose was 0.5 g/m^2 of body surface area, and the subsequent doses were increased by 250 mg, according to the white blood cell count nadir measured on day 14, with a maximum of 1500 mg per pulse. Patients assigned to the low-dose group received six fortnightly intravenous cyclophosphamide pulses at a fixed dose of 500 mg. In both arms of the trial, azathioprine (2 mg/kg/day) was started 2 weeks after the last Cytoxan dose. Mean serum creatinine in the low-dose group was 1.0 ± 0.6 mg/dL, and it was 1.0 ± 0.4 mg/dL in the high-dose group, at 10-year follow-up. Similarly, 10-year follow-up proteinuria was 0.5 ± 1.0 g/day in the low-dose group

and 0.6 ± 1.3 in the high-dose group. The investigators concluded that low-dose intravenous cyclophosphamide followed by azathioprine (now known as "Euro-Lupus regimen") achieved remission rates as favorable as those of the high-dose cyclophosphamide therapy. Because this trial was conducted in white patients of European ancestry, its application to wider ethnic groups remains to be validated.

Mycophenolate mofetil

Although cyclophosphamide continues to be one of the cornerstones of therapy (both oral and intravenous regimens have trial support), efforts are under way to achieve remission with the fewest side effects. A mycophenolate mofetil (MMF) induction regimen has received considerable attention. MMF induction in patients with active lupus nephritis (class III, IV, or V) as compared with intravenous cyclophosphamide was shown to result in a greater number of complete and partial remissions of lupus nephritis.[98] The youngest patient enrolled in this trial was 19 years old. In this induction phase study, the most severe infections were noted in the cyclophosphamide-treated group. Follow-up data continue to support the usefulness of MMF induction; MMF-induced patients had similar plasma creatinine concentrations, urinary protein, and activity of urine sediment as patients who underwent induction with cyclophosphamide therapy. Although there was a trend toward a greater relapse rate in the MMF-induction patients (15%) compared with cyclophosphamide (11%), this study opened the door to using MMF as induction therapy, particularly in those patients with the greatest risk for the infertility side effects of cyclophosphamide.[98] Additional small studies in children have also shown a modest benefit of MMF in active or progressive lupus nephritis.[99–101] Long-term follow-up of MMF induction in lupus nephritis, compared with the data on efficacy of cyclophosphamide, is limited at present.

KEY POINT

MMF can be an effective induction agent in a selected population with proliferative lupus nephritis.

A major advantage of the use of MMF, especially in children, is its ease of administration (as an oral medication). However, treatment regimens need to limit MMF use in female patients at risk for pregnancy, given the risk of fetal malformation and miscarriage during the first trimester with the use of this agent.

Rituximab

Rituximab (Rituxan) is a humanized monoclonal antibody initially approved for treatment of B-cell malignant diseases. Rituximab has been considered in uncontrolled retrospective studies as an induction agent for patients with proliferative lupus nephritis. Its therapeutic mechanism is that of destruction of a specific population of B cells. Because B cells are the progenitors of the antibody-producing plasma cells, their modulation, in theory, could modulate SLE, an antigen-antibody driven disease. The efficacy and safety of a regimen of rituximab as compared with placebo were tested in the adult Lupus Nephritis Assessment with Rituximab (LUNAR) study).[102] Although rituximab therapy led to a greater response profile (greater reduction in anti-dsDNA and C3/C4 levels), it did not improve the clinical outcomes of the treated patient population (72 patients) at 1 year.

Failure of the LUNAR study dampened the expectation of the usefulness of rituximab as an induction agent, but its role in "resistant" proliferative glomerulonephritis is still being considered. Three separate uncontrolled studies have suggested the effectiveness of rituximab in this setting.[103–105] In a retrospective review of 19 patients who had rituximab added to their regimen after standard therapy (cyclophosphamide and prednisolone) failed, all patients responded with improved renal function, serologic findings, and hematologic profiles.[104] In another trial, the addition of rituximab allowed shortening of the cyclophosphamide regimen.[106] Sufficient follow-up to draw formal conclusions about long-term remission rates remains unclear.

Other biologic agents

Belimumab (Benlysta) is the newest anti–B-cell drug to be used in the setting of SLE. Belimumab is a human monoclonal antibody that inhibits the soluble form of the B-cell survival factor, B-lymphocyte stimulator (BLyS). It is approved by the Food and Drug Administration for patients with SLE who continue to have active antibody-positive lupus despite standard therapy (including glucocorticoids, antimalarial drugs, and immunosuppressive agents). Although belimumab was found to improve the SLE responder index (SRI)

KEY POINT

Rituximab and other biologic agents have not succeeded as induction agents in proliferative lupus nephritis.

in patients in randomized, controlled trials, there is no evidence for its efficacy in lupus nephritis.[107] Some more recent case reports, however, support its use as a maintenance agent in lupus nephritis.[108] Abatacept (Orencia), another monoclonal antibody that inhibits T-cell responsiveness by blocking the second signal from the antigen-presenting cell, has been approved for use in juvenile arthritis. In one trial, the addition of abatacept to a regimen of cyclophosphamide followed by azathioprine did not improve the outcome of lupus nephritis at either 24 weeks or 52 weeks.[109]

Plasmapheresis

Plasmapheresis has not been formally studied in lupus nephritis in children. In adult patients, a randomized controlled trial of plasmapheresis, with a standardized treatment protocol consisting of prednisone and cyclophosphamide, failed to improve the outcome of severe lupus nephritis.[110] Although plasmapheresis as a treatment modality for lupus nephritis has been abandoned, case reports support its use in the setting of antiphospholipid or TTP overlap with lupus syndromes.[111]

KEY POINT

Plasmapheresis, as a supportive therapy, has not been effective in the treatment of lupus nephritis.

CLASS V OR MEMBRANOUS LUPUS NEPHRITIS

Membranous lupus nephritis has the potential for morbidity secondary to uncontrolled nephrotic syndrome and, less commonly, chronic kidney disease or ESRD. Treatment of this disorder is not as clearly defined as that for the proliferative lesions, and no randomized trials have been published. Treatment regimens have included supportive therapy with angiotensin-converting enzyme inhibition in combination with systemic SLE-targeted immunosuppressive regimens or angiotensin-converting enzyme inhibition in combination with additional immunosuppressive agents including cyclosporine, azathioprine, MMF, or cyclophosphamide, with or without corticosteroids.[112] A retrospective review

KEY POINT

Treatment of class V lupus nephritis consists of supportive management of nephrotic syndrome and modest immunosuppressive therapy.

found no significant difference in achievement of response in either hematuria or proteinuria for membranous lupus nephritis as opposed to proliferative lupus nephritis.[113]

The low risk of ESRD from membranous lupus nephritis (approximately 5% to 15% at 10 years) has encouraged a less aggressive approach to management compared with proliferative lupus nephritis lesions.[114] However, the significant morbidity associated with uncontrolled nephrotic syndrome, including the potential for accelerated atherosclerosis, thrombosis, and infections, supports intervention. In addition, a retrospective review documented that the coexistence of membranous and proliferative lupus nephritis portends a worse renal prognosis than does the presence of a proliferative lesion alone (16.1% vs. 6%) and therefore justifies a more aggressive treatment plan.[113]

DILEMMA OF TREATMENT SELECTION IN CHILDREN

Limited randomized data exist for the application of each of the foregoing treatment modes in children. In general, pediatric nephrologists extrapolate from the adult patient literature to build treatment plans that reflect the best randomized controlled data combined with experience. Toward that end, proliferative lupus nephritis lesions are approached with combination regimens. A combination of corticosteroids and cyclophosphamide is the most frequently used regimen, although the length of therapy is variable. Reported steroid regimens have varied considerably; consistently, however, once remission has been established, steroids are tapered to the lowest clinically effective dose to limit side effects. Alternative induction regimens with agents such as MMF and corticosteroids are used because they offer fewer side effects, but long-term renal survival data are lacking. Similar to azathioprine, MMF has also gained a place in the maintenance phase of therapy for lupus nephritis lesions in children. Although not specifically structured for pediatric care, the American College of Rheumatology has suggested treatment guidelines which could provide a road map when considering the treatment options for pediatric patients with lupus nephritis (Figures 26.7 and 26.8).[115]

PATIENT OUTCOME

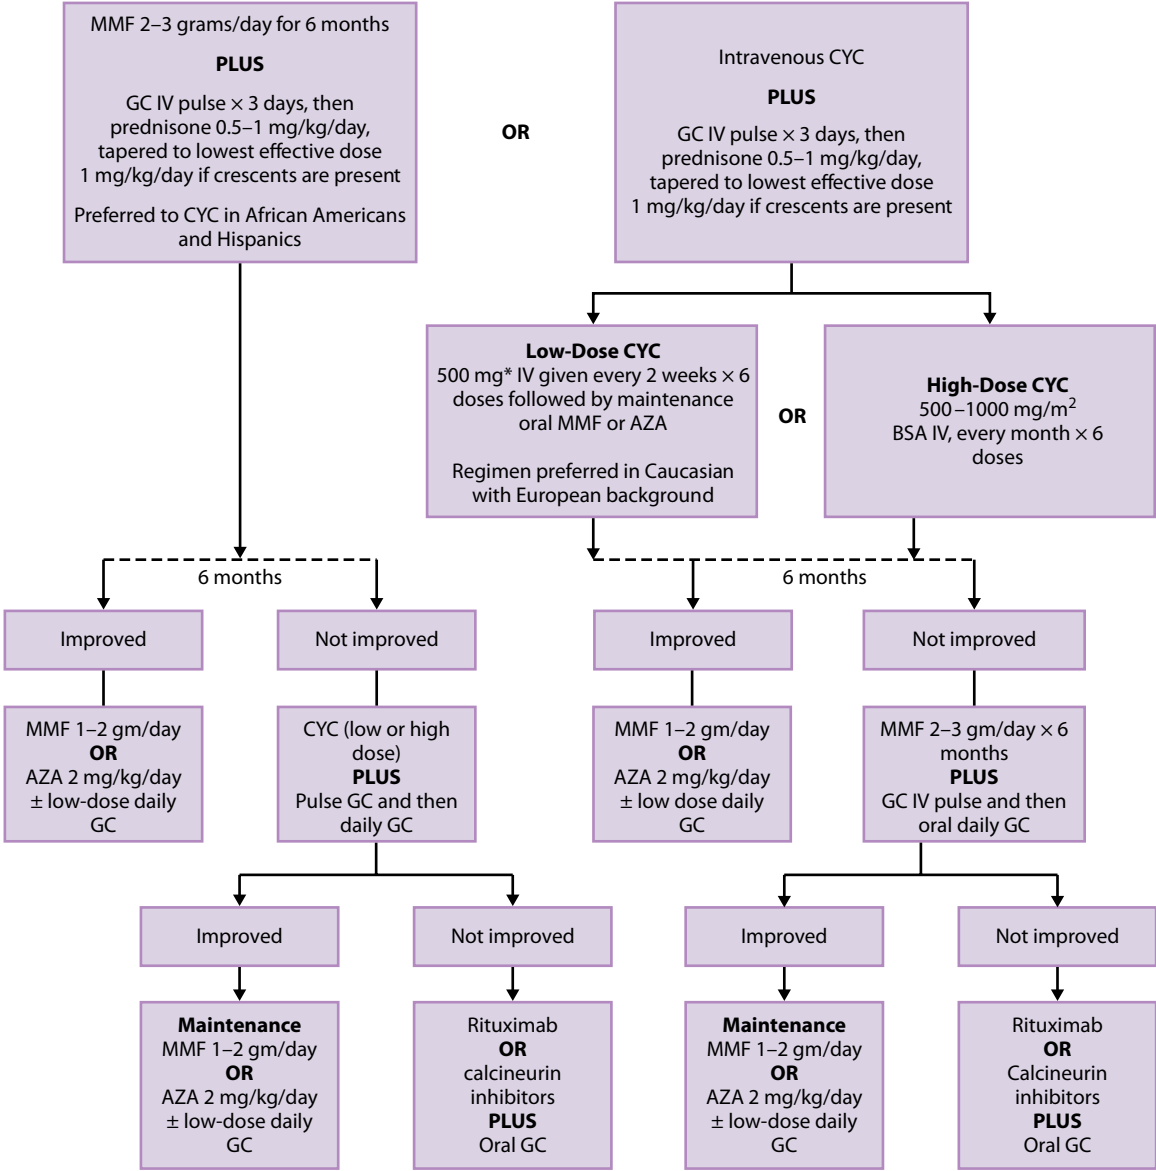
Although the 5-year survival for children with lupus nephritis is 83% to 97%, the 5-year renal survival can be variable and depends on the renal pathologic features.[21] Overall improvement in the prognosis of SLE, as well as lupus nephritis, has been demonstrated since the 1980s. In a retrospective analysis of children with WHO class III and IV lupus nephritis who were seen in the 1965 to


Figure 26.7 American College of Rheumatology guidelines for induction therapy in adult patients with biopsy-proven class III/IV lupus nephritis. Dosing of drugs in pediatric patients should be appropriately adjusted. AZA, azathioprine; BSA, body surface area; CYC, cyclophosphamide; GC, glucocorticoids; IV, intravenous; MMF, mycophenolate mofetil; *dose may require adjustment in children less than 1 year of age. (From Hahn BH, McMahon MA, Wilkinson A, et al. American College of Rheumatology guidelines for screening, treatment, and management of lupus nephritis. Arthritis Care Res [Hoboken]. 2012;64:797–808.)

1992 era, survival was reported to be 82.8% at 5 years and 67.7% at 10 years, and renal survival was 44.4% at 5 years and 29% at 10 years.[116] In a retrospective study of 66 Canadian children with biopsy-proven class IV lupus nephritis (1984 to 1991), the renal survival rate at 5,10, and 15 years was 87%, 72%, and 65%, respectively.[117] During a mean follow-up of 11 years, the overall mortality rate was 6%, with sepsis the most common cause of death. Pereira et al.[21] reported renal survival in childhood-onset lupus nephritis over a 30-year period (1980 to 2010). This retrospective study suggested that modern treatment protocols seem to offer a survival advantage, with 5-year renal survival rates as high at 91%. Indicators

of poor overall renal prognosis included nephrotic-range proteinuria, renal function lower than normal at presentation, and proliferative nephritis. In addition, escalating urine protein concentrations despite treatment portend a poorer renal prognosis.

KEY POINT

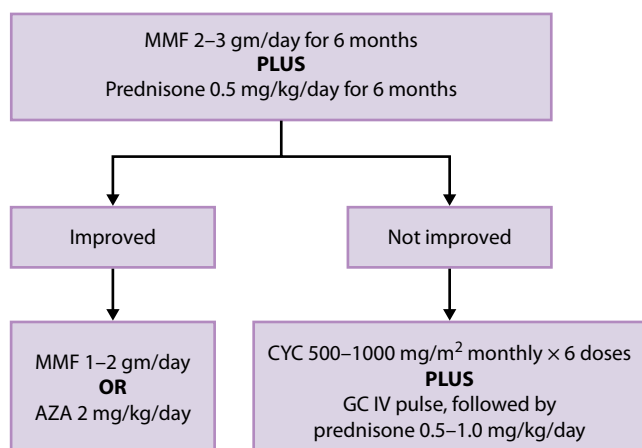
Indicators of poor renal prognosis include nephrotic range proteinuria, poor renal function at presentation, and a proliferative lesion on biopsy examination.


Figure 26.8 American College of Rheumatology guidelines for induction therapy in adult patients with biopsy-proven class V (membranous) lupus nephritis. Dosing of drugs in pediatric patients should be appropriately adjusted. AZA, azathioprine; CYC, cyclophosphamide; GC, glucocorticoids; IV, intravenous; MMF, mycophenolate mofetil.(From Hahn BH, McMahon MA, Wilkinson A, et al. American College of Rheumatology guidelines for screening, treatment, and management of lupus nephritis. Arthritis Care Res [Hoboken]. 2012;64:797–808.)

COMPLICATIONS

Complications resulting from lupus nephritis can be divided into two main categories: (1) those that result from the chronic disease itself and (2) those that are related to the toxicity of therapeutic regimens. Infection is a major cause of morbidity in pediatric patients with SLE, presumably resulting from hypocomplementemia and decreased number and function of neutrophils.[21,116,117] This problem is further complicated by the therapeutic use of immunosuppressive agents. Long-term follow-up of one NIH trial documented that 26% of patients taking cyclophosphamide developed a serious bacterial infection.[92] This number increased to 32% when steroids were added to the treatment regimen. These data are among the primary driving forces behind defining newer, less immunosuppressive, yet effective therapies.

Infertility is a significant concern associated with therapy for lupus nephritis. Boumpas et al.[118] reported that 51% of women who are more than 30 years old are at risk of ovarian failure after treatment with cyclophosphamide. The concomitant use of a gonadotropin-releasing hormone agonist, such as leuprolide acetate, has been suggested to induce a state of ovarian protection from the cyclophosphamide effect,[119] although general agreement on its efficacy and protocols describing how it is to be used are lacking. Bladder cancer and lymphoproliferative disorders have been documented following cyclophosphamide. In children and adolescents, the incidence of these side effects from the currently low-dose cyclophosphamide regimens is unknown but presumably low.

Steroid therapy alone or in conjunction with other immunosuppressives is associated with further complications. Avascular necrosis has been reported in as many as 30% of patients treated with significant methylprednisolone exposure. Cataracts without visual impairment are a well-documented morbidity associated with significant steroid use. Hyperglycemia, short stature, and osteopenia may also be caused by intense or prolonged courses of corticosteroids.

SUMMARY

SLE is a multisystem, autoimmune disorder that occurs in children, adolescents, and adults. Although SLE is more common in girls and women, in general, it affects African-American children more severely (Clinical Vignette 26.1). Renal disease associated with SLE can be quite diverse in pathologic features, as well as in long-term outcome. Whereas membranous nephropathy has a better clinical outlook, diffuse proliferative lesions are associated with risk of progressive chronic kidney disease and ESRD. Treatment with steroids and cyclophosphamide has been the "gold standard" for treatment of severe lupus nephritis, but MMF and lower-dose cyclophosphamide are being shown to be equally effective in controlling lupus-associated nephritis. Failure of some of the monoclonal biologic agents in recent years has been disappointing, and their role in treatment of lupus nephritis remains unclear at this point. Management of these patients requires care by a team of specialists, to optimize therapy and minimize the side effects of immunosuppressive therapies. Clearly, randomized, controlled trials of treatments found to be effective in adult populations also need to be conducted in children and adolescents, to develop the most effective treatment protocols for this age group.

Clinical Vignette 26.1

A 15-year-old African-American girl presents with a history of fatigue, joint swelling, and anorexia. She denied having had fever, but had an unintended 6-pound weight loss in the last 2 months. She reported a new symptom of shortness of breath while in dance class and denied facial or extremity edema. She has had bilateral wrist and knee pain and swelling for approximately 2 months. She reported visual sensitivity to light and appearance of a faint pink rash on her cheeks several times over the last 2 months. She denied mouth ulcers but has had increased hair loss over the previous 3 months. Past medical history is significant for gastroesophageal reflux. Family history is significant for systemic lupus erythematosus (SLE) in an aunt.

Urinalysis revealed the following: specific gravity, 1.022; 3+ protein; 3+ blood; 25 to 30 red blood cells (RBCs)/hpf; 5 to 10 white blood cells (WBCs)/hpf; 5 to 10 RBC casts; urine protein-to-creatinine ratio, 5.2; blood urea nitrogen (BUN), 31 mg/dL; creatinine, 2.8 mg/dL; albumin, 3.0 g/dL; WBC count, 4200/mm^3; hematocrit, 28%; platelet count, 100,000/mm^3; antinuclear antibodies (ANAs), 1:1280; Anti-dsDNA, 1:32; complement C3, 48 mg/dL (normal, 83 to 177 mg/dL); complement C4, 9 mg/dL (normal, 15 to 45 mg/dL); erythrocyte sedimentation rate (ESR), 32 mm/h; and C-reactive protein (CRP), 4 mg/dL (normal, less than 1.0 mg/dL).

Renal biopsy showed that more than 50% of glomeruli had evidence of endocapillary hypercellularity (Figure 26.9). Almost half of the affected glomeruli had cellular crescent formation, with distortion of the Bowman capsule. Moderate interstitial edema and some tubules contained prominent RBC casts. Scattered interstitial mononuclear leukocytes were also noted. The arteries and arterioles had no sclerotic or inflammatory changes. On immunofluorescence microscopy, findings were predominantly mesangial and some glomerular capillary wall granular staining with antisera specific for immunoglobulin G (IgG) 2+, IgA 1+, IgM 1+, C3 3+, C1Q 1+, kappa light chains 2+, and lambda light chains 1+. There was no extraglomerular staining. Electron microscopy revealed numerous mesangial and subendothelial immune complex–type electron-dense deposits. Rare subepithelial and intramembranous deposits were also identified. Endothelial tubuloreticular inclusions were present. There was effacement of the visceral epithelial cell foot processes with focal microvillous
Figure 26.9 Renal biopsy findings in the patient. The glomerulus on the right has endocapillary hypercellularity in the 5 to 10 o'clock position. In contrast, other capillary loops are open, with luminal red blood cells present.

transformation. Pathologic findings were consistent with class IV diffuse proliferative glomerulonephritis.

The patient was treated with a combination of corticosteroids and mycophenolate mofetil (MMF). The hematuria and proteinuria improved by 2.5 months, with a urine protein-to-creatinine ratio of 2.0, urinary microscopy showing 5 to 10 RBC/hpf, and serum creatinine decreasing to 1.5 mg/dL. Angiotensin-converting enzyme therapy was added. By 6 months the urine protein-to-creatinine ratio was 0.5, urinalysis showed 2 to 5 RBC/hpf of urine, and serum creatinine was 0.8 mg/dL. Based on this response, her steroid regimen was progressively weaned, she was begun on maintenance therapy with MMF, and she was continued on an angiotensin-converting enzyme inhibitor.

TEACHING POINTS

The patient in Clinical Vignette 26.1 presented with symptoms that are highly suggestive of systemic lupus erythematosus (SLE). The presence of hematuria, proteinuria, and red blood cell (RBC) casts in the urinary sediment, along with elevated blood urea nitrogen (BUN) and creatinine, is indicative of SLE nephritis, possibly with a diffuse proliferative pathologic process. Renal biopsy demonstrated a crescentic form of acute proliferative glomerular lesion, compatible with class IV lesions (ISN/RPS 2003). This patient received induction therapy with steroids and mycophenolate mofetil (MMF) and then maintenance therapy with MMF alone. Normalization of proteinuria and renal function occurred over the next 6 months.

Although induction with intravenous steroids and cyclophosphamide is the "gold standard" for treatment of the proliferative form of lupus nephritis, MMF and steroids were chosen for induction. The rationale for picking this regimen was that cyclophosphamide has greater potential for side effects, and, more importantly, investigators have demonstrated equipotency by MMF in lupus nephritis in some of the more recent clinical trials. This patient will need to be followed by the rheumatology and nephrology teams to monitor overall care of her SLE, with modulation of immunosuppression and monitoring of proteinuria and renal functions.

REVIEW QUESTIONS

1. Renal biopsy was performed in a 15-year-old African-American girl with known SLE for 3 months and a recently noted abnormal serum creatinine of 1.5 mg/dL for 2 weeks. The light microscopy findings of the renal biopsy were compatible with class IV (ISN/RPS 2003) changes. Recommendation for treatment of SLE nephritis in this case should be:
   a. Intravenous steroids and intravenous cyclophosphamide
   b. Intravenous steroids and rituximab
   c. Intravenous steroids and mycophenolate mofetil
   d. Option a or option c
   e. Option b or option c
2. SLE is more severe and more common in African Americans.
   a. True
   b. False
3. Indicator(s) of poor renal prognosis in lupus nephritis is (are):
   a. Nephrotic range proteinuria
   b. Increased serum creatinine at presentation
   c. Class III or IV renal pathologic features in renal biopsy
   d. All of the above
   e. None of the above
4. Glomerular mesangial and capillary wall immune deposits of IgA can be seen in:
   a. SLE nephritis
   b. IgA nephritis
   c. HSP nephritis
   d. All of the above
   e. Only b and c
5. Renal prognosis of class V lupus nephritis at 10 years is:
   a. ESRD in more than 50% patients
   b. ESRD in 10% to 25% patients
   c. ESRD in fewer than 5% patients
6. SLE is associated with:
   a. No genetic predisposition
   b. Familial aggregation
   c. Autosomal recessive inheritance
   d. Autosomal dominant inheritance

7. Steroids alone are effective in treatment of class III and class IV lupus nephritis.
   a. True
   b. False
8. The most common cause of death in lupus nephritis is:
   a. End-stage renal disease
   b. Associated cerebritis
   c. Overwhelming sepsis
   d. Thromboembolic complications
9. Morbidity associated with class V (membranous) lupus nephritis is caused by:
   a. Proteinuria and edema
   b. Thromboembolic events
   c. Infective events
   d. All of the above
10. Patients with class V (membranous) lupus nephritis should receive induction therapy with pulse IV steroids and IV Cytoxan protocol.
    a. True
    b. False
11. In treatment of proliferative lupus nephritis (class III and IV), mycophenolate mofetil (MMF) induction therapy is:
    a. Less effective than NIH regimen of IV Cytoxan
    b. More effective than NIH regimen of IV Cytoxan
    c. At least as effective as NIH regimen of IV Cytoxan
    d. There are no convincing comparative data available.

ANSWER KEY

1. d
2. a
3. d

Kidney disease in sickle cell anemia

IBRAHIM F. SHATAT AND SHERRON M. JACKSON

Sickle cell disease (SCD) affects more than 100,000 or 1 In 500 African Americans (AAs) in the United States. In SCD, a single gene mutation results in the substitution of valine for glutamate on the β chain of hemoglobin. This causes the abnormal sickle hemoglobin (HbS) to polymerize and form strands or fiber-like structures in hypoxic (or deoxygenated) state. Moreover, these strands of HbS bunch up together to form bundles that distort red blood cells (RBCs) into elongated sickled shapes. Such RBCs are prone to hemolysis and also to blocking tissue capillaries, thereby resulting in impaired oxygen delivery to every organ system in the body and tissue damage. Within the kidney, the entire nephron is affected by vaso-occlusion, ischemia, and infarction associated with SCD, ultimately leading to nephron loss. Evidence of renal disease in SCD or sickle cell nephropathy (SCN) begins early in childhood, and it can progress to chronic kidney disease (CKD) in adults. A schematic representation of renal manifestations of SCD by age is presented in Figure 27.1. This chapter discusses the epidemiology, pathogenesis, clinical manifestations, evaluation, and treatment of SCN in children and young adults.

EPIDEMIOLOGY

The spectrum of renal disease in SCD begins in early childhood, and it often manifests as hyposthenuria and polyuria. The age of onset of other renal disorders is variable. Although nephron injury in SCD starts in infancy, SCN manifests more prominently in the second decade of life. Studies in children have clearly characterized some of the common manifestations of SCN, including microalbuminuria, hyperfiltration, nephrotic syndrome, and CKD. Polyuria, enuresis, hematuria, renal papillary necrosis (RPN), and renal medullary carcinoma (RMC) are other well-described renal manifestations of SCD. In general, patients with homozygous SS disease (HbSS) demonstrate more significant renal injury than do patients with hemoglobin S-C disease (HbSC) or hemoglobin Sβ thalassemia. The prevalence of renal manifestations in patients with SCD and trait increases with age. Frequently, the renal manifestations correlate with the severity of SCD, as measured by the degree of hemolysis, hemoglobin levels, and the presence of other sickle cell morbidities.[1]

In a study of more than 2000 medical records of children with SCD, the prevalence of gross hematuria was 6.3%. Preexisting hematuria was significantly associated with the risk of early development of acute kidney injury (AKI) and CKD. Hematuria may originate from either kidney, although a preponderance of left-sided renal bleeding has been observed.[2,3]

KEY POINT

The spectrum of kidney complications begins in childhood as hyposthenuria.

Proteinuria is the hallmark of glomerular injury. Early studies reported the prevalence of proteinuria
Figure 27.1 Kidney disease manifestations of sickle cell disease from childhood through young adulthood. CKD, chronic kidney disease; ESRD, end-stage renal disease.

in young children with SCD to be 5% to 6%.[4,5] In more recent studies, the prevalence of microalbuminuria and proteinuria in teens and young adults with SCD was 16% to 40%.[6–11] McPherson et al.[6] examined the prevalence and clinical correlates of albuminuria and CKD in 410 pediatric patients. Of these patients, 20.7% had microalbuminuria, 26.5% met the Kidney Disease Improving Global Outcomes study (KDIGO) definition for CKD, with CKD I in 14.8% and CKD II in 11.6%.[6] The prevalence of CKD in adults with SCD ranges from 5% to 30%.[12,13] Adults with SCD develop CKD at a much younger age than do patients with HbSC. Hypertension, proteinuria, nephrotic syndrome, hematuria, and anemia generally predict progressive and severe renal disease. Patients with CKD have a significantly higher mortality rate compared with patients with SCD patients who do

not have CDK, and this is true for both HbSS and HbSC.[12] Guasch et al.[14] studied 300 adult patients with HbSS and noticed that sickle glomerulopathy affected the majority of older adults, and its prevalence was much higher than previously reported on the basis of dipstick protein. Sixty-eight percent of patients had increased albumin excretion rates. Approximately 26% of those patients demonstrated macroalbuminuria and evidence of CKD.[14]

PATHOGENESIS

An outline of the pathogenesis of renal disease in SCD, primarily based on the principles of microvascular obstruction and tissue damage, is shown in Figure 27.2. However, the clinical spectrum of SCN cannot be fully explained by vaso-occlusive pathophysiologic processes alone. Genetic factors undoubtedly influence renal and other complications in SCD. Platt et al.[15] and Lebensburger et al.[16] identified low fetal hemoglobin levels as a risk factor in adults with early death. It has long been noted that the presence of β globin Central African Republic haplotype is associated with renal involvement.[17] Some studies suggest that microdeletions of α globin genes in α thalassemia are protective and are associated with lower prevalence of proteinuria.[18] Genetic polymorphisms may explain the variation for risk of developing CKD.

HEMATURIA

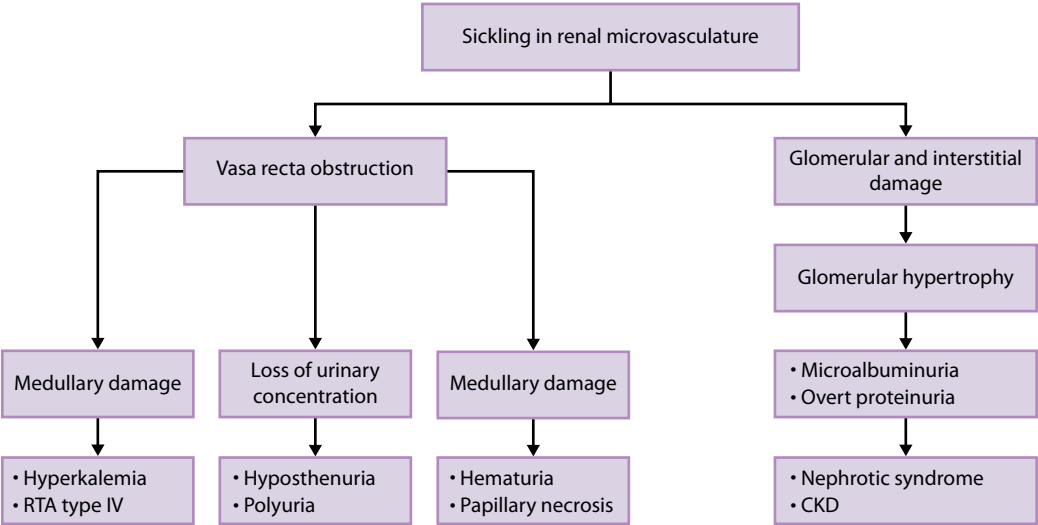
Microscopic or painless visible hematuria is a common manifestation of injury to different parts of the nephron or the collecting system in SCD. Hematuria is especially common in patients with sickle cell trait.


Figure 27.2 Pathogenesis of nephropathy in sickle cell disease. CKD, chronic kidney disease; RTA, renal tubular acidosis.

Sickling in the renal microcirculation, especially In the vasa recta, is promoted by the hypoxemic, acidic, and high osmotic renal medullary environment. This leads to microvascular obstruction, vascular congestion, ischemia, papillary injury, and hematuria.

URINARY CONCENTRATING DEFECT

The earliest evidence of kidney injury in SCD consists of a defective urinary concentrating ability and hyposthenuria. The clinical consequences are the development of enuresis and polyuria and the potential for dehydration and worsening vaso-occlusive symptoms.[19] Cumulative damage to the renal medulla, vasa recta, and collecting ducts occurs after repeated vaso-occlusive events, and infarctions lead to the loss of the medullary concentration gradient needed for water reabsorption.[20] Blood transfusions have transiently reversed the concentrating defect, but the defect ultimately becomes an irreversible feature of SCN in children and young adults.[21]

TUBULAR DYSFUNCTION

Defects in urinary acidification and potassium excretion (type IV renal tubular acidosis [RTA]) in the distal tubule have been well described in SCD. However, these defects are not universal, and some patients seldom experience hyperkalemia or metabolic acidosis. The underlying mechanism is unclear but may be related to repeat sickling events, abnormal medullary blood flow, and chronic ischemia reperfusion injury. The hyperkalemia is not related to aldosterone deficiency but is believed to result from target organ damage resulting from medullary fibrosis and distal tubular damage. Aldosterone and renin levels may indeed be elevated in these patients, possibly in response to the relative hypovolemia and hyperkalemia.[19]

Patients with SCD demonstrate an enhanced proximal tubular activity with increased reabsorption of sodium, phosphorus, and β_2-microglobulin.[3] Increased tubular secretion of creatinine and uric acid is also well known and may reflect a functional adaptation to high uric acid generation.[22] Enhanced tubular secretion of creatinine may result in a lower than expected serum creatinine level in patients with SCD. Proximal tubular dysfunction is seen in young

> ### KEY POINT
>
> Patients with SCD have an increased proximal tubule activity with increased reabsorption of sodium and phosphorus, whereas tubular secretion of creatinine and uric acid is enhanced.

children and is independent of glomerular damage. Marsenic et al.[23] reported increased excretion of urinary retinol-binding protein (marker of proximal tubular dysfunction) in 15% of their study population.

HYPERFILTRATION

Localized prostaglandin release and increased nitrous oxide synthase contribute to increased renal blood flow in SCD.[13] Renal plasma flow is elevated in excess of glomerular filtration rate (GFR), and the result is a lower than normal filtration fraction, which can be reversed with prostaglandin inhibition.[24] Hyperfiltration peaks in childhood and declines in adulthood.[25]

IRON OVERLOAD

Early studies confirmed hemosiderin deposition in tubular epithelium, but it is unclear whether the iron deposits cause renal damage.[26,27] Schein et al.[28] detected kidney iron on magnetic resonance imaging and determined that the renal iron is the result of chronic hemolysis (evidenced by increased lactate dehydrogenase levels) and does not correlate with hepatic iron stores.

TUMORIGENESIS

RMC is an epithelial malignant tumor arising from the collecting duct epithelium. This tumor occurs almost exclusive in young black patients with sickle cell hemoglobinopathies, mainly sickle cell trait.[29] Chronic medullary hypoxia may be involved in the pathogenesis of RMC. A role of genetic abnormalities in the pathogenesis of RMC has been proposed, but no consistent genotype has been observed in these patients.[30,31]

> ### KEY POINT
>
> RMC occurs almost exclusively in young black patients with sickle trait (HbAS).

RENAL PAPILLARY NECROSIS

The exact mechanism of RPN is not entirely understood, but several factors contributing to this process have been described. It is well established that dehydration, acidosis, decreased oxygen tension, and high osmolality present in the renal medulla are the main triggers of RBC sickling in this anatomic region of the kidney. Additionally, blood

(a)   (b)
Figure 27.3 **(a)** Light microscopy of renal biopsy in a patient who died in sickle crisis. Red blood cell sickling is seen within the glomerular capillaries. There are also extensive congestion and sickling in the peritubular capillaries. **(b)** Marked red blood cell sickling is evident within the vasa recta. (From Fogo A. Sickle cell nephropathy. Am J Kidney Dis. 2001;37:E34–5.1.)

flow in the vasa recta is much slower than in the cortical vessels, thus leading to more time for the hyperosmolar interstitium to induce RBC sickling. This process, in turn, increases the viscosity of blood, which causes even further slowing of the medullary blood flow. The sluggish flow ultimately leads to the formation of microthrombi and local microinfarctions, as well as a reduction in the number of functional vasa recta in the medulla. Loss of the vasa recta disrupts the concentration gradient in the medulla and results in isosthenuria.[32]

SICKLE GLOMERULOPATHY

The presence of sickle cells in the glomeruli and congestion of the peritubular capillaries can be demonstrated in the renal biopsy specimens of patients with SCD, especially during sickle crises (Figure 27.3). Glomerular enlargement, increased intraglomerular pressure, and hyperfiltration are the hallmarks of established SCN and are thought to contribute to the development of focal segmental glomerulosclerosis (FSGS) seen in these patients (Figure 27.4). FSGS is the most common glomerular disorder seen in SCN.[33,34] In a review of 18 renal biopsy specimens from patients with SCD and glomerular involvement, Maigne et al.[27] described 4 histopathologic variants in SCD: FSGS in 39%, membranoproliferative glomerulonephritis (MPGN) in 28%, thrombotic microangiopathy glomerulopathy in 17%, and specific SCD
Figure 27.4 Sickle glomerulopathy. Light microscopy of a 16-year-old patient with HbSS disease and proteinuria showing focal segmental glomerulosclerosis. Red blood cell sickling in the glomerular capillaries is also seen. (Courtesy of Dr. Sally Self.)

glomerulopathy characterized by glomerular hypertrophy and congested peritubular capillaries in 17%. Long-term follow-up analysis revealed that 50% of patients exhibited CKD.[27] Apart from glomerular lesions, focal areas of tubulointerstitial fibrosis adjacent to sclerotic glomeruli are commonly seen. Immunofluorescence staining is nonspecific and may be positive for immunoglobulin M (IgM), C3, and C1q in the sclerotic segments. Results of electron microscopy are generally negative for immune electron-dense deposits.[33]

BLOOD PRESSURE

Children with SCD have lower clinic or office blood pressure (BP) readings than their healthy counterparts. This observation has been attributed to poor urinary concentrating

> **KEY POINT**
>
> FSGS is the most common glomerular disorder observed in SCD associated with proteinuria or nephrotic syndrome.

ability, volume depletion, lower body weight, anemia, reduced left ventricular afterload, and decreased blood viscosity secondary to anemia. Altered vascular responsiveness to angiotensin II and nitric oxide resistance are also believed to contribute to altered vascular reactivity and relatively low BP.[35,36] Available evidence suggests that children with SCD have increased prevalence of blunted BP dipping and nighttime hypertension.[37] The concept of "relative hypertension" (BP that is within normal limits but elevated to peer SCD population) has been considered in patients with SCD and has been implicated in silent cerebral infarcts in these patients.[38]

CLINICAL MANIFESTATIONS

Sickle cell nephropathy (SCN) is the term used for the plethora of clinical, biochemical, and pathologic renal abnormalities seen in patients with SCD. These manifestations often begin during early childhood, but their full clinical impact may not be evident until later in adolescence or young adulthood. The current model of SCN suggests that destruction of renal medulla induces production of renal vasodilating substances that feed back to the glomerulus and cause hyperfiltration. In turn, hyperfiltration leads to glomerulosclerosis and proteinuria, with impacts on kidney function and CKD.

HEMATURIA

Hematuria is, by far, the most common complication of sickle cell trait (HbAS). It can occur at any age and is more often reported with HbAS.[3] In a large study of SCD (HbSS), the prevalence of hematuria was 6.3%.[2] Hematuria was significantly associated with earlier development of CKD in patients in this study.[2] In a cohort of SCD-affected children from Saudi Arabia, hematuria and hemoglobinuria were present in 8.5% and 14.5%, respectively.[39] Gross hematuria associated with passage of clots or development of "clot colic" should alert the clinician to the possibility of papillary necrosis, either secondary to SCD or from excessive use of nonsteroidal anti-inflammatory agents (NSAIDs) by these patients for relief of pain.

Alternative causes of hematuria, such as stones, neoplasms, and urinary tract infection, should always be considered in patients with SCD, and the diagnostic workup should be similar to what may be indicated in other patients.

RENAL PAPILLARY NECROSIS

RPN is due to ischemic injury to the renal medulla seen in SCD and other disorders, such as analgesic abuse and urinary tract infections, particularly in the setting of diabetes mellitus (Figure 27.5). Although RPN is much more
Figure 27.5 Papillary necrosis. Cut section of the kidney showing loss of the papillary tips in upper pole pyramids (arrows). (Figure is in public domain, reproduced from Lonergan GJ, Cline DB, Abbondanzo SL. Sickle cell anemia: from the archives of the AFIP. RadioGraphics 2001;21:971–94.)

common in SCD (HbSS), it can also be seen in patients with sickle cell trait (HbAS).[40]

RPN commonly manifests with painless gross hematuria, and bleeding is typically mild and unilateral when visualized by cystoscopy. Left kidney involvement is more frequent, presumably because of its larger size and unique blood supply. Apart from gross hematuria, other symptoms of RPN include flank pain, abdominal pain, nausea, and vomiting. Fever, if present, is typically the result of superimposed infection. Papillary sloughing and passage of the tissue down the ureter can cause intense colicky flank or abdominal pain, in addition to hematuria. Confirmation of papillary sloughing can be sought by preserving the tissue passed in urine (often embedded in a clot) in formalin and by tissue microscopy in pathologic examination.

BLOOD PRESSURE

Clinic BP in patients with SCD is generally lower than that of the general population.[41] Systemic hypertension occurs in 2% to 6% of adults with SCD, compared with the published prevalence of 28% in the adult African-American population of the United States.[42,43] Transient hypertension in SCD is common during pain crises and in patients with CKD.

In a natural history study of 3317 patients with SCD who were 2 years old and older, significantly lower BP was correlated with body mass index, hemoglobin, renal function, and age, but the strength of the correlation varied among age and sex subgroups.[41] The risk for occlusive stroke increased with systolic BP (SBP) but not diastolic BP (DBP) in this study. Mortality was also related to elevated BP in male patients and to a lesser extent in female patients. In subjects with HbSC disease, BP also deviated from normal but to a lesser degree.[41] In another study examining factors associated with silent cerebral infarcts in SCD, the authors identified relatively high SBP as an independent determinant of such infarcts in these children.[37]

Adult and pediatric studies have also demonstrated a correlation between higher BP and microalbuminuria, an independent cardiorenal mortality risk factor.[9,13,43] In a study of 90 children with SCD, Becton et al.[9] found that clinic BP classification (prehypertensive and hypertensive) was independently associated with the presence of microalbuminuria. Stallworth et al.[2] reported that preexisting hypertension was significantly associated with the risk of developing AKI in children with SCD.

The prevalence of ambulatory hypertension and abnormal BP patterns on 24-h ambulatory BP (ABP) monitoring has not been well reported in children with SCD. One study, of 24-h ABP in 38 asymptomatic children with SCD, demonstrated that 17 (43.6%) subjects had ambulatory hypertension, whereas 4 (10.3%) were hypertensive based on their clinic BP.[38] Mean SBP dip and DBP dip were 8.3 ± 5.9% and 14.7 ± 7.6%, respectively. Twenty-three (59%) subjects had impaired SBP dipping, 7 (18%) had impaired DBP dipping, and 5 (13%) had reversed dipping. Clinic BP and ABP correlated modestly. These findings emphasize the need for close monitoring of patients with SCD to prevent long-term cardiac mortality risks.

RENAL MEDULLARY CARCINOMA

RMC is a rare and highly aggressive tumor that is seen almost exclusively in young black patients with sickle cell trait (Figure 27.6). Dimashkieh et al.[44] reviewed 55 cases of RMC reported in the literature, and the average age at tumor presentation was 21 years, with a male-to-female ratio of 2:1. The right kidney was involved three times more commonly.

Of the 55 patients, 50 patients had HbAS, 2 patients had HbSC, and 1 patient had HbSS disease, thus highlighting its occurrence in patients with sickle trait. The most common symptoms at the time of presentation of RMC are flank pain, hematuria, weight loss, and abdominal pain, but some patients present with cough secondary to metastatic involvement of the lungs.[32,44]

PROTEINURIA AND CHRONIC KIDNEY DISEASE

The reported prevalence of microalbuminuria and proteinuria in patients with SCD HbSS and HbSC genotypes ranges from 16% to 40%.[9,11] The prevalence of proteinuria in other genotypes is not well described. The prevalence of microalbuminuria increases with age, and this finding is uncommon before 7 years of age.[11] Microalbuminuria and proteinuria in SCD correlate with the number of vaso-occlusive crises, the severity of hemolysis, hemoglobin level, increasing age, BP, and pulmonary hypertension in children.[9] Many of these patients eventually develop overt proteinuria, which suggests an established sickle glomerulopathy. Although overt proteinuria may be seen up to 25% of patients with SCD, clinically evident nephrotic syndrome occurs in only 4% of cases.[33,45] FSGS is the dominant pathologic finding in 80% of such cases on renal biopsy. As many as 70% of patients with SCD and SCN may go on to develop end-stage renal disease (ESRD) in 2 years after diagnosis.[45] Hypertension and severe anemia are the other predictors of development of ESRD in patients with SCD.[12,46]

CKD can result from SCD and progression of SCN in children. In a cross-sectional observational study in 410 patients with SCD, 11.6% of these patients were noted to have CKD II.[9] The incidence of CKD I and CKD II combined was 26.5%. HbSC and HbSβ+ genotypes were associated with a higher risk for CKD in this study. In a smaller study of 48 children with SCD, Bodas et al.[47] found CKD II in 8.3% cases.

Although traditional thinking has been that sickle cell trait (HbAS), which affects 1 in 12 African Americans in the

(From Dimashkieh H, Choe J, Mutema G. Renal medullary carcinoma: a report of 2 cases and review of the literature. Arch Pathol Lab Med. 2003;127:e135–8.)

United States, does not lead to CKD, more recent reevaluations have demonstrated HbAS is also associated with a higher risk for CKD and ESRD.[48,49] Based on the US Renal Data System (USRDS) database, SCD as a cause of ESRD accounts for 0.1% of all patients started on hemodialysis in the United States.[50]

KEY POINT

Microalbuminuria or proteinuria affects 16% to 40% of patients with SCD and is the hallmark of glomerular injury.

ACUTE KIDNEY INJURY

AKI occurs frequently in patients with SCD, and it can manifest as an isolated organ injury or as part of acute multiorgan failure syndrome.[51] Sklar et al.[52] reported a twofold or greater increase in serum creatinine in 12 of 116 (10.3%) hospitalized patients with SCD. AKI was seen most often in association with infections and in patients with lower hemoglobin (mean, 6.4 vs. 8.7 g/dL). Volume depletion was the most common precipitating factor of AKI. The incidence of AKI in hospitalized adult patients has been shown to vary with the severity of vaso-occlusive complication (VOC). AKI in one study was reported in 2.3% with pain crisis, 6.9% for moderate acute chest syndrome, and 13.6% for severe acute chest syndrome.[53] The use of NSAIDs may also be a causative factor in the precipitation of AKI in some patients with SCD.[54] Rhabdomyolysis leading to AKI during severe exercise has also been reported in patients with sickle cell trait.[55]

TUBULAR DYSFUNCTION AND ENURESIS

The most common clinically manifest tubular abnormality in SCD is a urinary concentrating defect. The urine concentrating defect is unique to sickling hemoglobinopathies and is not seen in other anemias. In contrast, urinary dilution is normal.[21]

Most patients with HbSS are unable to achieve a urine maximal concentration of approximately 500 mOsm/kg after 14 to 17 hours of thirst and exogenously administered pitressin, compared with mean osmolality of 1055 ± 188 mOsm/kg in controls.[56] The defective urine concentrating ability appears to be age dependent, being less pronounced in infants and in children up to age 7 years.[56,57] Even patients with sickle trait have a diminished urinary concentrating capacity.[58] The urine concentrating defect in SCD is resistant to exogenous pitressin therapy, a finding indicating that the diabetes insipidus in SCD is of "nephrogenic" origin.[56] The nephrogenic diabetes insipidus associated with SCD is likely the result of hemodynamic changes in the renal medulla and vasa recta induced by ongoing sickling and tubulointerstitial damage.

An inability to concentrate urine in SCD results in an increased frequency of urination and enuresis in children with SCD and makes them susceptible to dehydration. Improvement in the concentrating defect in response to pharmacologic doses of intranasal desmopressin acetate (DDAVP) is variable and seems to be related to the percentage of sickle hemoglobin present in erythrocytes; vasopressin generation is normal.[58] Early indications are that treatment with hydroxyurea improves urine concentrating ability in children.[59]

Incomplete distal RTA may complicate SCD, but it is not usually a clinical problem.[19] The minimum urine pH achieved in response to ammonium chloride loading is not as low as in controls (5.8 vs. 5.1), but total ammonium excretion is normal. Consequently, titratable acidity is reduced.[60] Distal RTA with hyperkalemia (type IV) has also been described in SCD, with a reduced ability to lower urine pH in response to acid load and inadequate urinary potassium secretion, especially in patients with decreased renal function.[61] Metabolic acidosis and hyperkalemia in SCD are believed to result from aldosterone-independent end-organ failure secondary to medullary fibrosis and tubulointerstitial damage. β Blockers, potassium-sparing diuretics, or angiotensin-converting enzyme inhibitors (ACEIs) should be used with caution in patients with SCD because these drugs may cause hyperkalemia.

Because of the enhanced proximal tubular sodium reabsorption in patients with SCD, diuretic response may be poor. Similarly, because of enhanced proximal tubular phosphate reabsorption, which usually parallels sodium reabsorption, hyperphosphatemia may be seen in in some patients with SCD, especially in the presence of an increased phosphate load generated by hemolysis.[19]

In summary, the tubular dysfunction of SCD manifests a defect in urine concentration, whereas dilution is maintained. Hydrogen ion and potassium secretion functions are only mildly affected, and proximal tubular mechanisms are exaggerated.

KEY POINTS

- SCD is associated with a defect in urine concentration, whereas urine dilution capability is well maintained.
- SCD is characterized by supranormal proximal tubular function.

CLINICAL MANAGEMENT

HEMATURIA

Patients with SCD (HbSS) and sickle cell trait (HbAS) who develop gross hematuria need a thorough evaluation for all the usual diagnostic entities, such as urinary tract infection or renal stones. However, conditions that are unique to these

patients, such as RPN and the distinctive RMC, must also be considered in the diagnostic evaluation. Initial investigations should include urine analysis, culture, and renal ultrasound. Renal ultrasound findings can be nondescript and nonspecific, except in patients with RPN. A review of ultrasound studies in young patients with SCD (10 to 20 years old) found diffusely increased echogenicity in 9% and increased medullary echodensity in 3%.[62] Surprisingly, echodensity was greater in the clinically milder genotypes: 37% and 79% in patients with SC and S-Thal, respectively. These findings may indicate subclinical nephrocalcinosis or iron deposition.

Because of the radiation-associated risk, renal computed tomography (CT) scan should be considered only if it is diagnostically essential. If sustained gross hematuria is present, cystoscopy with ureteroscopy may be required. More recently, magnetic resonance urography (MRU) has been used to define the renal anatomy and function (Figure 27.7).

Continued gross hematuria should be considered a form of renal sickle crisis in patients known to have HbSS or HbAS. The treatment of hematuria in SCD involves bed rest, analgesics, and adequate fluid intake to ensure a high urinary flow. Blood transfusion to reduce the burden of circulating RBCs with sickle hemoglobin should be considered.

Vasopressin and ε-amino caproic acid (EACA or Amicar) have both been used with variable success in controlling severe urologic hemorrhage associated with HbSS or HbAS.[63,64] However, caution must be exercised when using
Figure 27.7 Coronal postcontrast fat-saturated T1-weighted three-dimensional magnetic resonance volumetric interpolated breath-hold examination (VIBE) demonstrates partially sloughed material within the medial left upper pole minor calyx (upper arrow) giving a subtle golf ball-on-a-tee calyceal contour. The left lower pole minor calyx is clubbed from resorption of the papilla (lower arrow). (Courtesy of Dr. Paul G. Thacker, Jr.)

EACA because this antifibrinolytic agent may predispose to the formation of clots that can obstruct the urinary collecting system. If prolonged and life-threatening bleeding is localized to one side, a limited surgical approach may be considered. Unilateral nephrectomy is generally not recommended because bleeding may recur in the contralateral kidney.

RPN can be a diagnostic and management challenge in patients with HbSS and HbAS. These patients present with persistent hematuria and may have abdominal pain resulting from clot-induced colic. Renal ultrasound evaluation may be sufficient to demonstrate a roughened, sloughed papillary tip with a preserved base of the calyx or formation of a sinus that communicates between the renal pelvis and the calyx (Figure 27.8). An intravenous pyelogram (IVP) may show the classic "ring shadow" (Figure 27.9) in the area of necrotic papilla, but this procedure carries the risk for AKI in these patients. Eventually, a calcified papilla may be evident in a renal ultrasound scan or an abdominal x-ray study. The presence of sloughed papillae in the urine is diagnostic, but It has low sensitivity. In some cases, direct visualization of renal calyces with ureteroscopy is required to reach the diagnosis.[32]

Apart from the principles of therapy described previously for managing renal hemorrhage, low-dose, oral EACA may be considered in patients with RPN who have severe hemorrhagic manifestations.[64,65] ACEIs have been shown to induce a 50% increase in papillary blood flow in experimental studies, and these drugs may be considered as preventive therapy in these patients.[20] However, during an episode of active bleeding, ACEI therapy may aggravate hematuria by increasing blood flow to the tissues affected by hemorrhage. Ureteroscopy and the use of a balloon ureteral dilator to tamponade the bleeding site has also successfully stopped bleeding in some patients with RPN.[66]

PROTEINURIA AND NEPHROTIC SYNDROME

Evaluation of proteinuria in patients with SCD should begin with quantification of the degree of proteinuria. First morning urine sample should be used to quantify urinary protein excretion (urine protein-to-creatinine ratio). A 24-h urine collection is generally not necessary in children. Serum total protein and albumin, along with renal function and serum cholesterol, should also be measured. Tubular proteinuria can also occur in patients with SCD as a result of tubulointerstitial damage, and it needs to be evaluated by urine protein electrophoresis. Eventually, patients with progressively increasing proteinuria or nephrotic syndrome should undergo a renal biopsy to confirm the presence and type of sickle glomerulopathy. As indicated earlier, glomerular hypertrophy and FSGS are the dominant pathologic lesions in such cases.

Treatment of microalbuminuria, as well as of overt proteinuria, by ACEIs has been found to useful in small and short-duration studies.[8,33,45,46] A Cochrane review of
Figure 27.8 Renal papillary necrosis. **(a)** Tomographic intravenous pyelography of an 18-year-old patient with abdominal pain and hematuria. The middle pole calyx has a possible sinus tract (*). **(b)** Ultrasonographic visualization of the same kidney. The middle pole exhibits deep extensions into the papilla, likely to be sinus tracts. (Courtesy of Dr. JI Scheinman. From Scheinman JI. Sickle cell disease and the kidney. Nat Clin Pract Nephrol. 2009;5:78–88.)

the literature, however, was unable to find evidence that administration of ACEIs is associated with improvement in microalbuminuria and proteinuria in SCD.[67] There is also no well-documented evidence to suggest that corticosteroids or other immunosuppressive therapies are helpful in inducing remission of nephrotic syndrome in such patients. Moreover, corticosteroids are tolerated poorly by patients

Figure 27.9 Papillary necrosis in sickle cell disease. Frontal view of the right kidney obtained during excretory urography showing a small, round collection of contrast material in an area of missing papillary tip (arrow). (Figure is in public domain, reproduced from Lonergan GJ, Cline DB, Abbondanzo SL. Sickle cell anemia: from the archives of the AFIP. RadioGraphics 2001;21:971–94.)

with SCD and may also precipitate veno-occlusive crises in these patients.[68]

CHRONIC KIDNEY DISEASE

Hyperfiltration is the hallmark of SCD in early infancy, which continues throughout childhood and in young adults in most patients.[6,69,70] A gradual decline in estimated GFR (eGFR) is noted in patients with SCD throughout childhood, adolescence, and adulthood. CKD in patients with SCD is uncommon before the teen years, and CKD stage II has been reported in approximately 11% patients.[6]

In part, because of supernormal proximal tubular secretion of creatinine in SCD, creatinine clearance often overestimates the GFR. The Pediatric Hydroxyurea Phase III Trial (BABY HUG) study evaluated GFR in infants by using 99m-technetium (^{99m}Tc)–diethylene triamine penta-acetic acid (DTPA) and creatinine clearance estimates using Schwartz formulas.[69,70] The mean DTPA GFR in this study was 125.2 ± 34.4 mL/min/m^2, whereas the Schwartz classic formula estimates were higher, at 184.4 ± 55.5 mL/min/1.73 m^2.[69] eGFR based on the CKid-Schwartz (k = 0.413) formula, however, correlated better with DTPA-derived GFR in infants.[70] A disparity of up to 30% may be noted between creatinine clearance and inulin clearance in patients with SCD.[19,71] Additionally, many children with SCD are underweight, with low muscle mass, and this feature adds to the complexity of interpreting GFR estimates based on serum creatinine. Whether serum cystatin-C is better indicator of renal function than serum creatinine in SCD is unclear.[10,72]

Although serum creatinine has its drawbacks as a marker for estimating GFR, mostly leading to its overestimation, formulas based on serum creatinine remain the most practiced bedside and practical standards. National Heart, Lung and Blood Institute (NHLBI) guidelines for the management of SCD recommend checking renal function (creatinine, blood urea nitrogen, urinalysis) annually for children 12 months old and older as part of the suggested routine clinical laboratory evaluations.[73]

As CKD advances in patients with SCD, they need to be followed and cared for in a manner similar to other patient groups with a similar stage of renal dysfunction. A unique aspect in the management of SCD-related CKD and ESRD is the treatment of associated anemia. Whereas erythropoietin (EPO) use in anemia of CKD and ESRD is an accepted therapy, its safety and effectiveness in SCD-related CKD and ESRD have not been well established. In general, EPO response in SCD-related CKD and ESRD has been noted to be unpredictable. The dose of EPO for adequate erythropoiesis in these patients is significantly higher than the standard dose (less than 200 units/kg/dose), sometimes as high as 1500 units/kg/dose.[74,75] Past concerns with use of EPO in patients with SCD-related CKD and ESRD have been increased veno-occlusive sickle cell crises and increased thrombotic events.[74] However, more recent experience in the treatment of these patients with EPO found the therapy to be safe and effective, although some patients have experienced increased veno-occlusive sickle cell crises.[75]

BLOOD PRESSURE

Because BP in patients with SCD is generally lower than in the general population, "normal" BP readings in these patients may indeed reflect elevated BP. However, optimum target BP in SCD has not been established. It is also unclear whether treatment is needed for such patients with "normal" BP and whether there would be any beneficial effects of such therapy. In general, there should be a lower threshold for treating these patients for hypertension. It is also important to consider the class of antihypertensive agents prescribed for these patients. Because an increased risk of hyperkalemia in SCD can be seen with the use of β blockers and ACEIs, caution should be exercised in the use of these drugs. Diuretic agents in patients with SCD, who have obligate hyposthenuria, can cause dehydration and also can precipitate vaso-occlusive events.

RENAL TUBULAR DISORDERS

Treatment of tubular disorders in SCD is usually unnecessary in patients with normal renal function. The risk of dehydration caused by decreased urinary concentrating ability requires prompt treatment of underlying conditions, as well as appropriate intravenous fluid therapy. The BABY HUG trial data suggest that urinary concentrating ability in SCD can be improved with the use of hydroxyurea, and this option can be considered in such patients.[70,76] Metabolic acidosis should also be avoided because it may facilitate the onset of veno-occlusive crisis.

KEY POINT

Hydroxyurea is associated with better urine concentrating ability and less renal enlargement.

Hyperuricemia, resulting from increased urate production, may be aggravated by diuretics (especially thiazides) that inhibit urate secretion. Severe hemolysis, ACEIs, or β blockers can aggravate hyperkalemia, especially in the presence of renal insufficiency. The use of these drugs, as noted previously, should be considered cautiously.

DIALYSIS AND KIDNEY TRANSPLANTATION

The prolonged survival of patients with SCD has led to an increase in the prevalence of SCN and ESRD.[12,77] The average age of renal failure is 40 years, but early signs, such as microalbuminuria, may be apparent at an earlier age.[78] Adequate predialysis care reduces mortality among patients with SCD and ESRD. Using data provided by the Centers for Medicare and Medicaid Services (CMS), McClellan et al.[79] examined the relationship between mortality and pre-ESRD care in incident patients with SCD and ESRD. These investigators found that patients with SCD and ESRD who received predialysis nephrology care had a lower death rate than did patients with SCD and ESRD who did not receive predialysis nephrology care.[79] Patients with SCD and ESRD also had inferior survival rates compared with patients with ESRD from other causes at 1 year after starting dialysis.

KEY POINT

Adequate predialysis care reduces mortality among patients with ESRD who have SCD.

In the years 1989 to 1995, ESRD from SCD accounted for only 0.5% and 0.2% of the pediatric patients registered in the dialysis and transplant arms, respectively, of the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) database. Mean graft survival at 12 and 24 months after transplant was 89% and 71%, respectively. Patient survival was 89%.[80] Huang et al.[81] reported improved survival among kidney transplant recipients with SCD from 2000 to 2011, compared with the 1988 to 1999 era. Multivariate Cox proportional hazard models, however, revealed an increased mortality risk with SCD in both eras. Despite a less satisfactory outcome, available evidence strongly indicates that transplantation is a better

option for the patient with SCD and ESRD. Increased vaso-occlusive crises and allograft sickling events, however, remain challenges in these patients. SCN has been reported to recur in the transplanted kidney after as short a time as 3.5 years.[82]

SUMMARY

SCD is a multiorgan disorder that can affect the kidney and lead to CKD and ESRD. Renal injury or SCN starts early in childhood. Efforts to prevent sickling, examine potential renoprotective agents, and develop biomarkers to identify early kidney injury and patients at risk of disease progression are among the most important avenues in understanding and preventing the renal consequences of SCD.

Kidney transplantation offers better survival option for patients with ESRD. With advances in the transplant field, bone marrow coupled with kidney transplantation is becoming a more promising option for patients with SCD and ESRD.

More emphasis is needed on well-structured transition care programs from childhood to adulthood. Children with SCD have lower clinic or office BP than their healthy counterparts. The significance of having normal BP for age, sex, and height (relative hypertension) in children with SCD is unknown. Abnormalities in ABP measurements and patterns in children with SCD are prevalent and require more attention from health care providers. ABP monitoring is a valuable tool in identifying masked hypertension and abnormalities in circadian BP.

REVIEW QUESTIONS

1. Hematuria is *more often* reported with:
   a. HbSS
   b. HbSC
   c. HbS/β thal
   d. Hb AS
   e. Hb AA

2. The *most common* manifestation of tubular abnormality in SCD is:
   a. Urine concentration defect
   b. Urine acidification defect
   c. Edema
   d. Urine dilution defect
   e. a and d

3. In patients with sickle cell disease, the *most common* glomerular pathologic finding on renal biopsy is:
   a. Minimal change disease
   b. FSGS
   c. MPGN
   d. IgA nephropathy
   e. Membranous nephropathy

4. All the following statements about sickle cell nephropathy are correct *except:*
   a. Treatment of hematuria in SCD involves bed rest and maintenance of a high urinary flow.
   b. Patients with sickle cell disease are at a lower risk of developing hyperkalemia when treated with ACEIs and β blockers.
   c. The reported prevalence of microalbuminuria and proteinuria in patients with sickle cell disease ranges from 16% to 40%.
   d. Renal medullary carcinoma is present almost exclusively in young black patients with sickle cell trait.
   e. Children with sickle cell disease have lower clinic BP measurements than their age-, sex-, height-matched counterparts.

5. All of the following statements regarding tubular function in patients with sickle cell disease are correct *except:*
   a. Sodium reabsorption is increased.
   b. Phosphate reabsorption is increased.
   c. Potassium reabsorption is increased.
   d. Urate secretion is increased.
   e. Creatinine secretion is increased.

6. The *earliest* manifestation of kidney injury in childhood is:
   a. Acidosis
   b. Enuresis
   c. Hyposthenuria
   d. Hypertension
   e. Proteinuria

7. Mechanisms of renal injury include all of the following *except:*
   a. Immune complex deposits in the basement membrane
   b. Hypoxia in the vasa recta
   c. Polymerization of sickle hemoglobin
   d. Hyperfiltration in the glomerulus
   e. Medullary fibrosis

8. All of the following factors are strong predictors of chronic kidney disease *except:*
   a. Proteinuria
   b. Hematuria
   c. CAR haplotype
   d. Nephrotoxic medications
   e. Nephrotic syndrome

9. All of the following are known correlates of microalbuminuria and proteinuria *except:*
   a. Degree of hemolysis
   b. Increasing age
   c. Elevated blood pressure
   d. Pulmonary hypertension
   e. Higher hemoglobin levels

Kidney disease associated with diabetes mellitus and metabolic syndrome

KANWAL KHER AND MICHELE MIETUS-SNYDER

Diabetes mellitus is the most common metabolic disorder affecting humans. The hallmark of this condition is hyperglycemia, which can develop from a lack of insulin production, peripheral resistance to the metabolic actions of insulin, or both. In adults, diabetes mellitus is the leading cause of chronic kidney disease (CKD), loss of vision, and nontraumatic amputations. This chapter will discuss the clinical spectrum of renal disease seen in diabetes mellitus and obesity-metabolic syndrome. Both of these disorders, although well recognized in adults, are increasingly being encountered in children and adolescents.

CLASSIFICATION OF DIABETES

From a clinical point of view, diabetes mellitus is classified into distinct types. Type 1 diabetes mellitus (DM1) is more common in childhood and adolescence and results from insulin deficiency, usually secondary to immune destruction of pancreatic β cells in the islets of Langerhans. On the other hand, type 2 diabetes mellitus (DM2) is more common in adults and results from resistance to insulin in peripheral tissues. The incidence of DM2 in children and adolescents has, however, been rising globally in the last decade.[1] A combination of relative insulin deficiency

and peripheral resistance to insulin action can be seen in some patients, especially in young adults.

EPIDEMIOLOGY OF DIABETES MELLITUS

The SEARCH for Diabetes in Youth Study estimates that 191,986 children and adults younger than 20 years of age have diabetes mellitus in the United States. Of this, 166,984 have DM1 and 20,262 have DM2. The remaining 4740 patients have other forms of diabetes.[2] Overall prevalence of diabetes mellitus in children and adolescents is estimated to be 2.22 per 1000 children, with the majority of this (1.93 of 1000 children) accounted for by DM1 and 0.24 of 1000 by DM2.[3]

DIABETIC NEPHROPATHY

Diabetic renal disease or nephropathy (DN) is an insidious and a common complication of diabetes mellitus. At its onset, DN is clinically silent and the only detectable abnormality may be presence of microalbuminuria (or also known as albuminuria). Overt proteinuria, nephrotic syndrome, hypertension, and

a decline in renal function eventually evolve in these patients.

EPIDEMIOLOGY

DN is the single largest cause of end-stage renal disease (ESRD) in adults in the United States, accounting for 44.1% cases.[4] In contrast, diabetes mellitus is a lesser known cause of ESRD in children and adolescents. The number of patients with the diagnosis of ESRD secondary to diabetes, between 0 and 19 years of age in the United States Renal Data System (USRDS) in the 2008 to 2012 era was only 57 of 6204 patients, representing only 0.9% of the pediatric ESRD population. Of the 57 patients, 34 had DM2 and 23 had DM1.[4] It is important to recognize that many children with diabetes mellitus are likely to grow into adulthood and will remain at risk for development of DN and ESRD later in their lives.

KEY POINTS

- Diabetes mellitus is the most common cause of ESRD in adults.
- Diabetes mellitus is an uncommon cause of ESRD in children.
- Risk for DN rises with duration of diabetes mellitus.

In general, the risk for developing DN increases with the increasing duration of diabetes mellitus. Using microalbuminuria as evidence for DN, the German Diabetes Documentation System in children and young adults with DM1 demonstrated that 4.3% had abnormal urinary microalbumin excretion. Extending the follow-up data to age 40 years in these children showed that 25% patients eventually developed microalbuminuria.[5] Swedish data in childhood-onset DM1 with a mean disease duration of 29 years demonstrated microalbuminuria in 20% cases, and frank proteinuria was noted in another 12% of cases.[6] In Brazilian children with DM1, Salgado et al.[7] reported the incidence of microalbuminuria to be 11.2% after a mean disease duration of 11.32 ± 4.02 years. ESRD in this population was reported to be 2.9%. The cumulative incidence of ESRD in Finnish children with DM1 was 2.2% at 20 years and 7.8% at 30 years following the diagnosis of disease.[8] Several

---

KEY POINTS

- Of children with DM1, 25% to 40% eventually develop DN in their lifetime.
- Risk for DN may be decreased by good glycemic control.

---

studies have observed that microalbuminuria occurs earlier in DM2 in children and young adults compared to DM1.[9,10]

PATHOGENESIS OF DIABETIC NEPHROPATHY

DN in both DM1 and DM2 is believed to be the consequence of poorly controlled hyperglycemia. An integrated view of the mechanisms leading to renal injury in diabetes mellitus is evolving. Available evidence points to accumulation of injurious metabolic by-products, such as glycosylated compounds, involvement of the renin-angiotensin system, and endothelial and podocyte injury being involved in the pathogenesis of DN (Figure 28.1).

Formation of advanced glycation end products

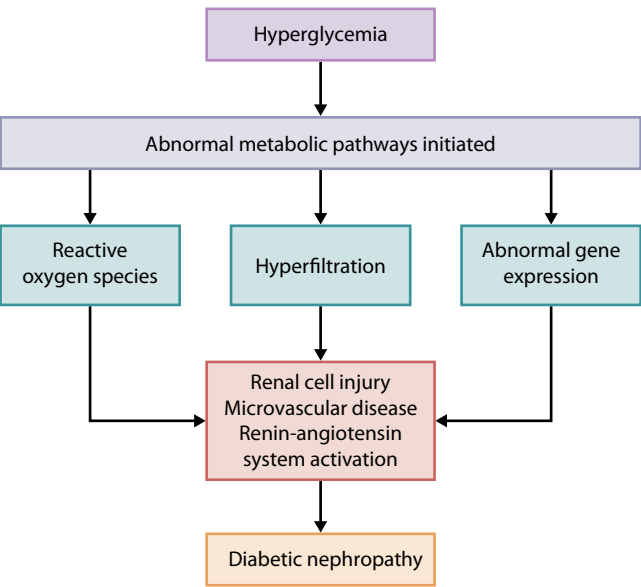
Glucose in diabetic patients reacts nonenzymatically with proteins, lipids, and nucleic acids to form Schiff bases characterized by carbon-nitrogen double bonds. Rearrangement of Schiff bases leads to the formation of intermediate Amadori products, eventually forming advanced glycation end products (AGEs), such as carboxymethyl lysine, pentosidine, imidazolone, and pyrraline. AGEs bind to lysozymes and specific cellular receptors, such as receptor for AGE (RAGE).[11] Consequences of this interaction are diverse alterations of cellular functions, such as decreased production of nitric oxide (NO) and increased production of oxidative radicals, cytokines, and growth factors. This shift in the internal milieu of the tissues promotes damage of cellular structures and is believed to play a leading role in the pathogenesis of DN.


Figure 28.1 An over view of the pathogenic pathways and mediators in the development of diabetic nephropathy.

Increased oxidative stress

Due to the persistent hyperglycemic state in diabetes mellitus, as much as 30% of glucose may be metabolized via the polyol pathway, depleting intracellular nicotinamide adenine dinucleotide phosphate (NADPH). These intracellular events lead to enhanced intracellular oxidative stresses, generated by decreased NO synthesis.[11]

Vascular injury and profibrotic events

Hyperglycemia induces intracellular protein kinase (PKC) with profound downstream impact on the expression of genes that modulate effects on vascular tone, vascular permeability, and angiogenesis. Specifically, PKC activation is associated with downregulation of nitric oxide synthase (eNOS) and upregulation of endothelin 1 and vascular endothelial growth factor (VEGF).[12] All of these lead to vascular injury, increased vascular permeability, increased production of profibrotic cytokine transforming growth factor β-1 (TGB β-1), and mesangial matrix expansion.[12] An imbalance in the factors that promote vascular injury and those that prevent vascular injury is believed to be involved in the pathogenesis of diabetic microvascular disease and DN.[11–13]

Podocyte injury

Hyperglycemia induces podocyte injury and apoptosis via a variety of mechanisms and may be a mediator of glomerular injury in DN.[14] Moreover, insulin also plays a profound role in maintaining the actin cytoskeletal and structural integrity of podocytes. The action of insulin is mediated via insulin receptors present on the podocyte cell surface.[15] Morphometric studies of renal biopsies in diabetic patients have demonstrated a decreased podocyte number, even before the onset of microalbuminuria, suggesting podocyte injury to be an early pathogenic event of DN.[16–18]

Renin-angiotensin system

Experimental work by Brenner and colleagues laid the foundation for our understanding of the role played by renin-angiotensin system in the pathogenesis of DN.[19] Diabetic rats have been shown to have increased intraglomerular pressure, hyperfiltration, relative vasoconstriction at the efferent end of the glomerular capillary, and resultant albuminuria.[20] Renin was proposed as the possible agent for these intraglomerular vascular changes. Using the angiotensin-converting enzyme (ACE) inhibitor enalapril, Zatz et al.[21] further demonstrated an improvement in intraglomerular pressure, hyperfiltration, and improvement in albuminuria in this experimental diabetes model. Brenner et al.[22] eventually proposed a central role for the renin-angiotensin system in the evolution of hyperfiltration and DN. At a clinical level, however, the plasma renin level in DN is variable and can be either normal or suppressed.[23,24] These findings and other experimental evidence suggests the possible role of intrarenal renin-angiotensin activation in these patients.[25–27]

Glomerular hyperfiltration

Increased glomerular filtration rate (GFR) or hyperfiltration has been well documented in early DN.[19,28] As noted earlier, Brenner et al. demonstrated hyperfiltration in experimental diabetes mellitus model and proposed its central role in the pathogenesis of DN.[20–22] Hyperfiltration has been demonstrated to result in progressive injury to the surviving nephrons, resulting in ongoing renal injury and eventual nephron loss. Hyper-reninemia was proposed by Brenner et al.[22] to cause selective efferent arteriolar constriction, leading to intraglomerular hypertension and resultant hyperfiltration.

KEY POINTS

- The renin-angiotensin system has been implicated in the pathogenesis of glomerular hyperfiltration and ongoing renal injury.
- Use of ACE and angiotensin-receptor blockers (ARBs) has improved the prognosis of DN.

Leading away from glomerulocentric pathogenesis of hyperfiltration in patients with DN, some investigators have suggested a possible role of tubuloglomerular feedback (TGF) in its pathogenesis.[29] TGF refers to a protective mechanism in which increased tubular sodium concentration resulting from hyperfiltration stimulates a proportionate feedback to the corresponding afferent arterioles of the glomeruli, causing them to constrict and reduce glomerular blood flow and GFR. TGF is mediated by release of adenosine triphosphate (ATP) from the macula densa in response to increased tubular sodium concentration as a result of increased GFR. ATP is converted to adenosine, which binds to the adenosine A1 receptor (A1AR) in the afferent arteriole, causing vasoconstriction. In contrast, decreased distal sodium delivery to macula densa results in vasodilatation of the afferent arteriole and an increase in the superficial nephron GFR.[29,30] A clear understanding of the role played by TGF in the pathogenesis of DN has not emerged yet.

Genetic predisposition

DN develops in only approximately 30% to 40% of patients with DM. Some epidemiologic observations suggest the possibility of familial clustering of DN.[31] So far, no definitive susceptibility genes for DN have been identified. Recent genome-wide association scan for susceptibility to DN, using single nucleotide polymorphisms (SNPs) genotyping, has revealed possible associations with two candidate loci near *FRMD3* and *CARS* genes.[32] In a Japanese study SNP-rs1411766 in chromosome 13q was found to be highly associated with DN.[3]

Table 28.1 Clinical stages in the evolution of diabetic nephropathy

Clinical stage	Disease duration (Yr)	Glomerular filtration rate	Microalbuminuria	Hyperfiltration
Latent disease stage	Begins early <10	Elevated	No	Yes
Microalbuminuria stage	10–15	Normal or elevated	Yes	Yes
Overt proteinuria stage	>15	Normal or decreased	Overt albuminuria	No
End-stage renal disease	30-40	Severely decreased	Overt albuminuria	No

CLINICAL MANIFESTATIONS

Although a few cases of early onset of DN have been reported in childhood, it is unusual to see overt DN before a decade of established disease state.[34] Kimmelstiel and Wilson[35] described the autopsy findings of DN in patients who manifested proteinuria, nephrotic syndrome, and hypertension. Although advanced DN is well known to be associated with severe proteinuria and CKD, early observable manifestations of DN are subtle and characterized by increased GFR (hyperfiltration) and microalbuminuria.

Clinical course of DN is a continuum of clinical manifestations that can be arbitrarily divided into following four stages (Table 28.1).

Latent disease

Hyperglycemia-induced hyperfiltration is an early observable abnormality in DM.[28] At this stage, patients are asymptomatic, blood pressure is normal, and there is no detectable microalbuminuria. Renal size is normal or slightly increased on ultrasound examination. In DM1, this phase can last for 10 to 15 years of the disease during childhood.

Microalbuminuria stage

Presence of microalbuminuria (also known as albuminuria) in patients with DM1 or DM2 is now recognized as an early marker of DN.[36–38] Most studies indicate that it takes 10 to 15 years for microalbuminuria to be noticed in patients with childhood onset of DM1.[39] In a Danish study, none of the patients younger than 15 years of age had an elevated albumin excretion rate.[40] In the Oxford Regional Prospective Study, the cumulative prevalence of microalbuminuria was 25.7% (95% confidence interval [CI] 21.3% to 30.1%) after 10

years of DM and in 50.7% (CI 40.5% to 60.9%) after 19 years of diabetes.[41]

Patients continue to have hyperfiltration in the microalbuminuria stage, but as the disease progresses, GFR declines and may appear to be "normal."[36,37] Presence of a normal GFR and microalbuminuria in a patient with DM1 or DM2 of long-standing duration should be viewed as an indicator of disease progression. Blood pressure is usually normal in this stage of DN but nephromegaly may be noted by ultrasound evaluation.[42] With effective therapy, regression of microalbuminuria has been reported in some patients with DM1.[43,44]

ALBUMINURIA DETECTION

Available urine protein detecting dipsticks (Albustix or Multistix) are only able to detect proteinuria greater than 30 mg/dL. Low-level proteinuria, below 30 mg/dL, is defined as microalbuminuria (also known as albuminuria), which can be detected by immunodiffusion or other laboratory techniques. Although a 24-hour urine collection is the most accurate method for quantifying microalbuminuria, timed urine collections are often difficult or inaccurate in children. Consequently, a spot sample of ratio of urine microalbumin (or albumin) to creatinine (ACR) is a practical alternative. Using this technique, microalbuminuria is defined as urinary albumin to creatinine ratio (ACR) of greater than 30 mg/g of creatinine. Diagnostic reliability of spot urine albumin to creatinine ratio and its linear correlation with microalbuminuria in a 24 hour urine sample is well established.[45,46] To avoid erroneous results because of orthostatic proteinuria seen in older children and adolescents, it is recommended that ACR be obtained in the first morning sample of urine.[46] Guidelines for diagnosis of albuminuria are presented in Table 28.2.

KEY POINTS

- DN has a long latent period, which manifests with hyperfiltration (increased GFR) only.
- Microalbuminuria is a marker of DN.
- Microalbuminuria should be assayed in the first morning urine sample to avoid overestimation because of orthostatic proteinuria.

Table 28.2 Definition of normal and abnormal urinary albumin excretion

	24-Hour urinary albumin (mg/24 hr)	Spot urine albumin/creatinine (mg/g creatinine)
Normal	15–50	<10–15
Microalbuminuria	30–299	<30
Overt proteinuria	>300	>200

Overt proteinuria stage

Overt proteinuria develops in an advanced stage of DN in a patient with progressive disease. The degree of proteinuria in DN can range from moderate (approximately 500 mg/day) to severe (greater than 3 g/day) and can be associated with nephrotic syndrome. Decline of renal function and hypertension is common at this clinical stage.[35,37,39] Transitioning from (micro)albuminuria to overt proteinuria takes 10 to 15 years.[39–42] Rapid progression from microalbuminuria to CKD, without an identifiable overt proteinuria stage, has been reported occasionally.[47]

End-stage renal disease

With declining renal function in DN, proteinuria usually decreases and nephrotic syndrome may seem to improve. In general, the time course of ESRD in most studies involving children with DM1 has been noted to be 25 to 30 years (Figure 28.2), but early onset of ESRD also has been reported.[5,48,49] In the cohort of patients with DM1 from 1970 to 1980, the unadjusted cumulative incidence of ESRD at 25 years was 9.3%.[48] The unadjusted hazard of ESRD in this study was noted to be reduced by 70% compared to the cohort from 1922 to 1969. The authors credit better glycemic control to be an important factor in reducing the incidence of ESRD in the 1970 to 1980 cohort. Similarly, in another study of DM1 children, ESRD at 40 years of the disease duration was noted to be 9.4%.[5] Hypertension, if uncontrolled, may further accentuate progression of renal injury, accelerating the onset of ESRD. In addition to ESRD, patients demonstrate evidence of microvascular disease in other organs, such as retinopathy, loss of vision, coronary artery disease (CAD), and stroke. Joslin Clinic data suggest that despite significant (85%) use of ACE inhibitors (ACEIs) in patients, cumulative risk for ESRD in white patients with DM1 (1991 and 2004 cohort) remains high (52%).[49]

> ### KEY POINTS
>
> - ESRD occurs in approximately 10% of diabetics.
> - Poor hypertension control may accelerate decline of GFR.
Figure 28.2 Time course of clinical events in the progression of nephropathy in type 1 diabetes mellitus.

RENAL PATHOLOGY

The hallmark of DN in its advanced state is the lesion known as diabetic glomerulosclerosis, which was first described by Kimmelstiel and Wilson[35] in 1936. These patients had diabetes mellitus, advanced proteinuria, and hypertension, and renal pathologic findings on autopsy demonstrated glomerulosclerosis. Early renal lesions of DN, however, can be subtle and may be difficult to differentiate from other nondiabetic nephropathies. A consensus report of the Renal Pathology Society proposed four classes of morphologic changes in DN (Table 28.3). These classes are reflective of progression of the renal disease in these patients (Figure 28.3).[50] Although DN

Table 28.3 Renal pathology in diabetic nephropathy*

Class	Pathologic description	Basement membrane	Mesangial lesion	Nodular sclerosis
I	Glomerular basement membrane thickening	Thickening on electron microscopy	Normal	No
II	Mesangial expansion			No
	IIa (mild)	Thickened	Mesangial expansion affecting < 25%	
	IIb (severe)	Thickened	Mesangial expansion affecting > 25%	
III	Nodular sclerosis (Kimmelstiel-Wilson lesions)	Wrinkled and thickened	Mesangial expansion, mesangiolysis	Yes Lesions affect < 50% glomeruli; at least one convincing Kimmelstiel-Wilson lesion
IV	Advanced diabetic glomerulosclerosis	Wrinkled and thickened		Yes Lesions affect > 50% of glomeruli

* Based on the classification proposed by: Cohen-Tervaert TW, Mooyaart AL, Amann K, et al.; Renal Pathology Society. Pathologic classification of diabetic nephropathy. J Am Soc Nephrol. 2010;21:556–63.
Figure 28.3 Representative examples of the morphologic lesions in diabetic nephropathy (DN). Class I glomerular changes in panels (a) and (b). **(a)** Glomerulus showing only mild ischemic changes, with splitting of Bowman's capsule. No clear mesangial alteration. **(b)** Electron microscopy of this glomerulus showing the thickened glomerular basement membrane with a mean width of 671 nm, enabling the lesion to be categorized as class I. Class II glomerular change in panels (c) and (d). **(c)** The mesangial expansion does not exceed the mean area of a capillary lumen (IIa), whereas in panel **(d)** it does (IIb). Class III glomerular changes in panels (e) and (f). **(e)** The lesion in panel (e) is not as convincing for Kimmelstiel-Wilson lesion; therefore (on the basis of the findings in this glomerulus) the finding is consistent with class IIb. **(f)** Class III Kimmelstiel-Wilson lesion. For the purpose of the classification, at least one convincing Kimmelstiel-Wilson lesion (as in panel [f]) needs to be present. Class IV glomerular lesion in panels (g) and (h). **(g)** This is an example of glomerulosclerosis (glomerulus from the same biopsy as panel [h]). **(h)** Signs of class IV DN consist of hyalinosis of the glomerular vascular pole and a remnant of a Kimmelstiel-Wilson lesion on the opposite site of the pole. For the purpose of the classification, signs of DN should be histopathologically or clinically present to classify a biopsy with global glomerulosclerosis in more than 50% of glomeruli as class IV. (Reproduced with permission from: Cohen-Tervaert TW, Mooyaart AL, Amann K, et al.; Renal Pathology Society. Pathologic classification of diabetic nephropathy. J Am Soc Nephrol. 2010;21:556–63.)

KEY POINT

The Renal Pathology Society has proposed four morphologic classes of DN.

classification is primarily based on changes noted in glomeruli, concomitant tubulointerstitial changes often accompany the glomerular lesions and must be considered in the prognostication of the clinical disease. In general, the histopathology of DN in DM1 is indistinguishable from that of DM2.

It is important to recognize that diabetic patients also can have nondiabetic renal disease, such as glomerulonephritis and tubulointerstitial nephritis.[51] These also need to be carefully distinguished from DN.

MANAGING DIABETIC NEPHROPATHY

Pediatric nephrologists are increasingly asked to participate in the care of diabetic children, adolescents, and young adults. Care of these patients is best considered as a team of clinical providers, educators, nurses, and nutritionists. Such a team management approach can prevent and reduce the incidence of complications such as DN, retinopathy, cardiovascular disease, and neuropathy associated with DM.

Glycemic control

In general, there has been a decline in the prevalence of DN in DM1 since the 1950s. This has been largely attributed to a better glycemic control in diabetic patients. The American Diabetic Association (ADA) recommends a hemoglobin (Hb) A1c goal of 7% in adults with DM1 and DM2.[52] Target HbA1c in children and adolescents recommended by the International Society for Pediatric and Adolescent Diabetes (ISPAD) consensus guidelines of 2009 is less than 7.5%.[53] Unfortunately, available pediatric data suggest that targets for glycemic control are rarely met in children and adolescents. Amed et al.[54] reported that only 7.4% of patients with diabetes mellitus in the pediatric age group achieved target HbA1c and the needed compliance for follow-up (missed clinic visits).

KEY POINTS

- Good glycemic control is HbA$_{1c}$ goal of 7.
- Good glycemic control is the best strategy for prevention of DN.
- Target glycemic control is difficult in children.

A tighter control of diabetes and lowering the target of HbA1c to 6.5% has been suggested by some studies in adults.[55,56] These studies point to a substantial decline in

microvascular disease, including DN in patients treated with a tighter HbA1c target. In the Diabetes Control and Complications Trial (DCCT) that evaluated intensive treatment protocol to achieve near normal glucose control in patients with DM1 in a randomized controlled study demonstrated a 50% reduction in the risk for impaired renal function compared to conventional therapy.[55] Similarly, the international consortium of investigators in the ADVANCE collaborative reported a 65% reduction in the risk for ESRD in patients with DM2 in whom a tight glycemic control target HbA1c of 6.5% or less was maintained over a median duration of 5 years.[56] A meta-analysis of tight glycemic control of DM2 has also suggested a lower incidence of microalbuminuria, but the evidence for reduction in the renal end points of doubling of serum creatinine and ESRD was less convincing.[57] Concern has, however, been expressed by some that despite a positive impact of tight glycemic control on microvascular disease and nephropathy, such an approach may not be advocated at this time because of adverse cardiovascular outcome noted in the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study.[58,59]

Early detection of nephropathy

Microalbuminuria (or albuminuria) is the hallmark of early DN, which can progress to overt proteinuria. Microalbuminuria is also an independent risk factor for cardiovascular disease and ESRD in diabetic patients.[60,61] Except in a rare patient, microalbuminuria in DM1 usually appears in those with the disease duration of more than a decade after onset. On the other hand, microalbuminuria is an early feature of DM2. This difference has been attributed to possible endothelial injury and hypertension that often accompanies DM2.[62] Another interesting feature of pediatric DM1 is that microalbuminuria has been reported to be reversible with effective treatment.[44]

The Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines of the National Kidney Foundation recommend that screening for microalbuminuria be initiated after 5 years of onset of DM1, and at the time of diagnosis of DM2.[63] This screening should consist of measuring urinary ACR in a spot urine sample obtained in the clinic and checking serum creatinine to estimate GFR. An elevated ACR should be reconfirmed in a first morning sample in an adolescent diabetic patient, preferably within 3 months.

Angiotensin-converting enzyme inhibitors

The therapeutic role of ACEIs in reducing the rate of progression of DM is well established.[64–66] The effectiveness of ACEIs was initially demonstrated in the murine models of diabetes and the five-sixth renal ablation models established by Brenner et al.[19–22] More recently, therapeutic effectiveness of ARBs, alone or in concert with an ACEI, to reduce

microalbuminuria and progression of DN also has been established.[67–69]

> ### KEY POINTS
>
> - ACEIs and ARBs have helped slow the progression of DN at the microalbuminuria stage.
> - Risk for hyperkalemia with ACEI and ARBs requires close monitoring.
> - Early use of ACEI and ARBs to prevent development of microalbuminuria is unclear.

The timing of ACEI and ARB therapies in DM1 and DM2, however, has been a subject of considerable debate. Although it is tempting to consider that early start of ACEIs and ARBs might prevent the onset of microalbuminuria in diabetic patients, clinical trials have provided mixed results. Mauer et al. suggested that ACEI may not help in preventing onset of microalbuminuria in those without it, but others have demonstrated benefits of ACEIs and ARBs therapy in patients with DM2 without evidence of microalbuminuria.[66,70,71] KDOQI guidelines (2012) recommend against early use of ACEI and ARBs in DM1 and DM2 as a strategy to prevent DN in patients with normal blood pressure (nonhypertensive patients).[72]

Combined use of ACEIs and ARBs in treatment of DN has been suggested by some to be beneficial in preventing the progression of DN, since this drug combination blocks the entire cascade of the renin-angiotensin system. This combination has been shown to have an additive effect in reducing proteinuria in some studies.[73] Others have not been able to demonstrate a significant clinical benefit of combining ACEIs and ARBs in the treatment of adult patients with diabetes.[74] Some recent studies have, indeed, suggested that there is an increased risk for side effects, such as hyperkalemia and acute kidney injury in patients treated with a combination of ACEI and ARBs. These studies discourage the use of combination therapy in the treatment of DN.[75,76]

The antirenin drug aliskiren has been approved as a therapeutic agent for treatment of hypertension, and its use in treatment of early DN has been considered in clinical trials.[77] However, despite improved microalbuminuria, the incidence of hyperkalemia, hypotension, worsening of renal function, and death has been reported in a significant number of patients in these studies.[77,78] In 2012, the U.S. Food and Drug Administration issued a safety alert against the use of the combination of aliskiren, ACEIs, and ARBs for treatment of DN.[79]

Cardiovascular disease and hypertension

The Joslin Clinic study in juvenile-onset DM1 demonstrated that most of the CAD-related deaths occurred beyond the third decade of life.[80] The cumulative mortality

in the Framingham Heart Study from CAD was 35% ± 5%, compared to 8% in males and 4% in females in the nondiabetic population.[81] The risk factors associated with CAD in diabetes are hypertension, lipid profile abnormalities, atherosclerosis, and endothelial injury.[82]

Onset of hypertension in DM1 often coincides with the development of overt DN and proteinuria.[83] As a part of the metabolic syndrome or obesity-associated DM2, hypertension may be present at the time of initial detection of the disease. For pediatric patients, the ADA recommends that blood pressure readings higher than the 95th percentile for age and gender be considered thresholds for pharmacotherapy for hypertension.[84] Interestingly, an intensive effort to reduce systolic BP to 120 mm Hg in adults in the ACCORD study did not reduce the rate of a composite outcome of fatal and nonfatal major cardiovascular events in adults with DM2.[85] Cochrane meta-analysis also concluded that there is no clear evidence to suggest that blood pressure lower than accepted standard targets need to be achieved in hypertensive patients with diabetes.[86]

Apart from being an effective antihypertensive treatment, ACEIs and ARBs also have a beneficial effect on DN and remain the drugs of choice for treatment of hypertension in this population. Calcium channel blockers are also effective therapies in treating hypertension in diabetic patients and are neutral in their impact on glycemic control.[87] These are usually used as adjuncts to ACEIs and ARBs in the management of hypertension in diabetic patients. A recent report about calcium channel blockers helping β cell loss in the pancreas is interesting and may change the utility of calcium channel blockers in the management of hypertension in diabetes.[88] Thiazide diuretics and β blockers should be avoided in patients with prediabetes and diabetes, because this class of drugs is known to worsen the glycemic control in patients with diabetes and even accelerate the development of diabetes in those with impaired glucose metabolism.

In addition to pharmacotherapy, usual hypertension management strategies, such as lower salt intake, exercise, and caffeine avoidance should also be instituted in the management of hypertension in diabetics patients. Weight reduction strategies in metabolic syndrome and DM2 associated with obesity should be an important element in the management of hypertension in these patients.

Dyslipidemia is a common finding in diabetic children with poor glycemic control, magnifying their risk for CAD. Lipid abnormalities consisting of elevated total cholesterol and low-density lipoprotein (LDL) cholesterol, low high-density lipoprotein (HDL) cholesterol, elevated apolipoprotein B, and a relatively normal to elevated serum triglyceride level.[89–92] Dyslipidemia is more common in DM2 versus DM1. In a large study of young adults and adolescents, DM2 dyslipidemia was demonstrated in 33% of patients compared to 19% of patients with DM1.[91] Although duration of the disease does not appear to influence dyslipidemia in diabetic patients, poor glycemic control over

time is associated with a worse lipid profile.[92] It is prudent to address the dyslipidemia in these patients by appropriate dietary advice and use of statins. Indeed, in adults with DM2, the use of statins has significantly increased to 52.2% of subjects during the years 2007 to 2010.[93] In a recent pediatric study, however, only 1% of pediatric patients with diabetes-associated dyslipidemia were recorded to be receiving any pharmacotherapy.[91]

METABOLIC SYNDROME

The term *syndrome X* was coined in 1988 to denote an association of cardiovascular mortality with hypertension, dyslipidemia, and insulin resistance, resulting from of obesity.[94,95] Other expressions have been proposed over the past several decades to describe this clinical constellation, but most have adopted the term *metabolic syndrome* (MetS). The criteria proposed for defining MetS by the third report of the National Cholesterol Education Program Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III) (ATPIII) and those from the World Health Organization (WHO) are most widely used and are listed in Tables 28.4 and Table 28.5.[96–98]

CLINICAL CONSTELLATION

Although obesity is easily definable by body mass index (BMI) or weight criteria (Table 28.6), MetS is a constellation of clinical findings and its definition is still somewhat loose.

Table 28.4 Adult treatment panel III clinical criteria for metabolic syndrome in adults

Risk factor	Defining level
Abdominal obesity, given as waist circumference	
Men	>102 cm (>40 inches)
Women	>88 cm (>35 inches)
Triglycerides	≥150 mg/dL
High-density lipoprotein cholesterol	
Men	<40 mg/dL
Women	<50 mg/dL
Blood pressure	≥130/≥85 mm Hg
Fasting glucose	≥110 mg/dL

Source: Reproduced from: Anonymous. Third report of the National Cholesterol Education Program Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). NIH Publication No. 02-5215, September 2002. Bethesda, MD: National Institutes of Health.

Table 28.5 World health organization clinical criteria for metabolic syndrome

Insulin resistance, identified by one of the following:
- Type 2 diabetes
- Impaired fasting glucose
- Impaired glucose tolerance
- For those with normal fasting glucose levels (<110 mg/dL), glucose uptake below the lowest quartile for background population under investigation under hyperinsulinemic, euglycemic conditions

Plus any two of the following:
- Antihypertensive medication and/or high blood pressure (≥140 mm Hg systolic or ≥ 90 mm Hg diastolic)
- Plasma triglycerides ≥ 150 mg/dL (≥1.7 mmol/L)
- High-density lipoprotein < 35 mg/dL (<0.9 mmol/L) in men or < 39 mg/dL (1.0 mmol/L) in women
- Body mass index > 30 kg/m² and/or waist-to-hip ratio > 0.9 in men, > 0.85 in women
- Urinary albumin excretion rate ≥ 20 μg/min or albumin-to-creatinine ratio ≥ 30 mg/g

Table 28.6 Characteristics of obesity-associated focal segmental glomerulosclerosis

Identifying features of obesity-associated and metabolic syndrome–associated FSGS

Clinical features
- Patients may not manifest edema
- Modest and subnephrotic-range proteinuria is usual
- Higher albumin than idiopathic FSGS
- Lower cholesterol than idiopathic FSGS
- More indolent course with slower progression

Biopsy features
- Large glomeruli
- Modest foot-process effacement on electron microscopy
- Increased foot-process width
- Segmental sclerosis is less common compared to idiopathic FSGS
- Global sclerosis is comparable to idiopathic FSGS
- Hyperplasia of juxtaglomerular apparatus is common

Gene expressions
Glomerular gene expression heightened for:
- Lipid metabolism
- Inflammatory cytokines
- Insulin resistance

FSGS, focal segmental glomerulosclerosis.

Table 28.7 Classification of obesity by body mass index

Obesity classification	Body mass index (kg/m²)
Ideal	18.5–24.9
Overweight	25.0–29.9
Obesity	≥30
Class I	30–34.9
Class II	35.0–39.9
Class III	≥40

Source: World Health Organization. Obesity: preventing and managing the global epidemic. Report of a WHO Consultation. WHO Technical Report Series 894. Geneva: World Health Organization; 2000. Document is in public domain.

A common approach is to require existence of at least three of the following clinical and biochemical findings:

- Increased waist circumference
- Hyperglycemia
- Elevated systolic and/or diastolic blood pressure
- Elevated fasting triglycerides
- Low HDL cholesterol
- Microalbuminuria

There are no universally accepted criteria for definition of MetS in children and adolescents.[99] Consensus, however, exists in that the common constellation of clinical and biochemical findings associated with the insulin resistance experienced in children and adolescents are often precipitated by excess weight, notably ectopic adiposity.[100] As with BMI, changing percentile norms must be considered when evaluating waist measures in children and adolescents. A more meaningful alternative is to consider the waist-to-height ratio, which is normally at or just below 50%, but reaches between 50% and 60% and above with severe visceral adiposity.[101] Ethnic and racial factors affect the MetS diagnostic parameters in adults, and adjusted ethnic and racial specific cutoffs have been proposed.[102]

KEY POINT

Pediatric criteria for MetS have yet to be established.

EPIDEMIOLOGY

As with adults, the pediatric prevalence of MetS varies considerably and is a function of the criteria chosen, as well as the population demographics. In the 2430 children reported in the Third National Health and Nutrition Examination Survey (1988 to 1994), overall MetS prevalence was 4%, but its prevalence in overweight children was 30%.[103] As the degree of obesity increases, the prevalence

of MetS increases, occurring in 38.7% of moderately obese (mean BMI 33.4 kg/m^2) and 49.7% of severely obese (mean BMI 40.6 kg/m^2) children and adolescents.[104]

> ### KEY POINT
>
> The prevalence of MetS in obese children may be as high as 30%.

ETIOPATHOGENESIS

Genetics

The MetS clusters in families and its prevalence varies across ethnic groups.[105,106] Heritability has been estimated to be as high as 24% to 61%, but no short list of candidate genes has emerged from study in this area.[107] Both candidate gene analyses and genome-wide association scans have hinted at complex gene networks with pleiotropic effects.[108,109] Multiple candidate genes have been identified, each making a small contribution to the pathologic processes of MetS. Many of these genes contribute to insulin regulation and energy metabolism.[110] Environmental triggers, such as a sedentary lifestyle and an energy-rich diet, may be equally important in in the causation of obesity and activation of these genetic influences.[111]

Intestinal microbiome

Some of the most provocative theories on the origins of the MetS relate to the possible interactions between human superorganism cells and resident gut flora. Intestinal bacteria have been causally implicated in the inflammatory processes associated with obesity and insulin resistance by increasing gut permeability, permitting excessive microbial translocation.[112]

Adipocyte-triggered systemic inflammation

It is increasingly apparent that obesity triggers systemic inflammatory response and insulin resistance, both of which are present in MetS. Preadipocytes are phagocytic cells that resemble macrophages in both morphology and patterns of gene expression.[113] In obesity, as in an infection, adipose tissue and infiltrated monocytes and macrophages release proinflammatory adipokines (Figure 28.4), notably TNF-α, interleukin-6 (IL-6), retinol binding protein-4 (RBP-4),

> ### KEY POINT
>
> Obesity leads to a state of inflammation and insulin resistance.
Figure 28.4 Obesity as an inflammatory state. Obesity is characterized by hyperplasia of the adipose cells. Excess calories are shunted into ectopic and hypertrophied adipocytes. Adipocyte dysfunction leads to monocyte and macrophage infiltration in the location of ectopic hypertrophied adipocytes. Release of cytokines from these tissue sites leads to a state of ongoing inflammation and insulin resistance.

and leptin, together with macrophage chemoattractant protein-1 (MCP-1). The mechanism for insulin resistance during inflammation induced by obesity is believed to be a physiologic response to make glucose available for the metabolic needs of an activated immune system.[114] Aging and a sedentary lifestyle also may influence this proinflammatory state in obesity and has been proposed as a possible mechanism for the development of MetS.[115]

Nutrient metabolic quality

Not all calories are created equal. Qualitative and quantitative nutrient features are important in microbial translocation of endotoxin across the intestinal barrier—the putative inflammatory root cause of insulin resistance and the MetS. Diets high in calorie content, such as refined starches, sugar, saturated and trans fats, and low in long-chain polyunsaturated omega fatty acids, natural antioxidants, and fiber from fruits and vegetables have been shown to promote inflammation and insulin resistance, and contribute to the development of the MetS.[116] Low consumption of fish, fruit, and

vegetables, combined with a sedentary lifestyle, has been considered an important factor in the development of MetS and preventable cardiovascular deaths.[117,118] Additionally, excess intake of branched-chain amino acids (protein), ethanol, and fructose can overwhelm hepatic clearance mechanisms and their metabolic accumulation may be associated with the MetS.[119] Fortunately, a fourth injurious dietary additive, trans-fatty acids, is being eased out of the food supply. These four substrates that are not regulated by insulin deliver metabolic intermediates to hepatic mitochondria and promote lipogenesis and the ectopic adipose storage—a feature characteristic of MetS.

Defective adipose tissue storage of calories

Obesity is characterized by a diminished differentiation and proliferation (hyperplasia) of the adipose cells to meet the storage demands of excess calories. Without sufficient adipose cells for fat storage, excess calories are shunted into ectopic and hypertrophied adipocytes. These hypertrophied adipocytes become dysfunctional, have inadequate vascular supply, and are at a heightened risk for apoptosis. As shown in Figure 28.4, the outcome of adipocyte dysfunction is monocyte and macrophage infiltration and initiation of an inflammatory cycle in these tissue sites.[120]

RENAL PATHOLOGIC FINDINGS IN OBESITY-RELATED GLOMERULOPATHY

The impact of obesity on renal glomerular structure has been well known since the early 1970s and has been further characterized recently.[121,122] Obesity and increased BMI are, indeed, independent risk factors for development of CKD, ESRD, and hypertension.[123,124]

Obesity and MetS lead to similar renal injury and are often grouped together under the heading of obesity-related glomerulopathy (ORG). Two pathologic lesions pathognomonic of ORG are glomerulomegaly and focal segmental glomerulosclerosis (FSGS). Glomerular hypertrophy is the most widely described abnormality in ORG (Figure 28.5). In age-matched patients (3.6 to 30 years), Cohen[122] noted a significant increase in the glomerular area in obese patients. Others have also demonstrated glomerulomegaly in the renal biopsies of obese children and adults.[125–127] In a study of 6818 renal biopsies, Kambham et al.[121] noted that the mean glomerular diameter in patients with ORG was 226 ± 246 mm (range, 172 to 300 µm), compared to 168 ± 12 µm (range, 138 to 186 µm) in age- and sex-matched controls.[121] Animal models of obesity (Zucker obese rats) also demonstrate glomerulomegaly as a part of their systemic organ dysfunction profile.[128]

> ### KEY POINT
>
> Obesity and MetS result in glomerular hypertrophy and FSGS.

The second type of renal lesions seen in association with obesity is FSGS (O-FSGS). Prevalence of O-FSGS in the renal biopsies of obese patients is unclear and variable (Table 28.6). Whereas erra et al. reported O-FSGS in only 5.3% of white patients from Spain, two studies from China noted O-FSGS to be present in 55.6% to 70% of obese patients with proteinuria.[124,126-129] All of these studies were conducted in adult patients. Although similar to classic FSGS, the following findings distinguish O-FSGS from classic FSGS (Figure 28.6)[121,127–130]:

- Glomerulomegaly as a prominent feature
- A lesser degree of global sclerosis and segmental sclerosis in the affected glomeruli
- A lesser degree of the foot process effacement (fusion)
- Tubulointerstitial disease less prominent
- Mesangial matrix expansion and sclerosis, along with basement membrane thickening—changes suggestive of "diabetes-like" morphology
Figure 28.5 Glomerular hypertrophy seen in light microscopy. **(a)** A normal-sized glomerulus (area < 30,000 µm²) and **(b)** an excessively enlarged one (area > 40 000 µm²). (Reproduced with permission from: Goumenos DS, Kawar B, El Nahas M, et al. Early histological changes in the kidney of people with morbid obesity. Nephrol Dial Transplant. 2009;24:3732–8.)
Figure 28.6 Representative light microscopy, immunohistology, and electron microscopy of obesity associated–focal segmental glomerulosclerosis (O-FSGS). **(a)** Mild or early FSGS with segmental increase in mesangial cellularity and matrix (arrow). **(b)** In advanced stages of FSGS, segmental sclerosis enlarges and the capillary tuft begins to adhere to Bowman's capsule (arrow). **(c)** When segmental adhesion and sclerosis proceed, more of the capillary lumen is obliterated and global sclerosis is about to develop. **(d)** In addition to focal glomerulosclerosis in the four adjacent glomeruli, glomerular size is increased, indicative of glomerular hypertrophy. RENAL MANIFESTATIONS OF OBESITY-RELATED GLOMERULOPATHY AND METABOLIC SYNDROME

Patients with ORG and MetS may be clinically asymptomatic but may have elevated urinary microalbumin excretion. Proteinuria, when present, is usually subnephrotic in range, but nephrotic-range proteinuria has been reported in a minority of cases. Serum albumin is usually better preserved, despite significant proteinuria, and a clinical nephrotic state is uncommon.[125] For example, Kambham et al.[121] noted a nephrotic-range proteinuria in 48%, but clinical nephrotic syndrome was present in only 5.6% cases of ORG. Hypertension is common in these patients. Hyperfiltration, resulting in increased GFR, is noted in the early stages of ORG-MetS.[121,124] This is followed by gradually increasing serum creatinine, which has been seen in 35% to 50% patients in some studies, eventually leading to ESRD in

some.[123] The annual ESRD rate in white patients with ORG-MetS has been estimated to be approximately 7%.[131]

MANAGEMENT

Management of renal consequences of obesity and metabolic syndrome is directly linked to effective of metabolic syndrome. Management of these patients is best offered by a multidisciplinary team consisting of a nutritionist, exercise trainer, nephrologist, and a specialist in lipid disorder. The strategy includes weight reduction, identification and treatment of risk factors for coronary heart disease, and treatment of hyperfiltration.

Weight reduction

Weight reduction is part of the composite management of MetS, referred to as *therapeutic lifestyle changes* (TLCs).[96] TLC alone has been shown to decrease the incidence of MetS in at-risk adults by 41%.[132] TLC also reduces the incidence of diabetes mellitus in patients with prediabetes.[133] Additionally, modest weight loss is also associated with a decrease in fasting insulin and leptin and an increase in adiponectin levels.[134] The positive impact of weight reduction on the degree of proteinuria also has been documented

---

KEY POINT

Obesity- and MetS-induced FSGS is usually associated with modest subnephrotic-range proteinuria.

in some studies.[125] Reduction of saturated fat, trans fats, and cholesterol in the diet has the added benefit of lowering serum LDL cholesterol profile, a risk factor for coronary heart disease (CHD).

Insulin-sensitizing agents

Metformin, a drug originally derived from the plant *Galega officinalis,* which had been used for treatment of diabetes mellitus, is also useful in the treatment of MetS.[132,135] Metformin also has been noted to reduce the incidence of diabetes mellitus in patients with prediabetes.[133] Metformin provides a dual impact by decreasing hepatic glucose synthesis as well as by increasing glucose uptake in peripheral tissues. In effect, metformin increases tissue sensitivity to insulin and is also referred to as an insulin sensitizer. Thiazolidinediones, also known as glitazones (rosiglitazone and pioglitazone), are other types of clinically useful insulin sensitizers in MetS prediabetes management.[136,137]

Hypertension and glomerular hyperfiltration

ACEIs and ARBs are recommended to be the primary therapeutic choice in treatment of hypertension in patients with MetS. Apart from managing hypertension, the advantage of ACEIs and ARBs in MetS patients is their ability to diminish glomerular hyperfiltration.[138] Use of ACEIs and ARBs also helps reduce microalbuminuria and overt proteinuria in these patients.[125]

Dyslipidemia

To reduce CHD risk, use of statins has been highly recommended in adults with MetS.[96] However, this benefit has to be balanced with the reported diabetogenic potential of statins in adults.[139] Although useful in children with dyslipidemia, the Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents does not recommended statin use below 10 years of age.[140,141]

SUMMARY

Metabolic syndrome and obesity-related diabetes (type 2) is being increasingly encountered in children and adolescents. Good glycemic control is essential in preventing nephropathy and other microvascular complications of diabetes. Use of ACEIs in early treatment of nephropathy associated with diabetes is recommended to prevent onset of proteinuria, CKD, and ESRD. Unfortunately, these drugs have not been shown to forestall onset of nephropathy, when used as preventive agents in the early course of the disease. Macrovascular complications, such as CAD, atherosclerosis, and stroke continue to be the leading causes of mortality, in addition to CKD and need for dialysis and transplantation.

Clinical Vignette 28.1

A 17-year-old Hispanic female with known obesity presented to the renal clinic for management of hypertension. She was the product of 37 weeks of gestation born via cesarean section, with a birth weight 9 lb. Pregnancy was complicated by maternal obesity, a 50-lb weight gain during pregnancy, and eclampsia, but there was no history of gestational diabetes in the mother. The patient was not breast fed and was advanced on formula and progressed by 4 months to rice cereal and onto solid foods in response to a "robust appetite." The patient had always been husky for age and had accelerated weight gain with menarche at 8.5 years.

The patient was initially referred to multidisciplinary care at an obesity clinic at 12 years of age, when her BMI was above the 95th percentile, with central adipose distribution (waist-to-height ratio, 68%). Review of systems was positive for gastrointestinal reflux disease and heavy snoring during sleep. She had no history of sleep apnea, but she reported daytime sleepiness. She has been on oral contraceptives and has had regular menstrual cycle. Weight management strategies were discussed at the initial visit, but she was lost to follow-up until this referral for new onset of hypertension

The patient's family history was positive for DM2 on the maternal side of the family with associated hypertension and dyslipidemia. Her maternal great-grandmother also had DM2 and was on dialysis by 60 years of age. Her paternal grandfather had a stroke in his 50s.

The patient is in grade 11 and has been struggling academically. She reports long-standing difficulty in keeping up with her peers in physical education. She does not seek after-school activities and watches TV for an average of 4 to 6 hours per day.

Physical examination showed height, 60 inches (5th percentile); weight, 180 lb (97th percentile); BMI, 37.2 kg/m² (99th percentile); and blood pressure, 128/78 mm Hg (systolic SBP 97th percentile, diastolic 88th percentile). Moderate acanthosis nigricans was seen around the back of her neck. Ambulatory blood pressure monitoring (ABPM) showed more than 75% of daytime readings and more than 90% of nighttime readings exceeding limits for age, gender, and height. Blunted nocturnal dipping was noted.

A fasting metabolic screen showed total cholesterol, 180 mg/dL (high); triglycerides, 185 mg/dL (high); HDL cholesterol, 38 mg/dL (low); non-HDL cholesterol, 182 mg/dL (high); lipoprotein a, 95 nmol/L (high); LDL cholesterol, 105 mg/dL (high); glucose, 95 mg/dL (normal); 2-hour oral glucose tolerance test, 148 mg/dL (abnormal); fasting insulin, 35 mU/L(high); HbA1c 6.2% (high); alanine transaminase, 34 international units/L (high); normal electrolytes, blood urea nitrogen (BUN), 16 mg/dL; and creatinine, 1.1 mg/dL. Urinalysis was negative for protein; the urine (micro)

albumin-to-creatinine ratio (ACR) was 3.0 mg/mmol and 25-OH vitamin D was 12 (low).

TEACHING POINTS

- This 17-year-old adolescent female of Hispanic ancestry with a lifelong history of obesity presented with clinical and biochemical evidence of insulin resistance and cardiometabolic sequelae consistent with MetS. These include central adiposity, hypertriglyceridemia, low HDL level, and systolic hypertension. Hyperglycemia is masked by hyperinsulinism, but her 2-hour oral glucose tolerance test result is abnormal and the elevated HbA1c reflects suboptimal glucose regulation. Elevated ALT is consistent with nonalcoholic fatty liver disease. Disordered sleep history is suggestive of obstructive sleep apnea that can aggravate insulin resistance. BUN and creatinine levels are both at upper limits of normal. Evidence of prediabetes, as well as the lack of nocturnal dipping on ABPM and upper range of normal ACR heightens the potential for CKD.[123,134]
- She is at an increased risk for insulin resistance on the basis of her Latino ancestry, positive family history of DM2 and early cardiovascular disease, large size for gestational age birth weight, maternal obesity, and excessive maternal weight gain during gestation.
- Her risk is further accentuated by a sedentary lifestyle and poor dietary habits. Although there is ample room for lifestyle improvements, this patient will need adjunct insulin-sensitizing and antihypertensive medications with intensive reinforcement of nutritional and activity changes.
- She is also at high risk for developing CKD later in life.[142] Measures need to be implemented to stem this momentum toward a diagnosis of DM2 and CKD.

REVIEW QUESTIONS

1. In the pediatric age group (up to 19 years), diabetes mellitus accounts for ESRD in:
   a. 10% to 15%
   b. 20% to 50%
   c. >1%
   d. >10%

2. Advanced glycation products result from nonenzymatic reaction of glucose with proteins, lipids, and nucleic acids.
   a. True
   b. False

3. Podocyes lack insulin receptors.
   a. True
   b. False

4. Renin-angiotensin induces glomerular injury in diabetic nephropathy by:
   a. Systemic hypertension
   b. Glomerular hypertension
   c. Increasing podocyte apoptosis
   d. Increasing tubular sodium concentration and inducing tubuloglomerular feedback

5. The classic pathologic lesion in diabetic nephropathy is:
   a. Kimmelstiel-Wilson lesion
   b. Large glomeruli (glomerulomegaly)
   c. Focal segmental glomerulosclerosis
   d. Wire loop lesion

6. The latent phase of diabetic nephropathy in diabetes mellitus type 1 lasts:
   a. <5 years
   b. 5 to 10 years
   c. 10 to 15 years
   d. 30 to 40 years

7. Microalbuminuria in a diabetic 17-year-old girl is best tested in a:
   a. Random sample obtained in any time
   b. Random sample obtained late in the afternoon
   c. First morning urine sample
   d. Random sample obtained after ambulating for 4 hours

8. Microalbuminuria in a patient with diabetes mellitus type 1 indicates:
   a. Early diabetic nephropathy
   b. No clinical significance
   c. Onset of ESRD
   d. Development of Kimmelstiel-Wilson lesion

9. A 25-year-old man with onset of diabetes mellitus at 3 years of age had been lost to follow-up in nephrology for 3 years. He had sporadic visits with his internist and endocrinologist. Upon his return to the nephrology clinic, his estimated GFR was 100 mL/min/1.73 m^2, and he now has well-documented microalbuminuria and his hemoglobin A1c was 11.5%. His previous known GFR, obtained 3 years ago, was 135 mL/min/1.73 m^2. Which of the following best reflects diabetic nephropathy in this patient?
   a. His disease has not progressed, because he has a normal GFR.
   b. He is now cured of diabetic nephropathy, because he does not have hyperfiltration
   c. Microalbuminuria in presence of normal GFR has no clinical significance.
   d. His renal disease has progressed, because he now has albuminuria and his GFR has should be considered to have declined from a state of hyperfiltration to "normal."

10. Which of the following statements *best* characterizes the use of angiotensin-converting enzyme inhibitors in diabetic nephropathy?
    a. ACEIs are ideally started at the time of the diagnosis of diabetes mellitus to prevent development of microalbuminuria.
    b. Evidence to suggest that ACEIs prevent development of microalbuminuria is lacking.
    c. ACEIs improve diabetes control.
    d. ACEIs prevent progression of microalbuminuria.

11. The central findings of metabolic syndrome are:
    a. Insulin resistance and hyperglycemia
    b. Hypertension
    c. Obesity with increased waist circumference
    d. Dyslipidemia
    e. Microabluminuria
    f. All of the above
    g. Only a, b, and e

12. Obesity and metabolic syndrome are characterized by molecular markers of systemic inflammation.
    a. True.
    b. False.

13. Renal pathologic findings in obesity and metabolic syndrome characteristically demonstrate:
    a. Glomerulomegaly (large glomeruli)
    b. FSGS with less pronounced morphologic changes
    c. Basement membrane thickening
    d. Lesser degree of foot-process fusion
    e. All of the above
    f. Only a, b, and d

Kidney in viral infections

JEFFREY B. KOPP

Viral infections can cause a variety of renal diseases, which can lead to significant morbidity. Renal injury by human immunodeficiency virus (HIV-1), hepatitis B virus (HBV), and hepatitis C virus (HCV) has been well described. The clinical manifestations of these viral infections can range from subtle abnormalities, such as sodium wasting, microscopic hematuria, or proteinuria, to severe nephritic syndrome, nephrotic syndrome, acute kidney injury (AKI), and thrombotic microangiopathy (TMA). Diagnostic evaluation of viral infections has significantly improved in the last decade with availability of viral load detection by quantitative polymerase chain reaction (PCR) testing for many agents in both urine and blood. Therapeutic approaches to treatment of viral infections also have been advanced, especially in the case of HIV-1 infection. This chapter will review the three important viral pathogens noted here and also include a brief description of nephropathies related to cytomegalovirus (CMV), parvovirus B19 (PVB19), and Epstein-Barr virus (EBV).

HUMAN IMMUNODEFICIENCY-1 VIRUS

EPIDEMIOLOGY

In 1983, reports of the first cases of pediatric acquired immunodeficiency syndrome (AIDS) occurred in the United States.[1,2] AIDS was initially described in two age groups of the pediatric population:

1. Infants infected through vertical transmission
2. Children who acquired infection through blood transfusions

Subsequently, pediatric AIDS became a major public health concern worldwide, particularly in sub-Saharan Africa, where approximately 600,000 children are born with HIV-1 infection per year.[3] By the end of 2001 in the United States, pediatric AIDS cases represented approximately 1.2% of the total cases of AIDS, predominantly affecting minority populations. African Americans make up approximately 65% of all children with HIV-1 infection or AIDS, and more than 40% of these children are at risk for renal complications.[3-5]

KEY POINTS

- Approximately 40% of children with HIV infection are at risk for renal complications.
- The morphologic type of renal disease is variable.

CLINICOPATHOLOGIC VARIANTS

HIV-1 infection is associated with a variety of glomerular diseases (Table 29.1): (1) HIV-associated collapsing glomerulopathy (frequently referred to as HIV-associated nephropathy [HIVAN], (2) HIV-associated glomerulonephritis (HIV-associated GN), and (3) HIV-associated thrombotic microangiopathy (HIV-associated TMA).[6-10]

Table 29.1 Renal diseases associated with viral infections

HIV-1	• Collapsing glomerulopathy
	• Glomerulonephritis
	  • Lupus-like glomerulonephritis
	  • Membranoproliferative glomerulonephritis
	  • IgA nephropathy
	• Others
	  • Membranous nephropathy
	  • Fibrillary and immunotactoid nephropathy
	  • Thrombotic microangiopathy

HBV	• Membranous nephropathy—most common in children • Membranoproliferative glomerulonephritis • IgA nephropathy • Polyarteritis nodosa
HCV	• Membranoproliferative glomerulonephropathy (with or without cryoglobulinemia)

Abbreviations: HBV/HCV, hepatitis B/C virus; HIV, human immunodeficiency virus; IgA, immunoglobulin A.

Among African-American patients, collapsing glomerulopathy is the most common clinicopathologic disorder, whereas HIV-associated GN is most prevalent among white, Hispanic, and Asian patients. During early years of the AIDS epidemic in children, Strauss et al.[4] estimated the prevalence of childhood HIVAN to be approximately 10% to 15%. These data were based on clinical criteria, histology from studies of predominantly African American pediatric patients, or both.

KEY POINT

Kidney lesions associated with HIV infection include collapsing glomerulopathy, HIVAN, immune complex disease, thrombotic angiopathy, and drug-induced nephrotoxicity.

Human immunodeficiency virus collapsing glomerulopathy

CLINICAL MANIFESTATIONS AND BACKGROUND

Patients with HIVAN often present with asymptomatic proteinuria and are usually normotensive. Renal ultrasound classically shows enlarged, echogenic kidneys. Although HIVAN can occur at any stage of the disease, including the time of seroconversion, it is most commonly seen in patients with advanced HIV disease.[11] In the initial years of the HIV epidemic, this syndrome was characterized by a rapid progression to end-stage renal disease (ESRD). Further, these patients also had increased mortality on dialysis.

Abbott et al.,[12] using the data from the U.S. Renal Data System (USRDS), showed that 2-year survival was 36% for patients with HIVAN on dialysis, compared to 64% for those with ESRD of other causes between 1992 and 1997. In recent years, with the widespread use of combined antiretroviral therapy (cART), the incidence of HIVAN has plummeted.

KEY POINT

cART has markedly decreased the incidence of HIVAN.

Patients of African descent have striking susceptibility to developing HIVAN, with nearly 90% of the cases occurring in black individuals. Of patients with HIVAN, 25% have first-degree or second-degree family members with ESRD, suggesting a genetic predisposition to glomerular injury.[13] HIVAN is the third leading cause of ESRD in blacks 20 to 64 years of age, after diabetes mellitus and hypertension.[7] Based on the USRDS, the relative risk for ESRD from HIV-associated nephropathy is approximately 18-fold increased among African Americans compared to white patients.[14] The basis for this striking predilection is a pair of variants in *APOL1,* encoding apolipoprotein L1, that are exclusively present in individuals of African descent and make up 35% of alleles in African Americans.[15] The presence of two *APOL1* risk alleles is associated with an odds ratio of 29 for HIVAN.[16]

PATHOLOGIC FINDINGS

The renal histologic findings are characterized by segmental or global collapse and sclerosis of the glomerular tuft (Figure 29.1). Podocytes, which are normally postmitotic
Figure 29.1 HIV-associated collapsing glomerulopathy in a 33-year-old patient. The light microscopy shows collapse of the glomerular tuft. Vacuolization and crowding of the glomerular epithelial cells are commonly seen and reflect the primary epithelial cell injury in this disease.

cells, reenter the cell cycle and proliferate, in some cases forming pseudocrescents, and lose differentiation markers. There is tubular injury with atrophy and microcyst formation (Figure 29.2).

PATHOGENESIS

The HIV-1 genome contains nine genes (*gag, pol, vif, vpr, vpu, rev, tat, env,* and *nef*), which encode 15 proteins. These viral accessory proteins have pleiotropic effects on cell function and are implicated in renal injury. *vpr* induces G2 cell cycle arrest, perturbs mitochondrial functions, induces (and in some cells prevents) apoptosis, and alters gene transcription by acting as a coactivator. Roles of other accessory proteins in inducing renal injury have not been excluded. *tat* and *nef* each induce proliferation of podocytes, a distinctive feature of HIVAN.[17,18] A series of studies using transgenic mice bearing various portions of this genome have suggested which genes may be responsible for renal injury. HIV-1 transgenic mice carrying a replication defective HIV-1 provirus that lacks *gag* and *pol* develop renal disease characterized by podocyte dysplasia and proliferation, glomerular capillary tuft collapse, focal segmental glomerulosclerosis (FSGS), and tubular injury and do so even in the absence of immunosuppression and viral replication.[19,20] Deletion of *nef* from the transgene reduced the severity of interstitial nephritis, but it did not prevent the development of glomerular disease in one transgenic line.[21] More recently, mice bearing *tat* and *vpr* or *vpr* alone developed FSGS.[22] These data from transgenic mice indicate that *vpr* induces FSGS and *nef* contributes to interstitial nephritis.[22–24]

Because expression of HIV-1 gene products within podocytes and tubular epithelial cells can induce all the features of HIV-associated FSGS, the next question has been to understand how those gene products enter renal parenchymal cells. The data regarding direct infection of renal epithelium by HIV-1 have long been controversial. Bruggeman et al.[25] provided supportive evidence to suggest that HIV-1 viruses can directly infect the renal tissue. They detected HIV-1 in the renal tissue by RNA in situ hybridization and DNA in situ PCR. HIV-1 RNA was detected in renal tubular epithelial cells, glomerular visceral and parietal epithelial cells, and interstitial leukocytes. In addition, the distribution of HIV-1 infection of renal tubules is similar to the pattern of microcystic tubular disease, a prominent histologic feature of the nephropathy. These findings support the direct infection of renal parenchyma by the HIV-1 virus.[26]

> ## KEY POINTS
>
> - The kidney may serve as a reservoir for HIV-1.
> - Evidence suggests direct infection of the kidney cells by HIV-1 virus.

Infection of renal epithelial cells by HIV-1 has another important implication. The kidney may serve as a reservoir for HIV-1. Marras et al.[27] detected variation in the HIV-1 envelope sequences in the renal tubular epithelium of HIV-infected patients, indicating that renal epithelium can support viral replication. Furthermore, the envelope sequences of HIV-1 found in renal epithelium were distinct from the sequences derived from the same patient's peripheral blood samples, suggesting that the renal epithelium is a distinct reservoir for viral replication from the blood.

TREATMENT

Although HIVAN is an important cause of renal failure in the United States, no randomized controlled trials have been carried out to assess various therapies. Thus, recommendations are based on retrospective or uncontrolled studies. It is likely that cART prevents the onset or slows progression of HIVAN (based on the epidemiologic evidence of fewer patients reaching ESRD in recent years) and may reverse clinical manifestations (based on anecdotal reports).[11,28] Angiotensin-converting enzyme inhibitors (ACEIs) also have been shown to reduce proteinuria and progression of renal disease in HIV-infected patients.[29,30]

The role of immunosuppressive therapy has been explored but it is no longer considered appropriate. Studies using prednisone in patients with renal dysfunction and HIV-1 infection show some efficacy in preserving renal function and reducing proteinuria.[31,32] However, these studies are not well controlled and not all reported patients underwent renal biopsy. Another retrospective study suggested the efficacy of combination therapy with cART and glucocorticoids.[33] The mean renal survival to
Figure 29.2 HIV-associated tubulointerstitial changes in a 20-year-old patient. The pathologic findings include asymmetric, occasionally massive, tubular epithelial cell cytoplasmic protein resorption droplets, acute tubular epithelial injury with focal simplification, and variable microcystic change.

ESRD was 26 months for those treated with the combination therapy, 6 months for those given cART alone, and 3 months for those given neither cART nor glucocorticoids. Although no studies have suggested the efficacy of glucocorticoids in children with HIVAN, a very small study reported remission of proteinuria with cyclosporine therapy in three children who had steroid-resistant renal disease.[34] Again, the study was not a controlled trial and was done before the era of cART, making it difficult to draw any conclusion.

Several novel therapies have been tested in animal models of HIVAN and offer some prospect for translation to clinical care. Cyclin-dependent kinase inhibitors were found to inhibit podocyte proliferation and induce re-expression of normal podocyte differentiation markers in vitro.[35] Gherardi et al.[36] reported reversal of collapsing glomerulopathy in HIV-transgenic mice with cyclin-dependent kinase inhibitors. He and colleagues demonstrated that retinoid acts in a similar fashion.[37] Sharma et al.[38] showed that Notch pathway inhibition attenuates glomerular injury in HIV-transgenic mice.

Human immunodeficiency virus–associated immune complex kidney disease

In the absence of a national registry of renal biopsy findings, the true prevalence of HIV-associated immune complex kidney disease is unknown. Several different histologic descriptions have been reported for HIV-associated GN, including a lupus-like pattern, membranoproliferative glomerulonephritis (MPGN), membranous nephropathy (MN), fibrillary and immunotactoid GN, postinfectious GN, and immunoglobulin A (IgA) nephropathy. It is not always possible to discern if the renal disease is a consequence of the HIV-1 infection or if it is a coincidental occurrence. For example, patients with HIV disease are often coinfected with HBV or HCV, each of which can be associated with glomerular diseases, such as membranous glomerulopathy and MPGN.

The pathogenesis of these forms of HIV-associated immune complex kidney disease is not clear. In IgA nephropathy, immune complexes containing HIV proteins have been found in the mesangium, possibly delivered from plasma, or forming in situ, leading to renal parenchymal inflammation.[39] Guidelines for treatment are limited by the lack of prospective, randomized, and controlled trials, but therapies have included antiretroviral therapy, ACE inhibitors, and prednisone.[40,41]

Human immunodeficiency virus and thrombotic microangiopathy

Since the first report of HIV-associated TMA in 1984, it has been increasingly recognized as a common microvascular injury in this infection.[42] A retrospective study demonstrated that 15 of 224 AIDS patients (7%) had evidence of TMA at the time of death.[43] The pathologic findings include occlusive thrombi in small arteries and arterioles, and detachment of glomerular endothelial cells from the basement membrane (Figure 29.3). Affected patients typically present with hemolytic-uremic syndrome characterized by renal insufficiency, microangiopathic hemolytic anemia, and thrombocytopenia. The pathogenesis of TMA involves endothelial injury caused by toxins, vasoactive peptides, or immune factors. Infection of microvascular endothelial cells by HIV-1 has not been confirmed, and the mechanisms that induce microvascular damage in HIV-1 infection are poorly understood. There are no data to suggest that HIV-associated TMA should be treated differently from idiopathic or autoimmune forms of TMA. Therapies have included plasmapheresis, prednisone, or both, with limited success in HIV-associated TMA.

Drug-induced nephrotoxicity in human immunodeficiency virus infection

Drug-induced acute renal failure, with or without chronic progression, is a common cause for renal insufficiency in the HIV population. Examples include AKI kidney injury resulting from pentamidine, foscarnet, cidofovir, amphotericin B, and aminoglycosides.[44–46] Acute renal failure also may result from crystal precipitation following the use of sulfadiazine or intravenous acyclovir.[47,48] Indinavir may cause renal calculi and obstruction.[49]
Figure 29.3 Light microscopy of renal biopsy in a child with HIV-associated thrombotic microangiopathy. The glomerular capillaries are collapsed, and red cell fragments are present in several capillary loops. Arrows outline an arteriole with endothelial swelling and luminal narrowing secondary to thrombosis. (Reproduced with permission from Turner ME, Kher K, Rakusan T, et al. Atypical hemolytic uremic syndrome in human immunodeficiency virus-1-infected children. Pediatr Nephrol. 1997;11:161.)

In recent years, tenofovir, a nucleoside analogue reverse transcriptase inhibitor (NtRTI) has emerged as the most common cause of drug-associated renal dysfunction (Table 29.2). Its renal toxicity is predominantly characterized by proximal tubular dysfunction, demonstrated by normoglycemic glucosuria, proteinuria, hematuria, and hypophosphatemia.[50,51] The proteinuria associated with tenofovir is usually mild, but nephrotic-range proteinuria also has been described.[52] Some patients also developed signs of distal tubular toxicity, presenting with diabetes insipidus.[53] The frequency of tenofovir renal toxicity in prospective cohort studies rises with increased therapy duration.[54–56] Prompt recognition of the syndrome and discontinuation of tenofovir therapy offers the best chance for improvement in renal function, although complete reversal may not occur. Continued administration of tenofovir may lead to chronic kidney disease in some patients. Renal function improves in most patients on discontinuation of the drug, but persistent glucosuria and proteinuria with elevated creatinine, suggesting irreversible damage, have been documented in some cases.[55,56] Renal biopsies in these patients have shown acute tubular necrosis, particularly involving proximal tubules.[51]

Tenofovir, an acyclic nucleoside phosphonate, belongs to a unique class of nucleoside analogues, which also include cidofovir and adefovir. Many of the adverse effects associated with these agents have been attributed to mitochondrial toxicity, because phosphorylated forms of some nucleoside reverse transcription inhibitors are potent inhibitors of mitochondrial DNA polymerase.[57] Drug-related deficiencies in the mitochondrial oxidative phosphorylation system lead to disruption in pyruvate oxidation and increased lactic acid production.[58] Thus, organs rich in mitochondria, such as muscle, liver, and kidney (particularly the proximal tubules), are at increased risk for the clinical toxicities, which can manifest as myopathy, liver

Table 29.2 Features of tenofovir renal toxicity

Presentation	Fanconi syndrome
	Hypokalemia
	Proteinuria (usually < 3 g/day)
	Diabetes insipidus (rare)
	Nephritic syndrome (rare)
Onset	At any time during therapy
Renal biopsy	Acute tubular necrosis involving mostly proximal tubules
Risk factor	Concurrent use of lopinavir/ritonavir

steatosis, lactic acidosis, and Fanconi syndrome. These nucleoside analogues undergo renal tubular secretion through proximal tubules (via human renal organic anion transporter-1). Therefore, the accumulation of the drug in the proximal tubules likely plays an important role in nephrotoxicity. Given the possible nephrotoxicity, patients taking tenofovir (especially those also on lopinavir or atazanavir, which can increase the serum concentration level of tenofovir) need to be monitored regularly. The decision regarding when the drug should be stopped needs to be individualized.

The new face of human immunodeficiency virus kidney disease

The widespread and chronic use of cART has led to a new set of renal diseases, similar to those seen in the general population, including particularly diabetic nephropathy and arterionephrosclerosis.[59] In many cases, these appear after a decade or more of cART therapy and thus may affect HIV-positive individuals at substantially younger ages compared to the general population, who tend to manifest renal dysfunction resulting from these diseases after the age of 50 or 60. The mechanisms are likely complex but include a chronic inflammatory state associated with low-level viral replication and immune activation and the effects of cART that promote disorders of glucose and lipid metabolism, including diabetes mellitus and metabolic syndrome.[60]

HEPATITIS B VIRUS

Chronic HBV infection is a global public health problem affecting approximately 350 million people, or 5% of the world's population. The prevalence of HBV carriers varies from less than 1% in nonendemic areas (North America, Western Europe, Australia, and New Zealand) to 3% to 5% in intermediate areas (Mediterranean countries, Japan, Central Asia, Middle East, and Latin and South America) and to 10% to 20% in endemic areas (Southeast Asia, China, and sub-Saharan Africa).[61]

In nonendemic areas, HBV infection is predominantly a disease of adults, being transmitted largely through intravenous drug use or sexual contact. In the endemic countries, however, HBV is a common disease of childhood, with either vertical or horizontal transmission. This difference in the age at initial infection is likely to be responsible for the wide variability in prevalence of chronic HBV infection in different parts of the world.

The risk for chronicity in HBV infection is inversely related to the age at infection.[62] The risk for chronic infection in infants younger than 1 year of age is thus as high as 90% compared to 10% to 40% at 4 to 6 years and 1% to 5% in adults. Given that the majority of HBV infection cases occur during the first year of life in many endemic areas, it is not

surprising that the burden related to the complications of chronic HBV infection is also highest in these areas.

CLINICOPATHOLOGIC VARIANTS

Various clinicopathologic forms of renal diseases have been described in patients with chronic HBV infection. These include MN, MPGN, mesangial proliferative GN, IgA nephropathy, and polyarteritis nodosa (see Table 29.1).[62,63] Although there also have been reports of lupus nephritis, FSGS, and minimal-change nephrotic syndrome, it is unclear if these were incidental findings. The most widely accepted pathogenesis for HBV-associated renal disease is the deposition of immune complexes of viral antigen and host antibody.

Membranous nephropathy

MN is the most common form of HBV-associated nephritis in children, accounting for more than 85% of HBV-associated renal disease undergoing renal biopsy. HBV envelope antigen (HBeAg) is believed to be the primary antigen present in the subepithelial deposits.[64] Approximately 30% to 60% of children with HBV-associated membranous nephropathy (HBV-associated MN) undergo spontaneous remission, usually in association with development of anti-HBeAg seroconversion, over 6 to 24 months.[65] In a study of 71 children with HBV-associated MN from Cape Town, South Africa, the average time of clearance of HBeAg to remission was 5 months.[63] This is in contrast to adults, who tend to develop progressive nephropathy in approximately 25% of affected individuals. The presentation of HBV-associated MN also differs between pediatric and adult patients. Whereas adults tend to present with nephrotic syndrome, children can remain asymptomatic and the proteinuria may be incidentally discovered during a routine urine and serologic screening. In addition, there is a stronger male predominance in children affected by HBV-associated MN and children are also less likely to experience acute hepatitis compared to adults.[62]

Mesangioproliferative glomerulonephritis (immunoglobulin A nephropathy)

Chronic HBV infection has been associated with mesangial proliferative GN with deposition of IgA and HBV surface antigen in the mesangium.[66] Bhimma et al.[67] reported that 6 of 23 children with HBV-associated nephropathy other than membranous disease had mesangial proliferative GN. It is unclear if the deposited IgA has anti-HBV surface antibody activity.

Membranoproliferative glomerulonephritis

HBV-associated membranoproliferative glomerulonephritis (MPGN) is characterized by the deposition of antigen-antibody complexes in the mesangium and subendothelial space. These glomerular deposits are mainly composed of IgG and complement C3, and both HBV surface and envelope antigens have been implicated in this GN.[68] MPGN typically occurs in association with mixed cryoglobulinemia, particularly in the setting of coinfection with HCV.

Polyarteritis nodosa

Polyarteritis nodosa, a large-vessel vasculitis caused by antigen-antibody complex deposition in the vessels can be associated with infection with HBV.[69] The clinical presentation is comparable to that of polyarteritis that is not associated with HBV and typically occurs within 4 months after the onset of HBV infection.

TREATMENT

Therapy for HBV renal diseases has focused on antiviral therapies, although the data from controlled studies are limited. In general, immunosuppression for HBV-associated renal disease is of no proved benefit, particularly in children with MN in whom spontaneous recovery over 6 to 24 months is common.

Antiviral therapies

Currently, the three medications approved for treatment of chronic HBV infection in adults are interferon-α (IFN-α), lamivudine, and adefovir dipivoxil. Of these, IFN-α and lamivudine are approved for use in children in the United States. Several controlled trials in children with HBV infection have evaluated the efficacy of IFN-α in different parts of the world. Response rate, defined as HBeAg seroconversion or disappearance of plasma HBV DNA, tends to be highest in Western countries at 20% to 58% and lower in Asian countries at approximately 17%.[70–74] The difference in response rates may not be due to ethnicity but rather to the fact that a higher proportion of patients from endemic areas are infected at birth and are in the immune-tolerant phase of infection. It is unclear why such patients are less likely to respond to antiviral therapy. Based on current data, IFN-α may be effective therapy for HBV-associated MN, particularly in young children in nonendemic areas.

Experience with lamivudine in children with chronic HBV infection is limited. Although the available data suggest its efficacy and safety in children, the benefit of

lamivudine must be balanced against the risk for selecting resistant mutants. Children with higher baseline alanine aminotransferase and histologic activity index scores on liver biopsy are more likely to respond to lamivudine.[75] The optimal duration of therapy is unclear. Lamivudine should be used for at least 1 year and continued for at least 6 months after HBeAg seroconversion. Adefovir has been evaluated as monotherapy for adults with chronic HBV infection and those who have developed resistance to lamivudine.[76] Other potential antiviral agents that require further studies in children include pegylated IFN, famciclovir, and lobucavir.

Immunosuppression

Glucocorticoids or cytotoxic agents, which are used in primary MN, have no proved benefit in patients with HBV-associated MN.[77] Indeed, immunosuppression may lead to greater viral replication and exacerbation of chronic hepatitis. One exception may be in patients with active vasculitis who may require a short course of steroid treatment to control the inflammatory response.[78]

Immunoprophylaxis

The most important strategy to improve morbidity and mortality associated with chronic HBV infection is immunoprophylaxis. HBV vaccination given as part of routine immunization in endemic areas is highly effective in reducing the incidence of HBV-associated MN.

HEPATITIS C VIRUS

HCV infection, the leading indication for liver transplantation, remains a significant cause for morbidity and mortality in adults. It is, however, a less common cause of liver disease in children. In the United States, 60,000 to 100,000 children (0.2% to 0.4% of all children) are estimated to have chronic infection with HCV, although the specific incidence in children is unknown.[79] The prevalence is much higher in children (50% to 95%) who received multiple transfusions of blood and blood products before 1992.[80]

The predominant route of HCV infection in children is perinatal transmission. The incidence of vertical transmission of HCV is approximately 2% to 5% in HCV RNA–positive mothers, but coinfection with HIV-1 can more than quadruple the risk to approximately 20%.[81] Among adolescents, risk factors also include intravenous or intranasal drug use and use of contaminated tattoo instruments.

The natural history of HCV in the pediatric population is now better defined. In general, infections acquired early in infancy (either by transfusion or vertical transmission) can undergo spontaneous clearance more frequently than infections acquired later in life, and the reported cure rates

vary from 9% to 45%.[82-85] Another general observation is that HCV is often mild and less progressive during childhood, although hepatic cirrhosis generally occurs in the third decade of life.[85]

KEY POINT

MPGN is the predominant glomerular disease associated with HCV, most often related to cryoglobulinemia.

HEPATIC C NEPHROPATHY

The predominant glomerular disease associated with HCV is MPGN, usually in the setting of cryoglobulinemia.[86] Other forms of glomerular disease associated with HCV in adults include MN and fibrillary and immunotactoid glomerulonephropathy.[87-89] To date, no studies have examined whether treatment of children with HCV infection reduces their subsequent risk for cirrhosis, hepatocellular carcinoma, or renal complications. There are no systemic studies of HCV-associated nephropathy in children. Interestingly, 19% of children with ESRD tested for HCV infection in one study in the 1990s were found to have a positive result, suggesting that HCV may be an important association in progressive renal disease in children.[90] On the other hand, HCV appears to be less commonly associated with MPGN in children.[91]

CLINICAL MANIFESTATIONS

Unlike with HBV, in children with HCV renal disease is rare, usually occurring in those with long-standing infection and the available clinical data is scant. In adults, HCV-associated renal disease is characterized by proteinuria, nephrotic syndrome, microscopic hematuria, elevated serum creatinine, hypocomplementemia (low C3 and C4), falsely positive antinuclear antibodies, and positive rheumatoid factor.[89] Cryoglobulins are detected in 50% to 70% of patients. Despite a mild clinical course of HCV infection in children, it is unknown if these patients will continue to have a benign course in the future. Those with cryoglobulinemia also may present with palpable purpura, arthralgia, and neuropathy.

PATHOLOGIC FINDINGS

The predominant glomerular disease associated with HCV is MPGN (Figure 29.4), usually in the setting of cryoglobulinemia. Histopathologic examination shows typical changes associated with MPGN, including lobular glomeruli, increased mesangial cellularity, and intracapillary accumulations of eosinophilic material representing precipitated
Figure 29.4 Light microscopy of hepatitis C virus–associated membranoproliferative glomerulonephritis in a 15-year-old patient. The glomerular tuft has a lobular appearance with focal areas of increased glomerular cellularity and mesangial expansion.

immune complexes or cryoglobulins.[87–89] Electron microscopy shows subendothelial immune complex deposits (Figure 29.5) and may have a finely fibrillary or tactoid pattern characteristic of cryoglobulin deposition. Although the pathogenesis of glomerular injury in HCV is unclear, it is believed to result from deposition of circulating immune complexes of HCV, anti-HCV, and rheumatoid factor at the site of injury. Apart from MPGN and immunotactoid nephropathy, IgA nephropathy and MN have also reported in patients with HCV infection.[92]
TREATMENT

The therapy for renal diseases associated with HCV, particularly MPGN, focuses on treatment with antiviral agents. A few small and nonrandomized studies have evaluated the efficacy of the combination therapy in HCV-associated MPGN with IFN-α and ribavirin.[93–101] In general, these studies have suggested efficacy in lowering or clearing viral titers, improving clinical symptoms (related to cryoglobulinemia) and decreasing proteinuria, with variable impact on renal function.

HCV therapy has been revolutionized recently by the introduction of new direct acting anti-viral agents, replacing ribavirin and interferon alpha for some viral genotypes. The current list of these new agents, generally used in particular combinations, includes ledispasvir, sofosubvir, paritaprevir, ombitasvir, dasabuvir, daclatasvir, simeprevir and telaprevir. Case reports suggest that these agents can be safely used in renal transplant patients (1) and in hemodialysis patients (2). Results of the use of these agents in HCV glomerular disease are likely to appear soon.

For more severe or acute cryoglobulinemic renal disease or systemic vasculitis, antiviral therapy does not seem to prevent progression of renal injury.[102] In such cases, combination therapy with anti-inflammatory and cytotoxic drugs may be necessary to prevent new antibody formation. Plasmapheresis is also frequently used in conjunction to remove the circulating cryoglobulins. Although there are no controlled trials, observations suggest that this regimen may lead to improvement in renal function in over 50% of patients.[102,103]

Figure 29.5 Electron micrograph of HCV-associated type I membranoproliferative glomerulonephritis. The glomerular capillary wall is markedly thickened with immune deposits and by interposition of mesangial cell processes.

CYTOMEGALOVIRUS

Primary infection with human CMV occurs most often in childhood or in industrialized countries, in the teenage and young adult years. The evidence linking CMV infection to glomerulopathy is moderately strong; although still limited to isolated case reports of the syndromes listed later, many have shown convincing localization of viral DNA or protein to glomeruli. Renal manifestations include MPGN, MN,

KEY POINT

PVB19 is the only parvovirus clearly linked to human glomerulopathy.

TMA, collapsing glomerulopathy, and interstitial nephritis.[104–107] Some but not all cases have involved immunocompromised patients, including renal transplant.

HUMAN PARVOVIRUS B19

PVB19, a single-stranded DNA virus discovered by an Australian virologist, Yvonne Cossart, in 1975, is the only parvovirus clearly linked to human disease.[108] In 1993, Brown et al.[109] discovered that the receptor for PVB19 is blood-group P antigen or globoside (Gb4). This explains the primary tropism of PVB19 for erythroid precursors. Gb4 is also expressed in other cell types, such as lung, heart, liver, kidneys, synovium, endothelium, and vascular smooth muscle.[110] PVB19 is the etiologic agent of erythema infectiosum, or fifth disease, a highly contagious childhood exanthem. PVB19 also has been implicated in a wide spectrum of diseases, including polyarthropathy, acute aplastic crisis (particularly in patients with increased erythropoiesis), chronic anemia (in immunocompromised hosts), and hydrops fetalis.[111] In addition, PVB19 has been increasingly reported in association with various renal diseases (Table 29.3).

ACUTE GLOMERULONEPHRITIS AND THROMBOTIC MICROANGIOPATHY

The most frequently reported renal disease in PVB19 infection is acute postinfectious glomerulonephritis (AGN). Nineteen cases of PVB19-associated AGN have been reported to date in children and adults without any underlying diseases.[108–120] PVB19-induced AGN typically occurs within 2 weeks (range, 3 to 45 days) of the viral infection. Usual presentation is with acute nephritic syndrome and hypocomplementemia.

The histopathologic description of PVB19-induced AGN includes endocapillary, mesangial proliferative GN or both. Immunofluorescence typically shows granular deposition of C3, IgG, IgM, or a combination of these along capillary walls and in the mesangium. Electron microscopy may demonstrate subendothelial electron-dense deposits; subepithelial deposits are generally absent. Immunohistochemical analysis using monoclonal antibody against PVB19 antigen has shown positive staining along capillary walls and in the mesangium, suggesting that the immune complexes with PVB19 may be implicated in the development of AGN.[112,115,116] The diagnosis of acute PVB19-associated GN is suggested by immunostaining of kidney tissue and specific IgM antibody and plasma PCR detection of the viral genome.

Renal biopsies of some patients with B19-induced AGN also had features consistent with TMA, including subendothelial widening, mesangiolytic changes, and thrombotic lesions (Figure 29.6).[112,115] Although the exact pathogenesis is unknown, PVB19 may cause endothelial injury by an immune complex–mediated mechanism and by direct cytotoxicity of the endothelial cells. The observation that the vascular endothelial cells express PVB19 receptor suggests that the virus may directly infect and injure endothelial cells.[111] PVB19 infection has been associated with TMA in four renal allograft recipients and in a healthy adult.[121,122] Given that PVB19 may cause renal injury through various pathways, AGN and TMA may represent phenotypic variants of the same disease, rather than two distinct pathologic entities.

TREATMENT

Most of the patients with PVB19-induced AGN recovered spontaneously without any specific treatment. Clearance of PVB19 and fall of IgM titers usually take approximately 8 weeks following the initial infection. Low titers, however, may persist up to 6 months, and some patients may not show full recovery for 6 months. The therapy for patients with no underlying medical conditions thus remains supportive. For immunocompromised hosts or those with persistent symptoms, intravenous immunoglobulin may be considered. Successful treatment of chronic PVB19 infection with intravenous immunoglobulin therapy has been reported in patients with lymphoma, acute PVB19-induced

myocarditis, PVB19-induced chronic fatigue syndrome, and recurrent PVB19 infection with collapsing glomerulopathy in a renal transplant patient.[123–126]

FOCAL SEGMENTAL GLOMERULOSCLEROSIS AND COLLAPSING GLOMERULOPATHY

The initial cases of FSGS in patients with PVB19 infection were observed in patients with sickle cell disease. Markenson et al.[127] first described the link between renal disease and PVB19 in two siblings with sickle cell disease who developed nephrotic syndrome following PVB19-induced aplastic crises. Wierenga et al.[128] also described a similar report in seven patients with sickle cell disease presenting with nephrotic syndrome following PVB19 infection. The renal biopsy performed during the acute phase in four patients revealed segmental proliferative GN without significant immune complex deposition. In the fifth patient who underwent renal biopsy 4 months following the onset of symptoms, the diagnosis of FSGS was made. Tolaymat et al.[129] reported a similar pediatric case of FSGS and established the first direct association between glomerular disease and PVB19 by demonstrating the viral DNA in renal specimens by PCR. Tanawattanacharoen et al.[130] examined PVB19 DNA in renal biopsy specimens and found that the prevalence of the viral DNA was greater among patients with idiopathic FSGS and collapsing FSGS (85%) than other glomerular diseases (54%). Similarly, Moudgil et al.[131] also reported 78% prevalence of PVB19 DNA in renal biopsies of patients with collapsing glomerulopathy compared to the prevalence of 26% in controls. Despite these studies, the link between PVB19 and collapsing glomerulopathy remains to be fully demonstrated, with more studies needed of localization of viral protein or DNA to glomeruli at the time of initial presentation.

The renal prognosis of patients developing FSGS in the setting of sickle cell disease remains guarded. Among the seven patients reported by Wierenga et al.,[128] only one recovered completely, one reached ESRD within 3 months and died, and the rest had persistently impaired creatinine clearance, four with proteinuria. Because sickle cell disease itself is associated with adaptive FSGS, it is unclear how much of the progression of the renal disease in these patients is directly attributable to PVB19 infection. The benefit of immunosuppressive therapy in these patients also remains unclear, and management needs to be individualized with frequent monitoring and aggressive control of other renal risk factors such as hypertension and avoidance of nephrotoxins.

EPSTEIN-BARR VIRUS

Although the most common clinical presentation with EBV infection is infectious mononucleosis in adolescents and adults, most EBV infections are asymptomatic or nonspecific in infants and children.[132] The diagnosis of EBV infection in children is challenging, not only because of its atypical presentation but also because EBV serology in children differs from that in adults or adolescents. First, heterophil antibodies are rarely seen in young children. Second, although IgM antibodies to EBV capsid antigen are considered to be a reliable marker of the infection, it is detected by the conventional indirect immunofluorescence method in a limited number of children.[133] Third, antibody to EBV nuclear antigen (anti-EBV NA IgG), a late-onset antibody, tends to develop earlier in children than in adults.[134] Therefore, detection of anti-EBV NA IgG does not rule out the possibility of acute EBV infection in children.

CLINICAL MANIFESTATIONS

Mild renal involvement in EBV infection may be present in approximately 16% of patients with infectious mononucleosis.[135] Acute renal failure in patients with EBV infection is rare, and its incidence has been reported to be 1.6% in one study, although this rate may be higher in more severely affected individuals.[135] In a recent retrospective study of 165 Taiwanese children hospitalized with serologically proved primary EBV infection, Tsai et al.[136] reported that 8 had acute renal failure (4.8%). Fever was the most common presentation in these 8 children, with the classic triad of fever, pharyngitis, and lymphadenopathy being present in only 1 patient. Specific renal manifestation included bilateral flank pain and evidence of tubular damage, such as microscopic hematuria, mild proteinuria, glucosuria, or poor concentrating ability on urinalysis (Table 29.4). The creatinine levels typically peaked within 3 weeks following the clinical onset (range, 3 to 17 days) in this study. Except for 1 patient who died of gastrointestinal bleeding, the remaining 7 children recovered their renal function within 1 week to 1 month.

PATHOLOGIC FINDINGS

The most common pathologic abnormality in renal failure associated with EBV infection is acute tubulointerstitial nephritis. Other reported forms of EBV-associated renal disease are distinctively rare and include immune complex GN, minimal-change disease, and hemolytic uremic syndrome.[137–139] Although the pathogenesis of EBV-associated

Table 29.4 Renal manifestation of Epstein-Barr virus–associated nephropathy

Renal biopsy	Tubulointerstitial nephropathy

interstitial nephritis remains enigmatic, Becker et al.[140] postulated that EBV infection of renal proximal tubular cells may evoke a cellular immune response that leads to interstitial damage. Using in situ hybridization and PCR, these authors detected EBV DNA exclusively in the renal tissue of patients with idiopathic chronic interstitial nephritis. The EBV genome was detected primarily in renal proximal tubular cells. Moreover, the authors detected the CD21 antigen, the receptor for EBV in B lymphocytes, also on proximal tubular cells and this was significantly upregulated with EBV infection. The authors speculate that induction of interstitial nephritis by EBV may be the consequence of cellular immune response by infected proximal tubular epithelial cells.

TREATMENT

The role of glucocorticoid therapy remains unclear in treatment of patients with complications of EBV infection. Therapy with glucocorticoids has led to variable results. In the absence of data derived from controlled studies, specific guidelines regarding indications for glucocorticoid use in EBV-associated interstitial nephritis are difficult to formulate. Likewise, there is no conclusive evidence regarding efficacy of acyclovir to improve outcome or prevent complications in EBV infection.

SUMMARY

A number of viruses have been associated with human renal disease. They may cause disease by infecting the cells, such as is the case with HIV, but frequently they cause disease through the formation of immune complexes, as is the case with hepatitis viruses. Recognition of viruses as possible agents of renal disease is emerging as a new field in nephrology, especially as it relates to kidney transplantation. Lessons learned from the 2014 Ebola infection epidemic reinforce our need to understand pathogenesis of kidney disease in viral infections and develop effective measures to prevent and treat such infection disorders.[141,142] Quick and early diagnostic tools and containment strategies will be the primary key in effective management of globally transmissible viral diseases. Because specific antiviral treatments do not exist for all viral infections, therapeutic needs in this area should spur growth in the pharmaceutical advances in the years to come.

ACKNOWLEDGMENT

Clinical Vignette 29.1

A 9-year-old girl presents with bilateral leg edema and thirst. She has been well until these symptoms appeared recently. Three months ago she visited her parents' relatives in the Philippines for an extended visit. While there she had a brief febrile illness characterized by anorexia and mild abdominal pain. Parasite workup was unremarkable, and she recovered after several days.

On physical examination she was not ill appearing. Findings were confined to 2+ pitting edema extending half-way between the ankles and the knees on the tibia. Urinalysis showed 3+ protein and trace blood. Serum chemistry findings included normal electrolytes; blood urea nitrogen and creatinine of 15 mg/dL and 0.62 mg/dL, respectively; and albumin of 2.1 g/dL and cholesterol of 217 mg/dL. Serum complement levels were normal. A percutaneous renal biopsy was performed and revealed thickened glomerular basement membranes. Electron microscopy showed dense epimembranous deposits with thickened glomerular basement membrane that in some places suggested a spikelike appearance. A diagnosis of MN was made. A blood test for HBeAg was positive, and the patient was started on pegylated IFN-α therapy.

TEACHING POINTS

- This vignette presents a typical case of a child with MN secondary to hepatitis B. The diagnosis of MN was suggested by the normal complement levels in the face of a nephritic-nephrotic clinical presentation.
- MN is sufficiently uncommon in children that an infectious cause must be ruled out before presuming that it is idiopathic.
- The fact that this patient was in a country where hepatitis B is more endemic than in the United States and that she had a gastrointestinal illness further suggested the possibility of hepatitis B.
- Importantly, the appropriate treatment is to address the presence of the viral infection.

REVIEW QUESTIONS

1. HIVAN may manifest with which of the following?
   a. Immune complex glomerulonephritis
   b. Collapsing glomerulopathy
   c. Drug-induced nephrotoxicity
   d. None of the above
   e. All of the above
2. The incidence of HIVAN is:
   a. Increasing
   b. Decreasing
   c. Holding steady
3. The *most* common form of kidney disease associated with hepatitis B infection is:
   a. Membranoproliferative glomerulonephritis
   b. Postinfectious glomerulonephritis
   c. Minimal-change disease
   d. Membranous nephropathy
   e. Focal segmental glomerulosclerosis
4. A 9-year-old child presents with fever, rash, enlarged spleen, and swollen gums. Urinalysis shows 2+ protein and 3+ blood. A kidney biopsy shows a proliferative lesion with epimembranous immune complex deposits. This child is likely to have infection with which of the following viruses?
   a. Hepatitis C
   b. Hepatitis B
   c. Human immunodeficiency virus-1
   d. Epstein-Barr
   e. Parvovirus B19

ANSWER KEY

1. e
2. b
3. d
4. d

Kidney failure

Acute kidney injury

PRASAD DEVARAJAN AND STUART L. GOLDSTEIN

Acute kidney injury (AKI) is defined functionally as a rapid decline in glomerular filtration rate (GFR) that leads to accumulation of waste products such as blood urea nitrogen (BUN) and creatinine. The term *acute kidney injury* has largely replaced acute renal failure (ARF) because ARF overemphasizes the discrete event of failed kidney function, whereas AKI accounts for a continuum of renal dysfunction that better characterizes the clinical spectrum of AKI. AKI is a common problem affecting all ages, the leading reason to seek nephrology consultation, and associated with serious consequences and unsatisfactory therapeutic options.[1–5] The etiology of AKI varies widely according to age, geographic region, and clinical setting. Functional AKI induced by dehydration (or prerenal azotemia) is usually reversible with early fluid therapy. However, despite decades of research and technical advances in clinical care, the prognosis for patients with intrinsic AKI in the intensive care setting remains poor, and clinicians now recognize that patients are dying "of," and not just "with," AKI.[6,7] Moreover, a significant proportion of children with severe AKI will have long-term sequelae including chronic kidney disease (CKD). Fortunately, the cellular and molecular tools of modern science are providing critical new insights into the pathogenetic mechanisms of AKI. These newly discovered pathways are yielding novel early biomarkers for the prediction of AKI and its consequences, as well as innovative strategies for the proactive treatment and prevention of AKI.

DEFINITIONS

The most important advances in the AKI field would not have been possible without a standardized AKI definition, which took initial form as the empirically proposed RIFLE criteria (Risk, Injury, Failure, Loss, and End-Stage Kidney Disease) in 2004, with pediatric modifications (pRIFLE) in 2007 (Table 30.1).[8,9] The RIFLE criteria have been subjected to multiple validation studies in adults and children, and almost all these studies uniformly demonstrated an independent association with increasing AKI severity, morbidity, and mortality.[10,11] Further refinement of the RIFLE criteria (the Acute Kidney Injury Network or AKIN criteria) included the addition of another criterion point of a 0.3 mg/dL serum creatinine rise

Table 30.1 pRIFLE classification of acute kidney injury

Stage	Estimated creatinine clearance*	Urine output
R = Risk	eCCl decrease by 25%	<0.5 mL/kg/h for 8 h
I = Injury	eCCl decrease by 50%	<0.5 mL/kg/h for 16 h
F = Failure	eCCl decrease by 75% or eCCl <35 mL/min/1.73 m²	<0.3 mL/kg/h for 24 h or anuric for 12 h
L = Loss	Persistent failure >4 wk	—
E = End stage	End-stage renal disease (persistent failure >3 mo)	—

Solution: Akcan-Arikan A, Zappitelli M, Loftis LL, et al. Modified RIFLE criteria in critically ill children with acute kidney injury. Kidney Int. 2007;71:1028–35.

Abbreviations: eCCl, estimated creatinine clearance; pRIFLE, pediatric risk, injury, failure, loss, and end-stage renal disease.

* The estimated creatinine clearance is calculated using the modified Schwartz formula.

in less than 48 h, given that both adult and pediatric studies have shown independent associations with poor outcomes at this creatinine threshold.[12–14] Finally, in 2012, RIFLE, AKIN, and pRIFLE were harmonized into a single definition by the Kidney

---

KEY POINTS

- Despite limitations of serum creatinine, the KDIGO AKI definition and staging should be used to guide clinical care.
- The KDIGO AKI can also be used as a standardized criterion and outcome measure in AKI studies.
- Advances in critical care have increasingly rendered pediatric AKI a hospital-acquired disease, especially in developed countries.

Table 30.2 Kidney disease improving global outcomes (KDIGO) acute kidney injury criteria

Stage	Serum creatinine	Urine output
1	1.5–1.9 times baseline OR ≥0.3 mg/dL rise increase	<0.5 mL/kg/h for 6–12 h
2	2.0–2.9 times baseline	<0.5 mL/kg/h for ≥12 h
3	3.0 times baseline OR Increase to ≥4.0 mg/dL (>18 yr of age) OR Decrease in eGFR <35 mL/min/1.73m² (<18 yr of age) OR Initiation of renal replacement therapy	≤0.3 mL/kg/h for ≥24 h OR Anuria for ≥12 h

Solution: Kidney Disease: Improving Global Outcomes (KDIGO) Acute Kidney Injury Work Group—KDIGO clinical practice guideline for acute kidney injury. Kidney Int Suppl. 2012;2:1–138.

Abbreviations: eGFR, estimated glomerular filtration rate.

Disease Improving Global Outcomes (KDIGO) AKI Consensus Conference (Table 30.2).[15] It is recommended that the KDIGO AKI definition and staging be used to guide clinical care and as a standardized criterion and outcome measure in AKI studies until supplemented or supplanted by validation, acceptance, and widespread clinical integration of the novel AKI biomarkers discussed later in this chapter. One limitation of the KDIGO AKI definition is the use of serum creatinine to estimate GFR because changes in serum creatinine concentrations often lag behind changes in GFR until a steady state has been reached.

CLINICAL CLASSIFICATION

Traditionally, AKI has been classified as prerenal (functional response of structurally normal kidneys to hypoperfusion, usually associated with dehydration, sepsis, or other diseases leading to hypotension), intrinsic renal (involving structural damage to the renal parenchyma usually from nephrotoxic medications, prolonged hypoperfusion, or glomerulonephritis), or postrenal (urinary tract obstruction). This classification remains convenient for understanding mechanisms, as well as the clinical approach to AKI. With the discovery and validation of novel AKI functional and structural biomarkers (discussed later), the terminology is changing to functional, structural, and combined AKI, to depict the clinical situation and therapeutic response more appropriately.[16]

KEY POINTS

A clinically useful classification categorizes AKI into:

- Prerenal
- Intrinsic renal
- Postrenal

EPIDEMIOLOGIC CLASSIFICATION

AKI may also be classified according to the epidemiologic circumstances in which it occurs. Community-acquired AKI is more likely to be associated with a single predominant insult, most commonly volume depletion, and it is frequently reversible. The medical approach is often conservative and expectant, including discontinuing the insult, providing supportive fluid and electrolyte management, and awaiting spontaneous recovery of renal function. In contrast, hospital-acquired AKI, especially in the critical care setting, is frequently multifactorial and is often part of more extensive multiorgan failure. This form of AKI often accompanies other organ disease processes and markedly complicates their management and outcomes. Management is more aggressive, with early initiation of renal replacement therapies to optimize the overall care of the severely compromised patient. Recovery may be partial, and there are significant short-term and long-term consequences.

KEY POINTS

AKI may be classified by epidemiologic association:

- Community-acquired AKI, often reversible and associated with a common source of renal insult
- Hospital-acquired AKI, often multifactorial, severe, and frequently associated with multiorgan failure

OLIGURIC AND NONOLIGURIC ACUTE KIDNEY INJURY

AKI may also be classified according to the urine output as being nonoliguric, oliguric (urine output less than 1 mL/kg/h in infants, less than 0.5 mL/kg/h in children, or less than 400 mL/day in adults), or anuric. Measurement of urine output is especially useful in the critical care setting because the degree of oliguria reflects the severity of the kidney injury, has important implications for volume and electrolyte imbalances, and provides prognostic information. However, even moderately severe forms of AKI secondary to

KEY POINTS

Based on urine output, AKI can be classified into:

- Oliguric AKI
- Nonoliguric AKI

nephrotoxins, and the majority of AKI seen in neonatal intensive care, are typically nonoliguric.

EPIDEMIOLOGY

Advances in the care for critically ill neonates, infants with congenital heart disease, and children with bone marrow and solid organ transplantation, sepsis, and hypotension have led to a dramatic broadening of the epidemiology of pediatric AKI. Older pediatric epidemiologic data were mostly generated from single centers and reported hemolytic-uremic syndrome and other primary renal diseases as the most prevalent causes. More recent single-center data have detailed the underlying causes of pediatric AKI in large cohorts of children and have demonstrated nephrotoxic medication exposure or nonrenal primary illnesses as the most common causes of AKI. In fact, primary kidney diseases encompass only 7% to 10% of cases of AKI in hospitalized children.[1,17]

Although the precise incidence of pediatric AKI is not known, it appears to be rising, especially in hospitalized children.[18] AKI rates based on hospital coding data from a large US multicenter dataset revealed a rate of 3.9 per 1000 at-risk pediatric hospitalizations.[19] In addition, the specific clinical setting and patient's clinical condition often determine AKI development rates. For instance, 40% of all children undergoing cardiac surgical procedures develop AKI.[20–22] AKI rates of 20% have been reported in very low birth weight infants.[23] Whereas 10% of all patients in a pediatric intensive care unit (ICU) develop AKI,[24] the rate increases to 60% to 80% in children receiving invasive mechanical ventilation and one vasoactive medication.[9,25] Outside the ICU, 25% of all noncritically ill children receiving an aminoglycoside or three or more nephrotoxic medications will develop AKI.[26–28] Thus, advances in critical care have increasingly rendered pediatric AKI a hospital-acquired disease, especially in developed countries. Such data are important to understand because they can allow clinicians to stratify risk in patients for more active surveillance and potentially decrease or mitigate AKI rates and severity.

PRERENAL AZOTEMIA AND FUNCTIONAL ACUTE KIDNEY INJURY

Prerenal AKI should be considered an appropriate functional response of intrinsically normal kidneys to hypoperfusion. It is the most common form of AKI encountered globally, accounting for 40% to 55% of all

cases. Oliguria in this clinical circumstance represents an appropriate renal response to preserve intravascular volume. Prerenal azotemia is often associated with dehydration, sepsis, or other causes leading to transient hypoperfusion, and it is usually rapidly reversed by restoration of renal perfusion. However, it is critical to understand that functional AKI or prerenal azotemia does not automatically imply fluid responsiveness, and in some situations, such as liver failure, heart failure, and nephrotic syndrome, fluid restriction is the mainstay of treatment.[29] The common causes of prerenal azotemia are listed in Table 30.3.

PATHOPHYSIOLOGY

The kidneys are endowed with 25% of the cardiac output at rest, to perform critical homeostatic functions, and any decrease in circulatory volume evokes a primeval systemic response leading to the release of potent vasoactive agents (Figure 30.1). These responses help maintain perfusion to other organs by normalizing circulatory volume and blood pressure, but at the potential expense of GFR. There is an intense baroreceptor-mediated activation of the sympathetic nervous system and renin-angiotensin axis, with resultant renal vasoconstriction mediated by angiotensin II and norepinephrine. In addition, angiotensin II promotes avid sodium and water reabsorption by the uninjured tubule cells, thus often resulting in the oliguria and decreased fractional excretion of sodium (FENa) that are the hallmarks of prerenal AKI. Furthermore, the release of antidiuretic hormone in response to hypovolemia and a rise in extracellular osmolality result in

Table 30.3 Common causes of prerenal azotemia or functional acute kidney injury

Mechanism	Etiology

	ACE inhibitors
	Hepatorenal syndrome

Abbreviation: ACE, angiotensin-converting enzyme.

enhanced water reabsorption by the intact collecting duct, which further contributes to the oliguria.

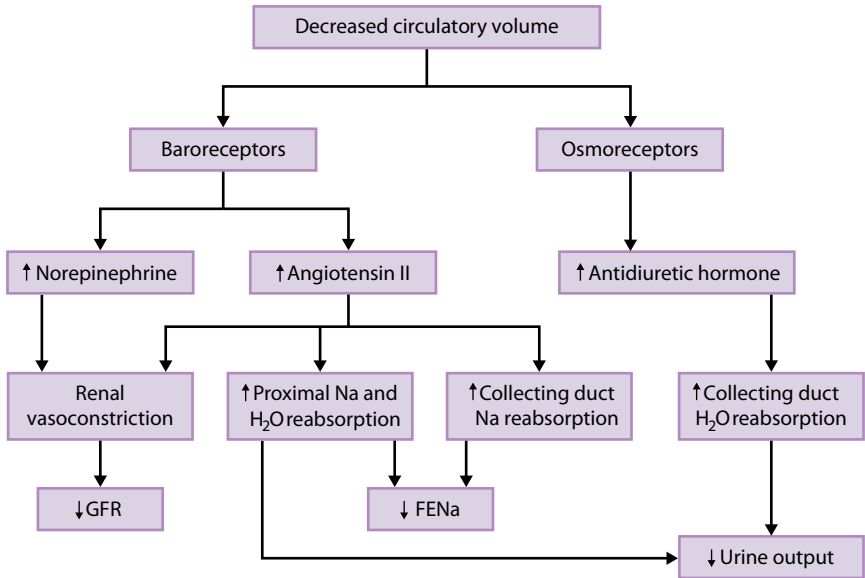
Concomitantly, at least three distinct intrarenal compensatory mechanisms are brought into play that help maintain GFR in the prerenal states (Figure 30.2). Myogenic autoregulation refers to the rapid dilatation of the afferent arterioles in physiologic response to a reduction in lateral stretch following hypoperfusion.


Figure 30.1 Pathophysiology of prerenal and functional acute kidney injury. FENa, fractional excretion of sodium; GFR, glomerular filtration rate; Na, sodium.
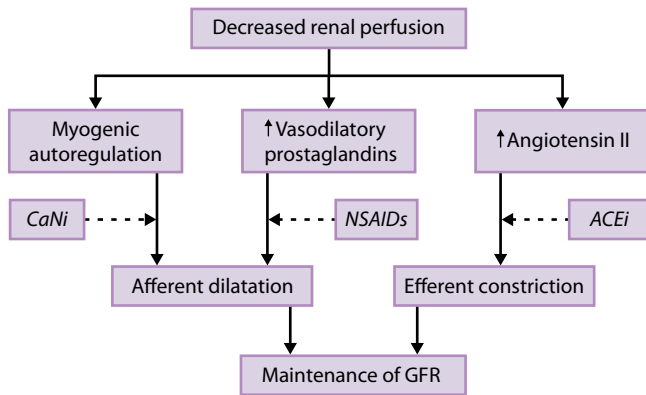

Figure 30.2 Mechanisms that maintain glomerular filtration rate (GFR) in prerenal and functional acute kidney injury. Iatrogenic interference can precipitate a reduction in GFR. These include the use of calcineurin inhibitors (CaNi), nonsteroidal anti-inflammatory drugs (NSAIDs), and angiotensin-converting enzyme inhibitors (ACEi). Broken lines represent inhibitory effects.

Calcineurin inhibitors such as tacrolimus and cyclosporine are known to impair the myogenic response and render the transplanted kidney more susceptible to prerenal azotemia. The role of this response in hypoperfusion states has been challenged, and some investigators have suggested a more important role for autoregulation in maintaining intraglomerular pressure during systemic hypertension.[30] A more effective compensatory mechanism mediating afferent arteriolar dilatation involves the intrarenal production of vasodilatory prostaglandins.[31] Under normal physiologic conditions, the cyclooxygenase (constitutional COX-1 and inducible COX-2) enzyme systems catalyze the intrarenal production of prostaglandins that mediate afferent arteriolar dilatation. This system is dramatically upregulated by volume depletion. Nonsteroidal anti-inflammatory drugs inhibit this response and can precipitate AKI, especially in the presence of decreased circulatory volume.[32,33] For example, the use of indomethacin for patent ductus arteriosus closure in neonates results in AKI in as many as 40% of cases.

Another common pediatric situation in which AKI may occur is the use of ibuprofen in febrile children with a dehydrating illness. A third mechanism for maintaining GFR involves the differential effect of angiotensin II on the efferent arteriole. Whereas angiotensin II tends

KEY POINTS

- Some forms of prerenal AKI (liver failure, heart failure, and nephrotic syndrome) require fluid restriction.

KEY POINT

Prostaglandins maintain GFR by mediating afferent arteriolar dilatation. Nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit this response and can precipitate intrinsic AKI in prerenal states.

to constrict both the afferent and efferent arterioles, this effect is more marked in the efferent arteriole, and it leads to increased hydrostatic pressure across the glomerulus.[34] Obvious interference with this compensation occurs following angiotensin-converting enzyme (ACE) inhibitor therapy. In clinical practice, the use of ACE inhibitors markedly increases the incidence of AKI in patients at risk (e.g., undergoing cardiac surgery) preoperatively and postoperatively.[35,36]

Compensatory mechanisms that maintain GFR in prerenal azotemia can be overwhelmed during states of prolonged reduction in renal perfusion pressure, and intrinsic AKI can then ensue. Thus, prerenal and intrinsic AKI can, therefore, be considered along a continuum of renal hypoperfusion states and can evolve from former to the latter in appropriate clinical situations. Substantial evidence for this concept derives from clinical studies demonstrating increased concentrations of biomarkers of tubule damage in patients with prerenal AKI.[37]

INTRINSIC ACUTE KIDNEY INJURY

Intrinsic AKI is most frequently caused by prolonged ischemia or nephrotoxins (Tables 30.4 and 30.5), and it

is associated pathologically with acute tubular necrosis (ATN). Consequently, it is common clinical practice to use the terms intrinsic AKI and ATN interchangeably. In the clinical setting, intrinsic AKI is frequently multifactorial, with concomitant ischemic, nephrotoxic, and septic components and with overlapping pathogenic mechanisms.

MORPHOLOGY OF HUMAN ACUTE TUBULAR NECROSIS

ATN is a misnomer because frank tubular cell necrosis is rarely found in human AKI. Instead, one sees effacement and loss of proximal tubule apical brush border, disruption of microvilli, patchy loss of tubule cells with exposure of denuded basement membrane, focal proximal tubular dilatation and distal tubular casts, and areas of cellular regeneration (Figure 30.3). Necrotic cell death is restricted to the outer medullary regions (S3 segment of the proximal tubule and medullary thick ascending limb of Henle's loop). Conversely, apoptotic cell death has been reported in both distal and proximal tubules, in both ischemic and nephrotoxic forms of human AKI.[38,39] An intense inflammatory response, with peritubular accumulation of leukocytes, is typical in experimental models of AKI but appears to be less prominent in human AKI. In addition, peritubular capillaries in the outer medulla display a striking vascular congestion.[40–44] The molecular, biochemical, and cellular mechanisms underlying these morphologic changes are identifying several novel pathways.[45–48] Only selected mechanisms that are currently providing promising therapeutic approaches are outlined in this chapter.

HEMODYNAMIC ALTERATIONS

Intrinsic AKI is characterized by persistent hemodynamic abnormalities (Figure 30.4). Total renal blood flow is reduced to approximately 50% of normal in response to persistent renal vasoconstriction in established AKI.[49] Furthermore, there are regional alterations in renal blood flow, with marked congestion of the outer medullary region. Oxygen tension is normally low in this region, which ironically contains tubular segments with high energy requirements, namely the S3 segment of the proximal tubule and medullary thick ascending limb. The postischemic congestion worsens the relative hypoxia, thereby leading to prolonged injury and necrotic cell death in these segments. Mechanisms underlying these hemodynamic alterations relate primarily to endothelial damage.[42–44] This damage

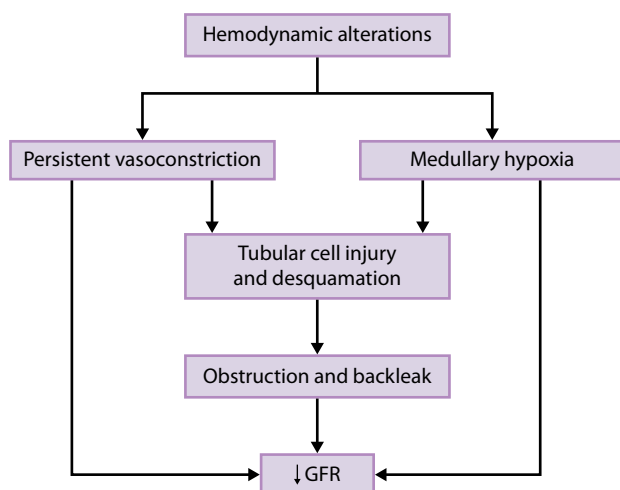
leads to a local imbalance of vasoactive substances, including enhanced release of the vasoconstrictor endothelin and reduced release of vasodilatory endothelium-derived nitric oxide.[49] Indeed, plasma endothelin levels are increased in human patients with septic AKI. However, although endothelin receptor antagonists ameliorate ischemic AKI in animals, human data are lacking.[50] A human trial of endothelin receptor antagonist for prevention of contrast-induced AKI resulted in a paradoxical exacerbation of nephrotoxicity.[51] It is now apparent that these hemodynamic abnormalities cannot fully account for the profound loss of renal function, and several human trials of vasodilators such as dopamine have failed to demonstrate improvement in GFR in established AKI despite augmentation of renal blood flow.[52]


Figure 30.4 Pathophysiology of intrinsic and structural acute kidney injury: hemodynamic alterations and their consequences. GFR, glomerular filtration rate.

TUBULAR DYNAMICS

Three well-known alterations in tubular dynamics in intrinsic AKI are obstruction, backleak, and activation of tubuloglomerular feedback.[49] The consistent findings of proximal tubular dilatation and distal tubular casts in human AKI are indicative of obstruction to tubular fluid flow. The intraluminal casts stain strongly for Tamm-Horsfall protein, which is normally secreted by the thick ascending limb as a monomer. Conversion into a gel-like polymer is enhanced by the increased luminal sodium concentration typically encountered in the distal tubule in AKI as a result of impaired proximal tubule sodium reabsorption.[53] This provides an ideal environment for cast formation along with desquamated tubule cells and brush-border membranes. However, it is unlikely that obstruction alone can account for the profound dysfunction in clinical AKI because human studies using forced diuresis with furosemide or mannitol did not improve the renal recovery rate of patients with established AKI.[54–56] Similarly, although movement of the glomerular filtrate back into the circulation has been shown to occur, this accounts for only a very minor component of the decrease in GFR in human AKI.[49] Finally, a role for activation of tubuloglomerular feedback has been proposed.[57] By physiologic considerations, the increased delivery of sodium chloride to the macula densa caused by abnormalities in the injured proximal tubule would be expected to induce afferent arteriolar constriction, mediated by adenosine through A1 adenosine receptor (A1AR) activation, and thereby decrease GFR.[58] Thus, research efforts have focused on specific adenosine receptor antagonists as potential therapeutic agents. Initial animal studies using the nonselective adenosine receptor antagonist theophylline yielded encouraging results in terms of preserving renal blood flow when the drug was administered before ischemic injury and in improving blood flow in

established ischemic AKI. However, in more recent studies, genetic deletion of the A1AR resulted in paradoxical worsening of ischemic renal injury, and exogenous activation of A1AR was renoprotective.[59] Thus, tubuloglomerular feedback activation following ischemic injury may represent a beneficial phenomenon that limits wasteful delivery of ions and solutes to the damaged tubules. The protective effects of adenosine inhibition on renal blood flow preservation may be mediated by distinct A2 adenosine receptor activation and are currently under investigation.[60]

ALTERATIONS IN TUBULAR CELL METABOLISM

A profound reduction in intracellular adenosine triphosphate (ATP) content is a hallmark of AKI that occurs early after injury, and it triggers a number of metabolic consequences in tubule cells.[61] These events are detailed later, and their interrelationship is illustrated in Figure 30.5.

Alterations in tubule cell adenine nucleotide metabolism have been well documented. Oxygen deprivation leads to a rapid degradation of ATP to adenosine monophosphate (AMP) and to hypoxanthine. These metabolites are freely diffusible, and their depletion precludes resynthesis of ATP during reperfusion. In addition, ATP depletion results in mitochondrial damage with cessation of oxidative phosphorylation, thus leading to further depletion of energy stores. Although provision of exogenous adenine nucleotides or thyroxine (which stimulates mitochondrial ATP regeneration) can ameliorate the cellular injury in animal models of ischemic AKI, these substances have proven

ineffective in established human AKI.[62] An increase in free intracellular calcium has also been documented following AKI, but its role has remained controversial. Increased intracellular calcium could potentially lead to activation of proteases and phospholipases. A meta-analysis suggested that calcium channel blockers may provide some protection from renal injury in the transplant setting, but evidence for their efficacy in other forms of AKI is currently lacking.[63]

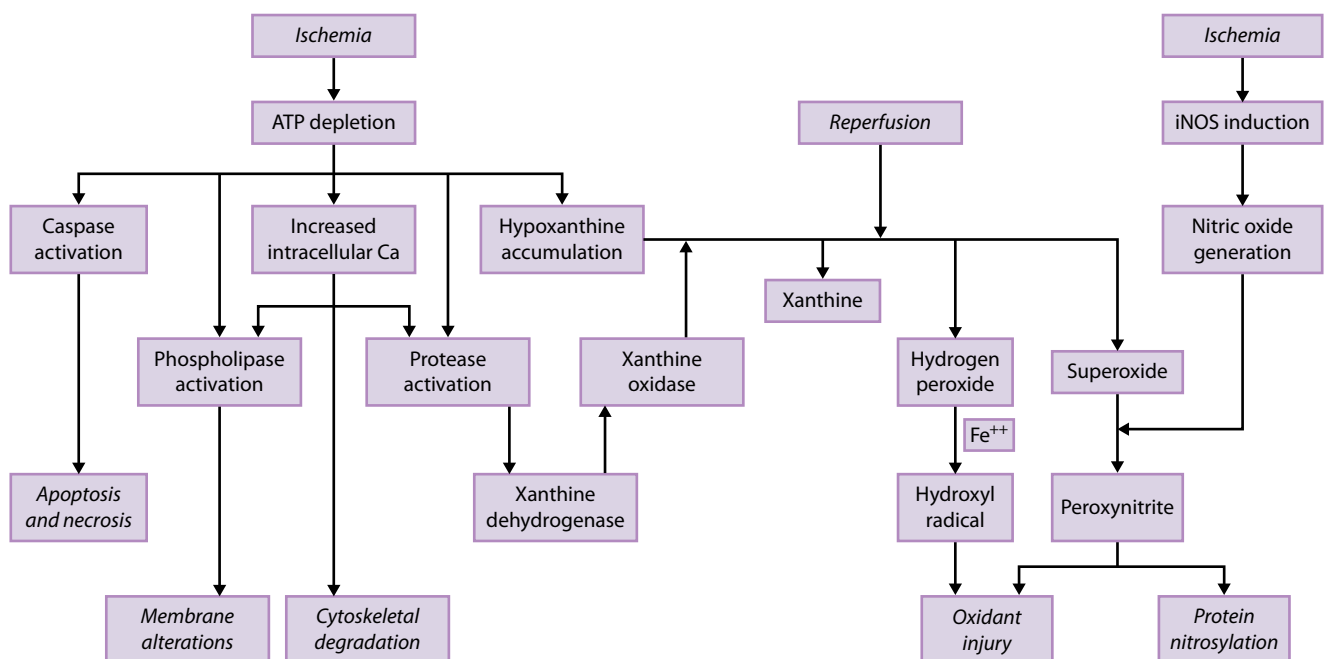
There is now substantial evidence for the role of reactive oxygen species in the pathogenesis of intrinsic AKI. During reperfusion, the conversion of accumulated hypoxanthine to xanthine generates hydrogen peroxide and superoxide. In the presence of iron, hydrogen peroxide forms the highly reactive hydroxyl radical. Concomitantly, ischemia induces nitric oxide synthase in tubule cells, and the nitric oxide generated interacts with superoxide to form peroxynitrite, which results in cell damage through oxidant injury, as well as protein nitrosylation.[61] Furthermore, at the subcellular level, mitochondrial swelling and damage are early and well-documented consequences of hypoxic, ischemic, and nephrotoxic tubule cell injury. The resultant alterations in the mitochondrial electron transport chain lead to a significant increase in superoxide production and release. Indeed, human studies have documented a dramatic increase in oxidative stress with AKI.[64] Several scavengers of reactive oxygen molecules protect against ischemic AKI in animal models, but human studies have been inconclusive. As an alternative approach, the iron scavenger deferoxamine ameliorates ischemia-reperfusion injury in animal models, but the associated toxicity precludes its clinical use in human AKI. Three advances have emerged in the area of iron chelation. The first is the


Figure 30.5 Metabolic consequences of acute ischemia and reperfusion injury to kidney tubule cells. Inhibition of these pathways may provide novel therapeutic approaches to acute kidney injury. ATP, adenosine triphosphate; Ca, calcium; Fe^{++}, iron, iNOS, inducible nitric oxide synthase.

availability of human apotransferrin, an iron-binding protein that protects against renal ischemia-reperfusion injury in animals by abrogating renal superoxide formation.[65] The second is the discovery of neutrophil gelatinase–associated lipocalin (NGAL), an endogenous iron-transporting protein, as one of the most highly induced genes and proteins in the kidney following early AKI.[66] Administration of NGAL provided significant functional protection in an animal model of AKI.[67] The third is the availability of deferiprone, an iron chelator that is approved by the Food and Drug Administration to treat patients with thalassemia and iron overload resulting from blood transfusions. The potential therapeutic use of NGAL and deferiprone in human AKI is currently under investigation.

ALTERATIONS IN TUBULAR CELL STRUCTURE

The cell biologic response of the tubule cell to ischemic or nephrotoxic AKI is multifaceted and includes loss of cell polarity and brush borders, cell death, dedifferentiation of viable cells, proliferation, and restitution of a normal epithelium, as illustrated in Figure 30.6. The major mechanisms underlying this morphologic sequence of events are summarized here.

AKI results in an early, rapid disruption of the apical actin cytoskeleton and redistribution of actin from the apical domain and microvilli into the cytoplasm.[68] This results in loss of brush-border membranes, which contribute to cast formation and obstruction. Disruption of the apical cytoskeleton also results in loss of tight junctions and occludens junctions that accounts for the backleak of glomerular filtrate. Ischemic and nephrotoxic insults also result in the early disruption of at least two normally basolaterally

polarized proteins, namely sodium, potassium-ATPase (Na,K-ATPase) and integrins. The Na,K-ATPase is normally tethered to the spectrin-based cytoskeleton at the basolateral domain by the adapter protein ankyrin. This provides the driving force for the normal reabsorption of salt and water by the proximal tubule. Tubule cell injury leads to a reversible cytoplasmic accumulation of Na,K-ATPase, ankyrin, and spectrin in viable cells.[69] Postulated mechanisms leading to loss of Na,K-ATPase polarity include disruption of the cortical actin cytoskeleton and cleavage of spectrin by ischemia-induced activation of proteases such as calpain.[49] The consequence is impaired proximal tubular sodium reabsorption leading to the high FENa that is characteristic of intrinsic AKI. The β_1-integrins are normally polarized to the basal domain, where they mediate cell-substratum adhesions. Tubule cell injury leads to a redistribution of integrins to the apical membrane, with consequential detachment of viable cells from the basement membrane. There is good evidence for abnormal adhesion between these exfoliated cells within the tubular lumen, mediated by an interaction between apical integrin and the Arg-Gly-Asp (RGD) motif of integrin receptors.[70] Administration of synthetic RGD compounds attenuated tubular obstruction and renal impairment in animal models of ischemic AKI, but human studies are lacking.

AKI leads to tubule cell death by at least two pathophysiologic mechanisms.[71] Necrosis is characterized by loss of membrane integrity, cytoplasmic swelling, nuclear pyknosis, cellular fragmentation, and an inflammatory response. Apoptosis is characterized by cytoplasmic and nuclear shrinkage, DNA fragmentation, and breakdown of the cell into apoptotic bodies that are rapidly removed by phagocytosis. These two forms of cell death frequently coexist and are two extremes of a continuum. Following
Figure 30.6 Structural consequences of acute ischemia and reperfusion injury to kidney tubule cells. Novel therapeutic approaches in acute kidney injury have targeted prevention of cell death, inhibition of inflammation, and acceleration of the endogenous recovery process. PMN, polymorphonuclear leukocyte.

AKI, the mode of cell death depends primarily on the severity of the insult and the resistance of the cell type. Necrosis occurs following more severe injury and in the more susceptible proximal tubules that normally have to operate at high levels of energy consumption. Apoptosis predominates during physiologic cell death, after less severe injury, and especially in the injury-resistant distal nephron segments. Mounting evidence now indicates that apoptosis is a major mechanism of early tubule cell death in both animal and human models of AKI.[71–80] Considerable attention has therefore been directed toward unraveling the molecular pathways involved in renal tubule cell apoptosis. Multiple intracellular signaling pathways, including the intrinsic (Bcl-2 family, cytochrome c, caspase 9), extrinsic (Fas, Fas-associated death domain protein [FADD], caspase 8), and regulatory (p53) factors, appear to be activated during AKI, as illustrated in Figure 30.7. In addition, the mitochondrial damage that occurs early in AKI results in direct release of cytochrome c, with activation of downstream apoptotic pathways. Inhibition of apoptosis holds promise in AKI, and certain pharmacologic agents that inhibit p53 or the caspases are currently under investigation.[81] One promising example is the use of small interfering RNA molecules (siRNA) that inhibit p53, which have been shown in animal studies to provide structural and functional protection against ischemic and nephrotoxic AKI.[82] Human trials of p53 siRNA are currently under way.

Renal tubule cells possess a remarkable ability to regenerate and proliferate after ischemic injury.[83] Morphologically, repair is heralded by the appearance of dedifferentiated tubule cells. In the next phase, the cells upregulate genes encoding for a variety of growth factors such as insulin-like growth factor I (IGF-I), hepatocyte growth factor (HGF), fibroblast growth factor (FGF), and bone morphogenetic protein 7 (BMP-7), and undergo marked proliferation. In the final phase, cells undergo redifferentiation until the normal fully polarized epithelium is restored. Thus, during recovery from ischemia, renal tubule cells recapitulate processes similar to those during normal kidney development.[80,83,84] Understanding the molecular mechanisms of repair may provide clues to accelerating recovery from AKI. The potential use of growth factors, progenitor cells, and mesenchymal stem cells (MSCs) as therapeutic strategies in AKI is currently under active investigation.[85,86] Most notable among these are MSCs that promote kidney repair by secreting growth factors (vascular endothelial growth factor [VEGF], HGF, IGF-I) with potent antiapoptotic, mitogenic, anti-inflammatory, and angiogenic properties. Modified MSCs that have been expanded from normal bone marrow cells and rendered immune privileged and genetically stable are currently being investigated for safety and efficacy in human AKI.

Figure 30.7 Major tubule cell apoptotic pathways in human acute kidney injury (AKI). The extrinsic pathway requires activation of plasma membrane receptors such as Fas and the tumor necrosis factor receptor TNF-R1, with subsequent signal transduction and activation of caspase 8. The intrinsic pathway requires translocation of Bax to the mitochondria, thereby forming pores for the release of cytochrome c and activation of caspase 9. Cross-talk between these pathways is provided largely by the regulatory molecule p53. Bax translocation is prevented by Bcl-2 and Bcl-xL. Both caspases 8 and 9 activate caspase 3, which initiates the final morphologic cascades of apoptosis. Inhibition of the central regulatory molecule p53 and the terminal executor caspases hold promise in human AKI. BID, BH3 interacting death domain; FADD, Fas-associated death domain protein.

INFLAMMATORY RESPONSE AND COMPLEMENT

There is now increasing evidence in animal and human studies for a prominent role of inflammation in the pathogenesis of AKI.[40,41] The major components of this response include endothelial injury, leukocyte recruitment, and production of inflammatory mediators by tubule cells. Endothelial injury plays a critical role in the pathophysiology of AKI. It is manifested by endothelial swelling, endothelial apoptosis, narrowing of the blood vessels, abnormal retrograde blood flow on reperfusion, and the induction of adhesion molecules such as intercellular adhesion molecule 1 (ICAM-1) and P-selectin that promote endothelial-leukocyte interactions. Although ablation of the ICAM-1 gene and pretreatment with ICAM-1 antibody rendered mice resistant to ischemic AKI, human trials with anti–ICAM-1 antibody did not prevent AKI in deceased donor kidney transplant recipients.[87] Morphologically, neutrophils, macrophages, dendritic cells, B cells, and T cells have all been shown to aggregate in peritubular capillaries following ischemic AKI in humans, and the relative roles of these leukocyte

subtypes remain under investigation.[48] Neutrophils are the first inflammatory cells to attach to the activated endothelium and accumulate in the peritubular capillary network in both animal and human AKI. They produce reactive oxygen species and cytokines that aggravate the kidney injury. However, blockade of neutrophil function or neutrophil depletion provides only partial protection from AKI in animal models. Similarly, experimental models depleting macrophages or dendritic cells have resulted in partial amelioration of AKI. Translation of these immune cell depletion approaches to human AKI is likely to be challenging.

The injured proximal tubule epithelium is an active participant in the inflammatory response and can generate some mediators that potentiate the process. These include cytokines such as tumor necrosis factor-α (TNF-α) and interleukin-6 (IL-6), and the chemotactic cytokines (monocyte chemoattractant protein-1 [MCP-1], IL-8, RANTES [regulated on activation, normal T cell expressed and secreted]). Human studies have shown that the plasma levels of the proinflammatory cytokines IL-6 and IL-8 predict death in adults with AKI.[88] Strategies that modulate the inflammatory response may provide significant beneficial effects in human AKI. One promising example is α-melanocyte-stimulating hormone (α-MSH), a potent anti-inflammatory and antiapoptotic cytokine that inhibits several proinflammatory cytokines (TNF-α, IL-10), and neutrophil adhesion molecules. In animal studies, α-MSH and its synthetic analogues protect from AKI that was caused by ischemia-reperfusion, nephrotoxins, and sepsis.[89] Human clinical trials using synthetic α-MSH analogues are currently ongoing.

The complement system is an important contributor to inflammation after ischemic AKI. The primary mechanism is by activation of the alternative complement pathway, leading to marked upregulation of the C5a component on proximal tubule cells and macrophages.[90] Pharmacologic inhibition of this pathway by using synthetic C5a receptor blockers resulted in dramatic protection from ischemic AKI in animal models.[91] Human trials should be highly feasible, given the selective nature, stability, and excellent bioavailability of synthetic C5a receptor antagonists.

SEPSIS

Although sepsis is one of the most common causes of AKI, the pathogenesis of septic AKI remains incompletely understood, in part because of the limitations of rodent models. Small studies have revealed the surprising finding that unlike in ischemic or nephrotoxic AKI, human patients with early septic AKI demonstrate a paradoxical increase in renal blood flow despite a reduction in GFR. Large animal models of septic AKI have confirmed this finding of GFR deterioration despite renal vasodilation and increased renal blood flow.[92] Thus, septic AKI is a hyperemic injury that contrasts with the persistent vasoconstriction characteristic of ischemic AKI. It is likely that the same mechanisms that lead to systemic arterial vasodilation in sepsis

are also operative at the level of the glomerular arterioles. Dilation of both afferent and efferent arterioles, but with a greater efferent than afferent dilation, may account for the decreased GFR despite the increased renal blood flow. Other unique aspects of septic AKI could include an exacerbated endothelial dysfunction and more pronounced complement activation.[93] C5a receptor blockers are especially efficacious in animal models of septic AKI.

POSTRENAL ACUTE KIDNEY INJURY

Postrenal AKI is a result of obstruction to the outflow tract on both sides and is uncommon beyond the neonatal period. Postrenal AKI is usually reversed by relief of the obstruction, but it is accompanied by very significant postobstructive diuresis. The common causes of postrenal AKI are listed in Table 30.6. The pathophysiology and management of the obstructive nephropathy syndrome that can result from congenital obstruction are detailed in Chapter 47.

CLINICAL MANIFESTATIONS OF ACUTE KIDNEY INJURY

Until it becomes severe, AKI is largely asymptomatic, and its detection must begin with having a high index of suspicion and an awareness of the risk factors. AKI most commonly manifests with a progressive accumulation of fluid or nitrogenous wastes in a predisposed patient who has been exposed to one or more of the etiologic factors outlined in Tables 30.3 to 30.6. Less frequently, one encounters an increase in BUN and creatinine that is not readily explained. In all cases, the evaluation requires a complete history, physical examination, laboratory evaluation, renal imaging, and, rarely, a kidney biopsy. A diligent search for all drugs and medications ingested is especially important,

Table 30.6 Common causes of postrenal acute kidney injury

Mechanism	Etiology
Congenital	Posterior urethral valves
	Ureteropelvic junction obstruction in a solitary kidney
	Bilateral ureterovesicular obstruction
Acquired	Calculi
	Clots
	Neurogenic bladder
	Drugs that cause urinary retention
	External compression by pelvic and abdominal tumors
	Bladder tumors

even when another obvious cause for AKI is evident. The initial approach to a patient with known or suspected AKI should be directed toward (1) identifying the underlying cause, (2) distinguishing between prerenal and intrinsic AKI, (3) discriminating between AKI and CKD, (4) determining the severity of AKI, and (5) considering a diagnostic fluid challenge.

IDENTIFYING THE UNDERLYING CAUSE

The initial history should be directed toward uncovering an obvious risk factor for AKI, such as those listed in Tables 30.3 to 30.5. Additional relevant aspects of the AKI history and physical examination are shown in Table 30.7 and Table 30.8, respectively. These aspects, in combination with a careful urinalysis with microscopy, yield the cause of AKI in the majority of cases. A short duration of vomiting, diarrhea, or decreased oral intake associated with decreased urine output and typical physical findings of dehydration suggests prerenal volume-responsive functional AKI. Bloody diarrhea with oliguria is consistent with the hemolytic-uremic syndrome. A history of pharyngitis or impetigo a few weeks before the onset of gross hematuria

> ### KEY POINT
>
> Assessing the degree of fluid overload is critical for management and prognosis of patients with AKI.

Table 30.7 Relevant history in patients with suspected acute kidney injury

- Fluid loss
  - Diarrhea
  - Vomiting
  - Burns
  - Surgery
  - Shock
- Nephrotoxic agents
  - Nonsteroidal anti-inflammatory drugs
  - Antibiotics and other nephrotoxins
  - Contrast agents
- Glomerular disease
  - Streptococcal infection (poststreptococcal glomerulonephritis)
  - Bloody diarrhea (hemolytic-uremic syndrome)
  - Fever, joint complaints, rash (systemic lupus erythematosus)
- Obstruction
  - Anuria
  - Poor urinary stream

Table 30.8 Relevant clinical examination in acute kidney injury

Clinical sign	Diagnostic interpretation
Signs of intravascular volume depletion	Prerenal azotemia
Signs of fluid retention: edema, hypertension	Fluid overload, intrinsic renal disease
Signs of underlying systemic diseases associated with renal involvement: butterfly rash, joint swelling, purpuric rash, fever, macular rash, palpably enlarged kidneys	Systemic lupus erythematosus Henoch-Schönlein purpura Interstitial nephritis Polycystic or multicystic kidney disease Renal vein thrombosis
Signs of urinary obstruction: poor urinary stream, urinary dribbling, palpably enlarged urinary bladder, history of urinary catheterization	Bladder outlet obstruction

or edema suggests poststreptococcal glomerulonephritis. Edema should also prompt a search for nephrotic syndrome, cardiac failure, or liver failure, which would suggest prerenal or functional AKI that should not be treated with fluid resuscitation. Fever, joint complaints, and a malar rash are indicative of systemic lupus erythematosus. In hospitalized patients, nephrotoxic medications or periods of hypotension are commonly associated with intrinsic AKI, and they should be diligently sought.

The urinalysis is the most important noninvasive test in the diagnostic evaluation. Typically, the urine in conditions that result in prerenal AKI contains little protein or blood. In contrast, proteinuria and hematuria are prominent in causes leading to intrinsic AKI. A heme-positive urine by dipstick in the absence of red blood cells in the sediment suggests hemolysis or rhabdomyolysis. Characteristic findings on microscopic examination of the urine sediment can suggest certain diagnoses. Muddy brown granular casts and epithelial cell casts are highly suggestive of intrinsic AKI

> ### KEY POINTS
>
> - The initial approach to a patient with suspected AKI should be directed toward the following:
>   - Identifying the underlying cause
>   - Distinguishing among prerenal (functional), intrinsic (structural), and postrenal AKI
>   - Determining the severity of AKI
> - The urinalysis and determination of fractional sodium excretion are the most important bedside tools in the diagnostic evaluation of AKI.
Figure 30.8 Urine microscopy of a patient with acute kidney injury after a cardiac surgical procedure shows a "muddy brown" cast.

Table 30.9 Urinary indices in prerenal and intrinsic acute kidney injury

Test	Prerenal AKI	Intrinsic AKI
Urine specific gravity	>1,020	<1,012
Urine/plasma creatinine	>40	<20
Urine Na (mEq/L)	<20	>40
FENa	<1%	>2%

AKI, acute kidney injury; FENa, fractional excretion of sodium.

or ATN (Figure 30.8). The finding of red blood cell casts is diagnostic of glomerulonephritis. The concurrent findings of red blood cell casts, dysmorphic red blood cells, heavy proteinuria, or lipiduria indicate a "nephritic" urinary sediment. This is commonly associated with AKI caused by glomerulonephritides. Pyuria with white cell and granular or waxy casts are suggestive of tubular or interstitial disease or urinary tract infection. White blood cells and white blood cell casts may also be seen in acute glomerulonephritis.

DISTINGUISHING BETWEEN PRERENAL AND INTRINSIC ACUTE KIDNEY INJURY

This determination is important because (1) the treatment and prognosis are different, and (2) prompt identification and management of prerenal AKI can prevent the progression to intrinsic AKI. As noted earlier, urinalysis with microscopy often provides an initial differentiation between prerenal and intrinsic AKI. The further distinction is based on the principle that prerenal or functional AKI is associated with maximal reabsorption of solutes and water by the intact proximal tubule, whereas the proximal tubule cell damage typical of intrinsic or structural AKI results in impaired reabsorptive capacity. Urinary indices based on this principle are shown in Table 30.9.

The FENa is a convenient bedside screening test for making this distinction. It is calculated from measured concentrations of sodium (Na) and creatinine (Cr) in the urine (U) and plasma (P), as follows:

$$FENa = ([U / P]Na) / ([U / P]Cr) \times 100$$

An FENa of less than 1% suggests prerenal AKI, in which the reabsorption of almost all the filtered sodium

represents an appropriate response to decreased perfusion. An FENa greater than 2% suggests intrinsic AKI with proximal tubule injury. An FENa between 1% and 2% is nondiagnostic. In neonates, the FENa is generally higher because of their decreased ability to reabsorb sodium that results from immaturity of proximal tubule function. Further, FENa determinations should be interpreted in the context of such considerations as hydration status and sodium intake. The FENa can be low (less than 1%) in conditions such as congestive heart failure, nephrotic syndrome, contrast nephropathy, or pigment nephropathy. The FENa can be high following administration of loop or distal tubule diuretics or administration of a sodium load, which increases urinary sodium excretion. The fractional excretion of urea (FEUrea) has been proposed as a more accurate determinant of prerenal AKI in children, especially in patients receiving diuretics.[94]

By the same principle of increased proximal tubule solute reabsorption, the BUN-to-creatinine ratio in the serum is markedly elevated (to more than 20) in prerenal AKI. This is because the proximal tubule can avidly reabsorb urea but is impermeable to creatinine. However, increases in BUN without AKI can be encountered in patients receiving steroids or total parenteral nutrition, in catabolic states, and in those with gastrointestinal bleeding.

DISTINGUISHING BETWEEN ACUTE KIDNEY INJURY AND CHRONIC KIDNEY DISEASE

A kidney and bladder ultrasound scan is a sensitive, noninvasive modality that not only can differentiate between AKI and CKD, but also can rule out a postrenal cause. Typically, the kidneys in AKI are normal or enlarged, with increased echogenicity, whereas those in CKD are frequently small and shrunken. Other distinguishing features are shown in Table 30.10.

DETERMINING THE SEVERITY OF ACUTE KIDNEY INJURY

Estimating the baseline pre-illness serum creatinine can determine the severity of AKI and allow for classification based on the pRIFLE and KDIGO criteria. This estimation is best achieved when a previously drawn serum creatinine

Table 30.10 Features distinguishing acute kidney injury from chronic kidney disease

Clinical and laboratory parameter	Acute kidney injury	Chronic kidney disease
Onset of kidney disease	Sudden	Long-standing kidney disease
Hypertension	Onset with AKI	Long-standing hypertension
Linear growth	Normal	Linear growth retardation
Urinalysis	"Muddy brown" casts	No "muddy brown" casts
	No broad urinary casts	Broad waxy urinary casts
BUN and creatinine	Progressively increasing	Stable, but elevated BUN and creatinine
Bone x-ray studies for osteodystrophy	Normal bone x-ray study	Renal osteodystrophy
Parathyroid hormone	Normal	Elevated
Anemia	Usually mild and explainable by acute onset of disease	Anemia usually severe, normocytic and normochromic
Renal ultrasound	Normal or enlarged kidneys; may be echogenic	Small shrunken and echogenic kidneys

Abbreviations: AKI, acute kidney injury; BUN, blood urea nitrogen.

level is available. If not, the baseline kidney function in children can be estimated using the Schwartz formula:

$$\text{Estimated creatinine clearance in mL/min} = kL / P_{cr}$$

where L = height (cm), P_{cr} = plasma creatinine in mg/dL, and k = proportionality constant.

The value of the proportionality constant was previously reported to be age dependent and was quoted to be 0.45 in the first year of life, 0.55 in children and adolescent girls, and 0.70 in adolescent boys. More recent investigations allowed for a simplification of this formula and indicated that a single uniform k value of 0.413 provides a good approximation of GFR in children between 1 and 16 years of age and both genders.[95] However, this simplification was derived in patients with CKD and has not been validated for use in AKI.

Another important index of AKI severity is the degree of fluid overload, which is especially useful in the assessment of the critically ill patient. Several pediatric AKI studies have demonstrated that increasing degrees of fluid overload are independently associated with mortality.[96–98] The extent of fluid overload during a hospitalization period can be estimated by the following formula:

$$\text{Fluid overload (\%)} = [\text{Total fluid in (liters)} - \text{Total fluid out (liters)}] / \text{Admission weight in kg} \times 100$$

The importance of assessing fluid overload was demonstrated by the Prospective Pediatric Continuous Renal

Replacement Therapy (ppCRRT) Registry Group, through the analysis of its 340-patient cohort by using a tripartite classification for percentage of fluid overload at CRRT initiation.[98] Patients who developed a greater than 20% fluid overload at CRRT initiation had a significantly higher mortality rate (66%) than did patients who had a 10% to 20% fluid overload (43%) and those with a less than 10% fluid overload (29%). The association between degree of fluid overload and mortality remained after adjusting for intergroup differences and severity of illness. When fluid overload was dichotomized to greater than 20% and less than 20%, patients with a greater than 20% fluid overload had an adjusted mortality odds ratio (OR) of 8.5 (95% confidence interval [CI], 2.8 to 25.7).

Routine laboratory evaluation for the presence of metabolic complications can also assist in establishing AKI severity. AKI is associated with several life-threatening complications, about which the clinician must constantly be diligent. Fortunately, these complications are uncommon in patients who receive dialytic therapies. Common complications are listed in Table 30.11. Hyponatremia is usually dilutional (secondary to fluid retention and administration of hypotonic fluids). Less common causes of hyponatremia include sodium depletion (hyponatremic dehydration) and hyperglycemia (serum sodium concentration decreases by 1.6 mEq/L for every 100 mg/dL increase in serum glucose higher than 100 mg/dL). Hypernatremia in AKI is usually a result of excessive sodium administration (inappropriate fluid therapy or overzealous sodium bicarbonate administration).

Hyperkalemia in AKI results from reduction in GFR, reduction in tubular secretion of potassium, increased catabolism, and metabolic acidosis (each 0.1-unit reduction in arterial pH raises serum potassium by 0.3 mEq/L). Hyperkalemia is most pronounced in patients with excessive endogenous production (rhabdomyolysis, hemolysis, and tumor lysis syndrome). High–anion gap metabolic acidosis is secondary to the impaired renal excretion of acid

KEY POINT

Fluid overload greater than 20% at CRRT initiation is associated with higher patient mortality.

Table 30.11 Complications of acute kidney injury

Metabolic	Cardiovascular	Gastrointestinal	Neurologic	Hematologic	Infectious
Hyperkalemia	Pulmonary edema	Nausea, vomiting, anorexia	Altered mental status	Anemia	Pneumonia
Metabolic acidosis	Arrhythmias	Malnutrition	Irritability	Bleeding	Sepsis
Hyponatremia	Pericarditis	Gastritis	Seizures	—	Infected IV sites
Hypocalcemia	Myocardial Infarction	GI bleeding	Somnolence	—	—
Hyperphosphatemia	Hypertension	GI ulcers	Coma	—	—

Abbreviations: GI, gastrointestinal; IV, intravenous.

and the impaired reabsorption and regeneration of bicarbonate. Acidosis is most severe in shock, sepsis, or impaired respiratory compensation. Hypocalcemia results from increased serum phosphate and impaired renal conversion of vitamin D to the active form. Hypocalcemia is most pronounced in patients with rhabdomyolysis. Metabolic acidosis increases the fraction of ionized calcium (the active form). Therefore, overzealous bicarbonate therapy can decrease the concentration of ionized calcium and precipitate symptoms of hypocalcemia, including tetany, seizures, and cardiac arrhythmias. Hyperphosphatemia in AKI is primarily caused by impaired renal excretion, and it can aggravate hypocalcemia. During recovery from AKI, the vigorous diuretic phase may be accompanied by significant volume depletion, hypernatremia, hypokalemia, and hypophosphatemia.

ROLE OF DIAGNOSTIC FLUID CHALLENGE

A common clinical situation is one in which patients present with an increase in BUN and serum creatinine and with a history and physical findings consistent with a prerenal cause, but the duration of the prerenal insult is unknown. Another common diagnostic dilemma occurs when a patient presents with an increase in serum creatinine, but the cause is unclear. In both these cases, a fluid challenge may be diagnostic as well as therapeutic. Typically, fluid challenges in children consist of crystalloid at a dose of 10 to 20 mL/kg, repeated once or twice until urine output improves. A reduction in BUN and serum creatinine would indicate a prerenal cause, whereas an absence of improvement in these parameters (or the development of fluid overload, or both) would confirm the diagnosis of intrinsic AKI. Fluid challenges should be avoided in children with prerenal AKI because of non–volume-responsive states such as liver failure, heart failure, and nephrotic syndrome.

ROLE OF KIDNEY BIOPSY

A renal biopsy is rarely indicated in AKI, but it should be considered when noninvasive evaluation fails to establish a diagnosis. Renal biopsy in children with AKI is most commonly indicated in patients with suspected rapidly progressive or crescentic glomerulonephritis, in suspected lupus nephritis to classify the renal disease, and in kidney transplant recipients with suspected acute allograft rejection. Pathologic findings of AKI in the renal biopsy include normal appearing glomeruli, renal tubules demonstrating tubular cell loss, the presence of denuded tubular epithelial cells in the tubular lumen, and a lack of an inflammatory interstitial infiltrate (see Figure 30.8). Acute renal transplant allograft rejection, conversely, has distinct pathologic findings.

CONCERNS WITH USING SERUM CREATININE MEASUREMENTS

A progressive increase in serum creatinine (typically 1 to 2 mg/dL/day) is the hallmark of intrinsic AKI, and it has served as a biomarker of AKI for several decades. However, serum creatinine concentration is a flawed AKI biomarker, for several reasons: Serum creatinine does not differentiate the nature, type, and timing of the renal insult.[99] Changes in serum creatinine concentrations often lag behind changes in GFR until a steady state has been reached, which can take several days. Dialysis readily clears serum creatinine, thereby rendering this marker useless in the assessment for improving renal function once dialysis has begun. Even normal serum creatinine concentrations can vary widely with age, gender, diet, muscle mass, nutrition status, medications, and hydration status. In the acute setting, it is estimated that more than 50% of kidney function must be lost before the serum creatinine even begins to rise. However, animal studies have shown that although AKI can be prevented or treated by several maneuvers, these measures must be instituted very early after the

KEY POINT

Using serum creatinine for the diagnosis of AKI is fraught with imprecisions, but it is currently the most widely available tool.

insult, well before the serum creatinine rises. The lack of early biomarkers of AKI in humans has hitherto impaired our ability to launch potentially effective therapies in a timely manner.

NOVEL BIOMARKERS

The genomic and proteomic tools of modern science have identified novel markers for the early stress response of the kidney that serendipitously appear in the urine or plasma well before a change in serum creatinine is detected.[99] Many of these markers are being developed and validated as early noninvasive biomarkers for the prediction of AKI and its clinical outcomes in humans. This is a rapidly evolving field, and the current status of the most promising examples is summarized in Table 30.12.

The most widely studied and validated early biomarker of AKI in children is NGAL.[100] In a prospective study of 71 children undergoing cardiopulmonary bypass (CPB), levels of NGAL in the urine and plasma were significantly elevated within 2 h of bypass in those children who subsequently developed AKI (defined as a 50% increase in serum creatinine) 1 to 3 days postoperatively.[101] A subsequent prospective study of 374 infants and children undergoing CPB confirmed these findings and additionally established cutoff thresholds, as well as a strong association between early NGAL measurements and hard clinical outcomes, including length of hospital stay and the duration and severity of AKI.[102] A prospective multicenter study of 311 children undergoing cardiac surgical procedures confirmed the early rise of plasma and urine NGAL concentrations (within 6 h postoperatively) in subjects who developed an increase in serum creatinine 2 days later. Early NGAL concentrations were also shown to be associated with longer hospital and ICU stays and with longer duration of mechanical ventilation. Furthermore, the additional of NGAL significantly improved the risk prediction for AKI over clinical models alone.[103] A multicenter pooled analysis of existing NGAL studies in children and adults has been published, confirming the utility of this marker for the early diagnosis of AKI and its clinical outcomes in several clinical situations.[104] One study examined a combination of biomarkers in 220 children undergoing cardiac surgical procedures.[21] Urinary NGAL was increased in AKI patients within 2 h of bypass initiation, urine IL-18 and liver-type fatty acid binding protein (L-FABP) were increased within 6 h, and urine kidney injury molecule 1 (KIM-1) increased at the 12-h time point. All markers correlated with AKI severity and clinical outcomes, and improved the risk prediction for AKI over clinical models. Thus, they represent temporally sequential markers, and a panel of such biomarkers may therefore help establish the timing of injury and plan appropriate therapies. Standardized clinical laboratory platforms for the measurement of urine and plasma NGAL are now available in most countries globally.

Table 30.12 Novel urinary biomarkers for the prediction of acute kidney injury and its outcomes*

Biomarker	Source	Function	Cardiac surgery	Kidney transplant	ICU/ED
NGAL	Distal tubule and collecting duct	Regulates iron trafficking, promotes tubule cell survival	2 h post-CPB 2 days pre-AKI Predicts AKI severity, dialysis, and death	6 h post-transplant 2–3 days pre-DGF Predicts long-term graft loss	On admission 1–2 days pre-AKI Predicts AKI severity, dialysis, and death
IL-18	Proximal tubule	Promotes tubule cell apoptosis and necrosis	6 h post-CPB 2 days pre-AKI Predicts AKI severity, dialysis, and death	6 h post-transplant 2–3 days pre-DGF predicts long-term graft loss	On admission 1–2 days pre-AKI Predicts AKI severity, dialysis, and death
L-FABP	Proximal tubule	Antioxidant, suppresses tubulointerstitial damage	6 h post-CPB 2 days pre-AKI Not tested for outcomes	Not tested	On admission 1–2 days pre-AKI Predicts AKI severity, dialysis, and death
KIM-1	Proximal tubule	Promotes epithelial regeneration, regulates apoptosis	12 h post-CPB 1 day pre-AKI Not tested for outcomes	Not tested	On admission 1–2 days pre-AKI Predicts AKI severity, dialysis, and death

Abbreviations: AKI, acute kidney injury, typically defined as AKIN stage I or greater; CPB, cardiopulmonary bypass; DGF, delayed graft function; ICU, intensive care unit; ED, emergency department; IL-18, interleukin-18; KIM-1, kidney injury molecule 1; L-FABP, liver-type fatty acid binding protein; NGAL, neutrophil gelatinase–associated lipocalin.

* Times shown (in hours or days) are the earliest time points when the biomarker becomes significantly increased from baseline.

PREVENTION

Preventive measures include vigorous fluid administration in patients at high risk for developing AKI, adequate fluid repletion in those patients with hypovolemia, avoidance of hypotension in critically ill children by providing inotropic support as needed, and close monitoring of renal function and drug levels in children receiving nephrotoxic medications.

HYDRATION

Vigorous fluid administration has been successfully employed to prevent AKI in patients at high risk, including those with hemoglobinuria, myoglobinuria, early tumor lysis syndrome, renal transplantation, other major surgical procedures, and use of nephrotoxic agents such as radiocontrast, cisplatin, and amphotericin. The efficacy of preoperative hydration strategies was demonstrated by a meta-analysis of 20 randomized controlled trials that investigated the renoprotective effects of perioperative hemodynamic optimization among 4220 adult surgical patients who were undergoing elective or emergency procedures.[105] Postoperative AKI was significantly reduced by perioperative hemodynamic optimization when compared with the control group of patients who did not receive similar goal-directed therapy (OR, 0.64; 95% CI, 0.50 to 0.83).

KEY POINTS

- The only proven measures to prevent AKI are vigorous, goal-directed fluid administration, avoidance of hypotension, and minimizing of exposure to nephrotoxic medications.
- Management of AKI includes treatment of the underlying cause, fluid and electrolyte management, nutritional support, adjustment of drug dosing, and renal replacement therapy.

FLUID RESUSCITATION

A child with a clinical history and physical examination findings consistent with hypovolemia and impending or established prerenal AKI requires immediate vigorous intravenous fluid therapy with normal saline (10 to 20 mL/kg over 30 min, repeated twice if necessary, until urine output is reestablished). Careful observation should be employed to avoid excessive hydration. If urine output does not improve after restoration of intravascular volume, more invasive monitoring may be required to guide further therapy. In children not responsive to volume repletion alone, preservation of blood pressure and renal perfusion with appropriate inotropic agents is essential to prevent AKI.[106–109]

MINIMIZING NEPHROTOXIC IMPACTS

The importance of monitoring serum creatinine levels as a measure of kidney function in children receiving nephrotoxic drugs has been brought into focus in a retrospective single-center study of 1660 noncritically ill hospitalized children.[27] Children who developed AKI as defined by the serum creatinine–based pRIFLE criteria had significantly greater odds of exposure to one or more nephrotoxic medications than did patients without AKI (OR, 1.7; 95% CI, 1.04 to 2.9). Both increasing dose and duration of nephrotoxin use were associated with increased development of AKI. It is crucial that clinicians caring for patients requiring potentially nephrotoxic drugs use appropriate drug dosing based on the knowledge of altered pharmacokinetics in early AKI and be vigilant in monitoring for drug efficacy and toxicity. One study demonstrated decreasing AKI duration when systematic daily serum creatinine monitoring policy was put into practice for children who received multiple nephrotoxic medications.[28]

INTERVENTIONS OF UNCLEAR BENEFIT

These include mannitol, loop diuretics, low-dose dopamine, fenoldopam, atrial natriuretic peptide, and N-acetylcysteine. The potential use of these agents in AKI prevention is discussed here.

Mannitol

Experimental studies suggest that mannitol may be protective by causing diuresis (which minimizes intratubular cast formation) and by acting as a free radical scavenger (thereby minimizing cell injury). In the clinical setting, the efficacy of mannitol for prevention of AKI is inconclusive, and its use can result in significant side effects including volume expansion, hyperosmolality, and pulmonary edema. Its use for prevention of AKI is not recommended.

Loop diuretics

Furosemide induces forced diuresis, and it also reduces active sodium chloride (NaCl) transport in the thick ascending limb of the loop of Henle; the ensuing decrease in energy requirement may protect the tubule cells in the presence of a decrease in energy delivery. However, the available evidence from clinical studies in adults does not support the routine use of diuretics as prophylaxis for AKI.[55] Although controlled studies have demonstrated that the administration of furosemide to patients in the early stages of AKI does not significantly alter the natural history of the disease, furosemide can potentially convert the syndrome from an oliguric form to a nonoliguric form and therefore simplify fluid, electrolyte, and nutritional management. In addition, a prospective assessment of a furosemide challenge, or furosemide "stress" test, was able to predict which adult patients would have worsening AKI based on a lack of response to the furosemide within 2 h.[110]

Dopamine

The use of a low "renal dose" of the inotropic agent dopamine (0.5 to 3 mg/kg/min) had been common in the critical care setting because of its renal vasodilatory and natriuretic effects. However, prospective randomized studies of adult patients at risk for AKI have not shown a beneficial renoprotective effect of "low-dose" dopamine.[111,112] There are risks associated with even low-dose dopamine, including tachycardia, arrhythmias, myocardial ischemia, and intestinal ischemia. Therefore, the routine use of dopamine for prevention of AKI is not recommended.

Fenoldopam

This is a potent, short-acting, selective dopamine A-1 receptor agonist that increases renal blood flow and decreases systemic vascular resistance. A meta-analysis of 16 randomized studies with a total of 622 adult patients administered fenoldopam and 668 given placebo or other therapy (principally low-dose dopamine) for the prevention or treatment of AKI concluded that fenoldopam significantly reduced the risk for AKI, the need for dialysis, and mortality rates.[113] Experience with fenoldopam in the pediatric age group is limited. A small prospective single-center randomized double-blind controlled trial of children undergoing CPB revealed a significant reduction in the urinary AKI biomarker NGAL at the end of the surgical procedure and 12 hours after ICU admission in the group receiving fenoldopam.[114] Confirmation of the benefits of fenoldopam in a large multicenter randomized controlled trial is required before routinely recommending this agent for the prevention of AKI.

Natriuretic peptides

Atrial natriuretic peptide (ANP) and B-type natriuretic peptide (BNP) block tubular reabsorption of sodium and vasodilate the afferent arteriole. The renoprotective effects of these agents have been evaluated primarily in trials of adults undergoing cardiac surgical procedures and with congestive heart failure. Although initial data seemed promising, more recent evidence from large randomized trials failed to show a clinic benefit from these agents.[115,116] Pediatric data for the renoprotective effects of natriuretic peptides are limited. In a small retrospective study of 20 children with decompensated heart failure, recombinant human BNP (nesiritide) resulted in increased urine output and decreased serum creatinine concentrations.[117] Pending further randomized controlled trial data, the routine use of natriuretic peptides for prophylaxis against AKI is not recommended.

N-acetylcysteine

N-acetylcysteine (NAC) is a free radical scavenger antioxidant agent that counteracts the deleterious effects of reactive oxygen species in the generation of tubule cell injury and also has vasodilatory properties. Several meta-analyses examined the efficacy of NAC in the prevention of AKI following cardiac and other major surgical procedures, as well as the prevention of contrast-induced nephropathy in adults. Given that the overall direction of the data is toward benefit and the agent is well tolerated and relatively inexpensive, the use of NAC in high-risk patients is generally recommended.[15] Although NAC is commonly used in children for treatment of acetaminophen toxicity and other forms of acute liver failure, data for its renoprotective effects in the pediatric population are limited. The routine use of NAC for AKI prophylaxis in children is therefore not recommended, with the exception of judicious use in children with CKD who are at high risk for contrast-induced nephropathy.

MANAGEMENT

The basic principles of the general management of the child with AKI include treatment of the underlying cause, fluid and electrolyte management, nutritional support, adjustment of drug dosing, and renal replacement therapy. In general, prompt consultation and referral to a pediatric nephrologist are recommended for the management of intrinsic AKI, especially in the critically ill child.

FLUID VOLUME BALANCE

Appropriate immediate fluid management is crucial in children with AKI. Based on the underlying cause, comorbid conditions, and possible previous therapy, the child may be hypovolemic, euvolemic, or hypervolemic. Accurate initial assessment, and careful follow-up with accurate records of fluid input and output as well as body weights, physical examinations, and additional invasive monitoring as needed, will guide the appropriate fluid therapy. A child with a clinical history and physical examination consistent with hypovolemia requires immediate intravenous fluid therapy in an attempt to restore renal function and prevent the progression of prerenal AKI to intrinsic AKI. Commonly used fluids are crystalloid solutions, such as normal saline (10 to 20 mL/kg given over 30 min, repeated twice as needed, monitoring vital signs for appropriate responses). If urine output does not increase and renal function fails to improve with the restoration of intravascular volume, bladder catheterization is recommended to confirm the anuria, and other forms of invasive monitoring may be required to assess the child's fluid status adequately and help guide further therapy. Conversely, a child with signs of fluid overload may require immediate fluid removal or fluid restriction. In such a child who is fluid replete and oliguric for less than 24 h, a trial of furosemide may be attempted to convert the AKI from an oliguric type to a nonoliguric type. Furosemide-induced diuresis can simplify fluid, electrolyte, and nutritional management. Furosemide should be

promptly discontinued if the bolus doses do not result in a diuretic response, as would be expected in patients with established AKI. Care should be taken to avoid hypotension from overzealous diuretic therapy because that can increase the risk of nonrecovery of kidney function or death. The risk of ototoxicity from furosemide use in this setting remains significant. In addition, there is evidence in adults with established AKI that the use of diuretics may be associated with adverse clinical outcomes. Diuretics should not be used to postpone initiation of dialysis. Early consideration for renal replacement therapy is essential in a child with AKI and fluid overload, especially if the required fluid restriction is a hindrance to adequate nutrition.

Once euvolemia has been established, the clinician must pay careful attention to ongoing fluid losses (insensible water loss of approximately 300 to 500 mL/m^2/day in addition to replacement of urine and gastrointestinal losses) and gains (fluids, medications, and nutrition administered). Insensible water losses are higher in febrile children and lower in ventilated children with decreased respiratory losses. In patients with fluid overload, the achievement of negative balance may require replacement of less than the total urine output. Renal replacement therapy should be considered for children in intensive care with AKI and a greater than 10% fluid overload who are not expected to recover kidney function expeditiously.

ELECTROLYTE AND ACID-BASE BALANCE

Appropriate electrolyte management is crucial in children with AKI and is also based on the underlying cause, comorbid conditions, and expected complications. In general, electrolyte disturbances are asymptomatic and require a high index of suspicion and routine monitoring for early detection. Patients with oligoanuric AKI should not receive potassium or phosphorus unless they exhibit significant hypokalemia or hypophosphatemia. Sodium intake should be restricted to 2 to 3 mEq/kg/day, to prevent sodium and fluid retention with resultant hypertension. Children with polyuric AKI are at risk for electrolyte losses, which may need to be replaced. Ongoing therapy in such patients can be guided by monitoring of plasma and urinary electrolytes.

Hyperkalemia in children with AKI is usually asymptomatic, but it can constitute a medical emergency. Symptoms are nonspecific and may include malaise, nausea, and muscle weakness. Electrocardiographic changes should be looked for in all patients suspected to have hyperkalemia, including (in sequence according to the severity of hyperkalemia) tall peaked T waves, prolonged PR interval, flattened P waves, widened QRS complex, and ventricular tachycardia and fibrillation. The management of hyperkalemia depends on the onset and severity and is outlined in Table 30.13. Mild to moderate hyperkalemia (serum potassium of 5.5 to 6.5 mEq/L) is treated by eliminating all sources of potassium from the diet or intravenous fluids and administration of an ion exchange resin such as sodium polystyrene sulfonate. This therapy requires several hours of contact with the colonic mucosa to be effective. In addition, patients with hyperkalemia who continue to have some urine output may benefit from the kaliuresis induced by intravenous administration of loop diuretics such as furosemide, but care should be exercised to avoid fluid depletion and hypotension. Emergency treatment is indicated when the serum potassium exceeds 6.5 mEq/L or if any electrocardiographic changes are present. In addition to ion exchange resin, such patients should receive calcium gluconate on an emergency basis to counteract the effects of hyperkalemia on the myocardium. Uptake of potassium by cells can be stimulated by infusion of glucose and insulin (in the absence of significant fluid overload), the β-agonist albuterol by nebulizer, or intravenous sodium bicarbonate. In practice, the definitive therapy for significant hyperkalemia in oliguric AKI often includes dialysis, and the nondialytic therapy outlined earlier serves mostly to tide over the crisis.

High–anion gap metabolic acidosis is common in AKI. Administration of sodium bicarbonate should be initiated only in life-threatening situations in which respiratory compensation is inadequate, or the acidosis is contributing to worsening hyperkalemia. In cases of severe or progressive acidosis following shock, serious infections, or other hypercatabolic states, supplemental bicarbonate may be required to correct and maintain arterial pH to more than 7.2 until the underlying disease is controlled. In general, children with serum bicarbonate levels that are greater

Table 30.13 Nondialytic pharmacotherapy of hyperkalemia

Agent	Mechanism	Dose	Onset of action
Sodium polystyrene sulfonate (Kayexalate)	Exchanges Na$^+$ for K$^+$ across colonic mucosa	1 g/kg PO or PR with sorbitol	1–2 h
Calcium gluconate	Stabilizes the myocardial membrane potential	50 mg/kg IV (max. dose 2 grams) over 5–15 min	Immediate
Glucose and insulin	Stimulate cellular uptake of K$^+$	Glucose 0.5 g/kg, insulin 0.1 unit/kg over 30 min	30 min
β Agonists (albuterol)	Stimulate cellular uptake of K$^+$	5–10 mg dose by nebulizer	30 min
Sodium bicarbonate	Shifts K$^+$ into cells	1 mEq/kg IV over 10 min	15 min

Abbreviations: IV, intravenously; K$^+$, potassium; Na$^+$, sodium, PO, orally; PR, rectally.

than 14 mEq/L or with an arterial pH greater than 7.2 do not require bicarbonate administration. Overzealous use of bicarbonate therapy in AKI can precipitate hypocalcemia and hypernatremia.

NUTRITIONAL SUPPORT

AKI is associated with marked catabolism, and aggressive nutritional support is crucial to enhance the recovery process. Adequate calories to account for maintenance requirements and supplemental calories to combat excessive catabolism should be administered. Infants should receive at least 120 Kcal/kg/day, and older children should be administered at least 150% of maintenance caloric intake. In addition, AKI in critically ill children results in abnormal amino acid synthesis, as well as increased protein catabolism. Furthermore, all forms of renal replacement therapy (including continuous venovenous hemofiltration [CVVH], continuous venovenous hemodialysis [CVVHD], and continuous venovenous hemodialfiltration [CVVHDF]) result in amino acid losses of up to 20% of the amount normally provided by parenteral nutrition.[118] Therefore, children with AKI should be provided with at least 3 g/kg/day of daily protein intake, and those undergoing renal replacement therapy should receive replacement for the additional 20% of amino acid losses. Some recommendations aim to maintain the BUN at the 40 to 80 mg/dL range as a guide to determine whether adequate protein intake is being provided for children undergoing replacement therapy. Hyperalimentation should be considered early because the majority of children with AKI will encounter nausea and anorexia and will not be able to tolerate the oral or other enteral routes. If adequate protein and calorie nutrition cannot be achieved because of fluid restriction, renal replacement therapy should be instituted early in the course of the illness.

DRUG DOSING

Nephrotoxic agents should be avoided in AKI because they may worsen the injury and delay recovery of function. Critically ill children with AKI are at risk for adverse outcomes of drug therapy. It has been reported that approximately half of patients with reduced renal clearance receive drug doses that are 2.5 times higher than the recommended maximum dose. Drug dosing in the setting of AKI is complicated by several factors. Pharmacokinetic changes include decreases in protein binding and drug metabolism. The volume of distribution of hydrophilic agents can increase as a result of fluid overload and decreased binding of the drug to serum proteins, and drug doses must be adjusted to account for these changes. Serum creatinine–based renal function estimations most often overestimate renal clearance in AKI. Many drugs are significantly cleared by renal replacement therapies. To ensure efficacy and prevent toxicity, therapeutic drug monitoring is highly recommended. However, in the absence of drug monitoring (as is the case for most medications), adequate concentrations can be inferred only from the clinical response.

Pharmacologic management of children with AKI is best accomplished by close collaboration and consultation with trained pharmacology and pharmacy teams. In general, the dose of all medications should be adjusted based on residual renal function, to avoid toxic accumulation of drugs and their metabolites that are normally excreted by the kidney, as well as to avoid worsening the AKI. When the GFR falls to less than 50% of normal, most drugs excreted by the kidney require modifications in dose or scheduling. However, patients with documented AKI in the early phase with a rising creatinine should be assumed to have a GFR of less than 10 mL/min, and medications should be dosed accordingly, irrespective of the absolute value of the serum creatinine, because of the known delay in serum creatinine to rise to steady-state levels. Where possible, treatment should be modified empirically according to systemic drug-level targets.

RENAL REPLACEMENT THERAPY

The common indications for acute dialytic therapy in AKI include the following: (1) fluid overload that is unresponsive to diuretics or is a hindrance to adequate nutrition; (2) hyperkalemia that is unresponsive to nondialytic therapy; (3) refractory hypertension; and (4) symptomatic uremia, including pericarditis, pleuritis, and neurologic symptoms. The choices available include hemodialysis (HD), peritoneal dialysis (PD), and CRRT. These modalities are described in detail in other chapters, and only general comments pertaining to AKI are included here. The choice of dialysis modality depends on the clinical status of the patient, the expertise of the physician, and the availability of appropriate resources. HD requires central vascular access, specialized equipment and technical personnel, anticoagulation (except in patients with coagulopathy), and the ability to tolerate a large extracorporeal volume. Critically ill patients frequently require pressor support for effective HD. The advantage of HD in the setting of AKI lies in its ability to correct imbalances in fluid, electrolyte, and acid-base status rapidly. The advantages of PD include ease of performance and no requirement for specialized equipment, personnel, or systemic anticoagulation. PD is frequently the therapy of choice in neonates and small infants.

The transition from the use of adaptive CRRT equipment to production of hemofiltration machines with volumetric control allowing for accurate ultrafiltration flows has led to a change in pediatric renal replacement therapy modality prevalence patterns.[119,120] Accurate ultrafiltration and blood flow rates are crucial for pediatric CRRT because the extracorporeal circuit volume can comprise more than 15% of a small pediatric patients' total blood volume, and small inaccuracies in ultrafiltration may represent a large percentage of the patient's total body water. Polls of US pediatric nephrologists demonstrate increased CRRT use over PD as the preferred modality for treating pediatric AKI. CRRT is

especially useful in the presence of hemodynamic instability and multiorgan dysfunction because it allows for gentle, continuous management of fluid overload.

CRITICALLY ILL PEDIATRIC PATIENTS

As opposed to adults, children tend to develop severe and life-threatening multiorgan dysfunction syndrome very early in their ICU course. Methods to identify patients at risk and aggressive initiation of supportive measures such as CRRT could conceivably improve the outcome. For example, children who receive CRRT and have a requirement for pressor support display a higher mortality than those who do not need pressors in the course of their AKI treatment.[121] As noted earlier, more recent data demonstrate that worsening fluid overload is an independent risk factor for mortality in critically ill children who receive CRRT, irrespective of the severity of illness.[98] These results suggest that early initiation of CRRT at lesser degrees of fluid overload may allow for more optimal nutrition and blood product provision without the further accumulation of fluid or catabolic waste products, thereby improving the outcome.

INFANTS

Infants and neonates with AKI present unique problems for renal replacement therapy provision. Delivery of HD or CRRT entails a significant portion of their blood volume to be pumped through the extracorporeal circuit. Therefore, extracorporeal circuit volumes that comprise more than 10% to 15% of patient blood volume should be primed with whole blood to prevent hypotension and anemia. Because the prime volume is not discarded, it is important to not reinfuse the blood into the patient at the end of the treatment, to prevent volume overload and hypertension. Short-term PD requires much less technical expertise, expense, and equipment compared with intermittent HD and CRRT. PD catheters can be placed quickly and easily. Initial dwell volumes should be limited to 10 mL/kg of the patient's body weight, to minimize intra-abdominal pressure and the potential for fluid leakage along the catheter tunnel. Although PD may deliver less efficient solute removal than HD or CRRT, its relative simplicity and minimal associated side effects allow for renal replacement therapy provision in settings lacking pediatric dialysis–specific support and personnel. CRRT has been prescribed since the mid-1980s for treatment of AKI in critically ill infants. A more recent evaluation of the CVVH course for 90 infants weighing less than 10 kg demonstrated very few technical complications using newer CVVH machinery.[122,123] Survival for infants receiving CRRT has been noted to be at 35% to 38%, which is similar to survival rates for older children. A newer neonatal CRRT device, the Cardio-Renal, Pediatric Dialysis Emergency Machine (CARPEDIEM), with a low extracorporeal volume of 42 mL and fluid balance errors of only 1 mL/h, is undergoing evaluation in Europe currently.[124]

CONGENITAL HEART DISEASE

Using recent definitions, the incidence of infant AKI after CPB ranges from 40% to 60%, with survival rates ranging up to 90%.[20,21,103,125] Risk factors for death include increasing underlying complexity of the congenital heart disease and poor cardiac function. A trend toward providing PD therapy earlier in the post-CPB course has been reported, and a study of 20 patients demonstrated 80% patient survival.[126] Improved survival with early PD initiation may result from prevention of fluid overload and from increased clearance of CPB-induced proinflammatory cytokines. Some institutions have advocated the prophylactic use of PD immediately postoperatively to prevent fluid accumulation in patients with high-risk underlying diagnoses such as hypoplastic left heart syndrome, transposition of the great arteries, or anomalous pulmonary venous return.

PROGNOSIS AND OUTCOME

In general, pediatric AKI has serious short-term and long-term consequences. The outcome depends on the cause, the age of the child, and comorbidities. In terms of mortality, severe AKI requiring renal replacement therapy in children is still associated with a mortality rate of approximately 30% to 50%, and this has not changed appreciably since the 1980s. Infants less than 1 year of age have the highest mortality rate. In the largest study reported to date, 3396 admissions to a single pediatric ICU in the United States were retrospectively analyzed using RIFLE criteria to define AKI.[24] Those patients who presented with AKI on admission to the ICU had a 32% mortality rate, and those who developed AKI at any time during the ICU stay had a 30% mortality rate. AKI on admission to the ICU was associated with an increased risk of mortality (adjusted OR, 5.4; 95% CI, 3.5 to 8.4). Development of AKI during the ICU stay was associated with an even greater risk of mortality (adjusted OR, 8.7; 95% CI, 6.0 to 12.6) and a fourfold increase in length of hospital stay.

Despite important technical advances in renal replacement therapies and critical care, children with severe AKI have a concomitant increasing severity of illness, so that an improvement in survival rates is not readily apparent. In a

KEY POINTS

- Severe AKI requiring renal replacement therapy in children is still associated with a mortality rate of 30% to 50%.
- Long-term follow-up for development of CKD is warranted for children who survive an episode of AKI.

retrospective analysis of 344 patients from the Prospective Pediatric Continuous Renal Replacement Therapy (ppCRRT) Registry, the overall mortality rate was 42%.[17] There was better survival in patients with principal diagnoses of drug intoxication (100%), primary renal disease (84%), tumor lysis syndrome (83%), and inborn errors of metabolism (73%). Survival was lowest in patients with liver disease or transplant (31%), pulmonary disease or transplant (45%), and bone marrow transplant (45%).

Information regarding the long-term outcome of children after an episode of AKI is beginning to accumulate. In a multicenter pooled analysis of 3476 children with hemolytic-uremic syndrome who were followed up for a mean of 4.4 years, the combined average death and end-stage renal disease rate was 12% (95% CI, 10% to 15%), and the combined average renal sequelae rate (CKD, proteinuria, hypertension) was 25% (95% CI, 20% to 30%).[127] Thus, long-term follow-up appears to be warranted after an acute episode of hemolytic-uremic syndrome. Long-term follow-up of premature infants with neonatal AKI has shown a 45% rate of renal insufficiency.[128] Prominent risk factors for progression include an increased random urine protein-to-creatinine ratio and a serum creatinine level greater than 0.6 mg/dL at 1 year of age. More recent long-term follow-up studies demonstrate that 40% to 60% of patients surviving an AKI episode have a sign of CKD, including proteinuria, hyperfiltration, low estimated GFR, or hypertension.[129,130] Collectively, these data strongly suggest that long-term follow-up is warranted for children who survive an episode of AKI.

SUMMARY

Acute kidney injury represents a very significant and potentially devastating problem in pediatric medicine. The precise incidence of pediatric AKI is not known, but it appears to be rising. Outstanding advances in basic research have illuminated the pathogenesis of AKI and have paved the way for successful therapeutic approaches in animal models. However, translational research efforts in humans have yielded disappointing results. A major reason for this is the lack of early markers for AKI, akin to troponins in acute myocardial disease, and hence an unacceptable delay in initiating therapy. In current clinical practice, AKI is typically diagnosed by measuring serum creatinine, which is an unreliable indicator during acute changes in kidney function. However, animal studies have shown that although AKI can be prevented or treated by several maneuvers, these measures must be instituted very early after the insult. The lack of early AKI biomarkers in humans has hitherto crippled our ability to launch potentially effective therapies in a timely manner. Fortunately, several potential candidates are currently being developed and tested as sequential noninvasive early biomarkers for the prediction

of AKI and its severity. It is likely that not any one biomarker but a collection of strategically selected proteins may provide the hitherto elusive "AKI panel" for the early and rapid diagnosis of AKI. Such a tool would be indispensable for the timely institution of potentially effective therapies in human intrinsic AKI, a common clinical condition still associated with a dismal prognosis and in which early intervention is desperately needed. Clinical Vignette 30.1 illustrates the course of AKI in a young boy.

ACKNOWLEDGMENT

Clinical Vignette 30.1

A previously healthy 5-year-old 20-kg boy was brought to the emergency department 2 days ago, with complaints of fever, vomiting, and ankle pain. On arrival, he had a temperature of 103° F, heart rate of 150/min, blood pressure of 76/42 mm Hg, and a tender erythematous rash over his left ankle. Laboratory test results showed a blood urea nitrogen (BUN) of 45 mg/dL and serum creatinine 0.8 mg/dL. He received two fluid boluses of 0.9% NaCl (40 mL/kg in total), as well as intravenous ceftriaxone. With no improvement in blood pressure, he was transferred to the intensive care unit. He remained hypotensive and required multiple additional fluid boluses and vasopressors. By the next morning, the initial blood culture results returned positive for Gram-positive cocci in clusters. Intravenous vancomycin was added to his regimen. The BUN was 80 mg/dL and serum creatinine was 2.0 mg/dL.

By the second day, the patient developed oliguria and peripheral and pulmonary edema, and he needed mechanical ventilation. His weight was now 25 kg, and the total fluid intake and output were very imbalanced (6 L in and 1 L out). The BUN was 120 mg/dL and the serum creatinine was 4.5 mg/dL. Multiple doses of intravenous furosemide failed to result in a diuretic response. A kidney ultrasound scan done at the bedside showed bilaterally enlarged and echogenic kidneys, with no hydronephrosis. The blood culture returned positive for methicillin-resistant *Staphylococcus aureus*. A nephrology consultation was requested.

TEACHING POINTS

1. At the time of renal consultation, it was quite obvious that the child in Clinical Vignette 30.1 had acute kidney injury (AKI). However, even at

the time of initial presentation to the emergency department, there was evidence of AKI. A healthy 5-year-old child should have a serum creatinine in the 0.5 mg/dL range. At presentation, the history of fever and vomiting and the physical findings of tachycardia and hypotension would be compatible with community-acquired prerenal AKI secondary to dehydration. The initial elevated blood urea nitrogen (BUN)–to-creatinine ratio (45/0.8 = 56) also supports this assessment. If measured before fluid therapy, the fractional excretion of sodium (FENa) would have been less than 0.1%.

2. Sometime during the early course of his illness, there was clearly a deleterious shift from prerenal to intrinsic AKI. This is evidenced by several findings. First, both the BUN and serum creatinine continued to rise despite aggressive fluid resuscitation. Second, he was nonresponsive to loop diuretics. Third, the absence of shrunken kidneys on ultrasound makes chronic kidney disease less likely, and the absence of hydronephrosis eliminates obstruction. Fourth, many potential causes of intrinsic AKI are apparent, including prolonged hypotension, sepsis, and nephrotoxins.

3. This child already satisfies the indications for initiation of renal replacement therapy. First, he has severe fluid overload (25%). Second, his high fluid requirements (for nutrition, vasopressor drips, antibiotics, crystalloids and colloids, and blood products) are likely to continue. Third, he requires clearance of accumulating uremic toxins. Given his tenuous clinical condition, the treatment of choice would be continuous renal replacement therapy. In addition, adequate nutrition should be provided (by total parenteral nutrition), potassium intake should be restricted, and additional nephrotoxin use should be avoided. Antibiotics should be continued to treat the underlying cause. His short-term prognosis remains guarded and depends on the efficacy of renal and other supportive care. He will require long-term follow-up because he is at risk for developing chronic kidney disease in the future.

REVIEW QUESTIONS

1. You have just initiated peritoneal dialysis for a 5-year-old boy with acute kidney injury (AKI) resulting from hemolytic-uremic syndrome following infection with Shiga toxin–producing *E. coli*. The family is inquiring about the chances of renal function recovery. Of the following, the *most* appropriate statement regarding the natural history of AKI is:
   a. Complete renal recovery is the rule.
   b. Kidney transplantation is the only hope for renal recovery.
   c. Progression to chronic kidney disease occurs in 25% of children with dialysis requiring HUS.
   d. Renal recovery is aided by the use of diuretics.
   e. Renal recovery is unusual in children with dialysis-requiring AKI.

2. A 4-week-old infant with cyanotic heart disease, renal dysplasia, and a baseline serum creatinine of 1.2 mg/dL undergoes a diagnostic cardiac catheterization with contrast. Five days later, in preparation for cardiac surgery, the anesthesiologist checks a renal panel and notes that the serum creatinine is now 2.2 mg/dL. The urine output is normal, and the urinalysis shows a trace amount of protein. Of the following options, the most likely explanation for the increase in serum creatinine is:
   a. Contrast nephropathy
   b. Laboratory error
   c. Prerenal azotemia
   d. Worsening cardiac function
   e. Worsening chronic kidney disease

3. A 3-day-old infant was born at 36 weeks of gestation by emergency cesarean section for fetal distress and placental abruption. Apgar scores were 2 and 3 at 1 and 5 minutes, respectively. He was placed on mechanical ventilation and given intravenous hydration. He also received a single dose of ampicillin and gentamicin,

which was not continued because the result of admission blood culture was negative. Today, the serum creatinine is 2.5 mg/dL. Of the following, the most likely cause of the acute kidney injury is:
a. Nephrotoxicity
b. Perinatal asphyxia
c. Prematurity
d. Respiratory distress syndrome
e. Sepsis

4. You have initiated therapy with enalapril for essential hypertension in a 14-year-old boy. At follow-up 2 weeks later, his blood pressure has normalized. However, the serum potassium level is 5.5 mEq/L in a nonhemolyzed sample (increased from a baseline of 4.2 mEq/L). Of the following, the most likely explanation for the hyperkalemia is:
a. Decreased glomerular filtration rate
b. Decreased renal blood flow
c. Excessive dietary intake of potassium
d. Increased distal tubular reabsorption of potassium
e. Increased proximal tubular reabsorption of potassium

5. You are seeing a 10-day-old male infant born at 38 weeks of gestation. The delivery was complicated by placental abruption and a tight nuchal cord, with Apgar scores of 2 and 3 at 1 and 5 minutes, respectively, requiring initiation of mechanical ventilation. For the past 2 days, his serum creatinine concentration has been 1.6 mg/dL, increased from 1.2 mg/dL at 1 day of age. The serum electrolytes are normal, and the infant does not have oliguria, edema, or hypertension. Of the following, the most appropriate statement regarding the current serum creatinine measurement is that it:
A. Is normal for his age
B. Is not reflective of kidney dysfunction because the urine output is normal
C. Reflects acute kidney injury
D. Reflects maternal renal function
E. Reflects physiologic maturation

6. You are seeing a 3-year-old girl who was admitted 5 days ago with oliguric acute kidney injury secondary to fever, vomiting, and dehydration. Her oral intake has remained poor, and she has been on an intravenous regimen of D5 0.25% NaCl to replace insensible water losses. Today, the serum sodium is 148 mEq/L, her weight is down by 5%, and her parents report many wet diapers last night. Of the following, the most likely cause of the hypernatremia in this patient is:
a. Excessive glucose intake
b. Excessive sodium administration
c. Laboratory error
d. Recovering acute kidney injury
e. Worsening acute kidney injury

7. You are consulted on a 2-year-old boy with tetralogy of Fallot who is scheduled to undergo a definitive intracardiac repair procedure. During infancy, he underwent a palliative Blalock-Taussig shunt placement and developed moderate postoperative acute kidney injury that resolved spontaneously. Of the following, the most appropriate intervention to reduce the risk of developing acute kidney injury following his upcoming intracardiac repair is the preoperative administration of:
a. Fluids to optimize perioperative hemodynamics
b. Furosemide to induce diuresis
c. Mannitol to scavenge free radicals
d. N-acetylcysteine to provide an antioxidant
e. Renal-dose dopamine to induce renal vasodilation

8. You are consulting on a 5-year-old girl who was admitted to the ICU 2 days ago for the management of sepsis. Laboratory testing today shows a bicarbonate level of 14 mmol/L, BUN 50 mg/dL, and serum creatinine 2.0 mg/dL. The ICU team is contemplating bicarbonate therapy for the metabolic acidosis. Of the following, the most likely consequence of bicarbonate therapy in this situation is:
a. Hyperchloremia
b. Hyperkalemia
c. Hyperphosphatemia
d. Hypocalcemia
e. Hyponatremia

9. You are seeing a 6-yearold boy who was admitted to the critical care unit 3 days ago with septic shock. He has required multiple boluses of crystalloids and colloids for hypotension and multiple blood products for disseminated intravascular coagulation. His urine output has been decreasing for the past 24 h, and he has been anuric for the past 12 h. He has developed generalized edema, and his weight is now 26 kg (up from an admission weight of 20 kg). He has received two doses of intravenous furosemide (3 mg/kg) during the past 12 h, with no diuretic response. Of the following, the most appropriate next step in his management is:
a. Continue furosemide every 6 h.
b. Initiate mannitol diuresis.
c. Start fenoldopam.
d. Initiate a trial of IV normal saline bolus.
e. Prepare for renal replacement therapy.

10. You are seeing a 5-year-old boy who initially presented to the emergency department about 24 h ago with a 3-day history of fever, vomiting, poor oral intake, and 1 day of no urine output. Initial assessment in the emergency department found tachycardia, hypotension, lethargy, and diffuse abdominal tenderness. He was given fluid resuscitation, started on intravenous vancomycin (10 mg/kg/dose every 6 h) and gentamicin (2.5 mg/kg/dose every 8 h), and admitted for close observation. He continues to have anuria. The serum creatinine concentration today is 1.6 mg/dL (increased from 0.8 mg/dL at

initial presentation). Of the following, the *most* appropriate next step in the management of this patient's intravenous antibiotic regimen is:

a. Adjust the antibiotics for a glomerular filtration rate (GFR) of 75 mL/min.
b. Adjust the antibiotics for a GFR of 50 mL/min.
c. Adjust the antibiotics for a GFR of 10 mL/min.
d. Continue the current regimen of antibiotics.
e. Stop all antibiotics.

Chronic kidney disease

KIRTIDA MISTRY

Chronic kidney disease (CKD), which includes end-stage renal disease (ESRD), is a major public health concern in the United States and worldwide. Once ESRD develops, lifesaving renal replacement therapy (RRT), either dialysis or renal transplant, is required to ameliorate the complications of advanced kidney failure. Despite advances in the delivery of RRT, outcomes in adults and children remain disappointing, with significant morbidity and mortality and decreased quality of life.

In the United States, the prevalent ESRD population in all age groups increased over 10-fold from 60,000 in 1980 to 615,899 in 2011, and medical management costs totaled $49.3 billion in 2011.[1] The last three decades have seen a steady increase in the incidence of pediatric ESRD in the United States. Since 2000, the adjusted incident rate of ESRD for patients 0 to 19 years of age has increased 10.1%.[1] This chapter will provide a general overview of pediatric CKD, including epidemiology, causes, classification, pathophysiology, clinical manifestations, and management, including strategies to slow progression.

DEFINITION AND CLASSIFICATION IN CHILDREN

CKD refers to irreversible anatomic or functional kidney damage. The National Kidney Foundation Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines defined and classified CKD in 2002 (Table 31.1).[2] There are two pediatric exceptions: (1) the criteria for duration longer than 3 months does not apply to infants younger than 3 months, and (2) the glomerular filtration rate (GFR) criteria of less than 60 mL/min/1.73 m^2 cannot be used in children under 2 years of age since developmental immaturity in this age group is associated with mean GFR of less than this value. Thus, the diagnostic criteria for reduced GFR in this particular population must be compared to age-matched normative values (Table 31.2).[2,3] The KDOQI classification has been modified and adopted by the Kidney Disease Improving Global Outcomes (KDIGO) work group in 2004 and revised in 2012 (Table 31.3).[3,4]

Table 31.1 Kidney Disease Outcomes Quality Initiative (KDOQI) criteria for the definition of chronic kidney disease

1. Kidney damage for 3 months or longer, as defined by structural or functional abnormalities of the kidney, with or without decreased glomerular filtration rate, manifest by either:
   a. Pathologic abnormalities
   b. Markers of kidney damage, including abnormalities in the composition of the blood or urine, or abnormalities in imaging tests
2. Glomerular filtration rate less than 60 mL/min/1.73 m² for 3 months or longer, with or without kidney damage

Source: KDOQI clinical practice guidelines for chronic kidney disease: evaluation, classification, and stratification. Am J Kidney Dis. 2002;39:S1–266.

GFR in children may be estimated (eGFR), using serum creatinine and length (Table 31.4) by numerous mathematical formulas.[5–7] The original Schwartz and Counahan-Barratt formulas were derived using the Jaffe method of serum creatinine measurement,

Table 31.2 Normative glomerular filtration rate values using inulin clearance in healthy children younger than 2 years

Age	Mean GFR ± SD (mL/min/1.73 m²)
Preterm babies	
1–3 days	14.0 ± 5
1–7 days	18.7 ± 5.5
4–8 days	44.3 ± 9.3
3–13 days	47.8 ± 10.7
8–14 days	35.4 ± 13.4
1.5–4 mo	67.4 ± 16.6
Term Babies	
1–3 days	20.8 ± 5.0
3–4 days	39.0 ± 15.1
4–14 days	36.8 ± 7.2
6–14 days	54.6 ± 7.6
15–19 days	46.9 ± 12.5
1–3 mo	85.3 ± 35.1
Infants	
4–6 mo	87.4 ± 22.3
7–12 mo	96.2 ± 12.2
1–2 yr	105.2 ± 17.3

Table 31.3 Chronic kidney disease stages according to glomerular filtration rate

KDOQI		KDIGO	
Stage	GFR in mL/min/1.73 m²	Category	GFR in mL/min/1.73 m²
1	≥90	G1	≥90
2	60–89	G2	60–89
3	30–59	G3a	45–59
4	15–29	G3b	30–44
5	<15 or dialysis	G4	15–29
		G5	<15

Abbreviations: GFR, glomerular filtration rate; KDOQI, Kidney Disease Outcomes Quality Initiative; KDIGO, Kidney Disease Improving Global Outcomes.

KEY POINTS

- CKD is characterized by irreversible anatomic or functional kidney damage, even though GFR may be normal.
- Because GFR is normally low in the first 2 years of life, comparison to age-matched norms of GFR should be considered in defining CKD in such patients.

in which serum creatinine is determined by a colorimetric reaction with alkaline picrate. The modified Schwartz formula is based on the enzymatic method for measuring serum creatinine, a methodology adopted by most laboratories. The modified Schwartz equation is the currently preferred method for calculating eGFR in children, but should be used only if serum creatinine is measured by the enzymatic method. An equation using serum creatinine, blood urea nitrogen (BUN), cystatin C, and height has been proposed to enhance accuracy in of eGFR (see Table 31.4).

The serum creatinine values are lower by 0.3 to 0.4 mg/dL when measured by the enzymatic method compared to the Jaffe reaction. Hence, the estimated GFR is higher if the enzymatic method is used.[8] In patients

KEY POINTS

- Original Schwartz GFR estimation formula is used when serum creatinine is measured by Jaffe method.
- Modified Schwartz formula is applicable only if serum creatinine is measured by enzymatic method.
- MDRD equation should be used only in individuals 18 years of age and older.

Table 31.4 Estimation of the glomerular filtration rate

Equation for eGFR in mL/min/1.73 m²	Method of serum creatinine measurement
Original Schwartz	Jaffe reaction

$$\frac{k \times \text{length in cm}}{\text{Serum creatinine in mg/dL}}$$

Age	Value of k
Preterm infants	0.33
Full term infants	0.45
Children ≤ 13 years and adolescent girls	0.55
Adolescent boys up to age 18 years	0.7

Counahan-Barratt	Jaffe reaction

$$\frac{0.43 \times \text{length in cm}}{\text{Serum creatinine in mg/dL}}$$

Modified Schwartz	Enzymatic

$$\frac{0.413 \times \text{length in cm}}{\text{Serum creatinine in mg/dL}}$$

Schwartz using creatinine and cystatin C	Enzymatic

$39.1 \times (\text{Height/serum creatinine in mg/dL})^{0.516} \times (1.8/\text{cystatin C})^{0.294} \times (30/\text{BUN})^{0.169} \times (1.099) \text{ if male} \times (\text{Height}/1.4)^{0.188}$

Modification of Diet in Renal Disease	Enzymatic

$175 \times (\text{Serum creatinine in mg/dL})^{-1.154} \times (\text{Age})^{-0.203} \times (0.742 \text{ if female}) \times (1.212 \text{ if African American})$

Abbreviation: eGFR, estimated glomerular filtration rate.

18 years and older, the most frequently used equation for estimating GFR is the Modification of Diet in Renal Disease (MDRD) study equation (see Table 31.3).[9] This equation is not applicable in children, but has been validated in white and African-American populations between the ages of 18 and 70 years with GFR less than 60 mL/min/1.73 m².[9]

EPIDEMIOLOGY

The National Health and Nutrition Examination Survey (NHANES) data demonstrated that 10.8% of the population, or approximately 19.2 million people, in the United States have CKD.[10] It is important to note that clinical CKD, especially ESRD or stage 5 CKD, represents the tip of the iceberg of the CKD spectrum in the community (Figure 31.1). Most pediatric epidemiologic studies have focused on patients with more advanced CKD or ESRD, excluding patients with milder forms of CKD, who may advance to ESRD in adulthood. Consequently, there is limited information about the epidemiology of the early stages of CKD in the pediatric population.

The most complete published pediatric epidemiologic data come from the ItalKid Project, a prospective, population-based Italian registry of children and young adults younger than 20 years old with an eGFR less than

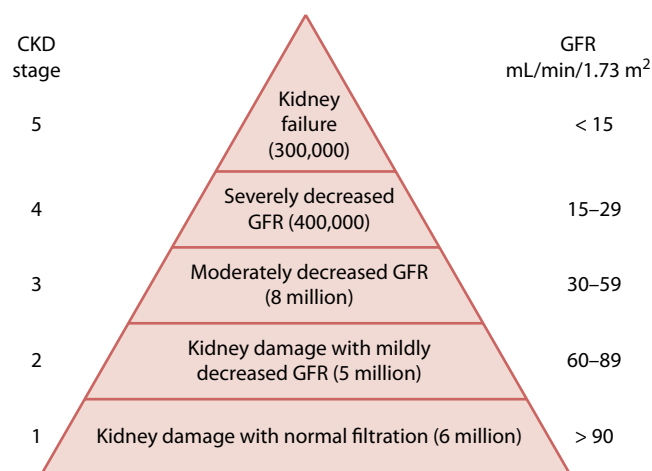
75 mL/min/1.73 m².[11] The mean incidence of CKD in this study was 12.1 cases and point prevalence 74.7 per million. The male-to-female ratio in the study was 2.03, a finding also seen in other registries, including the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS).[12] In the ItalKid study, 57.6% of all cases were


Figure 31.1 National Kidney Foundation and Kidney Disease Outcomes Quality Initiatives stages of chronic kidney disease (CKD). GFR, glomerular filtration rate. (Prevalence data in the triangle from: Coresh J, Selvin E, Stevens LA, et al. Prevalence of chronic kidney disease in the United States. JAMA. 2007;298:2038–47.)

due to hypoplasia and dysplasia, with or without urologic malformations.[11] This contrasts with adults, in whom type 2 diabetes and hypertension account for the majority of patients with CKD.[1]

Not surprisingly, studies evaluating more severe stages of CKD reveal lower incidences and prevalence. In Sweden, the incidence and prevalence rate of KDOQI stage 4 and 5 (KDIGO category G4 and G5) CKD in children 6 months to 16 years was estimated to be 7.7 and 21 per million, respectively.[13] Similarly, the annual incidence of CKD in Lorraine, France was reported to be 7.5 per million children under 16 years of age.[14] In Japan, a national study revealed prevalence of CKD stages 3 to 5 to be only 2.98 In 100,000 children.[15]

In the United States, epidemiologic data outlining the incidence of the early stages of CKD are lacking. In the United States Renal Data System (USRDS), the incidence rate of ESRD between 2007 and 2011 in children up to 19 years, was 15.2 per million population.[1] The incidence increases with age in children, and children under 4 years have the lowest incidence of ESRD.[12]

Worldwide comparative data published by the USRDS in 2005 revealed the highest unadjusted incidence of pediatric ESRD to be in the United States (Figure 31.2).[16] The prevalence in this analysis (Figure 31.3) is highest in Italy, although a wider age range of 0 to 24 years is reported in the Italian data.

There are striking racial and ethnic variations in the incidence and prevalence of ESRD in the United States, with the highest rates reported in African Americans and the lowest in whites.[1] Outcomes also vary by race. In the NAPRTCS 2008 Annual Report, whites with CKD are more likely to receive a transplant and African Americans are more likely to initiate dialysis.[17]

ETIOLOGY

In the vast majority of children with CKD, it is secondary to congenital anomalies of the kidney and urinary tract (CAKUT). This contrasts with disease in adults, who most commonly have CKD secondary to glomerular disease, most commonly diabetic nephropathy, followed by hypertensive glomerulosclerosis and other chronic glomerulonephritides.

CAKUT and congenital nephropathies account for roughly two-thirds of cases of pediatric CKD in the more economically developed countries, whereas acquired causes prevail in less developed countries.[18] Table 31.5 shows the causes of CKD in children in the United States, as reported in the NAPRTCS database. CAKUT progresses more slowly to ESRD than
Figure 31.2 Global incidence of end-stage renal disease in 2003, ages 0 to 19 years. For Italy, the age group is 0 to 24 years. Bethesda, MD: National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases; 2005.

glomerulonephritis; therefore, registries determining the causes of CKD primarily using data from ESRD patients, like USRDS, report lower incidence of CAKUT. The causes of CKD from various global registries and studies are compiled in Table 31.6.[1,11,17,19–22]

KEY POINTS

- CAKUT is the most common cause of CKD in children, worldwide.
- Racial differences are seen in the prevalence of CKD in children.
- FSGS is the most common acquired cause of CKD in African-American children.

Although CAKUT predominates as the cause of CKD in children in the NAPRTCS registry, a racial difference in the cause of CKD and ESRD is evident.[17] Whereas patients with focal segmental glomerulosclerosis (FSGS) comprise 14.4% of all dialysis patients, patients with FSGS account for 23.7%
Figure 31.3 Global prevalence of end-stage renal disease in 2003, ages 0 to 19 years. For Italy, the age group is 0 to 24 years. of African-American dialysis patients and 30% of African-American dialysis patients 13 years of age or older. The next most prevalent diagnoses among African-American children younger than 13 years of age are obstructive uropathy and renal dysplasia (both 11.5%) and in patients 13 years of age and older the diagnosis is lupus nephritis (10.1%).[17] FSGS accounts for 11.7% of all white dialysis patients. Renal dysplasia (15.7%) remains most common for white children, and obstructive uropathy (13.8%) is also most prevalent among whites 13 years of age and older.[23]

PROGRESSION

Most patients with CKD progress to ESRD slowly over a period of many years, sometimes over decades. Disease-independent pathways play a decisive role in the progression of renal injury in established CKD. Several mechanisms are postulated to play a role in the progressive loss of kidney function and include perturbations in filtration or hemodynamics, hypertension, proteinuria, podocyte injury, proinflammatory cytokines, and profibrotic growth factors (Figure 31.4).

Table 31.5 2008 North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) showing details of cause of chronic kidney disease in 7037 participants in the U.S. Voluntary Registry

KEY POINT

Progression of CKD to ESRD is multifactorial.

HYPERFILTRATION

Reduced nephron mass (number), whether congenital or acquired, is associated with hyperfiltration in the surviving nephrons. Elegant experiments conducted by Brenner and colleagues established that nephron loss leads to compensatory hypertrophy, intraglomerular hypertension, increased

single-nephron GFR (hyperfiltration), and eventual glomerular injury and glomerulosclerosis in the remnant nephron population.[24–29] These adaptive changes, although an attempt to maintain GFR in the face of nephron loss, result in ongoing glomerular injury and eventual glomerulosclerosis in the surviving nephrons, perpetuating nephron loss. The mechanisms by which hyperfiltration leads to glomerulosclerosis are not entirely clear, but possibilities include glomerular vasodilatation, glomerular hypertension, and stretch-induced cellular injury.[29–31] It is likely that many of these pathogenic mechanisms are interrelated.

The subject of glomerular hyperfiltration and glomerular injury has been studied well in renal disease associated with diabetes mellitus.[32–34] Hyperfiltration in these patients precedes any overt manifestation of renal disease, including microalbuminuria. Amelioration of hyperfiltration by angiotensin-converting enzyme inhibitors (ACEIs) and preventing progression of renal disease in diabetes mellitus have been substantiated in several clinical studies.[35,36] Indeed, ACEIs are now recommended for prevention of hyperfiltration-induced glomerular injury and microalbuminuria in diabetes mellitus. KDOQI, however, does not recommend starting ACEIs in normotensive patients with diabetes with normal urinary microalbulinuria.[37]

Other children at risk for hyperfiltration injury and increased likelihood for CKD are those born with decreased nephron mass as a result of low birth weight, presence of a solitary kidney, those who have undergone therapeutic uninephrectomy, and those with sickle cell disease.[38–41] The clinical implications of hyperfiltration in the congenital and acquired disorders in children are beginning to be understood. The impact of solitary kidney on development of renal injury was studied in the KIMONO study in the Netherlands.[42] Of the 407 children with a solitary kidney,

37% met the criteria for evidence of renal injury, such as presence of hypertension, proteinuria, an impaired GFR, or the need to use renoprotective agents. CKD developed in 6% of these children during follow-up (mean of 9 years). Sanna-Cherchi[43] et al. also cautioned about a poor renal outcome of patients with solitary kidney in the spectrum of CAKUT. In contrast, Wikstad et al.[44] did not report any patients with CKD among 36 patients with single kidney (congenital and uninephrectomy) who were followed for 7 to 40 years. These investigators, however, demonstrated hyperfiltration in all of their patients, and microalbuminuria was present in 47%. Use of ACEIs in patients with a solitary kidney to reduce glomerular hypertension and ameliorate injury in CAKUT, although intuitive, has not been examined in well-controlled clinical studies. At least one study from Italy reports no clear benefit of ACEI in children with CAKUT.[45]

Definition of hyperfiltration in published studies is variable and not clearly delineated in either adults or children.[46] In children, there is an added requirement to consider age-related and gender-related normal values for accurate representation of hyperfiltration. GFR above two standard deviations (SDs) from the mean for age is a suggested definition of hyperfiltration.[47] Lacking any clinical markers of hyperfiltration, microalbuminuria is used as a surrogate of hyperfiltration-induced renal injury, especially in diabetic patients. It is important to recognize that hyperfiltration is an important physiologic response to metabolic challenges, such as following a protein meal and during pregnancy.[48,49]

SYSTEMIC HYPERTENSION

Systemic hypertension is a well-known hemodynamic risk-factor for progression of CKD.[50,51] Conversely, CKD is also a recognizable risk factor for all-cause cardiovascular mortality.[52] In an observational study of 23 patients with CKD secondary to chronic glomerulonephritis, a significant correlation was demonstrated between blood pressure and the rate of decline of renal function.[53] The impact of blood pressure control on progression of CKD was studied in the MDRD study in adults. Improved blood pressure control in this study was shown to lower rate of decline of GFR in patients who had nondiabetic renal disease with proteinuria exceeding 1 g/day.[54] In the NAPRTCS study of 3834 patients aged 2 to 17 years, hypertension was determined to be an independent predictor of progression of CKD to ESRD.[55]

The degree to which systemic blood pressure needs to be lowered to achieve a positive impact on progression of CKD has been a matter of debate. Intensive blood pressure control, using drugs to inhibit the renin-angiotensin-aldosterone system (RAAS) in patients with CKD and significant proteinuria (>1 g/day) was studied by Bianchi et al.[56] These investigators demonstrated that the rate of decline of eGFR was lower in patients on an intensive blood pressure control regimen. However, the study also pointed out that such a therapy did not reverse the progression of CKD and the side effects associated with such intensive therapy were likely to be severe and unacceptable. The Effect of Strict Blood Pressure

Control and ACE Inhibition on the Progression of CRF in Pediatric Patients (ESCAPE) trial in children recommended that for a protective effect on progression of CKD, 24-hour mean blood pressure targets need to be set below the 50th percentile for age and gender.[57] Sarafidis et al.[58] reviewed this subject and suggested that the degree of blood pressure decline should be tailored in patients with CKD to the cause of the CKD, and whether significant proteinuria is present.

The pathophysiologic mechanisms by which systemic hypertension induces progressive renal damage are complex and include presence of preglomerular vasodilatation and efferent arteriolar constriction induced by RAAS, allowing transmission of elevated systemic blood pressure to the glomeruli, intraglomerular hypertension, and intraglomerular endothelial injury.[59,60]

RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM

The RAAS is an important regulator of blood pressure, extracellular volume, and tissue perfusion. Renal diseases are often characterized by an increased renin production (hyper-reninemia) and have an activated RAAS. Renin produced in the juxtaglomerular apparatus of the kidney converts angiotensinogen to angiotensin I (ATI), which transforms to angiotensin II (ATII) by the action of ACE in the pulmonary vascular bed. ATII, a potent vasoconstrictor, mediates its action by binding to angiotensin type 1 and 2 receptors in the heart, blood vessels, and kidneys. ATII action, mediated via the type 1 receptor on the cardiovascular system, results in vasoconstriction and cardiac hypertrophy.[61] Another aspect of ACE is that it also hydrolyzes and inactivates bradykinin, a vasodilator.[62,63] It is postulated that the vasodilatory effect of ACEIs on the kidney (efferent arteriole) is mediated via bradykinin, apart from inhibiting RAAS.[64]

The RAAS promotes progression of CKD by hemodynamic and nonhemodynamic mechanisms. ATII, acting on the glomerular capillaries leads to predominant efferent arteriolar vasoconstriction, increasing intraglomerular hydrostatic pressure, promoting intraglomerular hypertension, and increasing single-nephron GFR (hyperfiltration). Evidence from experimental studies in animals indicates that the abnormally high transcapillary hydrostatic pressure results in impairment in the size selectivity of the glomerular filtration barrier, leading to proteinuria.[65]

ATII also acts as a nonhemodynamic promoter of glomerular injury. ATII is a growth-promoting factor that regulates cell proliferation, apoptosis, and fibrosis.[66,67] It also enhances production of proinflammatory cytokine response, such as tumor necrosis factor alpha (TNF-α), interleukin-1 (IL-1), interleukin-6 (IL-6), and chemokines (e.g., monocyte chemoattractant protein-1 [MCP-1]), all of which promote inflammation and are likely to worsen glomerular injury.[66] ATII enhances production of cell adhesion molecules, reactive oxygen species, and profibrotic growth factors, all of which induce and perpetuate glomerular injury.[61] Other glomerulosclerosis-promoting actions of AT II consist of inducing hyperplasia and hypertrophy in the vascular smooth muscle cells and glomerular mesangial cells.[68]

Finally, ATII stimulates aldosterone production in the adrenal cortex. In turn, aldosterone mediates distal nephron sodium and water retention and potassium excretion. Adverse effects of aldosterone on the kidney and in the pathogenesis of fibrosis are summarized in the report by Remuzzi et al.[69] Aldosterone promotes endothelial remodeling, making these cells larger and stiffer, contributing to protein leak through intercellular gaps, and the endothelial dysfunction observed in hyperaldosteronism.[70] Other mechanisms whereby aldosterone can induce kidney injury includes induction of reactive O_2 species; increased expression of proinflammatory cytokines and growth factors such as osteopontin, MCP-1, IL-6, and IL-1; and inhibition of extracellular matrix degradation.[71–73]

The protective impact of blocking RAAS on progression of CKD has been well documented in clinical studies.[74] Some early studies have demonstrated regression of glomerulosclerosis by inhibition of aldosterone pathways, opening the door for potentially new therapeutic approaches in the prevention and progression of CKD.[75,76]

PODOCYTE AND GLOMERULAR CELL INJURY

Injury to various cell lines within the glomeruli is relevant to progression of CKD. The terminally differentiated glomerular visceral epithelial cells or podocytes are capable of hypertrophy but not hyperplasia. Thus, when these cells are injured or lost, they cannot be replaced by new cells. Podocytes are pivotal in maintaining the permselectivity of the filtration barrier and are the source of vascular

---

KEY POINTS

- ATII mediates progression of CKD via hemodynamic and nonhemodynamic mechanisms.
- Use of ACEIs in preventing progression of CKD has been well studied in diabetic nephropathy, and this therapy is used in most other forms of CKD, as well.
- Controlled trials of ACEIs in preventing progression of CKD in CAKUT are scant.

KEY POINTS

- Podocytes are a biologically active and essential part of filtration barrier.
- Podocyte loss or injury leads to progressive glomerulosclerosis.

endothelial growth factor (VEGF) and angiopoeitin, which maintain capillary endothelial growth and permeability.[77,78] Podocyte injury or loss leads to progressive glomerulosclerosis in many glomerular diseases, including idiopathic and inherited forms of FSGS.[79,80]

Endothelial injury also generates growth factors that lead to cell proliferation; metabolic derangements, especially lipid accumulation; and increased extracellular matrix deposition.[81] Mesangial cells, when injured and under the influence of ATII and cytokines, hypertrophy, with increased extracellular matrix production, a major source of scar tissue in glomerulosclerosis.[82]

GROWTH FACTORS AND CYTOKINES

Many cytokines and growth factors are proinflammatory and profibrotic and play a role in progression of CKD. ATII increases the expression of transforming growth factor-1, TNF, osteopontin, vascular cell adhesion molecule-1, nuclear factor-B, platelet-derived growth factor, basic fibroblast growth factor, plasminogen activator inhibitor-1, and insulin-like growth factor (IGF).[61,69]

PROTEINURIA AND HYPERLIPIDEMIA

Proteinuria is a manifestation of many renal diseases, and it also can mediate ongoing inflammation and fibrosis in the kidney. Significance of proteinuria as a prognostic indicator in progression of CKD has been demonstrated in numerous clinical studies.[54,83] Inflammatory response induced by proteinuria promotes ongoing tubulointerstitial and renal injury and fibrosis by (1) direct tubular toxicity of protein, (2) via complement activation in the tubular lumens.[84–87] Reducing proteinuria in CKD is accompanied by an improvement in the rate of decline of GFR.[88]

Lipid metabolism is altered in CKD and contributes to atherosclerosis and glomerulosclerosis. Small, dense low-density lipoprotein (LDL) particles are increased in concentration and cause antioxidant renal and vascular damage.[89] The role of dyslipidemia in progression is not fully established. Although the MDRD study was not able to establish dyslipidemia as an independent risk factor for progression of CKD, other clinical and experimental evidence has linked dyslipidemia to progression of CKD.[90–94] Moreover, dyslipidemia of CKD is a risk factor for cardiovascular disease and has been linked to abnormalities in the carotid intima media in children with CKD.[95,96] Statins, although advocated for use in adults with dyslipidemia of CKD, are not recommended in children younger than 18 years of age.[97]

CLINICAL MANIFESTATIONS

Clinical manifestations of CKD in children depend on the cause. Children with glomerular disease may have gross hematuria and/or edema. Many congenital abnormalities are detected prenatally by ultrasound. Approximately 0.5% of pregnancies are found to have a fetal abnormality of the kidney or urinary tract.[98] These anomalies may be causative of CKD and ESRD in infants and children. Other children with CKD may present with more subtle symptoms such as polydipsia, polyuria, nocturia, and enuresis secondary to the urine concentrating defect associated with CKD, especially in diseases such as renal dysplasia or nephronophthisis. Other children with CKD may manifest poor linear growth, abnormal urinalysis, or the presence of hypertension.

In some cases, children present for the first time because of symptoms of uremia resulting from advanced CKD and ESRD (Table 31.7). Normocytic, normochromic anemia is sometimes the first manifestation of CKD in children, which may have been discovered during hematology consultation for evaluation of anemia. Others may be evaluated in endocrinology for growth retardation before being discovered to have CKD. Although it occurs less frequently now, some patients with CKD may be discovered because of renal osteodystrophy and associated skeletal deformities.

Table 31.7 Clinical manifestations of uremia

System	Clinical manifestation
Metabolic	Electrolyte abnormalities: Hyperkalemia, metabolic acidosis, hyponatremia
	Hypocalcemia
	Hyperphosphatemia
	Hyperuricemia
Musculoskeletal	Bone pain
	Renal osteodystrophy
	Muscle cramps and/or weakness
Hematologic	Iron deficiency
	Anemia
	Platelet dysfunction
Neurologic	Cognitive impairment
	Headache
	Seizures
	Encephalopathy

	Pericarditis
	Pulmonary edema
Gastrointestinal	Anorexia
	Weight loss
	Nausea, emesis
Endocrine	Poor growth
	Amenorrhea
	Dyslipidemia
	Insulin resistance
	Delayed puberty
Integumentary	Pruritus
	Hyperpigmentation or hypopigmentation
Other	Fatigue, edema, insomnia, pica

Screening to identify children at risk for developing CKD may improve the rate of early detection and provide opportunities for early intervention (Table 31.8). American Academy of Pediatrics guidelines recommend monitoring growth from birth and blood pressure during annual visits with primary care physicians, beginning at age 3 years. Blood pressure should be monitored from the newborn period if there are risk factors, as delineated in the Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents.[99]

The most common complications of CKD and associated prevalence rates are: hypertension 60% to 70%, anemia 37% to 38%, metabolic bone disease 17%, growth failure 12% to 16%, and fluid and electrolyte disturbances 12%.[100,101] The prevalence of all complications increase with advancing CKD.[101]

HYPERTENSION AND CARDIOVASCULAR DISEASE

Children on dialysis have the same risk factors for development of cardiovascular disease as adults. These include hypertension, dyslipidemia, physical inactivity, hyperhomocysteinemia, hyperparathyroidism, inflammation, and left ventricular hypertrophy (LVH).[102] Hypertension is most commonly the result of fluid overload or activation of the RAAS. It also may be, at times, attributed to medications used to treat glomerular diseases, such as corticosteroids and calcineurin inhibitors.

Table 31.8 Risk factors for the development of chronic kidney disease in children

Preterm birth
Small for gestational age
Family history of genetic kidney disease
History of acute kidney injury
Congenital anomalies of the kidneys and urinary tract (CAKUT)
Vesicoureteral reflux, especially high-grade and associated with recurrent urinary tract infection and scarring
History of acute nephritis
History of nephrotic syndrome
History of hemolytic-uremic syndrome
History of Henoch-Schönlein purpura
Hypertension
Diabetes
Obesity
Systemic and autoimmune conditions that affect the kidneys (e.g., systemic lupus erythematosus)
Sickle cell trait or sickle cell disease
Spina bifida and neurogenic bladder

KEY POINT

Cardiovascular disease is the leading cause of death and morbidity in children with ESRD.

Children with CKD and ESRD have increased mortality rate and adjusted all-cause mortality is 6.5 to 7.9 times greater than in the general population.[1] Cardiovascular disease is the leading cause of death in adults and children with ESRD.[23,103,104] In fact, cardiovascular mortality surpasses that from infection in children with ESRD.[1] In a study of children and young adults 0 to 30 years of age in the USRDS database, cardiac deaths were approximately 1000 times more frequent in those who developed ESRD during childhood than in the general pediatric population.[105] The most common cardiovascular events in children on dialysis are arrhythmias (19.6%), valvular heart disease (11.7%), cardiomyopathy (9.6%), and cardiac arrest (3%).[106]

LVH, left ventricular dilation, and systolic and diastolic dysfunction are known complications in pediatric chronic dialysis patients.[107] The prevalence of LVH in pediatric dialysis patients is high and may be more prevalent in hemodialysis versus peritoneal dialysis patients.[107] LVH usually results from hypertension, but other factors such as anemia, fluid overload, hyperparathyroidism, and uremia also contribute.[108,109]

Data about the prevalence and consequences of atherosclerosis in children with CKD is emerging. Carotid intimal-medial thickness abnormalities, coronary artery calcification, and decreased arterial wall compliance are indicators of atherosclerosis and predict cardiovascular disease. Whereas the incidence of coronary artery calcifications may be low in pediatric patients, young adults who present with ESRD in childhood have evidence of calcification.[110] Risk factors for vascular calcifications include duration of dialysis, severity and duration of hyperphosphatemia, high calcium intake, and severity of hyperparathyroidism.[110,111]

ANEMIA

Parameters for the diagnosis of anemia are gender-dependent and age-dependent. The KDOQI guidelines define anemia as a hemoglobin concentration less than the 5th percentile for children older than 1 year and more than 2 SD below the mean for infants (Table 31.9).[112] Anemia adversely affects patient quality of life, and studies show an improvement following its correction.[113–115]

As kidney function declines, anemia worsens.[116] In the Chronic Kidney Disease in Children (CKiD) study, patients with a GFR less than 30 mL/min/1.73 m^2 had a fourfold to fivefold higher risk for anemia compared to those with a GFR of 50 mL/min/1.73 m^2 or greater.[100] In adults with

Table 31.9 Hemoglobin values in different age groups for diagnosis of anemia

Age	Hemoglobin (g/dL) level 2 standard deviations below the mean
1–3 days	14.5
1 wk	13.5
2 wk	12.5
1 mo	10
2 mo	9
3–6 mo	9.5
6–12 mo	10.5

Age (years)	5th percentile hemoglobin (g/dL)	
	Male	Female
1–2	10.7	10.8
3–5	11.2	11.1
6–8	11.5	11.5
9–11	12	11.9
12–14	12.4	11.7
15–19	13.5	11.5

Source: Kidney Disease Outcomes Quality Initiative. Clinical practice guidelines and clinical practice recommendations for anemia in chronic kidney disease. Am J Kidney Dis. 2006;47:S11–145.

CKD, hemoglobin begins to decline when eGFR is below 60 mL/min/1.73 m^2.[117] In the CKiD study, there was a linear decrease in hemoglobin below a threshold iohexol measured GFR of 43 mL/min/1.73 m^2, independent of age, race, gender, and underlying diagnosis.[116]

The pathophysiology of anemia in CKD is primarily due to erythropoietin deficiency, although iron and vitamin deficiencies, reduced red blood cell life span, bone marrow suppression secondary to retained inhibitors in uremia, blood loss, and chronic inflammation play a role. Erythropoietin is produced by interstitial peritubular fibroblasts in the renal cortex in response to hypoxia.[118]

Patients with CKD are at increased risk for iron deficiency secondary to chronic blood loss because of platelet dysfunction and hemodialysis. However, they also have altered iron homeostasis. Dietary iron is absorbed in the duodenum and recycled from senescent red blood cells. Circulating transferrin transports iron to maturing red blood cells for incorporation into hemoglobin. Most of the body's iron is bound to hemoglobin. A smaller proportion is stored in hepatocytes and macrophages in the reticuloendothelial system.

Transferrin deficiency of unclear cause leads to reduced iron transport in CKD. This contributes to increased accumulation of stored iron as ferritin, leading to functional iron deficiency. Additionally, there is an inherent inability to mobilize stored iron from macrophages and hepatocytes. This may be partially mediated by hepcidin, a small peptide secreted by the liver that inhibits intestinal iron absorption

and iron release from the reticuloendothelial system.[119] Hepcidin is inhibited by iron deficiency and upregulated in inflammation and CKD.[120] Reduced renal clearance of hepcidin may also lead to higher levels in CKD. Hepcidin levels correlate with ferritin levels and markers of inflammation and increase with deteriorating renal function, being highest in dialysis patients.[121,122]

CHRONIC KIDNEY DISEASE AND MINERAL AND BONE DISORDER

The mineral and endocrine functions of the kidney are critically important in the regulation of bone formation and remodeling during growth. Aberrations or disruption of these functions begin during early stage 3 CKD and progress as severity of renal failure advances. Bone abnormalities are almost universal in dialysis patients.

Normal kidney function maintains mineral homeostasis. In healthy children, calcium balance is positive to sustain growth and bone mineral accumulation. The process of optimizing peak bone mass by young adulthood is critical to maintaining life-long bone health and protecting against osteoporosis in adulthood.[123,124] Thus, bone disease resulting from CKD in childhood has long-term consequences.

Along with its effect on the skeletal system, disordered mineral and bone metabolism in children with CKD also affects the cardiovascular system. Therefore, the KDIGO guidelines recommend using the term *CKD-MBD* for describing the full spectrum of this disorder. *Renal osteodystrophy* is the term used to described the impact on the skeletal system.[125] Although biochemical abnormalities of mild hyperparathyroidism and 1,25-dihydroxyvitamin D (1,25-D) deficiency may occur before stage 3 CKD, most children are asymptomatic.[126] With advancing CKD, renal osteodystrophy also progresses with manifestations of skeletal deformities, fractures, muscle and bone pain, avascular necrosis, and growth failure.

As CKD progresses, normal serum and tissue concentrations of phosphorus and calcium are disrupted and perturbations occur in the regulation of parathyroid hormone (PTH), 25-hydroxyvitamin D (25-D), 1,25-D, fibroblast growth factor-23 (FGF-23), and growth hormone. In children, monitoring of serum levels of calcium, phosphorus, PTH, and alkaline phosphatase should begin at CKD stage 2.[127]

Hyperphosphatemia usually begins in stage 3 CKD as a result of reduced glomerular clearance of phosphate. This leads to a lower ionized calcium and secondary hyperparathyroidism. The kidney fails to respond adequately to PTH, which normally promotes phosphaturia and calcium reabsorption. Hyperphosphatemia also inhibits the 1α-hydroxylase enzyme in proximal tubular cells, decreasing 1,25-D levels, which in turn, worsens hypocalcemia secondary to reduced gastrointestinal absorption.

FGF-23 is a hormone secreted by osteocytes, and its primary target of action is the kidney. It promotes phosphaturia and decreases production of calcitriol.[128] Stimuli for FGF-23 secretion include increased dietary phosphorus intake and increased 1,25-D levels.[129] Compared to serum PTH and phosphorus, FGF-23 level rises more dramatically and earlier in CKD, presumably as a physiologic adaptation to maintain normal serum phosphate levels.[130] Studies in adults have shown that increased FGF-23 is more strongly associated with mortality than elevated phosphorus.[131,132] It has been shown to be associated with LVH, endothelial dysfunction, and progression of CKD.[133] Other CKD-MBD abnormalities include vitamin D receptor downregulation and skeletal resistance to the calcemic effect of PTH.[134]

KEY POINTS

- FGF 23 regulates phosphorus and vitamin D metabolism.
- FGF-23 level rises earlier than that of phosphorus in CKD and tracks more closely with mortality than hyperphosphatemia.
- FGF-23 is associated with findings of LVH.

GROWTH FAILURE

Impaired growth is a complication of CKD, and it increases with progression of CKD. Along with short stature, poor growth is associated with increased morbidity and mortality in children with CKD.[135,136] The risk for death increases by 14% for each 1 SD score (SDS) decrease in height.[135] Short children with CKD have higher rates of hospitalization and poorer school attendance.

Quality of life is also adversely affected by short stature. Adults with childhood onset of ESRD are significantly more likely to have a positive perception of quality of life if they are satisfied with their adult height.[137] In the CKiD population, parents reported an increase in physical and social functioning in children who exhibited catch-up growth as measured by increase in height SDS.[138]

KEY POINTS

- Poor growth is associated with increased morbidity and mortality in children with CKD.
- Malnutrition is one of the most important contributors to growth impairment in children with CKD.
- Growth hormone level is normal in CKD.
- IGF-1 levels are low to normal.
- Target resistance to IGF-1 is common.

Regular assessment of nutrition and growth is recommended for children with stage 2 or higher CKD.[139] In the general population, short stature is defined as height more than 2 SD below the mean height of other children the same age and gender. This correlates to height less than the 2.5th percentile. A single measurement of height is much less important in assessing growth than is the pattern of growth over a period of time. A slowed growth velocity that progressively deviates from a previously defined percentile is concerning.

Normal growth velocity in children fluctuates with age. Although there are variations around this, growth velocity is roughly 25 cm/yr in the first year of life, 10 cm/yr from age 1 to 4 years, and 5 cm/yr from age 4 years to puberty. There are three phases of growth: infantile, childhood, and pubertal, each under the influence of different predominant environmental or hormonal factors.[140] The infantile phase refers to the first 2 years, when growth velocity is at its most rapid. Although nutritional status is the primary determinant of growth during this time, growth hormone begins to play an increasingly important role after the first 12 months. The childhood phase has a slower, more constant rate of growth under the primary influence of growth hormone and thyroid hormone. Finally, the pubertal phase is characterized by the more rapid growth velocity of 8 to 14 cm/yr, with gonadal sex steroids and growth hormone providing the stimulus.[116]

Calculation of mid-parental height provides insight to the expected adult height of the child. The calculation is as follows:

$$\text{Female: } \{[\text{Father's height (cm)} - 13 \text{ cm}] + \text{Mother's height (cm)}\} \div 2.$$

$$\text{Male: } \{[\text{Mother's height (cm)} + 13 \text{ cm}] + \text{Father's height (cm)}\} \div 2.$$

The value obtained in the above calculation, ±8.5 cm provides the 3rd and the 95th percentile values of expected mid-parental height in the child.

KDOQI guidelines define short stature as height SDS less than –1.88 or height for age less than the 3rd percentile.[139] In the general population, the prevalence of short stature is approximately 3% to 5%. In the NAPRTCS registry, almost 37% of children with CKD had growth impairment at the time of enrollment.[16] Factors associated with more severe height deficits were young age, lower GFR, and anemia.[16] The NAPRTCS 2011 annual dialysis report shows that at dialysis initiation, patients have a mean SDS of –1.60. Height deficits are worse for males and younger patients.[23]

The pathogenesis of short stature in children with CKD is multifactorial. Contributing factors include comorbid conditions, malnutrition, CKD-MBD (renal osteodystrophy, hyperparathyroidism or hypoparathyroidism), abnormalities in the growth hormone insulin like growth factor-1 (IGF-1) IGF-1 axis, fluid and electrolyte disturbances, metabolic acidosis, inadequate dialysis, and medications (e.g., corticosteroids).

KEY POINT

Short stature is defined as height SDS less than −1.88 or height-for-age below the 3rd percentile.

Malnutrition is one of the primary contributors to growth impairment in children with CKD. The impact of nutrition is especially important in infants, who may never achieve catch-up growth because of the dramatic growth that occurs during infancy. Reduced caloric intake because of anorexia, nausea, and vomiting is common in CKD, and almost all children with these symptoms have some form of disordered gut motility, ranging from gastroesophageal reflux and delayed gastric emptying to gastric dysrhythmias.[142] Furthermore, altered taste sensation, excessive and preferred water intake over food in polyuric children, the increased intra-abdominal pressure associated with peritoneal dialysis, and elevated levels of inflammatory cytokines such as leptin, TNF-α, IL-1, and IL-6 are additional factors contributing to reduced intake.[143]

Metabolic demands and nutritional losses also may be higher in patients with CKD. Metabolic demands increase during times of acute illness and infection, and inflammation is associated with increased energy expenditure. Amino acid and protein losses during peritoneal dialysis demand increased intake to maintain adequate nutrition in children with already compromised ability to maintain sufficient intake.[144] Sodium deficiency has been associated with poor growth, and adequate replenishment is important for their continued growth. Children with polyuric, salt-wasting CKD can maintain or improve growth when repleted with sodium and water.[145]

Growth hormone is an anabolic peptide that stimulates growth. Perturbation in the growth hormone axis is an important contributor to short stature in children with CKD. Growth hormone is secreted in a pulsatile manner by the anterior pituitary gland in response to the balance between two hypothalamic hormones: the stimulatory influence of growth hormone–releasing hormone (GHRH) and inhibitory effect of somatostatin. The largest and most predictable growth hormone peak occurs soon after onset of sleep.

Once produced by the anterior pituitary, growth hormone acts in the liver and the local tissue sites to stimulate production of IGF-1. Although liver is the dominant source of circulating IGF-1, tissue level and local production of IGF-1 under the influence of growth hormone are believed to be a significant determinants of growth.[146] In animal studies, circulating levels of IGF-1 must be reduced by more than 85% before growth is affected.[147]

Growth hormone levels are increased in children with CKD, likely as a result of increased secretion and reduced renal clearance, whereas IGF-1 levels are usually normal (Figure 31.5).[146,148] These findings are suggestive of
Figure 31.5 The growth hormone (GH)–insulin-like growth factor 1 (IGF-1) axis involved in linear growth in children. Abnormalities in the growth hormone axis seen in chronic kidney disease (CKD) are represented in the right side boxes. Somatostatin inhibits and GHRH stimulated growth hormone secretion. GHRH, growth hormone–releasing hormone; JAK, Janus kinase; STAT, signal transducer and activator of transcription.

peripheral resistance to growth hormone and IGF-1.[149,150] The mechanism of growth hormone resistance appears to be the result of altered postreceptor signaling, rather than reduced number of growth hormone receptors in target organs.[149] Growth hormone binds to its target cell membrane growth hormone receptor, stimulating phosphorylation of Janus kinase 2 (JAK2), a tyrosine kinase. This sequentially stimulates phosphorylation of the growth hormone receptor and cytoplasmic STAT signaling proteins 1, 3, and 5, which translocate to the cell nucleus and activate genes regulated by growth hormone, including the *IGF-1* gene. Suppressor of cytokine signaling *(SOCS)* genes are also activated by this process, and they serve as a negative feedback mechanism, suppressing JAK2. In animal models, impaired phosphorylation of JAK2 and STAT proteins, possibly because of upregulation of SOCS2 and 3, contribute to growth hormone resistance and growth retardation in CKD.[151] Chronic inflammation is believed to be the stimulus for SOCS upregulation in CKD.[152]

Bioavailability of IGF-1 is also significantly altered in CKD. Almost all of the IGF-1 in the bloodstream is bound to six IGF binding proteins (IGFBP 1 to 6) and is inactive, with only 1% being free and bioactive.[153] In CKD, clearance of the IGFBP is reduced, increasing their circulating level and making even less free IGF-1 available for its biologic activity.[154]

Another GHRH, ghrelin, is synthesized in the stomach and to a lesser extent in the hypothalamus and pancreatic islet cells.[147] It has been shown to cause hyperphagia and obesity in rats, increases appetite and food intake in humans, and may stimulate growth hormone secretion.[155] However, its exact role in growth hormone axis regulation and impact on growth is still being investigated.[156]

FLUID AND ELECTROLYTE ABNORMALITIES

Hyperkalemia is common in CKD and worsens as GFR declines. The principal cause of hyperkalemia in CKD is decreased renal excretion of potassium. Hypoaldosteronism, which may be due to decreased renin production by the kidney or to medications that either inhibit aldosterone production or block its action, may be the additional cause of hyperkalemia in some. Hyperkalemia also may be secondary to movement of potassium from the intracellular into the extracellular space, as is seen in metabolic acidosis or use of medications such as β-adrenergic blockers.

The kidney has an important role in the excretion of acid produced by normal metabolism. A normal Western diet results in the production of 1 to 3 mEq/kg/day hydrogen ions in children, which must be buffered and subsequently excreted by the kidney. Impaired acid excretion is common in CKD, especially as GFR decreases to less than 30

mL/min/1.73 m². Adverse consequences associated with metabolic acidosis include muscle wasting, bone disease, impaired growth, insulin insensitivity, abnormalities in growth hormone and thyroid hormone secretion, and increased β$_2$-microglobulin accumulation.

NEUROCOGNITIVE FUNCTION

Before the 1980s, CKD in children, especially if it developed during infancy, was associated with developmental delay of gross motor and language skills, microcephaly, hypotonia, seizures, and dyskinesia.[157] These complications have decreased because of a variety of interventions, including improved nutrition of infants with tube feedings, discontinuation of the use aluminum-based binders, and improved dialysis technology.[158]

Approximately 12% to 23% of children with ESRD have cerebral atrophy on neuroimaging.[159,160] Electroencephalogram (EEG) abnormalities are found in about 25% to 50% of children with CKD. EEG slowing worsens as CKD progresses, and children with CKD have slower peripheral nerve conduction velocities.[161] Potential clinical risk factors for development of neurocognitive deficits include increased disease severity, longer duration of disease, and younger age of onset of kidney disease.[162] Studies evaluating intelligence quotient (IQ) scores in older children are limited. Most children with CKD have normal IQs.[163] However, when compared with siblings, children with CKD, even following transplant, have significantly lower IQs.[164]

Speech and language are adversely affected in children with CKD.[165] Memory, especially short-term visual and verbal memory, is reduced, deficiencies in executive functioning required for problem solving are present, and attention span is diminished.[164,165] The central nervous system adverse effects of CKD have long-term consequences. Verbal performance and full-scale IQ scores and educational attainment are reduced in adults with childhood-onset ESRD.[166] Lower rates of employment and low occupational level are associated with dialysis longer than 8 years.[167]

QUALITY OF LIFE

A Dutch study evaluated quality of life of adults with childhood-onset ESRD, adult-onset ESRD, and the general population.[168] Compared with the general population, dialysis patients had a higher prevalence of impaired quality of life in physical functioning, role limitations because of physical health, social functioning, and general health perception. Quality of life is substantially impaired in adults with new-onset ESRD.[169] A higher number of comorbid conditions, a lower hemoglobin level, and lower residual renal function were independently related to poorer quality of life.[169]

ENDOCRINE DYSFUNCTION

THYROID HORMONE AXIS

CKD affects both the hypothalamus-pituitary-thyroid axis and peripheral thyroid hormone metabolism. Adult uremic patients have higher rates of thyromegaly, goiter, nodules, and carcinoma.[170] The most common thyroid abnormality is sick euthyroid syndrome, a condition characterized by abnormal thyroid function tests in the setting of nonthyroid illness. The prominent alterations are low serum triiodothyronine (T_3) and elevated reverse T_3 (rT_3), also termed low T_3 syndrome. Unlike in other conditions with sick euthyroid syndrome, CKD does not cause elevated total rT_3 because of redistribution to the extravascular space and increased cellular uptake. However, free rT_3 is elevated as a result of reduced renal clearance.[170]

Serum thyroid-stimulating hormone (TSH) concentrations are usually normal or elevated in CKD, but its response to thyroid-releasing hormone (TRH) is reduced. TSH bioavailability may be reduced.[170] Total and free T_4 and T_3 levels are usually decreased, and patients can have clinical or subclinical hypothyroidism. In hemodialysis patients receiving heparin anticoagulation, free T_4 may be elevated secondary to heparin-induced inhibition of T_4 binding to its binding proteins.[170]

GONADAL HORMONES

Delayed pubertal progression occurs in children with CKD, and this further increases the risk for growth retardation. These children exhibit a state of compensated hypergonadotrophic hypogonadism with elevated gonadotropins and decreased or low-normal gonadal hormones.[171] They also have evidence of hypothalamic-pituitary-gonadal dysregulation with blunted response of luteinizing hormone to gonadotropins and decreased luteinizing hormone pulsatility and bioactivity, leading to anovulation in females.[171] Finally, estradiol and testosterone levels are reduced secondary to uremia, either through direct toxic effects or hyporesponsiveness of the gland.[171]

MANAGEMENT

The goals of therapy in children with CKD are:

1. Treat reversible kidney disease
2. Slow progression to ESRD
3. Manage complications
4. Prepare for RRT

The complexity of care, economic demands, and emotional burden to the patients and their families tend to increase as CKD advances. Compared to adults, children with CKD require more resources, specialized care, and care coordination to achieve optimum outcomes.[172] Support from a multidisciplinary team that includes the nephrologist, primary care physician, pharmacist, nurse, social worker, dietitian, and psychologist is crucial to success. Other members of the team may include other subspecialists such as surgeons and urologists, child life specialists, educators and school counselors, and speech, occupational, and physical therapists.

TREATMENT OF REVERSIBLE KIDNEY DISEASE

There are many causes of an acute decline of GFR in the setting of CKD. Every attempt should be made to prevent acute or chronic renal injury, ameliorate its effect, and treat the underlying cause promptly to prevent irreversible and accelerated progression of CKD. Common causes of acute kidney injury include volume depletion, use of nonsteroidal anti-inflammatory agents, administration of nephrotoxic medications, contrast nephropathy, RAAS blockade, and urinary outflow obstruction. Early referral to a nephrologist and appropriate management may lessen the burden and severity of complications and, in fact, reduces mortality.[173]

SLOWING PROGRESSION

Therapeutic interventions at earlier stages of CKD to prevent additional nephron loss and kidney function decline are effective in adults. These strategies include RAAS blockade, blood pressure control, proteinuria reduction, strict glycemic control in diabetics, and dietary protein restriction. Many of these strategies to slow progression in adults have been adopted in the care of pediatric patients with CKD, and data to support their use is increasing.

Inhibition of the RAAS, using either ACEIs or angiotensin receptor blockers (ARBs), is effective in preventing and slowing the rate of GFR decline in CKD. This benefit is likely tightly correlated to the antiproteinuric effect of these agents, but exceeds their antihypertensive effect. In the Ramipril Efficacy in Nephropathy (REIN) study of chronic nondiabetic nephropathies, ACEIs were superior in reducing the rate of GFR decline, despite equivalent blood pressure control, compared to placebo.[174] There may be an additional benefit of combining an ACEI and an ARB, especially in diabetic patients, which results in greater reduction of proteinuria and blood pressure; however, long-term studies are lacking on their effect on CKD progression.[175] In addition, there is an increased incidence of adverse events.

Because aldosterone appears to play a role in renal fibrosis, independent of ATII, the aldosterone receptor antagonists spironolactone and eplerenone have been studied in

adults with CKD. In a randomized study, the addition of spironolactone to an ACEI or ARB led to a smaller decline in GFR than occurred in the control group but was associated with significantly more hyperkalemia.[176]

Hypertension is common in patients with CKD and is a modifiable risk factor for reducing cardiovascular disease and slowing progression of CKD. All patients with CKD should have their blood pressure monitored regularly. Unfortunately, data suggest that hypertension is underdiagnosed and undertreated in children with CKD.[177,178]

Effective blood pressure control delays the progression of CKD in adults, and antihypertensive agents that inhibit the RAAS provide superior protection because of their added antiproteinuric, anti-inflammatory and antifibrotic properties. The ESCAPE trial showed that aggressive blood pressure control in children with stage 2 to 4 CKD (eGFR 15 to 80 mL/min/1.73 m^2), targeting a 24-hour mean arterial blood pressure less than the 50th percentile, was superior in delaying rate of deterioration of GFR compared to a target between the 50th and 90th percentiles.[57] All patients received the maximum dose of ramipril, an ACEI, and thus the benefit was due to improved blood pressure control not to an ACEI effect.

Current KDOQI guidelines for children with CKD and recommendations from the National High Blood Pressure Education Program Working Group (NHBPEP) for all children are for target blood pressure below the 90th percentile, or less than 120/80 mm Hg, whichever is lower.[179] The KDIGO guideline recommends initiating antihypertensive therapy in children with CKD when blood pressure is consistently greater than the 90th percentile for age, gender, and height.[3] Based on the findings in the ESCAPE trial, KDIGO recommendations are to achieve target blood pressure (particularly if proteinuria is present) below the 50th percentile for age, gender, and height, unless limited by symptoms or signs of hypotension. Because of the proved benefits of these agents, it is recommended that an ARB or ACEI be used in children with CKD in whom treatment with blood pressure–lowering drugs is indicated, irrespective of the level of proteinuria.[3]

Other factors that may slow progression to ESRD include protein restriction in experimental models and clinical adult studies.[180,181] The mechanism involves reduced cytokine expression, reduced intraglomerular pressure, and increased matrix synthesis.[182] In general, the effect on slowing progression is small and there is a concern of malnutrition. In children, there is no evidence that protein restriction delays progression of CKD.[183] The adverse effects on nutrition and growth remain of significant concern, and thus the current recommendations are to provide children with their recommended daily allowance of protein.

Cholesterol-lowering therapy with statins and correction of anemia have been studied in adults; however, little evidence exists that these interventions slow progression of CKD. Although no association was found between hyperuricemia and progression, there may be some evidence that allopurinol slows progression of renal disease in patients with CKD and reduces cardiovascular and hospitalization risk.[59,160,184,185]

MANAGEMENT OF COMPLICATIONS

KDOQI and KDIGO guidelines are available for the management of anemia, CKD-MBD, and nutrition in CKD.[3,112,124,125,139,186,187] These topics are reviewed in detail in other chapters (Chapters 32, 33, and 34). The focus in this chapter will be on growth hormone therapy in children with CKD.

GROWTH HORMONE THERAPY

Growth impairment, defined by KDOQI as height SDS less than –1.88 or height-for-age below the 3rd percentile, is common in children with CKD.[139] Regular assessment of nutrition and growth is recommended for all children with CKD stage 2 or higher. Weight for age, length or height for age, length or height velocity for age, and body mass index for age should all be plotted and monitored. Mid-parental height should be calculated and plotted to gauge genetic potential.

The pathogenesis of short stature in children with CKD is multifactorial and includes comorbid conditions, malnutrition, CKD-associated bone disease, abnormalities in the growth hormone–IGF-1 axis, fluid and electrolyte disturbances, metabolic acidosis, inadequate dialysis, and medications (e.g., corticosteroids). Improving growth therefore requires corrective management of malnutrition, electrolyte abnormalities, metabolic acidosis, hyperparathyroidism, and optimization of dialysis adequacy before the initiation of recombinant human growth hormone (rhGH).

rhGH is effective and safe in treating short stature in children with CKD, yet in the NAPRTCS registry there appears to be significant undertreatment of this condition. Whereas almost 37% of children with CKD had growth impairment at the time of enrollment, only 6.3% of patients were on growth hormone therapy at entry.[16,188]

Unfortunately, children with CKD and short stature very often do not attain normal adult height. Even following renal transplant, final adult height remains significantly reduced.[189,190] In a retrospective study, median height SDS was below the 3rd percentile for age at initiation of dialysis, decreased during dialysis, and did not improve following kidney transplant; approximately 74% of patients had a final height below the 3rd percentile.[190]

The effect of growth hormone treatment on the final adult height of children with CKD was studied by Haffner et al.[191] The adult height of 38 children with CKD who were treated with growth hormone for up to 8.8 years was compared with that of 50 children with CKD who did not receive growth hormone. Height SDS improved significantly in the group treated with growth hormone from a mean of –2.85 to –1.5, compared to deterioration from a mean of –1.5 to

–2.1 in the control group. Thus, the children treated with rhGH had catch-up growth and the untreated children had persistent growth failure. Even though the mean final adult height was below the genetic target height, 65% of the treated children reached an adult height within the normal range (within 2 SD of normal height). The mean final adult height was approximately 11.1 cm and 16 cm below the genetic target height in rhGH-treated and untreated children, respectively.[191]

Following renal transplantation, growth is adversely affected by glucocorticoid therapy, allograft dysfunction, and abnormalities in the growth hormone–IGF-1 axis.[192] Treatment with rhGH improves growth in children following transplant without increasing the rate of allograft rejection or loss.[193] Children with CKD before reaching ESRD requiring RRT with either dialysis or renal transplant have a better response to growth hormone therapy.[194] Thus, rhGH should be initiated early in CKD when indicated, to maximize growth potential.

The recommended rhGH dose for the treatment of growth failure in CKD is 0.35 mg/kg/wk (28 international units/m²/wk), divided into once-daily subcutaneous injections administered in the evening. This dose is higher than that used in patients with growth hormone deficiency. Based on the pathophysiology and results of clinical studies, to be effective, rhGH needs to be prescribed in pharmacologic doses. The dose should be adjusted periodically for weight gain. Emerging data suggest that much higher doses of rhGH (0.7 mg/kg/wk) during puberty improve growth potential even further without significant adverse effects.[195] Further study is required before extending this to the CKD population.

Active malignancy is a contraindication to rhGH use, and caution should be exercised in patients at risk for developing malignancies. Once nutritional and metabolic factors have been corrected and a decision made to initiate rhGH, eligibility should be confirmed by obtaining bone age radiograph, thyroid studies, and hemoglobin A1c. Pubertal stage should be assessed.

Once treatment is initiated, patients should be monitored for adverse effects such as benign intracranial hypertension, glucose intolerance, and slipped capital femoral epiphysis. Patients should have an annual bone age x-ray. If response to therapy is poor despite adequate adherence, referral to an endocrinologist may be required for further evaluation.[196]

Growth hormone therapy should be discontinued when the epiphyses close, and once the patient's height goal has been achieved (based on mid-parental height or 50th percentile for age). It should also be discontinued if the patient develops malignancy, slipped capital femoral epiphyses, benign intracranial hypertension, severe hyperparathyroidism (PTH greater than 900 pg/mL for stage 5 CKD, lower values for earlier CKD stages), nonadherence, and at the time of renal transplant.[196] Growth should be monitored following discontinuation and, if there are no contraindications, can be restarted if growth failure recurs.

PREPARING FOR RENAL REPLACEMENT THERAPY

Patients and families should be prepared for the progression of CKD to ESRD. Planning for RRT, whether dialysis or renal transplant, should begin during stage 4 CKD or when the GFR is less than 30 mL/min/1.73 m².[2] As renal function declines, patients should be followed more closely for development of uremic symptoms.

Determination should be made about the timing of the initiation of RRT and type and placement of dialysis access. Veins for dialysis access should be preserved. Generally, it is recommended that RRT be initiated when eGFR declines to less than 15 mL/min/1.73 m². Earlier RRT may be required if symptoms or signs of uremia develop or if CKD-BMD, malnutrition, growth impairment, or neurocognitive dysfunction is difficult to manage.

Patients and families should receive counseling for choices of RRT, and psychosocial and economic preparation. It is advisable for them to meet with the dialysis and transplant teams before initiating RRT. Social work, psychological, and child life support become increasingly important to provide support to the child and family and help them cope with the medical, psychosocial, and economic implications of impending RRT.

Children are more likely to undergo preemptive transplantation than adults, especially when there are available living donors.[172] Race, economic factors, and educational background are factors that determine rates of preemptive renal transplantation using deceased donors.[197]

The rate of preemptive transplant in children in the NAPRTCS registry is approximately 25%.[16] The rate of preemptive transplantation differs significantly between recipients of living (34%) and deceased donor (13%) allografts; between males (28%) and females (20%); and across races, with preemptive transplantation rates of 31% in whites, 14% in blacks, and 16% in Hispanics.[16] The 6- to 12-year-old age group is most likely to be preemptively transplanted, with a rate of 28%.

There is some evidence that preemptive transplant is beneficial and associated with improved long-term outcomes of graft survival than transplantation following dialysis.[197,198] However, it is uncertain whether patient survival is improved. Unless contraindications exist, preemptive transplant should be pursued in all children, irrespective of whether a living donor is available.

In addition to close clinical monitoring of progression of CKD, reciprocal plot of serum creatinine over time (usually years) may provide an approximate time range when a target serum creatinine necessary to initiate RRT would be reached (Figure 31.6).[199] Such a plot facilitates planning for placement of an arteriovenous fistula or peritoneal dialysis catheter or planning for transplant surgery. The caveat in this approach is that decline of renal function and rise of serum creatinine seldom bear a linear relationship over time and a rapid decline of renal function and a steep slope in the plot are possible and may not be predictable.
Figure 31.6 Reciprocal relationship of serum creatinine and time. *Plot a* represents a linear and a predictable plot for reaching a target serum creatinine (e.g., 10 mg/dL in an adult) for starting dialysis therapy. *Plot b* represents an improvement in the rate of decline of renal function. *Plot c* represents an accelerated decline of renal function.

OUTCOME IN CHILDREN

Children with CKD have a higher mortality rate than age-related and gender-related cohorts. The mortality rate in children 1 to 19 years of age in the United States in 2011 was 0.256 per 1000 population.[200] This compares to an overall mortality rate of 41 per 1000 patient-years at risk for children receiving renal replacement therapies. The risk is highest in patients undergoing hemodialysis (64 in 1000 patient-years), followed by peritoneal dialysis (45 in 1000 patient-years) and kidney transplant (10.4 in 1000 patient-years).[1]

Similarly high mortality rate (3.6%) of children with CKD was also reported in the NAPRTCS registry.[16] One-year outcomes of pediatric ESRD patients on dialysis in the USRDS database is unchanged since 2002, with 38% receiving a kidney transplant and 4% dying.[1] Mortality rate adjusted for age, gender, race, Hispanic ethnicity, and diagnosis is highest in the youngest children, possibly reflecting an increased survival of neonates with significant comorbidities.[1]

For children beginning ESRD therapy in 2002 to 2006, the 5-year survival was 89%, with the lowest survival in children younger than 4 years (80%). By modality, the highest 5-year survival probability was in children with a transplant (96%), compared to 75% and 80% in those treated with hemodialysis or peritoneal dialysis, respectively.[1]

In Australia and New Zealand, 10- and 20-year survival of pediatric patients with ESRD was 79% and 66%, respectively.[201] Mortality in children was 30 times higher than children without ESRD. Overall, a trend toward improved survival was observed over the four decades of the study. Risk factors for death included young age when RRT is initiated (four times higher in children under 1 year of age vs. those 15 to 19 years of age) and treatment with dialysis (more than four times higher risk than those with a renal transplant).

SUMMARY

CKD is a complex disorder that presents numerous management challenges, especially in the very young. Because almost half of the patients have abnormalities of the urinary tract, a close collaboration between urologists and nephrologist is essential for a successful outcome. Impact of CKD on the families and caregivers at home can be substantial, and providing support through teams of appropriate ancillary staff is an essential aspect of the care of these patients. Preparation of children and families for dialysis and kidney transplantation also requires specialized care. Although hemodialysis is possible even in neonates, vascular access remains challenging in children. Many children require dialysis through a central catheter, adding to the lack of eventual vascular resources in these patients. Transplantation is the goal for all children with CKD, but the life span of even a successful kidney transplant is finite. Despite these challenges, significant progress has been made in the care of children with CKD in the last 20 years. This includes availability of treatments, such as erythropoietin and growth hormone therapy. With technology galloping toward the development of replacement organs from patient's own cells, let us hope that the next 20 years will remain full of promise for children with CKD.

REVIEW QUESTIONS

1. The *most* common cause of CKD in children is:
   a. Focal segmental glomerulosclerosis
   b. Polycystic kidney disease
   c. Congenital anomalies of the kidneys and urinary tract (CAKUT)
   d. Immune-mediated glomerulonephritis
   e. Hemolytic-uremic syndrome

2. The incidence of ESRD in children:
   a. Decreases with increasing age
   b. Remains the same throughout childhood and adolescence
   c. Is highest in children younger than 4 years
   d. Increases with advancing age

3. In the United States, FSGS is the predominant cause of CKD in:
   a. African Americans
   b. Hispanics
   c. Whites
   d. Native Americans
   e. Asian Americans

4. Mortality of children with ESRD is highest in which age group?
   a. 0 to 4 years
   b. 5 to 14 years
   c. 15 to 19 years

5. Angiotensin II plays a role in progression of CKD by:
   a. Causing predominant afferent over efferent arteriolar vasoconstriction
   b. Decreasing single-nephron GFR
   c. Increasing proinflammatory cytokines, chemokines, and cell adhesion molecules
   d. Stimulating aldosterone, which itself is injurious to the kidney
   e. a, b, and d
   f. c and d

6. What is the *most* common complication of CKD in children?
   a. Anemia
   b. Hypertension
   c. Fluid and electrolyte abnormalities
   d. Growth failure
   e. Mineral and bone disorder

7. The prevalence of LVH in pediatric dialysis patients is:
   a. 10%
   b. 20%
   c. 30%
   d. Up to 50%
   e. Up to 75%
8. In children the fastest rate of growth occurs:
   a. During infancy
   b. Age 1 to 4 years
   c. Age 4 to 10 years
   d. During puberty
9. All of the following contribute to growth impairment in children with CKD, *except:*
   a. Malnutrition
   b. Anemia
   c. GH deficiency
   d. Altered post–receptor signaling of JAK2 and STAT proteins
   e. Reduced bioavailability of IGF-1
10. All of the following central and neurocognitive deficits occur in children with CKD *except:*
    a. Cerebral atrophy
    b. Speech and language delay
    c. Lower educational attainment
    d. Lower IQ scores
    e. Macrocephaly and hydrocephalus

11. In children with CKD, all but one of the following therapeutic interventions slow progression.
    a. ACE-inhibitors or angiotensin receptor blockers
    b. Blood pressure control
    c. Minimizing proteinuria
    d. Cholesterol-lowering therapy

Anemia in chronic kidney disease

MEREDITH ATKINSON

Anemia is a common complication in children with chronic kidney disease (CKD), and it increases in prevalence with advancing disease stage. In addition to being costly to treat, anemia is associated with a variety of adverse clinical consequences including death, hospitalizations, and the development and progression of cardiovascular risk factors such as left ventricular hypertrophy (LVH).[1–3] The introduction of recombinant human erythropoietin (rHuEPO) in the late 1980s revolutionized anemia management by decreasing the need for red blood cell transfusions in patients with CKD. However, there is increasing concern about potential adverse effects of treatment with erythropoiesis-stimulating agents (ESAs). Anemia management in children continues to focus on avoiding transfusions by correction of iron deficiency and the use of ESAs. This chapter reviews the definition, risk factors, and pathophysiology of anemia in children with CKD, with specific attention to current therapeutic strategies and ongoing challenges in its management. The Kidney Disease: Improving Global Outcomes (KDIGO) workgroup published an evidence-based clinical practice guideline for anemia in chronic kidney disease.[4]

DEFINITION, MONITORING, AND INITIAL EVALUATION

Normal hemoglobin (Hb) levels vary among individual persons based on age and sex.[5–7] The application of adult normative Hb thresholds has been shown to underestimate the prevalence of anemia substantially in patients with CKD who are less than 18 years old.[8] Consequently, the KDGIO clinical practice guideline for anemia uses World Health Organization (WHO) age-specific Hb values to define the level at which an evaluation for the cause of anemia should be initiated (Table 32.1).[4] An alternative source for specific Hb thresholds to define anemia in children 1 to 19 years old is the National Health and Nutrition Examination Survey (NHANES) III data from 1988 to 1994, which reports age- and sex-specific fifth percentile values (Table 32.2).[5] In children without an established diagnosis of anemia, Hb should be measured at least annually in those with stage 3 CKD, at least twice annually in those with stage 4 to 5 CKD, and at least every 3 months in those undergoing dialysis. Hb should be measured more frequently for clinical indications and in children with known anemia.[4]

Because anemia in children with CKD may not be associated solely with EPO deficiency (particularly in patients with only mildly impaired renal function), the initial laboratory evaluation should include a complete blood count to assess red blood cell indices (mean corpuscular hemoglobin, mean corpuscular volume, and mean corpuscular hemoglobin concentration), the absolute reticulocyte count, and serum ferritin and transferrin saturation (TSAT) to assess the adequacy of iron for erythropoiesis.[4] Vitamin B_{12} and folate deficiency are uncommon but easily correctable causes of anemia and should be included in an initial laboratory evaluation, particularly in the setting of macrocytosis.[4] Anemia with concurrent lymphopenia or thrombocytopenia should prompt an evaluation for malignancy, autoimmune disease, or drug toxicity. Microcytosis is most commonly secondary to iron deficiency, but it may be caused by a hereditary hemoglobinopathy, which should be screened for if indicated. Reticulocytosis may result from chronic blood loss or hemolysis, and it should prompt testing for blood in the stool and

Table 32.1 World Health Organization age-specific hemoglobin thresholds for the definition of anemia in children

Age (yr)	Hemoglobin (g/dL)
0.5–5	<11.0
5–12	<11.5
12–15	<12.0
>15: male	<13.0
>–15: female	<12.0

Table 32.2 Age- and sex-specific fifth percentile hemoglobin values for children 1 to 19 years of age based on population-based data from the National Health and Nutrition Examination Survey (NHANES) 1988 to 1994

Age (yr)	Hemoglobin (g/dL)	
	Male	Female
1–2	10.7	10.8
3–5	11.2	11.1
6–8	11.5	11.5
9–11	12.0	11.9
12–14	12.4	11.7
15–19	13.5	11.5

Source: Hollowell JG, van Assendelft OW, Gunter EW, et al. Hematological and iron-related analytes—reference data for persons aged 1 year and over: United States, 1988–94. Data from the Third National Health Examination Survey. Vital Health Stat 11. 2005;(247):1–156.

serum markers of hemolysis. The use of aluminum-containing phosphate binders has historically been linked to aluminum toxicity and anemia, but the rare use of these binders has virtually eliminated this complication.[9] Other correctable causes of anemia that are not CKD should be ruled out in patients before initiation of treatment with an ESA.

KEY POINT

The initial anemia evaluation in children with CKD should include a complete blood count with red blood cell indices and reticulocyte count, assessment for iron and other nutritional deficiency, and screening for occult blood loss if indicated.

EPIDEMIOLOGY AND RISK FACTORS

The level of kidney function is the key risk factor for the development of anemia in CKD. Data from the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) cohort has consistently shown that the risk for anemia increases as CKD stage advances, with a prevalence of 73% at stage 3, 87% at stage 5, and more than 93% at stage 5.[10,11] Within the Chronic Kidney Disease in Children (CKiD) cohort study, Hb declined as iohexol-determined glomerular filtration rate decreased to less than 43 mL/min/1.73 m[2], although anemia can also be observed at higher rates.[12] Furthermore, among children prescribed an ESA, more than 20% of those at stage 4 and more than 40% at stage 5 demonstrate persistently low Hb levels.[10]

Other independent risk factors for the anemia of CKD include treatment with antihypertensive agents[10,11]; hypertension may be a marker of disease severity, but ACE inhibitors may also contribute to anemia by inhibition of erythropoiesis.[13] In the International Pediatric Peritoneal Dialysis Network (IPPN) registry, low residual renal function, low serum albumin, increased parathyroid hormone levels, high serum ferritin, and the use of bioincompatible dialysate were associated with low Hb levels.[14] Race is also a recognized risk factor for anemia. Among children enrolled in the CKiD study, African Americans have consistently lower Hb levels than white children, even after adjusting for level of kidney function.[7] Although normal Hb levels in healthy children differ by race and ethnicity, current anemia management guidelines do not recommend varying Hb targets or approach to treatment by race.[15]

ADVERSE ASSOCIATIONS

The anemia of CKD is associated with substantial morbidity in children. Among children on dialysis, low Hb is a strong and independent predictor of death and is associated with increased frequency of hospitalization.[1,14,16,17] Even in the predialysis population, anemia has been associated with an almost 40% increased risk for all-cause hospitalization in children with stage 2 to 5 CKD.[11] Anemia is an important cardiovascular risk factor in children, and it increases the risk for development of LVH independently of elevation in blood pressure, even in mild to moderate CKD.[2,18,19] In children receiving peritoneal dialysis, both hypertension and LVH increase with increasing degree of anemia.[14] Anemia also adversely affects quality of life, including neurocognitive development and exercise capacity.[20] Anemic adolescents with CKD report greater limitations in physical functioning, schoolwork, and activities with friends and family, independent of level of kidney function.[21] Correction of anemia with ESAs has been associated with increased catch-up growth in children with CKD.[22] Finally, there is some evidence in adults that early treatment of mild anemia delays the initiation of renal replacement therapy, and anemia in adolescents with CKD is associated with an accelerated decline in glomerular filtration rate.[23,24] Data from the NAPRTCS registry has also shown anemia to be a risk factor for CKD progression.[25] One proposed mechanism for this is increased production of profibrotic cytokines secondary to renal tissue hypoxia.

Although these and other comorbidities are multifactorial in origin, anemia likely contributes to their development, and its treatment may mitigate some of the risk.

An additional potential adverse effect of anemia is an increase in human leukocyte antigen (HLA) antibodies in patients requiring red blood cell transfusions. Leukoreduction of blood products has been shown to be ineffective for decreasing HLA sensitization, and red blood cell transfusions lead to clinically significant increases in HLA antibody strength and breadth, thus adversely affecting the viability of future transplants.[26,27]

KEY POINT

The adverse associations of anemia in children with CKD include increased risk for hospitalization and death, decreased quality of life, and increased risk for LVH.

PATHOGENESIS

A complex interaction of factors is responsible for decreasing Hb values as kidney disease progresses (Table 32.3 and Figure 32.1), but impaired EPO production by failing kidneys is a central cause. EPO is a 30.4-kDa glycoprotein encoded by a gene on the seventh chromosome that was first identified and cloned in 1985.[28–30] Although human EPO is produced by hepatocytes prenatally, the primary production site shifts to the peritubular fibroblasts in the renal cortex at birth.[31] Circulating EPO regulates erythroid proliferation and survival, primarily by an antiapoptotic mechanism, by binding to cell surface receptors of erythroid progenitor cells in the bone marrow.[28,29] EPO also acts as a growth factor to enhance red blood cell maturation.[29] The primary stimulus for EPO expression is hypoxia; EPO production is increased by a hypoxia-inducible transcription factor that controls the EPO gene.[28,31] Although EPO production can be decreased in CKD by destruction of peritubular fibroblasts, dysregulation of the renal oxygen-sensing mechanism has also been shown to contribute to inappropriately low EPO production in patients, independent of damage to EPO-producing cells.[32] EPO production in CKD may also be downregulated by the decreased distal tubular sodium reabsorption caused by decreased GFR, which then signals a decrease in EPO production.[28,33] Although measurement of EPO in patients with CKD has revealed levels in the normal to slightly increased range, the levels are inappropriately low for the degree of anemia; EPO levels are 10 to 100 times higher in anemic patients with normal kidney function.[9,28]

Iron-restricted erythropoiesis is also an important cause of the anemia of CKD. Iron restriction may be secondary to absolute iron deficiency, to functional iron deficiency in which accessible iron stores are depleted by an ESA-stimulated bone marrow, or to impaired iron trafficking in the setting of inflammation.[34] The markers of iron status most often used clinically are serum ferritin, a marker of stored iron, and TSAT, which measures circulating iron available for delivery to the bone marrow. Children with CKD are at risk for absolute iron deficiency because of a variety of factors, including decreased nutritional intake and poor enteral absorption, as well as blood loss through the gastrointestinal tract, menstruation, frequent phlebotomy, and hemodialysis.[9,33] Patients with absolute iron deficiency have low serum ferritin and TSAT levels. In patients with functional iron deficiency who are receiving ESAs, the rate of enteral iron absorption or release from reticuloendothelial cells is inadequate to meet the demands for erythropoiesis.[34] These patients often have low TSAT values with normal or high levels of ferritin, and selected patients may benefit from treatment with intravenous (IV) iron.[35] Inflammation also results in impaired iron trafficking through the actions of the iron-regulatory protein hepcidin, production of which is directly upregulated by inflammatory cytokines and which is cleared from the circulation by glomerular filtration.[34,36] Hepcidin causes internalization and degradation of the primary cellular iron exporter, ferroportin, that result in trapping of stored iron within enterocytes and reticuloendothelial cells.[36,37]

Table 32.3 Pathogenic factors in the development of the anemia of chronic kidney disease in children

- Impaired or dysregulated erythropoietin production
- Iron-restricted erythropoiesis
  - Absolute iron deficiency
  - Functional iron deficiency
  - Impaired iron trafficking
- Inflammation (chronic or acute)
- Nutritional deficiencies
  - Folic acid, vitamin B_{12}, carnitine
  - Uremia or inadequate dialysis
  - Hyperparathyroidism or bone mineral metabolism disorder
- Chronic blood loss, hemolysis
- Medications (ACEi, nonadherence)
- Pure red cell aplasia
- Hemoglobinopathies

ACEi, angiotensin converting enzyme inhibitor.

KEY POINT

Impaired EPO production and iron-restricted erythropoiesis are primary causes of the anemia of CKD.
Figure 32.1 Schematic representation of the mechanisms underlying anemia of chronic kidney disease (CKD). Iron and erythropoietin (EPO) are crucial for red blood cell (RBC) production in the bone marrow. Iron availability is controlled by the liver hormone hepcidin, which regulates dietary iron absorption and macrophage iron recycling from senescent RBCs. Several feedback loops control hepcidin levels, including iron and EPO. In patients with CKD (particularly in patients with end-stage kidney disease who are undergoing hemodialysis), hepcidin levels have been found to be highly elevated, presumably from reduced renal clearance and induction by inflammation, leading to iron-restricted erythropoiesis. CKD also inhibits EPO production by the kidney and may also lead to circulating uremic-induced inhibitors of erythropoiesis, shortened RBC life span, and increased blood loss. The black and gray arrows represent normal physiology (black for iron and hormonal fluxes and gray for regulatory processes). The blue arrows represent the additional effects of CKD (blue for activation and red for inhibition). ESA, erythropoiesis-stimulating agent. (Adapted from Babitt JL, Lin HY. Mechanisms of anemia in CKD. J Am Soc Nephrol.. 2012;23:1631–4.)

Beyond iron deficiency, nutritional deficiencies of vitamin B$_{12}$, folate, carnitine, and vitamin C may also contribute to anemia in CKD. Deficiency of folate, which is required for DNA synthesis during erythropoiesis, has been observed in children undergoing dialysis, and when it was corrected in a small pediatric hemodialysis cohort, Hb increased and ESA dose requirement decreased.[38] CKD, and especially long-term hemodialysis, is a leading cause of secondary carnitine deficiency because of its ready dialyzability, among other contributing factors, including decreased dietary intake.[39] Some studies have suggested that L-carnitine supplementation can prolong red blood cell life span and stimulate erythropoiesis by inhibiting apoptosis, but there have been no large-scale randomized clinical trials conducted to evaluate whether supplementation is effective as an adjunctive treatment for anemia in patients undergoing dialysis.[39] Vitamin C enhances absorption of dietary iron, contributes to the mobilization of intracellular

stored iron, and increases carnitine synthesis. Vitamin C deficiency is common in patients undergoing dialysis as a result of restricted nutritional intake, increased vitamin C catabolism in the setting of inflammation, and perhaps dialytic clearance.[40] However, as with carnitine, there have been no clinical trials to assess the effects of vitamin C supplementation on anemia in patients undergoing dialysis.[40]

Chronic uremia also contributes to anemia through hemolysis; exposure to uremic serum shortens the life span of erythrocytes from healthy subjects, with cell survival time decreased by as much as 50%.[30] The mechanisms seem to be premature changes in the cell membrane and cytoskeleton of red blood cells resulting from uremic toxins and increased oxidative stress.[41] Initially, increased red blood cell production compensates for anemia, but this mechanism is no longer effective once EPO production decreases.[30] Hyperparathyroidism has also been associated with ESA hyporesponsiveness, likely because of decreased

bone marrow production of red blood cells in the setting of myelofibrosis.[28,42,43] Finally, ESA-induced pure red cell aplasia (PRCA) is an increasingly rare hematologic disorder that was first described in the late 1990s. PRCA is characterized by a severe and progressive normocytic anemia, reticulocytopenia, and the almost complete absence of erythroid precursors in the bone marrow; affected patients become transfusion dependent.[44] ESA-induced PRCA is secondary to the development of neutralizing antibodies that block the interaction between an ESA (including epoetin alfa or beta, darbepoetin alfa, or endogenous EPO) and its receptor.[44] Most initial cases of ESA-induced PRCA were seen in countries where epoetin alfa formulated with a polysorbate 80 stabilizer was administered subcutaneously to patients with CKD, and regulatory advisories have subsequently discouraged this practice.[45] The evaluation of suspected PRCA includes bone marrow examination and measurement of anti-EPO antibodies.[44]

TREATMENT

IRON SUPPLEMENTATION

Both absolute iron deficiency and defects in iron handling make substantial contributions to the development of anemia because red blood cells cannot be produced in the absence of iron. The goal of iron supplementation is to prevent iron deficiency in ESA-treated patients, to raise Hb in iron-deficient patients not yet treated with ESAs, and to reduce the ESA dose required to maintain Hb levels. Iron supplementation is indicated in patients with depleted iron stores and in patients who are likely to have a clinically significant increase in red blood cell production.[4] However, the challenge is to avoid the use of iron in patients who are unlikely to benefit. Patients with hepcidin-mediated iron sequestration are unlikely to absorb enteral iron supplements or to mobilize iron stored as ferritin for the purposes of erythropoiesis. It is clear that administration of iron, and in particular IV iron, increases oxidative stress; hence iron should not be given to patients who cannot use it effectively to increase red blood cell production.[34,46,47]

Assessment of iron stores

The gold standard test for quantification of body iron stores is bone marrow iron staining, but for practical considerations this is rarely performed clinically.[48] The most widely available and clinically utilized tests are serum ferritin, considered to be a reflection of stored iron, and TSAT, an indicator of the amount of iron available for transport to the bone marrow for erythropoiesis.[48–50] Ferritin and transferrin provide the safe storage and transport, respectively, of the highly reactive iron element. There are various other potentially useful markers of iron status in patients with CKD including reticulocyte Hb content, percentage of hypochromic red blood cells, soluble transferrin receptor, and

erythrocyte zinc protoporphyrin, but none have yet achieved widespread clinical use.[50] The definition of absolute iron deficiency in healthy children, from population-based data, includes serum ferritin values less than 10 to 12 ng/mL and TSAT values lower than 10% to 15%.[51] The current KDIGO clinical practice recommends initiation of oral iron (IV iron in patients undergoing hemodialysis) in anemic children with CKD who are not treated with ESA when the TSAT is 20% or lower and the serum ferritin is 100 ng/mL or lower.[4] Additionally, for children receiving ESA therapy, oral (or IV in the case of hemodialysis) iron supplementation should be provided to maintain the TSAT at more than 20% and the ferritin greater than 100 ng/mL.[4] There is no evidence that targeting a higher ferritin of 200 ng/mL, as has been recommended in adults, is appropriate in pediatric patients.[4] Routine use of iron supplementation to target TSAT greater than 30% or ferritin greater than 500 ng/mL is not recommended, given that the risks and benefits of doing so have not been adequately studied in either adults or children.

KEY POINTS

- Ferritin and TSAT are the most widely used markers of iron stores in children with CKD.
- Goal thresholds in ESA-treated children are TSAT greater than 20% and ferritin greater than 100 ng/mL.

Ferritin and TSAT have limitations and may not accurately reflect iron that can be used in the bone marrow for erythropoiesis. Children with CKD, and in particular children undergoing long-term dialysis, may demonstrate normal or elevated ferritin levels, low TSAT levels, and persistent anemia despite ESA therapy, findings indicative of inflammation-mediated iron-restricted erythropoiesis.[34,52] Ferritin is the main intracellular storage molecule for iron, and it allows for storage of iron while minimizing the risk of oxidation by free iron.[50] Measurement of ferritin concentration in the serum depends on its leakage from the intracellular compartment into the serum, and the process by which ferritin enters the circulation is not completely understood.[50] Ferritin is also an acute phase reactant, and its production is upregulated by inflammatory stimuli, thus confounding its usefulness as an accurate indicator of accessible stored iron.[49,50] Studies in children with CKD have demonstrated that higher serum ferritin values are associated with lower Hb values,[14,48] a finding suggesting that an elevated ferritin level may be a marker of inflammation rather than an accurate indicator of iron stores. Given that TSAT is calculated from serum iron divided by total iron binding capacity, which is a negative acute phase reactant, its value may also be artificially increased by inflammation.[49,50] There is evidence that serum iron, as an indicator of accessible iron stores, may be more closely associated with clinical outcomes in adults undergoing hemodialysis.[53] In a study of children with CKD

who were not undergoing dialysis, serum iron lower than 50 μg/dL was more closely associated with lower Hb than either low ferritin or low TSAT, a finding suggesting that low serum iron values in the setting of normal or increased ferritin and low Hb may be useful indicators of iron-restricted erythropoiesis secondary to inflammation and hepcidin-mediated impaired iron trafficking.[48]

Route of administration

The choice of route of iron therapy (oral vs. IV) should take into account a variety of factors, including the relative severity of iron deficiency and anemia and the response, tolerance, and adherence to earlier treatment with oral iron.[4] Although oral iron supplementation is generally inexpensive and readily available, it may have limited efficacy for maintaining adequate iron stores as a result of poor enteral absorption coupled with issues of adherence. Children undergoing long-term hemodialysis in particular may be poorly responsive to enteral iron supplements secondary to chronic blood loss and inflammation. The efficacy of IV iron preparations in improving measured iron stores, increasing Hb concentration, and decreasing ESA doses required to maintain Hb has been confirmed in studies in children undergoing hemodialysis.[9,54,55] IV iron increases Hb levels in children with CKD who are not undergoing dialysis and who are not treated with ESAs.[56] Various IV iron preparations are available, including iron dextran, iron gluconate, and iron sucrose, but any formulation may be associated with potentially severe acute reactions that require close monitoring.[4,9] The spectrum of toxicity can range from hypotension and dyspnea to anaphylaxis, potentially mediated by immune mechanisms or acute induction of oxidative stress, and toxicity has been observed more commonly with iron dextran preparations.[4] Administration of IV iron preparations should be avoided in patients with active systemic infections out of concern that many pathogens require iron for proliferation.

KEY POINTS

- Oral iron supplementation is safe and efficacious in children with CKD, but children with more advanced CKD or undergoing dialysis may have poor enteral iron absorption.
- IV iron preparations are available when there is a poor response to enteral supplements.

ERYTHROPOIESIS-STIMULATING AGENTS

The development of rHuEPO in the 1980s and its clinical utility for replacing endogenous EPO were critical developments in the management of the anemia of CKD in children. One of the most significant effects of its widespread use was a reduction in the need for regular blood transfusions in

patients with advanced CKD, thereby decreasing the occurrence of transfusion-associated viral infections, iron overload, and allosensitization.[4,26,27,57] However, clinical trials performed in adults have raised concerns about the safety and efficacy of using escalating ESA doses to normalize Hb levels. The Normal Hematocrit Trial (in hemodialysis recipients) and the Correction of Hemoglobin and Outcomes in Renal Insufficiency (CHOIR) Trial (in CKD not treated with dialysis) both found that the use of epoetin alfa to target higher hematocrit or Hb levels was associated with increased risk for death and adverse cardiovascular events, including myocardial infarction and stroke.[58,59] Subsequently, the Trial to Reduce Cardiovascular Events With Aranesp Therapy (TREAT) trial, performed in more than 4000 adults with diabetes and CKD, randomized subjects to either darbepoetin alfa to achieve Hb levels greater than 13 g/dL or placebo, with only rescue darbepoetin alfa for Hb lower than 9 g/dL. The intervention group had an increased risk for stroke, thus providing additional evidence that ESA treatment to normalize Hb in CKD may lead to adverse events.[60] None of these trials clarified whether higher Hb level or high ESA dose was the more significant contributor to adverse outcomes, although a prospective study performed in adults undergoing hemodialysis found that patients with naturally occurring higher Hb levels were not at increased risk for death.[61,62] Proposed mechanisms for the adverse outcomes associated with ESA use include trophic effects on vascular endothelial or smooth muscle cells.[63]

In 2011 the US Food and Drug Administration changed ESA product labeling to recommend that the previously identified Hb target range of 10 to 12 g/dL should be replaced by the practice of using the lowest possible ESA dose to prevent red blood cell transfusions, and that ESA dosing should be reduced or interrupted for Hb levels exceeding 11 g/dL.[64] Observational studies in pediatric patients undergoing dialysis have demonstrated associations between increased ESA dose and death.[14,65] However, no randomized controlled trials examining the effects of ESA administration on clinical outcomes in children with CKD have been performed, and the current recommendations regarding safe target Hb levels in children treated with ESAs are still extrapolated from adult studies.

KEY POINT

Trials in adults have found ESA use to be associated with increased incidence of stroke and other adverse outcomes, but no such randomized controlled trials have been performed in children with CKD.

Types of agents

Several types of both short-acting and long-acting ESAs are available worldwide, and new formulations continue to

emerge, requiring ongoing attention to relative safety and efficacy in children compared with adults. There is currently no definitive evidence of superiority in patient outcomes for any particular ESA brand.[4] Among rHuEPO types, epoetin alfa is a commonly used form of rHuEPO in the United States, and epoetin beta is more commonly used in Europe.[66] Short-acting epoetin formulations reach maximum efficacy when dosed one to three times weekly and are more effective when given by the subcutaneous route (half-life, 19 to 24 h) rather than the IV (half-life, 6 to 8 h) route.[67] In contrast, darbepoetin alfa, an EPO analogue with a longer half-life than rHuEPO, has maximum efficacy when given every 2 weeks.[4,33,67] Darbepoetin alfa may be administered intravenously or subcutaneously, and although drug clearance, half-life, and bioavailability are similar between adults and children regardless of route of administration, absorption when given subcutaneously may be more rapid in children.[68] Longer dosing interval compared with rHuEPO has made subcutaneous darbepoetin alfa an attractive alternative for anemia management in younger children and is likely to improve adherence. A randomized clinical trial in children with CKD stages 4 and 5 demonstrated that darbepoetin alfa is as safe and effective as rHuEPO for the correction of anemia.[69] A potential limitation of darbepoetin alfa in children is the reported discomfort associated with injection. A randomized controlled trial in children with end-stage renal disease demonstrated that subcutaneous injection of darbepoetin alfa was associated with significantly higher pain perception in children than was subcutaneous epoetin beta.[70] A potential explanation is the more physiologic pH of the buffer in the epoetin beta preparation than in the darbepoetin alfa preparation.[70]

> **KEY POINT**
>
> Darbepoetin alfa is a safe and effective treatment for the anemia of CKD in children, with an advantage of a longer dosing interval compared with rHuEPO.

Additional long-acting ESAs include the continuous EPO receptor activator (CERA) methoxy polyethylene glycol-epoetin beta, which has a half-life of 134 h after subcutaneous administration, thus permitting an extended administration interval of 4 weeks.[67] However, there are limited studies of CERA safety and efficacy in children.

Initiation, dosing, and monitoring

The KDIGO clinical practice guideline for anemia recommends that the selection of the Hb concentration at which to begin ESA therapy be the result of consideration of the benefits and risks of treatment in individual patients. ESA initiation should be considered for Hb levels persistently lower than 10 g/dL, and Hb levels less than 9 g/dL in patients undergoing dialysis should be avoided. In children

receiving ESA therapy, the goal Hb level should be 11 to 12 g/dL.[4] The goal after ESA initiation is for a rate of increase in Hb concentration of no more than 1 to 2 g/dL per month.[4] The starting dose range for epoetin alfa or epoetin beta is 20 to 50 international units/kg three times weekly (subcutaneously or intravenously) with dose adjustments as necessary to maintain Hb in range to avoid transfusion and not to exceed upper limit of 11-12 g/dL.[4] In children older than 1 year, darbepoetin alfa should be initiated at 0.45 μg/kg intravenously or subcutaneously dosed once weekly, or 0.75 μg/kg dosed every 2 weeks subcutaneously.[4]

> **KEY POINT**
>
> The goal Hb level in children receiving ESA therapy is in the range of 11 to 12 g/dL.

The dosing requirements of rHuEPO may differ substantially between children and adults. Based on registry data, young children require higher rHuEPO doses than adults, ranging from 275 to 350 units/kg/week for infants to 200 to 250 units/kg/week for older children.[28] Children and adolescents undergoing long-term hemodialysis have been found to require higher absolute doses of rHuEPO than adults to maintain target Hb levels, despite lower body weight.[71] In contrast to typical drug dosing in children, which is based on body size to account for decreased volume of distribution, rHuEPO dose requirement appears to be independent of weight.[71,72] It has been shown that an absolute rHuEPO dose of 1000 units given intravenously to both adults and children can increase Hb by 0.4 g/dL, a finding suggesting that dosing schemes based on Hb deficit rather than weight may be useful.[73] The potential mechanisms for increased rHuEPO dose requirement in children are not clear, but they may include increased presence of nonhematopoietic EPO binding sites (e.g., endothelial, kidney, brain, and skeletal muscle cells) resulting in increased drug clearance or increased EPO demand during periods of accelerated body growth.[28,29,73]

> **KEY POINT**
>
> Children may require higher absolute rHuEPO doses than adults.

ESA dose adjustments should be made based on Hb response to treatment, including rate of change, ESA dose, and other pertinent clinical circumstances.[4] ESA dose adjustments after initiation should generally not be made until after the first 4 weeks of therapy, and no more often than every 2 weeks in the outpatient setting, because the effects of therapy are not likely to be seen after shorter intervals.[4] When a decrease in Hb is necessary, ESA dose should

be decreased but not necessarily held, given that a pattern of holding and reinitiating ESA therapy can lead to Hb cycling around the desired target range.[74] Long-acting ESAs such as darbepoetin alfa, with its increased half-life and lower binding affinity for the EPO receptor, stimulate erythropoiesis for longer periods of time and thus may cause higher than intended Hb levels in clinical practice. This effect can be avoided by using lower starting doses and making less frequent dose adjustments than in children treated with short-acting ESAs.[67]

KEY POINT

Adjustment of ESA dosing should be controlled to minimize large fluctuations in Hb level.

ONGOING THERAPEUTIC CHALLENGES

In some patients, despite iron supplementation combined with escalating ESA therapy, Hb levels are not corrected to even a minimal goal, or these patients may need very large doses of ESA to increase or maintain Hb.[75] Given the need for efficacious anemia therapy along with concern for the potential adverse effects of escalating ESA doses to achieve higher Hb concentration, addressing ESA hyporesponsiveness has become a key component of anemia management. There is no single accepted definition of ESA hyporesponsiveness, but it is generally characterized as persistent Hb deficit despite 1 month of appropriate weight-based dosing or after 3 months of high-dose ESA treatment (rHuEPO in excess of 400 units/kg weekly or darbepoetin alfa in excess of 1 μg/kg weekly).[75,76] The current KDIGO anemia management guidelines discourage repeated ESA dose escalations beyond double the weight-based dose patients have been either initiated on or maintained on before developing ESA hyporesponsiveness, with maximal doses no greater than four times the initial weight-based dose.[4]

Data from NAPRTCS has demonstrated that more than 40% of children with stage 5 CKD have low Hb levels despite ESA treatment.[10] Clinical risk factors for ESA hyporesponsiveness identified in children undergoing hemodialysis include chronic inflammation, nutritional deficits, and chronic blood loss.[71] Although there are various potential mechanisms underlying ESA hyporesponsiveness, inflammation plays a central role.[77] Identification of the inflammation-mediated upregulation of hepcidin in patients with CKD, with resulting iron-restricted erythropoiesis, has clarified our understanding of this state.[78–81] Although ESA hyporesponsiveness may be chronic, shorter-term clinical events such as infections or surgical procedures may significantly affect response to ESA therapy. The potential risks and benefits of significant escalation in ESA dose versus red blood cell transfusion must be assessed for individual patients.[4]

SUMMARY

Anemia is prevalent and is associated with adverse outcomes in children with CKD. Although various factors contribute to anemia risk, EPO insufficiency and iron deficiency are the major underlying etiologic factors, and they are the mechanisms most commonly targeted by current therapies. Ongoing therapeutic challenges include hepcidin-mediated iron-restricted erythropoiesis and concerns about the safety and efficacy of escalating ESA doses for refractory anemia. Most recommendations regarding ESA use and dosing are based on data from adult trials; there have been no interventional studies examining the effects of ESA administration on clinical outcomes in children. Nevertheless, ESAs continue to be important components of CKD care in children; use of ESAs should balance the risks and benefits.

REVIEW QUESTIONS

1. The initial laboratory evaluation for anemia in a child with CKD should include which of the following?
   a. Complete blood count
   b. Reticulocyte count
   c. Ferritin
   d. Transferrin saturation
   e. All of the above

2. Which of the following is *not* associated with the anemia of CKD in children?
   a. Increased risk for hospitalization
   b. Increased fracture risk
   c. Decreased quality of life
   d. Increased risk for mortality
   e. Increased risk for left ventricular hypertrophy

3. The primary site of endogenous erythropoietin production in children is:
   a. Hepatocytes
   b. Renal tubular epithelial cells
   c. Erythroid progenitor cells in bone marrow
   d. Peritubular fibroblasts in the renal cortex
   e. Juxtaglomerular apparatus

4. Which is the primary physiologic stimulus for increased EPO gene expression?
   a. Hypoxia
   b. Anemia
   c. Increased distal tubular sodium reabsorption
   d. Uremia
   e. Decrease in blood pressure

5. Iron-restricted erythropoiesis can include:
   a. Absolute iron deficiency
   b. Depletion of accessible iron stores by ESA-stimulated bone marrow
   c. Inflammation-associated impairment in iron trafficking
   d. a and b only
   e. a, b, and c

6. Children receiving ESA therapy should receive iron supplementation as indicated to maintain:
   a. Ferritin greater than 50 ng/mL and transferrin saturation greater than 20%
   b. Ferritin greater than 100 ng/mL and transferrin saturation greater than 10%
   c. Ferritin greater than 100 ng/mL and transferrin saturation greater than 20%
   d. Ferritin greater than 500 ng/mL and transferrin saturation greater than 30%
   e. Ferritin greater than 100 ng/mL and transferrin saturation greater than 30%

7. All of the following are possible indications for IV iron administration *except:*
   a. Poor enteral iron absorption
   b. Poor adherence to oral iron supplementation regimen
   c. Long-term hemodialysis status
   d. Active systemic infection
   e. ESA hyporesponsiveness

8. Short-acting recombinant human erythropoietin formulations have longer half-lives and are more effective when administered:
   a. Subcutaneously
   b. Intravenously
   c. Enterally
   d. Peritoneally
   e. With hemodialysis

9. Potential advantages of darbepoetin alfa compared with short-acting recombinant human erythropoietin include:
   a. Longer interval between doses
   b. Improved adherence
   c. Decreased pain with administration
   d. a and b only
   e. a, b, and c

10. The goal rate of hemoglobin increase after initiation of an ESA is:
    a. 1 to 2 g/dL per week
    b. 1 to 2 g/dL per month
    c. 1 to 2 g/dL over 3 months
    d. Increase to goal hemoglobin of 11 g/dL over 1 month
    e. Increase to goal hemoglobin of 12 g/dL over 3 months

Chronic kidney disease bone and mineral disorder

KATHERINE WESSELING-PERRY AND ISIDRO B. SALUSKY

Childhood and adolescence are a crucial time for developing a healthy skeletal and vascular system; alterations in bone modeling and remodeling, or vascular biology in youth carry consequences that severely affect quality of life as well as life span. In childhood, chronic kidney disease (CKD) causes disordered regulation of mineral metabolism with subsequent alterations in bone modeling, remodeling, and growth. These alterations occur early in the course of CKD and, in addition, are associated with the development of cardiovascular calcifications. Because growth failure and short stature are clinically apparent and concerning to patients, families, and physicians alike, optimization of growth and final adult height has been a focus of CKD management in children for decades. However, cardiovascular disease is the leading cause of mortality in both adults and children with kidney disease and abnormal mineral metabolism, bone disease, and its therapies are closely linked to cardiovascular pathologic processes. Together, these alterations are termed CKD mineral and bone disorder (CKD-MBD).[1]

CKD-MBD is defined as a systemic disorder of mineral and bone metabolism resulting from CKD that manifests as either one or a combination of the following: (1) abnormalities of calcium, phosphorus, parathyroid hormone (PTH), or vitamin D metabolism; (2) abnormalities in bone histology, linear growth, or strength; and (3) vascular or other soft tissue calcification. Fibroblast growth factor 23 (FGF23), a recently characterized hormone produced in the bone, has been defined as a key regulator of mineral metabolism and cardiovascular disease in the context of CKD-MBD. *Renal osteodystrophy* is the specific term used to describe the bone pathologic process that occurs as a complication of CKD and is therefore one aspect of the CKD-MBD. Although the definitive evaluation of renal osteodystrophy requires a bone biopsy, this procedure is not routinely performed in the clinical setting. However, bone histomorphometry continues to be the gold standard for the assessment of three essential aspects of bone histology: turnover, mineralization, and volume.[1]

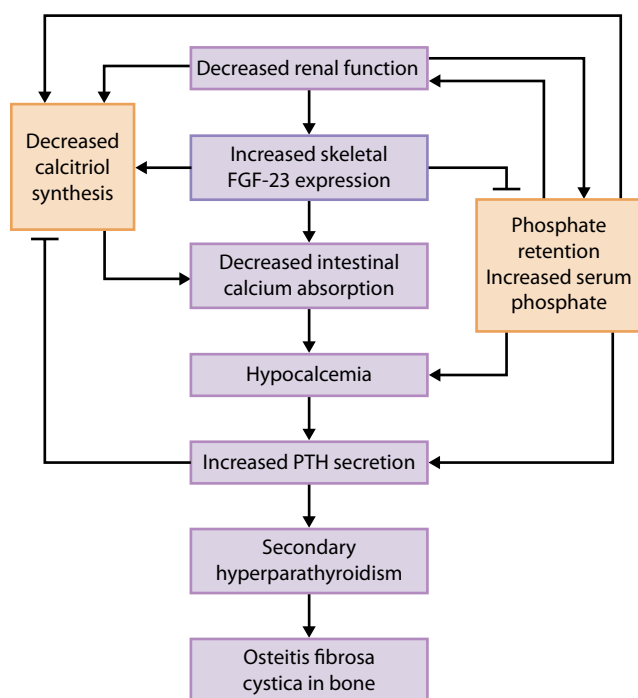
KEY POINTS

- CKD-MBD is a systemic disorder resulting from CKD that has findings in bone as well as in vascular and other soft tissues.
- Renal osteodystrophy is the bone pathologic process of CKD and therefore is one aspect of CKD-MBD.

PATHOGENESIS OF SECONDARY HYPERPARATHYROIDISM

Hyperparathyroidism and bone disease associated with CKD are the results of numerous underlying pathophysiologic derangements in mineral metabolism. Although the presence of secondary hyperparathyroidism in CKD has been well known, recent discoveries have shed a new light on its pathogenesis.

ROLE OF FIBROBLAST GROWTH FACTOR 23

As early as stage 2 CKD (glomerular filtration rate [GFR] between 60 and 90 mL/1.73 m²/min), circulating levels of FGF23 begin to rise in adults and children (Figure 33.1).[2,3] Increased levels of FGF23 are due to a combination of its decreased renal excretion, changes in degradation, and increased osteocytic production.[4-6] The cause of increased osteocytic FGF23 expression has not been completely defined. Whereas oral phosphate loading stimulates FGF23 production, serum phosphorus levels remain within the normal range or are slightly diminished in the early CKD stages and phosphate balance is neutral in patients with CKD stages 3 to 4.[7,8] Therefore, mechanisms other than hyperphosphatemia have been suggested to cause elevated circulating FGF23 levels in CKD. These phosphate-independent mechanisms for


stimulation of FGF23 production include a decrease in the expression of membrane-bound Klotho (a co-receptor for FGF23 signaling), iron deficiency–mediated stimulation of FGF23 transcription, increased levels of cleaved αKlotho, a potent stimulator or FGF23 production, and a state of chronic inflammation seen in CKD.[9-12]

> ### KEY POINTS
>
> - FGF23 is a key phosphaturic agent (like PTH).
> - FGF23 acts by reducing the renal expression of phosphate cotransporters: NaPi2a and NaPi2c.
> - Increases in circulating FGF23 levels are the earliest serologic indication of osteocyte dysfunction in CKD.
> - FGF23 is a key regulator of mineral metabolism and cardiovascular disease in patients with CKD.

Early increases in FGF23 may be the first sign of altered osteocyte function in CKD.[6,13,14] Later in the course of CKD, increasing serum phosphorus and PTH, decreasing renal FGF23 excretion, and active vitamin D sterol therapy are likely to further increase circulating FGF23 levels.[4,7,15,16] The effects of increasing FGF23 on mineral metabolism are profound. Of these, its most prominent impact is on increasing renal phosphate excretion (phosphaturic action) by (1) reducing the expression of renal phosphate cotransporters NaPi2a and NaPi2c, (2) suppressing renal 1α-hydroxylase activity, and (3) stimulating 24-hydroxylase leading to enhanced metabolism of the biologically active 1,25-dihydroxyvitamin D (1,25[OH]$_2$D).[17]

With progression of CKD, rising serum FGF23 values result in a decline in circulating 1,25(OH)$_2$D levels, leading to an inverse relationship of circulating 1,25(OH)$_2$D levels and FGF23.[13] Available evidence suggests that FGF23 also may regulate PTH secretion. In vitro and in vivo experiments indicate that FGF23, by activating the mitogen-activated protein kinase (MAPK) pathways in the parathyroid gland, also directly suppresses through PTH release (Figure 33.2).[15,18]

ROLE OF 1,25-DIHYDROXYVITAMIN D

In CKD, reduced circulating 1, 25(OH)$_2$ D contributes to secondary hyperparathyroidism and parathyroid gland hyperplasia through the following ways:

- Decreased intestinal calcium absorption
- Decreased 1,25(OH)$_2$D binding to the vitamin D receptor (VDR)
- Decreased VDR expression
- Reduced calcium-sensing receptor (CaSR) expression

Figure 33.1 Diagrammatic representation of pathogenesis of renal osteodystrophy.
Figure 33.2 Regulatory mechanisms among bone, kidney, parathyroid gland, and gut. Fibroblast growth factor 23 (FGF23), 1,25-dihydroxyvitamin D$_3$, and parathyroid hormone (PTH) regulate each other's expression and secretion and thereby balance mineral ion homeostasis. FGFR, fibroblast growth factor receptor; PTHR, parathyroid hormone receptor; RXR, retinoid-X receptor; VDR, vitamin D receptor. (Redrawn and adapted from concepts in: Lanske B, Densmore MJ, Erben RG. Vitamin D endocrine system and osteocytes. Bonekey Rep. 2014;3:494. doi: 10.1038/bonekey.2013.228. eCollection 2014.)

Administration of 1,25(OH)$_2$D has been shown to suppress *PTH* gene transcription, both in vitro (bovine parathyroid cell culture) and in vivo (intact rats), and to also increase FGF23 production. In conjunction with the VDR, 1,25(OH)$_2$D binds vitamin D response elements in the parathyroid glands that inhibit pre-proPTH gene transcription.[19,20] 1,25(OH)$_2$D administration also appears to increase the number of VDRs in the parathyroid glands in a dose-dependent manner. The number of receptors for calcitriol in parathyroid glands appears to be reduced in animals and humans with CKD, when compared to either patients undergoing renal transplantation or patients with primary hyperparathyroidism.[21–23] In a positive feedback loop, 1,25(OH)$_2$D itself increases *VDR* gene expression in the parathyroid glands, further suppressing *PTH* gene transcription.[24]

1,25(OH)$_2$D$_3$ also increases the expression of the CaSR, the expression of which has been documented to be reduced in hyperplastic parathyroid tissues obtained from patients with secondary hyperparathyroidism.[25] Also, 1,25(OH)$_2$D deficiency in animals is associated with decreased expression of CaSR mRNA (CAR) in parathyroid tissue, whereas 1,25(OH)$_2$D$_3$ therapy increases CAR expression in a dose-dependent manner.[26] Calcitriol also may directly modulate parathyroid cell proliferation by altering the expression of specific replication-associated oncogenes, such as c-*myc* and c-*phos* proto-oncogenes.[27] Thus, low levels of calcitriol may allow parathyroid cells to proliferate while the administration of calcitriol suppresses proliferation of parathyroid cells. It is important to keep in mind, however, that studies in VDR knockout mice have shown that if serum concentrations of calcium and phosphorus are normalized by the use of a rescue diet, parathyroid hyperplasia does not occur.[28,29] Interestingly, it also has been shown that 1,25(OH)$_2$ vitamin D may be important in renal tissue fibrosis. Reductions in 1,25(OH)$_2$ vitamin D levels may prevent or reduce the development of renal tissue fibrosis through a non–VDR dependent mechanism.[30]

ROLE OF 25-HYDROXYVITAMIN D

Deficiency of 25(OH) vitamin D (25[OH]D) results from multiple factors in patients with CKD. Many are chronically ill, with little outdoor (sunlight) exposure. CKD dietary restrictions, particularly of dairy products, curtail the intake of vitamin D–rich food and lead to decreased dietary calcium intake.[31] Patients with CKD (particularly those with darker skin pigment) display decreased skin synthesis of vitamin D$_3$ in response to sunlight compared with individuals with normal kidney function.[32,33] Proteinuric diseases further exacerbate D deficiency in the CKD population as a result of urinary loss of 25(OH)D bound to vitamin D binding protein.[34,35]

Data also suggest that catabolism of 25(OH)D through 24-hydroxylase is increased in CKD and may play an important role in the development and maintenance of

(25[OH]D) deficiency state.[36] Low levels of 25(OH)D also contribute to the development of secondary hyperparathyroidism—both directly and through limiting the substrate for the formation of 1,25(OH)$_2$D. Apart from its conversion to 1,25(OH)$_2$D$_3$, 25(OH)D also may directly affect tissues. For example, supplementation with ergocalciferol has been shown to decrease serum PTH levels and to delay the development of secondary hyperparathyroidism in patients with CKD.[37–40] Furthermore, 1α-hydroxylase activity is present in the parathyroid glands and 25(OH)D is converted within the gland to 1,25(OH)$_2$D$_3$, resulting in PTH supression.[40] By itself, 25(OH)D administration also suppresses PTH synthesis, even when parathyroid gland 1α-hydroxylase is inhibited, indicating that 25(OH)D may directly contribute to PTH suppression.[40] Low levels of 25(OH)D may exacerbate secondary hyperparathyroidism in the context of CKD. Therefore, prevention of vitamin D deficiency has been advocated in early CKD.

ROLE OF PHOSPHORUS

Even though hyperphosphatemia usually manifests only in late stages of CKD, phosphorus retention and hyperphosphatemia are important triggers in the pathogenesis of secondary hyperparathyroidism. Development of secondary hyperparathyroidism is prevented in experimental animals with CKD when dietary phosphorus intake is lowered in proportion to the GFR.[41] Dietary phosphate restriction also can reduce previously elevated serum PTH levels in patients with moderate renal failure, and aggressive phosphate control in uremic rats not only decreases PTH and FGF23 but also decreases renal fibrosis, left ventricular hypertrophy, and overall mortality.[42–44]

Phosphorus retention and hyperphosphatemia indirectly promote the secretion of PTH in several ways. In the context of hyperphosphatemic, inorganic phosphorus complexes with calcium and lowers serum levels; the ensuing hypocalcemia stimulates PTH release. Phosphorus also enhances the secretion of FGF23, thereby impairing renal 1α-hydroxylase activity, which diminishes the conversion of 25(OH)D to 1,25(OH)$_2$D$_3$.[7] Finally, phosphorus can directly enhance PTH synthesis by decreasing cytosolic phospholipase A2 (normally increased by CaSR activation), leading to a decrease in arachidonic acid production and enhancing PTH secretion.[45] Hypophosphatemia also decreases PTH mRNA transcript stability in vitro, suggesting that phosphorus itself affects serum PTH levels, probably by increasing the stability of the PTH mRNA transcript.[46]

CALCIUM-SENSING RECEPTOR EXPRESSION

Alterations in parathyroid gland *CAR* expression occur in secondary hyperparathyroidism and contribute to parathyroid gland hyperplasia. The CaSR is a seven-transmembrane G protein-coupled receptor with a large extracellular N-terminus, which binds acidic amino acids and divalent cations.[47] Low extracellular calcium levels result in decreased calcium binding to the receptor, a conformational relaxation of the receptor and a resultant increase in PTH secretion, while activation of the receptor by high levels of serum calcium decrease PTH secretion.[48,49] The expression of the CaSR in hyperplastic parathyroid tissue obtained from patients with renal failure is reduced by 30% to 70%, using immunohistochemical techniques.[25,50]

CAR transcription is regulated by vitamin D through two distinct vitamin D response elements in the gene's promoter region. Alterations in vitamin D metabolism in renal failure can account for changes in calcium sensing by the parathyroid glands, and vitamin D may act upstream of *CAR* in preventing parathyroid cell hyperplasia.[51,52] Decreased expression and activity of the CaSR have been linked to decreased responsiveness in PTH secretion to altered calcium levels.[53] Consequently, decreased expression of the CaSR results in an insensitivity to serum calcium levels with subsequent uncontrolled secretion of PTH. Increased stimulation of the CaSR by calcimimetics has been shown to decrease PTH cell proliferation, implicating the CaSR as a regulator of cell proliferation, as well as PTH secretion.[54]

ROLE OF SKELETAL RESISTANCE TO PARATHYROID HORMONE

Resistance of the skeleton to the hypercalcemic action of PTH is another potential cause of hyperparathyroidism in patients with renal insufficiency (Figure 33.3). It has been demonstrated that the increase in serum calcium in response to infusion of PTH is significantly less in patients with renal failure than in healthy subjects.[55,56] Although the actions of different fragments of the PTH molecule are still uncharacterized, in vitro and in vivo experimental data indicate that one or more amino-terminally truncated PTH(1-84)
Figure 33.3 Parathyroid hormone (PTH) levels corresponding to high and normal to low turnover bone histology in different stages of chronic kidney disease (CKD). BFR, bone formation rate; 1st PTH-IMA, first-generation immunometric assay; 2nd PTH-IMA, second-generation immunometric assay. See text for details.

fragments antagonize the calcemic actions of PTH(1-84) and diminish bone cell activity, and may, therefore, modulate bone metabolism. Synthetic PTH(7-84), which appears to be similar to naturally occurring circulating amino-terminally truncated PTH fragments, inhibits the formation of tartrate-resistant acid phosphatase (TRAP)-positive bone resorbing cells in vitro and inhibits bone formation in vivo.[57–59]

Nguyen-Yamamoto et al.[60] and Slatopolsky et al.[61] demonstrated that PTH(7-84), with or without a mixture of other carboxyl-terminal PTH-fragments, inhibits the calcemic effect of PTH(1-34) in vivo, indicating that these actions are not mediated through the PTH/PTHrP receptor, but instead via a receptor that interacts only with carboxyl-terminal portions of PTH. In humans, Wesseling-Perry et al.[56] demonstrated that dialysis patients with hyperparathyroid bone disease secondary to increased levels of PTH(1-84), also have increased circulating levels of PTH(7-84) and are resistant to the calcemic actions of PTH(1-34). Thus, a growing body of evidence suggests that at least some of the different carboxyl-terminal PTH fragments have biological activity and circulating amino-terminally truncated PTH fragments may play a role in the skeletal resistance to the full-length PTH molecule.

KEY POINTS

- Some carboxyl-terminal PTH fragments have biological activity.
- Circulating amino-terminally truncated PTH fragments may play a role in skeletal resistance to the full-length PTH molecule.
- First-generation immunoassays for PTH measures not only intact PTH but also some of the fragmented PTH molecules, as well (amino-terminus truncated). These assays overestimate PTH by 40% to 50%.
- Second-generation immunoassays for PTH do not detect large PTH fragments. Clinical application of this finding is still unclear.

Over the last few years, a series of observations have highlighted important shortcomings of the first-generation immunometric assays (IMA) for measuring PTH (1st PTH-IMA). Studies by D'Amour et al.[62–64] demonstrated that 1st PTH-IMAs detect not only the intact PTH molecule but also additional PTH fragments truncated at the amino terminus. Indeed, most of the detection antibodies, which are usually directed against epitopes within the amino terminus of the hormone, detect not only PTH(1-84) but also one or several amino-truncated fragments of the PTH molecule, some of which coelute from reverse-phase high-performance liquid chromatography column with synthetic PTH(7-84).[63] By contrast, second-generation immunometric PTH assays (2nd PTH-IMAs) use detection antibodies that interact with epitopes comprising the first four amino

terminal amino acids of human PTH and thus recognize only PTH(1-84) and possibly PTH fragments that are truncated at the carboxyl terminus or modified within the 15 to 20 region, but not PTH(7-84).[48,61,65] PTH levels determined by 1st PTH-IMA overestimate the concentration of PTH(1-84) by 40% to 50% in both healthy individuals with normal renal function and those with varying degrees of CKD.[62,63] Unlike 1st PTH-IMAs, the 2nd PTH-IMAs do not detect these large PTH fragments.[48,61,65–67]

Monier-Faugere et al.[66] suggested that 2nd PTH-IMA and, mainly, the ratio between PTH(1-84) and amino-truncated PTH fragment (calculated from the differences in PTH levels determined between 1st and 2nd PTH-IMAs) could be a better predictor of bone turnover than 1st PTH-IMA. However, these findings were not confirmed by subsequent investigations and available data do not support the claim that 2nd PTH-IMAs provide an advantage over 1st PTH-IMAs for the diagnosis of the different subtypes of renal bone diseases.[67,68] Furthermore, the variation in PTH assays across manufacturers makes interpretation of their values and their relationships to bone turnover difficult to assess. More recently, discrimination of nonoxidized from oxidized forms of PTH has been shown to not only discriminate between active and inactive forms of the molecule but also predict adverse outcomes in dialysis patients.[69] These assays are not currently available for clinical practice, and their value as predictors of the different subtypes of renal osteodystrophy as well as the response to therapeutic interventions remains to be defined. Current guidelines suggest that PTH values, as determined by current commercially available assays, be maintained within a broad range—between two and nine times the range for individuals with normal renal function—in patients treated with maintenance dialysis.[70]

KEY POINT

Current guidelines suggest that in patients on dialysis therapy, PTH values, as determined by current commercially available assays, be maintained within a broad range—between two and nine times the range for individuals with normal renal function.

CONSEQUENCES OF ABNORMAL MINERAL METABOLISM IN CHRONIC KIDNEY DISEASE

BONE DISEASE

Renal bone disease is a common complication of CKD and is nearly universal at the start of dialysis therapy. Whereas the term *CKD-MBD* refers to the alterations in mineral

(a)

(b)
Figure 33.4 Bone histology, osteitis fibrosa. **(a)** Under light microscopy, increases in cellular activity, osteoid accumulation, erosion, and fibrosis are visible. **(b)** An increase in double tetracycline labeling signifies an increase in bone turnover rate.

metabolism and the effects on both the cardiovascular and skeletal systems in the CKD population, the term *renal osteodystrophy* is used specifically to describe the bone pathologic processes defined by bone histomorphometry that occur as a complication of CKD.[70]

BONE TURNOVER

Traditionally, the lesions of renal bone disease have been characterized according to alterations in bone turnover, ranging from high bone turnover (secondary hyperparathyroidism, osteitis fibrosa) to lesions of low bone turnover (adynamic bone disease and osteomalacia). However, alterations in skeletal mineralization and volume are also common in pediatric patients in CKD[71] and may contribute to outcomes such as fractures, skeletal deformities, and poor growth that persist despite normalization of bone turnover.[72] Bone histomorphometry is the gold standard for the diagnosis of different types of bone diseases associated with CKD, providing measures of bone turnover, mineralization, and volume, and all may be altered in patients with CKD, occurring concomitantly with alterations in circulating levels of PTH, calcium, phosphorus, 1,25D, 25(OH)D, and FGF23.[70]

Abnormalities in bone turnover, driven by circulating PTH concentrations, are prevalent in both adult and pediatric patients with advanced stages of CKD.[73,74] PTH activates the PTH/PTHrP receptor on osteocytes and osteoblasts, thereby directly increasing the cellular activity of osteoblasts and, indirectly, the activity of osteoclasts.[75–77] Elevated bone turnover is evident in patients with moderate-to-advanced stages of CKD, although a substantial proportion of adults with CKD stages 2 to 4 have low bone turnover.[71,79] With progression of CKD, skeletal resistance to PTH develops secondary to multiple factors that include accumulation of circulating PTH fragments and down-regulation of the PTH receptor. At the same time, elevated circulating levels of PTH result in increased resorption of

bone matrix and release of mineral into the circulation.[55,80] Prolonged exposure to elevated PTH levels and increases in bone turnover may lead to peritrabecular fibrous changes in bones. This form of renal osteodystrophy associated with prolonged secondary hyperparathyroidism is often termed *osteitis fibrosa cystica* (Figure 33.4).[73]

A state of low-turnover bone disease (adynamic renal osteodystrophy) defined as decreased bone formation rate in conjunction with decreased cellular activity and an absence of excessive osteoid accumulation, is most common in adult dialysis patients (Figure 33.5). This condition may occur, especially in children treated with maintenance dialysis, as a result of overly aggressive therapy with active vitamin D sterols and calcium salts. In addition to the increased risk for fractures and vascular calcifications observed in adults with adynamic bone, this form of bone disease in children treated with dialysis is associated with a further decline in growth.[80,81]
Figure 33.5 Bone histology, adynamic bone. Under light microscopy, decreased cellular activity with minimal osteoid accumulation. Very little or no double tetracycline labeling (not shown) signifies a decrease in bone turnover rate.

Although bone turnover is undoubtedly affected by changes in circulating PTH in advanced CKD, data from animals and humans suggest that changes in bone turnover occur before alterations in circulating mineral, PTH, or vitamin D concentrations are apparent and that these changes are mediated in large part by alterations in osteocyte biology.[6,77,82] Lund et al.[82] demonstrated that renal ablation in mice resulted in low bone turnover if circulating levels of calcium, phosphate, $1,25(OH)_2D$, and PTH were kept constant, suggesting that some changes in bone turnover, particularly in early CKD, are independent of measurable changes in divalent ion homeostasis.[82] Subsequently, Sabbagh et al.[77] demonstrated similar findings in *Jck* mice, in whom increased osteocytic sclerostin expression was related to changes in bone turnover with progressive CKD.[77] Indeed, sclerostin is an inhibitor of Wnt signaling–mediated bone turnover and its increased expression results in suppression of bone formation and the development of adynamic bone in early stages of CKD.[77] PTH, on the other hand, suppresses sclerostin expression, and, in moderate-to-severe CKD, a rising PTH level inhibits skeletal sclerostin expression, allowing bone formation rates to rise.[77,78]

BONE MINERALIZATION

As discussed earlier, renal osteodystrophy traditionally has been defined by lesions in bone turnover; however, alterations in skeletal mineralization are also prevalent in children with CKD.[69,78] Increases in unmineralized bone (osteoid) in conjunction with delayed rates of mineral deposition are common. Defective mineralization that is associated with low to normal bone turnover is termed *osteomalacia*. The histomorphometric characteristics of osteomalacia include (1) the presence of wide osteoid seams, (2) an increased number of osteoid lamellae, (3) an increase in the trabecular surface covered with osteoid, and (4) a diminished rate of mineralization or bone formation, as assessed by double tetracycline labeling. Fibrosis is often absent. Defective mineralization in combination with increased bone formation rates is termed *mixed uremic osteodystrophy* and is characterized by wide osteoid seams, prolonged mineralization times, bone marrow fibrosis, and increased bone formation rates.[70] Patients with mixed lesions often display high serum PTH and alkaline phosphatase levels along with lower serum calcium levels.[74]

Although the mechanisms of skeletal mineralization are incompletely understood, factors such as 25(OH)D deficiency and altered FGF23 metabolism have been implicated in their pathogenesis. In the general population, nutritional 25(OH)D deficiency results in osteomalacia and a similar phenotype may occur in patients with CKD. Phosphate depletion, as may occur with frequent dialysis, also may result in osteomalacia. FGF23 may play a role; both overexpression[84–86] and ablation[87,88] of FGF23 in mice with normal renal function are associated with abnormal mineralization of osteoid, although by different mechanisms. The phosphaturic effect of increased FGF23 may cause rickets and osteomalacia through an insufficiency of mineral substrate.

The mechanisms leading to impaired mineralization in FGF23-null animals, which have severe hyperphosphatemia and normal or elevated serum calcium levels, remain uncertain; however, osteomalacia in these animals suggests that FGF23 may play a direct role in skeletal mineral deposition. Although the ramifications of defective mineralization remain to be established, increased fracture rates and bone deformities are prevalent in patients with CKD despite adequate control of bone turnover.[72,89] These complications may be due, in part, to alterations in bone mineralization.

BONE VOLUME

Because PTH is anabolic at the level of trabecular bone, high levels of serum PTH are typically associated with increases in bone volume, trabecular volume, and trabecular width. However, bone volume also may be low (termed *osteoporosis*), particularly in individuals with underlying age-related bone loss or in those treated with corticosteroids. Low bone volume is rare in the pediatric CKD population.[74]

EXTRASKELETAL CALCIFICATION

The association between extraskeletal calcifications and CKD has been known for many years,[90] but the link between the two has been clearly defined over the last decade. Currently, vascular calcification is included as part of the definition of CKD-MBD. These lesions have their origins in CKD before dialysis and are also common in childhood CKD (Figure 33.6).[91–93] The mortality rate in adults and children with CKD is markedly higher than that in the general population, and cardiovascular disease is the leading cause of death in this patient population.[94]
Figure 33.6 Coronary artery calcification scores in 39 children and young adults with end-stage renal disease who were treated by dialysis, according to age. Coronary artery calcification was assessed by electron-beam computed tomography. (Reprinted with permission from: Goodman WG, Goldin J, Kuizon BD, et al. Coronary-artery calcification in young adults with end-stage renal disease who are undergoing dialysis. N Engl J Med. 2000;342:1478–3).

In contrast to the calcified atherosclerotic plaques that develop in the vascular intima with the aging process, uremia facilitates calcification of the tunica media. This form of calcification is associated with decreased distensibility of blood vessels, causing a rigid "lead pipe" pathologic finding that is associated with increased risk for congestive heart failure.[95] Electron beam computed tomography (EBCT), used in the assessment of vascular calcifications in the adult population, and measurements in adults with CKD as well as in young adults who were treated with maintenance dialysis as children have demonstrated that a significant proportion of this population has evidence of vascular calcification.[91] Carotid ultrasound measurement of intimal medial thickness has also been validated for the assessment of cardiovascular pathologic processes in adults and children, with increased thickness being associated with worsening disease.[96,97]

Osteoblasts and vascular smooth muscle cells have a common mesenchymal origin, and vascular tissues in the uremic milieu express osteoblast differentiation factors.[98,99] Core binding factor-1 (Cbfa1; also known as Runx1) is thought to trigger transformation of mesenchymal cell to osteoblasts, and arteries obtained from patients with end-stage renal disease show increased levels of this protein.[98] Upregulation of the sodium-dependent phosphate transporter PIT-1 likely also contributes to increased calcification, and upregulation of promineralization factors such as osteopontin, bone sialoprotein, osteonectin, alkaline phosphatase, type I collagen, and bone morphogenic protein-2 (BMP-2) is potentiated by the uremic milieu.[100–104] By contrast, expression of calcification inhibitors, such as fetuin A, matrix Gla protein, and Klotho, is suppressed.[105–108]

Hypercalcemia, hyperphosphatemia, elevated levels of the calcium-phosphorus ion product, and high doses of vitamin D sterols have been implicated in the pathogenesis of cardiovascular calcification.[91,92] However, as many as 40% of adult patients with CKD stage 3—patients with normal circulating calcium and phosphorus concentrations—have evidence of vascular calcification, suggesting that other factors in the context of CKD contribute to this process.[109,110] Increased circulating levels of FGF23 levels have been implicated in increased cardiovascular mortality in adult dialysis patients.[111] Whether FGF23 contributes to cardiovascular calcification itself remains controversial, but current data suggest a role for the hormone in the development of left ventricular hypertrophy.[111–114] Klotho, the cofactor necessary for mediating the actions of FGF23 on phosphate homeostasis, also has been implicated in vascular calcification. Animals lacking the Klotho gene display elevated levels of phosphorus, 1,25(OH)$_2$D and consequently serum calcium, along with vascular calcification and features of premature aging. CKD is associated with low circulating levels of Klotho, which have been implicated in vascular dysfunction.[109] Because of the complex interplay among calcium, phosphorus, vitamin D, FGF23, and PTH, the contribution of PTH levels to cardiovascular disease and mortality remains controversial.[115]

The pathophysiology of cardiovascular disease in CKD is multifactorial, and thus treatment strategies are also multifaceted and vary according to stage of CKD. Therapies that are effective in early CKD may not be effective in later stages. Lipid-lowering agents decrease mortality in adults with pre-dialysis CKD and in those with stable renal allografts but have not been shown to benefit patients treated with dialysis.[116–118] By contrast, normalization of mineral metabolism (by avoiding hypercalcemia and hyperphosphatemia, limiting calcium intake, and avoiding adynamic bone) is effective at slowing the progression of cardiovascular calcification in patients with CKD and those treated with maintenance dialysis.[119–121] Furthermore, the use of calcium-free binders is associated with a slowing of progression in vascular calcification scores. A recent meta-analysis of clinical trials comparing the long-term consequences of calcium-based binders versus non–calcium-based demonstrated an advantage with the use of calcium-free binders on cardiovascular disease, vascular calcifications, and mortality in patients with CKD.[119,121]

Although high levels of FGF23 have been associated with vascular calcification and mortality, it is unknown whether early control of FGF23 levels, as with the use of phosphate binders in early CKD, might lead to improvements in cardiovascular health.[122–125] Treatment with vitamin D sterols has been associated with improved survival in dialysis patients,[126–129] despite elevated FGF23 levels.[16] Calcimimetic therapy, on the other hand, may provide an additional option for the reduction of PTH, FGF23, and cardiovascular disease. Decreases in parathyroid gland hyperplasia, bone disease, and vascular calcification were found in rodents with renal failure who were treated with calcimimetics.[129–131] Early case reports suggested that calcimimetic therapy also could reduce vascular calcification burden in dialysis patients.[132] A recent prospective trial in 3883 adults with advanced secondary hyperparathyroidism (the EVOLVE trial), however, failed to demonstrate a beneficial effect of calcimimetics on either cardiovascular events or on mortality.[133]

It is critical to monitor the consequences of the vascular calcification process in view of the observations that cardiovascular disease remains the leading cause of death across the spectrum of CKD, including in the dialysis and renal transplant populations. At different stages of CKD, the relative importance of individual risk factors, the value of different biomarkers, and the consequences of the different therapeutic interventions may vary.

GROWTH RETARDATION

Growth retardation is the hallmark of CKD in children. Growth failure worsens as renal function declines; the average height of children with even mild CKD (GFR 50 to 70 mL/min/1.73 m^2) is 1 standard deviation (SD) below the average for healthy children. Moderate CKD (GFR 25 to 49 mL/min/1.73 m^2) is associated with a height SD of –1.5, and, at the time of initiation of dialysis, the mean height SD

is −1.8. Boys, younger patients, and those with prior renal transplants are at greatest risk for growth failure.[134]

Acidosis has been linked to delayed linear growth in patients with renal tubular acidosis and normal renal function, and its correction often leads to acceleration in growth velocity.[135] Acidotic rats have been found to have decreased growth hormone secretion, serum insulin-like growth factor 1 (IGF-1), and hepatic IGF-1 mRNA expression. Moreover, metabolic acidosis has been shown to inhibit the effects of growth hormone in rats with normal and decreased renal function.[136,137] Growth plate mRNA levels of growth hormone receptor, the IGF-1 receptor, and IGF-1 are downregulated, and IGF-binding proteins are upregulated.[138]

Calcitriol deficiency, secondary hyperparathyroidism, and bone deformities also contribute to growth retardation; however, the optimal target values for PTH in children at all stages of CKD that will maximize growth remain controversial. In children with moderate CKD, some data indicate that normal growth velocity is achieved when PTH levels are maintained within or close to the normal range[139]; others have demonstrated a linear correlation between growth and PTH levels in the same patient population, with those with the highest PTH values displaying the highest growth velocity.[138] Treatment for secondary hyperparathyroidism with large, intermittent doses of calcitriol and calcium-based phosphate binders has been shown to reduce bone formation and suppress osteoblastic activity in both adults and children.[16,141] However, adynamic bone disease may develop and linear bone growth decrease, despite serum PTH levels in the range recommended by the Kidney Disease Outcomes Quality Initiative[142,143] during intermittent vitamin D sterol therapy. Maintaining serum PTH levels between 300 and 500 pg/mL reduces the frequency of these complications, but whether it will have an effect on final height is not known.[16]

The predominant factor leading to growth retardation has not been defined yet, but one commonly used medication, calcitriol, exerts dose-dependent inhibitory effects on cell proliferation of chondrocytes and osteoblasts in vitro. In addition, vitamin D sterols increase expression of a number of IGF binding proteins (IGFBPs). IGFBP-2, -3, -4, and -5 sequester IGF-1 and may exert IGF-1–independent antiproliferative effects through their own receptors.[144]

Growth hormone resistance contributes to impaired linear growth in renal failure. In CKD, poor growth develops despite normal or increased serum growth hormone levels.[145] Uremia has been associated with diminished hepatic growth hormone receptor and IGF-1 mRNA expression, defects in postreceptor growth hormone–mediated signal transduction,[146] reductions in serum growth hormone binding protein levels,[150] and increased synthesis and reduced clearance of IGF binding proteins.[147] Improved growth velocity during recombinant human growth hormone (rhGH) therapy has been ascribed to increased bioavailability of IGF-1 to target tissues. Children who are treated with maintenance dialysis respond less well to rhGH therapy than do children with less severe CKD; the mechanisms for differences in response to growth hormone therapy remain to be determined. Notably, also, bone formation rate increases out of proportion to changes in PTH values during treatment with rhGH, complicating the noninvasive assessment of renal osteodystrophy during therapy.[148] Thus, although growth hormone is effective in improving final height in early CKD stages, the effects are markedly diminished in dialyzed patients and after renal transplantation.

CARDIOVASCULAR DISEASE

Cardiovascular disease is the most common cause of mortality in patients with all stages of CKD, with young (i.e., 20 and 30 year old) dialysis patients displaying the same rates of mortality from cardiovascular disease as 80-year-old individuals in the general population.[149] Cardiovascular disease is not limited to adults, but is also common in children with CKD. In addition to traditional risk factors for cardiovascular disease (i.e., hypertension and smoking) found in the general population, risk factors for vascular disease in predialysis CKD and dialysis patients include hypercalcemia, hyperphosphatemia, elevated levels of the calcium-phosphorus ion product, and treatment with high doses of calcium salts and vitamin D sterols. However, 40% of adult patients with stage 3 CKD, without these known risk factors, show evidence of vascular calcification and changes in carotid artery wall thickness are apparent in children as early as CKD stage 2.[97,110]

KEY POINTS

- The causes of growth retardation in childhood CKD are multifactorial.
- Growth hormone levels are normal in CKD.
- Growth hormone resistance is seen in patients with CKD.
- Diminished hepatic growth hormone receptors and decreased IGF-1 mRNA expression are common in CKD.
- Pharmacotherapy with rhGH increases bioavailability of IGF-1.
- Response to rhGH is better in children with predialysis CKD than in children who are on dialysis.

KEY POINTS

- Cardiovascular disease is the leading cause of death in CKD.
- Uremia facilitates calcification of the tunica media of the arteries, decreasing distensibility of the vessels, also known as a "lead pipe" pathologic finding.

In contrast to the calcified atherosclerotic plaques that develop in the vascular intima of aging individuals with normal kidney function, uremia facilitates calcification of the tunica media. This form of calcification is associated with decreased distensibility of blood vessels, causing a rigid "lead pipe" pathologic finding that is associated with increased risk for congestive heart failure.[150] EBCT is used in assessment of vascular calcifications in the adult population, and measurements in young adults who were treated with maintenance dialysis as children demonstrated that a significant proportion of this population has evidence of vascular calcification.[93] Carotid ultrasound measurement of intima medial thickness has been validated for the assessment of cardiovascular pathologic processes in children, with increased thickness associated with worsening disease.[97] The prevalence of vascular changes in children with early CKD—patients who not only lack the mineral metabolism-associated risk factors common in the dialysis population but who also lack traditional adult risk factors such as obesity, diabetes, hypertension, and smoking[97]—suggest that factors unique to CKD and independent of circulating mineral content contribute to vascular disease.

The pathophysiology of vascular calcification in patients with CKD differs from that observed in the general population, although the mechanisms by which vascular calcifications develop remain to be fully elucidated. In atherosclerotic plaques, calcium deposition is observed primarily in the intima and vascular deposition of mineral in CKD occurs primarily in the tunica media.[150] In patients with compromised renal function, the entire smooth muscle layer surrounding arteries may be replaced not only by calcium deposits but also by tissue that resembles bone. Osteoblasts and vascular smooth muscle cells have a common mesenchymal origin. In patients with CKD, Cbfa1 is thought to trigger mesenchymal cell to osteoblast transformation. Mice deficient in Cbfa1 fail to mineralize bone, and arteries obtained from patients undergoing renal transplantation show increased levels of the protein.[98,151] Uremia potentiates expression of pro-mineralization factors including the sodium-dependent phosphate transporters PIT-1 and PIT-2, osteopontin, bone sialoprotein, osteonectin, alkaline phosphatase, type I collagen, and bone morphogenic protein-2 (BMP-2) while expression of calcification inhibitors, such as fetuin A and matrix Gla protein, is suppressed in CKD.[150]

Throughout the past several years, elevated circulating values of FGF23 have been linked to cardiovascular disease in patients with all stages of CKD and experimental data have defined a direct role for FGF23, independent of changes in mineral metabolism, on pathologic changes in cardiac myocytes. Although the effects of circulating FGF23 on mineral metabolism require the presence of Klotho as the coreceptor of FGF receptors,[152] some of the effects on the cardiovascular system appear to be Klotho independent. FGF23 levels are often hundreds-fold to thousands-fold higher in patients with renal failure compared to those detected in individuals with normal kidney function, and these values have been associated with an increased prevalence of left ventricular hypertrophy and with premature mortality in adults with all stages of CKD.[111,153] Experimental data have demonstrated that these associations may reflect a direct effect of FGF23 on the myocardium that induces myocyte hypertrophy in a Klotho-independent manner.[114] However, it is important to note that Klotho is expressed in arteries, although not in myocardium, and decreases in vascular Klotho, as occur with progressive CKD, have been linked to loss of vascular elasticity.[9]

CALCIPHYLAXIS

Calciphylaxis is a unique syndrome characterized by ischemic necrosis of the skin, subcutaneous fat, and muscles. Although calciphylaxis is uncommon in children, it may develop in patients with advanced renal failure not yet treated by dialysis, in those treated with regular dialysis, and even in patients with well-functioning kidney transplants.[154] Two distinct types of the syndrome are recognized: proximal calciphylaxis, which affects the thighs, abdomen, and chest wall and acral calciphylaxis, which involves sites distal to the knees and elbows, such as the toes, fingers, and ankles.[155] The former has a poor prognosis, with death occurring in more than 80% to 90% of affected patients. This syndrome is often accompanied by morbid obesity and hypoalbuminemia. Many patients have severe secondary hyperparathyroidism, and most have a history of severe and uncontrolled hyperphosphatemia, but it has been described in patients with adynamic osteodystrophy.[155,156] Some patients may have defective regulation of coagulation.[157] The appearance of this syndrome in renal transplant recipients receiving glucocorticoids suggests that steroids also may play a role. Patients with calciphylaxis frequently die of secondary infection.

A significant number of patients with calciphylaxis improve after parathyroidectomy, and a few have healed after substantial reductions in levels of serum phosphorus. Parathyroidectomy and aggressive control of serum

---

KEY POINTS

Factors promoting vascular calcification include:

- Cbfa1
- Sodium-dependent phosphate transporters PIT-1 and PIT-2
- Osteopontin
- Bone sialoprotein
- Osteonectin
- Alkaline phosphatase
- Type I collagen
- Bone morphogenic protein-2 (BMP-2)

phosphate levels therefore are indicated in those with evidence of severe secondary hyperparathyroidism. However, secondary hyperparathyroidism should be well documented before parathyroidectomy, because adynamic bone has been associated with this syndrome. Although ischemic lesions and medial vascular calcifications are common in uremic patients with diabetes, such lesions rarely improve after parathyroidectomy. Calcimimetics, as well as sodium-thiosulfate (a calcium chelating agent) and pamidronate, have been used effectively in some individuals.[158,159] Hyperbaric oxygen therapy also has been advocated, and some patients will require amputation of the extremities as a result of advanced disease process.[159]

BONE BIOPSY

Although not routinely performed in the clinical setting, a bone biopsy should be considered in all patients with CKD who have fractures with minimal trauma (pathologic fractures), suspected aluminum bone disease, or persistent hypercalcemia despite serum PTH levels between 400 and 600 pg/mL.[142] For bone labeling, a 2-day course of tetracycline is administered at 15 mg/kg/day (divided into twice-daily or thrice-daily doses). Phosphate binders should be withheld during labeling because they may interfere with gut absorption of tetracycline. Fourteen days later, the 2-day course is repeated. For children younger than 8 years old, tetracycline dosage usually is kept below 10 mg/kg/day to avoid toxicity. Histochemical staining procedures may demonstrate deposition of abnormal components such as iron, aluminum, and oxalate within bone.[160]

MANAGEMENT OF CHRONIC KIDNEY DISEASE AND MINERAL AND BONE DISORDER

To minimize complications in the skeleton and prevent extraskeletal calcification, particular attention must be paid to alterations of bone and mineral metabolism in CKD. The specific aims of management of CKD-MBD are to (1) maintain blood levels of serum calcium and phosphorus near normal limits, (2) prevent hyperplasia of the parathyroid glands and maintain serum PTH at levels appropriate for the stage of CKD, (3) avoid the development of extraskeletal calcifications, and (4) prevent or reverse the accumulation of toxic substances such as FGF23, aluminum and β_2-microglobulin.

DIETARY MANIPULATION OF CALCIUM AND PHOSPHORUS

As active vitamin D levels fall during the progression of renal disease, calcium absorption in the gut and kidney diminishes and hypocalcemia evolves in advanced CKD. Patients with untreated CKD commonly ingest as little as 400 to 700 mg of elemental calcium per day in their diet. Calcium-rich foods such as dairy products, unfortunately, also are high in phosphorus. Thus, increasing dietary consumption of calcium to meet daily needs is accompanied by excessive intake of phosphorus, which cannot be excreted in the face of renal failure. As a result, calcium supplementation in the form of calcium-containing salts is often required. The total amount of calcium supplementation provided, however, must be monitored carefully, because values above 1.5 g/day are associated with positive calcium balance in patients with CKD stages 3 and 4 disease[8] and may lead to hypercalcemia and vascular calcification.

The development of hyperphosphatemia occurs in the vast majority of patients with advanced renal insufficiency. Hyperphosphatemia and an elevated calcium-phosphorus ion product have been reported as independent risk factors for vascular calcification and mortality in adult dialysis patients.[119,120] Thus, treatment goals include maintaining serum phosphorus levels within normal limits for age (Table 33.1) and avoiding a calcium-phosphorus ion product above 55. The average phosphorus intake of both adults and children in the U.S. population is approximately 1500 to 2000 mg/day, and 60% to 70% of the dietary intake is absorbed. In early stages of renal failure, mild dietary phosphate restriction is sufficient to prevent hyperphosphatemia and also may modulate the progressive rise in circulating FGF23. However, strict adherence to dietary phosphate restriction is often difficult because low-phosphate diets are unpalatable, especially to older children and adults, and because phosphorus intake is directly linked to protein

Table 33.1 Age appropriate normal values of serum calcium, phosphorus, and alkaline phosphatase

Age (yr)	S-Phosophorus (mg/dL)	S-Calcium (Total) (mg/dL)	S-Calcium (ionized) (mM)	Alkaline phosphatase (International units)
First yr	4.8–7.4	8.8–11.3	1.22–1.4	
1–5	4.5–6.5	9.4–10.8	1.22–1.32	100–350
6–12	3.6–5.8	9.4–10.3	1.15–1.32	60–450
13–20	2.3–4.5	8.8–10.2	1.12–1.30	40–180

Table 33.2 Dosing of ergocalciferol in vitamin D deficiency

Serum 25(OH) D (ng/mL)	Definition	Ergocalciferol dose	Duration	Comment
<5	Severe vitamin D deficiency	8000 international units/day (or 50,000 IU per week) PO × 4 wk, then 4000 international units/day × 8 wk	3 mo	Measure 25(OH)D levels after 3 mo
5–15	Mild vitamin D deficiency	4000 international units/day (or 50,000 IU every two weeks) PO	3 mo	Measure 25(OH)D levels after 3 mo
16–30	Vitamin D insufficiency	2000 international units/day PO	3 mo	Measure 25(OH)D levels after 3 mo

Source: K/DOQI Workgroup. K/DOQI clinical practice guidelines for cardiovascular disease in dialysis patients. Am J Kidney Dis. 2005;45(Suppl 3):S1, 2005. Reproduced with permission

intake, with 10 to 12 mg of phosphorus accompanying each gram of protein. Adequate protein intake is necessary for growth in children and for maintenance of lean body mass in adults. Current dietary recommendations suggest that adults with CKD ingest 0.8 to 1 g/kg/day of protein and that children, depending on age, ingest 1 to 2.5 g/kg/day.[142,143] This translates to a minimum phosphate ingestion of 800 mg/day in an 80-kg person.

Patients treated with dialysis require dietary phosphorus restriction, in addition to phosphate-binder therapy, because standard prescription peritoneal dialysis and hemodialysis remove insufficient amounts of phosphate (300 to 400 mg/day for peritoneal dialysis and 800 mg/treatment for hemodialysis) to maintain normal serum phosphorus levels. On the other hand, the use of daily, slow, continuous hemodialysis has been associated with excellent control of serum phosphorus levels, often allowing phosphate-binding agents to be discontinued.[161,162] Indeed, some patients have developed hypophosphatemia and required the addition of phosphorus to the dialysate solution to prevent the long-term consequences of hypophosphatemia.[161,162]

PHOSPHATE-BINDING AGENTS

Phosphate-binding agents reduce intestinal phosphate absorption by forming poorly soluble complexes with phosphorus in the intestinal tract. Aluminum-containing phosphate binders were used frequently in the past, but long-term treatment led to bone disease, encephalopathy, and anemia.[163] The use of aluminum-containing phosphate binders, therefore, should be restricted to the treatment of patients with severe hyperphosphatemia (greater than 7 mg/dL) associated with hypercalcemia or an elevated calcium-phosphorus ion product, because both conditions will be aggravated by calcium-containing compounds. In such cases, the dose of aluminum hydroxide should not exceed 30 mg/kg/day and the lowest possible dose should be given for only a limited period of approximately 4 to 6 weeks.[164] Plasma aluminum levels should be monitored regularly. Concomitant intake of citrate-containing compounds should be avoided, because citrate enhances intestinal aluminum absorption and increases the risk for acute aluminum intoxication.[165]

To avoid aluminum-related bone disease and encephalopathy, the use of aluminum-free phosphate binders has been advocated. Among these, calcium-containing salts are widely used for control of hyperphosphatemia and also serve as an additional source of supplemental calcium. Several calcium salts, including calcium carbonate, calcium acetate, and calcium citrate, are commercially available. Calcium carbonate is the most commonly used compound, and studies in adults and children have documented its efficacy in controlling serum phosphorus levels.[166] The recommended dose is proportional to the phosphorus content of the meal and is adjusted to achieve acceptable serum levels of calcium and phosphorus.

Large doses of calcium carbonate may lead to hypercalcemia, particularly in patients treated concomitantly with active vitamin D sterols or those with adynamic bone.[167] Hypercalcemia usually is reversible with reductions in the dose of oral calcium salts, dose of vitamin D sterol, and dialysate calcium concentration. To avoid the development and progression of cardiovascular calcifications, it is currently recommended that elemental calcium intake should not exceed 2 g/day, with less than 1500 mg of calcium given as calcium-containing phosphorus binders.[70,142,143] It is important to consider that adult patients with CKD stage 3 or 4 who ingest 1.5 g/day of calcium carbonate are in positive calcium balance. Although requirements in children are not well defined, calcium intake should be considered in light of age-based recommendations.[168]

Comparison studies between calcium carbonate and calcium acetate have demonstrated that an equivalent dose of calcium acetate binds twice as much phosphorus, but the relative incidence of hypercalcemia varies among studies.[169] Calcium citrate is an effective phosphate-binding agent but should be used with caution in patients with renal failure because of enhanced intestinal aluminum absorption when given in combination with aluminum-containing phosphate binders.[170] Calcium ketoglutarate is less calcemic than calcium carbonate and has anabolic benefits, but gastrointestinal side effects and high cost of therapy often limit its use.[171]

To limit the vascular calcification risks associated with the use of calcium salts and the bone and neurologic toxicity associated with aluminum hydroxide, alternative phosphate

binders have been developed. Sevelamer hydrochloride (RenaGel), a calcium-free and aluminum-free hydrogel of cross-linked polyallylamine, has been shown to lower serum phosphorus levels, the calcium-phosphorus ion product, and PTH without inducing hypercalcemia in adult patients treated with hemodialysis.[119] Sevelamer also halts the progression of vascular calcifications, although such lesions increase during calcium-containing binder therapy in adult hemodialysis patients.[119] In addition to its effects on serum phosphorus levels, sevelamer has been shown to decrease concentrations of total serum cholesterol and low-density lipoprotein cholesterol, but to increase high-density lipoprotein levels.[172] These effects may offer additional benefits in reducing cardiovascular complications in patients with ESRD. Acidosis may occur in patients treated with sevelamer. A newer formulation of sevelamer, sevelamer carbonate (Renvela), also has been introduced. This new compound is as effective a phosphate binder as sevelamer hydrochloride, with less potential to induce acidosis.[173]

Other alternative phosphate-binding agents include magnesium, iron, and lanthanum compounds. Magnesium carbonate lowers serum phosphorus levels, but magnesium-free dialysate solutions should be used in those treated with dialysis.[174] Large doses, however, result in diarrhea, limiting the use of this compound as a single agent. Iron compounds, such as stabilized polynuclear iron hydroxide and ferric polymaltose complex, have proved effective phosphate binders in short-term studies in adults with CKD.[175]

Clinical trials have demonstrated that lanthanum carbonate (Fosrenol) also effectively controls serum phosphorus and PTH levels without increasing serum calcium values. Lanthanum carbonate lowers serum phosphorus and PTH levels without causing hypercalcemia, adynamic bone disease, or osteomalacia.[176] However, lanthanum is a heavy metal that accumulates in different organs in animals with normal renal function.[177] Lanthanum also accumulates in the bone of dialysis patients, where its presence persists despite discontinuation for as long as 2 years. Additional long-term studies are therefore needed to confirm the absence of toxicity before this agent is recommended for widespread use in pediatric patients with CKD. It is important to also consider the different effects of phosphate binders on FGF23. Indeed, FGF23 levels remained unchanged or increase with calcium-based binders; by contrast, FGF23 levels appear to decrease with calcium-free phosphate binders and a recent meta-analysis demonstrated improved overall mortality and cardiovascular disease with the use of calcium-free versus calcium-based binders across the spectrum of CKD.[121]

VITAMIN D THERAPY

Despite dietary phosphate restriction, the intake of phosphate-binding agents, the use of an appropriate level of calcium in dialysate solution, and an adequate intake of calcium, progressive osteitis fibrosa cystica secondary to hyperparathyroidism develops in a significant number of uremic patients. Treatment with active vitamin D sterols is aimed at controlling serum PTH levels and the resultant high turnover bone disease. Current evidence indicates that two main issues should be considered with respect to vitamin D therapy: first, treatment of 25(OH)D deficiency, a common finding in patients with renal disease, in itself may reverse hyperparathyroidism. Second, treatment with active vitamin D sterols is useful in pharmacologically reducing PTH levels.

Assessment and treatment of 25(OH) vitamin D deficiency

Measurement of 25(OH)D levels and treatment of vitamin D deficiency are an important part of the management of hyperparathyroidism in patients with CKD. Although current guidelines are controversial, the National Academy of Medicine, formerly the Institute of Medicine, suggests that 25(OH)D values be maintained above 20 ng/mL.[178] Current recommendations from the National Kidney Foundation stratify vitamin D deficiency into three categories: (1) severe deficiency, defined as serum levels less than 5 ng/mL; (2) mild deficiency, equivalent to serum concentrations of 5 to 15 ng/mL; and (3) vitamin D insufficiency, with levels between 16 and 30 ng/mL.[142] Thus, ergocalciferol treatment should be initiated in patients with CKD when 25(OH)D levels fall below 30 ng/mL (Table 33.2).

Treatment with active vitamin D sterols

Active vitamin D sterols act through a variety of pathways to decrease PTH production—by increasing calcium absorption in the gut and kidney, by binding to the CaSR, by increasing skeletal sensitivity to PTH, and by altering prepro-PTH transcription. Calcitriol (Rocaltrol®) has been widely used for many years to control secondary hyperparathyroidism in both adults and children. The efficacy of daily oral doses of calcitriol for the treatment of patients with symptomatic renal osteodystrophy has been well documented in several clinical trials.[68,179,180] With appropriate treatment, bone pain diminishes, muscle strength, gait, and posture improve, and osteitis fibrosa frequently resolves partially or completely. Doses of oral calcitriol in most clinical trials have ranged from 0.25 to 1.5 mcg/day. In patients with CKD, initial doses are determined by target PTH levels and specific stage of kidney disease.[181] In dialysis patients, $1,25(OH)_2D_3$ given thrice weekly by intravenous injection or by oral pulse therapy is effective in reducing serum PTH levels.[182] Dosage regimens range from 0.5 to 1 mcg to 3.5 to 4 mcg three times weekly or 2 to 5 mcg twice weekly. Low doses should be used initially, and dosage adjustments should be based on frequent measurements of serum calcium, phosphorus, and PTH levels (Table 33.3).

Oral 1α-$(OH)D_3$ (alfacalcidol) undergoes 25-hydroxylation in the liver to form calcitriol,[183] and this agent is used widely in Europe, Japan, and Canada. Calcitriol and

Table 33.3 Target ranges of plasma parathyroid hormone by stage of chronic kidney disease in children

CKD stage	GFR range	Target intact PTH level (pg/mL)
3	30–59	35–70
4	15–29	70–110
5	<15 or dialysis	200–300

Source: K/DOQI Workgroup. K/DOQI clinical practice guidelines for cardiovascular disease in dialysis patients. Am J Kidney Dis. 2005;45(Suppl 3):S1, 2005. Reproduced with permission CKD, chronic kidney disease; GFR, glomerular filtration rate; PTH, parathyroid hormone.

1α-$(OH)D_3$ are similarly effective for the treatment of secondary hyperparathyroidism in patients with CKD.

Although calcitriol and alfacalcidol are effective in decreasing PTH levels and preventing osteitis fibrosis cystica, treatment with these sterols in combination with calcium-based binders often results in hypercalcemia and hyperphosphatemia and contributes to the development of soft tissue calcification, which limits their use. Thus, new vitamin D analogues have been developed to prevent or minimize intestinal calcium and phosphorus absorption, while suppressing PTH levels as effectively as calcitriol. Three of these new vitamin D analogues are already on the market for use in patients with CKD: 22-oxacalcitriol (maxacalcitol) in Japan; 19-nor-1,25-$(OH)_2D_2$ (paricalcitol [Zemplar]); and 1α-$(OH)D_2$ (doxercalciferol [Hectorol]) in the United States.

19-Nor-1 α,25$(OH)_2D_2$ (paricalcitol) is effective in controlling serum PTH levels in adult patients with CKD stages 3 and 4, as well as in dialysis patients. The long-term consequences of therapy with paricalcitol in conjunction with the use of calcium-containing binders for vascular calcification and cardiovascular complications remain to be determined. Interestingly, in a large cohort of patients undergoing hemodialysis, higher survival rates were observed in dialyzed patients treated with paricalcitol when compared with those receiving calcitriol.[184]

1α-$(OH)D_2$ (1α-D_2, doxercalciferol), is equipotent to 1α-$(OH)D_3$ in intestinal calcium absorption and bone calcium mobilization in rats.[185] A comparative trial of calcitriol and doxercalciferol in the control of secondary hyperparathyroidism in pediatric patients revealed no differences between the two vitamin D sterols in the control of secondary hyperparathyroidism or the development of hypercalcemia.[6] Doxercalciferol also effectively controls secondary hyperparathyroidism in adult patients with stable CKD.[186] Similar to paricalcitol, a survival advantage has been observed in adult hemodialysis patients receiving paricalcitol over those treated with calcitriol.[128]

Active vitamin D therapy has been associated with protective effects on both the heart and the kidney. Active vitamin D sterols ameliorate cardiac hypertrophy in animals, and calcitriol therapy improves cardiac systolic function in hemodialysis patients. However, paracalcitrol did not affect cardiac structure when it was prospectively compared

in patients with CKD stages 3 and 4.[187] Administration of active vitamin D sterols reduces proteinuria, fibrosis, and podocyte hypertrophy in subtotally nephrectomized rats, and paricalcitol treatment decreases proteinuria in CKD patients.[188,189] These effects may be mediated by suppression of the renin-angiotensin system (RAS). In vitro studies have demonstrated that calcitriol, paricalcitol, and doxercalciferol all suppress the RAS to a similar degree.[190] 1,25$(OH)_2D_3$ has recently been shown to reduce renal fibrosis by a non–VDR-related mechanism.[31] However, all activated vitamin D analogues also may increase FGF23 secretion. Although the consequences of these increased levels in dialyzed patients remain to be completely determined, current evidence suggests that excessive circulating FGF23 is associated with increased mortality rates.[111]

CALCIMIMETICS

Cinacalcet (Sensipar), an allosteric activator of the calcium-sensing receptor, is now available for the treatment of secondary hyperparathyroidism. This small organic molecule reduces serum PTH levels and has been shown to decrease the calcium-phosphorus ion product in adult patients treated with maintenance dialysis, regardless of the specific phosphate-binding agent.[191] Experiments also have demonstrated that calcimimetics are able to halt the progression of parathyroid cell hyperplasia, and the antiproliferative effect of this agent shows promise for use of the molecule as a medical parathyroidectomy.[191] Calcimimetic therapy may provide an additional option for the reduction of both PTH levels and cardiovascular disease. Indeed, a decrease in parathyroid gland hyperplasia, bone disease, and vascular calcification were found in rodents with renal failure who were treated with calcimimetics.[129–132] Early case reports suggested that calcimimetic therapy could also reduce vascular calcification burden in dialysis patients.[132] However, a 2012 prospective trial in 3883 adults with advanced secondary hyperparathyroidism (the EVOLVE trial) failed to demonstrate a beneficial effect of calcimimetics on either cerebrovascular events or mortality.[133] Owing to the presence of the calcium-sensing receptor on the growth plate, these agents are not approved and should be used with caution in growing children.

PARATHYROIDECTOMY

In many cases when parathyroid surgery is needed and undertaken, the parathyroid tissue has become monoclonal and demonstrated an autonomous growth.[192] Patients with severe hyperparathyroidism are often unresponsive to vitamin D therapy and develop hypercalcemia without reduction in PTH values or parathyroid gland size (tertiary hyperparathyroidism).[193] Indications for parathyroidectomy are (1) the presence of hyperplasia, hypertrophy, or both of the parathyroid glands (as documented by the presence of biochemical and radiographic features and, if necessary, the findings of osteitis fibrosa cystica on bone

biopsy); (2) elevated serum PTH levels unresponsive to vitamin D sterol therapy; (3) persistent hypercalcemia; (4) pruritus unresponsive to dialysis or other medical treatment; (5) progressive extraskeletal calcification; (6) severe skeletal pain or fractures; and (7) calciphylaxis. Aluminum-related bone disease must be ruled out first in patients receiving low-dose calcitriol with persistent hypercalcemia.[194] Other causes of hypercalcemia, such as sarcoidosis, malignancy-related hypercalcemia, intake of calcium supplements, and the presence of adynamic or aplastic bone lesions not related to aluminum, also should be considered.[195]

When the decision has been made to perform parathyroid surgery, it is essential to avoid a marked postoperative fall in serum calcium levels caused by the "hungry bone" syndrome. Because of the severity of the bone disease, this fall can be much more marked and prolonged than after parathyroidectomy for primary hyperparathyroidism. Patients with CKD should receive daily oral calcitriol (0.5 to 1 mcg) or some sort of intravenous active vitamin D sterol for 2 to 6 days before parathyroid surgery and during the postoperative period to stimulate intestinal calcium absorption and to maximize the effectiveness of oral calcium salts. Within 24 to 36 hours after surgery, marked hypocalcemia with serum calcium levels below 7 to 8 mg/dL may develop. This condition may be associated with serious symptoms, including seizures resulting in fractures and tendon avulsion. For reasons that are still unclear, these seizures most often occur during the last 1 to 2 hours of a hemodialysis procedure or immediately thereafter.

To reduce the risk for seizures, an infusion containing calcium gluconate should be started in the operating room, on removal of the parathyroid glands. Calcium gluconate should be initiated at a rate of 100 mg of calcium ion per hour. Serum calcium should be measured every 4 to 6 hours, and the calcium gluconate infusion rate increased if the serum calcium level continues to fall. The infusion rate may exceed 200 mg/h. Enteral calcium carbonate is initiated once the patient is able to tolerate oral intake, and doses as high as 1 g (elemental calcium) given four to six times daily, along with vitamin D sterol in excess of 1 to 2 mcg/day (for calcitriol, doses of other agents vary according to their potency), are often needed for patients with marked hypocalcemia. The intravenous calcium drip is weaned as soon as the oral intake of calcium salts is able to maintain normal serum calcium levels. The duration of intravenous calcium requirements varies greatly across patients—most patients require intravenous therapy for 2 to 3 days, but severe hypocalcemia may persist for several weeks or months, necessitating permanent central catheter access for daily home infusions of 800 to 1000 mg of elemental calcium. Serum phosphorus levels may fall to subnormal levels postoperatively. Supplemental phosphate treatment will markedly aggravate the hypocalcemia, and patients should not be treated with phosphate unless serum phosphorus falls to below 2.0 mg/dL.[196]

Hyperplastic parathyroid glands may be infiltrated with ethanol or calcitriol to cause sclerosis of the parathyroid tissue. This technique has been used at some centers with variable efficacy in reducing hyperplastic tissue.[197,198] This technique is used currently by only a few centers worldwide.

GROWTH HORMONE THERAPY

rhGH should be considered in children with growth failure that does not respond to optimization of nutrition, correction of acidosis, and control of renal osteodystrophy. Serum phosphorus and PTH levels should be well controlled before the initiation of rhGH in children with CKD. Serum phosphorus levels should be less than 1.5 times the upper limit for age and PTH-IMA-1 levels less than 1.5 times the upper target values for the CKD stage before rhGH therapy is begun.[168] Growth hormone therapy will increase serum PTH levels during the first months of therapy; therefore, serum PTH levels should be monitored monthly. Current recommendations suggest that growth hormone therapy should be discontinued temporarily if PTH levels exceed three times the upper target value for the CKD stage[168]; however, it is important to note that growth hormone also directly increases bone formation rate, independent of PTH values, thus distorting the relationship between PTH and bone formation rate.[148]

BONE DISEASE AFTER SUCCESSFUL RENAL TRANSPLANTATION

Successful kidney transplantation corrects many of the abnormalities associated with renal osteodystrophy, but disorders of bone and mineral metabolism remain a major problem in such patients. Several factors, including persistent secondary hyperparathyroidism, prolonged immobilization, graft function, and, most important, use of different immunosuppressive agents, have been implicated in the development of bone disease after organ transplantation.

Hypercalcemia is not uncommon after renal transplantation. During the first several months following transplantation, it can be quite severe and patients with severe secondary hyperparathyroidism before renal transplantation are at the greatest risk. More often, hypercalcemia is less severe, with serum calcium levels between 10.5 and 12.0 mg/dL, and usually resolves within the first 12 months.[198] Parathyroidectomy should be considered when serum calcium levels are persistently above 12.5 mg/dL for longer than 1 year after transplantation.[199] Calcimimetic agents may be useful in preventing the need for parathyroidectomy in these patients, but it is important to note that adynamic bone disease may be present in hypercalcemic renal transplant recipients, despite apparently increased PTH values.[200,201]

Hypophosphatemia may occur early in the post-transplant period, mainly in patients with severe secondary hyperparathyroidism, although persistent post-transplant elevation of

serum FGF23 levels also may contribute.[202,203] The clinical manifestations are variable; some patients complain of malaise, fatigue, and muscle weakness.[204,205] Phosphorus supplementation should be considered when values are persistently below 2.0 mg/dL, primarily in pediatric patients.

Significant bone loss has been shown to occur as early as 3 to 6 months after kidney transplantation.[206,207] Several factors, including persistent alterations in mineral metabolism, prolonged immobilization, and the use of immunosuppressive agents required to maintain graft function, have been implicated in the development of bone disease after transplantation. Osteonecrosis, or avascular necrosis, is by far the most debilitating skeletal complication associated with organ transplantation. In approximately 15% of patients, osteonecrosis develops within 3 years of renal transplantation.[208,209] The occurrence of osteonecrosis in inpatients after cardiac, hepatic, and bone marrow transplantation suggests that glucocorticoids play a critical role in the pathogenesis of this disorder.[210,211]

In both adult and pediatric kidney recipients, bone histologic changes associated with secondary hyperparathyroidism have been shown to resolve within 6 months after kidney transplantation.[207] However, some patients have persistently elevated rates of bone turnover and others develop adynamic lesions, despite moderately elevated serum PTH levels.[212] Bone biopsy data from pediatric kidney recipients indicate that 67% of patients with stable graft function have features of normal bone formation, 10% have adynamic bone lesions, and 23% have bone lesions characteristic of secondary hyperparathyroidism.[213] Bone resorption typically is increased,[214] leading to a net loss of bone mass over time. Serum PTH levels are unable to discriminate among adynamic, normal, and increased bone turnover in the pediatric transplant population.[213] The use of maintenance corticosteroids has been implicated in these alterations; steroids decrease intestinal calcium absorption, enhance urinary calcium excretion, inhibit osteoblastic activity, decrease bone formation, and increase osteoclastic activity and bone resorption.[215–217] Likewise, cyclosporine has been reported to increase both bone formation and resorption and to reduce cancellous bone volume in the rat.[218,219] By contrast, azathioprine has been shown to have minimal impact on skeletal remodeling.[220] The role of other immunosuppressive agents, such as mycophenolate mofetil, as potential modifiers of bone formation and bone resorption has not been evaluated.

Although bone turnover may return to normal, defective skeletal mineralization is present in many pediatric transplant recipients.[213] Osteoid volume is increased, and mineral apposition rate is markedly reduced.[213] Although the factors responsible for the persistent increase in osteoid formation remain to be fully explained, corticosteroid use may contribute, as may persistent imbalances in PTH, vitamin D, and FGF23 metabolism.[203]

After successful kidney transplantation with standard immunosuppressive regimens (daily corticosteroids, calcineurin inhibitor, and antimetabolite), growth may be accelerated by an improvement in kidney function, but catch-up growth may not be observed even in children who undergo transplantation very early in life.[94] Moreover, height deceleration occurs in approximately 75% of patients who undergo transplantation before the age of 15 years.[221] The cause of persistent growth retardation is not completely understood, but immunosuppressive agents, persistent secondary hyperparathyroidism, altered vitamin D and FGF23 metabolism, and the persistence of defective skeletal mineralization may contribute. Used in children with significant height deficit after kidney transplantation, rhGH has produced a substantial increase in linear growth within the first year of therapy, but the magnitude of growth response may decline thereafter.[222]

Cardiovascular disease continues to be the leading cause of death after renal transplantation. In the post-transplant period, the presence of hypertension is strongly linked to increased intimal medial thickness and poor vessel distensibility in children.[223] Alterations in bone and mineral metabolism also may contribute, because impaired kidney function persists in most patients during the post-transplant period. Indeed, EBCT data indicate that vascular calcifications do not regress post-transplantation and do contribute to the burden of cardiovascular disease in this population.[224] Although FGF23 levels substantially diminished in the immediate period after renal transplantation, values are increased in long-term renal transplant recipients and have been associated with CKD progression and episodes of rejection, and cardiovascular morbidity in adult and pediatric renal transplant recipients.[225,226] Prospective studies are needed to further assess the effects of controlling effects of FGF23 on survival and cardiac disease.

Clinical Vignette 33.1

A 15-year-old boy with a history of prenatally diagnosed posterior urethral valves was followed in the CKD clinic. He had received adequate protein and calorie nutrition since infancy via a gastrointestinal tube. Acidosis was treated with bicarbonate supplementation, and his anemia was corrected with epoetin alfa (Epogen) and iron. His hypertension was well controlled with enalapril. His serum calcium, phosphorus, and PTH levels were maintained within the appropriate range for CKD stage. However, he had growth failure since 18 months of age. Growth hormone therapy was initiated because of his height being persistently below the 3rd percentile. Initially, he experienced some catch-up growth, which subsequently tapered off.

At 5 years of age he received a preemptive transplant from his mother. Growth hormone was reinitiated 6 months after his renal transplant, but he continued to be short for age. At age 15, he lost his allograft to medication noncompliance. Over the next 6 years, he was followed in the chronic dialysis unit and was repeatedly counseled on dietary phosphorus restriction and

on compliance with his calcium-based and calcium-free phosphate binders. However, his serum phosphorus concentrations persistently remained between 7 and 9 mg/dL, and his PTH remained above 1000 pg/mL. He had significant genu valgum deformity. At age 21, an EBCT demonstrated extensive coronary artery calcifications.

TEACHING POINTS

- This case illustrates the complex interplay among mineral metabolism, bone disease, and cardiovascular disease in pediatric CKD.
- Despite optimization of nutrition, mineral metabolism, and acidosis, children with CKD grow poorly. Although growth hormone therapy improves final height in many patients with predialysis CKD, many children have decreased final adult height despite growth hormone therapy.
- Hyperphosphatemia and secondary hyperphosphatemia are particularly problematic in children and adolescents treated with maintenance dialysis; compliance with dietary phosphate restriction and phosphate binder therapy are essential in this population so that active vitamin D sterol therapy can be used to control serum PTH concentrations.
- Long-standing secondary hyperparathyroidism is associated with bone deformities, while long-standing hyperphosphatemia contributes to progressive vascular calcification in both the pediatric and adult populations.

REVIEW QUESTIONS

A 12-year-old boy has come to a pediatrician's office for a school physical. He wakes up several times at night to urinate. On examination, he is found to be a pale boy with a height and a weight that are both below the 3rd percentile. He has Tanner 1 pubertal development and normal blood pressure. Serum electrolytes are sodium, 136 mmol/L; potassium, 3.8 mmol/L; chloride, 108 mmol/; total carbon dioxide, 18 mmol/L; blood urea nitrogen, 40 mg/dL; creatinine, 1.8 mg/dL (stage 3 CKD); phosphorus, 4 mg/dL; calcium, 9.9 mg/dL; parathyroid hormone, 170 pg/mL, and hematocrit, 28%.

1. An appropriate serum PTH level for this child with this degree of renal insufficiency is:
   a. 10 to 65 pg/mL
   b. 65 to 110 pg/mL
   c. 200 to 300 pg/mL
   d. >400 pg/mL
2. Growth hormone therapy should be initiated:
   a. Immediately, to maximize final height potential
   b. After correction of acidosis, anemia, and secondary hyperparathyroidism
   c. After the initiation of dialysis
   d. After successful renal transplantation
   e. Growth hormone therapy is contraindicated in this child
3. An 8-year-old girl presents with reflux nephropathy and growth failure and has the following serum biochemical determinations: Serum creatinine, 2.5 mg/dL (CKD stage 4); calcium, 8.9 mg/dL; phosphorus, 6 mg/dL; and PTH, 140 pg/mL. The first step in serum phosphorus management is:
   a. Initiation of a non–calcium-containing phosphate binder
   b. Nutritional assessment and phosphate restriction
   c. Vitamin D sterol therapy
   d. Growth hormone therapy
4. A 14-year-old boy with obstructive uropathy and stage 3 CKD has been treated with growth hormone therapy for the past 2 years. His growth velocity has been decreasing over the past 6 months. An indication to stop therapy would be:
   a. Serum PTH of 150 pg/mL
   b. Height at percentile corresponding to the mean parental height
   c. Tanner 2 pubertal development
   d. Increasing alkaline phosphatase activity
5. A 10-year-old boy receiving maintenance hemodialysis is treated with calcium carbonate and thrice weekly calcitriol to control his renal osteodystrophy. His serum PTH level is 700 pg/mL; phosphorus, 5 mg/dL; and calcium, 11.5 mg/dL. To ameliorate his hypercalcemia, the next step in his therapy should include:
   a. Dietary calcium restriction
   b. Bone biopsy
   c. Switching to a non–calcium-containing phosphate binder
   d. Increasing the calcitriol therapy

Nutrition in chronic kidney disease

SUN-YOUNG AHN AND ROBERT MAK

Maintenance of optimum nutrition continues to be a vital aspect in the care of children with chronic kidney disease (CKD). The nutritional status and requirements for these patients need to be evaluated regularly with the goals of maintaining a normal pattern of growth and body composition and avoiding electrolyte abnormalities, uremic toxicity, and malnutrition.[1] The association between poor linear growth and low body mass index (BMI) with increased risk for mortality in children with CKD underscores the importance of adequate nutrition in this patient population.[2,3] Because rates of linear growth and neurodevelopment are highest during the first 3 years of life, nutrition during this period is especially essential for reducing morbidity and mortality.[4] Indeed, growth failure during infancy in children with CKD has been primarily attributed to malnutrition.[5]

NUTRITIONAL ASSESSMENT

The Kidney Disease Outcomes Quality Initiative (KDOQI) established clinical practice guidelines for the evaluation of nutritional status in patients with CKD.[6] Children with CKD stages 2 to 5 and 5D (5D: patients on dialysis) should be evaluated at least twice as frequently as same-aged healthy children, with more frequent monitoring to be done in infants (Table 34.1). Parameters to be followed include dietary intake, length and height for age percentiles

or standard deviation score (SDS), length and height velocity-for-age percentiles or SDS, estimated dry weight and weight-for-age percentile or SDS, BMI-for-height age percentile or SDS, head circumference–for-age percentile, or SDS for children younger than 3 years of age, and normalized protein catabolic rate (nPCR) in adolescents with CKD stage 5D. The challenges of using age-matched children for comparison include the short stature and delayed puberty found in most children with CKD. Therefore, comparison by height age (age at which the child's height would be at the 50th percentile) or pubertal stage may be more appropriate.

KEY POINT

Children with CKD stages 2 to 5 and 5D should be evaluated at least twice as frequently as same-aged healthy children, with more frequent monitoring to be done in infants as well as patients with comorbidities such as cachexia, protein-energy wasting, and growth failure.

HEIGHT AND LENGTH

The length (children younger than 2 years) or height (children older than 2 years) should be measured regularly and plotted on the length-for-age or height-for-age

Table 34.1 Recommended parameters and frequency of nutritional assessment for children with chronic kidney disease stages 2 to and 5D

	Minimum interval (Mo)									
	Age 0 to < 1 yr			Age 1–3 yr			Age > 3yr			
Measure	CKD 2–3	CKD 4–5	CKD 5D	CKD 2–3	CKD 4–5	CKD 5D	CKD 2	CKD 3	CKD 4–5	CKD 5D
Dietary intake	0.5–3	0.5–3	0.5–2	1–3	1–3	1–3	6–12	6	3–4	3–4
Height or length-for-age percentile or SDS	0.5–2	0.5–2	0.5–1	1–6	1–3	1–2	6	6	6	1–3
Height or length velocity-for-age percentile or SDS	0.5-2	0.5-2	0.5-1	1-6	1-3	1-2	6	6	6	6

* Only applies to adolescents receiving hemodialysis.

curves, with percentiles and SDS calculated. Length can be measured using a length board, and height using a wall-mounted stadiometer. The KDOQI guidelines recommend using the 2006 World Health Organization (WHO) Growth Standards as a reference for children from birth to 2 years.[6] After 2 years of age, the Centers for Disease Control and Prevention (CDC) reference curves may be used because of minimal differences with the WHO Growth Standards after this time point. The WHO Growth Standards are based on children from diverse ethnic backgrounds growing under ideal conditions (nonsmoking mothers, high socioeconomic status, breast fed for at least 4 months, receiving regular health care) and therefore represent ideal growth.

WEIGHT

Assessment of euvolemic (or dry) weight in children with CKD can present a challenge because oliguric and anuric children may be fluid overloaded or polyuric children may be dehydrated. Therefore, a careful clinical examination is warranted, and indicators of volume status including edema, hypertension, pulse rate, skin turgor, or laboratory indices such as sodium or albumin levels, must be evaluated. The euvolemic weight can then be used to calculate the weight-for-age percentile and, SDS, or both. The height-for-age percentiles must be taken into account when looking at the weight-for-age percentiles. BMI takes into consideration both the weight and height and therefore is another parameter that is useful in assessing growth.

BODY MASS INDEX

As with weight and height, the percentile for SDS or BMI (weight in kg/length in m^2) relative to age can be determined based on the WHO Growth Standard for children younger than 2 years, and the CDC reference data for children older than 2 years of age. Children with CKD, however, may have delays in growth or differences in body proportions that render comparisons with healthy children of the same age inaccurate.[7] Therefore, relating BMI to height for age in pubertal or peripubertal children with CKD may provide better comparisons with children of similar height and maturation.[8] When interpreting BMI values, consideration must be given to the fact that the BMI does not reflect body composition and therefore fat mass. A patient who has an appropriate BMI for height or chronologic age may therefore not have an ideal body composition.[9]

HEAD CIRCUMFERENCE

Infants with CKD may be at greater risk for poor head growth.[10,11] Hence, head circumference should be measured

Table 34.2 Macronutrient distribution ranges

Macronutrient	Children 1–3 yr (%)	Children 4–18 yr (%)
Carbohydrate	45–65	45–65
Fat	30–40	25–35
Protein	5–20	10–30

Source: Health Canada. http://www.hc-sc.gc.ca/fn-an/alt_formats/hpfb-dgpsa/pdf/nutrition/dri_tables-eng.pdf.

routinely in children with CKD until 3 years of age,[6] along with percentiles, SDS, or both calculated from WHO Growth Standards. No studies have yet shown a correlation between head circumference and nutritional status in children with CKD; however, delayed head growth should prompt a neurodevelopmental evaluation and a thorough evaluation of nutritional status.

DIETARY ASSESSMENT

It is recommended that dietary intake be assessed with a minimum frequency of every 2 weeks to yearly in children with CKD, depending on the age of the child and stage of disease (Table 34.2). More frequent assessments are recommended for younger children and for children with advanced stages of CKD. Children who depend solely on enteral feeding may benefit from more frequent monitoring. The dietary intake should be assessed with either a prospective 3-day diet diary or three 24-hour diet recalls.[6] Either technique should include one weekend day to represent variations in the diet because of changes in schedules on weekends. Information obtained from either method can then be used by a registered dietitian to estimate the daily intake of energy, macronutrients, vitamins, and minerals and overall dietary adequacy.

NORMALIZED PROTEIN CATABOLIC RATE

Normalized protein catabolic rate (nPCR), which represents the protein catabolic rate normalized to weight, is used to objectively measure the dietary protein intake in patients on chronic hemodialysis who are in a nutritionally steady state. The nPCR formula is based on the urea generation rate (G; mg/min), which is calculated from the difference in blood urea nitrogen (BUN) level at the end of one hemodialysis session and the beginning of the next session. The urea generation rate can be derived using formal urea kinetic modeling or from the following algebraic equation[6]:

$$G \text{ (mg/min)} = [(C2 \times V2) - (C1 \times V1)]/t$$

where: C1 = postdialysis BUN (mg/dL)
C2 = predialysis BUN (mg/dL)
V1 = postdialysis total body water (dL; V1 = 5.8 dL/kg × postdialysis weight; kg)

V2 = predialysis total body water (dL; V2 = 5.8 dL/kg × predialysis weight; kg)

   t = time (minutes) from the end of the dialysis treatment to the beginning of the following treatment

The nPCR is then calculated by using the modified Borah equation[12]:

$$nPCR = 5.43 \times est\ G/V1 + 0.17$$

where V1 = total body water (L) post dialysis ($0.58 \times$ weight; kg)

Whereas a correlation between mean nPCR values and persistent weight loss of at least 2% was shown in adolescents, no link between nPCR values and weight loss was seen in younger patients.[13] Differences in protein metabolism and growth rate may be some reasons that nPCR offers no predictive value for weight loss in younger children. Because values used for Kt/V calculations are the same for nPCR calculations, the nPCR can be calculated monthly together with the Kt/V.

In patients on chronic peritoneal dialysis, the protein equivalent of nitrogen appearance (PNA) can be used to measure the protein intake. The PNA can be obtained by multiplying the total nitrogen appearance (TNA) by 6.25, which is based on the principle that 1 g of nitrogen is generated from 6.25 g of metabolized protein.[14] The TNA in children can, in turn, be calculated using the following formula[15]:

TNA (g/day) = 0.03 + 1.138 urea-N_{urine} + 0.99 urea-$N_{dialysate}$
+ 1.18 BSA (body surface area) + 0.965 protein-$N_{dialysate}$

where: N_{urine} = urea nitrogen content in urine
    $N_{dialysate}$ = urea nitrogen content in dialysate

Limited data exist on PNA in the pediatric population, and optimal normalization methods are not yet established. In adults, the PNA is normalized to ideal body weight.

SERUM ALBUMIN

Hypoalbuminemia has been linked to increased morbidity and mortality in both adults and children with CKD.[16–8] Therefore, the serum albumin level has customarily been considered a marker of nutritional status. Patients on chronic peritoneal dialysis lose significant amounts of protein through the dialysate, with infants on peritoneal dialysis having almost twofold more peritoneal protein loss per body surface area (m^2) compared to older children weighing more than 50 kg. This may lead to impaired growth and loss of growth potential.[19] Serum albumin levels are also decreased in states of inflammation, heavy urinary protein losses (nephrotic syndrome), and volume overload and are therefore not necessarily indicative of poor nutrition. Nevertheless, hypoalbuminemia is a biomarker of

morbidity and mortality in CKD patients and thus albumin levels should be regularly monitored.

MIDARM MEASUREMENTS

Triceps skinfold thickness (TSF) measures subcutaneous fat and was previously considered to reflect total fat mass. In addition, the midarm muscle area (MAMA) and midarm muscle circumference (MAMC), calculated from the TSF and midarm circumference (MAC), were thought to reflect total muscle mass. However, these measures since have been found to be unreliable because of various factors, including interoperator variability and the unclear relationship between MAMA and total muscle mass resulting from confounding variables such as fluid overload and abnormal fat distribution.[6] They are therefore no longer used in the routine nutritional assessment of patients with CKD.

BODY COMPOSITION MEASURE

Methods for determining body composition include the dual-energy x-ray (DXA) absorptiometry scan, which estimates fat mass, lean mass, and bone mineral density. DXA, however, cannot distinguish water content and lean body mass in patients with CKD and therefore may not provide accurate measures of lean mass in volume-overloaded subjects.[20] Other methods for measuring body composition include bioelectrical impedance, which estimates body fluid compartment volumes, and in vivo neutron activation, which measures certain total body elements. These methods have yet to be validated in children.[6,9] Most recently, Tsampalieros et al.[21] measured muscle and fat cross-sectional areas, expressed as gender-specific and age-specific Z scores, by quantitative computed tomography in children with CKD, and found significant muscle deficits as these children developed end-stage renal disease (ESRD). Further studies are needed to validate this new methodology and to justify its clinical utility.[21]

FACTORS CONTRIBUTING TO CACHEXIA AND PROTEIN ENERGY WASTING IN CHRONIC KIDNEY DISEASE

Cachexia or protein energy wasting is prevalent in adult patients with CKD.[22] Mortality in patients on dialysis is eight times higher compared with healthy individuals and higher than in patients with cancer and heart failure. Cachexia, chronic inflammation, and cardiovascular complications are comorbidities in patients with CKD associated with mortality. Ghrelin is an orexigenic hormone with additional effects on the regulation of inflammation and the cardiovascular system. It may play an important role in the pathogenesis of cachexia, inflammation, and cardiovascular complications in CKD. There are three circulating

products of the ghrelin gene: acyl ghrelin, des-acyl ghrelin, and obestatin, each with individual distinct functions on appetite regulation. Perturbations of these circulating ghrelin proteins have an impact on the overall orexigenic milieu of CKD.

KEY POINT

Cachexia or protein energy wasting is prevalent in adult patients with CKD. Ghrelin and leptin may play yin-and-yang roles in the pathophysiology of cachexia and cardiovascular complications in CKD.

Leptin is an anorexigenic hormone that is secreted from the adipocytes and interacts with ghrelin and other appetite-regulating hormones. Leptin also plays a role in regulating inflammation and the cardiovascular system. Indeed, ghrelin and leptin may play yin-and-yang roles in the pathophysiology of cachexia and cardiovascular complications in CKD.[23] Vitamin D deficiency is common in patients with CKD. Low vitamin D levels upregulate the renin-angiotensin-aldosterone system, increase inflammation, and cause endothelial dysfunction. Epidemiologic studies suggest an association between low vitamin D levels and risk factors for cardiovascular disease, but a causal relationship has not been established.[24] Vitamin D supplementation improves cachexia, inflammation, cardiovascular complications, and mortality in experimental CKD. Further understanding of these interactions in CKD pathophysiology is needed for potential large-scale clinical trials that may have an impact on the quality of life and survival of patients with CKD.

NUTRITIONAL MANAGEMENT IN CHRONIC KIDNEY DISEASE

Inadequate nutritional intake is prevalent in children with CKD, resulting in poor weight gain and delayed growth.[25] These children often require a program for enteral or parenteral nutritional supplementation to promote growth. The development of such a program requires a team approach in which the role of the dietitian is vital. Several components have to be considered in developing the dietary prescription, including energy, macronutrients, micronutrients, fluid, and electrolytes.

ENERGY

The caloric or energy requirements for children with CKD are similar to those of healthy children.[26,27] Therefore, the caloric intake for children with CKD should be determined from national recommendations of the estimated energy requirements based on chronologic age and gender.

The caloric intake can then be adjusted based on the individual patient's needs and response. For example, infants with low birth weight and patients with recurrent vomiting may require supplemental calories to maintain growth. On the other hand, patients on peritoneal dialysis who demonstrate excessive weight gain may need reduction of their energy intake to take into account the energy intake from dialysate glucose, which is estimated at 8 to 12 kcal/kg/day.[28,29] Several studies have established that optimizing energy intake results in improved weight gain and linear growth.[25,30–32] Children on chronic dialysis who received nutritional support through gastrostomy tube feedings showed improvement in weight and height SDS,[30] while initiation of enteral feeding before 2 years of age resulted in significant catch-up growth.

KEY POINT

The energy requirements for children with CKD are similar to those of healthy children. Therefore, the starting point for estimating caloric intake for children with CKD can be determined from national recommendations of the estimated energy requirements based on chronologic age and gender.

In a study of European children on chronic dialysis, overweight and obesity, rather than underweight, were highly prevalent. Short stature among kidney allograft recipients strongly correlated with overweight, whereas underweight appeared to be a problem only in infants. These findings suggest that nutritional management in children receiving chronic dialysis should focus as much on the prevention and treatment of overweight as on preventing cachexia and protein energy wasting.[33]

Nutritional intake can be optimized by concentrating feeds, selecting foods high in calories, and adding concentrated sources of carbohydrate and fat to the diet. Poor oral intake, recurrent emesis, and poor weight gain and growth should prompt initiation of tube feedings. Tube feedings can relieve the stress that comes with trying to meet nutritional requirements[34] and have a low complication rate.[30] Infants who are totally dependent on tube feedings should be provided oral stimulation exercises to encourage oral intake and also help their transition to complete oral feeding after successful renal transplantation.[35] Several centers have reported the successful transition of all tube-fed patients to complete oral feeding after transplantation.[36,37]

In children who are unable to receive their target nutritional requirements through enteral supplementation, intradialytic parenteral nutrition (IDPN) may be an option. A few pediatric studies have shown that IDPN was successful in inducing weight gain and increasing body mass index in a small group of poorly nourished HD patients.[38–40] Due to

Table 34.3 Recommended dietary protein intake for children with chronic kidney disease stages 3 to 5D

Age	DRI (g/kg/day)	Recommended for CKD stage 3 (g/kg/day) (100%–140% DRI)	Recommended for CKD stages 4–5 (g/kg/day) (100%–120% DRI)	Recommended for hemodialysis (g/kg/day)*	Recommended for peritoneal dialysis (g/kg/day)†

* DRI + 0.1 g/kg/day to compensate for dialytic losses.

† DRI + 0.15–0.3 g/kg/day depending on patient age to compensate for peritoneal losses.

CKD, chronic kidney disease; DRI, dietary reference intake.

limited data available, the ideal IDPN composition remains unknown. However, standard amino acids that fulfill the daily protein requirements for the child's age are typically used, together with dextrose and 20% or 30% lipid components. Electrolytes and minerals can be adjusted according to the patient's needs, and trace elements (zinc, copper, selenium, manganese, and chromium) can be added to the IDPN. The IDPN should be infused through the venous limb of the hemodialysis circuit to avoid clearance of the amino acids.

DISTRIBUTION RATIO OF MACRONUTRIENTS

The distribution of carbohydrate, protein, and fat intake for children with CKD is similar to that recommended for healthy children. For children older than 3 years of age, calories from carbohydrates should make up 45% to 65%, fat 25% to 35%, and protein 10% to 30% of total intake. For children 1 to 3 years of age, the distribution of calories from carbohydrate, fat, and protein should be 45% to 65%, 30% to 40%, and 5% to 20% of total caloric intake, respectively (see Table 34.2).[6] There is no consensus on macronutrient distribution for infants younger than 1 year of age. Therefore, the distribution of carbohydrate, fat, and protein should be consistent with infant formula, which is 36% to 56% carbohydrate, 40% to 54% fat, and 7% to 12% protein.[6] Because of the high risk for cardiovascular disease in children with CKD, unsaturated fat is preferable to saturated or *trans*-fat and complex carbohydrates to simple sugars.

PROTEIN

Restricting protein in the diet had been thought to slow the rate of progression of CKD. However, studies in both adults[41,42] and children[43,44] showed no benefit with low-protein diets, with some studies actually indicating potential adverse effects of a diet very low in protein, including possible increased risks for poor nutritional status and mortality.[41,42]

The KDOQI Nutrition Guidelines recommend maintaining the dietary protein intake at 100% to 140% of the dietary reference intake (DRI) for ideal body weight in children with CKD stage 3. Because nitrogen-containing waste products and phosphorus from protein intake can accumulate with decreasing kidney function, it is suggested that protein intake be reduced to 100% to 120% of the DRI in children with CKD stages 4 to 5. The protein requirements for these children may vary depending on various clinical conditions such as proteinuria and catabolism.

In children with ESRD, the KDOQI Nutrition Guidelines recommend that the starting point for estimating dietary protein intake be at 100% of the DRI for ideal body weight plus supplementation of protein losses that occur with dialysis.[6] For children on hemodialysis, an additional 0.1 g/kg/day is recommended to supplement the intradialytic losses. Because patients on peritoneal dialysis experience loss of protein through the dialysate ultrafiltrate that is inversely related to body weight and peritoneal surface area and protein supplementation differs according to the patient age and ranges from 0.15 to 0.3 g/kg/day (Table 34.3). Infants, who have a larger peritoneal surface area than older children, will therefore require more protein supplementation on a Gram-per-kilogram basis.

KEY POINT

In children with ESRD, the KDOQI Nutrition Guidelines recommend that the starting point for estimating dietary protein intake be at 100% of the DRI for ideal body weight plus supplementation of protein losses that occur with dialysis.

Because of the almost linear relationship between protein and phosphorus intake,[45] sources of protein that are

relatively low in phosphorus should be selected when possible. Protein derived from animal flesh contains the lowest amount of phosphorus (11 mg of phosphorus per 1 g of protein), whereas protein derived from plants (legumes and lentils), eggs, or dairy products contains higher amounts of phosphorus (20 mg of phosphorus per 1 g of protein).[6] However, because humans do not have the enzyme phytase to release phosphorus contained in the form of phytic acid in plants, the bioavailability of phosphorus from plants (50%) is lower than that from animal products (greater than 70%).[6,46] In addition, phosphate salts are frequently added to meat products, increasing their phosphorus content. Therefore, dietary protein that is not entirely derived from animal products and that also contains vegetable sources of protein is recommended.

CARBOHYDRATES

For healthy children of any age, calories from carbohydrate should constitute 45% to 65% of total caloric intake. Simple sugars should be restricted to avoid hypertriglyceridemia, especially in the early post-transplant period when there is a higher risk for developing glucose intolerance and hyperglycemia from corticosteroid and calcineurin inhibitor therapy.

Dietary fiber, which is found in most vegetables, fruits, and whole grains, can help reduce cholesterol levels and therefore decrease the risk for cardiovascular disease.[47] Fiber also can reduce constipation. However, the choice of fiber-containing foods is somewhat limited for children with CKD because of the potassium and phosphorus content in these foods. The KDOQI Nutrition Guidelines list foods containing fiber and their potassium and phosphorus content.[6] Other sources of fiber that can be added to meals or drinks include tasteless powdered forms that do not contain electrolytes (e.g., Benefiber, Unifiber). Children on strict fluid restrictions may be limited in the amount of fiber they can consume because of the water intake required with such a diet.

FAT

Dyslipidemia is frequently seen in patients with CKD.[48] In a cross-sectional study of children with CKD, 45% had dyslipidemia, among whom 32% had hypertriglyceridemia. There was a positive association between dyslipidemia and a lower GFR, higher BMI, and nephrotic-range proteinuria.[49] Other studies have shown the prevalence of hypertriglyceridemia and hypercholesterolemia to be as high as 63% to 88% and 61% to 93%, respectively, in children on peritoneal dialysis.[50] Dyslipidemia not only potentially accelerates the progression of CKD but is also an important contributor of cardiovascular disease in children with CKD.[51,52] Cardiovascular disease is the leading cause of morbidity and mortality in children with CKD, constituting nearly 25% of total deaths.[53] Therefore, regulating dietary fat intake is an important component of nutritional management in children with CKD.

KEY POINT

Dyslipidemia is frequently seen in patients with CKD. Dyslipidemia not only potentially accelerates the progression of CKD but is also an important contributor of cardiovascular disease in children with CKD.

The KDOQI Dyslipidemia Guidelines recommend that adolescents and postpubertal children with CKD follow the KDOQI dietary and lifestyle recommendations for adults and that prepubertal children follow the recommendations by the National Cholesterol Education Program.[53,54] The American Heart Association consensus statement on dietary recommendations for children and adolescents can be used as a guideline for managing dyslipidemia in patients with CKD.[55]

Children with CKD and dyslipidemia should be strongly encouraged to reduce their intake of total fat, cholesterol, and saturated and *trans*-fatty acids. Heart-healthy fats such as oils produced from plant sources such as canola, corn, soybean, and olives are recommended. These dietary changes should be implemented in conjunction with controlling caloric intake and increasing physical activity.[34] Restricting dietary fat to 30% of the total caloric intake has been shown to have no adverse effects on growth and development.[56] The primary goal for nutritional management in children with CKD is to meet energy, protein, and micronutrient requirements. Dyslipidemia management should be initiated after the patient is well-nourished.[6] For this reason, dietary or lifestyle recommendations should be implemented cautiously or avoided in malnourished children.

The beneficial effects of omega-3 fatty acids on cardiovascular disease and prevention have been widely studied in adults. Omega-3 fatty acids have been reported to reduce serum triglyceride levels, blood pressure, thrombotic risk factors, and inflammation in adult patients.[53,57–59] Recent studies, however, have questioned some of the previous cardioprotective effects reported for adult patients.[60] Studies looking at the effects of omega-3 fatty acids on children with CKD are limited. In a small study of 16 children (7 to 8 years of age) on dialysis, 8 weeks of daily oral fish oil supplementation (3 to 8 g/day) resulted in a 27.5% reduction in triglyceride levels.[61] Because of limited data, there are currently no established recommendations for the use of omega-3 fatty acids to treat hypertriglyceridemia in children with CKD.

KEY POINT

The distribution of carbohydrate, protein, and fat intake recommended for children with CKD is the same as that recommended for healthy children.

VITAMINS AND TRACE ELEMENTS

Patients with CKD are at increased risk for vitamin and trace element deficiencies as a result of inadequate intake, drug-nutrient interactions, urinary loss of protein-bound vitamins (such as vitamin D binding protein) in proteinuric patients, and loss of water-soluble nutrients through dialysis. A study of 30 children (9.3 ± 7.4 years old) on dialysis reported that the majority of patients had less dietary intake of water-soluble vitamins than the recommended daily allowance (RDA).[62]

25-Hydroxyvitamin D deficiency is commonly seen in pediatric dialysis patients.[63] In contrast, serum concentrations of vitamin A have been found to be normal or elevated without supplementation in patients on dialysis.[64,65] Supplementation with multivitamins may result in normal or higher than normal intake or serum concentrations for some of these vitamins,[62,64,65] which may be explained in part by the fact that the patients receive adult doses of renal multivitamins.

> **KEY POINT**
>
> Patients with CKD are at increased risk for vitamin and trace element deficiencies secondary to inadequate intake, drug-nutrient interactions, urinary loss of protein-bound vitamins in proteinuric patients, and loss of water-soluble nutrients through dialysis.

The KDOQI Nutrition Guidelines recommend dietary intake of at least 100% of the DRI for vitamins B_1, B_2, B_3, B_5, B_6, B_8, B_{12}, C (ascorbic acid), A (retinol), E (α-tocopherol), K, folic acid, copper, and zinc for children with CKD stages 2 to 5. If dietary intake does not meet 100% of the DRI, or if a vitamin or trace element deficiency is present in children with CKD stages 2 to 5, supplementation is recommended. In addition, children with ESRD should receive a water-soluble vitamin supplement. If available, a liquid containing the B vitamins and vitamin C can be used for infants and children unable to swallow tablets. If the liquid form is not available, an adult renal supplement containing the B vitamins and vitamin C can be crushed and dissolved in water. Infants and toddlers are usually given half a tablet and older children are given 1 tablet daily. Serum concentrations of vitamin A and E have been found to be normal or elevated without supplementation in dialysis patients; thus, supplementation of these fat-soluble vitamins, including vitamin K, is usually not recommended in patients with CKD, except in cases in which there is a documented deficiency (e.g., fat malabsorption).[34] For children on erythropoietin-stimulating agents, either oral or intravenous iron supplementation is typically required to replenish iron stores and prevent iron-deficient red blood cell formation.

CALCIUM, PHOSPHORUS, AND VITAMIN D

Calcium, phosphorus, and vitamin D homeostasis are altered in CKD, leading to metabolic bone disease. The kidneys are responsible for excreting excess phosphorus and converting 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D, the active form of vitamin D. Active vitamin D increases serum calcium levels by promoting calcium absorption from the intestines and inhibits parathyroid hormone (PTH) secretion by the parathyroid glands. As renal function declines, hyperphosphatemia and hypocalcemia develop, eventually leading to renal osteodystrophy. High-turnover osteodystrophy is associated with high PTH levels and can be prevented by close monitoring and management of serum calcium, phosphorus, and PTH levels through dietary measures, vitamin D treatment, and phosphate binders.[66]

> **KEY POINT**
>
> Calcium, phosphorus, and vitamin D homeostasis are altered in CKD, leading to metabolic bone disease. Vitamin D deficiency is also commonly seen in patients with CKD.

The KDOQI Bone Guidelines for children with CKD recommend restriction of phosphorus in the diet when serum PTH levels are above the recommended levels for the stage of CKD.[67] Phosphate binders should be initiated when dietary measures fail to control serum phosphorus levels within the goal range. Calcium-based phosphorus binders (e.g., calcium carbonate, calcium acetate) and non–calcium-containing phosphorus binders (e.g., sevelamer carbonate) are available for the treatment of hyperphosphatemia. Target level of calcium and phosphorus are age-based because normal levels of calcium and phosphorus are higher in younger age groups.

Active vitamin D directly inhibits PTH secretion by acting on vitamin D receptors in the parathyroid gland. Dosing for active vitamin D should take into account the reduced activity of chondrocytes and development of adynamic bone disease associated with large doses of vitamin D and oversuppression of PTH secretion.[68] Other limitations of active vitamin D therapy include hypercalcemia and hyperphosphatemia resulting from increased absorption from the gut. Alternative medications that have less of a hypercalcemic effect are now available, including less calcemic active vitamin D analogues (e.g., paricalcitol [Zemplar], doxercalciferol [Hectorol]), and calcimimetics (e.g., cinacalcet hydrochloride [Sensipar]). The latter increases the sensitivity of calcium-sensing receptors to extracellular calcium, thereby reducing PTH levels. However, there are few data supporting the use of calcimimetics in children with CKD.

The KDOQI Bone Guidelines for children with CKD include opinion-based and evidence-based recommendations

Table 34.4 Recommended target ranges for serum parathyroid hormone

Chronic kidney disease stage	Serum PTH level (pg/mL)
2	35–70
3	35–70
4	70–110
5	200–300

Abbreviation: PTH, parathyroid hormone.

for target serum PTH levels for each stage of CKD (Table 34.4).[67]

In addition, the recommended calcium-phosphorus product for children 12 years and younger is less than 65 mg^2/dL^2, and for children older than 12 years of age is less than 55 mg^2/dL^2.[67] These guidelines were established to minimize the risk for extraskeletal and vascular calcifications in children with CKD. Recent evidence suggests that markers for cardiovascular disease are optimum and growth is maintained when PTH levels are less than twice the upper limit of normal in children on dialysis.[69]

SUMMARY

The association between mortality and extremes of BMI in children with CKD heightens the importance of careful nutritional management in this patient population. Close assessment, monitoring, and management of nutritional status in CKD may have a critical impact on growth and neurodevelopment, especially in younger children.[4] Therefore, the active involvement of a registered dietitian, health care professionals, and caregivers is essential for providing proper nutritional care to children with CKD. Moreover, further clinical trials are needed to establish evidence-based guidelines for nutritional assessment and management in pediatric CKD.

REVIEW QUESTIONS

1. Which one of the following statements is true?
   a. No association has been found between low body mass index and increased risk for mortality in children.
   b. Growth failure in infants with CKD is mainly due to malnutrition.
   c. Rates of linear growth and neurodevelopment are highest during the second decade of life.
   d. The nutritional status of children with CKD should be evaluated with the same frequency as in same-aged healthy children.

2. Which one of the following parameters is *not* included in the typical nutritional assessment for a child with CKD?
   a. Head circumference-for-age percentile for children younger than 3 years of age
   b. Height-for-age percentile
   c. Weight-for-age percentile
   d. Triceps skinfold thickness

3. Which one of the following statements *most* accurately describes the factors contributing to cachexia in CKD?
   a. Ghrelin is an orexigenic hormone that may play a role in the pathogenesis of cachexia in CKD.
   b. The four circulating gene products of ghrelin include acyl ghrelin, des-acyl-ghrelin, obestatin, and melatonin.

    c. Leptin is an anorexigenic hormone secreted from leukocytes.

    d. Vitamin supplementation has been shown to have little effect on cachexia in experimental CKD.

4. Which one of the following statements is false?

    a. The energy requirements of children with CKD are higher than those of healthy children.

    b. The caloric intake for children with CKD should be determined from national recommendations of the estimated energy requirements based on chronologic age and gender.

    c. Children on chronic dialysis who receive nutritional support through gastrostomy tube feedings show improvement in weight and height SDS.

    d. The energy intake from dialysate glucose is approximately 8 to 12 kcal/kg/day.

5. For children older than 3 years of age, which of the following distributions of calories from carbohydrates, fat, and protein is recommended?

    a. Carbohydrates 25% to 35%, fat 45% to 65%, protein 10% to 30%

    b. Carbohydrates 10% to 30%, fat 45% to 65%, protein 25% to 35%

    c. Carbohydrates 25% to 35%, fat 10% to 30%, protein 45% to 65%

    d. Carbohydrates 45% to 65%, fat 25% to 35%, protein 10% to 30%

6. Which of the following macronutrients is lost through the peritoneal dialysate ultrafiltrate?

    a. Protein

    b. Carbohydrates

    c. Lipids

    d. None of the above

7. Which of the following statements is true?

    a. Dyslipidemia is rare in patients with CKD.

    b. Children on PD have low prevalence rates (30% to 40%) of hypertriglyceridemia.

    c. Dyslipidemia potentially accelerates the progression of CKD.

    d. Restricting dietary fat to 30% of the total caloric intake has adverse effects on growth.

8. Which one of the following vitamin supplements is recommended in children on dialysis?

    a. Vitamin A

    b. Vitamin E

    c. Vitamin B

    d. Vitamin K

9. Which one of the following vitamins inhibits PTH secretion and at large doses causes adynamic bone disease?

    a. Vitamin A

    b. Vitamin E

    c. Vitamin C

    d. Vitamin D

10. Which of the following medications inhibits PTH secretion by increasing the sensitivity of calcium-sensing receptors to extracellular calcium?

    a. Calcitriol

    b. Paricalcitol

    c. Cinacalcet hydrochloride

    d. Doxercalciferol

PART G

Renal replacement therapies

Continuous renal replacement therapy

AKASH DEEP AND TIMOTHY E. BUNCHMAN

Acute kidney injury (AKI) commonly occurs in critically ill patients, and it affects nearly 30% to 40% of patients admitted to pediatric intensive care units (PICUs). Approximately 5% of patients in PICUs have AKI that requires supportive renal replacement therapy (RRT). Continuous RRT (CRRT) is an important adjunctive therapy in such patients. CRRT, as a technology, has evolved dramatically since the 1980s from an experimental modality to the accepted standard of care for hemodynamically unstable, critically ill pediatric and adult patients.[1–4] CRRT is now considered to be the treatment of choice for critically ill patients, with diagnoses ranging from volume overload to acute renal failure and complex multiorgan dysfunction syndrome (MODS).[5]

EARLY DEVELOPMENT

In 1977, Kramer et al.[6] demonstrated the efficacy of a unique system for ultrafiltration in patients with fluid overload. The device consisted of a capillary hemofilter that used the patient's systemic arterial blood pressure to drive ultrafiltration. This novel technique, termed continuous arteriovenous hemofiltration (CAVH), was initially adopted as a technology-independent alternative

to hemodialysis. Since then, the technique introduced by Peter Kramer has evolved and has been modified further to provide both convective and diffusive exchange of solutes for enhanced solute clearance. To achieve predictable and controlled ultrafiltration, pump-assisted systems were developed in early 1990s and replaced arterial blood pressure–driven systems. These pump-assisted techniques have collectively come to be known as continuous venovenous hemofiltration (CVVH). In the past decade, elaborate CVVH devices with added safety, ultrafiltration, and thermal control mechanisms have been introduced in clinical practice. These devices are a far cry from the simple and unconventional design envisioned by Peter Kramer.

INDICATIONS AND APPLICATIONS

In general, clinical indications for initiating CRRT in children are similar to those in the adults (Table 35.1). The most common use of CRRT is in children with AKI associated with fluid overload, severe or persistent hyperkalemia, or severe metabolic acidosis. Hypernatremia or hyponatremia (sodium level of less than or equal to 120 mEq/L or in a symptomatic patient) and uremic encephalopathy are other less

common clinical indications of CRRT. Nonrenal indications for CRRT include initial treatment of inborn errors of metabolism and hyperammonemia, prevention or treatment of tumor lysis syndrome, and treatment of intoxications.

CRRT is often considered the therapy of choice for hemodynamically unstable or critically ill patients who would not be considered optimal candidates for either intermittent hemodialysis or peritoneal dialysis. Indeed, the chief advantage of CRRT is its ability to allow correction of metabolic disorders and fluid and electrolyte disturbances with a minimal impact on hemodynamic stability in critically sick patients (Table 35.2). Because CRRT is a continuous therapy conducted over several days, the overall solute clearance achievable with this modality can be superior to that feasible with intermittent hemodialysis.[7–10] Slow and continuous clearance of solutes and intravascular fluid by CRRT in patients with AKI may also be more physiologic and lessen the likelihood of rapid metabolic shifts and the disequilibrium syndrome.

Successful application of CRRT requires patients to be connected to an extracorporeal circuit for prolonged periods and remain immobilized. This is especially important in small children, who may require sedation for the procedure to be conducted safely. CRRT procedures necessitate the placement of an appropriately sized intravascular catheter that can be associated with its own risks, such as blood stream infection, bleeding, and injury to other organs. The CRRT circuits also require the use of anticoagulation, thereby enhancing the risks of systemic bleeding. In the absence of an adequate blood warming mechanism in the CRRT circuits, hypothermia can ensue, and this can be especially consequential in infants.

Current generation of CRRT machines use a roller pump to draw blood from the patient through a venous access into the extracorporeal circuit and then back into the patient. The blood roller pump also generates the positive pressure needed to achieve ultrafiltration of blood within the hemofilter. The vascular access often used in CRRT consists of a double-lumen access

Acute Severe Metabolic Acidosis (A)

Electrolyte Abnormalities (E)
- Hyperkalemia
- Hypernatremia
- Hypocalcemia and hypercalcemia
- Hypophosphatemia and hyperphosphatemia

Intoxications (I)
- Low molecular weight, not protein bound
  - Gentamicin
  - Lithium
  - Ethylene glycol
  - Methanol
  - Ethanol
  - Salicylates
  - Acetaminophen
- High molecular weight, protein bound
  - Vancomycin
  - Phenobarbital
  - Carbamazepine
- Theophylline

Fluid Overload (O)
- Pulmonary edema not responsive to diuretics
- Oliguria
- Anuria

Uremia (U)

Metabolic and Miscellaneous (M)
- Inborn errors of metabolism
  - Urea cycle defects
  - Branched-chain amino acidurias
- Tumor lysis syndrome
- Hyperosmolality
- Coagulopathy and need for large volumes of blood products, combined with acute kidney injury
- Uncontrolled hyperthermia: core temperature higher than 39.5° Celsius
- Lactic acidosis

inserted into the venous circulation, such as the internal jugular or femoral vein.

DIFFUSION AND CONVECTION

Ion transport and solute exchange in CRRT can be achieved by diffusion, convection, or a combination of both. Diffusion, simply put, is the transfer of solute across a semipermeable membrane from an area of high concentration to an area of low concentration.[7–9]

KEY POINTS

- Fluid overload and AKI in hemodynamically unstable patients are the dominant clinical indications for CRRT.
- Nonrenal indications of CRRT include inborn errors of metabolism, tumor lysis syndrome, and intoxications.
- Some form of anticoagulation, either systemic (heparin) or regional (citrate), is necessary for effective CRRT.

Table 35.2 Advantages and disadvantages of continuous renal replacement therapy

Advantages	Disadvantages
• Hemodynamic stability	• Need for intravascular access
• Slow fluid and solute removal	• Need for anticoagulation
• Greater solute clearance (Kt/V)	• Need for patient immobilization
• Runs continuously	• Nutritional clearance
• ICU nurses troubleshoot the machines	• Higher cost

Abbreviations: ICU, intensive care unit; Kt/V, a measure of clearance in which K is dialyzer clearance of urea, t is dialysis time, and V is the volume of distribution of urea.

Diffusion of solutes is directly proportional to the concentration gradient across the semipermeable membrane, the diffusive coefficient of the solute, the temperature, the surface area of the interface, and the distance to traverse across the membrane.[7] Diffusion is effective at clearing low-molecular-weight solutes in CRRT, but solute clearance declines with increasing molecular weight.[9,10] In contrast, convection relates to transfer of solute across a semipermeable membrane in association with a significant amount of water across the membrane.[7–9] In other words, convection involves bulk removal of solutes dissolved in the ultrafiltrate that is removed in the CRRT procedure.[7,8]

TERMINOLOGY

Since its original description, the technology of conducting CRRT has changed considerably. It is important to understand the principles associated with these techniques to provide optimal clinical care for critically sick patients.

SLOW CONTINUOUS ULTRAFILTRATION

During the slow continuous ultrafiltration (SCUF) procedure, the CRRT circuit is used merely to ultrafilter plasma water (Figure 35.1A). This is the simplest form of CRRT and may be achieved with either a continuous arteriovenous (AV) system or a continuous venovenous system that uses a CRRT machine. In a poorly monitored circumstance, SCUF may result in a dangerously high fluid removal rate and may lead to shock and severe electrolyte abnormalities. Because solute clearance with SCUF is not substantial, its use as a CRRT modality has declined over the years.

CONTINUOUS VENOVENOUS HEMOFILTRATION

In CVVH, a sterile replacement electrolyte solution is infused into the CRRT circuit, either in a prefilter or a postfilter location, and the fluid is removed from the patient by ultrafiltration at a rate equal to the replacement fluid infusion if the patient is to stay euvolemic (Figure 35.1B). A positive or negative fluid balance can be achieved by decreasing or increasing the net ultrafiltration rate, respectively. A high ultrafiltration rate that is possible in this procedure provides a convective solute transport.

CONTINUOUS VENOVENOUS HEMODIALYSIS

Continuous venovenous hemodialysis (CVVHD) is characterized by adding diffusive solute removal by additional dialysis capability in the CRRT circuit. Sterile dialysate solution is infused through the dialyzer, which circulates outside the capillary membrane in a countercurrent manner, similar to hemodialysis (Figure 35.1C). The rate of dialysate flow, however, is substantially lower than that used in hemodialysis. Replacement fluid is not used in the CRRT circuit, but some CRRT machines may require a minimal amount of replacement fluid to be present in the circuit for optimal functioning of the device. Although a custom dialysate solution can be used, several brands of premixed sterile dialysate solutions are commercially available for this purpose. Because some ultrafiltration is done in most patients, the convective solute (and toxin) removal continues in CVVHD, *albeit* at a much slower pace.

CONTINUOUS VENOVENOUS HEMODIAFILTRATION

Continuous venovenous hemodiafiltration (CVVHDF) uses both convective and diffusive solute removal capabilities in CRRT. In addition to a dialysate set-up similar to that of CVVHD, replacement fluid is infused into the circuit in the predialyzer or the postdialyzer position (Figure 35.1D). Ultrafiltration removes fluid from the patient at a rate that is dictated by the patient's needs, and it provides convective solute removal, whereas the dialysis feature provides diffusive solute removal.
Figure 35.1 Diagrammatic representation of **(a)** slow continuous ultrafiltration (SCUF), **(b)** continuous venovenous hemofiltration (CVVH), **(c)** continuous venovenous hemodialysis (CVVHD), and **(d)** continuous venovenous hemodiafiltration (CVVHDF).

DEVICES

Several devices are now available commercially for use in CRRT modalities. These devices are based on the principle that a high hydraulic permeability hemofilter connected to the patient's central venous access by tubing is used to ultrafilter plasma in a slow but continuous manner. In most of the available CRRT machines, a peristaltic "arterial pump" helps pump blood into the extracorporeal circuit and also generates the hydrostatic pressure necessary for ultrafiltration in the hemofilter (Figure 35.2). Following ultrafiltration and convective solute exchange in the hemofilter, the blood is returned to the patient through the "venous" port of the vascular access. Some CRRT devices have a pump in the "venous" side of the extracorporeal circuit to control the flow of blood in the circuit. The dialysate used for diffusive solute clearance is pumped into and out of the hemofilter through its side ports. The dialysate is separated from the blood by the hemofilter capillary membrane and flows in a path that is countercurrent to the flow of the blood inside the capillary column. The flow of the dialysate into the hemofilter is controlled with one pump, whereas another pump administers the replacement filter into the extracorporeal circuit at the prehemofilter or posthemofilter location.

Pulsatile or piston action intravenous pumps were used in early versions of CRRT devices to control ultrafiltration rate during the procedure. These pumps can have an error rate of up to 30%, are inaccurate for control of ultrafiltration, and have been largely abandoned.[11] The ultrafiltration control error in the newer CRRT devices is only 1% to 2% of total ultrafiltration, and resultant improved control of therapy goals. The current generation of CRRT devices also provides for plug-in warming modules for the blood pathway, thus reducing the possibility of hypothermia. Some of the commonly used CRRT devices in the United States are shown in Figure 35.3.

HEMOFILTERS

Hemofilters used in CRRT are similar in design to hemodialyzers, except that the filter capillaries have significantly higher hydraulic permeability. Some CRRT devices permit interchangeability of hemofilters with varying size and permeability characteristics, whereas other devices require the use of specific hemofilter sets.

CLINICAL APPLICATION OF CLEARANCE TECHNIQUES

CRRT can be performed by using convection (CVVH), diffusion (CVVHD), or a combination of convection and diffusion (CVVHDF). Choosing the appropriate modality is determined by the patient's needs and
Figure 35.2 Diagrammatic representation of a continuous renal replacement therapy circuit.

the technical expertise and preferences of the staff. Another technical decision in conducting CRRT relates to the choice of replacement fluid infused in the pre-filter or postfilter position. Herein also, superiority of one method over the other has not been clearly established. Historical data in adults suggest that postfilter convection allows for greater solute clearance, but it has a higher risk of clotting because of hemoconcentration within hemofilter capillaries.

A sterile physiologic solution is used as dialysate (diffusive clearance), and a replacement fluid is infused directly into the CRRT circuit (for convective clearance). In septic patients with AKI, there may be a significant improvement in cytokine clearance in a convective mode over the diffusive mode. It is clear that low-molecular-weight substances, such as urea and citrate, are cleared equally by the diffusive and convective modes. As the molecular weight increases and molecular protein binding enhances, the convective mode of CRRT provides some advantage in clearance. Flores et al.[12] demonstrated that in the highly catabolic bone marrow transplant population, there appear to be improved survival rates in patients using the convective mode. Long-term multicenter studies are needed to look at the outcome and efficacy of convection versus diffusion in CRRT.

KEY POINTS

- SCUF as a CRRT modality is less commonly used at present. This technique can be useful in addressing urgent fluid overload concerns when machine set-up may take time or for managing cardiovascular surgical patients in the operating room.
- CVVH is best suited to remove larger molecules and may be beneficial in patients with sepsis. CVVH uses the convective or bulk removal technique.
- The CVVHD modality is ideally suited for patients with AKI because electrolyte balance and uremic toxin removal can be effectively managed by the process of diffusion.

VASCULAR ACCESS

The success of CRRT depends greatly on the adequacy of vascular access. Therefore, considerable thought must be given to the selection of site for insertion, as well as size and type of AV access in each patient.

Potential sites for placement of the AV access include the internal jugular vein, the subclavian vein, and the femoral vein. Because of lower risk of vascular stenosis and pneumothorax and its large size, the internal jugular site is a preferred site for placement of AV access. Moreover, placement of catheter is in the right side of the heart, which acts as a reservoir and allows access to the volume of blood needed for successful CRRT.[13] The internal jugular vein site access also allows easier rehabilitation of the patient while receiving CRRT. The femoral vein is a relatively large vessel and is also often used for access for CRRT. However, longer catheters with more "dead space" may be necessary for the tip of the vascular access to reach the common iliac vessel or the inferior vena cava. The subclavian vessel can also be used for vascular access, but because of the risk of pneumothorax, it is a less preferred access site. The size of the vascular access should be proportional to the size of the patient (Table 35.3). Umbilical arterial and venous catheters have been used in neonates in past, but these sites are not preferred because of the less than optimal blood flow achieved.

KEY POINT

Adequate blood flow and appropriate size and placement of the vascular catheter are the keys to a successful CRRT procedure.

While choosing the site of insertion of vascular access, it is important to avoid placement of the vascular access for CRRT close to other central venous accesses. This is to avoid siphoning of medications, especially inotropes and sedatives, from the patients into the hemofilter during the CRRT procedure.

BLOOD FLOW RATE

A minimum blood flow rate (BFR) of 30 to 50 mL/min, and ideally a BFR of 400 mL/min/1.73 m^2, should be targeted for successful CRRT. This BFR approximates to 10 to 12 mL/kg/min in infants, 4 to 6 mL/kg/min in children, and 2 to 4 mL/kg/min in adolescents. The maximum achievable BFR varies with the CRRT device used. The BFR is often dictated by the adequacy of the vascular access. The risk of a higher BFR is greater hemodynamic instability, but in clinical settings a greater BFR may also result in less circuit clotting.

DIALYSATE SOLUTION

At the inception of CRRT, the replacement or dialysate solutions used were lactate based, such as peritoneal dialysis solutions or Ringer lactate. Increased plasma lactate concentrations have been reported with the use of such

Table 35.3 Recommended catheter sizes and insertion sites in infants and children

Patient group/weight	Catheter size and manufacture	Preferred insertion site
Neonates		
3–5 kg	Two 5-French single lumen inserted separately	Femoral and internal jugular vein(s)
	7-French double lumen, 10 cm (Medcomp)	Internal jugular, femoral veins
	7-French double lumen, 13 cm (Cook)	Femoral vein
Infants/school-age Children		
5–15 kg	7-French triple lumen, 16 cm (Arrow)	Internal jugular, subclavian, or femoral veins
	8-French double lumen, 11–16 cm (Arrow)	
	9-French double lumen, 12–15 cm (Medcomp)	
10–30 kg	9-French double lumen, 12–15 cm (Medcomp)	
	10-French double lumen, 12–19.5 cm (Mahurkar)	
	11.5- or 12-French double lumen, 12–20 cm (Medcomp, Arrow, Mahurkar)

lactate-based solutions, especially in patients with acute hepatic failure.[14–17] Hemodynamic instability and poor cardiac performance have also been raised as concerns with lactate-based dialysate used in CRRT.[16,17]

In contrast, bicarbonate-based dialysate has been shown to result in a significant increase in the arterial pH and a decrease in the base deficit, as well as a trend toward a greater cardiac index, a lower infusion rate of dobutamine, and high oxygen delivery.[18,19] Distinct advantages of bicarbonate-based dialysate in improving cardiovascular functions in CRRT have also been documented in several clinical studies.[20–22] For these reasons, bicarbonate-based dialysate and replacement solutions are now recommended as the standard of care for CRRT. Since the early 2000s, several bicarbonate-based solutions for CVVH or CVVHD have become available commercially.[23] If citrate anticoagulation is used, a calcium free-bicarbonate-based solution may be the optimal choice.[24]

TIMING OF INITIATION

The optimal timing of CRRT initiation in patients with severe AKI remains uncertain, and this represents an important knowledge gap and a priority for high-quality research. Although a systematic review suggested that "earlier" initiation of CRRT improves survival, reliable data are limited by small study size, single-center experiences, and use of variable definitions to define "early" CRRT initiation. Karvellas et al.[25] performed a systematic review of the effect of CRRT timing on mortality rates in adult critically ill patients and included 15 studies published between 1999 and 2010. In a pooled analysis, early initiation of CRRT was associated with significantly reduced odds of death (odds ratio, 0.45; 95% confidence interval [CI], 0.28, 0.72).[25] This

analysis was, however, limited by the low methodologic quality of the included studies and by statistical heterogeneity. Another randomized controlled trial of CRRT timing (n = 106) found no difference in mortality. However, the study was underpowered to detect a clinically implausible absolute difference in mortality of less than 40%.[26]

ANTICOAGULATION

One of the key elements that determines the success of CRRT and the longevity of the circuit is prevention of clot formation in the extracorporeal circuit and the hemofilter. Some form of anticoagulation, which maintains the fluidity of blood and the circuit and yet has minimal systemic effects in the patient, is used to achieve this goal. Commonly used anticoagulants during CRRT are listed in Table 35.4.

> **KEY POINTS**
> - Early initiation of CRRT improves mortality rates.
> - Initiating CRRT after fluid overload of greater than 20% body weight is associated with higher mortality rates.

Saline flushes

Flushing the extracorporeal lines, blood pump, hemofilter, and air detectors with sterile normal saline can allow effective functioning of the CRRT procedure in a patient with bleeding diathesis or when anticoagulation is contraindicated. To

Table 35.4 Commonly used anticoagulants in continuous renal replacement therapy

- Saline flushes
- Heparin (unfractionated heparin)
- Low-molecular-weight heparin
- Citrate regional anticoagulation
- Prostacyclin
- Nafamostat mesylate
- Danaparoid
- Hirudin or lepirudin
- Argatroban (thrombin inhibitor)

adopt this technique, a three-way stopcock is placed at the connection of the "arterial" end of extracorporeal tubing and the vascular access. When performing a normal saline flush, the blood flow in the CRRT circuit is decreased to 100 mL/min to prevent the formation of bubbles in the blood tubing. The three-way stopcock is then closed to the patient and opened to a bag of normal sterile saline. The saline (10 to 20 mL) is then flushed through the CRRT circuit at a flow rate of 100 mL/min. The inner lumen of the tubing and the filter fibers are visually inspected during the procedure for evidence of any clot formation. The volume of normal sterile saline infused during the flush must be recorded as intravenous fluid administered to the patient.

Heparin

Heparin has long been the mainstay of anticoagulation in CRRT. Typically, the CRRT circuit is primed with 1 to 2 L of normal sterile saline containing 2500 to 5000 units/L of heparin. Then, a prefilter heparin infusion is initiated, usually at 10 to 20 units/kg/h, with a goal activated clotting time (ACT) of 180 to 220 sec. The ACT or activated partial thromboplastin time is used to monitor the adequacy of the heparinization. The ACT test is commonly performed at the bedside, thus decreasing the turn-around time from the laboratory. The heparin dose is highly variable and must be individualized. The main advantage of unfractionated heparin (UFH) is the experience people have when using heparin in various conditions, the short biologic half-life, the availability of an efficient inhibitor, and the possibility to monitor its effect with routine laboratory tests such as the ACT.

In spite of the vast experience in the use of UFH, it has some clinically significant side effects. Heparin is not removed by the CRRT process, thus leading to systemic heparinization of the patient and increasing the risk of bleeding in the patient. Severe bleeding events have been reported in 10% to 50% of patients undergoing CRRT.[27] Heparinization is monitored by measuring ACT every 30 min and adjusting the dose of heparin to keep it in 180 to 200 sec range. If the ACT is very high, then the heparin infusion is stopped altogether until it normalizes to the recommended range. The development of heparin resistance is not uncommon in critically ill patients, in whom antithrombin (AT) concentrations are often reduced as a result of consumption secondary to sepsis or systemic inflammation. AT degradation by elastase is also enhanced by heparin, and this adds to heparin resistance during critical illnesses.

An uncommon but feared side effect of heparin therapy is the development of heparin-induced thrombocytopenia (HIT). It has been reported to occur in 1% to 5% of patients as a result of development of anti–platelet factor 4-heparin (PF4/H) antibodies.[28] The PF4/H antibody is an immunoglobulin G (IgG) antibody that reacts with the heparin-PF4 complex on the platelet surface and triggers the clotting cascade. HIT usually occurs in the second week (7 to 10 days) after the start of heparin treatment. The presence of thrombocytopenia and frequent circuit clotting in a patient undergoing CRRT should alert the clinician to the possibility of HIT. The diagnosis of HIT can be established by presence of thrombocytopenia and circulating PF4/H antibodies. Discontinuation of heparin and use of an alternate form of anticoagulation, such as citrate, is necessary if the diagnosis of HIT is considered.

Another issue with the use of heparin is its unpredictable pharmacokinetics. The pharmacokinetics of heparin is not only time and dose dependent but also unpredictable, with considerable interpatient and intrapatient variability. Heparin binds not only to AT, but also to numerous other proteins and cells, thereby limiting its availability and reducing its anticoagulant effect. Some of these proteins are acute phase reactants, many of which are elevated in critically ill patients.

Clinicians have tried using various low-molecular-weight heparins (LMWHs) such as dalteparin, enoxaparin, and nadroparin in CRRT. These LMWHs differ in size, half-life, and activity. Because of their reduced chain length, LMWHs have higher anti-Xa and anti-IIa activity than does UFH. The pharmacokinetics of LMWHs is more predictable than that of UFH because of less plasma protein binding. The theoretical advantages include a more reliable anticoagulant response and a lower incidence of HIT. However, because of the stronger anti-Xa effect, reversal with protamine is less effective. Because LMWHs are renally excreted, their effects are prolonged in renal failure. Special coagulation assays are required to monitor anti-Xa activity. Furthermore, LMWHs are more expensive than standard heparin, and no difference in prolonging the hemofilter life has been convincingly demonstrated.

Citrate anticoagulation

In 1990, Mehta et al.[29] demonstrated the efficacy of citrate anticoagulation for CRRT circuits. Citrate anticoagulation is based on the concept of chelation of calcium to avoid clotting of blood in the CRRT circuit. Calcium is necessary for the activation of factors XI, IX, X, and prothrombin. Thus, chelation of free calcium by citrate inhibits the activation of the intrinsic pathway of coagulation, thereby resulting in anticoagulation.

Table 35.5 Adjustment of citrate infusion by circuit ionized calcium*

CRRT circuit iCa²⁺ (mmol/L)	Weight >20 kg Action	Weight <20 kg Action
<0.35	↓ rate by 10 mL/h	↓ rate by 5 mL/h
0.35–0.40	No change	No change
0.41–0.50	↑ rate by 10 mL/h	↑ rate by 5 mL/h
>0.50	↑ rate by 20 mL/h	↑ rate by 10 mL/h

Abbreviations: CRRT, continuous renal replacement therapy; iCa²⁺, ionized circuit calcium.
* Titrate citrate (ACD-A) drip to maintain CRRT circuit iCa²⁺ between 0.35 and 0.40 mmol/L. Physician review of therapy is indicated if ACD-A infusion rate is >200 mL/h.

By infusing citrate in the prefilter position and neutralizing calcium in the postfilter location, regional anticoagulation of the hemofilter, without systemic anticoagulation of the patient, can be achieved. Systemic intravenous calcium infusion needs to be carefully adjusted to prevent hypocalcemia induced by citrate infusion in the extracorporeal circuit. Citrate is removed by CRRT; its clearance has been reported to be equal to that of urea in CRRT, and no significant difference in clearance is noted between CVVH and CVVHD modes.[30]

Bunchman et al.[23,24] adopted citrate infusion protocols designed for use in pediatric patients. They administered ACD-A solution (Baxter Healthcare, Deerfield, IL) in the prefilter location through a three-way stopcock placed at the connection between the arterial bloodline and the vascular access. The ACD-A infusion (mL/h) is initiated at 1.5 times the BFR (mL/min) in the CRRT circuit. Calcium chloride (8000 mg calcium chloride/L of normal sterile saline or 8 mg/mL), or calcium gluconate (24 g of calcium gluconate/L of normal saline or 240 mg/mL) infusion is begun through either a third lumen of a triple-lumen dialysis catheter or through a different central venous line at 0.4 times the ACD-A infusion rate in mL/h. The circuit ionized calcium (iCa) is checked post-filter (after ACD-A infusion) with a target iCa of 0.35 to 0.50 mmol/L. The systemic ionized calcium is checked either through a central line or pre–ACD-A site in the arterial limb of the CRRT circuit, with a target iCa of 1.1 to 1.3 mmol/L.[23,24] The ACD-A and calcium chloride infusions are titrated according to guidelines given in Tables 35.5 and 35.6, respectively.

Complications of citrate anticoagulation include hypocalcemia, metabolic alkalosis, and citrate toxicity. Hypocalcemia is avoidable by following titration guidelines for infusion of the calcium chloride (Table 35.6). Metabolic alkalosis result from hepatic conversion of 1 mole of citrate to 3 moles of bicarbonate. In our experience, all children treated with ACD-A citrate anticoagulation developed metabolic alkalosis.[23,24] Indeed, failure to develop metabolic alkalosis while receiving citrate anticoagulation should lead to a search for underlying metabolic acidosis and a mixed acid-base disorder in the patient. The metabolic alkalosis is treated by decreasing the dialysate flow (in CVVHD mode) by approximately 30% and by substituting the replacement fluid with an equivalent volume (30%) of normal sterile.[24]

Citrate toxicity (or citrate lock) develops if the citrate infusion rate is higher than the combined capacity to remove it by CRRT and the hepatic metabolism in the patient. Citrate toxicity can be suspected by a rising total calcium and a decreasing ionized calcium concentration in the patient. The diagnosis is established by measuring the ratio of the total calcium to ionized calcium (systemic-to-CRRT ionized calcium).[31] A total-to-ionized calcium ratio of more than 2.5 represents citrate toxicity. Patients with hepatic dysfunction are especially prone to this complication. Although the overall prevalence of citrate toxicity was 12% in this single-center experience, it affected 33% of patients with AKI complicating hepatic failure.[31]

Apart from fewer bleeding complications compared with heparin use, citrate anticoagulation may also offer increased

Table 35.6 Adjustment of calcium chloride infusion by patient's peripheral ionized calcium*

Patient iCa²⁺ (mmol/L)	Weight >20 kg Action	Weight <20 kg Action
>1.30	↓ rate by 10 mL/h	↓ rate by 5 mL/h
1.10–1.30	No change	No change
0.90–1.10	↑ rate by 10 mL/h	↑ rate by 5 mL/h
<0.90	↑ rate by 20 mL/h	↑ rate by 10 mL/h

Abbreviations: iCa²⁺, ionized circuit calcium.
* Titrate calcium chloride drip rate to maintain the patient's iCa²⁺ between 1.10 and 1.30 mmol/L.

survival of the CRRT circuit. One study found that citrate-anticoagulated circuits lasted a median of 70 h, compared with a median of 40 h for heparin-anticoagulated circuits.[32] The rate of spontaneous circuit failure was 87% in the heparin arm and 57% in the citrate arm of the study.[32] A recent meta-analysis has also confirmed superiority of citrate over heparin anticoagulation in prolonging circuit life.[27] In contrast, in a multicenter prospective, noninterventional study, mean circuit life was similar between heparin- and citrate-anticoagulated systems (42.1 ± 27.1 vs. 44.7 ± 35.9 h, respectively).[33]

Prostacyclin

Because platelets play an important role in the coagulation cascade, inhibitors of platelet activation have been used for anticoagulation in CRRT, either alone or in combination with heparin. Prostaglandin I-2 (PGI_2), also known as prostacyclin, is synthesized endogenously from the arachidonic acid pathway by cyclooxygenase enzymes, and it acts on endothelium and platelets. PGI_2 and its synthetic derivative epoprostenol sodium (Flolan) inhibit platelet aggregation and adhesion, and they have been used as anticoagulants.[34] Antiplatelet action occurs at a dose between 2 and 8 ng/kg/min. Prostacyclin can cause hypotension from vasodilation at doses of 20 ng/kg/min. Although the vasodilator half-life is 2 min, the antiplatelet effect lasts for 2 h. Besides antiplatelet and vasodilatory actions, prostacyclin has anti-inflammatory and antimitogenic actions as well.

An important feature of prostacyclin is its heparin-sparing effect, which can be put to use especially in patients with decreased levels of antithrombin-3 (e.g., septic patients) who may have frequent circuit clotting despite treatment with heparin. The addition of prostacyclin to heparin not only potentiates the effect of heparin and results in a decreased need for heparin dose, but also, because of its antiplatelet action, can dramatically improve the hemofilter life. Prostacyclin has been compared with both heparin and citrate as an anticoagulant, with promising results.[35,36]

The most important drawbacks with the use of prostacyclin are its limited clinical experience and the paucity of published reports on its safety and efficacy. Systemic side effects include hypotension and an increase of intracranial pressure, both of which can be prevented or limited by infusion into the extracorporeal circuit, thus reducing the systemic levels related to extracorporeal elimination. Prostacyclin may be considered an anticoagulant in patients with increased risk of bleeding. An important limiting factor of prostacyclin is its high cost.

COMPLICATIONS

Complications of CRRT can result from technical issues, such as vascular access and device malfunction and failure, as well as those resulting from the clinical impacts of the procedure itself (Table 35.7).

Technical and equipment malfunction

Complications associated with the vascular catheter, such as kinking, partial or complete obstruction, or displacement, can lead to malfunction or cessation of the CRRT and clotting of the circuit. Circuit down-time due to above listed factors can result in delivery of less than optimal CRRT therapy dose in critically sick patients. In one study, prescribed dose was delivered to only 68% patients due to circuit downtime problems.[37] The CRRT device can experience technical failure or loss of integrity of the extracorporeal tubing set, and air may enter the blood circuit and result in air embolism. Newer CRRT devices, are, however, equipped with air detectors that clamp the blood return line to the patient if air is detected within the tubing set. Errors of ultrafiltration are less common with modern CRRT equipment, but may occur in small infants and newborns if the device controls are manually overridden by the operators. Finally, the efficiency of the hemofilter may deteriorate due to the accumulation of plasma proteins and blood cells along the intravascular side of the capillary filters.

Bleeding

Anticoagulation-associated bleeding is a well-known complication seen in CRRT.[27] The source of bleeding is often at the catheter exit site, but it can also be internal, usually at the vascular puncture site. Because of systemic heparinization, internal bleeding in the gastrointestinal tract and other vital organs can be severe.

Table 35.7 Complications of continuous renal replacement therapy

Technical complications	Clinical complications
• Vascular access failure	• Bleeding
• Circuit clotting	• Infection (catheter related and bacteremia)
• Occlusion of catheter	• Hypothermia
• Inadequate blood flow for clearance	• Nutritional losses
• Tubing malfunction or separation	• Hypotension
• Air embolism	• Electrolyte disturbance
• Loss of clearance over time	

Infection

The risk of infection from placement of the AV access can add significantly to morbidity in a critically ill patient. In suspected sepsis, blood should be cultured from the peripheral source, as well as from the dialysis catheter, to distinguish catheter colonization from a bacteremic state.

Hypotension

Despite the slow nature of CRRT, excessive ultrafiltration and hypotension can occur, especially if set alarms on the CRRT machines are manually overridden without addressing the underlying reason for the alarm. Hypotension is an even more important concern in small infants and neonates because excess ultrafiltration alarms in some CRRT devices are not activated unless 150 mL of fluid removal has occurred over 3 h. Therefore, such critically ill patients need heightened vigil for hypovolemia by the clinical staff.[38]

KEY POINTS

- Potassium phosphate 1 mmol/L provides 1.5 mol/L of potassium.
- Potassium chloride 1 mmol/L provides 1 mol/L of potassium.

Electrolyte disturbances

Hypokalemia and hypophosphatemia are common occurrences in CRRT, especially if the dialysate or replacement fluid has not been appropriately reconstituted. This is particularly important when CRRT is used in patients with intoxications or inborn errors of metabolism. Often, these children do not have AKI, and they can have ongoing renal excretion of potassium and phosphorus, in addition to losses encountered during CRRT, with resulting profound hypokalemia or hypophosphatemia, or both. Potassium can be added as potassium chloride or potassium phosphate in the dialysate or in the replacement fluid. Each mmol of potassium phosphate/L provides 1.5 mmol of potassium/L, whereas 1 mmol/L of potassium chloride provides 1 mmol/L of potassium.

The use of citrate anticoagulation and dextrose in the citrate infusion (ACD solution) may deliver significant amounts of glucose, thus enhancing the risk for hyperglycemia in the patient. Similar hyperglycemia can develop with the use of peritoneal dialysis solutions (Dianeal) as dialysate in CRRT.[39]

KEY POINTS

- Hypothermia may occur if the CRRT circuit is not supported by a blood warmer.
- Neonates and infants are especially susceptible to hypothermia during CRRT.
- Overriding fluid removal alarms on multiple occasions without addressing them appropriately can result in excessive ultrafiltration and hypotension.

Hypothermia

Extracorporeal circuits can have a cooling effect on the patient, and the patient's temperature may reach the ambient temperature in the room. This is especially likely if the CRRT device lacks blood-warming capability. The warming units are often add-on appliances to the CRRT devices and need to be purchased separately. As pointed out earlier, extracorporeal cooling of blood may mask the development of a clinical fever in the critically ill patient.

Nutritional losses

Hypermetabolism and malnutrition are common in AKI. Increased mortality and morbidity, as well as an increased length of hospital stay as a result of malnutrition, have been well established in adults.[40] Given these risks with AKI, the goals of therapy should be to maximize nutrition and to reverse the catabolic state in these patients. Optimal nutritional management of AKI in adults includes increasing the protein content while possibly providing adequate total caloric intake.[41,42] In adult patients with AKI who require CRRT, provision of 1 g/kg/day or more of protein has been associated with a trend toward a higher normalized protein catabolic rate (nPCR), and a smaller nitrogen deficit, as compared with a protein intake of less than 1 g/kg/day.[41] However, even with CRRT, it is often difficult to reverse the catabolic state in patients with AKI.[43]

Significant dialytic clearance of amino acids has been noted during CRRT, especially with the addition of dialysis. Loss of amino acids can range from 1.5% to more than 100% for some amino acids, and an even higher dialytic clearance is associated with the high ultrafiltration rate.[44] Maxvold et al.[45] compared amino acid loss and nitrogen balance in critically ill pediatric patients requiring CVVH and CVVHD who were receiving similar dialysate or replacement fluid rates and total parenteral nutrition. These investigators noted that amino acid loss was slightly greater with CVVH than with CVVHD, and

these losses accounted for approximately 12% and 11% of the total daily protein intake, respectively.[45] It has been suggested that amino acid intake should be enhanced by approximately 12 g/1.73 m²/day in addition to the standard recommendation of 1.5 g/kg/day of amino acids (protein) in pediatric patients undergoing CRRT.[45]

Micronutrients also are removed by both diffusive and convective CRRT. A net negative balance of selenium, copper, and thiamine, while having a slightly positive net balance of zinc, has been shown to occur with hemodialfiltration.[46] Trace element supplementation with selenium, and possibly other micronutrients, may be necessary in situations of prolonged CRRT.

NEONATES

The use of CRRT in the neonatal patient requires close attention to the potential for adverse events. Because of the small intravascular blood volume of these patients, careful attention must be paid to the volume status and the percentage of intravascular blood volume to be contained in the extracorporeal circuit. In order to avoid adverse events, such as hypotension, priming the CRRT circuit with blood is usually necessary in neonates and infants (also see below).

> ### KEY POINTS
>
> - Anaphylactic reaction to bradykinin release is a concern with hemofilters using the AN69 membrane.
> - The risk is highest in neonates, in the presence of metabolic acidosis, or when using stored blood for priming the CRRT circuit.

BLOOD FLOW RATE

The BFR in neonates and young infants is targeted at 5 to 10 mL/kg/min. However, this may lead to blood flow through the extracorporeal CRRT circuit that is too slow and may result in clotting of the CRRT circuit and the need for its frequent replacement. To overcome these problems, the CRRT blood flow should run at a minimum speed of 50 mL/min in neonates, regardless of body weight.

BLOOD PRIMING AND RISK OF (AN69) MEMBRANE REACTIONS

In neonates and infants, the calculated extracorporeal blood volume of more than 10% of the patient's estimated intravascular blood requires priming the CRRT circuit with whole blood, in order to prevent volume depletion and hypotension. Priming the circuit with normal saline or 5% albumin should be avoided because of the risk of hemodilution of the patient's hematocrit.

Serious life-threatening hyperkalemia, metabolic acidosis, and hypotension have been reported with priming of the CRRT circuits with stored unbuffered blood.[47,48] These manifestations are believed to represent a specific bioincompatibility associated with hemofilters that use the AN69 membrane. This reaction results from activation of leukocytes and release of bradykinin when stored acidemic blood comes in contact with this membrane.[47] Options to mitigate this potentially lethal side effect are as follows:

- To minimize the impact of the previously described complication, a "bypass maneuver" has been suggested. In this procedure, the patient's blood, after its first pass through the hemofilter, is discarded, while simultaneously providing a blood transfusion of packed red blood cells diluted with normal saline in a ratio of 1:1. The procedure requires placement of two three-way stopcocks on the venous return line of the extracorporeal circuit.[47] The patient's blood containing any activated leukocytes after contact with the hemofilter membrane is drained into a waste bag connected to the proximal three-way stopcock. Blood is transfused to the patient through the distal three-way stopcock. During the procedure, the CRRT device blood pump is set to a flow rate of 10 mL/min, and the packed red blood cell solution is infused at 600 to 900 mL/h (10 to 15 mL/min).[47] Buffering of the packed red blood cells to normalize the pH and neutralize the citrate content to minimize or prevent the bradykinin release has been recommended.[47]
- Buffering of the blood to improve the pH, potassium, and calcium can occur to offset some of the metabolic perturbations of blood bank blood, as listed in Table 35.8.

Table 35.8 Composition of the modified blood prime for AN69 filter

Component	Volume
Packed red blood cells	300 mL
Tris-hydroxy-methyl aminomethane (THAM)	50 mL
Calcium chloride (27%)	250 mg
Heparin (100 Units/mL)	5–7 mL (500–700 units)
Mix equal parts with:	
Sterile water	850 mL
Sodium bicarbonate (1 mEq/mL)	150 mL

- It has been reported that dialyzing the blood prime of a CRRT circuit for use in neonates has resulted in nearly physiologic correction of the metabolic acidosis and hyperkalemia commonly seen when using banked blood. The procedure is instituted by recirculation and zero-balance ultrafiltration hemodialysis of the blood prime before connecting the patient to the CRRT circuit.[49] "Z-BUF," another technique of predialysis of the priming blood, uses recirculation of blood after buffering it with 5% albumin in a ratio of 60:40.[50] Dialysate flow rate in the Z-BUF technique prime predialysis is recommended at 2 L/h, and the procedure is conducted for 30 min. Using this technique, these authors found that it nearly normalized the blood pH and serum electrolytes while having virtually no effect on tumor necrosis factor-α, interleukin-1β, and interleukin-6 levels before and after Z-BUF.[50] A significant reduction in bradykinin in the blood prime was also noted.[50]

OUTCOME

In one large pediatric series, survival rates of 25% and 41% were been reported in children weighing less than 3 kg and in those weighing between 3 and 10 kg, respectively.[51] Overall survival was 38%. The mean BFR in this series was 9.5 ± 4.2 mL/kg/min, and the mean duration of CRRT was 7.6 ± 8.6 days. Survivors weighing more than 3 kg required fewer vasopressor medications than did nonsurvivors, and there was no difference in outcome based on the use of convective or diffusive clearance. The clinical conditions associated with CRRT use in these patients were congenital heart diseases (16.5%), metabolic disorders (16.5%), multiple organ dysfunction syndrome (MODS) (15.3%), sepsis (14.1%), and liver failure (10.6%).

EXTRACORPOREAL MEMBRANE OXYGENATION

Managing CRRT and extracorporeal membrane oxygenation (ECMO) requires an appreciation of the effect of shunting blood flow from the membrane oxygenator to the hemofilter. CRRT may be accomplished either with a dedicated CRRT machine (CVVHD) or by the insertion of a postpump hemofilter.

CONTINUOUS ARTERIOVENOUS HEMOFILTRATION CIRCUIT SET-UP

A simpler form of CRRT on an ECMO circuit consists of a CAVH arrangement, using the ECMO pump itself to drive the extracorporeal circulation of blood through the CRRT hemofilter. In this arrangement, the arterial line is placed in the postpump position, either in the preoxygenator or postoxygenator position, with the venous return line returning to the bladder.

The main concern in this procedure is uncontrolled diversion of blood to the hemofilter, resulting in a "steal" phenomenon from the ECMO circuit. The steal phenomenon can be measured by the difference in ECMO blood flow necessary to maintain the mixed central venous oxygen saturation at the same level before and immediately after diverting blood flow to the hemofilter.[52] Calculating the hemofilter blood flow in this arrangement of CRRT on an ECMO circuit can be done using the following formula:

$$\text{Patient blood flow\%} = \frac{[\text{CaO}_2(\text{postoxygenator}) - \text{CvO}_2(\text{postoxygenator})] \times 100}{[\text{CaO}_2(\text{postoxygenator}) - \text{CvO}_2(\text{Prebladder})]}$$

Hemofilter (CRRT) blood flow% = 100 − Patient blood flow%

where CaO_2 is the arterial oxygen content and CvO_2 is the mixed venous oxygen content.

KEY POINT

The preferred sites for connecting the CRRT circuit in a patient on ECMO are the prebladder position for the arterial site and the postbladder position for the venous site.

LOW-PRESSURE CIRCUIT SET-UP

In infants and small children, the blood flow of an ECMO circuit may not result in a steal phenomenon from the CRRT bloodlines. However, with high blood flow of the ECMO circuit in children and adolescents, the steal phenomenon from the CRRT circuit can become evident and lead to poor solute and fluid clearance in the CRRT procedure. The steal phenomenon may also lead to increased "arterial" (access) pressure and alarms in the CRRT device. Similarly, if the venous line of the CRRT device is placed in the postpump

---

KEY POINTS

- Inborn errors of metabolism form an important indication for CRRT.
- For rapid correction of hyperammonemia, standard hemodialysis is preferred as the initial therapy. This can be followed by CRRT to prevent a rebound rise of plasma ammonia levels.

---

position of an ECMO circuit, the high blood flow may overcome the venous pressure in the CRRT circuit, result in the backflow of blood into the CRRT circuit, and cause venous pressure alarms in the CRRT device. Therefore, it is important to place both the "arterial" and "venous" lines of the CRRT in the low-flow sections of the ECMO circuit. Because of the foregoing considerations, the preferred location for placement of CRRT access is in the prebladder to the bladder position or from the bladder to the prebladder position.

OUTCOME

The outcome of CRRT on ECMO depends more on the underlying disorder requiring treatment with ECMO than on AKI requiring CRRT. One study found that 6 of 27 patients receiving ECMO therapy developed AKI and needed CRRT. Of these patients, only 2 survived.[53] Another retrospective study, of 35 pediatric patients less than 18 years of age who were receiving CRRT with ECMO therapy, found an overall survival of 43%, with 93% of survivors recovering renal function.[54] The latter study also found that the use of vasopressors on ECMO and CRRT portended a poor outcome of patients.

INBORN ERRORS OF METABOLISM

CRRT has been used effectively to correct metabolic derangements associated with a variety of inborn errors of metabolism. Children with a suspected or confirmed inborn error of metabolism often require extracorporeal therapy to achieve rapid correction of their metabolic disturbance. Accumulation of ammonia is the primary abnormality encountered in urea cycle disorders. In these patients, CRRT modalities can achieve excellent clearance of ammonia and rapid correction of the hyperammonemic coma.[55–63] The extracorporeal clearance of ammonia with CRRT always must be accompanied by the concomitant use of alternative pathway medications to decrease ammonia generation.

Branched-chain amino acidemias, such as maple syrup urine disease, methylmalonic acidemia, propionic acidemia, and isovaleric acidemia, have also been successfully treated using CRRT.[60] As in urea cycle disorders, CRRT provides rapid and ongoing removal of accumulated branched-chain amino acids and their ketoacid metabolites that are responsible for the neurologic sequelae of these disorders. However, hemodialysis may provide better clearance of ammonia in a shorter time and may be considered the initial therapy of choice, especially if the plasma ammonia level is very high. Following hemodialysis, CRRT may provide relief from the rebound of plasma ammonia level that is commonly noted in these patients.

MULTIPLE ORGAN DYSFUNCTION SYNDROME

MODS is defined as a clinical condition that is characterized by simultaneous failure of two or more organ systems.[64,65] The Prospective Pediatric CRRT (ppCRRT) Registry Group described MODS as the indication in 181 of 294 pediatric patients who underwent CRRT. In this cohort, sepsis (28.7%) and cardiovascular shock (16.0%) were the most common causes of MODS. The overall survival rate from MODS requiring CRRT support was 50.8%.[66] Mean fluid overload at the time of ICU admission and the Pediatric Risk of Mortality 2 (PRISM2) score at the time of initiation of CRRT had a significant impact on survival in these patients.[66] Survival rates were better for patients who had less than 20% fluid overload (survival, 61%) at the time of initiation of CRRT when compared with a greater than 20% fluid overload (survival, 32%).[66] These data support the concepts of goal-directed fluid therapy and early initiation of CRRT in treatment of MODS.

LIVER DISEASE

It has been well reported that coexisting liver and renal dysfunctions have a significant impact on hospital and intensive care mortality rates. The prevalence of AKI in adult patients with end-stage liver disease and cirrhosis has been estimated to be 10%–50%.[67,68] The cohort of patients with liver disease in ICUs who require RRT includes those with acute liver failure (ALF), acute decompensation of chronic liver disease, post–liver transplant renal failure, metabolic liver disease, and liver disease in patients who develop AKI as a part of multiorgan failure resulting from sepsis.

Significance of renal dysfunction in a patient with liver failure was demonstrated by the observations of du Cheyron et al.,[68] who compared a cohort of cirrhotic patients with mild and severe renal failure and those without renal failure. Patients with AKI had a hazard ratio of 4.1 for mortality, and all were associated with higher Acute Physiology and Chronic Health Evaluation (APACHE) and Sequential Organ Failure Assessment (SOFA) scores, as well as a higher crude mortality rate. The incidence of AKI in patients with ALF and acute decompensation of chronic liver disease varies from 40% to 75%. Defining the etiopathogenesis of ALF and AKI, assessing the need for detoxification therapy, and timing and dosing of CRRT are the key clinical tasks for the clinical team taking care of these patients.

The indications of CRRT in patients with ALF include AKI, metabolic abnormalities, hepatic encephalopathy (HE), the need to remove toxic metabolites resulting from hepatic dysfunction, and maintaining adequate fluid balance to ensure end-organ perfusion. Patients with ALF may have sepsis-like hyperdynamic circulation with vasoplegia

and intense arterial vasodilatation resulting from release of endogenous vasodilators. Systemic vascular resistance declines, and despite an increased cardiac output, a reduction in blood pressure is common. The renal autoregulation curve is shifted to the right in these patients, thus rendering renal hemodynamics even more perfusion pressure dependent and creating the environment for development of acute tubular necrosis and AKI.

The potential for recovery of hepatic function, the small organ donor pool, and the risk of death while awaiting liver transplantation have focused clinical efforts on detoxification liver support devices as bridges to transplantation or recovery. CRRT serves several purposes in ALF: (1) treatment of the associated AKI; (2) correction of high levels of ammonia, lactate, and other metabolic disturbances associated with ALF; and (3) manipulation of fluid balance.

In the absence of any relevant data, timing of initiation of renal support in ALF is entirely determined on clinical grounds. It is recommended that CRRT be initiated early in the course of ALF, as soon as the metabolic abnormalities such as hyperammonemia, increased lactate level, metabolic acidosis, and hyponatremia develop. Hyperammonemia is a particularly important factor in deciding the timing of initiation of CRRT in patients with ALF, because it can be associated with HE and intracranial hypertension (ICH). Bernal et al.[69] evaluated the relationships of the admission arterial ammonia concentration and other clinical variables in the development of HE and ICH. Arterial ammonia level was measured on admission to the ICU in 257 patients; 165 of these had ALF and severe HE. An ammonia level greater than 100 μmol/L predicted the onset of severe HE with 70% accuracy. ICH developed in 55% of patients with ALF and an arterial ammonia level greater than 200 μmol/L. After admission, ammonia levels remained high in those patients who developed ICH and fell in those who did not. Being an independent risk factor for the development of both HE and ICH, ammonia measurements could form part of the risk stratification for HE and ICH, and in identifying patients for ammonia-lowering therapies and invasive monitoring.[68]

The presence of renal dysfunction preoperatively, hypotension during and after transplantation, the need for infusion of blood products, and the use of nephrotoxic drugs are potential risk factors for development of AKI after liver transplantation. These patients may also require CRRT support in the immediate post-liver transplant course.

Anticoagulation for CRRT in liver disease needs to be considered carefully. Because patients with ALF usually have high INR, intuitively suggesting that anticoagulation may not be necessary in CRRT. However, it is important to recall that these patients have a deficiency of both procoagulant and anticoagulant factors, and there may also be a concurrent need for blood and blood product infusions in them. Depending on the balance among these competing aspects of coagulation, patients with ALF may be in a hypercoagulable state and result in frequent CRRT circuit or hemofilter clotting. Agrawal et al.[70] retrospectively reviewed CRRT circuit life in three groups of patients with liver disease who were treated with CRRT: ALF, acute on chronic liver disease, and after elective liver transplantation, with two control groups consisting of systemic sepsis and hematologic malignant disease. The mean filter life was low in all patients with liver disease and sepsis, being 11 ± 10.5 h in ALF, 11.6 ± 6.6 h in acute on chronic liver disease, 7.4 ± 5.1 h in liver transplantation, and 9.2 ± 6.5 h in systemic sepsis. After starting anticoagulation in a select group of patients with liver disease, filter life increased from 5.6 ± 3.4 h to 13 ± 5.1 h. There was no increased bleeding or requirement for blood transfusions in the anticoagulation-treated groups. These data suggest that careful anticoagulation may help in preserving CRRT circuit life in patients with advanced liver disease.[70]

MALIGNANT DISEASE

Tumor lysis syndrome (TLS), characterized by rapid destruction of a large solid tumor or white blood cell burden by chemotherapeutic agents, results in hyperuricemia, hyperkalemia, and hyperphosphatemia with associated hypocalcemia. CRRT has been demonstrated to normalize serum uric acid, potassium, and phosphorus levels in children at risk for development of tumor lysis syndrome.[71]

Another significant oncologic population at risk for development of AKI is the hematopoietic cell transplant recipient. It is estimated that 25% of children with hemopoetic cell malignancies develop TLS after initiation of therapy.[72] The incidence of AKI in these patients, defined as a doubling of the serum creatinine, is reported to be 25% to 50%.[73] The ppCRRT Registry Group reported on the outcomes of 44 pediatric bone marrow transplantation recipients who required CRRT.[12] Overall patient survival to ICU discharge was 40%, with a trend toward improved survival from 2003 to 2004 in the ppCRRT registry (36% and 44%, respectively). In this retrospective cohort study, mean airway pressure at the termination of CRRT was significantly greater (26.06 ± 2.02 vs. 8.44 ± 2.69 mm Hg) in the nonsurvivors compared with survivors. In this analysis, the percentage of fluid overload did not discriminate between survivors and nonsurvivors. The role of CRRT in the management of bone marrow transplant recipients with acute respiratory distress syndrome (ARDS) has been investigated by DiCarlo et al.,[74] who initiated CRRT concomitantly with intubation for ARDS in 6 pediatric bone marrow transplant recipients. These authors achieved a high rate of clearance (50 mL/min/1.73 m²) by performing hemofiltration with a replacement solution at 1800 mL/h and dialysis with a countercurrent dialysate solution at 1800 mL/h (termed as high efficiency CRRT). Eighty percent of these patients survived to hospital discharge with recovery of their native renal function. These findings suggest that early and aggressive use of CRRT in a bid to normalize fluid balance and use of high efficiency CRRT may be important in improving survival of hematopoietic cell transplant recipients who develop either AKI or ARDS.

HYPEROSMOLAR STATES

Hyperosmolar disorders secondary to hypernatremia have been associated with a mortality rate of up to 70% in pediatric patients.[75] Slow correction of hyperosmolality using CRRT and hypertonic dialysate or replacement fluid has been advocated.[5]

INTOXICATIONS AND POISONINGS

The ability of extracorporeal therapies to remove an intoxicant is affected by the volume of distribution of the drug. Generally, drugs with volumes of distribution of less than 1 L/kg (total body water) are amenable to dialytic removal.[76] Drugs with large volumes of distribution are less likely to be effectively removed by dialysis, and they are more likely to result in rebound elevations of blood levels following dialytic therapy. High-molecular-weight drugs are also more difficult to dialyze than are low-molecular-weight drugs. High-efficiency hemofilters can overcome this size barrier, to some extent. The degree of protein binding has a negative effect on a drug's dialyzability. However, if protein-binding sites are fully saturated, free drug may be amenable to dialytic clearance.

Numerous medications have been described as being cleared by CRRT. Although an extensive listing of all drugs removed by CRRT is beyond the scope of this chapter, some of the common drugs that can be removed include vancomycin, lithium, ethylene glycol, procainamide, theophylline, methotrexate, phenytoin, carbamazepine, and valproic acid.[77–86]

Use of albumin dialysis has been reported to aid in the removal of highly protein-bound drugs. Askenazi et al.[86] described the use of albumin dialysis using CVVHD to treat an acute, severe carbamazepine overdose. These investigators found a dramatic decrease in the serum half-life of carbamazepine (from 25 to 60 h to 7 to 8 h) by using albumin-dialysis CVVHD.[76] Phenytoin and valproic acid removal has been reported to be enhanced with albumin dialysis, compared with standard high-efficiency CVVHD.[85,87]

COMBINED CONTINUOUS RENAL REPLACEMENT THERAPY AND PLASMAPHERESIS

The combination of plasmapheresis and CRRT may be occasionally performed in the management of immune-mediated diseases complicated by AKI. In most instances, however, CRRT is discontinued during plasmapheresis and is resumed after the completion of the plasmapheresis. Stopping CRRT may cause citrate accumulation during plasmapheresis, thus leading to hypocalcemia, and it also poses a risk for hemodynamic instability.[88]

Yorgin et al.[89] described the use of concurrent plasmapheresis and CRRT in the treatment of a 14-year-old girl with leukemia. In this instance, the investigators placed a three-way stopcock at both the arterial and venous sides of the double-lumen dialysis catheter.[89] The three-way stopcocks allowed for parallel flow of the arterial blood through both the centrifugation plasmapheresis circuit and the CRRT circuit and parallel return of venous blood flow back to the patient. Alternately, in an in-series configuration, the plasmapheresis circuit draws the patient's blood from the arterial side of the double-lumen catheter, and the plasmapheresis in-port is connected to the venous line of the CRRT circuit. The patient's blood is returned through the venous return line of the plasmapheresis circuit. With this technique, citrate anticoagulation used in the plasmapheresis circuit can then undergo high dialytic clearance.

OUTCOME

Experience in using concurrent centrifugation plasmapheresis and CRRT is limited. Ponkivar et al.[90] reported the use of this approach in 21 neonates and infants. These authors found that recovery of renal function occurred in 47.6% of patients, with an overall patient survival rate of 42.9%. Complications of concurrent therapy include hemofilter thrombosis, catheter malfunction, hypotension and bradycardia, and pulmonary edema.[90]

SINGLE-PASS ALBUMIN DIALYSIS

The molecular adsorbent recirculation system (MARS) is an evolving technology for treatment of fulminant liver failure.[91] A meta-analysis of the published literature by Vaid et al.[92] suggested that MARS therapy leads to a significant decrease in the serum bilirubin concentration and West Haven grade of HE. Overall mortality, however, remained unchanged in this analysis. MARS is recommended as a bridge to orthotopic liver transplantation in patients with fulminant liver failure.

Because of the complexity and cost of the MARS circuit, efforts to adopt current CRRT machines to support patients with ALF have been considered. The use of CRRT for this purpose is known as single-pass albumin dialysis (SPAD). The purpose of this therapy is to provide dialytic clearance of protein-bound inflammatory mediators or toxins

Table 35.9 Survival in continuous renal replacement therapy by primary diagnosis

Clinical parameter	n	Survivors	% Survival
Sepsis	81	48	59
Bone marrow transplant	55	25	45
Cardiac disease or transplant	41	21	51
Renal disease	32	27	84
Liver disease or transplant	29	9	31
Malignant disease (no tumor lysis syndrome)	29	14	48
Ischemia/shock	19	13	68
Inborn error of metabolism	15	11	73
Drug intoxication	13	13	100
Tumor lysis syndrome	12	10	83

associated with ALF. In contrast to MARS, SPAD does not involve regeneration of the albumin dialysate, thus resulting in a single-pass of the albumin dialysate, which is then discarded.

In a retrospective analysis, Kortgen et al.[93] demonstrated that MARS and SPAD were comparable in biochemical improvement scores, the need for blood transfusions, overall health score, and mortality rates. Saur et al.[94] evaluated the in vitro clearance of bilirubin, ammonia, and bile acids by using MARS, SPAD, and CVVHDF. Clearance of bile acids was equal with MARS and SPAD, but the clearance of bilirubin was better with SPAD than with MARS. There was no difference in ammonia clearance among MARS, SPAD, and CVVHDF.[94] Ringe et al.[95] retrospectively analyzed data in nine patients with ALF who were treated with SPAD as a bridge to transplantation or as a detoxification method. These investigators found SPAD to be well tolerated and an effective detoxification mechanism in ALF, and it bridged 75% of patients successfully to transplantation. Most of these patients had a very low probability of survival by both Pediatric Index of Mortality 2 (PIM2) and Pediatric End-Stage Liver Disease (PELD) scoring.[95]

In vivo use of SPAD has been reported in case reports and case series to treat ALF secondary to Wilson disease and acute hepatitis.[96,97] Kreymann et al.[96] used a 44 g/L (4.4%) albumin dialysate solution by replacing 1 L of a 4.5-L bicarbonate-based dialysate with 20% albumin. CRRT was performed as CVVHDF, without apparent modification from the standard protocol. These authors found significant clearance of copper and total bilirubin, with a resultant improvement in the patient's HE and electroencephalogram. Collins et al.[97] reported on the use of SPAD in an adolescent girl with ALF secondary to Wilson disease who was bridged successfully to orthotopic liver transplantation. These authors used 5% albumin added to a bicarbonate-based dialysate and ran the dialysate at 1 to 2 L/h of flow.

This patient experienced a reduction in her transfusion requirements, serum copper concentrations, and conjugated bilirubin and improvements in her renal function and HE. Chawla et al.[98] compared bilirubin clearance by using both 1.85% and 5.0% albumin dialysate and found improved total bilirubin clearance using the 5.0% albumin concentration. It appears that a 5% (50 g/L) albumin concentration provides the best clearance in SPAD. Specific cautions in the use of SPAD include the potential for hypernatremia secondary to high sodium content in the commercially available albumin solution. Prevention of hypernatremia may require a custom-made dialysis solution with a reduced sodium chloride concentration.

PROGNOSTIC FACTORS

Early single-center reports of outcome following CRRT in pediatric patients found an overall survival rate of only 42%.[99] In a retrospective study, Goldstein et al.[100] reported results in 21 pediatric patients receiving CRRT; these investigators took into account the patient's severity of illness score by using the PRISM2 score. They identified the percentage of fluid overload as a predictor of mortality, after controlling for severity of illness. The ppCRRT registry, reporting on 273 pediatric patients, found an overall survival rate of 58%. Patients with hepatic failure or a hepatic transplant had the lowest survival rate (37%), and those with drug intoxication had the highest survival rate (100%).[101] In the ppCRRT analysis, mortality rates in patients weighing less than 10 kg were significantly higher (64%) than in patients with more than 10 kg body weight (43%, $P <0.001$).[102] Some European studies have demonstrated lower mortality rates with CRRT (36% to 39%) than the ppCRRT data.[103,104] Table 35.9 lists survival by primary disease indication for CRRT.

SUMMARY

CRRT has evolved since the 1980s as an efficient and safe treatment for AKI in both adult and pediatric patients. Newer dialysate and replacement fluid solutions are available, and now one can safely use bicarbonate as the buffer to minimize cardiovascular instability, as well as to minimize the possibility of confounding the serum lactic acid levels. Anticoagulation for maintenance of the CRRT circuit is critical to providing adequate fluid and electrolyte therapy in the pediatric patient with AKI, and citrate anticoagulation appears to have multiple benefits over heparin anticoagulation. Prostacyclin is an emerging anticoagulant with great promise. Vascular access is critical for proper functioning of a CRRT circuit, and ideally it should use the largest catheter possible. Finally, CRRT may be a useful therapy in other clinical conditions, such as hyperosmolality, intoxications, hematopoietic cell transplantation, tumor lysis syndrome prevention, extracorporeal hepatic support, and plasmapheresis.

REVIEW QUESTIONS

CASE 1

A 6-year-old, 20-kg child with leukemia during induction develops Gram-negative septic shock with multiorgan system failure. The child is intubated on 70% FIO_2 and a PEEP of 10 cm. The child is oliguric and is 18% fluid overloaded. The child's laboratory tests include the following: sodium, 140 mmol/L; potassium, 6.9 mmol/L; chloride, 105 mmol/L; bicarbonate, 14 mmol/L; BUN, 100 mg/dL; and lactate, 4.5 mmol/L. A recent ABG showed: pH, 7.23; pAO_2 of 90; and pCO_2 of 43. The child is receiving norepinephrine for maintaining hemodynamic stability. Current blood pressure is 90/60 mm Hg. The child is to be placed on CRRT.

1. Optimal size and site of placement of the vascular access is:
   a. 11-Fr dual-lumen catheter in subclavian vein.
   b. 8- or 9-Fr dual-lumen catheter in right internal jugular vein

c. 8- or 9-Fr dual-lumen catheter in femoral vein

d. 11-Fr dual-lumen catheter in femoral vein

2. Use of AN 69 membrane based hemofilter in this patient may be associated with the risk of:
   a. Hemofilter clotting more frequently
   b. Poor clearance, if used in convective mode
   c. Anaphylaxis
   d. AN69 membrane has less clinical risk than polysulfone membrane

3. If AN69 membrane hemofilter is used in CRRT, blood prime should be avoided in this patient due to presence of metabolic acidosis and enhanced risk of anaphylaxis.
   a. True
   b. False

4. To allow *optimal* functioning of CRRT, the ideal arterial and venous pressures (as noted on the CRRT monitors) should be:
   a. Greater than 50 mm and less than 400 mm
   b. Greater than −50 mm and less than −400 mm
   c. Greater than −150 mm and less than 200 mm
   d. Greater than −150 mm and less than −200 mm

5. In this septic patient, the *best* modality of CRRT is:
   a. Diffusive method (CVVHD)
   b. Convective method (CVVH)
   c. Slow continuous ultrafiltration (SCUF)
   d. Both convestive and diffusive methods (CVVHDF)

6. Small molecular solutes are removed equally well by convection and diffusion.
   a. True
   b. False

7. To optimize solute clearance, the *optimal* total volume of dialysate and replacement fluid (if using CVVHDF) is:
   a. 2000 mL/h/1.73 m²
   b. 35 mL/kg/h
   c. Either a or b
   d. Neither a nor b

8. Target net fluid ultrafiltration rate to be ordered should be:
   a. 10 mL/h
   b. 1 to 2 mL/kg/h
   c. 10 mL/kg/h
   d. 25 mL/kg/h

CASE 2

A 14-year-old female patient is admitted with new-onset AKI, oliguria, hyperkalemia, IDDM, dehydration. Her laboratory tests show: serum sodium, 175 mmol/L (uncorrected); glucose, 1300 mg/dL; and BUN, 90 mg/dL.

1. What is this patient's calculated serum osmolality (mOsm/L)?
   a. 280
   b. 380
   c. 480
   d. 542

2. Osmolality (mOsm/L) of the peritoneal dialysate (PD), 1.5% dextrose, low-calcium solution is:
   a. 280
   b. 300
   c. 320
   d. 344

3. Osmolality (mOsm/L) of hemodialysis dialysate is:
   a. 280
   b. 300
   c. 320
   d. 340

4. Osmolality (mOsm/L) of dialysate used in CRRT is:
   a. 280
   b. 300
   c. 320
   d. 340

CASE 3

A 16-year-old male patient is admitted to the intensive care unit with multimedication overdose. He has AKI and oliguria. He is unresponsive and but is hemodynamically stable. No seizures have been noted. If started on CRRT,

1. The *most important* factor(s) in determining drug clearance is(are):
   a. Protein binding
   b. Molecular weight
   c. Volume of distribution
   d. All of the above

2. The *preferred* form of renal replacement therapy (RRT) in this case is:
   a. PD
   b. CRRT convective
   c. CRRT diffusive
   d. CRRT convective and diffusive
   e. HD standard
   f. HD sigh flux

CASE 4

A 3-day-old male newborn infant is admitted to the intensive care unit with somnolence, refusal to feed for 2 days, and twitching of the face today. The child weighs 2.9 kg (240 mL intravascular blood volume). Serum electrolytes show: sodium, 140 mmol/L; potassium, 5 mmol/L;, CO_2 14 mmol/L; and arterial blood pH, 7.02. Ammonia level was 1500 μmol/L.

1. The *best* type of renal replacement therapy (RRT) that will lower ammonia most rapidly is:
   a. PD
   b. CRRT
   c. Hemodialysis, standard
   d. Hemodialysis, high flux

Hemodialysis

RAJ MUNSHI AND JORDAN M. SYMONS

Hemodialysis is the most efficient method of artificial renal support. It accomplishes molecular transfer at much higher rates than either peritoneal dialysis (PD) or continuous renal replacement therapy (CRRT). Hemodialysis is highly effective in short-term settings for management of critical volume overload or intoxication, and it serves as an important method for long-term maintenance dialysis. Children require special evaluation and monitoring for successful hemodialysis. This chapter discusses general principles of hemodialysis operation, vascular access, prescription, and management, with emphasis on the unique considerations for pediatric patients.

HISTORY

The earliest report of a child receiving hemodialysis was a little boy with uremia who was dialyzed by Georg Haas in 1924.[1,2] The child was Haas's second patient to tolerate the procedure, but the child did not survive. Later, Willem Kolff developed the first practical human hemodialysis machine: a rotating drum with 20 m of cellophane tubing in a stationary 100-L tank.[3] The first pediatric application of the Kolff machine came in 1950 in Boston by John Merrill et al.,[4] when they treated a 3½ year old boy with nephrotic syndrome as part of a study that included 42 adults. In 1955, Mateer et al.,[5] at the Children's Hospital of Pittsburgh, described performing hemodialysis in 5 children 15 to 17 years of age by using 50-foot cellophane tubing and a 32-L dialysate bath for 13 h. As with all patients up to this time, ongoing therapy was limited by the necessity for new access for each session. Six years after the advent of the Scribner shunt in 1960, the Seattle group reported long-term hemodialysis in a 15½ year old girl for 18 months.[6] This was followed by the description of 5 adolescents dialyzed by Fine et al. in 1968.[7] Kjellstrand et al.[8] were able to achieve dialysis in patients weighing less than 15 kg. Access was a challenge with smaller patients because there was increased clotting of the Scribner shunt, and these patients were too small for the arteriovenous fistula (AVF) described by Brescia et al. in 1963.[9] The need for better access drove Hickman[10] to develop the central venous catheter that now bears his name. The Hickman catheter allowed a more permanent access for small children requiring hemodialysis.[10] Other technological advances such as volumetric controls allowed for greater efficiency and

accuracy in ultrafiltration (UF) and solute removal. Ongoing progress allows us to offer hemodialysis to our pediatric patients as a method for metabolic and volume control in acute kidney injury (AKI), a means to address intoxications, and a bridge toward transplantation in those children with end-stage renal disease (ESRD).

PHYSIOLOGY OF MOLECULAR MOVEMENT AND REMOVAL

Dialysis involves the movement of molecules between the plasma and the dialysate, which are separated from each other by a semipermeable membrane. In hemodialysis, three processes remove uremic toxins: diffusion, convection, and adsorption. Water removal occurs through UF. A clear understanding of the underlying physical principles that occur in hemodialysis is essential.

Diffusion involves the movement of molecules down a concentration gradient (Figure 36.1A). Molecules in plasma are in constant random motion. The smaller the molecule, the faster that motion will be. When a semipermeable membrane separates blood and dialysate, molecules within these solutions randomly make contact with the membrane and move across to the opposite side. Smaller molecules have more contact with the membrane within a given period of time because of their increased rate of motion. If side A has more molecules as compared with side B, there will be increased contact with the membrane on side A and thus increased passage of the molecule from side A to side B. The final result will be movement of molecules from a solution of high concentration to a solution of lower concentration. When the concentration of a molecule within both solutions is equal, there will be zero net movement of that molecule because passage between solutions will be equal.

KEY POINTS

- *Diffusion* is the movement of molecules down a concentration gradient.
- *Convection* is the movement of molecules within a solution as a result of the movement of the solution.

Convection is the movement of molecules within a solution as a result of the movement of the solution (Figure 36.1B). Pressure is applied to solution A, thereby causing movement of the solution across the
Figure 36.1 Principles of dialysis. **(a)** Diffusion: movement of molecules from an area of high concentration to an area of low concentration. **(b)** Convection: movement of molecules as a result of the pressure-related movement of the solution.

semipermeable membrane and dragging dissolved molecules with it. Here it is not the random motion of the molecules contacting the membrane causing transfer of the molecule, but rather the force of motion of the solvent taking dissolved solute with it. This process is described as *solvent drag*. In convection, the rate-limiting factor is not the size of the molecule, but the size of the membrane pores. Molecules that are smaller than the membrane pore size move across the membrane, whereas molecules too large to pass are left behind.

Molecular transport across a semipermeable membrane, resulting from diffusion or convection, is limited by the size and distribution of its pores. Small molecules are able to pass through small and large pores, whereas larger molecules are limited to large pores. Molecules larger than the size of the pores on the membrane are not able to pass at all.

As blood flows through the dialyzer, proteins may be *adsorbed* to the dialyzer membrane. Once the dialyzer
Figure 36.2 Schematic representation of hemodialysis circuit blood loop and dialysate loop. P, pressure monitors.

is discarded, the molecules bound to the membrane are removed from the body.

Ultrafiltration (UF) is the passage of water, or any solvent, through a semipermeable membrane down a pressure gradient. This pressure gradient can be generated by mechanical hydrostatic pressure, termed hydrostatic UF, or by osmotic pressure, termed osmotic UF.

DIALYSIS WATER

The blood of a hemodialysis-treated patient is exposed to a large volume of dialysate during a hemodialysis session. Using a standard dialysate flow rate (Qd) of 500 mL/min, a patient receiving hemodialysis for 3 h each session, three times a week, encounters 270 L of fluid on a weekly basis. Consequently, the water used to generate dialysate must meet rigorous standards for chemical, bacteriologic, and endotoxin content to avoid illness or injury. Municipal water is purified by employing carbon filtration and reverse osmosis. Depending on the chemical composition and hardness of the municipal water, it may be necessary to employ a water softener before it is subjected to reverse osmosis.

KEY POINTS

- Water used in hemodialysis must meet stringent quality standards.
- Water quality affects morbidity and mortality in patients undergoing hemodialysis.

Guidelines for water purity for dialysis use are updated periodically and published in the United States.[11]

HEMODIALYSIS MACHINES

The hemodialysis apparatus can be divided into two main components: the blood circuit and the dialysate circuit (Figure 36.2). The blood circuit contains the tubing set, the blood pump, and the hemodialyzer (Figure 36.3A and B). The dialysate circuit contains the proportioning and dialysate delivery system, a complex, integrated network that prepares the dialysate during the procedure. Some devices do not employ a proportioning system to generate dialysate online during the hemodialysis session. In machines that do not have proportioning systems, the dialysate delivery system uses centrally preconstituted final solutions.

BLOOD CIRCUIT

Tubing set

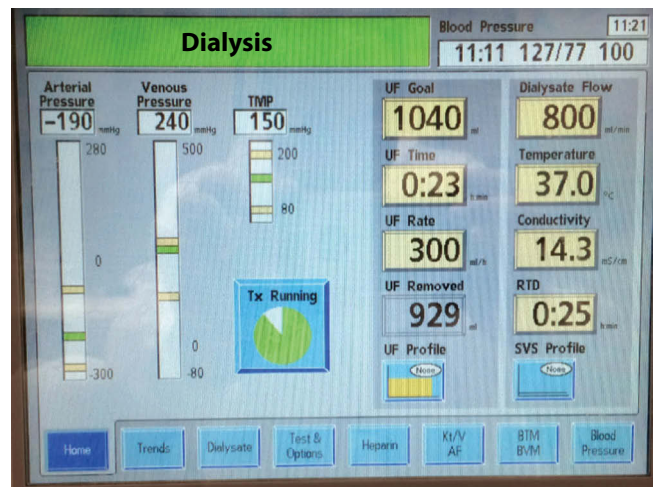
The tubing set can be divided into two parts: the arterial and venous segments. The *arterial segment* carries the blood from the patient to the hemodialyzer, and the *venous segment* returns the blood from the hemodialyzer back to the patient. The blood pump generates the blood flow; the revolutions per minute of the blood pump determine the blood flow rate (Qb). Usually, both the arterial and venous segments of the tubing set contain a drip chamber that allows separation of air, which rises to the top as blood flows through it. Some tubing sets have a venous drip chamber


Figure 36.3 **(a)** Hemodialysis machine demonstrating the blood pump (P), capillary dialyzer (CD), air detector (AD), and drip chamber in the arterial path (DC). **(b)** Hemodialysis machine monitor showing arterial pressure (−190 mm Hg), venous pressure (240 mm Hg), transmembrane pressure (TMP; 150 mm Hg), ultrafiltration and dialysate. (Courtesy of Fresenius Medical Care North America, Kaysville, UT.)

and not an arterial chamber. Pressure is monitored at multiple sites along the blood path. The pressure in the arterial (prepump) segment is negative, reflecting the pressure generated by the blood pump to draw blood into the tubing. The pressure in the venous (postpump) segment is positive, reflecting the resistance generated by the vascular access. The venous drip chamber also has a level and air detector, followed by a clamp distal to the drip chamber. If an alarm is activated by the pressure, air, or level detector, thus suggesting a safety risk to the patient, the blood return line will be clamped and the blood pump will stop. This clamp functions as the last line of control, and the machine malfunction needs to be addressed before blood can be returned to the patient.

Blood pump

The blood pump is a "demand-driven" pump, in that blood flow is set at a fixed rate. If the arterial access cannot provide the blood at a specified rate, the arterial line pressures will become more negative. If blood cannot be returned to the patient at a specified rate set by the blood pump, the venous pressures will become progressively more positive. Extremes of pressure may be incompatible with the function of the dialysis procedure, and they may put the dialysis membrane at risk for rupture or clotting.

This situation causes machine alarms and triggers the blood pump to stop.

Hemodialyzer

The hemodialyzer is a key component of the dialysis apparatus. It is where fluid removal and solute exchange occur across a semipermeable membrane. Historically, dialyzer designs have evolved from a drum, to parallel plates, and now to a hollow fiber capillary system (Figure 36.4). The hollow fiber dialyzers consist of thousands of capillary filters encased in transparent tubular casing and anchored by "potting material" at each end of the dialyzer. These dialyzers have a blood port at each end, one port for the blood inlet and the second port for the outlet. In close proximity to the blood port is the "header," where the blood collects before traveling into the hollow fibers. Within the body of the dialyzer are two dialysate ports, one for the inlet and the second for the outlet. The outlet port also serves as the exit for ultrafiltrate.

Membrane technology used within the dialyzer has evolved from plant-based cellulosic membranes to synthetic membranes. Cellulosic membranes contain free hydroxyl groups that activate complement and other inflammatory markers, thus leading to bioincompatibility.[12] Biocompatibility of the dialyzer membranes improved

after manufacturers modified the hydroxyl groups through chemical substitution, initially with acetate and later with tertiary amine, to create semisynthetic membranes. Most dialyzer membranes at present are synthetic, which are more biocompatible and also have greater hydraulic permeability. Some dialyzer membranes can also adsorb plasma proteins, immunoglobulins, and complement. Common synthetic membrane materials include polysulfone (PS), polyacrylonitrile (PAN), polycarbonate, polymethylmethacrylate (PMMA), and polyamide.

KEY POINT

Cellulosic dialysis membranes are the least biocompatible, whereas fully synthetic membranes are the most biocompatible.

The main function of the dialyzer is solute and fluid removal. In vitro testing by manufacturers allows reporting of solute clearance for molecules of various sizes, such as urea (molecular weight [MW], 60 Da), vitamin B_{12} (MW, 1355 Da), and β_2-microglobulin (MW, 11,000 Da). Knowledge of the clearance parameters of a given dialyzer permits a better understanding of its capabilities and allows a more specific dialysis prescription in patients. Clearance of various solutes (e.g., "uremic toxins," electrolytes) depends on the blood flow, dialysate flow, and dialyzer membrane characteristics that include thickness, surface area, pore size, and pore density.

DIALYZER CLEARANCE

When limitations of blood flow (Qb) and dialysate flow (Qd) are eliminated, one can isolate the membrane's ability to remove solutes, or its efficiency in clearing certain solutes. This measurement is termed the *mass transfer area coefficient* (KoA). KoA is the theoretical clearance of a solute at

KEY POINTS

- Clearance, expressed in mL/min, is the volume from which a substance is completely removed in a specified period of time.
- Dialyzer clearance depends on dialyzer surface area, its membrane characteristics, blood flow, and dialysate flow rate.
- KoA is the theoretical clearance of a solute at infinite Qb and Qd.
- Based on KoA$_{urea}$, dialyzer membranes are classified as low efficiency or high efficiency.

infinite Qb and Qd. Efficiency of a membrane is defined by how rapidly it completely removes urea from a solution (KoA$_{urea}$). Membranes are separated into low- and high-efficiency membranes: those with a KoA$_{urea}$ less than 500 mL/min are characterized as low-efficiency membranes, and those with a KoA$_{urea}$ greater than 500 mL/min are characterized as high-efficiency membranes.

In clinical settings, the restrictions of Qb and Qd cannot be eliminated. The actual clearance (K_D) achieved by a given dialyzer depends on operational characteristics beyond KoA and depends on Qb and Qd. K_D is lower with lower Qb or Qd and increases, within limits, with higher flows.

ULTRAFILTRATION CHARACTERISTICS

The ability of the membrane to remove plasma water is reported as the UF coefficient (K_{uf}). The K_{uf} signifies the volume of plasma water removed per hour per mm Hg of transmembrane pressure (TMP). A membrane with a K_{uf} less than 10 mL/h/mm Hg is considered low flux, whereas membranes with K_{uf} greater than 10 mL/h/mm Hg are considered high flux. UF volume achieved within a defined period of time depends on the K_{uf} and the TMP used to generate the ultrafiltrate:

$$UF = K_{uf} \times TMP$$

The term *flux* is also defined by the membrane's ability to clear middle molecules such as β_2-microglobulin. A dialyzer is considered low flux if KoA$_{\beta2\text{-microglobulin}}$ is less than 10 mL/min and high flux if it is greater than 10 mL/min.

DIALYZER STERILIZATION

Multiple techniques exist for commercial sterilization of the dialyzer and the tubing sets. Options include ethylene oxide (ETO), steam autoclaving, gamma irradiation, and electron beam irradiation. ETO can pose a risk of anaphylaxis for sensitive patients.[13] To avoid this reaction, proper rinsing of the dialyzer must be performed to ensure that all the ETO is removed before use. Electron beam irradiation has been associated with mild thrombocytopenia, especially with polysulfone and other synthetic membranes.[14]

DIALYZER REUSE

Some centers reuse a dialyzer for an individual patient over several sessions. The reuse procedure requires chemical cleaning, disinfection, and resterilization of the dialyzer after each hemodialysis session. This practice is decreasing and is generally not recommended for the pediatric population.

DIALYSATE CIRCUIT

Dialysate

The dialysate is a key component in the dialysis procedure. A patient dialyzing for 4 h at a dialysate flow of 500 mL/min requires 120 L of dialysate. Dialysate flows outside the dialyzer membrane capillaries in a countercurrent direction to the blood path and exchanges electrolytes and toxins. Thus, the purity of the water used to make the dialysate is of paramount importance. Because of the high volume of dialysate, most modern hemodialysis machines use concentrated solution or powders that are mixed by the hemodialysis machine with purified water to generate the dialysate during the session.

Dialysate concentrates are separated into two components, labeled "A" and "B" concentrates. The A concentrate contains the majority of the electrolytes and an acid, whereas the B concentrate contains the base, most often as bicarbonate. The concentrates are kept separate before initiation of the dialysis procedure to prevent precipitation because mixing of sodium bicarbonate ($NaHCO_3$) and calcium chloride ($CaCl_2$) would lead to precipitation of calcium carbonate ($CaCO_3$):

$$CaCl_2 + NaHCO_3 \rightarrow Ca(HCO_3)_2 + NaCl \rightarrow CaCO_3 + H_2O + CO_2$$
Acid is included in the A concentrate to keep the pH of the final dialysate solution lower than 7.4. Lower pH drives the chemical reaction noted earlier to the left, thereby preventing formation of highly insoluble calcium carbonate. Two types of acid are currently in use: acetate and citrate. Acetate comes in two concentrate forms, liquid and powder, that in the final dialysate solution make 4 mEq/L (liquid concentrate) or 8 mEq/L (powder concentrate) of acetic acid. Acetate is metabolized by the body to generate bicarbonate. Acid concentrates containing citrate have citric acid at 2.4 mEq/L, with 0.3 mEq/L of acetic acid in the final concentration.

The composition of typical dialysate delivered in treatment is presented in Table 36.1. Modern dialysis machines have the capability to adjust the concentration of components in the final dialysis by either using a different concentrate for the A component or by adjusting the blend of A and B components with the purified water. Dialysate concentrates for the A component come in various formulations to deliver the desired concentration of potassium (1, 2, 3, or

Table 36.1 Composition of dialysate

Component	Amount
Sodium	135–145 mEq/L
Potassium	0–4 mEq/L
Calcium	2.5–3.5 mEq/L
Magnesium	0.5–1.5 mEq/L
Chloride	98–112 mEq/L
Acetate/citrate	4–10/2.4 mEq/L
Glucose	0–200 mg/dL
Bicarbonate	35–40 mEq/L

4 mEq/L) and calcium (1.5, 2.5, or 3.0 mEq/L) in the dialysate. Selection of the initial concentrate permits adjustment of the potassium and calcium in the final dialysate without affecting the concentrations of the other electrolytes. In contrast, adjusting the final concentration of other components of the dialysate, specifically sodium and bicarbonate, is achieved by reprogramming the proportioning system to change the admixture of the concentrates with water. Consequently, this affects the concentration of the other electrolytes in that solution. For example, reduction of the sodium concentration by 4% reduces the final concentration of the other electrolytes by 4%.

> ## KEY POINT
>
> Adjusting the concentration of sodium and bicarbonate in the dialysate solution alters the concentrations of other electrolytes.

Dialysate delivery

The dialysate delivery system prepares the final dialysate in the dialysis machine, by using purified water and concentrated solutes. The components that make up the delivery system include the proportioning system, the volumetric control system, and the monitoring system.

Treated or purified water is sent to the machine *proportioning system,* which takes the necessary volume of water to dilute the A and B concentrates to generate the final dialysate. The final dialysate is checked for appropriate mixing by measuring its conductivity, which depends on its electrolyte concentration. Pure water has zero conductivity, whereas water containing solutes (salts) has higher conductivity. The conductivity of the dialysate, measured in millisiemens, is generally one-tenth of its sodium concentration. Thus, at a sodium concentration of 137 mEq/L the conductivity is 13.7 millisiemens. If the conductivity of the dialysate is within range, it will proceed to the dialyzer; failing this test, the dialysate will be diverted away from the dialyzer.

SAFETY DEVICES

Numerous safety mechanisms are present in modern dialysis machines that test for appropriate pressure, temperature, and dialysate content. Test failure causes an audible and visual alarm on the machine and may divert dialysate away from the patient or halt the dialysis machine completely. These systems are designed to ensure the patient's safety.

The *volumetric control system* protects the patient from excess UF. This is of paramount importance with high-flux dialyzers, which generate higher volumes of ultrafiltrate for a given TMP. UF control in the dialysis machines is achieved by numerous techniques, such as flow sensors, closed loop, or volumetric balancing. All these techniques are designed to provide safe and accurate UF.

The *blood leak detector,* which is located on the dialysate outflow tract, uses photo-optical sensors to detect red blood cells that have migrated from the blood to the dialysate through a fracture in the dialyzer. Some machines may have *pH sensors* on the proportioning system to ensure that both the A and B components are functioning and the final dialysate is well proportioned in its composition.

As described earlier, blood side monitors include arterial and venous pressure monitors, usually located in the drip chambers, and an air detector located in the venous drip chamber. To prevent catastrophic consequences such as blood loss, pressure limits are set to turn the blood pump off and clamp the venous line if the pressure limits are exceeded. The limits are usually −200 mm Hg for the arterial pressure and +200 mm Hg for the venous pressure. If there is venous needle dislodgment or catheter disconnection, the venous pressures will become very low, thus denoting the lack of resistance provided by the intravascular space; the blood pump will stop, and the venous line will be clamped to prevent exsanguination.

DIALYSIS PRESCRIPTION

Before hemodialysis is initiated, either in the short-term or long-term setting, careful assessment of the patient and clinical circumstances is required. Points include the indication for hemodialysis, appropriate vascular access, suitability of the patient for anticoagulation, assessment of vital signs with particular attention to blood pressure, selection of appropriate blood and dialysate flow rates, determination of the length of the dialysis session, and determinations of the dialysis dose and the UF goal. The guidelines for both short-term and long-term hemodialysis prescription are provided here and are outlined in Table 36.2.

INDICATIONS FOR SHORT-TERM HEMODIALYSIS

Initiation of short-term dialysis is required when medical management has failed to overcome complications of AKI. Clinical examples include fluid overload, electrolyte imbalance, acidosis, uremia leading to end-organ damage such as pericarditis, and encephalopathy, all refractory to medical intervention. Intoxication is another indication for short-term dialysis that may not be associated with AKI. Regardless of indication, an individualized approach is required when selecting a modality for renal replacement therapy, including consideration of the patient's size, access challenges, severity of illness, comorbidities, electrolyte imbalances, and level of blood urea nitrogen (BUN).

INDICATIONS FOR LONG-TERM HEMODIALYSIS

Controversy remains regarding the ideal time to initiate long-term dialysis support. The general trend among our colleagues who treat adults is earlier initiation of dialysis. The premise for this shift has been the assumption that an earlier start of dialysis (glomerular filtration rate, 10 to 15 mL/min/1.73 m^2) will provide a survival benefit. Observational studies have demonstrated that an earlier start of dialysis may improve survival,[15–17] but this finding was not supported by the Initiating Dialysis Early and Late (IDEAL) study, the only randomized controlled trial.[18]

In the pediatric population, as in adults, there is no single factor on which the clinician can rely to determine when to initiate long-term dialysis. Generally, indications to start dialysis can be separated into absolute and relative indications (Table 36.3). A specific factor that pediatric nephrologists should account for is growth, and some investigators hypothesize that adequate dialysis may reduce growth hormone resistance. The National Kidney Foundation Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines recommend that in a patient without significant manifestation of renal failure, one should consider dialysis initiation if the native creatinine clearance calculated by 24-h urine collection is less than 6 to 7 mL/min/1.73 m^2. This lower limit is derived from a weekly Kt/V of 2, the minimum target for standard Kt/V (see later for a discussion of dialysis adequacy and a definition and discussion of Kt/V).

VASCULAR ACCESS

The hemodialysis procedure requires vascular access to permit the patient's blood to flow through the hemodialysis machine. Without acceptable blood flow, the hemodialysis procedure cannot be successful. An ideal vascular access for hemodialysis is one that provides appropriate blood flow to permit adequate clearance and UF with a low complication rate and reliability to provide the necessary blood flow for repeated hemodialysis sessions. Vascular access methods for hemodialysis include temporary devices (central venous catheters) and permanent subcutaneous access systems,

Table 36.2 Components of the hemodialysis order set

which include the native AVF and the synthetic arteriovenous graft (AVG).

Currently, the AVF best meets the goals for hemodialysis vascular access and is therefore considered the preferred form of long-term access. The AVF is formed by subcutaneous anastomosis of an artery to an adjacent vein. One study demonstrated that the minimal venous and arterial lumen diameters should be 2.5 and 1.5 mm, respectively.[19] After anastomosis, it takes 2 to 4 months for the vein to dilate and for the venous wall to thicken enough to allow successful repeated needle access. The site of an AVF ideally should be the distal arm by creation of a radiocephalic fistula. This allows for more proximal sites to be used in the future if a complication occurs. In children, distal access in the wrist may not be possible because of size limitations; thus, more proximal access may need to be used for even initial AVF attempts.

An AVG provides the second-best option for permanent hemodialysis vascular access. An AVG differs from a native AVF in that a prosthetic tube, most often of

KEY POINT

In patients with ESRD, or at risk for ESRD, central lines should be avoided in the upper extremities to preserve future AVF access sites.

polytetrafluoroethylene (PTFE), bridges between a feeding artery and the recipient vein. The AVG requires less maturation time after its creation before it can be used because dilatation and thickening of the vein are not necessary. Generally, an AVG can be used within 1 to 3 weeks or even sooner if necessary. Because maturation of the native vein is not necessary, AVGs have a lower primary failure rate as compared with AVFs. However, the life span of the AVG is limited when compared with the AVF. The complication rate is also higher in AVGs, with more frequent infections and a greater need for surgical

Table 36.3 Indications for dialysis initiation

Absolute Indications

Uremia: life-threatening.

Neurologic: encephalopathy, confusion, asterixis, seizures, myoclonus, wrist and foot drop

Cardiac: pericarditis, pericardial effusion

Hematologic: bleeding diathesis

Hyperkalemia (life-threatening): refractory to medical management

Fluid overload (life-threatening): refractory to medical management

Absence of kidneys (congenital or after bilateral nephrectomy)

Anuria

Relative Indications

Uremia: subtle

Fatigue, reduced school or job performance, cognitive dysfunction, intermittent nausea or emesis, sleep dysfunction, and other conditions

Electrolyte imbalance (e.g., hyponatremia, hyperkalemia, hyperphosphatemia, hypercalcemia) difficult to medically manage

Malnutrition secondary to advanced chronic kidney disease

Growth failure secondary to advanced chronic kidney disease

Table 36.4 Acute dialysis catheter choices

Patient size	Catheter choice
Neonate	7-French double-lumen
	5-French single-lumen (requires two separate catheters)
3–6 kg	7-French double-lumen
6–30 kg	8-French double-lumen
15–30 Kg	9-French double-lumen
>30 kg	10-French double-lumen
	12.5-French double-lumen

and causes less patient discomfort as compared with the femoral site. In contrast, subclavian access is associated with increased risk of vascular stenosis that would result in loss of potential sites for AVF formation in the ipsilateral arm. Femoral access is a poor choice for long-term hemodialysis because of limitations on ambulation and a higher potential for complications, but it is a frequently used site for short-term hemodialysis given the relative ease of insertion. In neonates, umbilical catheters may also be used if other access sites have failed, but these catheters are often not successful as a result of poor flow dynamics, and they are not recommended.

ANTICOAGULATION

Exposure of blood to foreign surfaces results in clotting. To prevent clotting, anticoagulants are required when performing hemodialysis. Unfractionated heparin (UFH) is the most commonly used anticoagulant for dialysis. UFH works by activating antithrombin and inhibiting clotting factors, particularly factor Xa and thrombin. UFH is associated with platelet activation and aggregation, but by inactivating clotting factors on the platelet membrane, which limit binding and activation, it counterbalances this effect. The onset of action for UFH is within 3 to 5 min, and its half-life is 0.5 to 2 h.

Dosing of UFH for hemodialysis includes an initial bolus of 10 to 30 units/kg, which is administered through the venous access before connecting the patient, or into the arterial port before the hemodialyzer. Continuous infusion rates per session range from 10 to 20 units/kg/h. The dose of heparin is adjusted to obtain an activated clotting time of 150 to 200 sec (1.5 to 2 times normal). Alternatively, whole blood activated partial thromboplastin time (aPTT) can be followed with a goal of 80% greater than baseline during dialysis and 40% above baseline at the end of dialysis to prevent bleeding. Other techniques for dosing UFH include giving a large initial bolus without a maintenance infusion. Smaller additional boluses are administered as needed if clotting is

intervention to address problems with thrombosis, stenosis, and occlusion.

Central venous access for short-term or long-term hemodialysis can be achieved through a double-lumen catheter (most common) or through two single-lumen catheters. The hemodialysis catheter must be large and stiff enough to permit the required Qb for hemodialysis; standard central venous catheters designed for infusion of intravenous fluids are not acceptable. General recommendations based on weight or body surface area are available as an estimate of the catheter size that can be inserted (Table 36.4), but the largest catheter that can be safely inserted should be selected. Multiple central locations that permit needed high Qb can be considered for placement of the dialysis catheter. Potential sites for central venous cannulation include the jugular, femoral, and subclavian veins. The most desirable site for insertion of a double-lumen hemodialysis catheter is the right internal jugular vein. This vein provides access to a high–blood flow area in the superior vena cava and right atrium, permits a straight venous path for the operator from insertion site to the target location, can be readily used for insertion of either tunneled or nontunneled catheters, allows ambulation, is less susceptible to complicating venous stenosis that could limit future permanent vascular,

seen. UFH can be used to coat the dialyzer by rinsing the dialyzer with 3000 to 5000 units of UFH/L of saline. The dialyzer is subsequently rinsed with equal amounts of saline without heparin before connecting the patient. Side effects of UFH include pruritus, allergy, osteoporosis, hyperlipidemia, thrombocytopenia, and excessive bleeding.

ALTERNATIVES TO HEPARIN

Low molecular weight heparin (LMWH), which is a smaller fraction of UFH, retains its ability to activate antithrombin and bind and inactivate factor Xa, but it does not bind thrombin. Because of its longer half-life, LMWH can be administered as a single dose at the start of dialysis. The usual dose is 125 to 250 anti-Xa units/kg. Anti–factor Xa is monitored with a goal of 0.4 to 0.8 international units/mL to ensure that an appropriate therapeutic level is attained. It is believed that some of the side effects of UFH such as pruritus and hyperlipidemia are reduced with LMWH. LMWH is also associated with reduced activation of platelets and leukocytes. The risk of heparin-induced thrombocytopenia (HIT) is lower, although for patients found to have HIT from UFH, LMWH use is contraindicated.

> ### KEY POINT
>
> LMWH is contraindicated in patients with a history of HIT.

Another common alternative to heparin in the United States is the use of citrate. Citrate functions as an anticoagulant because of its ability to chelate calcium, which is an essential cofactor in the clotting cascade and for platelet activation. Citrate can be administered as an infusion, or citrate-containing dialysate may be used. Infusions are mostly used in CRRT, and numerous protocols exist to administer regional citrate appropriately and safely as an anticoagulant in CRRT.[20,21]

Dialysate solutions that have substituted some of the acetate in the acid bath with citrate have been found to function well as anticoagulants. The citrate in the dialysate binds calcium locally at the dialyzer membrane environment, thereby preventing clotting within the dialyzer. The dialysate citrate concentration is usually 2.4 mEq/L of citric acid. Monitoring of ionized calcium is not required in hemodialysis because the concentration of citrate is low, and thus the patient is not at risk for developing hypocalcemia. Citrate-containing dialysate appears to be effective as an anticoagulant, but some centers have found that additional reduced doses of systemic heparin are required.[22]

Other anticoagulation methods much less frequently used include heparinoids, direct thrombin inhibitors, prostacyclins, and other prostanoids. Each class of anticoagulant has specific risks and benefits.[20]

ANTICOAGULATION IN BLEEDING DIATHESIS

Many critically ill patients who require short-term dialysis may have a bleeding diathesis that precludes the use of systemic anticoagulation. Anticoagulation-free dialysis can be performed successfully by maximizing blood flow and performing prefilter intermittent saline flushes (10- to 20-mL flushes every 15 to 20 min). In younger patients with small vascular access, a high Qb may be difficult to achieve, wherein a dialyzer with a smaller surface area can be used to increase the relative Qb per fiber bundle.

BLOOD FLOW RATE

The maximum Qb is determined by the vascular access. Large double-lumen hemodialysis catheters (larger than 12 French) provide a Qb of at least 200 mL/min. By contrast, smaller-caliber catheters (e.g., 8 French) may produce a Qb of only 75 to 100 mL/min. Permanent vascular access (AVFs and AVGs) provides vastly superior Qbs of 300 mL/min or higher. Higher blood flow improves the efficiency of the hemodialysis session and permits greater mass transfer in a given period of time.

DIALYSATE FLOW RATE

The standard Qd is 500 mL/min. Some dialysis machines permit variation of the Qd, allowing flows as high as 800 mL/min. This also increases dialysis efficiency, but it has less impact than changes in Qb. If Qd is 150 to 250 mL/min faster than Qb, increasing Qd further will have a negligible effect on clearance.

EXTRACORPOREAL BLOOD VOLUME CONSIDERATIONS

Traditional physiologic principles suggest that the total extracorporeal volume of the blood circuit (tubing and dialyzer) should not exceed 10% of the patient's blood volume. Pediatric tubing sets and dialyzers with small priming

> ### KEY POINTS
>
> - Total extracorporeal volume of the blood circuit should not exceed 10% of the patient's blood volume.
> - In infants, priming of the circuit with blood or 5% albumin may be needed to avoid hypovolemia.

volumes have been developed for smaller patients. Despite best efforts, extracorporeal volume may exceed these limits in infants. In this setting, priming of the circuit with blood or colloid may be necessary to prevent hypotension during dialysis initiation.

DIALYZER SELECTION

The clinician selects the dialyzer with consideration of the biocompatibility of the membrane, priming volume, clearance, and UF characteristics. A dialyzer with a larger surface area and greater permeability permits greater mass transfer and UF, but the volume of blood required to fill such a dialyzer may be too large for a small child. Slow blood flow reduces the efficiency of mass transfer and may increase the likelihood of clotting. Choosing a dialyzer based on biocompatibility remains controversial. Some studies have documented reduced complement activation with biocompatible membranes, but improved clinical outcomes have not been convincingly achieved.[23] Consequently, the choice of dialyzer depends on a balance of multiple factors noted earlier and should be individualized.

DURATION OF DIALYSIS

Greater time on dialysis permits greater mass transfer of both small and middle molecules. In addition, longer time may allow more successful UF because the rate of fluid removal can be lowered, thus reducing the likelihood of hypotension and symptoms related to rapid depletion of the vascular compartment volume. Extended time on dialysis for the patient undergoing long-term dialysis may result in lost time in school and fewer opportunities for play and thus may have a negative impact on quality of life.

MASS TRANSFER EQUATION

Use of the mass transfer equation can guide the clinician's choice of dialyzer, blood pump speed, and session length. The mass transfer equation describes the changing blood concentration of a given molecule based on the dialysis session parameters (Figure 36.5):

$$C_t/C_0 = e^{-Kt/V}$$

where C_t and C_0 are the concentrations of the molecule in question at time t (end of the session) and at session start (time zero), respectively; K is the clearance coefficient for the molecule in question; t is session length in minutes; and V is volume of distribution for the given molecule, in milliliters.
Figure 36.5 The mass transfer equation describes the concentration of a molecule within the patient during the dialysis session. C_0, concentration of molecule at time zero; C_t, concentration at time t; K, dialyzer clearance coefficient for molecule in question; t, time in minutes; and V, volume of distribution of molecule in question, in milliliters.

BUN is the most commonly used molecular marker for determining the dialysis prescription; therefore, K would be the K_D for urea. The foregoing formula is particularly useful in gauging the dialysis prescription in the circumstances of short-term hemodialysis or with initiation of long-term hemodialysis.

EXAMPLE

Consider a new patient weighing 40 kg with a starting BUN concentration of 100 mg/dL. The clinician anticipates a blood pump speed of 200 mL/min and selects a dialyzer that has a K_D for urea of 180 mL/min at the given blood pump speed, based on the manufacturer's published data. Urea distributes within the total body water, which can be estimated as 60% of the body weight, or 24,000 mL in this case. Initial hemodialysis sessions often target lower levels of mass transfer to prevent the complications of dialysis dysequilibrium (see later). A 30% reduction of urea to a final target value of 70 mg/dL is reasonable in this case. To determine the length of the hemodialysis session with these parameters, the mass transfer equation can be rearranged to solve for t:

$$t \text{ (minutes)} = -\ln (C_t / C_0) \times (V / K)$$

$$t \text{ (minutes)} = -\ln (70 / 100) \times (24,000 / 180)$$

$$t \text{ (minutes)} = -\ln (0.7) \times 133.3$$

[natural log determination from scientific calculator]

$$t \text{ (minutes)} = -(-0.357) \times 133.3$$

$$t \text{ (minutes)} = 0.357 \times 133.3$$

$$t \text{ (minutes)} = 48$$

The mass transfer equation provides the clinician with a useful tool to manipulate the hemodialysis prescription. One can adjust the value of K by choosing an appropriate dialyzer or changing blood pump speed. This, along with adjusting the dialysis session time, can provide the desired level of mass transfer necessary for the given clinical situation. Measurement of BUN levels immediately before and after the dialysis session permits evaluation of the predicted mass transfer and subsequent fine tuning of the prescription.

The initial hemodialysis prescription for a new, highly uremic patient should provide urea reduction of no greater than 30%. The patient undergoes hemodialysis for 3 or 4 consecutive days, each day with progressively higher levels of mass transfer, until a full dose of greater than 70% urea reduction is achieved.

KEY POINT

To reduce the possibility of dialysis dysequilibrium, urea reduction in the first acute dialysis session should be restricted to approximately 30%.

The ongoing dialysis prescription and schedule depend on the clinical situation. In the short-term setting, only one or two hemodialysis sessions may be required for the treatment of intoxication, whereas other patients with AKI may be served best by daily hemodialysis to limit metabolic fluctuation, maintain relative volume stability, and permit delivery of fluids, medications, and nutrition. Other patients with more persistent AKI, or those with chronic renal failure who require maintenance dialysis, may receive hemodialysis on an alternate-day or three times a week schedule. Individual clinical needs may necessitate hemodialysis more frequently.

ULTRAFILTRATION

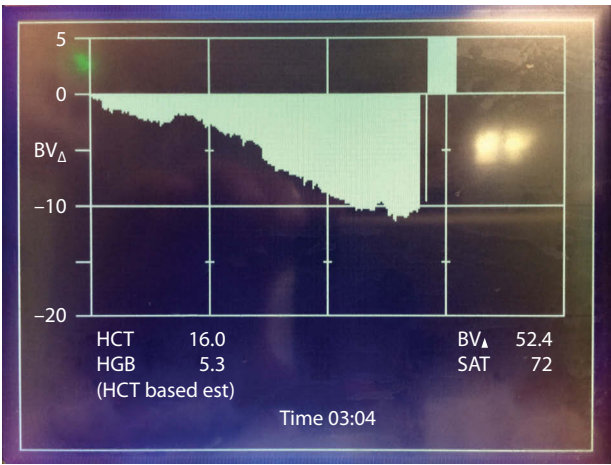
Each hemodialysis session requires a UF plan. UF control devices on modern hemodialysis machines permit precise levels of fluid removal throughout the hemodialysis session. The clinician must make a judgment about the level of UF that the patient can tolerate in the given session time. The hemodialysis machine can then be programmed to remove fluid from the patient at the desired rate. Careful monitoring of blood pressure, heart rate, and general patient status is required as the intravascular compartment volume contracts. This is especially true with smaller pediatric patients, in whom minor fluctuations in intravascular volume can have significant hemodynamic consequences. Blood volume monitoring devices (e.g., Crit-Line, Fresenius Medical Care North America, Kaysville, UT), which noninvasively measure the change in the patient's hematocrit during dialysis,


Figure 36.6 Screen shot from non-invasive blood volume monitor showing ultrafiltration data in a patient with newly diagnosed end-stage renal disease with anemia and pulmonary edema secondary to fluid overload. The patient has undergone ultrafiltration during the hemodialysis procedure to achieve approximately 10% reduction of intravascular volume. BV-delta, change in blood volume: HCT, hematocrit; HGB, hemoglobin; SAT, oxygen saturation. (Courtesy of Crit-Line, Fresenius Medical Care North America, Kaysville, UT.)

can be useful in monitoring fluid removal during dialysis (Figure 36.6).[24,25]

EFFECTIVENESS OF THE DIALYSIS PROCEDURE

DIALYSIS DOSE

The goals of dialysis are to rebalance serum solute concentrations, remove toxins, and attain a euvolemic state. Currently, we substitute BUN for the uremic toxins because of the ease of BUN testing and its ability to provide information about nutritional status. Determining the optimal dose of maintenance hemodialysis remains difficult. Using data from the National Cooperative Dialysis Study (NCDS), Gotch and Sargent[26] developed a method using the removal of urea as a proxy for the dose of hemodialysis. Despite controversy, using urea as an acceptable marker for small molecule clearance remains a standard method for measuring the quantity of dialysis delivered to the patient. The formal urea kinetic model, as well as various simplified estimating equations, allows the calculation of a mathematical derivative, known as Kt/V. Kt/V is a dimensionless ratio that represents the volume of plasma cleared (Kt) divided by the urea distribution volume (V) and is familiar as a component of the mass transfer equation. One may evaluate Kt/V and the movement of urea using a single-pool model or a more complex double-pool (equilibrated) model, which takes into account urea kinetics between cells and the vascular

compartment. Based on the early evaluation of the NCDS data and subsequent studies,[27] minimum levels of Kt/V have been established for adult populations.[28]

Current KDOQI guidelines for thrice-weekly maintenance hemodialysis recommend single-pool Kt/V (spKt/V) greater than 1.2, with a goal of greater than 1.4. These recommendations are based on studies in adults that demonstrate spKt/V lower than 1.2 to be associated with underdialysis and poor outcome.[27,29] The term "single pool" implies that the urea is sequestered mainly in the plasma and that equilibration of urea between various compartments of the body occurs almost instantaneously. In reality, equilibration takes 30 to 60 min to occur; consequently, spKt/V overestimates the amount of urea clearance. To correct for this, one can measure BUN 30 to 60 minutes after dialysis to calculate the *equilibrated Kt/V* (eKt/V). This value is likely more accurate, but it has not been correlated with outcome, as has been done for spKt/V.

The goal spKt/V of 1.2 to 1.4 assumes thrice-weekly hemodialysis. More frequent dialysis results in lower peak urea concentration before dialysis and requires a lower Kt/V value to yield similar results. Conversely, less frequent dialysis requires a higher Kt/V value. *Standard Kt/V* (stdKt/V) permits calculation of comparable Kt/V when dialysis is performed two to seven times a week. Three formulas can be used to calculate stdKt/V: those of Gotch and Sargent,[30] Leypoltd et al.,[31] and the Frequent Hemodialysis Network trial[32] formula. The formulas are complicated, but online calculators are available for use at: http://www.davita.com/ktvcalculator. The stdKt/V of 2.0 is considered the minimum dose of dialysis for all treatment modalities.

The *urea reduction ratio (URR)* is a much less complex technique that can be used to measure delivered dialysis dose. The calculation of URR is based on the simple ratio of the predialysis and postdialysis BUN levels, as follows:

$$\{(BUNpre - BUNpost) / (BUNpre)\} \times 100$$

This measurement of urea clearance is simple, but it has many limitations. The URR does not account for urea generation during dialysis or for the urea removed by UF because UF does not change the concentration of urea. It also does not provide any information regarding the patient's nutritional status. Urea kinetic modeling by Kt/V addresses many of these issues.

Although Kt/V allows a measurement to target minimally acceptable dialysis, the level of dialysis that is optimal remains unclear. Growing clinical data in small numbers of patients suggest that more frequent hemodialysis with schedules employing short daily sessions or long nocturnal sessions leads to improved biochemical parameters and a greater sense of patients' well-being.[33,34] There is also evidence that dialysis three times a week that achieves an spKt/V of 2.0 results in improved growth without growth hormone therapy.[35] It seems likely that a multipronged approach, considering urea kinetics, phosphate clearance, blood pressure control, nutritional status, overall patient health, and other parameters, will be necessary to define the optimal level of hemodialysis.

TECHNIQUE OF SAMPLING

The accuracy of Kt/V and URR measurements depends on appropriate sample collection. Dialysis staff must obtain blood samples for BUN before and after the dialysis session by using a standardized technique. The predialysis BUN sample must be obtained using a method that will avoid dilution of the blood that could lead to a spuriously low BUN value. The recommended method for obtaining the postdialysis sample is the "slow flow/stop pump" technique. Dialysate flow is minimized, UF is discontinued, and blood flow is reduced to 50 to 100 mL/min in the vascular access for 15 sec. The blood sample is obtained from the arterial limb, either with continued slow flow through the system or after fully stopping the blood pump.[36] This approach minimizes the effects of recirculation and urea rebound, which can lead to spurious results.

INADEQUATE DIALYSIS

Numerous factors can reduce dialysis adequacy and lead to insufficient mass transfer, volume overload, and symptoms. The clinician must evaluate the patient, laboratory values, and dialysis adequacy studies (Kt/V or URR) to determine whether dialysis is adequate. The finding of inadequate dialysis warrants an investigation into its possible causes.

RECIRCULATION

Recirculation describes the phenomenon whereby blood that has passed through the dialysis circuit is promptly drawn back into the "arterial end" of the blood loop on return into the vascular access. Thus, instead of returning to systemic circulation, the dialyzed blood constantly recirculates within the dialysis circuit. This reduces dialysis efficiency and can lead to inadequate delivery of prescribed dialysis dose. Recirculation can occur when attempting hemodialysis through a catheter using a Qb that is too high, when needle placement in an AVF or AVG is inappropriate, or when flow through the permanent vascular access is suboptimal. Low flow through an AVF or AVG is of particular concern because it can presage thrombosis of the vascular access. The dialysis team can evaluate the vascular access for recirculation by using an ultrasound dilution device or through blood sampling using a slow flow/stop pump technique[36] that obtains blood for BUN from the arterial line, venous line, and systemic circulation. The percentage of recirculation is characterized by a simple equation:

$$Recirculation = (Systemic\ BUN - Arterial\ BUN) / (Systemic\ BUN - Venous\ BUN) \times 100$$

A vascular access with significant recirculation (greater than 5% to 10%) should be evaluated for low internal blood flow.

UNDERPRESCRIPTION

Underdialysis may occur if the prescribed dose of dialysis is insufficient. The clinician should review all aspects of the dialysis prescription and ensure that they are optimized. This includes using the largest possible dialyzer, the highest Qb permitted by the vascular access, and sufficient time undergoing dialysis. As previously noted, many of these parameters are limited in the pediatric population because of the size of the patient and technical constraints of the vascular access. Careful attention to the prescription, optimized for the individual patient, helps to avoid underdialysis.

Once a prescription is optimized, the delivered dose must be evaluated on a regular basis. When the delivered dose falls to less than target levels (e.g., Kt/V less than 1.2), a systematic evaluation of the technical aspects of the dialysis procedure should be undertaken to determine whether there is an identifiable cause for inadequate dialysis delivery. Published guidelines[36] describe a sophisticated algorithm for hemodialysis dose troubleshooting. Conceptually, the investigation should center on the components of the prescription under the clinician's control, namely, the clearance (K) and the effective time on dialysis (t). Other factors that may have an effect on the calculated delivered dose include blood recirculation in the vascular access and errors in obtaining the blood sample for adequacy study.

DIMINISHED CLEARANCE

Because clearance on hemodialysis is a function of the dialyzer permeability surface area product (KoA), Qb, and Qd, the clinician should consider various factors that will cause the KoA, Qb, or Qd to differ from the values originally prescribed. Incorrect dialyzer, dialyzer volume loss from the reuse procedure, inappropriate dialysis machine settings, excessive dialyzer clotting, and machine miscalibration or malfunction are potential causes for clearance that is less than expected.

Perhaps the most common fundamental issue leading to diminished clearance in pediatric hemodialysis is lower than expected Qb, which is often a result of problems with the vascular access. Many pediatric patients are dialyzed with a central venous catheter as the vascular access, which can be particularly prone to problems with blood flow related to smaller caliber, thrombosis, kinking, and malposition. AVFs created in pediatric patients take longer to mature and may not achieve the high Qb values seen in adults. Poorly positioned needles or stenosis in the AVF or in an AVG can cause suboptimal blood flow and inadequate dialysis. Elevated pressures in the dialysis blood circuit causing machine alarms or clinical events such as hypotension may force the dialysis staff to reduce the Qb. Careful assessment of the vascular access and other factors with an effect on Qb is required when the delivered hemodialysis dose is inadequate.

DIMINISHED EFFECTIVE DIALYSIS TIME

The patient's time on dialysis may be shortened by patient-related issues such as late arrival for the session or request for early termination. Misinterpretation of orders or incorrect programming of the dialysis machine can also lead to a shortened session that delivers less dialysis than intended. Clinical events such as hypotension, nausea, or cramps may cause staff to terminate a dialysis session early. Technical problems with the machine or vascular access may cause temporary cessation of the dialysis session, which, if not compensated for by extending the session, will lead to reduced effective dialysis time. The clinician must perform a review of session parameters and engage in discussion with dialysis unit staff to determine causes of diminished effective dialysis time.

COMPLICATIONS

Complications in patients undergoing hemodialysis can be related to the hemodialysis procedure, the vascular access, or renal failure. Complications related to renal failure are addressed elsewhere in this text.

COMPLICATIONS RELATED TO THE HEMODIALYSIS PROCEDURE

Hemodialysis represents a fundamentally nonphysiologic procedure involving extracorporeal perfusion, rapid removal of volume and small molecules from the vascular compartment, fluid shifts, changes in osmolality, and exposure of the patient's blood to foreign materials and solutions. Nevertheless, hemodialysis can be performed safely and effectively with close attention to the patient and knowledge of technology. Safety has been increased by the development of biocompatible materials, use of multiple patient safety devices, implementation of carefully designed protocols, and appropriate observation by trained staff. However, complications do arise during the hemodialysis procedure, and the clinician must be aware of potential complications and of the methods to evaluate, treat, and prevent their occurrence.

Intradialytic hypotension

Low blood pressure during the hemodialysis session is a common complication. Potential causes of intradialytic hypotension are listed in Table 36.5. A common cause is overly aggressive UF that exceeds the vascular refilling rate. Hypotension can be treated by slowing the UF rate, providing intravenous saline to the patient, and placing the patient in the head-down (Trendelenburg) position. Careful clinical evaluation and planning of UF goals can avoid this complication.

Table 36.5 Etiology of dialysis-induced hypotension

Patient-Related Factors

- Impaired plasma refilling (? decreased UF coefficient of vascular wall)
- Decreased cardiac reserve (diastolic or systolic dysfunction)
- Impaired venous compliance
- Autonomic dysfunction (diabetic, uremic)
- Arrhythmias
- Anemia
- Drug therapy (vasodilators, β blockers, calcium channel blockers)
- Alteration of vasoactive substances in the blood
- Eating during treatment (increased splanchnic blood flow)
- Low dry-weight estimation

Procedure-Related Factors

- Decreased plasma osmolality (relatively large surface area membrane, high starting BUN)
- Excess absolute volume and rate of fluid removal (large interdialytic weight gain)
- Change in serum electrolyte (hypocalcemia, hypokalemia)
- Dialysate: acetate, too warm dialysate
- Membrane blood interaction
- Hypoxia

Uncommon Causes

- Pericardial tamponade
- Myocardial infarction
- Aortic dissection
- Internal hemorrhage
- Septicemia
- Air embolism
- Pneumothorax
- Hemolysis

Abbreviations: BUN, blood urea nitrogen; UF, ultrafiltration

Muscle cramps

Painful muscle contractions, most often seen near the end of the dialysis session, are frequent complications of hemodialysis therapy. These contractions are often seen in patients who require high rates of UF and are presumed to be related to relative intravascular volume depletion and subsequent hypoperfusion of the muscles. Electrolyte shifts during dialysis therapy are also implicated.[37] Similar to the approach with hypotension, maneuvers to permit refilling of the vascular compartment may alleviate painful cramps. Medications such as quinine have been used successfully to treat muscle cramping,[38] but they have not been validated in pediatric patients.

Dialysis disequilibrium

The dialysis disequilibrium syndrome is a neurologic disorder thought to be related to acute cerebral edema in the setting of hemodialysis. Symptoms can range from minor issues (headache, nausea, restlessness) to more severe findings (myoclonus, disorientation, blurred vision, seizure, coma) and even death.[37] Despite the knowledge of this potentially fatal complication since the 1960s, the precise mechanism remains elusive. One theory of dialysis dysequilibrium suggests that the increased efficiency of urea clearance from the blood to dialysate, as compared with movement of urea from brain cells and interstitium to blood, creates a transient gradient of higher osmolality in brain cells, a condition in which water would move into the brain and cerebral edema occurs. This effect is exacerbated for patients with significantly elevated BUN. Consequently, dialysis dysequilibrium has most often been seen in a first hemodialysis session or in the setting of a very high predialysis BUN. Limiting urea reduction to 30% in this setting seems to reduce the risk of dysequilibrium.

Allergic reactions

Exposure of blood to foreign materials during dialysis can lead to adverse reactions. Severe anaphylactoid reactions are uncommon, but sterilants and components of the dialysis membrane have been implicated as potential causes.[37] These reactions often occur early in the dialysis session and may be associated with dyspnea, feeling of warmth, angioedema, urticaria, and recurrence with similar dialysis equipment.[39] The hemodialysis session should be discontinued immediately when such a reaction is suspected. Oxygen and therapy for acute allergy (e.g., antihistamines, epinephrine, corticosteroids) may also be indicated. Future dialysis sessions should avoid the use of the offending materials. Milder reactions, such as back pain and chest discomfort, can also occur. The cause is unclear, and therapy is usually symptomatic.[37] Differentiation from more severe complications such as cardiac ischemia requires careful clinical evaluation.

The combination of angiotensin-converting enzyme (ACE) inhibitors and polyacrylonitrile (PAN) membranes has been associated with anaphylactic reactions.[40] PAN membranes activate Hageman factor and lead to the formation of kallikrein, with subsequent liberation of kinins such as bradykinin. ACE degrades bradykinin; thus, ACE inhibitors lead to accumulation of bradykinin, leading to anaphylactic reactions.

Air embolism

Air entry into the blood loop of the hemodialysis circuit can cause significant injury or death. This serious complication is relatively uncommon as a result of numerous patient safety devices built into the hemodialysis

machines. The blood pump stops when air enters the blood loop accidentally and prevents the entry of air into the patient through the vascular access. Air potentially can enter the hemodialysis blood circuit through loose connections or cracks in the tubing system. Clinical findings depend on the amount of air that has entered the patient and the status of the patient before air entry. Arterial air embolism results in occlusion and distal ischemia; venous air embolism can lead to obstruction of right ventricular outflow through the pulmonary venous system. Symptoms are often nonspecific, and a high index of suspicion is needed to recognize this complication. When air embolism is suspected, the dialysis session is terminated with care to prevent any further air entry. The patient is placed flat and supine and is provided with oxygen and volume expansion as necessary.[41] Evacuation of the air from the vascular system requires special expertise. Careful adherence to safety procedures in the dialysis unit can prevent this potentially devastating complication.

KEY POINT

If there is concern for air embolism, terminate the dialysis session, place the patient flat and supine, and provide oxygen and volume expansion.

Bleeding

Hemodialysis-treated patients are at increased risk for bleeding because of extracorporeal perfusion of blood through the hemodialysis circuit, uremia-associated platelet dysfunction, and systemic heparinization during the hemodialysis session. A minor manifestation may be prolonged oozing from AVF or AVG puncture sites; adjustment to the heparin prescription may be indicated in such circumstances. Careful titration of heparin dose and skilled nursing care can minimize the risks of more severe bleeding. Treatment of hemorrhage is supportive and includes volume expansion and correction of the acute cause. Neutralization of heparin with protamine sulfate can be considered,[37] but it carries risks of allergic reactions.

Dialysate concentrate

The acetate in the acid A bath is available in two concentrations and generates dialysate concentrations of 4 mEq/L (liquid concentrate) or 8 mEq/L (powder concentrate) of acetic acid. Acetate is metabolized into bicarbonate. The use of a higher concentration of acetate without reducing the B (sodium bicarbonate) concentrate can lead to metabolic alkalosis because acetate is metabolized to bicarbonate. The alkalosis results in transcellular shifting of potassium into cells, thereby placing the patient at risk for cardiac arrhythmias secondary to hypokalemia. On March 29, 2012, the Food and Drug Administration issued a class 1 recall on acetate-containing solutions. In patients with predialysis serum bicarbonate greater than 27 mEq/L, a higher concentration of acetic acid was linked to increased cardiovascular morbidity and mortality.

COMPLICATIONS RELATED TO VASCULAR ACCESS

Dialysis catheters and permanent vascular access for hemodialysis (AVFs and AVGs) share several potential complications, with some complications unique to the type of access.

Hemodialysis catheters

Bleeding complications can occur at the time of hemodialysis catheter insertion or, more rarely, at a later time in response to catheter erosion through a vessel. Placement of a catheter in a central vein promotes stenosis, which can complicate venous drainage from the affected limb and can limit the success of permanent vascular access placed at a later time within the drainage field of the stenotic vessel. Poor catheter function with diminished blood flow can result from catheter migration, kinking, side-hole occlusion at the catheter tip, fibrin sheath formation, or thrombosis. Repositioning of the patient, instillation of thrombolytic agents into the catheter, and surgical replacement of the catheter may be required to reestablish effective blood flow. Infection can complicate vascular catheter use; the presence of the foreign body within the patient's vascular space predisposes to bacterial infection. Aggressive use of parenteral antibiotics can salvage an infected catheter; patients with recalcitrant infections may require catheter removal and replacement.

Permanent vascular access

Primary AVFs may fail to mature after creation. This is of particular concern in children, whose vascular caliber is smaller than in adults. Careful preoperative evaluation of the patient's vascular potential, coupled with an experienced surgeon, maximizes successful fistula creation. AVGs avoid the issue of maturation, but they can be complicated by a higher failure rate. Complications of both AVGs and AVFs include infection, edema of the limb, and vascular steal syndrome. These complications are seen somewhat more frequently in AVGs. Permanent vascular access can also be complicated by stenosis, which may be amenable to angioplasty or surgical revision.
Figure 36.7 Incident and point prevalent patients with end-stage renal disease, 0 to 19 years old, by treatment modality in the United States. HD, hemodialysis; Inc, incidence; PD, peritoneal dialysis; Prev, prevalence; Tx, transplantation. (From US Renal Data System. Bethesda, MD: National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases; 2013.)

OUTCOME OF HEMODIALYSIS IN CHILDREN

Use of hemodialysis in the short-term setting has waned somewhat with the growing use of CRRT,[42] but hemodialysis remains an important modality in the acute setting, sometimes in conjunction with CRRT.[43] For children with ESRD, hemodialysis remains the most common modality for patients initiating renal replacement therapy[44] (Figure 36.7). The outcome for children undergoing long-term maintenance hemodialysis is somewhat more difficult to determine than for adults because most pediatric patients who undergo dialysis move on to renal transplantation. Cardiovascular disease is the primary cause of death, and patients younger than 10 years old are at the highest risk of morbidity and mortality. Fluid overload, uncontrolled hypertension, heart failure, and death continue to be major concerns. Pediatric patients undergoing hemodialysis have increased cardiovascular and overall mortality at 1 year when compared with pediatric patients undergoing PD and pediatric transplant recipients. Five-year survival is lower in pediatric patients undergoing hemodialysis (75%) than pediatric transplant recipients (95%) or those undergoing PD (81%).[44]

In contrast to adult patients, hospitalization rates related to cardiovascular disease and infection are on the rise, despite similar use of cardiovascular drugs. Hemodialysis-treated patients 0 to 9 years of age have higher rates of hospital admission because of catheter infection as compared with patients those receiving PD. Readmission rates for bacteremia and septicemia in pediatric patients are highest among hemodialysis-treated patients. Vascular access infections are more frequent in patients with catheters than in patients with AVFs or AVGs.[44]

SUMMARY

Hemodialysis remains an important technique for renal replacement therapy in children. Its efficiency makes it the clear preference for selected short-term indications. Well-established guidelines permit successful use in the long-term setting. Ongoing issues related to vascular access and determination of optimal dose require continued investigation. Promising new data on maintenance hemodialysis schedules that employ more frequent sessions may lead to improved outcomes for children with ESRD.

REVIEW QUESTIONS

1. A 16-year-old boy with a history of end-stage renal disease from focal segmental glomerulosclerosis has a failing renal allograft and will need to return to dialysis within the next 6 months. He and his family choose hemodialysis as their preferred modality. He is highly sensitized, and although he will be listed for renal transplant again, you anticipate that his waiting time will be at least 1 to 2 years. Of the following, the *most appropriate* recommendation for hemodialysis vascular access is:
   a. Arteriovenous fistula
   b. Arteriovenous graft
   c. Femoral venous catheter
   d. Internal jugular venous catheter
   e. Subclavian venous catheter

2. You are determining the appropriate hemodialysis prescription for a new patient in your hemodialysis unit. When choosing a dialyzer, you obtain the manufacturer's specifications regarding the K_{uf}. Of the following, the *most accurate* statement about K_{uf} is that it defines:
   a. The maximum theoretical limit for ultrafiltration at infinite transmembrane pressure
   b. The maximum theoretical limit for urea clearance at infinite blood and dialysate flow rate
   c. The minimum required transmembrane pressure necessary to prevent back-filtration
   d. The volume of blood cleared of urea in 1 min at a given blood flow rate
   e. The volume of fluid that will cross the membrane in 1 h at a given transmembrane pressure

3. A 12-year-old patient presenting to the emergency department with several weeks of fatigue, malaise, and weight loss is found to have renal failure with BUN 110 mg/dL and Cr 11.7 mg/dL. Renal ultrasound demonstrates small, echogenic kidneys bilaterally. You believe that the patient likely has had undiagnosed renal dysplasia and now has end-stage renal disease. The patient is tired and thin but alert without signs of volume overload. You make arrangements to initiate hemodialysis. Of the following, the *most appropriate* consideration in the initial hemodialysis prescriptions would be:
   a. Ensure vascular access that can provide blood flow of at least 300 mL/min.
   b. Avoid heparin anticoagulation for the first week.
   c. Preferentially choose a polysulfone dialyzer membrane.
   d. Target urea clearance of no more than 30%.
   e. Use a dialyzer with a high KoA.

4. During the dialysis process, several factors are responsible for molecular transport. Of the following, the *most accurate* statement regarding the physical principles of molecular transport that are active in hemodialysis is:
   a. Adsorption favors movement of smaller molecules over larger molecules.
   b. Convection favors movement of smaller molecules over larger molecules.
   c. Diffusion favors movement of smaller molecules over larger molecules.
   d. Ultrafiltration favors movement of smaller molecules over larger molecules.
   e. Under most circumstances in hemodialysis, small and large molecules transport equally.

5. The hemodialysis apparatus is complex and has multiple components designed to provide safe and effective therapy to the patient. Of the following, the option that *best* describes the two main components of the dialysis apparatus is:
   a. The blood circuit and the dialysate circuit
   b. The hemodialyzer and the vascular access
   c. The arterial segment and the venous segment
   d. The proportioning system and the ultrafiltration controller
   e. The "A" concentrate and the "B" concentrate

6. An 11-year-old girl is admitted to the intensive care unit with meningococcemia and renal failure as a secondary effect of her multiorgan dysfunction syndrome. Her potassium level has risen to 7.2 mEq/L, with changes on her electrocardiogram suggesting evidence for cardiac effects. You are preparing to perform emergency hemodialysis to correct the hyperkalemia. Of the following, the *most appropriate* option for vascular access would be:
   a. Arteriovenous fistula
   b. Arteriovenous graft
   c. Bilateral single-lumen cephalic vein catheters
   d. Femoral double-lumen venous catheter
   e. Subclavian double-lumen venous catheter

7. A 19-year-old male patient has been receiving hemodialysis for acute kidney injury for 8 weeks because of complications following liver transplantation. He has tolerated his sessions well, but he remains intubated in the intensive care unit. Over the last week, his platelet count has dropped, and the intensive care unit

team is concerned that he may have heparin-induced thrombocytopenia. They ask whether there are options to perform his hemodialysis sessions but limit his heparin exposure. Of the following, the method *most likely* to ensure effective hemodialysis sessions and also address the concern for heparin-induced thrombocytopenia would be to:
   a. Change unfractionated heparin to low-molecular-weight heparin.
   b. Eliminate heparin and use citrate-containing dialysate.
   c. Give a heparin bolus at the start of hemodialysis but avoid use of continuous infusion.
   d. Perform hemodialysis without anticoagulation.
   e. Use half the previous dose of unfractionated heparin.

8. A 10-month-old boy with end-stage renal disease from posterior urethral valves who is maintained on peritoneal dialysis develops fungal peritonitis and must make a temporary transition to hemodialysis. He weighs 7.7 kg and is polyuric. Of the following, the *most accurate* statement about plans for hemodialysis is that:
   a. Extended session length is likely required to achieve ultrafiltration goals.
   b. Heparin cannot be used as the anticoagulant.
   c. High metabolic needs will obligate use of a dialyzer with a high KoA.
   d. Outcome data indicate that the single-pool Kt/V target for this age group is 1.6.
   e. The patient will likely need blood prime of the hemodialysis circuit.

9. You are preparing the prescription for a 10-year-old girl with end-stage renal disease from renal dysplasia who will initiate hemodialysis. The patient has a new right-sided 10-French internal jugular catheter that you anticipate will deliver a blood flow rate of 150 mL/min. You have chosen a hemodialyzer with K_D for urea of 120 mL/min at that blood flow rate. The patient weighs 35 kg; she does not appear volume overloaded. You would like to target a urea clearance of approximately 30% for this first session. Of the following, the dialysis time that will *most likely* give a urea clearance closest to the target of 30% is:
   a. 30 min
   b. 60 min
   c. 90 min
   d. 120 min
   e. 180 min

10. You are reviewing the dialysis adequacy studies for your unit and notice that a patient has Kt/V this month of 1.1. The patient has been doing well on hemodialysis, growing, thriving and participating in school. Results of blood testing have been stable. Previous values for Kt/V over the last 6 months have been 1.4 to 1.6. His current prescription is as follows:
   Dialyzer: KoA 1100 mL/min
   Vascular access: 12-French right-sided internal jugular catheter
   Blood flow rate: 250 mL/min
   Session length: 3 h
   Schedule: Tuesday, Thursday, Saturday

   Of the following, the *most appropriate* next step to address the low Kt/V for this patient would be to:
   a. Adjust the dialysis schedule to Monday, Tuesday, Thursday, and Saturday.
   b. Change to a larger dialyzer with KoA 1400 mL/min.
   c. Increase dialysis time to 4 h/session.
   d. Refer the patient for urgent placement of an arteriovenous fistula.
   e. Review session characteristics and repeat Kt/V measurement.

Peritoneal dialysis

BRADLEY A. WARADY

Peritoneal dialysis (PD) has been recognized as an important modality for renal replacement therapy (RRT) since it was first used to treat children with acute kidney injury (AKI) in the 1960s. Its relative ease of administration has also been crucial to the successful treatment of infants and young children with end-stage renal disease (ESRD). This chapter provides an overview of PD that is pertinent to the clinical application of this RRT modality.

HISTORY

The peritoneal cavity has been used for the treatment of serious illness in children since the second decade of the 20th century. In 1918, Blackfan and Maxcy[1] described the successful use of intraperitoneal injections of saline solution in dehydrated infants, a method that is still used today in rural areas of some developing countries. The first reports of the use of PD to treat children with renal failure were published by Bloxsom and Powell in 1948[2] and by Swan and Gordon in 1949.[3] These articles appeared when the worldwide reported clinical experience with PD was fewer than 100 patients.[4] As detailed by Swan and Gordon,[3] the technique allowed large volumes of dialysate to flow continuously by gravity from 20-L carboys through a rigid metal catheter that had been surgically implanted into the upper abdomen. Dialysate was constantly drained from the peritoneal cavity by water suction through an identical catheter implanted in the pelvis. Today, this technique is termed continuous peritoneal lavage, and in some ways it foretold the current emphasis on continuous as opposed to intermittent PD therapies.

Swan and Gordon maintained fluid balance in their young patients by adjusting the dialysate dextrose concentration between 2 and 4 g/100 mL, as is generally done today. Excellent solute removal was achieved with an average daily dialysate delivery of 33 L. Dialysate temperature was regulated by adjusting the number of illuminated 60-watt incandescent light bulbs in a box placed over the dialysate inflow path. Although two of the three children treated for AKI by Swan and Gordon survived after 9 and 12 days of continuous peritoneal lavage, this technique did not attract much interest among physicians treating children with renal failure during this period, and it was more than a decade before the use of PD in children was again reported. During the 1950s, the development of disposable nylon catheters and commercially prepared dialysis solutions made PD a practical short-term treatment for AKI.[5] Successful adaptation of this technique, now known as acute intermittent PD (acute IPD), for use in infants and children with AKI was first reported by Segar et al. in 1961[6] and later by Etteldorf et al. in 1962.[7]

Although PD was successful in treating AKI, early attempts at PD appeared to offer little in the treatment of children with ESRD. These early acute IPD techniques required reinsertion of the dialysis catheter for

each treatment, thus making prolonged use in small patients essentially impossible.[8] The development of a "permanent" peritoneal catheter was first proposed by Palmer et al.[9,10] and was later perfected by Tenckhoff and Schecter.[11] This made long-term IPD an accessible form of RRT for adult and pediatric patients with ESRD. Boen et al.[12] and Tenckhoff et al.[13] independently devised automated dialysate delivery systems that could be used in the patient's home. With this development, long-term IPD became a practical and potentially desirable alternative to long-term hemodialysis (HD) for children with ESRD.

A new era in the history of PD as a treatment for children with ESRD was heralded in 1972 by the description of a "novel portable/wearable equilibrium dialysis technique" by Popovich et al.,[14] which is currently known as continuous ambulatory PD (CAPD). Pediatric nephrologists were quick to recognize the potential advantages of CAPD in young patients. Advantages of CAPD over HD in children included the maintenance of nearly steady-state biochemical control, avoidance of disequilibrium syndrome, greatly reduced dietary and fluid restrictions, and freedom from repeated dialysis needle punctures. CAPD also allowed children of all ages to receive dialysis at home and have nearly normal school attendance and other childhood activities. CAPD and, later, automated PD (APD) made possible the routine treatment of very young infants with ESRD, thereby extending the option of RRT to a patient population previously considered too young to be suitable for long-term treatment (Figures 37.1 to 37.5).

CAPD was first used in a child in 1978 in Toronto.[15,16] Since that time, CAPD and its many modifications (which together can be called continuous PD or CPD) have become the dialysis treatment modalities most commonly prescribed for children with ESRD throughout much of the world.[17]

Figure 37.3 Physio-Control peritoneal dialysis cycling machine.

EPIDEMIOLOGY

Dramatic growth in the use of CPD as maintenance dialysis treatment for children occurred worldwide during the 15 years following its introduction to pediatric dialysis. By 1993, ESRD patient registry reports showed that CPD was the most commonly prescribed long-term dialysis modality for children less than 15 years of age in the United States, Canada, Australia, New Zealand, the United Kingdom, the former West Germany, Israel, and the Netherlands.[18–20]

Data on CPD use in North American children have been compiled within the registry of the North American

Figure 37.1 Early automatic peritoneal dialysis cycler designed by Boen et al. (1960s).
Figure 37.4 Baxter PacX automated peritoneal dialysis cycler (1984). (Courtesy of Baxter Healthcare, Deerfield, Illinois.)

Pediatric Renal Trials and Collaborative Studies (NAPRTCS). The NAPRTCS has collected data on pediatric dialysis from more than 100 pediatric dialysis centers located in the United States, Canada, Mexico, and Costa Rica. Between 1992 and 2010, the NAPRTCS enrolled 7039 pediatric dialysis-treated patients 1 day to 20 years old.[21] Of these, the initial modality selected for 4430 (62.9 %) patients was CPD, most commonly performed with an automated cycling machine. Although most patients in all age groups were prescribed CPD, the preference for CPD over HD was most pronounced among younger patients. Eighty-five percent of infants and young children 0 to 5 years of age were treated with CPD, compared with 65% of children 6 to 12 years and 51% of patients more than 12 years of age.

Figure 37.5 Baxter HomeChoice Pediatric peritoneal dialysis cycler (2002). (Courtesy of Baxter Healthcare, Deerfield, Illinois.)

Noteworthy is the finding that the overall percentage of incident patients prescribed CPD decreased to 55.7% in 2008 to 2010.

Participation in the NAPRTCS is restricted to specialized pediatric dialysis centers staffed by pediatric nephrologists, a fact that may influence observations such as dialysis modality choice. Furth et al.,[22] in fact, showed that older children treated in nonpediatric units are more likely to receive maintenance HD than CPD. To that end, information from the 2013 edition of the United States Renal Data System (USRDS) Annual Data Report (ADR), which addresses RRT for all children (0 to 19 years old) in the United States with ESRD, regardless of the site of care (pediatric vs. adult dialysis units), revealed that at the time of ESRD diagnosis, 695 (49.2%) of the 1410 patients were initiated on HD, 396 (28%) were started on PD, and 280 (19.9%) received a preemptive renal transplant.[23] Earlier data from 12 pediatric registries in Europe also revealed similar statistics, with 48% of incident patients receiving HD, 34% PD, and 18% preemptive transplantation.[24] More recent data from 14 pediatric centers in Europe demonstrated slightly different results, with 50% of patients commencing therapy with PD and 34% with HD.[25] Patient and family choice and the age and size of the patient were the predominant factors influencing modality selection.

As would be expected with a pediatric cohort, data on modality status of prevalent patients with ESRD from the USRDS revealed that of 7983 patients, the majority (69%) had a kidney transplant, whereas 11% were maintained on PD.[23]

PRINCIPLES

The peritoneal solute exchange process is the sum of two simultaneous and interrelated transport mechanisms: diffusion and convection. Diffusion refers to the movement of solute down a concentration gradient, whereas convection refers to movement of solutes that are "transported" in a fluid flux, the magnitude of which is determined by the ultrafiltration rate.[26]

Several theories, each progressively more complex and more accurate, have been developed to model the movement of water and solute across the peritoneal membrane. A comprehensive model, known as the three-pore model provides the basis for widely held beliefs regarding solute transport mechanics. As the name suggests, the model postulates three types of peritoneal membrane pores:

1. Ultrasmall transcellular water pores or channels (aquaporins), which comprise 1% to 2% of the total pore area, but account for 40% of water flow, and are driven by osmotic forces.
2. Small pores, which are 4 to 6 nm in diameter and comprise 90% of total pore area. These pores are subject to both concentration gradients (diffusive forces) and osmotic gradients (convective forces).

3. Large pores, which are 200 to 300 nm in diameter and comprise the remaining 5% to 7% of total pore area. These pores allow larger molecules, such as albumin, to be transported from the peritoneal capillaries, possibly driven by hydrostatic forces within the capillary bed.

KEY POINTS

- The three-pore model describes the movement of water and solute across the peritoneum.
- Diffusion refers to the movement of solute down a concentration gradient, whereas convection refers to movement of solutes that are "transported" in a fluid flux.

Although water moves through all three pores, only the small and large pores allow convective solute transfer.[27–30]

MASS TRANSFER AREA COEFFICIENT

The term *mass transfer area coefficient* (MTAC) characterizes the diffusive permeability of the peritoneal membrane and the functional peritoneal surface area, and it is for the most part independent of dialysis mechanics.[26,31] Some studies in adult patients have provided evidence that the functional and not the anatomic peritoneal surface area participates in solute and water exchange, and the functional component accounts for only 25% to 30% of total peritoneal surface area.[32] The MTAC has also been variably defined as the area available for solute transport divided by the sum of resistances to peritoneal diffusion and represents the clearance rate (expressed in milliliters/min), which would be obtained in the absence of ultrafiltration or solute accumulation in the dialysate.[33] The MTAC, as applied to the current three-pore model of transperitoneal solute and water flux, equals the product of the free-diffusion coefficient for the solute, the fractional area available for diffusion (which is a percentage of the area of the unrestricted pores), and the term A_0/δ_X, which characterizes the diffusion distance across the peritoneum.[34] To date, very few studies have measured MTACs in pediatric patients.[35–38] In the largest such study, Warady et al.[38] found evidence of enhanced transport in the youngest patients, likely to result from differences in permeability, effective surface area, or possibly maturational changes of the peritoneum. In contrast, MTAC data in children using a three-pore model demonstrate values for children to be similar to those of adults, when the data are scaled to body surface area (BSA).[39]

ULTRAFILTRATION AND CONVECTION

Ultrafiltration represents the bulk movement of water along with permeable solutes across the peritoneum. The removal of fluid during an exchange reflects the interaction of the hydraulic permeability of the peritoneal membrane with the permeability of the membrane to the osmotically active solutes on either side of the membrane. In PD, the osmotically active agents in the dialysate fluid are either crystalloids, such as glucose, or colloids, such as icodextrin. In designing the dialysis prescription in terms of ultrafiltration, children receiving CAPD with 1.5% or 4.25% dextrose as the osmotic agent should expect the drainage volume to exceed the infused volume of dialysate by 15% to 25%, and 30% to 40%, respectively.[40] Conversely, children receiving APD with shorter dwell time of 30 to 40 min, using 1.5% and 4.25% dextrose dialysis solutions, should be expected to have drain volumes to exceed infused volumes by 4% to 8% and 12% to 18%, respectively.[40]

Convective mass transfer, which depends on fluid removal and peritoneal membrane permeability, contributes little to the movement of small solutes but is responsible for most of the large solute removal. Permeability to a specific solute can be characterized by the sieving coefficient, calculated by dividing the concentration of the solute in the ultrafiltrate by its concentration in plasma water. Studies by Pyle[41] demonstrated that the contribution of convection in a 4-h CAPD exchange with 4.25% dextrose is 12% for urea, 45% for inulin, and 86% for total protein.

Early studies and most clinical experience suggest that adequate ultrafiltration is often difficult to achieve in infants and young children. Schaefer et al.[27] suggested that the reduced ultrafiltration rate observed in infancy may actually be related to a greater total fluid "reuptake" or reabsorption from the peritoneal cavity. The reuptake phenomenon in these patients may be the result of increased lymphatic reabsorption rate (see later) or greater intraperitoneal pressure (IPP) in infants that generates a reversed transcapillary flux of fluid along hydrostatic and oncotic pressure gradients.[27]

Finally, the availability of icodextrin, a glucose polymer with an average molecular weight of 16,200 Da, allows the use of an osmotic agent that is characterized by an iso-osmotic and sustained colloid osmotic effect through the small pores. This agent improves ultrafiltration in patients undergoing CAPD and APD during long dwells, which may be essential for continuing CPD in patients experiencing loss of ultrafiltration. In a manner similar to the adult experience, de Boer et al.[42] found that 7.5% icodextrin is capable of maintaining ultrafiltration during a 12-h dwell in children, with the ultrafiltration capacity comparable to what could be obtained with 3.86% dextrose.[43] Because of its delayed ultrafiltration pattern compared with dextrose-based solutions, and out of concern for the potential side effects of its low-molecular-weight metabolites, icodextrin-containing solutions should be used only once daily during the long dwell.[44] Icodextrin has been reported to be less successful in some studies in infants, and this requires further evaluation.[45]

PERITONEAL FLUID AND LYMPHATIC ABSORPTION

During PD, dialysate fluid is continuously removed from the peritoneal cavity, both directly into the tissues surrounding the peritoneal cavity as a result of the intraperitoneal hydraulic

pressure and by the lymphatic vessels.[46] Whereas lymphatic absorption is believed by some investigators to account for only 20% to 30% of fluid reabsorption, the data on lymphatic absorption in children are especially conflicting.[47,48]

PRINCIPLES OF THE PERITONEAL EQUILIBRATION TEST

The peritoneal equilibration test (PET) was developed by Twardowski et al.[49] as a means of characterizing solute transport rates across the peritoneum in patients on PD. The reference curves, based on the kinetics of solute equilibration between dialysate and plasma (D/P ratio) after a 2-L exchange volume, irrespective of the patient's size, made it possible to categorize adult patients into those with high, high-average, low-average, and low peritoneal membrane solute transport rates. Such PET data provide important information on which to base the PD prescription in both adults and children.[50]

Adoption of a standardized PET procedure in children resulted from an appreciation of (1) the age-independent relationship between BSA and peritoneal membrane surface area and (2) the recommended use of an exchange volume scaled to BSA in studying peritoneal transport kinetics.[38,51--53] In the largest pediatric study to date, the Pediatric Peritoneal Dialysis Study Consortium (PPDSC) evaluated 95 children by using a test exchange volume of 1100 mL/m^2 BSA to develop reference kinetic data (D/P and D/D0 ratios), which can be used to categorize an individual pediatric patient's peritoneal membrane solute transport capacity (Figures 37.6 and 37.7).[38] Similar reference data have been generated from pediatric studies in Europe with a test exchange volume of 1000 mL/m^2 BSA.[53] Details of the 4-h PET procedure in children are provided in Table 37.1. More recently, several publications have proposed the use of a 2-h PET procedure in children, the so-called short PET, as previously described by Twardowski et al. The shortened study is less labor and cost intensive, and it may promote more frequent use of this test in clinical practice.[54,55]

KEY POINT

The PET characterizes solute transport rates across the peritoneum and aids the prescription process.

Because the transport capacity of a patient's peritoneal membrane is such an important factor to consider in determining the dialysis prescription, a PET evaluation should be conducted soon after the initiation of dialysis.[50,56] However, a PET performed within the first week after the initiation of CPD may yield higher transport results than a PET performed several weeks later.[57] Accordingly, whereas it may be most convenient to perform the initial PET at the conclusion
Figure 37.6 Peritoneal equilibration test results for creatinine. Shaded areas represent high, high-average, low-average, and low transport rates. The four categories are bordered by the maximal, mean +1 standard deviation (SD), mean, mean −1 SD, and minimal values for the population. Avg, average; D/P, dialysate-to-plasma ratio. (From Warady BA, Alexander SR, Hossli S, et al. Peritoneal membrane transport function in children receiving long-term dialysis. J Am Soc Nephrol. 1996;7:2385.)

of CPD training, the results after 1 to 2 months of CPD may more accurately reflect peritoneal transport properties.[50,57]

The PET evaluation should be repeated when knowledge of the patient's current membrane transport capacity
Figure 37.7 Peritoneal equilibration test results for glucose. Shaded areas represent high, high-average, low-average, and low transport rates. The four categories are bordered by the maximal, mean +1 standard deviation (SD), mean, mean −1 SD, and minimal values for the population. Avg, average; D/DO, dialysate glucose–to–initial dialysate glucose concentration ratio. (From Warady BA, Alexander SR, Hossli S, et al. Peritoneal membrane transport function in children receiving long-term dialysis. J Am Soc Nephrol. 1996;7:2385.)

Table 37.1 Peritoneal equilibration test procedure in children

- Dwell period: 4 h
- Fill volume: 1100 mL/m^2 body surface area*
- 2.3% to 2.4% anhydrous glucose dialysis solution (Europe)
- 2.5% dextrose dialysis solution (North America, Japan)
- Test exchange after prolonged (8 h) dwell, if possible as follows:
  - Drain the overnight dwell.
  - Record the length of the dwell and the volume drained. Also note the dextrose concentration and volume infused.
  - Infuse the calculated fill volume, note infusion time.
  - Keep patient in supine position.
  - Drain less than 10% of dialysate solution into the drain bag at 0, 120, and 240 min.
  - Invert bag for mixing and obtain sample. Reinfuse any remaining effluent.
  - Obtain blood sample after 120 min.
- Measure creatinine and glucose in each sample.
- Calculate dialysate-to-plasma (D/P) creatinine and dialysate glucose–to–baseline dialysate glucose (D/DO) concentration ratios.
- Determine transporter state by comparing creatinine and glucose equilibration curves with pediatric reference percentiles (Figures 37.6 and 37.7).

* In early infancy, volume may not be tolerable; in these cases, conduct the peritoneal equilibration test with regular daily exchange volume for evaluation.

is necessary for determination of the patient's optimal CPD prescription. Examples of this would be when there is evidence of decreased ultrafiltration capacity, such as unexplained volume overload, worsening of hypertension, or erythropoiesis stimulating agent (ESA)–resistant anemia. The other such indication for a repeat PET is impaired solute removal, such as that characterized by unexplained signs or symptoms of uremia, especially when the patient may have had repeated peritonitis episodes that can alter transport characteristics.[58]

PATIENT SELECTION

CPD can be attempted in any child whose peritoneal cavity is intact and will admit an adequate volume of dialysate. Experience has shown that CPD can be used successfully in children with the following conditions: polycystic kidney disease (usually after bilateral nephrectomy), prune belly syndrome, bilateral Wilms tumor, recent abdominal surgical procedures (if no draining wounds are present), or with

Table 37.2 Absolute contraindications to peritoneal dialysis in children

- Omphalocele
- Gastroschisis
- Bladder exstrophy
- Diaphragmatic hernia
- Obliterated peritoneal cavity

vesicostomy, cutaneous ureterostomy, colostomy, or ventriculoperitoneal shunt.[59–61] Absolute contraindications to PD are given in Table 37.2.

CPD is the therapy of choice for the treatment of ESRD in infants.[61–64] It is widely recognized that CPD can be an effective maintenance therapy in babies who develop ESRD as early as the first few days or weeks of life.[65] Of course, the provision of home CPD, especially to infants, does mandate an evaluation of the patient's family by the treating facility to determine the likelihood of success. In addition, participation of the patient's caregivers in a formal training program and assessment of their readiness to accept the substantial responsibilities associated with home dialysis, which is often referred to as the "burden of care", are other prerequisites for starting patients on CPD.[66]

KEY POINTS

- Peritoneal dialysis can be attempted in virtually any child whose peritoneal cavity is intact and will admit an adequate volume of dialysate.
- A pediatric PD program must include a multidisciplinary team to provide the necessary support to the patient and family.

Finally, a successful pediatric PD program must also be able to provide the necessary multidisciplinary services required by the child and family on an ongoing basis. These services are provided by a team consisting of nephrologists, nurse specialists, urologists, general surgeons, renal dietitians, renal social workers, psychologists, psychiatrists, child development specialists, child life therapists, speech pathologists, and chaplains. Compared with adult patients, children require a significantly greater investment of time and resources from the CPD team.[62,67,68]

PERITONEAL DIALYSIS ACCESS

A reliable peritoneal catheter is the cornerstone of successful CPD. Goals for PD access should include the attainment of rapid dialysate flow rates, the absence of fluid leaks, and a low incidence of catheter-related infections.

PERITONEAL DIALYSIS CATHETER

In general, most long-term PD catheters are constructed of soft material, such as silicone rubber or polyurethane. The catheters can be thought of as having two separate regions: the intraperitoneal portion and the extraperitoneal portion. The intraperitoneal portion contains holes or slots to allow the passage of dialysate. The shape of the intraperitoneal portion typically is straight or curled; the curled configuration is often associated with less pain with dialysate inflow and a decreased predisposition to omental wrapping of the catheter. The most common catheters with these characteristics used by pediatric patients have been the straight and curled Tenckhoff catheters (Figures 37.8 and 37.9).[21,69,70]
Figure 37.8 Swan-neck, double-cuff Tenckhoff peritoneal catheters with curled intraperitoneal portion.
Figure 37.9 Radiologic appearance of the peritoneal dialysis catheter location. Note the curled intraperitoneal portion within the pelvis.

The extraperitoneal portion of each of these catheters has one or two Dacron cuffs to prevent fluid leaks and bacterial migration and to fix the catheter's position. The shape of this portion of the catheter is also variable and may be straight or have a preformed angle (e.g., swan-neck or pail handle) to help create a downward-directed catheter exit site. The catheter characteristics themselves may influence the risk of peritonitis (see later), although this remains controversial.[21,71-73]

IMPLANTATION SITE

The catheter implantation technique and the immediate postoperative care ultimately influence the longevity of the PD access. Adoption of a lateral placement technique through the body of the rectus muscle has resulted in a decrease in catheter leakage (Figures 37.10 and 37.11).[69,74,75] Although an open surgical technique is used most often, there is a growing experience with laparoscopic placement of PD catheters in children, a technique that may result in rapid postoperative recovery and greater catheter longevity.[76] Irrespective of the implantation procedure, the catheter exit site should be directed lateral or downward, and the provision of preoperative antibiotics within 60 min the skin incision is recommended to decrease the incidence of postoperative peritonitis.[72,77,78] Most current recommendations suggest the preferential use of a first-generation cephalosporin in adults and children at the time of catheter placement.

It is believed that infants and young children with a vesicostomy, ureterostomy, or colostomy may benefit from placement of the catheter exit site as far from the stoma as possible to prevent contamination and infection. Placement of the exit site on the chest wall and with a downward orientation has successfully limited the number of infections in such high-risk situations in children and adults.[62,79,80]
Figure 37.10 A diagrammatic representation of the surface anatomy of the abdomen used for placement of a peritoneal dialysis catheter.
Figure 37.11 A diagrammatic representation of the S-shaped track of the peritoneal dialysis (PD) catheter through the subcutaneous tissue and the rectus muscle. Such an insertion configuration minimizes the possibility of a peritoneal fluid leak.

IMMEDIATE POSTOPERATIVE CARE

Following catheter insertion, catheter immobilization is imperative to prevent trauma to the healing exit site, but exit site sutures should not be placed because of the risk of subsequent infection.[78] Whenever possible, a delay of 10 to 14 days before using the long-term catheter is desirable to allow for completion of healing and a decreased risk of leakage.[81] Ideally, exit site care conducted during the immediate postoperative period should be performed weekly with mask and gloves and should be performed by trained dialysis staff. The initial low frequency of dressing changes is designed to prevent contamination of the exit site with bacteria and to decrease the likelihood of manipulation of the catheter, which increases the risk of exit site trauma.[82] The exit site should be cleansed with a nonirritating agent such as poloxamer 188, chlorhexidine, or normal saline and the exit site should be evaluated weekly for the quality of healing. Application of a topical antibiotic ointment or cream at the time of the weekly dressing change has been recommended by some clinicians.[77,83]

LONG-TERM CARE

There is little consensus regarding the optimal approach to long-term exit site care after healing is complete.[84] However, it does appear that cleansing the catheter exit site is best performed with sterile gauze and a sterile antiseptic solution, preferably chlorhexidine, sodium hypochlorite, or octenidine. It has also been recommended that a topical antibiotic be placed at the catheter exit site as a component of long-term exit site care.[77,78,85] After cleansing, the catheter should be well immobilized. Most pediatric patients are prescribed a dressing over the exit site that is changed as part of daily or alternate-day exit site care.

COMPLICATIONS

PERITONITIS

The single most significant complication in children maintained on CPD is peritonitis.[78,86–88] Present data make it clear that children have a significantly greater rate of peritonitis than adults, and many children experience an episode of peritonitis during their first year of CPD treatment.[21] Reductions in observed peritonitis rates have been reported in both adults and children by treatment of *Staphylococcus aureus* nasal carriage and the application of topical antibiotics (e.g., mupirocin or gentamicin) at the catheter exit site, as well as by important technical developments, such as disconnect systems and the flush-before-fill technique.[89–91] Systemic antibiotic use should be considered following touch contamination and before gastrointestinal or dental procedures.[78] The important contribution of prolonged dialysis

training, with an emphasis on proper hand hygiene, to the prevention of peritonitis has been well demonstrated.[92]

Incidence

In the 2011 NAPRTCS annual report, data on 4248 episodes of peritonitis revealed an annualized peritonitis rate of 0.64, or 1 infection every 18.8 patient-months.[21] The rate of peritonitis was highest in the youngest patients (0 to 1 years of age), who had an annualized peritonitis rate of 0.79, or 1 infection every 15.3 patient-months, in contrast to an annualized rate of 0.57 or 1 episode every 21.2 patient-months in children more than 12 years of age. A significant improvement in the overall annualized infection rate from 0.79 in 1992 to 1996 to 0.44 in recent years is noteworthy. In this same report, the annualized peritonitis rate was noted to be best with the following strategies: use of Tenckhoff catheters with straight intraperitoneal segments, double cuffs on the catheter, swan-neck tunnels, and downward-pointed exit sites.

Infecting organisms

Data from the International Pediatric Peritoneal Dialysis Network (IPPN) demonstrated that peritonitis in children is the result of Gram-positive organisms in 44% of episodes, Gram-negative organisms in 25%, and fungi (e.g., *Candida* species) in approximately 2% of episodes. The remaining 31% of episodes were culture negative in the IPPN registry. Of the Gram-positive organisms, coagulase-negative *Staphylococcus* was most common; *Pseudomonas* species was the most common Gram-negative organism in the United States, whereas other Gram-negative organisms were most common in other countries.[88]

Treatment

The current approach to the treatment of bacterial peritonitis relies primarily on the intraperitoneal administration of antibiotics (Table 37.3). Key prophylactic and treatment recommendations have been incorporated into the "Consensus Guidelines for the Treatment of Catheter-Related Infections and Peritonitis in Pediatric Patients Receiving Peritoneal Dialysis: 2012 Update," under the auspices of the International Society for Peritoneal Dialysis.[78] This set of 22 guidelines includes recommendations for empiric antibiotic therapy as well as for treatment of Gram-positive and Gram-negative peritonitis (Figures 37.12 to 37.14). The guidelines also emphasize that the center-specific antibiotic susceptibility pattern should help guide the selection of empiric therapy because of the geographic variation in the distribution of causative organisms.[84]

The most crucial element in the treatment of fungal peritonitis is removal of the PD catheter.[93] The duration of antifungal treatment following catheter removal should be 2 to

3 weeks or longer after complete resolution of the clinical symptoms of infection. Whereas the peritoneal penetration of amphotericin B with systemic administration is poor, fluconazole is characterized by excellent bioavailability and peritoneal penetration, and fluconazole is currently the drug of choice for treatment of infection with most *Candida* species.[94–96] Ideally, susceptibility testing should also be performed when yeast is detected.

SCLEROSING ENCAPSULATING PERITONITIS

Sclerosing encapsulating peritonitis (SEP) is a rare but a serious clinical complication of CPD that is characterized by the presence of continuous, intermittent, or recurrent bowel obstruction associated with gross thickening of the peritoneum.[97,98] Although primarily diagnosed in adults, SEP may also occur in children, typically those who have received CPD for more than 5 years. SEP is associated with a high mortality rate. The presence of peritoneal membrane thickening, peritoneal calcifications, or bowel adhesions on abdominal computed tomography (CT) scan in association with ultrafiltration failure is highly suggestive of the diagnosis, and it may be considered an indication to discontinue CPD. SEP has also been diagnosed in kidney transplant recipients, and this finding suggests a need for prolonged surveillance of all patients who have received long-term PD.[99,100] It is hoped that greater use of biocompatible dialysis solutions will be associated with less peritoneal membrane injury and a decreased incidence of SEP.[101,102]

EXIT SITE AND TUNNEL INFECTION

Catheter exit site and tunnel infections, most often caused by *Staphylococcus* or *Pseudomonas,* are associated with a significantly increased risk for the development of peritonitis.[103] As noted previously, the initial approach to prevention occurs at the time of catheter placement, usually in the form of a single dose of a first-generation cephalosporin, unless the patient is known to be colonized with a methicillin-resistant organism.[77,78,91] Preventive measures should continue in the immediate postoperative period and should include the delayed (2 to 6 weeks) initiation of dialysis to facilitate wound healing and minimize the risk of dialysate leakage. The catheter should also be securely immobilized

Table 37.1 Antibiotic dosing recommendations for the treatment of peritonitis

| Antibiotic Type | Therapy type | | Intermittent therapy* |
| | Continuous* | | |
	Loading dose	Maintenance dose	
Aminoglycosides (IP)†			
Gentamicin	8 mg/L	4 mg/L	—
Netilmicin	8 mg/L	4 mg/L	Anuric: 0.6 mg/kg
Tobramycin	8 mg/L	4 mg/L	Nonanuric: 0.75 mg/kg
Amikacin	25 mg/L	12 mg/L	—
Cephalosporins (IP)			
Cefazolin	500 mg/L	125 mg/L	20 mg/kg
Cefepime	500 mg/L	125 mg/L	15 mg/kg
Cefotaxime	500 mg/L	250 mg/L	30 mg/kg
Ceftazidime	500 mg/L	125 mg/L	20 mg/kg
Glycopeptides (IP)‡			
Vancomycin	1,000 mg/L	25 mg/L	30 mg/kg: repeat dosing: 15 mg/kg every 3–5 days
Teicoplanin§	400 mg/L	20 mg/L	15 mg/kg every 5–7 days
Penicillins (IP)†			
Ampicillin	—	125 mg/L	—
Quinolones (IP)			
Ciprofloxacin	50 mg/L	25 mg/L	—
Others			
Aztreonam (IP)	1,000 mg/L	250 mg/L	—
Clindamycin (IP)	300 mg/L	150 mg/L	—
Imipenem-cilastin (IP)	250 mg/L	50 mg/L	—
Linezolid (PO)	<5 yr: 30 mg/kg daily, divided into 3 doses 5–11 yr: 20 mg/kg daily, divided into 2 doses ≥12 yr: 600 mg/dose, twice daily	—	
Metronidazole (PO)	30 mg/kg daily, divided into 3 doses (maximum, 1.2 g daily)	—	
Rifampin (PO)	10–20 mg/kg daily, divided into 2 doses (maximum, 600 mg daily)	—	
Antifungals			
Fluconazole (IP, IV, or PO)	6–12 mg/kg every 24–48 h (maximum, 400 mg/daily)	—	
Caspofungin (IV only)	70 mg/m² on day 1 (maximum: 70 mg daily)	50 mg/m² daily (maximum, 50 mg daily)	—

Source: Warady BA, Bakkaloglu S, Newland J, et al. Consensus guidelines for the prevention and treatment of catheter-related infections and peritonitis in pediatric patients receiving peritoneal dialysis: 2012 update. Perit Dial Int. 2012;32(Suppl 2):S32–86.

Abbreviations: IP, intraperitoneally; IV, intravenously; PO, orally.

* For continuous therapy, the exchange with the loading dose should dwell for 3 to 6 h; all subsequent exchanges during the treatment course should contain the maintenance dose. For intermittent therapy, the dose should be applied once daily in the long-dwell, unless otherwise specified.

† Aminoglycosides and penicillins should not be mixed in dialysis fluid because of the potential for inactivation.

‡ In patients with residual renal function, glycopeptide elimination may be accelerated. If intermittent therapy is used in such a setting, the second dose should be time based on a blood level obtained 2 to 4 days after the initial dose. Redosing should occur when the blood level is <15 mg/L for vancomycin, or <8 mg/L for teicoplanin. Intermittent therapy is not recommended for patients with residual renal function unless serum levels of the drug can be monitored in a timely manner.

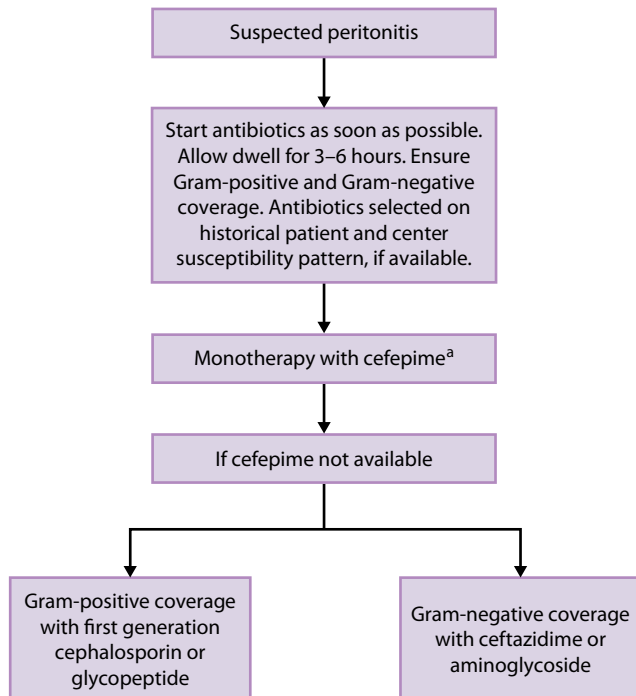
§ Teicoplanin is not currently available in the United States.


Figure 37.12 Empiric therapy of peritonitis. ᵃIf the center's rate of methicillin-resistant *Staphylococcus aureus* (MRSA) exceeds 10%, or if the patient has a history of MRSA infection or colonization, glycopeptide (vancomycin or teicoplanin) should be added to cefepime or should replace the first-generation cephalosporin for Gram-positive coverage. Glycopeptide use can also be considered if the patient has a history of allergy to penicillins and cephalosporins. (From Warady BA, Bakkaloglu S, Newland J, et al. Consensus guidelines for the prevention and treatment of catheter-related infections and peritonitis in pediatric patients receiving peritoneal dialysis: 2012 update. Perit Dial Int. 2012;32[Suppl 2]:S52.)

without the use of surgical sutures.[78] Regular assessment of the exit site and catheter tunnel and proper hand hygiene are additional important practice elements.

As noted earlier, attention to *S. aureus* nasal carriage in patients undergoing CPD is recommended because a substantial body of literature supports an association between nasal carriage and the development of catheter-related infections and peritonitis.[77,104] In families of children undergoing CPD, concern related to *S. aureus* nasal carriage extends to caretakers, given that as many as 45% of families with children undergoing CPD have been found to have one or more members with evidence of nasal carriage.[2] The use of mupirocin, intranasally or at the catheter exit site, has been associated with a decreased rate of exit site infections.[77,85,105] The occasional development of a *Pseudomonas* exit site infection in association with mupirocin use has prompted many investigators to recommend the prophylactic application of gentamicin ointment instead.[77,106]

Prompt diagnosis and effective therapy of exit site and tunnel infections (Table 37.4) are crucial to prevent peritonitis. Objective criteria for diagnosis have been developed based on experiences in children and adults. The isolation of a pathogen is not necessary if the clinical findings of an infection are readily apparent.[78,107]

Once the condition is diagnosed, antibiotic therapy should be chosen according to the susceptibilities of the cultured organism. The duration of treatment should be 2 to 4 weeks, and at least 7 days following complete resolution of the infection.[78] Treatment for at least 3 weeks is recommended for exit site infections secondary to *S. aureus* or *Pseudomonas aeruginosa*.

HERNIA

The incidence of hernias in children undergoing PD (8% to 57%) is inversely proportional to the patient's age, with the highest frequency of inguinal hernias occurring in patients less than 1 year of age.[108–110] Apart from age, other risk factors include increased IPP and the presence of anatomically weak sites in the abdominal wall. The most common presentation of a hernia is a painless swelling, with less frequent occurrence of discomfort or disfigurement.[109] More than 75% of hernias in patients on CPD require surgical repair, a procedure that typically is followed immediately by abstaining from CPD, followed by low-volume dialysis for several days.

FLUID LEAKS

Early fluid leaks that occur after catheter implantation (less than 30 days) usually manifest at the catheter exit site.[111–113] In contrast, later leaks may manifest as abdominal wall or genital edema, scrotal swelling, and apparent ultrafiltration failure. Potential risk factors for leaks include initiation of CPD immediately after catheter insertion, a median PD catheter insertion site, and weakness of the abdominal wall.

The diagnosis of a fluid leak is typically made by detecting the high glucose content of dialysate from fluid found at the exit site, by radiologic imaging with a T2-weighted magnetic resonance imaging scan (MRI) with an empty and filled abdominal cavity, or by CT with a contrast agent added in the dialysate.[111] Whereas leaks may be managed in some patients by the use of smaller exchange volumes, other patients may require a change from CAPD to APD and overnight cycling, or possibly catheter revision. Prevention of fluid leaks is preferable and may be best achieved by delayed initiation of CPD following catheter placement and application of fibrin glue at the deeper cuff at the time of catheter implantation.

HYDROTHORAX

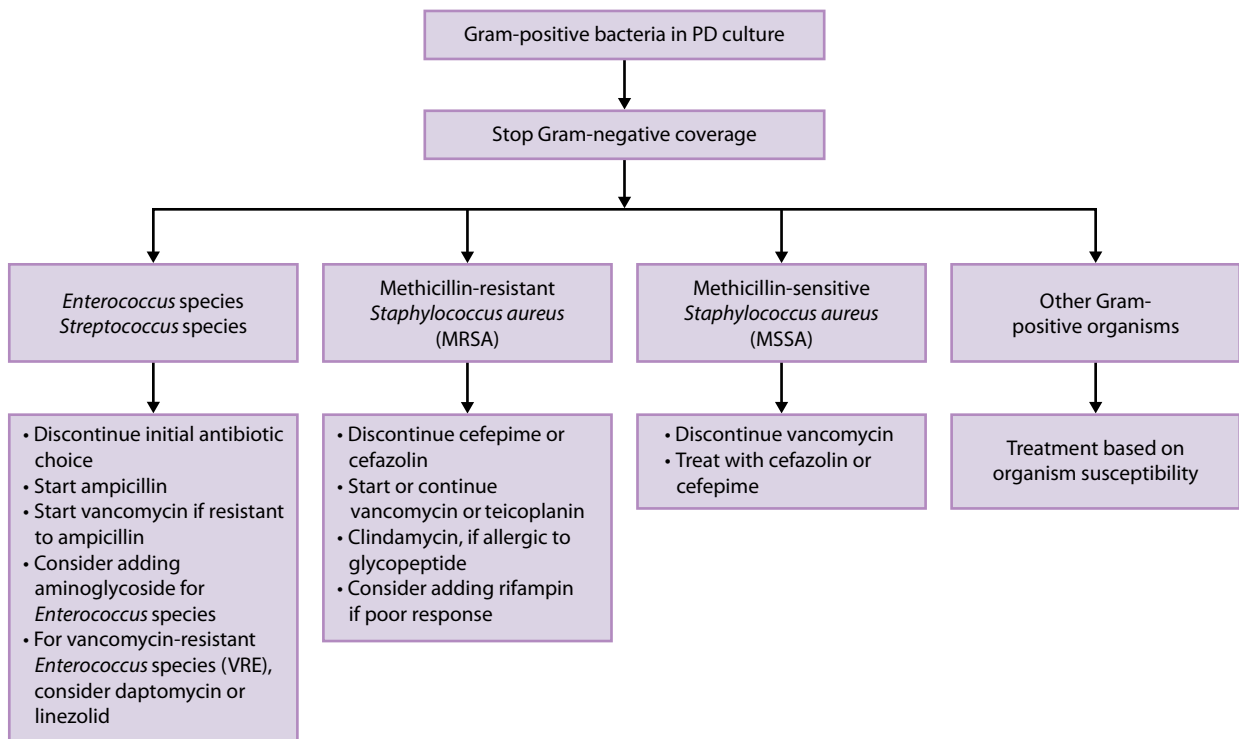
Hydrothorax, or the accumulation of dialysis fluid within the pleural space, is an uncommon complication of CPD with an incidence of 1.6% to 10%. Although the pathophysiology is not clear, contributing factors may include a disorder


Figure 37.13 Treatment of peritonitis with Gram-positive organism on culture. (From Warady BA, Bakkaloglu S, Newland J, et al. Consensus guidelines for the prevention and treatment of catheter-related infections and peritonitis in pediatric patients receiving peritoneal dialysis: 2012 update. Perit Dial Int. 2012;32[Suppl 2]:S54.)
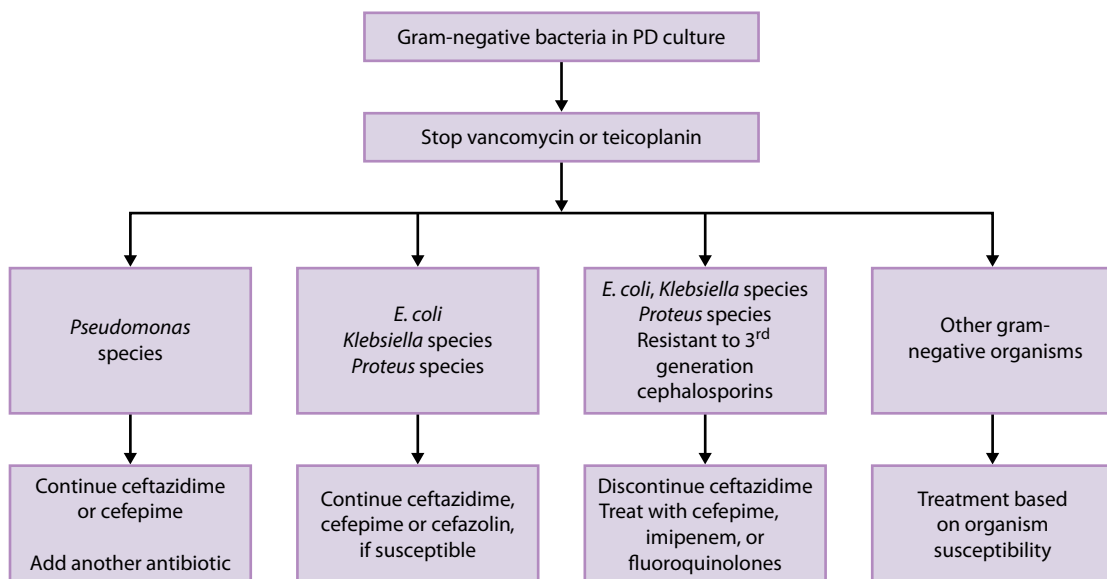

Figure 37.14 Treatment of peritonitis with Gram-negative organism on culture. PD, peritoneal dialysis. (From Warady BA, Bakkaloglu S, Newland J, et al. Consensus guidelines for the prevention and treatment of catheter-related infections and peritonitis in pediatric patients receiving peritoneal dialysis: 2012 update. Perit Dial Int. 2012;32[Suppl 2]:S56.)

Table 37.4 Oral antibiotics used in exit site and tunnel infection

Antibiotic	Recommended dose	Dose frequency	Per-dose maximum
Amoxicillin	10–20 mg/kg/day	Daily	1000 mg
Cephalexin	10–20 mg/kg/day	Daily or 2 times daily	1000 mg
Ciprofloxacin	10–15 mg/kg/day	Daily	500 mg
Clarithromycin	7.5 mg/kg/day	Daily or 2 times daily	500 mg
Clindamycin	30 mg/kg/day	3 times daily	600 mg
Dicloxacillin			
<40 kg	25–50 mg/kg/day	4 times daily	500 mg
>40 kg	125–500 mg/dose		
Erythromycin (as base)	30–50 mg/kg/day	3 or 4 times daily	500 mg
Fluconazole	6 mg/kg/day	Every 24–48 h	400 mg
Levofloxacin	10 mg/kg	Every 48 h	Day 1: 500 mg; then 250 mg
Linezolid			
<5 yr	10 mg/kg/dose	3 times daily	600 mg
5–11 yr	10 mg/kg/dose	2 times daily	
≥12 yr	600 mg/dose	2 times daily	
Metronidazole	30 mg/kg/day	3 times daily	500 mg
Rifampin*	10–20 mg/kg/day	2 times daily	600 mg
Trimethoprim	5–10 mg/kg/day	Daily	80 mg

Source: Warady BA, Bakkaloglu S, Newland J, et al. Consensus guidelines for the prevention and treatment of catheter-related infections and peritonitis in pediatric patients receiving peritoneal dialysis: 2012 update. Perit Dial Int. 2012;32(Suppl 2):S32–86.

* Should not be used as monotherapy, or used routinely in areas in which tuberculosis is endemic.

of lymphatic drainage, a pleura-peritoneal pressure gradient, congenital diaphragmatic defects, and increased IPP.[114] Hydrothorax may be detected incidentally on routine chest radiograph or may manifest soon after the initiation of CPD as shortness of breath. The hydrothorax is more common on the right side, quite possibly because the heart and pericardium prevent fluid movement across the left hemidiaphram.[115] In addition to the physical examination and chest radiograph, diagnosis of a hydrothorax may be made by thoracentesis and detection of fluid with the characteristic high glucose content of dialysate (greater than 300 to 400 mg/dL or pleural fluid to serum glucose concentration gradient greater than 50 mg/dL) or by scintigraphy, MRI, or CT. The subsequent continuation of PD has occurred following temporary cessation of PD (and the institution of HD), the use of APD and small nocturnal exchange volumes associated with a lower IPP, or obliteration of the pleural space with a variety of materials.[116,117] When a clear anatomic defect is noted, operative repair is characteristically successful.[117,118]

PERITONEAL DIALYSIS ADEQUACY

Providing adequate solute clearance with CPD requires the physician to be cognizant of the patient's BSA, peritoneal membrane solute transport capacity (as determined by the PET), and residual renal function (RRF) when designing the dialysis prescription.[102,119] Several computer-based dialysis modeling programs have been validated in children and can assist the prescription process.[120,121]

Although data that correlate solute removal and clinical outcome in children are lacking, current recommendations are that the minimal "delivered" dose of total (peritoneal and kidney) small solute clearance should be a volume of plasma cleared (Kt) of urea divided by the urea distribution volume, of at least 1.8/week.[50]

The total weekly Kt/V_{urea} is calculated as follows:

$$Weekly\ Kt/V_{urea} = \frac{(D_{ur} \cdot V_D)(U_{ur} \cdot V_u)}{P_{ur} \cdot V} \cdot 7$$

D_{ur}, U_{ur}, and P_{ur} are the dialysate, urinary and plasma concentrations of urea, V_D and V_U are the 24-h dialysate and urine volumes, and V is the urea distribution volume.

In the calculation of Kt/V_{urea}, it is most important to use an accurate estimate of V, which is considered to be equivalent to the total body water (TBW) volume. A set of anthropometric TBW prediction equations has been developed and validated in the pediatric PD-treated population.[122] The gender-specific formulas are as follows:

Boys: TBW = $0.10 \times (HtWt)^{0.68} - 0.37 \times$ weight

Girls: TBW = $0.14 \times (HtWt)^{0.65} - 0.35 \times$ weight

Apart from weekly Kt/V$_{urea}$, the clinical status of the pediatric patient should also be monitored closely as an important qualitative means of determining whether the patient is receiving adequate dialysis. A variety of clinical, metabolic, and psychosocial aspects of care should also be taken into consideration to determine a patient's well-being (Table 37.5).[123] Attention to volume status is imperative in view of the frequent presence of hypertension and left ventricular hypertrophy noted in children receiving CPD.[124] Figure 37.15 provides an evaluation algorithm for management of adequacy targets in patients undergoing CPD.

KEY POINT

Assessment of PD adequacy in children should take the total Kt/V and the patient's clinical status into consideration.

OUTCOME

An assessment of patient outcome must take into account short-term and long-term measures. Data on the health-related quality of life (HRQOL) of children with ESRD

Table 37.5 Clinical, metabolic, and psychosocial considerations in assessing the adequacy of long-term peritoneal dialysis treatment in pediatric patients

- Hydration status
- Nutritional status
- Dietary intake of energy, protein, salts and trace elements
- Electrolyte and acid-base balance
- Calcium phosphate homeostasis
- Control of anemia
- Blood pressure control

- Level of psychosocial rehabilitation

Source: Verrina E, Perri K. Technical aspects and prescription of peritoneal dialysis in children. In: Warady BA, Schaefer F, Alexander S, editors. Pediatric Dialysis, 2nd ed. New York: Springer; 2012. p. 169–203.

reveals that the HRQOL parameters of children undergoing dialysis are inferior to those of children with a successful kidney transplant. Risk factors for an impaired HRQOL should regularly be sought by repeated assessments and addressed if present.[125,126]

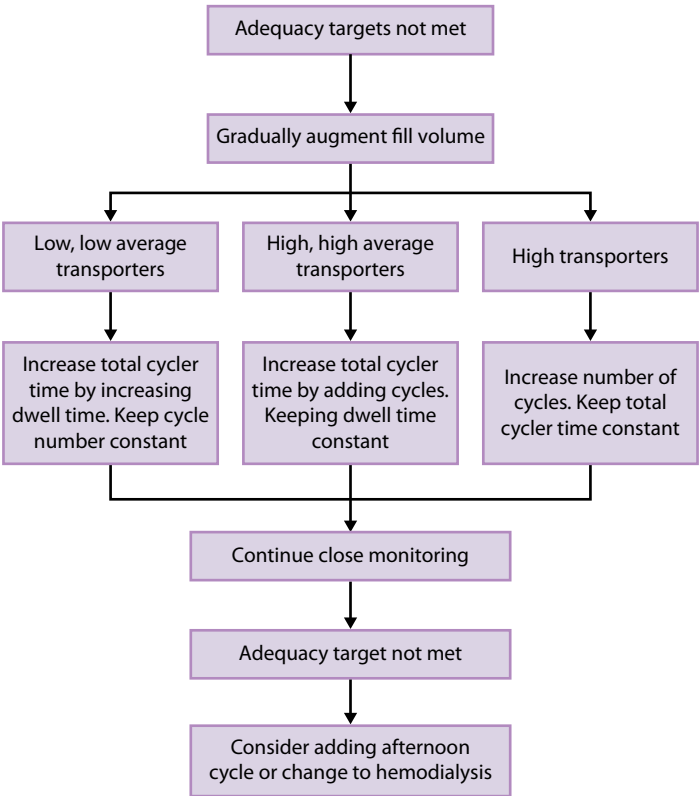
In a review of the pediatric USRDS mortality data derived from 1990 to 2010, mortality rates for both children and adolescents had decreased significantly over those decades,


Figure 37.15 Evaluation algorithm for management of dialysis adequacy profile in patients undergoing peritoneal dialysis.
Figure 37.16 One-year adjusted all-cause mortality rates in pediatric patients (from day 1), by age and modality. (From United States Renal Data System [USRDS] 2013 Annual Data Report: Atlas of Chronic Kidney Disease and End-Stage Renal Disease in the United States. Bethesda, MD: National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases; 2013.)

with the highest mortality rates still evident in patients who initiated dialysis at less than 5 years of age.[127] Additionally, the 2013 annual report of the USRDS continued to demonstrate that most PD-treated patients receive a kidney transplant over the course of 5 years, the outcome of PD-treated patients is inferior compared with transplant recipients, and cardiovascular disease and infection are the primary causes of death.[23] The 1-year adjusted all-cause mortality rate was 60.4 per 1000 patient-years for children undergoing HD, 45 for those undergoing PD, and 10.4 for transplant recipients (Figure 37.16). For those patients who initiated ESRD therapy in 2002 to 2006, the overall probability of surviving 5 years was 0.75 for patients undergoing HD, 0.80 for those undergoing PD, and 0.96 for transplant patients. In fact, the expected remaining lifetime (years) for patients with incident ESRD who were 0 to 14 years old and were undergoing dialysis was only 16.0 years, compared with 57.6 years for the transplant population of the same age and 72.8 years for the general population. These data emphasize that irrespective of the positive aspects of dialysis, one should aim to minimize the time a child spends on dialysis before transplantation whenever possible. Clinical Vignette 37.1 describes a child undergoing dialysis in whom transplantation is being considered.

KEY POINT

Mortality rates of patients undergoing HD and PD are higher than in kidney transplant recipients.

Clinical Vignette 37.1

D.W. is a 6-year-old boy who has developed end-stage kidney disease secondary to the presence of posterior urethral valves. Subsequent to a discussion between the dialysis team and his family regarding renal replacement therapy options, a swan-neck peritoneal dialysis catheter was placed. Automated peritoneal dialysis was initiated following the training of his parents to provide home therapy. His dialysis prescription included seven exchanges nightly after his peritoneal equilibration test evaluation revealed him to be a low-average transporter. An assessment of his clearance revealed his total Kt/V to be 1.9, and his overall well-being was felt to be good. Patient's course on dialysis was unremarkable until he developed an episode of *Staphylococcus aureus* peritonitis in association with an exit site infection with the same organism. Treatment consisted of intraperitoneal vancomycin with complete resolution of the infections. His parents are currently being evaluated as possible transplant donors.

TEACHING POINTS

This clinical course of the patient in Clinical Vignette 37.1 illustrates the usual clinical course of a patient with end-stage renal disease. The decision for placement of the peritoneal dialysis catheter is made after discussions are held between the patient's family and the dialysis team. The pros and cons of all forms of renal replacement therapy (peritoneal dialysis, hemodialysis, and renal transplantation) are reviewed during

this discussion. Dialysis prescription is empirically started and is modified after the peritoneal equilibration test data are available. Eventual transplantation is the goal for all pediatric patients who are receiving dialysis therapies.

REVIEW QUESTIONS

1. The greatest percentage of prevalent pediatric patients receives which of the following renal replacement modalities?
   a. Peritoneal dialysis
   b. Hemodialysis
   c. Kidney transplant

2. Which of the following peritoneal membrane pores comprise 90% to total pore area?
   a. Aquaporins
   b. Small pores
   c. Large pores

3. Convective mass transfer is responsible for only a small portion of large solute removal.
   a. True
   b. False

4. The PET test should be performed with which one of the following solutions for all older children and adolescents undergoing PD?
   a. Icodextrin
   b. The regular clinical fill volume for that patient
   c. 1100 mL/m^2 of a mixture of 2.5% and 4.25% PD solution
   d. 1100 mL/m^2 of 2.5% PD solution

5. Which one of the following is not an absolute contraindication to long-term PD?
   a. Gastroschisis
   b. Ventriculoperitoneal shunt
   c. Omphalocele
   d. Obliterated peritoneal cavity

6. Which of the following measures has not led to a decreased rate of peritonitis in children and adults? (Choose one)
   a. Topical application of antibiotic at catheter exit site
   b. Flush before fill technique
   c. Disconnect systems
   d. Use of Tenckhoff catheter with curled intraperitoneal portion

7. Which of the following is not true about hernias that develop in pediatric patients undergoing PD? (Choose one)
   a. The incidence is directly proportional to the patient's age.
   b. More than 75% require surgical repair.
   c. Raised IPP is a risk factor for hernia development.
   d. Surgical repair should be followed by no/low-volume dialysis.

8. The achievement of PD adequacy should take all but which one of the following factors into consideration?
   a. Peritoneal membrane solute transport capacity
   b. Frequency of peritonitis
   c. Patient's body surface area
   d. Residual renal function

9. The term "V" in Kt/V is equivalent to which one of the following?
   a. Volume of the peritoneal dialysis solution
   b. Total blood volume
   c. Total body water
   d. Volume of ultrafiltrate

10. An important cause of mortality in pediatric patients undergoing PD includes which one of the following?
    a. Cardiovascular disease
    b. Inadequate Kt/V
    c. Poor catheter function
    d. Loss of residual kidney function

ANSWER KEY

Renal transplantation

ASHA MOUDGIL AND STANLEY C. JORDAN

Renal transplantation is generally regarded as the treatment of choice for end-stage renal disease (ESRD) in children and adolescents. Although long-term dialysis therapy is possible, it is generally considered a bridge to renal transplantation for pediatric patients with ESRD. Compared to chronic dialysis, renal transplantation offers survival advantage, improved nutrition and linear growth, decreased hospitalization rate, and improved quality of life.[1] Preemptive renal transplantation provides an opportunity for the child and the family to bypass dialysis altogether and remains a viable option for patients with a suitable living donor. Renal transplantation requires lifelong immunosuppressive therapy, and adherence to treatment is paramount. Additionally, transplant recipients are at risk for complications of chronic immunosuppression and ongoing chronic kidney disease (CKD) both of which require close monitoring. This chapter outlines the key concepts of kidney transplantation process in children including long-term post-transplant management.

INDICATIONS AND CONTRAINDICATIONS TO TRANSPLANTATION

Most children with ESRD are considered good candidates for renal transplantation, because the spectrum of comorbidities seen in adults is often absent. Although there is no clear agreement on the contraindications to renal transplantation in children, the generally practiced absolute and relative contraindications to renal transplantation are listed in Table 38.1.[2,3]

Patients with ESRD secondary to immune-mediated diseases should wait until the underlying disease is in remission. Those with childhood malignancies should be free of recurrence for a period of 2 to 5 years, based on the site and type of malignancy.[3] Children with oxalosis and other genetic disorders, such as methylmalonic acidemia, should be considered for a combined liver and kidney transplant.[4–6] Patients with human immunodeficiency virus (HIV) infection can

Table 38.1 Contraindications to renal transplantation in children

Absolute Contraindications
- Acute infection
- Untreated malignancy
- Oxalosis and other genetic syndromes that might benefit from a combined liver and kidney transplant
- Life-limiting coexisting medical conditions: Advanced cardiac, pulmonary, neurologic, or other systemic disease
- Multiorgan failure
- Progressive neurologic illness
- Pregnancy

Relative Contraindications
- Uncontrolled HIV infection
- Untreated hepatitis C infection
- Untreated hepatitis B infection
- MAI, BKV, and other infections
- Ventilator dependent children*
- Recurrent FSGS in previous transplant
- Active immune-mediated glomerulonephritis (SLE, Good-Pasteur's syndrome, ANCA-associated GN)
- Persistent vegetative state*
- Extreme obesity and malnutrition
- Psychosocial concerns, including poor adherence with medical regimen

* Some centers would consider these as absolute contraindications.
Abbreviations: ANCA, Antineutrophil cytoplasmic antibody; BKV, BK virus; FSGS, focal segmental glomerulosclerosis; GN, glomerulonephritis; HIV, human immunodeficiency virus; MAI, *Mycobacterium avium-intracellulare*; SLE, systemic lupus erythematosus.

undergo transplantation, provided infection is under control and they meet other selection criteria.[7] Those with evidence of chronic hepatitis C and B infection should be evaluated by a hepatologist before listing. Evaluation should include a liver biopsy for staging of the disease and consideration for treatment with antiviral therapy on dialysis before transplantation. Post-transplant immunosuppressive regimens in these patients should be chosen carefully because induction with T-cell depleting agents can result in fulminant progression of hepatitis C and B infections.[8]

As a result of advancements in medical technology there is an increase in the number of children with ESRD who have survived extreme prematurity, complex malformations, and associated comorbidities. Some of these children have physical, neurodevelopmental, or both disabilities and are medically fragile. Increasingly, children dependent on external life-sustaining support for feeding, ventilation, or both are receiving dialysis care and need consideration for

transplantation. Although the Centers for Medicare and Medicaid Condition of Participation (482.90) mandates that transplant centers must have a fair and nondiscriminatory patient selection process for determining transplant candidacy, no clear guidelines exist for transplant candidacy for medically fragile children.[9] A careful evaluation should be done of the child's overall comorbidities and their impact on survival by seeking the advice of medical teams with expertise in these difficult conditions. Involvement of the family and an ethicist, along with a patient advocate from the community, is essential in considering the risks and benefits of renal transplantation in such children.[10]

Nonadherence to medical treatment is an important challenge to successful outcome of renal transplantation.[11] Nonadherence of the patient on dialysis is considered a relative contraindication to renal transplantation in many centers. However, there is limited consensus on defining nonadherence to medical therapy, which can be poor phosphorus control or fluid balance, poor compliance with prescribed home dialysis, or frequent unanticipated absences from in-center hemodialysis.

DONOR SOURCE

As in the adults, children can receive renal transplantation from living or deceased donors. Living renal transplant donation can be from either an individual who is related to the child (parents or siblings older than 18 years of age) or an unrelated person.[12] Living donor (related and unrelated) allografts have a longer half-life compared to those obtained from the deceased donors.[1,13] This is thought to be the result of a relatively healthy organ and elimination of cold ischemia time. Increased cold ischemia time increases the risk for acute rejection as a result of enhanced expression of human leukocyte antigens (HLAs) and adhesion molecules on the surface of endothelial and renal tubular cells.[14]

ORGAN PROCUREMENT AND ALLOCATION FOR CHILDREN

ORGAN PROCUREMENT PROCESS

The U.S. Congress passed the *National Organ Transplant Act* in 1984 and established the Organ Procurement and Transplantation Network (OPTN) to facilitate and regulate organ transplantation in the

United States. The United Network for Organ Sharing (UNOS), an independent nonprofit organization, was established in 1984 and is under federal contract to operate OPTN since 1986.[15] UNOS is divided into 11 operational regions, with each region having a number of organ procurement organizations that are responsible for the procurement of organs from deceased donors and their shipment to the recipient hospitals. UNOS is responsible for allocation of deceased organs to all potential recipients in the United States and has standard policies and procedures that are periodically updated as new research becomes available.[16] All living donors and potential recipients are also listed on the UNOS website (known as UNET) to track all transplants occurring in the United States and for outcome research.

DECEASED ORGAN ALLOCATION

After the evaluation and decision that the patient should receive a deceased organ renal transplant, the first step is to list potential recipients on the UNOS waiting list. There are no set qualifying criteria for pediatric patients to be listed on the UNOS waiting list. Generally, patients are eligible for listing when they enter chronic dialysis or have measured or estimated glomerular filtration rate (GFR) of less than 20 mL/min/1.73 m². However, children can be listed at higher GFR if clinically warranted and at the discretion of the transplant center. Information on the HLA typing and unacceptable HLA antigens (presence of specific antibodies to HLA molecules in the recipient sera) is entered in the UNOS database. These unacceptable antigens are used to estimate calculated panel reactive antibodies (CPRA), and the result is considered for point allocation of deceased donor organs. Once listed, the potential recipient starts accumulating time on the waiting list.

UNOS employs point-based allocation policies developed through collaborative efforts between the transplant community, the Scientific Renal Transplant Registry (SRTR), and OPTN.[16] These allocation policies are based on scientific evidence to optimize outcomes in transplant recipients and are revised periodically as new data become available. UNOS allocates points based on a number of recipient and donor factors (the detailed discussion is beyond the scope of this chapter). Zero antigen–mismatched kidneys are mandated to be shared across the geographic and time zones in the United States.

Once an organ becomes available, donor information is entered in UNET. The list of prospective blood group–compatible recipients having no anti-HLA antibodies directed at HLA molecules of this particular donor (virtual cross-match negative) is generated.

An offer is made to the first recipient with the most points. Allocation preferences are given to multivisceral transplants, highly sensitized patients, recipients who have been organ donors in the past, and pediatric recipients. Over the years, the organ allocation process has been refined. No points are assigned for medical urgency.

ALLOCATION OF ORGANS TO PEDIATRIC RECIPIENTS

Children are given priority for high-quality kidneys. Kidneys from deceased donors are classified using the Kidney Donor Profile Index (KDPI). The KDPI score (1 to 100) is based on the age, weight, height, ethnicity, serum creatinine, history and duration of hypertension and diabetes, cause of death, presence of hepatitis C, and whether the donation is after cardiac death (DCD).[17] Kidneys with lower KDPI score have better long-term survival. Because there are allocation advantages for deceased donors in children, it is important to list eligible pediatric patients before their 18th birthday to give them access to high-quality organs.

DATA ANALYSIS

A number of scientific registries maintain ESRD databases and transplant outcomes.[1,15] These include the United States Renal Data System (USRDS), SRTR, and the North American Pediatric Renal Trials and Collaborative Study (NAPRTCS). All transplant centers are mandated to send information pertaining to all transplant recipients to the UNOS periodically. The SRTR in collaboration with UNOS plays a critical role in policy development through ongoing data analysis and development of statistical, analytic, and simulation models.[18] NAPRTCS, a consortium of pediatric ESRD and transplant centers was established in 1987 with the scientific objectives of capturing information about current practice and trends in immunosuppressive therapy in children.[1] Participation in NAPRTCS is voluntary.

IMMUNOLOGIC BARRIERS TO TRANSPLANTATION

A number of immunologic barriers to successful transplantation exist, of which the most important are blood group antigens, HLA mismatches and preexisting anti-HLA antibodies before transplant, and development of de novo donor-specific antibodies (DSA) following transplant.[19]

BLOOD GROUP

ABO compatibility between donor and recipient is generally considered an absolute prerequisite for successful transplantation.[20] ABO antigens are expressed on the surface of endothelial cells, in addition to red blood cells (RBCs). Blood group antibodies (anti-A, anti-B, and anti-AB) are naturally occurring isoagglutinins that bind to the endothelium, causing cell swelling, destruction, and irreversible graft loss known as hyperacute rejection (HAR). The rules that govern blood transfusion also apply to solid organ transplantation. Individuals with type O blood group are considered universal donors, and those with type AB blood group are regarded as universal recipients. Experience in solid organ transplantation, including kidneys, across blood group barriers has begun to evolve in many centers in the United States and Japan. In these studies, blood group isoagglutinins are removed by plasmapheresis, or immunoadsorption, followed by intense immunosuppression.[21] Rh blood group antigen matching is traditionally not considered a requirement for successful renal transplantation.

HUMAN LEUKOCYTE ANTIGEN TYPING

Genetic differences among individuals are recognized by differences in the composition of major histocompatibility complex antigens, also known as *HLA antigens*.[22] HLA antigens help differentiate self from nonself and fight invading organisms. The genes encoding these antigens are present on the short arm of chromosome 6. Based on their structural differences, HLA antigens are divided into class I (A, B, and C) and class II (DR, DQ, DP). HLA class I antigens are present on all nucleated cells. RBCs lack HLA antigens. HLA class II antigens are present on macrophages, dendritic cells, endothelial cells, and B cells. T cells, renal tubular epithelial cells, and endothelial cells increase expression of class II molecules on stimulation with cytokines such as interferon-gamma (IFN-γ).

Histocompatibility genes are extremely polymorphic and are expressed as codominant alleles. The concentration of HLA genes in one defined area of the chromosome allows these genes to be inherited as a packet, or haplotype. Individuals inherit 1-haplotype from each parent. Children are 1-haplotype matched with their biologic parents. Siblings can be complete HLA matched, 1-haplotype matched, or completely mismatched, depending on the recombination of their haplotypes.

The HLA type of an individual can be determined by conventional serologic methods or DNA-based typing. Once the HLA typing is determined, the number of matched and mismatched antigens between the recipient and the prospective donor can be calculated. The number of mismatches, or nonshared HLA antigens, between the donor and the recipient may differ from the number of shared antigens or matches because of some yet unidentified HLA antigens or inheritance of two copies of the same HLA allele. From the renal transplant perspective, currently only six antigen pairs (A, B, and DR), inherited from each parent, are considered in the allocation process. However, by DNA typing other alleles (*A, B, C, DRA1, DRB1, DRB3/4/5, DQB1, DQA1, DPB1, and DPA1*) can be identified. HLA mismatching determines the extent of anticipated allogeneic response.[14] Recently, DQ and DP antigen mismatches between donor and recipients have been identified to play an important role in the development of de novo DSAs after transplant.[23]

Identical twins are fully matched or are zero mismatched. Generally these perfectly matched recipients do not require post-transplant immunosuppression. The first successful human transplant was done between identical twins. Availability of potent immunosuppressive therapy has, to some extent, attenuated the effect of HLA matching on short-term allograft survival and the incidence of acute rejection. However, HLA matching, in particular DR matching, continues to have an effect on long-term renal allograft survival. HLA identical grafts have a longer half-life compared to those that are less well matched. The high degree of polymorphism makes complete HLA matching between two random individuals an exceedingly rare event.

Current clinical practice in the United States is to share all six antigen matched or zero mismatched kidneys from deceased donors in the entire national recipient waiting list pool and across the geographic regions of the country.[16] Fewer than 20% of kidneys transplanted in the United States from deceased organ donors are zero mismatched and transported across the country. The potential benefits of sharing these kidneys come at a price of increased cold ischemia time associated with organ transport, sometimes over several time zones.

ANTI–HUMAN LEUKOCYTE ANTIGEN ANTIBODIES

Anti-HLA antibodies can exist before transplant or develop after transplant. Transplant recipients can develop anti-HLA antibodies as a result of sensitization events that include blood transfusions, previous transplants, pregnancies, and, rarely, infections. With widespread use of recombinant erythropoietin in ESRD patients, allosensitization as a result of blood transfusion has decreased considerably. When present, preexisting anti-HLA antibodies bind to HLA antigens expressed on the surface of allograft endothelial cells and can cause HAR and immediate graft loss. These antibodies are particularly deleterious if they are directed at HLA class I antigens and are able to activate the complement cascade by binding to complement proteins. Anti-HLA antibodies developing after transplant (de novo) are specific to the donor, are known as DSA, and can result in an accelerated graft loss. DSA can develop as a result of nonadherence, inadequate immunosuppression, or viral infections.[24]

Testing for anti-HLA antibodies has undergone remarkable technologic enhancements.[19] The oldest and least sensitive method for testing anti-HLA antibodies is the complement-dependent cytotoxicity assay. The complement-dependent cytotoxicity assay involves testing donor's T and B cells for lympholysis by anti-HLA antibodies in the recipient's serum, in the presence of complement. Enzyme-linked immunosorbent assay (ELISA) and flow cytometry have provided an increasing order of sensitivity for detection of anti-HLA antibodies. Cells from the donor as well as HLA antigen–coated beads can be used for ELISA or flow cytometry. Antibodies to specific HLA antigens can be characterized by flow cytometry or Luminex technology, using single HLA antigens coated on spherical particles known as single antigen beads. In recipients with anti-HLA antibodies to specific HLA antigens, transplant from donors with these HLA antigens should be avoided and these antigens are listed as unacceptable antigens on the UNOS-UNET. Donors carrying unacceptable HLA antigens are automatically excluded from the organ offer. These unacceptable antigens are used to define CPRA as described in the following section.

CALCULATED PANEL REACTIVE ANTIBODIES

Adopted by UNOS in 2006, the CPRA procedure is based on a calculation of the reaction frequency of a listed set of unacceptable mismatches for a patient, against a panel of 10,000 recently added deceased donors.[25] The CPRA is derived from HLA antigen/allele group and haplotype frequencies for different racial and ethnic groups in proportion to their representation in the national deceased donor population. The CPRA values are rounded to the nearest one hundredth percentage and give a measure of the chances of a patient finding a compatible donor from the donor pool. The use of CPRA is made much easier by use of solid-phase assays such as Luminex assays, especially those involving the use of single antigen beads. These assays allow precise characterization of anti-HLA antibodies. The strength of the mean fluorescence intensity (MFI) is used to assess immunologic risk and to help decide whether or not a particular antigen should be listed as unacceptable on the UNET.

CROSS-MATCH

Cross-match determines the compatibility between a specific recipient and a donor and is the final pretransplantation immunologic screening step. The test involves testing recipient's serum against donor T and B cells to detect any preformed antibodies against donor's lymphocytes. Until recently, cross-matching was routinely done by complement-dependent cytotoxicity assay. Immunoglobulin (IgM) autoantibodies in a recipient's serum can give a false-positive result in this assay. These antibodies can be inactivated by pretreatment of serum with dithiothreitol (DTT), which disrupts the S-S bonds in IgM. A negative cross-match after DTT treatment excludes alloantibodies, whereas a positive T-cell cross-match is indicative of preformed alloantibodies and is a contraindication to transplantation from that specific donor. The sensitivity of the cross-match is enhanced many-fold by antihuman globulin ELISA assay and flow-cytometry cross-match. These tests are especially useful for highly sensitized patients and those undergoing retransplant. Most transplant centers use flow-cytometry cross match routinely.

IMMUNOBIOLOGY OF ALLOGRAFT REJECTION

Allograft rejection is an orchestrated process.[14] The physical process of reimplanting and reperfusing organs for transplantation initiates ischemia-reperfusion injury. The recipient's innate immune system can recognize these markers of tissue injury and result in upregulation of the inflammatory response genes. The consequence of such a response is an increased production of the proinflammatory cytokines, such as interleukin (IL)-1, IL-6, tumor necrosis factor-alpha (TNF)-α, and type I interferon, all of which trigger release of antigens from the graft. Additionally, there is increased expression of adhesion molecules by the endothelial cells that promote their adhesion with the inflammatory cells. Donor antigens released from the graft are taken up by the antigen-presenting cells (APCs) of either donor or recipient origin. Recipient APCs (macrophages, dendritic cells, B lymphocytes) process donor antigens into small peptides that are subsequently presented on their cell surface in association with HLA class I or II molecules. These APCs then leave the graft and migrate to secondary lymphoid

tissues, where they activate naive recipient T-cells that have specific receptors for HLA-allopeptide complexes (indirect allorecognition). Additionally, recipient T cells can directly recognize donor APCs bearing HLA molecules loaded with self-peptide (direct allorecognition). CD4+ T lymphocytes recognize HLA class II and CD8+ T lymphocytes recognize HLA class I associated allopeptides. Direct pathway of antigen presentation plays an important role early on after transplant, whereas indirect pathway plays a more prominent role later on. The ability of T cells to recognize and respond to alloantigens is identical to their ability to respond to foreign antigens and infectious agents.

> ## KEY POINTS
>
> - Precise characterizations of anti-HLA antibodies have become feasible with solid-phase assays such as Luminex and availability of single HLA antigen–coated beads.
> - Specific unacceptable antigens are listed on the UNET for each recipient and help determine CPRA.
> - Flow cross-match is the most sensitive assay currently available and is most widely used.

Within secondary lymph nodes, T-cells respond to allo-antigens presented by APCs in a sequence of three signals (Figure 38.1). Signal I, or antigenic signal, is the interaction between HLA-allopeptide complex and CD4+ T-cell receptor. Signal II is a costimulatory signal mediated by a number of pathways. These include CD40/CD40 ligand interaction that increases γ-IFN, which upregulates B7 expression and subsequently the B7-CD28 interaction, a powerful costimulator of T-cell activation. When T cells receive both signals I and II, there is an activation of a number of enzymes, followed by an increase in cytosolic calcium. Cytosolic calcium binds to calcineurin that turns on the nuclear factor activating transcription (NFAT) and mitogen activated protein kinases (MAPKs), which promote synthesis of interleukin-2 (IL-2) and γ-IFN. IL-2 enhances synthesis of other cytokines, including IL-3, IL-4, IL-5, IL-6, and TNF-α.

Signal III consists of secreted IL-2 interacting with the IL-2 receptor present on the surface of these T-cells. This interaction stimulates a series of enzymatic reactions and drives the cell into division, resulting in clonal expansion and differentiation of graft reactive CD4+ lymphocytes. However, before cell division, de novo synthesis of purine and pyrimidine nucleotides occurs in T cells. If T cells receive only signal I without signal II, they undergo apoptotic cell death.

Activated CD4+ T cells provide help to CD8+ T cells, B cells, macrophages, natural killer (NK) cells, and platelets through secreted cytokines. CD8+ T cells, also known as cytotoxic T cells, secrete granzyme and perforins that cause cell death in the allografts. IL-3, IL-4, and IL-5 stimulate B cells that produce antibodies against donor antigens. IL-1
Figure 38.1 Signal pathways to T-cell activation. Signal I: Interaction between antigen-presenting cells presenting allopeptides and CD4+ T-cell receptor of the recipient. Signal II: includes a number of costimulatory pathways, of which the most important are interaction between B7-1/B7-2 and CD28, and CD40 and CD40 ligand. On receiving both signal I and II, there is an increase in cytosolic calcium that activates calcineurin and promotes synthesis of interleukin-2 (IL-2) and other cytokines. Mitogen-activated protein kinases are also activated in the T cells on receiving signals I and II, leading to promoter gene stimulation. IL-2 and other cytokines generated from T-cell activation act on the T-cells' surface (as signal III), sending downstream signals to activate the target of rapamycin (TOR), which induces immune cells into cell cycle division and causes T-cell proliferation. CD40L = CD40 ligand.

and TNF−α facilitate activation of macrophages and other inflammatory cells, and IL-6 stimulates platelets. These activated T cells and other inflammatory cells (B cells, macrophages, and platelets) leave the lymph nodes and enter the circulation to infiltrate the allograft causing allograft destruction and inflammation (Figure 38.2). IL-6 also appears to be critical in reversing the action of regulatory T (Treg) cells that might prevent allograft rejection. Allografts containing disparate HLA antigens generate a stronger signal I and are more likely to experience rejection compared to those more closely related to the recipient's HLA.

KEY POINTS

- Donor exchange programs and desensitization protocols offer opportunities for transplantation in highly sensitized individuals.
- Graft loss can result in a highly sensitized state in pediatric patients.

IMMUNOSUPRESSIVE THERAPIES

Immunosuppressive drugs help overcome immunologic barriers to transplantation and are essential for transplant survival.[26] The drugs or procedures used before or at the time of transplantation to suppress unwanted allograft-directed immune responses are referred to as *induction*

therapies. The medications are used for long-term maintenance of the immunosuppressed state in the recipient for graft survival. Induction therapies are more potent than the maintenance immunosuppressive medications.

INDUCTION THERAPIES

Induction therapies include antibodies, high-dose intravenous (IV) methylprednisolone, plasmapheresis, and splenectomy. Induction antibodies can be directed at T cells, B cells, or the complement cascade and can be monoclonal or polyclonal. Antibodies target the cell surface molecules of the immune-competent cells and do not enter into the cells.[27] Antibodies can be depleting or nondepleting antibodies. Depleting antibodies cause cell death, whereas nondepleting antibodies interfere with cell function.

Polyclonal antibodies

Polyclonal antibodies include antithymocyte globulin raised in horses (ATG) and rabbits (Thymoglobulin) and IV immunoglobulin (IVIg). Both ATG and Thymoglobulin contain antibodies against multiple T-cell surface antigens (CD2, CD3, CD4, CD5, CD8, CD11, CD18, CD28, CD45, and T-cell receptor) and cause extensive T-cell depletion. IVIg downregulates production of antibodies in addition to neutralizing preexisting antibodies. IVIg also causes upregulation of Fc-gamma (Fcγ) receptor IIB on B cells and is a modifier of complement activation and injury.[28] Thymoglobulin is commonly used for induction in renal
Figure 38.2 Orchestration of different cells in causing allograft destruction. Activated CD4+ T cells secrete cytokines that stimulate a number of cells participating in graft destruction. Activated B cells mature into plasma cells that secrete alloantibodies, causing complement-mediated allograft damage. Activated cytotoxic lymphocytes secrete granzyme and perforins that cause direct damage to the allograft cells. Activated macrophages and natural killer (NK) cells also participate in graft destruction. Activated platelets add thrombotic component to the graft destruction. ADCC, antibody-dependent cellular toxicity.

transplant recipients because of superior performance compared with that of ATG.

Monoclonal antibodies

Monoclonal antibodies include anti–IL-2R antibody (basiliximab), anti-CD52 monoclonal antibody (alemtuzumab), anti-CD20 antibody (rituximab), and anti–membrane attack complex antibody (eculizumab). Basiliximab binds to the α-chain of IL-2 receptor, making it unavailable for IL-2 binding and subsequent cell division (blocking signal III) and is a nondepleting antibody. Alemtuzumab is a humanized monoclonal antibody that targets the CD52 antigen on lymphocytes, monocytes, macrophages, and NK cells, causing extensive lymphocyte depletion. Rituximab binds to C20 on pre-B and B cells causing their depletion but does not affect plasma cells. Basiliximab, Thymoglobulin, or alemtuzumab are used for standard induction, whereas IVIg and rituximab are used in highly sensitized recipients. Eculizumab is used for induction in patients with ESRD secondary to atypical hemolytic uremic syndrome (HUS).[29] Plasmapheresis is used for recurrent focal segmental glomerulosclerosis FSGS, in highly sensitized recipients, and for prevention of atypical HUS. Splenectomy is rarely used for ABO-incompatible and highly sensitized transplant recipients. Characteristics, doses, and side effects of commonly used induction therapies are shown in Tables 38.2 and 38.3.

These pharmacologic agents are capable of acting on targets inside the cells (Figure 38.3) and maintain a state of immunosuppression for long-term viability of the allograft. These agents include calcineurin inhibitors (CNIs), such as cyclosporine A (CsA) and tacrolimus; antiproliferative agents such as mycophenolate mofetil (MMF); azathioprine and sirolimus; and corticosteroids (prednisone, prednisolone, and methylprednisolone). A summary of these drugs is given in Table 38.4.

Calcineurin inhibitors

CsA and tacrolimus bind to cyclophilin and FK binding proteins, respectively, and inhibit the activity of the enzyme intracellular calcineurin in T cells. Nuclear factor activating transcription (NFAT) translocation to the nucleus is consequently blocked, preventing transcription of IL-2 and other cytokine genes.

Antiproliferative agents

Azathioprine and MMF act as antiproliferative agents by inhibiting de novo purine synthesis that is necessary for cell division. Mycophenolic acid (MPA), the active metabolite of MMF, is a potent, selective, noncompetitive, and reversible inhibitor of inosine monophosphate dehydrogenase, an enzyme required for de novo purine synthesis. MPA inhibits T- and B-lymphocyte proliferation that is critically

Table 38.2 Pharmacologic agents available for induction therapy of renal transplants

Name	Antibody type	Origin	Target and mechanism of action
Antithymocyte globulin (Thymoglobulin)*	Polyclonal	Rabbit	T-cell receptor, CD3, CD4, CD8, CD2, CD18, CD25, CD44, CD45, CD28, CD11A, B7 integrin, CD54, HLA class I and DR, and β2 microglobulin-depleting antibody
Intravenous immunoglobulin G, or IVIg (Gammagard, Carimune, Gamunex)	Polyclonal	Human	Multiple putative mechanisms: Immunomodulation, upregulation of Fcγ III receptor on B cells, modifier of complement activation and injury, nondepleting antibody
Basiliximab (Simulect)	Monoclonal	Mouse, chimeric	CD25 on T cells, nondepleting antibody
Alemtuzumab (Campath)	Monoclonal	Rat, humanized	CD52 on mononuclear cells, depleting antibody
Rituximab (Rituxan)	Monoclonal	Mouse, chimeric	CD20 on pre-B and B cells, depleting antibody
Eculizumab (Soliris)	Monoclonal	Mouse, humanized	Complement C5, blocks formation of membrane attack complex

* Brand names of the drugs are given in parentheses.
Abbreviations: CD, Cluster determinant (cluster of antigens that characterize a cell surface marker with which antibodies react); Fcγ, Fc-gamma receptors that bind to Fc region of the antibody.

Table 38.3 Dose, duration, and side effects of induction therapies available for clinical use in renal transplantation

Induction Therapy	Dose	Route and duration	Side effects
Antithymocyte globulin (Thymoglobulin)	1.5 mg/kg/d	IV over 6–8 house via central line for 4–7 days	Fever, chills, anaphylaxis, leukopenia, thrombocytopenia, Increased risk for CMV and PTLD
Basiliximab (Simulect)	10 mg or 12 mg/m² for < 35 kg, 20 mg for > 35 kg	IV, day 0 and 4	Same as placebo
Alemtuzumab (Campath)	0.3–0.4 mg/kg/dose	IV or s/c, 1-2 doses	First-dose reaction, allergic reaction, and increased incidence of infections
Methylprednisolone (Solumedrol)	10–15 mg/kg	IV push in the OR	Salt and water retention, gastric ulceration, insomnia, impaired wound healing, growth retardation, cataract, osteopenia
Intravenous Immunoglobulin G, or IVIG	2 gm/kg/dose	IV infusion over 4 hours, variable duration	Headache, aseptic meningitis, chills, rarely acute renal failure in preparations containing sucrose
Rituximab (Rituxan)	375–750 mg/m²/dose	IV infusion, 1–4 doses	Fever, chills, anaphylaxis, hypogammaglobulinemia, increased risk for bacterial infections
Eculizumab (Soliris)	Loading dose 1200 mg, then 900 mg weekly. See package insert for weight based guidelines.	IV, variable duration	Increased risk for infection with encapsulated bacteria

Abbreviations: CMV, Cytomegalovirus; OR, operating room; PTLD, post-transplant lymphoproliferative disorder.
Figure 38.3 Mechanism of action of common immunosuppressive medications used in clinical practice. Corticosteroids have inhibitory action on the antigen APCs. Belatacept inhibits the interaction between CD28 on T cells and the costimulatory ligands (B7-1/B7-2) (blocking signal II). Immunoglobulin G and Thymoglobulin (not shown) have antibodies to the multiple cell surface receptors on T cells. Cyclosporine A and tacrolimus inhibit calcium-activated calcineurin, blocking interleukin-2 (IL-2) gene promotor action and synthesis of IL-2. Basiliximab blocks interaction of IL-2 with IL-2R (blocking signal III). Rapamycin binds to TOR and blocks the entry of cells into the cell cycle after IL-2 binds to IL-2R. Mycophenolate mofetil and azathioprine inhibit purine synthesis required for cell division. CD40L, CD40 ligand.

Table 38.4 Maintenance immunosuppressive drugs

Name of the drug	Dose	Side effects
Prednisone	2 mg/kg/day to be tapered to 0.5 mg/kg/day in 2 wk, 0.1–0.15 mg/kg/day over 6 mo	Excessive weight gain, hypertension, hyperglycemia, cushingoid features, acne, growth suppression, osteoporosis, gastric ulceration, impaired wound healing, mood change, cataracts
Cyclosporine A	6–8 mg/kg/day at the onset, adjust dose according to levels	Nephrotoxicity, hypertension, hirsutism, gingival hyperplasia, tremors
Tacrolimus	0.1–0.15 mg/kg/day, adjust dose according to levels	Nephrotoxicity, tremors, diabetes mellitus, hair loss, increased absorption in diarrhea
Azathioprine	2 mg/kg/day	Myelosuppression, hepatotoxicity
Mycophenolate mofetil	1200 mg/m^2/day to a maximum of 1500 mg BID	Myelosuppression, diarrhea
Sirolimus	Loading dose 6 mg/day followed by 2–5 mg/day, adjust according to levels	Hypertriglyceridemia, mucosal ulcers, thrombocytopenia, pneumonia

dependent on de novo purine synthesis. Additionally, MPA also alters the expression of cell surface adhesion molecules by inhibiting glycosylation of lymphocyte and monocyte glycoproteins. Sirolimus, also known as rapamycin, acts on the molecular target of rapamycin (mTOR) and blocks the ability of cells to enter the cell cycle.

Corticosteroids

Corticosteroids primarily act on the APCs and inhibit their ability to produce IL-1 and other cytokines.[30] Many cytokine genes, including IL-2 have a glucocorticoid response element (GRE) in the 5′ regulatory region that serves as a target for corticosteroid and intracellular glucocorticoid receptor complex. Binding of this complex with GRE blocks transcription of cytokines. High-dose methylprednisolone causes lympholysis and therefore is useful for the treatment of acute allograft rejection.

NOVEL IMMUNOSUPPRESSIVE DRUGS

Currently, a few immunosuppressive agents are in different phases of clinical trials.[31] Belatacept (costimulation inhibitor, CTLA4Ig) was recently approved for use in Epstein-Barr virus (EBV)-positive adults by the U.S. Food and Drug Administration; it has potential benefits because of lack of nephrotoxicity and neurotoxicity and might replace chronic CNI therapy. Belatacept therapy provides GFR advantage and decreases the risk for post-transplant hypertension and metabolic complications. Initial data from the controlled clinical trials are encouraging, but the current recommendation is not to use this drug in EBV-naive individuals at the time of transplant because of high risk for developing post-transplant lymphoproliferative disorder (PTLD).[32] Other studies with

Belatacept induction combined with Thymoglobulin show promise for development of CNI-free and steroid-free protocols with low rejection rates. At this point, no data are available in children. A multicenter randomized conversion study is currently underway in the United States and Europe and will evaluate the efficacy and safety of Belatacept immunosuppression in EBV-seropositive children with a stable renal transplant (NCT 01791491).[33]

If efficacious, Belatacept would eliminate the use of chronic nephrotoxic CNI therapy as maintenance immunosuppression in children. Major concerns with Belatacept include higher risk for early rejection in the CNI-free environment and the increased risk for infectious complications, including CMV, EBV, and polyoma BKV nephropathy.

ASKP1240 is a fully human monoclonal antibody directed against CD40. It inhibits CD40/CD40L complex among B cells, T cells, APCs, and endothelial cells. Prolonged allograft survival has been noted in primate transplants, and human phase II studies are underway.[31] TOL101 is a murine monoclonal IgM antibody against αβ subunit of T-cell receptor. As TOL101 is not active against γδ T-cell receptor, it inhibits T-cell proliferation while preserving tolerogenic effects of γδ T-cell receptors. TOL101 is currently in phase I/II trial.[31]

PRETRANSPLANT EVALUATION OF RECIPIENT

The pretransplant evaluation is aimed to ensure and enhance patient's suitability as a transplant recipient and identify any potential contraindications to transplant. Table 38.5 lists the principles of pretransplant evaluation applicable to children.

Table 38.5 Principles of pretransplant evaluation process in pediatric recipients

1. History and physical examination
   Determine the cause of end-stage renal disease
   Identify comorbidities
   Genitourinary, lower spine, perineum, and neurologic examination
   Nutrition evaluation and optimization
   All age-appropriate immunizations, including Pneumovax-23 and meningitis
2. Psychosocial evaluation and counseling of the child and family
3. Immunologic evaluation: ABO and human leukocyte antigen (HLA) typing, screening for anti-HLA antibodies
4. Evaluation for exposure to infections: Antibodies to viral infections (cytomegalovirus, Epstein-Barr virus, herpes simplex virus, human immunodeficiency virus, varicella zoster virus, hepatitis B and C), hepatitis B surface antigen, serologic tests for syphilis, chest x-ray, and tuberculin testing
5. Urologic evaluation: Urinalysis and urine culture, ultrasonography including postvoid images of the bladder, vesicocystourethrogram. Voiding diary, uroflow, urodynamics, and, rarely, cystoscopy in patients with complicated urologic problems
6. Optional: Neurocognitive evaluation, hematologic evaluation if suspected to be at risk for thrombosis, cardiac, pulmonary, dental, and ophthalmologic as indicated
7. Financial screening and counseling

UROLOGIC EVALUATION AND PREPARATION

Approximately a third of children undergoing renal transplantation have some form of structural abnormalities or dysfunction of the urinary tract, such as posterior urethral valve (PUV), vesicoureteric reflux, prune belly syndrome, neurogenic bladder, Hinman syndrome, and exstrophy of the bladder. The abnormal high-pressure bladder can contribute to allograft failure. Consequently, urologic evaluation and management is an important preparatory step for children being evaluated for renal transplantation. Such an evaluation may include examination of the lower urinary tract anatomy by contrast vesicocystourethrogram (VCUG), assessment of bladder compliance and emptying function by postvoid ultrasound, uroflow studies, and urodynamic studies. Any necessary urinary tract reconstructive surgery should be done in advance of transplantation.

DETERMINING CAUSE OF END-STAGE RENAL DISEASE

Establishing the cause of ESRD is important, because many diseases have the potential for recurrence in the transplant. These include FSGS, atypical HUS, and membranoproliferative glomerulonephritis (MPGN). In these cases strategies should be developed to optimize the timing of transplant and monitor for recurrence and treatment. The potential for recurrence of primary glomerular diseases is not considered a contraindication to transplantation. Children with Alport syndrome can develop anti–glomerular basement membrane (GBM) antibodies after transplant secondary to the absence of α-3, -4 and -5 subtypes of collagen IV in their native kidney basement membrane. Similarly, children with congenital nephrotic syndrome secondary to nephrin mutations can develop antinephrin antibodies, causing damage to the allograft.

IDENTIFYING COMORBID CONDITIONS

Pretransplant evaluation should be aimed at identifying clinical, physiologic, psychological, and socioeconomic conditions that may have an impact on the successful outcome of a renal transplant. Patients should be screened for chronic infections, which may require treatment and planning before renal transplantation. Native nephrectomies for chronic infection of the kidneys, severe nephrotic syndrome (congenital nephrotic syndrome or idiopathic FSGS), polyuria with severe fluid and electrolyte wasting, polycystic kidneys, intractable hypertension, large renal masses, or nephrolithiasis may be necessary in some children. Careful review of other comorbid conditions should be done to assess whether these require special provisions after transplant or may serve as relative or absolute contraindications to transplantation.

IMMUNOLOGIC EVALUATION

Immunologic evaluation includes determining the blood group and HLA typing and identifying specific anti-HLA antibodies. The final step is to perform a cross-match with the prospective donor as described earlier.

GENERAL HEALTH MAINTENANCE

Age-appropriate immunizations, including hepatitis B, varicella, Pneumovax, meningitis, and human papillomavirus (HPV) immunizations should be provided to children before transplantation procedure because response to immunizations may be blunted after transplantation.[34] Immunity to live viral vaccines (measles, mumps, rubella, and varicella) should be documented, and children should be revaccinated if not immune because live virus vaccines are contraindicated after renal transplant. Growth and nutritional status should be optimized, because both malnutrition and obesity result in increased risks for complications after transplantation.

PSYCHOSOCIAL EVALUATION

Psychosocial evaluation and planning are paramount to success of transplant. Nonadherence to medical therapy is an important barrier to allograft survival, particularly in adolescents. Therefore, a careful assessment of the child and family's ability to adhere to long-term immunosuppression and medical therapy should be conducted and documented. There is an increased prevalence of mood and adjustment disorders in the children and family members of those with chronic illness. Referral to psychiatrist and or counseling may be desired. The family support system may need to be strengthened to ensure an optimal long-term outcome.

DONOR EVALUATION

LIVING DONOR EVALUATION

It is generally recommended that a physician not familiar with the child's needs should evaluate living donors to ensure that they are medically suitable for a donation kidney. An outline of donor workup is shown in Table 38.6. The UNOS Ad Hoc Living Donor Committee has published living kidney donor evaluation guidelines.[35]

DECEASED DONOR EVALUATION

All deceased donors undergo comprehensive evaluation and management after the decision for donation is made. The goal is to identify any conditions that may preclude

Table 38.6 Evaluation of living donors

1. Detailed history and physical examination
2. Psychosocial screening and counseling
3. Renal function tests, including 24-hour urine collection for protein and creatinine measurement, liver function tests, screening for diabetes
4. Age-appropriate screening for cardiovascular health and malignancies
5. ABO, Rh, and human leukocyte antigen typing
6. Screening for infections: Antibodies to viral infections (human immunodeficiency virus, cytomegalovirus, Epstein-Barr virus, hepatitis B and C), hepatitis B surface antigen, serologic tests for syphilis, chest x-ray, and tuberculin testing and screening for infection pertaining to the geographic area of origin
7. Renal and renovascular anatomy: Renal ultrasound, renal angiography or spiral computed tomography scan or magnetic resonance imaging of kidneys with magnetic resonance angiography and magnetic resonance venography

donation or require special provisions after transplant. There are standardized protocols for donor management for optimization of organ function after transplant. The details of management are beyond the scope of this chapter. The deceased donors are divided into brain-dead donors or those from whom donation is obtained after cardiac death (DCD). DCD donors pose an increased risk for delayed graft function (DGF); pulsatile preservation may decrease this risk.

SURGICAL PROCEDURE

LIVING DONOR NEPHRECTOMY

Kidney from a live donor can be procured by open donor nephrectomy (ODN) or laparoscopic donor nephrectomy (LDN). LDN was first used to procure kidneys for transplant in 1995.[36] LDN is offered at most of the transplant centers in the United States. LDN has shortened the hospital stay and recovery time for donors and has decreased the need for analgesia. Short-term graft outcomes for kidneys obtained by LDN are comparable to those obtained by ODN. Analysis of UNOS data shows a higher incidence of DGF and acute rejection in young recipients (0 to 5 years) of kidneys obtained by LDN, raising a concern for the use of this practice in this age group. However, there is a need to update these data with increased experience gained with LDN countrywide.

DECEASED DONOR NEPHRECTOMY

Kidneys are obtained from deceased donors by standard ODN procedure. Renal artery or arteries are on a patch of aorta known as the Carroll patch. The left renal vein is longer than the right renal vein. Extreme care is taken to preserve blood supply to the lower part of the ureter to prevent ischemia as ureteric supply comes from multiple vessels. After nephrectomy, the kidney is placed in cold preservative solution or placed on a pump with which the cold preservative solution is pumped into the renal artery. Cold ischemia time is the time gap between placement of kidney into the cold preservative solution and the time it is taken out for implantation into the recipient. Warm ischemia time is the timegap between removal of the kidney from the preservative solution and the time when blood starts to perfuse into the recipient renal artery. The shorter the cold and warm ischemia times, the better is the organ function. The warm ischemia time is much more detrimental to organ function than cold ischemia time.

ORGAN IMPLANTATION PROCEDURE

The renal allograft is placed extraperitoneally in the iliac fossa in children weighing greater than 20 kg.[37] The donor renal artery and vein are connected to the child's common iliac or external iliac artery and vein, using an end-to-side

anastomosis technique. In infants and young children less than 20 kg, the donor kidney is placed intraperitoneally in the abdomen and the renal artery and vein of the allograft are connected to the side of the aorta and inferior vena cava, close to the bifurcation (Figure 38.4).

These general surgical principles are applied to both living and deceased donor renal transplants. Meticulous detail to the vascular anastomosis technique is required in children. This is especially important in young infants, in whom the vessel size is considerably smaller than in adults and older children. In the case of multiple arteries in the living donor, they can be anastomosed separately or joined together in side-to-side anastomosis and then connected to the recipient vessels. Multiple renal arteries in deceased donors are usually on the common aortic (Carroll) patch.

The ureter is generally connected to the bladder using ureteroneocystostomy. Attention should be paid to preserve the arterial supply of the lower segment of the ureter, because interruption of the blood supply to this segment may result in ureteral ischemia and consequent urinary leaks or ureteral stricture.

PERIOPERATIVE TRANSPLANT MANAGEMENT

FLUID AND ELECTROLYTES

Children may need to be dialyzed before renal transplantation if they are hyperkalemic or severely fluid overloaded,
Figure 38.4 Surgical anastomoses and placement of an extraperitoneal renal allograft. Donor renal artery and vein are connected to the lower end of recipient's aorta and inferior vena cava, respectively.

particularly if they receive an organ from a deceased donor that may not be expected to function right away. Hypovolemia should be avoided at all costs. Except in polyuric children, preoperative IV fluids are not necessary in most cases. Close attention needs to be paid to intravascular volume in the operating room by infusion of crystalloid and colloid solutions in particular at the time of vascular anastomosis because an adult kidney can sequester up to 250 mL of the recipient's blood volume. This may represent a significant change in total blood volume in an infant or a small child (blood volume of a 10-kg child is 80 mL/kg, 800 mL) and cause hypotension if not appropriately replaced. As a result, appropriate intraoperative fluid management is critical in infants and young children.[37]

Central venous pressure (CVP) should be maintained between 10 to 15 cm H_2O before removal of the aortic cross clamps to ensure good blood flow to the allograft, because hypoperfusion can promote allograft thrombosis. Vasopressors such as dopamine may be required to help maintain adequate blood pressure. Mannitol (0.5 to 1 g/kg) and furosemide (1 to 2 mg/kg) at the time of removal of the cross clamp are often used to induce diuresis in the transplanted organ. Occasionally, an intra-arterial vasodilator such as verapamil may be given to overcome renal arterial vasospasm.

Postoperative fluid and electrolyte management includes replacement of insensible losses and urine output with an appropriately constituted fluid. Five percent dextrose is used for insensible losses, and replacement of urine output can be achieved with a fluid with an electrolyte composition approximating that of urine electrolytes. Usually, 1/2 normal saline with 20 mEq of sodium bicarbonate per liter can be used as initial urine replacement. Further adjustments in the composition of the replacement fluids should be based on the serum and urine electrolyte analysis. To facilitate function of the transplanted organ, CVP is generally maintained at 8 to 10 cm H_2O in the first 24 hours.

Fluid and electrolyte status needs to be monitored and managed carefully in patients with DGF. Dialysis should be used judiciously as aggressive fluid removal during dialysis can result in hypovolemia and superimposed acute tubular necrosis (ATN), further impeding the recovery of graft function.

IMMUNOSUPPRESSIVE MANAGEMENT

The goal of immunosuppressive therapy is to prevent allograft rejection, while avoiding complications of excessive immunosuppression such as infections and malignancy. Immunosuppressive therapy is most intense in the first few weeks to months.

Most centers use some form of induction therapy that may include basiliximab in standard-risk and Thymoglobulin or alemtuzumab in high-risk transplant recipients (highly sensitized, retransplants, and patients with DGF) or in steroid avoidance protocols. Infants and young children may benefit from induction therapies because they have more

intense allograft-directed immune responses and usually metabolize immunosuppressive medications at a faster rate than adults.

CsA, tacrolimus, prednisone, azathioprine, MMF, and sirolimus are used in various combinations for maintenance immunosuppression and are initiated around transplant surgery. Steroids have been traditionally used in most immunosuppression protocols. IV steroids are often used intraoperatively and for the first few postsurgery days, followed by oral therapy after adequate gastrointestinal function is achieved. A combination of CNI (CsA or tacrolimus) and antiproliferative agents (azathioprine, MMF, or sirolimus) is initiated soon after transplantation. To avoid nephrotoxicity in patients with DGF, CNI use is avoided until satisfactory allograft function is apparent. The use of CsA as a primary immunosuppressive agent has been largely replaced by tacrolimus in recent years.[13] Similarly, MMF has replaced azathioprine. Sirolimus is being used selectively in pediatric renal transplantation.

Because of a high toxicity profile associated with long-term steroid use, attempts have been made to eliminate steroid use in maintenance immunosuppressive protocols. In the earlier studies, steroid withdrawal was associated with a high incidence of acute rejection. Steroid withdrawal or avoidance has been successful in protocols using tacrolimus in combination with MMF. Steroid avoidance studies have shown no increased risk for acute rejection and benefits in reducing post-transplant dyslipidemia and hypertension, although growth advantage is not always realized, especially in postpubertal children.[38] Leukopenia and anemia are more prevalent in children on steroid avoidance protocols. Although short-term data are useful, long-term effects on graft survival are lacking. A combination of tacrolimus and MMF with or without steroids is the most commonly used maintenance immunosuppressive regimen in both adults and children.[13]

KEY POINTS

- Most children receive some form of induction therapy.
- Steroid withdrawal protocols may improve growth and metabolic parameters.
- A combination of tacrolimus and MMF with and without steroids is the most commonly prescribed maintenance immunosuppressive regimen.

In steroid-based protocols, steroids are gradually tapered, and by the end of 3 months most children receive low-dose prednisone at 0.1 to 0.2 mg/kg/day either daily or on alternate days. Generic formulations have become available for tacrolimus, CsA, and MMF. Although shown to be bioequivalent in healthy volunteers, data in children after transplant is lacking. Transplant physicians should be familiar with the mechanism of action of various drugs, drug interactions, dosages,

and side effect profiles of the immunosuppressive agents. Inadvertent use of drugs that interact with immunosuppressive medications can result in significant complications and morbidity. Prevention and treatment of infections should be an integral part of immunosuppressive management and should be incorporated in the protocols.

ANTI-INFECTIVE PROPHYLAXIS

Anti-infective prophylaxis is important in preventing opportunistic infections. The American Society of Transplantation has published guidelines for the prevention and management of infections after solid-organ transplantation.[39] Trimethoprim-sulfamethoxazole (TMP-SMX) is used for prophylaxis against *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) pneumonia (PCP) and urinary tract infection (UTI). The usual dose is 5 mg/kg/day (based on the trimethoprim component with a maximum daily dose of 320 mg) given on thrice-weekly schedule, such as Monday-Wednesday-Friday or on three consecutive days per week. Duration of PCP prophylaxis is usually for 4 to 6 months but may need to be prolonged, depending on the intensity of immunosuppression and therapy of acute rejection episodes.

In children allergic to TMP-SMX or those with G6PD deficiency, inhaled (>6 years of age) or IV pentamidine (<6 years of age) can be used once a month. The dose of inhaled pentamidine is 300 mg via Respirgard II inhaler and for IV pentamidine is 4 mg/kg/dose. Alternatively, dapsone or atovaquone could be used in children allergic to TMP-SMX. TMP-SMX also serves as prophylaxis for nocardia and toxoplasmosis. Suppressive therapy can be continued in children at high risk for UTI. Nystatin (2 to 5 mL) as swish and swallow three or four times per day is prescribed for 4 to 6 weeks following transplantation for fungal prophylaxis.

KEY POINTS

- Post-transplant infections are an important cause of morbidity and hospitalizations in transplant recipients.
- Prospective monitoring and prompt treatment of infections is an important therapeutic strategy, especially when immunosuppression is augmented.

Cytomegalovirus (CMV) prophylaxis is necessary for patients at high risk (donor CMV IgG positive/recipient CMV IgG negative) or moderate risk (recipient CMV IgG positive) for developing CMV infection. Oral valganciclovir dose in milligrams ($7 \times BSA \times CrCl$, calculated using a modified Schwartz formula). is often used for 3 to 6 months. If the calculated Schwartz creatinine clearance exceeds 150 mL/min/1.73 m², then a maximum value of 150 mL/min/1.73m² should be used in the equation. Herpes simplex

virus (HSV) infections can be prevented by low-dose acyclovir in children who are not receiving valganciclovir.

TRANSPLANTATION IN HIGHLY SENSITIZED RECIPIENTS

It is extremely difficult to find compatible organs for highly sensitized patients. In recent years, these individuals have been successfully transplanted using varying desensitization protocols including high-dose IVIg, rituximab, plasmapheresis, bortezomib, or eculizumab.[20] There are few data in children on the use of such protocols. However, there are increasing numbers of highly sensitized pediatric patients awaiting renal transplantation who may benefit from these interventions.

Transplant centers need to develop an infrastructure of an advanced HLA laboratory, plasmapheresis unit, and renal pathology services before considering ABO or HLA incompatible transplantation and using desensitization protocols. Donor exchange programs between incompatible donor-recipient pairs are becoming popular to transplant individuals with positive cross-match against their respective donors. However, it is likely exchange programs alone will not be successful in transplanting the very highly HLA–sensitized patients. These patients will likely need a combination of desensitization and paired exchange. There are several national donor exchange programs available. UNOS is currently piloting a kidney paired exchange program with the ultimate intent of making it available nationwide.[40]

POST-TRANSPLANT MONITORING

Transplant recipients need close monitoring, particularly in the first few months of transplant, to assess renal function, adequacy of tacrolimus drug levels, monitoring for infections, adherence with medications and their side effects, and other complications, including PTLD.[41] The risk for acute rejection has decreased significantly from 50% to 60% to less than 10% in the first 6 months of transplantation. Surveillance for malignancy should be included in long-term management. Frequency of monitoring decreases with time as the risks for rejection and infection wane. However, the risks for late acute rejection episodes, development of de novo DSA, and nonadherence increase with time.

There are no immunologic markers for adequacy of immunosuppression. Therefore, judgment regarding adequacy of immunosuppression is usually based on careful clinical evaluation for acute rejection and infections. Measurement of cytokines (granzyme and perforins), or chemokines in the urine by polymerase chain reaction (PCR) has been shown to correlate with acute rejection.[42] The gene profiling of blood and biopsy tissue by microarray technology also holds some promise in differentiating cases of acute rejection from those with stable graft function.[43] These tests, however, are not used widely for routine clinical purposes and their value relative to careful assessment of renal function over time coupled with renal allograft biopsies is unclear.

COMPLICATIONS OF TRANSPLANTATION

DELAYED GRAFT FUNCTION

DGF refers to transplants that fail to function after blood flow through the allograft is established. There are varied definitions of DGF, of which the most commonly employed is the need for dialysis in the immediate postoperative period.[44] DGF is more common in organs transplanted from deceased donors because of factors during terminal stages of death, especially in those with increased cold ischemia time. DGF is more prevalent in organs obtained from DCD donors because of an increase in warm ischemia time. A higher incidence of DGF also has been observed in young recipients (0 to 5 years of age) transplanted with laparoscopically procured kidneys.[45] Other well-known causes include acute renal arterial or venous thrombosis, ATN, and HUS. Urinary obstruction secondary to blood clots, urine leakage, and obstructed Foley catheter may mimic DGF (Table 38.7). DGF increases the risk for acute rejection and has deleterious effects on long-term graft survival. During DGF, there is an increased expression of HLA class II molecules on the graft endothelium; thus increasing propensity for acute rejection.[14]

Prompt management of primary DGF is crucial to prevent graft loss. Urinary obstruction and graft blood flow can be assessed by Doppler renal ultrasound, and function can be assessed by MAG-3 nuclear renal scan. Presence of an adequate renal blood flow with a lagging excretory function is suggestive of ATN. Surgical exploration may be necessary if vascular thrombosis is suspected. ATN is managed conservatively. Dialysis should be performed carefully, and hypotension should be avoided as it may impede recovery from DGF. CNI and other nephrotoxic drugs should not be used, and sirolimus should be avoided because it delays recovery from DGF.[46] Induction therapy may need to be intensified to prevent acute rejection. If the allograft is found to be nonviable by MAG-3 scan or biopsy, an allograft nephrectomy is recommended.

SURGICAL COMPLICATIONS

Surgical complications include renal arterial or venous thrombosis, lymphocele, perirenal serous fluid collection, hematoma, urinary leaks, and obstruction at the ureterovesical junction (UVJ). Patients at risk for thrombosis include those on peritoneal dialysis, those younger than 2 years of age, recipients of deceased donors under 5 years of age, and those with cold ischemia time greater than 24 hours. Patients with severe nephrotic syndrome may be at increased risk for thrombosis. Placement of an adult kidney

Table 38.7 Differential diagnosis of post-transplant graft dysfunction

Clinical state	Diagnostic possibilities
Acute increase in serum creatinine (20% above baseline or an increase of ≥ 0.3 mg/dL)	Acute rejection
	Acute calcineurin inhibitor nephrotoxicity
	Dehydration
	Urinary obstruction
	Pyelonephritis
	BK virus infection
Slow increase in serum creatinine (creatinine creep)	Interstitial fibrosis and tubular atrophy
	Chronic calcineurin inhibitor nephrotoxicity
	Urinary tract obstruction or functional bladder dysfunction
	Recurrent or de novo glomerulonephritis
	BK virus nephropathy
	Renal artery stenosis
Hypertension	Fluid overload in the peritransplant period
	Side effects of steroids, calcineurin inhibitor
	Acute rejection
	Transplant renal artery stenosis
	Interstitial fibrosis and tubular atrophy
	Recurrent and de novo glomerulonephritis
	Diseased native kidneys
	Excessive weight gain and obstructive sleep apnea
Proteinuria	Recurrent and de novo glomerulonephritis
	Interstitial fibrosis and tubular atrophy
	Chronic calcineurin inhibitor nephrotoxicity
	Acute rejection
	Transplant glomerulopathy

in children less than 2 years of age results in unique hemodynamic challenges. High aortic blood flow is necessary to prevent arterial thrombosis in infants and children transplanted with adult-sized kidneys.[47]

Several disorders of coagulation causing deficiency of protein C, protein S, antithrombin III, and plasminogen and genetic mutations for factor V Leiden, prothrombin, and methyl-tetrahydrofolate reductase have been described in the general population.[48] Patients with antiphospholipid antibodies are also at high risk for thrombosis. The role of these predisposing factors in post-transplant thrombosis is emerging.[48]

Lymphocele, perirenal serous fluid, or blood collections are common surgical complications in the immediate post-transplant period. Increased incidence of lymphocele also has been noted with the use of sirolimus.[46] Lymphoceles may resolve spontaneously. However, large fluid collections can cause urinary obstruction. Percutaneous aspiration or surgical drainage may be needed in such cases. Urinary leaks are uncommon because of the current practice of using lower doses of steroids and closer attention to urologic surgical techniques. Urinary obstruction at the UVJ may be a manifestation of ureteral ischemia, CMV infection, polyoma BKV infection, or acute rejection. Ureteral stents may be used for prevention and treatment of UVJ obstruction.[50] UTIs are more common in patients who have stents but can be prevented by the use of TMP-SMX prophylaxis.

ALLOGRAFT REJECTION

Allograft rejection can be hyperacute, acute, or chronic. HAR occurs because of preformed antibodies to the ABO and HLA antigens. The onset of HAR occurs within minutes to an hour of perfusing the allograft. The allograft shows signs of mottling, followed by vascular thrombosis, and allograft failure. Less commonly, it can manifest as primary nonfunction of the graft. The incidence of HAR has become an extremely rare event in recent years, in particular in primary transplant recipients, as a result of wide availability of sensitive techniques for detecting preformed anti-HLA antibodies and cross-match. Once established, HAR is not amenable to therapy and graft loss is the usual outcome.

Acute rejection

Acute allograft rejection can occur any time after transplantation. In the early immunosuppression era, acute rejection

occurring within the first 3 to 6 months of transplantation known as early acute rejection was a common occurrence. With the advent of potent induction and maintenance immunosuppressive medications, the incidence of early acute rejection has dropped significantly to less than 10% for those transplanted in recent years compared to 68.9% before 1990.[1] However, significant numbers of pediatric patients are experiencing acute rejection after 6 months of transplant, known as late acute rejection. Acute rejection occurring within 1 week of transplantation is known as accelerated acute rejection and has a relatively poor outcome. This also should suggest the possibility of antibody-mediated rejection (AMBR) mediated by DSA reactive with donor HLA or antibodies directed at non-HLA autoantigens on the transplant endothelium. Early diagnosis and treatment of acute rejection are most important for both short-term and long-term graft survival. The relationship between acute rejection and poor long-term graft survival has been clearly demonstrated. In children, tacrolimus-based therapy is known to be associated with fewer episodes of acute rejection when compared to CsA-based therapy.[51]

The classical clinical features of acute rejection, including fever, oliguria, hypertension, proteinuria, and graft tenderness, are rarely observed with current immunosuppression unless a patient is nonadherent with medical therapy. More commonly, children present with an increase in serum creatinine on routine blood monitoring. An increase in serum creatinine of 20% above baseline or greater than 0.3 mg/dL should raise a concern for acute rejection. The differential diagnosis of acute rejection includes dehydration, CNI toxicity, urinary obstruction, and BKV nephropathy (see Table 38.7). A definitive diagnosis of acute rejection is made by biopsy of the transplant kidney. Acute rejection can be T-cell mediated (TCMR) or ABMR or a combination. The Banff classification (Table 38.8) is most widely used for the diagnosis of acute rejection.[52] The characteristic pathologic features of TCMR are interstitial inflammation and tubulitis (Figure 38.5).

Table 38.8 Banff diagnostic criteria

	Classification	Characteristics
1	Normal histology	
2	Antibody-mediated rejection (ABMR)	Positive C4d staining and circulating donor-specific antibodies with renal dysfunction *Acute ABMR*: Three histologic variants • ATN like picture • Capillaritis (glomerulitis, neutrophils, and/or mononuclear cells (MNC) in the peritubular capillaries (PTC) • Arterial involvement (transmural inflammation and fibrinoid change) *Chronic ABMR:* Evidence of chronic tissue injury such as glomerular double contours, PTC basement membrane multilayering, IFTA, or fibrous intimal thickening in arteries
3	Borderline T-cell–mediated rejection (borderline TCMR)	• *Mild tubulitis* (1–4 MNC/tubular cross section (t1), with moderate interstitial inflammation (25%–50% parenchyma affected (i2), or severe interstitial inflammation (i3) • *Foci of moderate tubulitis* (4–10 MNC/tubular cross section (t2), or severe tubulitis (>10 MNC/tubular cross section (t3), with no/trivial interstitial inflammation (<10% parenchyma affected (i0), or minimal interstitial inflammation (<25% parenchyma affected (i1)
4	T-cell mediated rejection (TCMR)	*Acute TCMR* • *IA*: At least 25% of parenchyma showing interstitial infiltration (i2 and i3) and foci of moderate tubulitis (t2) • *IB*: Just like class IA except there is more severe tubulitis (t3) • *IIA*: Mild-to-moderate intimal arteritis (<25% of luminal area, v1) • *IIB*: Severe intimal arteritis (>25% of the luminal area, v2) • *III*: Transmural (e.g., the full vessel wall thickness) arteritis, v3 *Chronic TCMR*: Same as acute TCMR with chronic changes of IFTA
5	Interstitial fibrosis and tubular atrophy (IFTA)	*Grade I*: <25% of cortical area *Grade II*: 25%–50% of cortical area *Grade III*: 50%–75% of cortical area *Grade IV*: >75%
6	Renal damage not related to rejection	Changes related to recurrent FSGS, CNI toxicity, or recurrent glomerulonephritis

Abbreviations: ATN, acute tubular necrosis; CNI, calcineurin inhibitor; FSGS, focal segmental glomerulosclerosis; IFTA, interstitial fibrosis and tubular atrophy; MCN, mononuclear cells.
Figure 38.5 Acute renal transplant rejection. **(a)** Light microscopy photomicrograph of renal transplant biopsy showing acute cellular rejection. Extensive lymphocyte infiltration of the interstitium and tubules is seen. **(b)** Higher magnification photomicrograph showing lymphocytes infiltrating into the tubular epithelial lining (arrows).

ABMR is characterized by the presence of a combination of features that include detection of de novo DSA, presence of glomerulitis and peritubular caplilliritis, and C4d in the peritubular capillaries (Figure 38.6) and graft dysfunction. It is important to recognize that the most recent Banff recommendations do not require C4d positivity for diagnosis of ABMR. However, the diagnosis of ABMR does require the presence of DSA and evidence of inflammation in glomeruli and peritubular capillaries.[53] Borderline or grade 1A acute rejection is usually treated with IV methylprednisolone (10 to 15 mg/kg/day for 3 to 5 days). Thymoglobulin (1.5 mg/kg/day for 5 to 7 days) or alemtuzumab (0.3–0.4 mg/kg/dose, 1-2 doses) can be used for steroid-resistant acute rejection or higher grade acute rejection episodes.[54,55] A switch to tacrolimus from CsA or increasing the dose of tacrolimus also can be used to treat borderline acute rejection. Therapies including plasmapheresis, rituximab, IVIg, bortezomib, and eculizumab are currently being used for the treatment of ABMR.[56] Late acute rejection may be associated with the development of de novo DSA, nonadherence to medical therapy, and high coefficient of variation of tacrolimus levels and is less amenable to therapy.[57]

CHRONIC ALLOGRAFT FAILURE RESULTING FROM IMMUNOLOGIC CAUSES

Chronic allograft failure can occur secondary to immunologic or nonimmunologic causes and is histologically characterized by thickening and narrowing of the lumen of
Figure 38.6 Acute antibody-mediated allograft rejection. **(a)** Peritubular capillaritis showing infiltration by mononuclear cells and polymorphonuclear cells into peritubular capillaries suggestive of acute antibody-mediated rejection. **(b)** Immunoperoxidase staining showing c4d positive staining in the peritubular capillary walls. C4d is normally present in glomerular capillaries, which serve as an internal control.

the blood vessels and interstitial fibrosis and tubular atrophy (IFTA). Acute rejection including ABMR and chronic ABMR are immunologic causes of IFTA. IFTA can be mild, moderate, or severe. Transplant glomerulopathy, a form of chronic ABMR, is characterized by thickening of glomerular capillary walls and increased mesangial matrix and cellularity (Figure 38.7).[58] Both IFTA and transplant glomerulopathy have a significant negative impact on long-term allograft survival and are commonly associated with the presence of DSA. Because there are no well-established therapies for IFTA and transplant glomerulopathy, the most important strategy is to prevent it by monitoring patient adherence with medication.

INFECTIONS

Infections constitute the most common reason for hospitalization after renal transplantation.[39] Infectious complications after transplantation usually follow a predictable pattern. In the first month after transplant, infectious complications are related to technical and mechanical problems, such as wound infections, UTI, pneumonia, and fungal infections. Between 1 and 6 months post-transplant, common infectious events involve viral pathogens, such as CMV, EBV, HSV, human herpes virus (HHV), varicella zoster virus, parvovirus (PV) B19, polyoma BKV, PCP, and fungal infections. Beyond 6 months, the patterns of infections in patients on stable maintenance immunosuppression and with good allograft function are similar to those seen in the general population. Patients who develop opportunistic infections more than 6 months post-transplant are generally those who have higher serum creatinine, are receiving higher doses of maintenance steroids, or have had recurrent acute rejection episodes requiring intensification of immunosuppression.

Hepatitis B and C infections may become a clinical concern in long-term survivors of kidney transplants. This may be due to reactivation of these viruses in the recipient or occur as a result of infection acquired in the peritransplant period. Tuberculosis is a serious problem in developing countries because of the high risk for exposure and the immunosuppressed state of these patients. A number of donor-derived infections, including deaths resulting from the West Nile and rabies viruses have been reported in transplant recipients of organs from deceased donors. Proper screening of donors by sensitive assays, including nucleic acid testing, and a high index of suspicion for infections prevalent in the community and prompt treatment are necessary.

UTI in the allograft may be related to abnormal bladder function or vesicouretic reflux in the transplanted ureter. Most patients present with symptoms of fever, malaise, dysuria, and graft tenderness, and some may present with elevated creatinine. However, no difference in the long-term outcome of patients with and without pyelonephritis has been noted.

Risk factors for different HHV infections, clinical features, diagnosis, treatment, and prevention are shown in Table 38.9. Of these, CMV and BKV infections have long-term deleterious effects on the allograft. Figure 38.8 shows renal biopsy sample of a child showing viral inclusions in tubular cells suggestive of BKV nephropathy.

HYPERTENSION

Of pediatric kidney transplant recipients, 50% to 80% develop hypertension.[1] In the immediate post-transplant period, hypertension may be related to fluid overload, high-dose steroids, and acute rejection. Presence of diseased native kidneys, side effect of medications (CNI and prednisone), acute rejection, recurrent glomerulonephritis, and renal artery stenosis may be the cause of hypertension beyond the first few weeks post-transplantation. NAPRTCS data and other studies suggest that hypertension and use of antihypertensive drugs are significant risk factors for subsequent graft failure. Pediatric patients treated with antihypertensive drugs during the first month after transplantation are noted to have worse linear growth over the first two post-transplant years compared to those who do not require antihypertensive medications.[1]

Post-transplant hypertension is a major amplifier of the CKD-cardiovascular disease continuum and should be managed aggressively.[59] Hypertension is managed with a low-sodium diet and antihypertensive medications. Reduction of corticosteroid dose also may improve blood pressure control. Calcium channel blockers are particularly useful in the treatment of hypertension in the early post-transplant period because of their ability to counteract vasoconstrictive effects of CNI. However, the use of calcium channel blockers may be associated with development of significant edema.

Angiotensin-converting enzyme inhibitors (ACEIs) may be useful in the long-term management of hypertension and in prolonging the life of the allograft because of their inhibitory effect on expression of transforming growth factor-β and other growth factors, IFTA, and their ability to ameliorate proteinuria.[60] However, ACEI

Table 38.9 Post-transplant infections

Disease	Risk factors	Clinical features	Diagnosis	Treatment	Prevention
Cytomegalovirus (CMV)	D+/R– Polyclonal antibodies Induction Recurrent acute rejections	Viral syndrome Pneumonia Hepatitis Myelosuppression Colitis	q-PCR, Pp 65 Ag assay	IV GCV+/– Cytogam Valganciclovir	Valganciclovir Monitoring by PCR
HHV-6 and HHV-7	Net state of immunosuppression	Myelosuppression Hepatitis Pneumonia Encephalitis Exacerbates	q-PCR	No data	No data
HHV-8	Net state of immunosuppression	Kaposi sarcoma	q-PCR	Chemotherapy	No data
Varicella zoster virus (VZV)	Net state of immunosuppression	Disseminated zoster, pneumonia	DFA for VZV	IV acyclovir until lesions crusted	
Parvovirus B19 (PVB19)	Net state of immunosuppression	Aplastic anemia	q-PCR, PVB19 IgM, bone marrow	IVIg	No data
BK virus	Net state of immunosuppression	Graft dysfunction Hemorrhagic cystitis	q-PCR, renal biopsy, decoy cells in urine	Decrease IS Cidofovir, Lefllunomide Quinolones	Avoidance of excessive immunosuppression Monitoring by PCR
Pneumocystis jiroveci, also known as *Pneumocystis carinii* pneumonia (PCP)	Net state of immunosuppression	Interstitial pneumonitis	DFA on sputum/BAL	IV TMP-SMX	TMP-SMX Aerosolized or IV Pentamidine Dapsone Atovaquone

Abbreviations: BAL, Bronchoalveolar lavage; DFA, direct fluorescent antibody; GCV ganciclovir; IV, intravenous; IVIg, intravenous immunoglobulin G; PCR, polymerase chain reaction; q-PCR, quantitative PCR; TMP-SMX, trimethoprim-sulfamethoxazole.

drugs are difficult to use in renal transplant recipients because they may cause increases in serum creatinine and serum potassium and anemia, especially if used in the early post-transplant period. Renal artery stenosis is best treated by percutaneous transluminal angioplasty or surgical correction.[61]
Figure 38.8 Renal biopsy of a child showing BK virus nephropathy. The renal tubular cells show viral inclusions. Immunoperoxidase staining with antibodies to SV40.

HEMATOLOGIC COMPLICATIONS

Hematologic complications of transplantation include anemia, erythrocytosis, and, rarely, leukopenia and thrombocytopenia. Anemia after transplant may be related to bone marrow suppression secondary to MMF, azathioprine, sirolimus, CsA, or tacrolimus.[62] The incidence of hematologic complications is higher in patients on steroid-free protocols. Aplastic anemia can occur secondary to PVB19 and CMV infections. Hemolytic anemia may result from recurrent or acquired HUS. Hemolytic anemia can result from the administration of high-dose IVIg in patients with A, B, and AB blood groups.[63]

Erythrocytosis is sometimes seen after transplant in children. The risk factors include male gender, retention of native kidneys, smoking, renal artery stenosis, and rejection-free course.[62] Erythrocytosis can be treated with ACEIs and rarely by phlebotomy. Neutropenia and thrombocytopenia may occur after transplant as a side effect of medications, viral infections, or residual hyperparathyroidism.[62]

GROWTH RETARDATION

Although an acceleration of growth velocity is commonly seen in the majority of children following successful renal transplantation, growth retardation may continue to be a concern in some. Post-transplant growth velocity is better in children who receive transplant at young age (younger than 5 years), have good allograft function, are on minimal (prednisone dose < 0.15 mg/kg/day) or no steroids, or are on alternate-day steroids.

Children with continued post-transplant growth retardation may benefit from recombinant growth hormone therapy. Growth hormone therapy is usually not considered in the first year following transplantation, because children may demonstrate a spontaneous growth spurt. When growth hormone therapy is used, linear growth is best in the first year of therapy with a somewhat slower growth seen in the second and third years.[64,65]

Treatment with growth hormone should continue until full potential for growth is realized or puberty is reached. Treatment with growth hormone can lead to glucose intolerance, slipped capital femoral epiphysis, and intracranial hypertension. However, the incidence of these complications is not higher than in the control ESRD population.[64] An increased risk for acute rejection with growth hormone therapy in early clinical studies has not been substantiated.[64] Patients with one or more episodes of acute rejection before initiation of growth hormone therapy may be at a higher risk for acute rejection afterward. Close monitoring of renal function and acute rejection is therefore desirable. The dose of CsA or tacrolimus may need to be increased after initiation of growth hormone.[64,65]

RECURRENCES OF PRIMARY DISEASES IN ALLOGRAFTS

Several diseases that cause ESRD have potential to recur in allografts. These include FSGS, atypical HUS, MPGN, IgA nephropathy, Wegener granulomatosis, lupus nephritis, and Henoch-Schönlein purpura.[41,66]

Focal segmental glomerulosclerosis

Recurrence of FSGS is seen in 30% to 40% of those undergoing primary transplant and approximately 80% of those undergoing repeat transplants.[67] Graft failure occurs in 50% of these cases. Clinical manifestations include massive proteinuria, hypoalbuminemia, and often the full-blown picture of nephrotic syndrome. Recurrence of FSGS may happen immediately or weeks to months after transplantation. Predictors of recurrence include patients who have had a rapid progression to ESRD from the time of initial diagnosis (less than 3 years), poor response to therapy, white race, and presence of mesangial proliferation in the biopsy sample. Patients with FSGS secondary to genetic mutations have a low risk for recurrence. Live donor transplant recipients may have a higher rate of recurrence, but this is not considered a contraindication to live donor transplantation. However, if a primary transplant has been lost to FSGS recurrence, a second living donor for a repeat transplantation should be considered with great caution, careful patient and family preparation, and informed consent of the donor and the family.

A protein permeability factor has been isolated in the sera of patients with FSGS and is reported to predict recurrence and the severity of FSGS in the transplant. The precise nature of this factor has not been identified. Several therapeutic interventions have been suggested in small single-center trials and anecdotal reports. These include plasmapheresis, high-dose CsA, pulse methylprednisolone, immunoadsorption with protein-A columns, cyclophosphamide, and rituximab. Although intensive plasmapheresis treatment for the first 6 to 8 weeks is generally considered, an occasional patient has been treated with long-term plasmapheresis.[67] Galactose was able to reduce the plasma permeability factor but did not induce complete or partial remission in two children with post-transplant recurrent FSGS.[68] Recently, treatment with abatacept (a costimulatory inhibitor targeted at B7-1) was noted to be useful in four patients with recurrent FSGS and B7-1 expression on the podocytes.[69]

Hemolytic-uremic syndrome

Atypical HUS usually recurs in the allograft, resulting in graft failure. Shiga-toxin–associated HUS without underlying complement abnormalities does not recur. Plasmapheresis and eculizumab have been used successfully to treat atypical HUS recurring after transplant, the latter being more successful. Ideally, eculizumab should be used prophylactically to prevent recurrence.[29]

Recurrent, as well as de novo, HUS in renal transplants has been linked to the use of CsA and tacrolimus.[70] Recurrence of HUS may be present without evidence of hemolysis or thrombocytopenia in more than half of the cases. Typically, recurrent HUS manifests shortly after starting treatment with CsA or tacrolimus, with features of declining urine output, increasing serum creatinine level, and hematuria or proteinuria. A renal biopsy establishes the diagnosis. Discontinuation of CNI and plasmapheresis may help salvage some grafts. However, overall prognosis remains poor. Substitution of CSA for tacrolimus (or vice versa) has been recommended by some. Successful use of sirolimus in this situation also has been reported. De novo transplant micoangiopathy may manifest in a similar manner, but is usually a manifestation of ABMR.

Membranoproliferative glomerulonephritis

MPGN, especially type II, has the potential to recur in transplants.[66] MPGN type I has recurrence rate of 30% to 40%, whereas MPGN type II may recur in 90% of allografts and may be caused by uncontrolled stimulation of complement cascade. These patients are usually asymptomatic and may show some proteinuria and hematuria. Usually,

recurrence leads to slow deterioration of allograft function. Plasmapheresis, high-dose steroids, rituximab, and eculizumab may be useful in salvaging graft function in patients with rapid deterioration.

Recurrent IgA nephropathy, lupus nephritis, and Wegener granulomatosis usually do not cause allograft failure.

De novo glomerulonephritis

De novo glomerulonephritis, including membranous glomerulonephritis, IgA nephropathy, FSGS, collapsing glomerulopathy, steroid-resistant nephrotic syndrome in patients with Finnish type congenital nephrotic syndrome, and anti-GBM disease in patients with Alport syndrome can be seen after renal transplantation.[71–73]

Post-transplant recurrence of nephrotic syndrome occurs in approximately 25% children with Finnish type congenital nephrotic syndrome secondary to *NPHS1* gene mutations.[74] Manifestation with proteinuria, hypoalbuminemia, and edema may start immediately or as late as 3 years post-transplant. Precedent infection with CMV or EBV may be seen in some.

The histologic lesion is often minimal-change disease, and glomerular endothelial cell swelling has been noted in some. Response to steroids and cyclophosphamide is poor, and graft loss occurs in more than 50% of cases. Antinephrin antibodies have been shown to play a role in the recurrence of nephrotic syndrome.[73] Plasma exchange in combination with cyclophosphamide or rituximab may be useful.

Anti-GBM disease can occur in approximately 5% of patients with Alport syndrome who demonstrate complete absence of the α-3, -4 or -5 portion of type IV collagen in the basement membrane. Crescentic glomerulonephritis with linear IgG deposits in the GBM may occur and lead to rapid graft loss.[73]

SIDE EFFECTS OF PHARMACOTHERAPY

Immunosuppressive medications have significant side effects, which are listed in Table 38.4. Tacrolimus and cyclosporine (CNIs) are nephrotoxic medications and can cause acute increase in creatinine. Renal biopsy showing isometric vacuoles in the tubules (Figure 38.9) is diagnostic of CNI toxicity. Side effects and toxicities of therapies can become an important concern in transplant patients. This may lead to nonadherence and delayed episodes of acute rejection, particularly in the teenagers.

METABOLIC COMPLICATIONS

A number of metabolic complications can be seen in children following renal transplantation. These include hypomagnesemia, hypophosphatemia, hypercalcemia, hyperkalemia, renal tubular acidosis, bone and mineral disorders, and dyslipidemia. Hypomagnesemia commonly
Figure 38.9 Calcineurin inhibitor (CNI)-induced acute tubulopathy. Proximal renal tubules showing isometric vacuoles that are characteristic of CNI toxicity. The vacuoles are small and evenly distributed throughout the cytoplasm of the affected tubular cells.

occurs from renal tubular magnesium wasting as a result of the use of CsA, tacrolimus, or diuretics.[41] Oral replacement with magnesium oxide is needed to control hypomagnesemia. Hypomagnesemia has been noted to be a risk factor for new onset of diabetes after renal transplantation (NODAT). Hyperkalemia and renal tubular acidosis may be a manifestation of CNI toxicity, acute rejection urinary obstruction, or use of ACEIs. Isolated hyperkalemia may be associated with TMP-SMX therapy.[41]

Bone and mineral disorders

The pathogenesis of post-transplantation bone disease is multifactorial and includes the persistent manifestations of pretransplantation CKD mineral and bone disorder, peritransplantation changes in the fibroblast growth factor 23 (FGF23)–parathyroid hormone–vitamin D axis, metabolic perturbations such as persistent hypophosphatemia, hypomagnesemia, hypercalcemia, and the effects of immunosuppressive therapies.[75] Vitamin D deficiency is prevalent in children after renal transplantation. Hypophosphatemia resulting from residual hyperparathyroidism and increased FGF23 is commonly seen following renal transplantation. Hyperparathyroidism resolves slowly post-transplant and may require therapy with cinacalcet (Sensipar). In rare cases, parathyroidectomy may be needed.

Hypophosphatemia may persist long term in approximately 25% of patients even after a successful transplant, the pathogenesis of which is not well understood.[75] Post-transplant fractures occur more commonly at peripheral

sites than at central sites. Although there is significant loss of bone density after transplantation, the evidence linking post-transplantation bone loss and subsequent fracture risk is circumstantial. Presently, there is no optimal therapy for post-transplant bone disease. Combined pharmacologic therapy that targets multiple components of the disordered pathways has been used. Although bisphosphonate or 1,25 dihydroxyvitamin D therapy can preserve bone mineral density after transplantation, there is no evidence that these agents decrease fracture risk. Bisphosphonates pose potential risks for adynamic bone disease.[76]

Dyslipidemia

A number of lipid abnormalities are being recognized in children after transplant that include elevated blood levels of total cholesterol, low-density lipoprotein cholesterol, very-low-density lipoprotein cholesterol, and triglycerides and decrease in levels of high-density lipoprotein cholesterol. Theses lipid abnormalities may be seen in as many as 50% of children.[77] The contributing factors include use of steroids, CsA, tacrolimus, sirolimus, excessive weight gain, and insulin-dependent diabetes mellitus (IDDM). Dyslipidemia is an important contributor to cardiovascular morbidity and mortality and may contribute to functional deterioration of the graft in the adult population. There is a paucity of data on adverse effects of dyslipidemia and their management in children.[77]

Obesity

Excessive weight gain and its consequences are important considerations in transplant recipients. The factors responsible for obesity in the general population combined with the use of steroids may play a part. Excessive weight gain may be responsible for sleep apnea, nocturnal enuresis, hypertension, dyslipidemia, and glucose intolerance.[41] NAPRTCS data have shown an increasing prevalence of obesity in pediatric transplant recipients. Obese children between the ages of 6 and 12 years in this study were at higher risk for death compared to nonobese patients, and death was more likely due to cardiopulmonary disease.[78] Early and intense nutritional counseling should be undertaken to prevent this serious complication.

Diabetes mellitus

Approximately 5% of children develop NODAT after transplantation. The risk is somewhat higher with the use of tacrolimus compared to CsA; both of these medications are toxic to islet cells. Other contributing factors may be the repeated use of pulse steroid therapy, family history of diabetes, excessive weight gain, and hypomagnesemia. Steroids cause insulin resistance. Rigorous management of NODAT is essential for long-term patient and graft survival.[41]

CHRONIC ALLOGRAFT DYSFUNCTION

Chronic allograft dysfunction histologically characterized by IFTA, ultimately leads to allograft failure and the return of patients to dialysis.[79] Both immune and nonimmune factors contribute to IFTA. The immune-mediated factors were mentioned earlier, and nonimmune factors include DGF, chronic nephrotoxicity related to CsA or tacrolimus, hypertension, hyperglycemia, hyperlipidemia, donor and recipient size mismatch, recipient weight, donor age, CMV and BKV infections, and recurrent and de novo glomerular lesions.

MALIGNANCY

The risk for malignancy is increased with the intensity and duration of immunosuppression. Malignancies are uncommon in the pediatric age group, but may become a problem as survival of these children increases with successful transplantation. The most important malignancy observed in children is PTLD.

PTLD includes a spectrum of conditions that range between infectious mononucleosis and malignant neoplasia. A large body of literature exists demonstrating the pivotal role of EBV in most cases of PTLD in pediatric solid organ transplant recipients; approximately 85% to 90% of cases of PTLD are EBV driven.

Most cases of PTLD occur in children who are seronegative for EBV at the time of transplantation.[80,81] Primary EBV infection after transplantation can potentially come from several sources, including donor organ, perioperative use of blood products, and subsequent community acquisition of the virus. Its incidence varies from 1% to 10% (usually close to 1%) in most series. The risk for PTLD is bimodal, being highest in the first year post-transplantation and increases again after 7 years of transplantation. However, patients remain at risk indefinitely. The spectrum of clinical features include nonspecific viral syndrome, weight loss, sore throat, abdominal pain, lymphadenopathy, tonsillar enlargement, hepatosplenomegaly, focal neurologic signs, and allograft dysfunction (Figures 38.10 and 38.11).

Diagnostic evaluation of patients with suspected PTLD and management is outlined in Tables 38.10 and 38.11. Strategies to prevent PTLD include close monitoring for EBV replication by PCR and appropriate adjustment of immunosuppressive therapies. The role of antiviral agents and IVIg infusions in preventing PTLD in children with high viral load needs formal clinical trials. Treatment of PTLD includes reducing immunosuppression and use of rituximab in the early stages, and rituximab in combination of chemotherapy may be used in late stages of PTLD.[81] Surgical resection and radiation therapy may be needed in localized cases.
Figure 38.10 Chronic calcineurin inhibitor (CNI) nephrotoxicity. Renal biopsy shows strip fibrosis of the renal interstitium, with normal-appearing tubules between areas of interstitial fibrosis.

Table 38.10 Diagnostic evaluation of patient with suspected post-transplant lymphoproliferative disorder

1. Complete blood count with differential
2. Serum electrolytes, blood urea nitrogen, creatinine, liver function tests, lactate dehydrogenase, uric acid, serum immunoglobulins
3. Chest radiograph, computed tomography (CT) scan of chest, abdomen, and pelvis
4. Stool for occult blood
5. Biopsy of the lymph nodes and or allograft with immunophenotyping of the cells by immunohistochemistry and flow cytometry, molecular studies for clonality, Epstein-Barr virus (EBV) demonstration in the biopsy tissue by in situ hybridization
6. EBV viral load in blood by quantitative polymerase chain reaction
7. Other investigations: Bone scan; bone marrow aspirate; brain CT, magnetic resonance imaging, positron-emission tomography scan; lumbar puncture; gastrointestinal endoscopies, as indicated

Table 38.11 Therapeutic approach to a patient with post-transplant lymphoproliferative disorder

1. Reduction of immunosuppression: Useful in early and polymorphic post-transplant lymphoproliferative disorder (PTLD)
2. Antiviral therapy with valganciclovir: Unproved benefit but widely used
3. Cytomegalovirus immunoglobulin G
4. Anti–B-cell antibodies such as rituximab, useful in polymorphic PTLD persisting after reduction of immunosuppression
5. Interferon-alpha: May cause severe rejection and usually not recommended
6. Chemotherapy in combination with rituximab: Burkitt lymphoma, refractory PTLD, monomorphic PTLD, and late-onset disease
7. Surgery ± radiation: Reserved for bowel obstruction, localized lesions, or those compressing critical structures
8. Experimental therapies: Autologous or human leukocyte antigen matched Epstein-Barr virus–specific cytotoxic T-cell infusions
Figure 38.11 Positron-emission tomography scan of a child with post-transplant lymphoproliferative disorder. The patient presented with abdominal pain, and a mass was detected in the para-aortic area of the abdomen. This scan shows positive pickup by the tumor mass as well as lymph nodes of the mediastinum and cervical region. Kidney transplant is also visualized.

NONADHERANCE IN TRANSPLANTATION

Nonadherence to the medical regimen is widely prevalent in children. Nonadherence is seen in approximately half of the recipients of deceased organs, and its prevalence increases in adolescents. It may be responsible for 25% of graft loss in children. It may vary from occasional nonadherence to complete nonadherence. Occasional nonadherence could be secondary to forgetfulness, misunderstanding of instructions, or change in routine. Measuring nonadherence is difficult and cumbersome. Often, patients and families would not admit to nonadherence, and, if they do, the extent is usually understated. Manual or electronic pill counting or assessment of refills may be helpful in determining nonadherence but is labor intensive.

Increased coefficience of variation of tacrolimus levels and de novo development of DSA have been suggested as objective markers of nonadherence.[57] Risk factors include disorganized family structure, adolescence, and history of previous graft loss as a result of nonadherence. Parents and children should be reminded to pay special attention while traveling, around vacation times, and when children first leave home to be independent. Counseling, continuing education, planning medication timings, using a pillbox, automated reminders using cellphone alarms and text messaging, involving children and their caretakers in decision-making processes and frequent clinic visits are some of the strategies to improve adherence to medications.[11,83,84] In addition, there are several online tools available to children and adolescents to help increase adherence to medications.

TRANSITION OF CARE

A systematic transition of children to adult care is paramount to success of the allograft, because a chaotic transition may lead to allograft failure.[84] A systematic analysis of the adolescent readiness skills including psychosocial evaluation, financial planning, health knowledge, and self-management skills should be undertaken and a close communication with the adult providers should be maintained until smooth transition occurs.

SUMMARY

Renal transplantation is a most rewarding endeavor because it transforms the lives of chronically ill children to near normal in a matter of weeks to months, with an improvement in their growth, neurodevelopment, and quality of life. Short-term graft survival has improved significantly in young children.[85] However,

it remains poor in adolescents.[13,85] This is likely due to a large degree of nonadherence. Meticulous attention to the proper management of immunosuppressive medications, infections, and CKD-related complications is needed to improve long-term patient and graft survival (Table 38.12). The benefits of transplantation come at a price of life-long treatment with immunosuppressive medications with concomitant side effects. The ongoing challenges include prevention and treatment of late acute rejection, de novo DSA, finding reliable noninvasive immune-monitoring tools, successful transplantation of highly sensitized patients and those with recurrent FSGS, decreasing the cardiovascular morbidity and mortality and improving bone-mineral disorders in the long-term survivors, dealing with the organ shortage, improving adherence particularly in adolescents, psychosocial rehabilitation of the children and their families, and, finally, the elusive goal of tolerance.

Table 38.12 Principles of long-term management of kidney transplant patients

- Minimize immunosuppression without causing acute rejection
- Diagnose and treat late acute rejection promptly
- Screen for de novo donor-specific antibodies development
- Diagnose and improve nonadherence
- Optimize blood pressure control
- Screen and treat dyslipidemia
- Screen and treat albuminuria
- Screen and treat anemia
- Screen and treat new onset of diabetes after renal transplantation
- Maintain optimal weight, growth, and nutrition
- Optimize cardiovascular outcome
- Optimize bone and mineral health
- Maintain age-appropriate immunizations for child and family, including special immunizations recommended for immunosuppressed children
- Screen for infections and malignancy
- Screen for psychological disorders and provide appropriate timely help
- Optimize child's and family's quality of life
- Planned transition of care

Clinical Vignette 38.1

A 13-year-old African-American boy with ESRD secondary to posterior urethral valves who had been on chronic hemodialysis for 6 months was referred for renal transplantation. He underwent valve fulguration

in the neonatal period. There was no history of any other surgeries or blood transfusions. There was no history of other comorbidities. He was one of eight siblings, four of them above 18 years of age. His parents were in mid-40s and were otherwise healthy. His weight and height were at 10th percentile and blood pressure was normal. Immunizations were up to date, he was immune to varicella and hepatitis B. His blood group was A+ and CPRA was 0%. He tested negative for antibodies to human HIV and hepatitis C and was seropositive for CMV and EBV.

He had a daily urine output of approximately 1.5 L while on hemodialysis. Urodynamic study before transplantation indicated adequate bladder capacity and no significant postvoid residual. The family was educated about merits of living-related transplant and the role of adherence in the transplant survival. After completing workup and receiving additional vaccines with Pneumovax-23, meningitis, and HPV and undergoing dental and cardiac evaluation, he was placed on the deceased donor list.

None of the family members volunteered to donate a kidney for him, and he received a kidney from a 20-year-old donor who had died in a motor vehicle accident. The donor's terminal creatinine was 0.9 mg/dL. The recipient was 1B and 1DR matched (four-antigen mismatched) with the donor. Flow cross-match was negative. Both recipient and donor were positive for antibodies to CMV and EBV. The cold ischemia time was 12 hours and warm ischemia time was 30 minutes. The donor kidney had three arteries (two were on the Carroll patch and one was found to be separate), two veins, and a single ureter.

Intraoperatively, the child received a single dose of anti-IL2R antibody (daclizumab, 1 mg/kg) and 10 mg/kg IV methylprednisolone. Post-operatively, he continued to make urine but had a relatively slow drop in creatinine. However, he did not require dialysis postoperatively. An ultrasound of the transplant kidney showed ischemia of the lower third of the allograft, corresponding to the blood supply of the lower pole artery.

Because of slow recovery of graft function, and ischemia of the transplant, his induction therapy was changed to Thymoglobulin for 5 days. His creatinine came down from 11.0 mg/dL before transplant to 1.8 mg/dL over a period of 5 days. Tacrolimus and MMF were started on postoperative day 4 and continued as maintenance immunosuppression along with tapering doses of prednisone. He was discharged home on the 7th day with a serum creatinine of 1.6 mg/dL that came down to 1.3 mg/dL over the next month. He received antifungal prophylaxis with nystatin for 8 weeks and CMV prophylaxis with valganciclovir and TMP-SMX prophylaxis for PCP and UTI for 6 months post-transplant. On routine follow-up visits, he was noted to have stable graft function (serum creatinine ranging from 1.3 to 1.5 mg/dL, normal blood pressure, low-grade proteinuria (2+ protein on dipstick and random urine protein-to-creatinine ratio of 0.5), and therapeutic tacrolimus levels.

At 11 months post-transplantation, he came to the emergency department with abdominal pain, mostly on the right side (over his transplant kidney). He denied any history of fever, dysuria, nausea, or vomiting and missing any medications. He was noted to have stable vital signs; he was afebrile. There were no clinical signs of dehydration, and his blood pressure was elevated at 135/85 mm Hg. Laboratory testing showed the serum creatinine to be markedly elevated at 9.8 mg/dL; the electrolytes were normal, although the serum bicarbonate level was low at 14 (normal anion gap metabolic acidosis). The tacrolimus level was undetectable. Ultrasound of the transplant kidney showed a slight increase in the kidney size from baseline ultrasound obtained in the immediate post-transplant period, the resistive index was increased to 0.85, and there was no evidence of hydronephrosis. He was suspected to have acute rejection, which was confirmed by renal biopsy to be Banff grade 1B. There was no evidence of glomerulitis or peritubular capillaritis. The biopsy was negative for C4d by immunofluorescence assay. In addition, there was mild IFTA. A biopsy sample was negative for BKV by immunoperoxidase stain. Plasma viral load for BKV, EBV, and CMV by quantitative PCR was negative. DSAs were detected against DR53 and DQ8 antigens with peak MFI of 5000 and 8000, respectively; C1Q binding was negative for these antibodies.

He was treated with IV methylprednisolone (10 mg/kg/day) for 3 days, followed by 7 days of Thymoglobulin for steroid-resistant acute rejection. In addition, he was treated with two doses of IVIg (2 g/kg/dose), given 4 weeks apart, and one dose of rituximab (750 mg/m^2) given after 2 weeks of first dose of IVIG. He also was given fungal prophylaxis with nystatin for 8 weeks and TMP-SMX and valganciclovir for 6 months for PCP and CMV prophylaxis, respectively. His creatinine came down to 2.5 mg/dL at the end of therapy. There was improvement in DSA titers when checked 4 weeks after completion of therapy.

The patient admitted to missing his medications, because his mom was not supervising him anymore. He and his family were counseled extensively, and he was closely monitored in the transplant clinic, seen every 2 to 4 weeks. He had two more episodes of acute allograft rejection at 4 and 8 months later. He responded partially to pulse methylprednisolone. His subsequent biopsy results showed progressively increasing IFTA in addition to acute rejection, and he returned to hemodialysis 25 months after transplant. He underwent transplant nephrectomy for intractable pain over the graft and hematuria. He became highly sensitized with CPRA of 100% and broad sensitizations against multiple class I and II antigens and has been on hemodialysis for 5 years.

TEACHING POINTS

- The patient described in this case highlights several key issues related to pediatric transplantation.
- The patient had no comorbidities and had a panel reactive antibody level of 0%, which is typical of most children with ESRD.
- His late acute rejection episodes after transplant highlight the impact of poor transplant medication adherence on long-term transplant outcome.
- Late acute rejections resulting from nonadherence are highly prevalent in the adolescent population and lead to development of de novo DSA and graft loss as seen in this child. Moreover, there are no clear predictors of poor post-transplant adherence in the pretransplant state, as demonstrated by this case. A highly sensitized state, as seen in this child can, unfortunately be the outcome of a failed transplant state.
- Ischemia of the lower third of the allograft in this patient resulted from thrombosis of the inferior pole artery and he suffered graft injury from it.
- Arterial thrombosis can be a significant surgical concern in children, especially with multiple renal arteries.

REVIEW QUESTIONS

1. A 5-year-old previously healthy child developed acute kidney injury as a result of septic shock. He received continuous renal replacement therapy for 1 month and then transitioned to peritoneal dialysis as his kidneys failed to recover. He received a number of blood transfusions during his stay in the ICU. His parents ask about the option of kidney transplant. He has otherwise completely recovered and weighs 15 kg. He is CMV IgG positive and EBV IgG negative. The *most* important challenge posed for kidney transplant in this child is:
   a. Size of 15 kg
   b. Potential for sensitization because of number of blood transfusions
   c. EBV negative status
   d. CMV positive status

2. A 10-year-old with ESRD secondary to FSGS underwent living kidney transplant from a family friend. The kidney worked immediately with good urine output and decrease in creatinine. At 36 hours later, he developed severe oliguria and creatinine started to increase. The next step in workup of graft dysfunction includes which of the following?
   a. Urinalysis and urine for ratio of protein to creatinine
   b. Renal ultrasound with Doppler
   c. MAG-3 renal scan
   d. VCUG

3. A 15-year-old girl underwent kidney transplant 4 years ago for ESRD secondary to renal dysplasia with stable serum creatinine level of 0.6 mg/dL. For the past year, she often missed clinic appointments, and her tacrolimus trough levels are quite variable, including some undetectable levels. She has come to the clinic after 8 months and after repeated reminders. On questioning, she denies missing any medications. During clinic visit, she is asymptomatic but her serum creatinine level is 1.1 mg/dL and her tacrolimus level is therapeutic. You plan for renal biopsy. The *most* likely finding on biopsy would be:
   a. Acute rejection
   b. Tacrolimus toxicity
   c. BKV nephropathy
   d. Urinary tract infection

4. A 9-year-old with ESRD secondary to PUV presents for kidney transplant. He has daytime increased frequency and nighttime incontinence. VCUG shows a small-capacity trabeculated bladder. The next step in preparation of this child for transplant includes:
   a. Ultrasound and urinalysis and urine culture
   b. Urodynamic studies, bladder augmentation, and use of a Mitrofanoff procedure for catheterization before transplant
   c. Bladder augmentation and use of a Mitrofanoff procedure for catheterization after transplant
   d. No special preparation needed, because bladder would enlarge after transplant

5. A 6-year-old girl with blood group A+ with ESRD secondary to renal dysplasia, CPRA of 40% is being worked up for living-related transplant. She has four potential donors. Which one is the *best* donor for this child?
   a. A 30-year-old mom with blood group O+, flow cross-match is negative, and there are no donor specific antibodies.
   b. A 32-year-old dad with blood group A+, child has moderately strong donor-specific antibody to DR53, flow B-cell cross-match is positive, and CDC cross-match is negative.
   c. A 22-year-old unrelated six-antigen mismatched donor with blood group O+, flow cross-match negative, and there are no donor-specific antibodies.
   d. A 3-year-old brother with five-antigen mismatch, blood group O+, flow cross-match is negative, and there are no donor-specific antibodies.

6. A 16-year-old girl who received a kidney renal transplant approximately 4 months ago was doing well, with a baseline creatinine level of 0.7 mg/dL. She was on tacrolimus 1 mg capsule (4 mg PO BID) and mycophenolate mofetil (CellCept) 500 mg PO BID. You receive a call from her mother stating that she has been accidentally taking 4 (5 mg) capsules of tacrolimus for the past 2 days. When seen in the emergency room, you expect to see:
   a. Hypertension, tremors, and headache
   b. Increase in creatinine, high serum potassium, low CO_2 and magnesium, and high tacrolimus level in blood
   c. A and B
   d. Stable creatinine, normal serum K and CO_2, and high magnesium and tacrolimus level

7. A 12-year-old kidney transplant recipient presents to the clinic with unexplained weight loss and intermittent vague abdominal pain for the past 2 to 3 months. He had ESRD secondary to nephronophthisis and received a kidney transplant 8 years ago from a deceased donor. He has been stable until recently and has not had any acute rejections. He has no fever and denies any other symptoms. His physical examination is normal, except for weight loss of 6 kg. His BP is normal and his creatinine is at its baseline of 0.6 mg/dL and urinalysis is normal. You would like to start the workup of his weight loss, and the tests that would be *most* useful are:
   a. CMV and BKV viral loads
   b. Interferon-γ release assay for tuberculosis
   c. LDH, uric acid, EBV viral load

d.   CT scan of abdomen, chest, and pelvis
e.   Hemoglobin A$_{1c}$

8.   A 9-year-old child transplanted with his father's kidney 9 days ago is seen for post-transplant follow-up in the clinic. You notice that he has a swelling near the allograft and in the suprapubic area, which is mildly tender to touch. He had ESRD secondary to renal dysplasia, his Foley catheter was removed on postoperative day 5, and he was discharged home on postoperative day 6 with a serum creatinine of 0.7 mg/dL. His serum creatinine today is 1.3 mg/dL. Renal ultrasound with Doppler shows good perfusion and normal renal transplant morphology and resistive index. An anechoic fluid collection is present next to his transplant and in the pelvis, which was not present 4 days ago. Which tests would help in determining the cause of acute renal dysfunction in this child?

a.   Renal biopsy
b.   Pharmacokinetics of tacrolimus
c.   MAG-3 renal scan and VCUG
d.   Needle aspiration of fluid and measurement of creatinine in this fluid
e.   c and d

9.   A 4-year-old child who received a CMV mismatched kidney transplant comes to clinic 3 months after transplant with a history of low-grade fever for 2 days. He had received induction with Thymoglobulin for 4 days and is on steroid withdrawal protocol. His CBC shows a white cell count of 1.5 K and a platelet count of 120 K, decreased from 4.2 K and 240 K, respectively, 1 week ago. His creatinine has increased by 0.2 mg/dL from the baseline. You make a diagnosis of CMV infection based on elevated CMV viral load. The next *best* step in management of this child is:

a.   Decrease MMF and continue the remainder of management because he is already receiving valganciclovir.
b.   Admit for intravenous ganciclovir and monitor renal function and CMV viral load.
c.   Perform renal biopsy to rule out acute rejection before starting any therapy.
d.   Suspect resistant CMV infection and discontinue all immunosuppression.

10.   The impact of delayed graft function on the outcome of kidney transplants is:

a.   It would increase the risk for acute rejection.
b.   It has a negative impact on long-term graft survival.
c.   You need to increase the intensity of immunosuppression.
d.   a, b, and c
e.   It does not increase acute rejection or have an impact on graft survival.

ANSWER KEY

1.   b
2.   a
3.   a
4.   b
5.   a
6.   c
7.   d
8.   e
9.   b
10.   d

Hypertension

Hypertension in children and adolescents

KAREN MCNIECE REDWINE

Hypertension has become an epidemic among adult populations. Worldwide, uncontrolled hypertension is the number one attributable cause of death,[1] and it is the leading disease burden.[2] In fact, hypertension contributes to almost three times the attributable risk for cardiovascular mortality as all other risk factors combined, including smoking, abnormal glucose, and poor diet quality (approximately 41% versus less than 14%).[3] Only in the last few decades, however, has the impact of hypertension in children been recognized. The precursors for adult cardiovascular disease clearly begin in childhood. Blood pressure (BP) tracks from childhood into adulthood.[4,5] In addition, traditional adult cardiovascular risk factors such as elevated BP, increased body mass index (BMI), and dyslipidemia have been associated with atherosclerotic changes in children as young as 2 years old.[6,7] Thus, hypertension should no longer be considered an adult disease. This chapter provides an overview of the epidemiology, pathophysiology, etiology, detection, and diagnostic evaluation of hypertension in children. Therapy of pediatric hypertension is discussed in Chapter 40.

EPIDEMIOLOGY

The prevalence of hypertension increases with age. Although hypertension was originally reported to be rare during the first 2 decades of life (less than 1%),[8] more recent data suggest that between 3.2% and 5.1%

of children and adolescents have hypertension.[9–15] Therefore, it is one of the most prevalent chronic diseases of childhood.[16] In addition, 15% of adolescents have prehypertension.[9,13] This increase in pediatric hypertension has been attributed in part to a rising rate of obesity observed since the 1990s. Both hypertension and prehypertension increase as BMI increases, and up to 30% of overweight adolescents have a diagnosable BP disorder (Figure 39.1).[13] Along with this increasing rate of obesity has come a shift in prevailing hypertensive diagnoses from those associated with secondary causes to essential hypertension, especially among adolescents.

KEY POINT

Although secondary hypertension is more common in children than adults, obesity-related "essential" hypertension has become the most common form of pediatric hypertension.

DEFINITION OF HYPERTENSION

BP values used to define hypertension in adults are derived from numerous studies associating BP level with cardiovascular sequelae.[17] Similar studies have not been performed in children because it takes decades for these events to occur. Consequently, abnormal BP values in children are based on
Figure 39.1 Prevalence of hypertension and prehypertension by body mass index (BMI) percentile after three measurements in 6790 adolescents in Houston, Texas. (Adapted from McNiece KL, Poffenbarger TS, Turner JL, et al. Prevalence of hypertension and pre-hypertension among adolescents. J Pediatr. 2007;150:640–4, 4e1.)

normative percentiles generated from pooled data of multiple large cross-sectional studies of "healthy" populations.[18] Normative values of BP in children are based on gender, height, and age because all three have been shown to affect developmental changes in BP independently (Tables 39.1 and 39.2).

BP values lower than the 90th percentile are considered normal. Children with either systolic or diastolic BP between the 90th and 95th percentiles have prehypertension. However, adolescents with BP higher than 120/80 mm Hg and lower than the 95th percentile should also be considered prehypertensive, regardless of the 90th percentile. Recognizing prehypertension is important, to intervene early with nonpharmacologic measures to prevent the development of persistent hypertension.

Children with systolic or diastolic BP persistently higher than the 95th percentile have hypertension. It is currently recommended that hypertension in children be staged to assess the need for more immediate evaluation and treatment. Patients with BP values between the 95th and 99th percentiles plus 5 mm Hg have stage 1 hypertension. BP greater than the 99th percentile plus 5 mm Hg represents stage 2 hypertension and warrants more rapid intervention (Table 39.3). Unless

KEY POINTS

- BP readings between the 90th and 95th percentiles are designated as prehypertension.
- Hypertension in children is defined as having a blood pressure greater than the 95th percentile for gender, height, and age on three separate occasions.

a patient has severe or symptomatic hypertension, elevated values must be confirmed on at least three occasions to reduce the statistical bias associated with the current classification system.

Occasionally, patients have consistently elevated BP readings (greater than the 95th percentile) in the physician's office, but BP is normal (less than the 90th percentile) at home. Termed "white coat hypertension," this phenomenon is best diagnosed with 24-h ambulatory BP monitoring. Although the significance of white coat hypertension in children has yet to be determined, this may not be an entirely benign condition and represents an intermediate pathophysiologic state between normal BP and hypertension.[19] Ambulatory BP monitoring may also be useful for identifying several other BP abnormalities, including masked hypertension, nocturnal hypertension, and decreased diurnal variation. However, because of the specialized equipment required and complexities of this procedure in children, ambulatory monitoring should be performed only by physicians who have experience with its use and interpretation.[18]

PATHOPHYSIOLOGY

It is helpful to consider the two main determinants of BP, cardiac output and peripheral vascular resistance, when discussing the pathophysiology of hypertension (Table 39.4). Clinical disorders that increase either determinant raise BP. Although both cardiac output and peripheral vascular resistance can increase independently through various mechanisms, they also have a dependent relationship. For example, if the initiating hypertensive event is caused by a rise in cardiac output, a compensatory rise in peripheral vascular resistance develops over time. Even if the inciting event resolves and cardiac output returns to normal, BP may remain elevated in response to the ongoing elevated peripheral vascular resistance

KEY POINT

Blood pressure is determined by the product of cardiac output and peripheral vascular resistance. An increase in either leads to hypertension.

Cardiac output is a product of stroke volume and heart rate. Most mechanisms of persistent hypertension are predominantly associated with an increased stroke volume and only slight increases in heart rate. Despite this observation, elevated heart rate has important prognostic significance for cardiovascular disease.[20] Increased stroke volume is usually caused by increased intravascular volume. This may occur with either excessive fluid retention or shifting of fluid from the extravascular space to the intravascular space.[21,22]

Table 39.1 Blood pressure levels for boys by age and height percentile

Age (yr)	BP Percentile	Systolic BP (mm Hg) Percentile of height							Diastolic BP (mm Hg) Percentile of height						
		5th	10th	25th	50th	75th	90th	95th	5th	10th	25th	50th	75th	90th	95th

Sodium retention from excess intake or increased renal tubular reabsorption is a major contributor to increased intravascular fluid. Activation of the renin-angiotensin-aldosterone system (Figure 39.2) and hyperinsulinemia both contribute to the development of hypertension through this pathway.[23,24] Cardiac output also increases with increased sympathetic tone, which directly increases cardiac contractility and heart rate and stimulates renin release to expand intravascular volume further.

Changes in peripheral vascular resistance can occur with either functional or structural abnormalities. Increased angiotensin II, elevated sympathetic activity, increased endothelins (e.g., prostaglandin H_2 [PGH_2]), decreased endothelial relaxation factors (e.g., nitric oxide), and genetic abnormalities in vascular cell receptors are all associated with increased vascular smooth muscle contractility and thus raise peripheral vascular resistance.[25] Investigators have also suggested that uric acid, which is known to be elevated in some hypertensive children, may play a role in the pathogenesis of the renal arteriolar changes seen in essential hypertension.[26-28] These changes in vascular compliance are frequently associated with inflammation, and collectively they lead to endothelial dysfunction and vascular remodeling. Although this process may be reversible in some patients,[29] over time it typically progresses to intimal fibrosis and atherosclerosis, which is more likely to be permanent. The complexities by which these multiple factors interact to lead to long-standing hypertension remain elusive, particularly with respect to the development of essential hypertension.

Table 39.3 Classification of blood pressure in children with therapy recommendations

BP classification	BP compared with 2004 Working Group normative values (percentile for age, gender, and height)	Treatment recommendations
Normal BP	<90th	Encouragement of healthy diet, sleep, and physical activity
Prehypertension	90th to <95th or if BP ≥120/80 mmHg even if <90th	Weight management counseling if overweight; introduction of physical activity and diet management; initiation of pharmaceutical therapy if compelling indications* exist
Stage 1 hypertension	95th to 99th + 5 mm Hg (on ≥3 separate occasions)	Weight management counseling if overweight; introduction of physical activity and diet management; initiation of pharmaceutical therapy if lifestyle modifications fail or compelling indications* exist

TECHNIQUE OF MEASURING BLOOD PRESSURE

Using proper BP measurement technique is essential when diagnosing hypertension. Incorrect technique can lead to either an erroneous diagnosis of hypertension or failure to identify a child with hypertension. Casual BP measurements should be obtained with the patient in a comfortable seated position, back supported, and feet firmly on the floor after at least 5 min of rest.[30,31] Alternatively, for infants and young children, BP may be measured with the patient supported in a caregiver's lap or lying down.[32] Readings should always be taken in the upper arm with the arm resting at heart level, the method used for generating current normative data. Readings obtained in a leg may be 10 to 20 mm Hg higher than arm pressures. Thus, hypertension should never be diagnosed based on elevated leg pressures, unless there are extenuating circumstances.

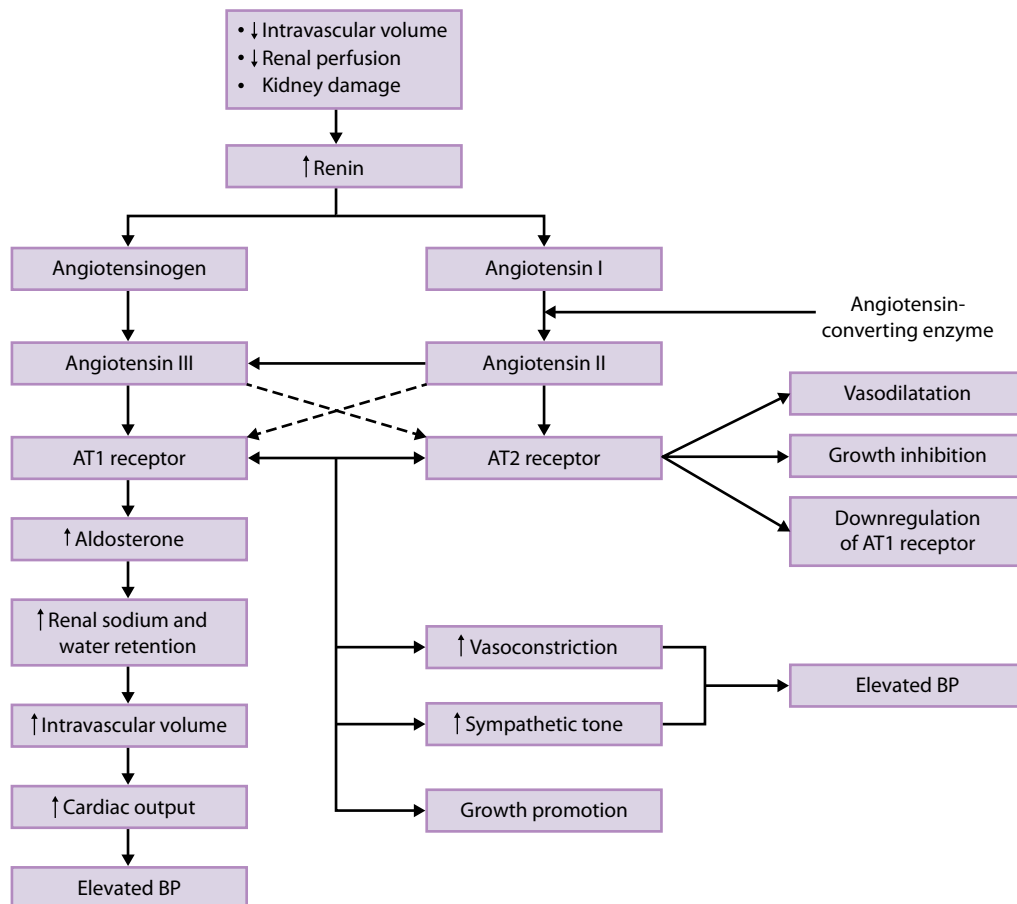
Selecting an appropriately sized cuff is critical when measuring BP. Commercial standards are not uniform, and cuff labeling is not always appropriate (e.g., not all 10-year-old children should have their BP measured with the "child


Figure 39.2 Renin-angiotensin-aldosterone system in blood pressure regulation. AT1 receptor, angiotensin I receptor; AT2 receptor, angiotensin II receptor; BP, blood pressure.

* Calculated so that the largest arm would still allow the bladder to encircle the arm by at least 80%.

Table 39.6 Korotkoff sounds for auscultatory blood pressure measurement

Korotkoff sounds		Sound characteristics
First sound	K_1	Snapping sound first heard; indicates systolic BP
Second sound	K_2	Muffled sound or murmur; no clinical significance
Third sound	K_3	Louder and crisp tapping sound; no clinical significance
Fourth sound	K_4	Softer or muted sound, ~5–10 mm Hg above diastolic BP; has been used as indicator of diastolic BP; not recommended in children
Fifth sound	K_5	Disappearance of sound; indicates diastolic BP

Abbreviation: BP, blood pressure.

cuff"). Thus, the BP cuff should be chosen based on the actual size of the child's arm and the size of the bladder in the cuff. The BP cuff bladder width should be at least 40% of the midarm circumference (point midway between the olecranon and the acromion), and the length should be at least 80% of the circumference of the arm without overlapping.[18] Using a cuff that is too small can produce erroneously high BP values, whereas too large a cuff may generate results slightly lower than the patient's actual BP. The larger cuff size should be chosen for patients whose midarm circumference measures in the transition zone between cuff sizes, even if the cuff seems too large. The BP cuff size recommendations of *The Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents* are given in Table 39.5.[18]

Several noninvasive techniques exist for measuring BP. The gold standard is auscultatory measurement using a mercury manometer.[33] However, mercury manometers have been phased out in many settings out of environmental concerns over mercury exposure. Aneroid manometers may also be used to obtain similar auscultatory measurements. Routine maintenance and recalibration, however, are critical for aneroid manometers to maintain their accuracy.[34,35]

AUSCULTATORY METHOD

Irrespective of the measuring device, the auscultatory technique requires listening for Korotkoff sounds (Table 39.6) over the brachial artery while slowly deflating the BP cuff. The bell of the stethoscope should be used because it allows the listener to hear softer sounds more clearly. Systolic BP is recorded at K_1 (Korotkoff phase 1), which is the onset of sound. This may be followed by a long pause (termed the auscultatory gap) before sounds begin a rhythmic tapping. Diastolic BP is defined at K_5, the point at which sound disappears completely. Although K_4 (muffling of sounds) is no longer recommended to define diastolic BP, it may be useful in young children in whom K_5 is close to zero.[18]

AUTOMATED DEVICES

Most automated BP devices use oscillometric techniques to measure BP. These monitors have some advantages over standard auscultatory methods, such as increased ease of use and decreased observer error and bias. However, they do not measure systolic and diastolic BP in the same way that the current normative values were obtained. Rather than determining Korotkoff sounds, oscillometric monitors measure mean arterial pressure by capturing the amplitude of oscillation generated by the compressed arterial wall as the BP cuff deflates. Proprietary calculations, which vary among manufacturers, are then used to calculate systolic and diastolic BP from this measured mean arterial pressure.[36] The relationship between mean arterial pressure and systolic and diastolic BP is highly influenced by vascular compliance. Because vascular compliance is typically higher in children than in adults, it is important to choose an oscillometric device that has been validated in children. Overall, oscillometric measurements are similar to those obtained with auscultatory techniques; however, systolic BP tends to be slightly higher, particularly with the first reading.[37,38] For this reason, it is recommended that any BP reading greater than the 90th percentile that is obtained by oscillometric techniques be confirmed using auscultatory methods. Routine maintenance of this equipment according to the manufacturer's recommendations is also important to preserve its accuracy.

CLINICAL MANIFESTATIONS

Most patients with essential hypertension are identified at a routine physical examination or during a physician's visit for another complaint. Although typically asymptomatic, some of these patients may complain of headaches, dizziness, fatigue, or other mild cardiovascular symptoms. Patients with secondary hypertension present more frequently with symptoms related to their underlying disease (e.g., hematuria with glomerulonephritis or hot flashes and weight loss with hyperthyroidism), rather than symptoms of high BP.

> ### KEY POINT
>
> Mild hypertension may be asymptomatic or may lead to nonspecific symptoms, whereas more severe hypertension may produce life-threatening clinical manifestations.

HYPERTENSIVE EMERGENCIES

Although less common, severe hypertension can manifest with life-threatening signs and symptoms. Neurologic symptoms are the most common manifestations of hypertensive emergencies in children, although heart failure and renal insufficiency have also been reported.[39] Most children with hypertensive emergencies have a secondary form of hypertension, but reports describing the prevalence of hypertensive crises vary widely (e.g., 20% to 50% in patients with renovascular hypertension).[40,41]

Hypertensive encephalopathy typically manifests with headache that progresses to mental status changes and seizures. Other reported symptoms include facial palsy (particularly Bell palsy),[42] visual changes that may progress to blindness,[39,43] and coma. These symptoms are caused by a disruption in the normal autoregulatory mechanisms of cerebral blood flow that occurs in acute hypertension.[44] With severe, abrupt increases in BP, the cerebral vasculature is unable to constrict adequately to maintain consistent cerebral blood flow. This leads to cerebral hyperperfusion and subsequent edema.[45] When BP increases slowly, these cerebral autoregulatory mechanisms are able to adapt.[46] Thus, hypertensive encephalopathy is most commonly seen in patients with a sudden rise in BP, such as children with acute glomerulonephritis, and rarely in patients with chronic hypertension.

The most common lesion seen with brain imaging of children with hypertensive encephalopathy is the posterior reversible encephalopathy syndrome (PRES) that affects the parieto-occipital white matter (Figure 39.3). These changes can be seen on computed tomography (CT)
Figure 39.3. Magnetic resonance imaging of brain of an adolescent patient with posterior reversible encephalopathy syndrome (PRES) caused by sudden and severe hypertension.

scan or magnetic resonance imaging (MRI) of the brain. PRES manifests with clinical findings of headache, change in sensorium, confusion, and focal seizures. Apart from severe and sudden elevations in BP, PRES can also be seen in systemic lupus erythematosus and eclampsia. Imaging abnormalities in PRES may persist for weeks after clinical symptoms resolve.[45]

> ### KEY POINT
>
> PRES is a unique clinical and radiologic manifestation seen in patients who develop sudden and severe elevation of BP.

The long-term outcomes of patients following a hypertensive emergency are related in part to appropriate management strategies. Early case series reported significant sequelae of hypertensive encephalopathy, with more than 50% of survivors having long-term neurologic deficits. However, since the introduction of intravenous infusions of antihypertensive medications, which have allowed for a slower reduction in BP, outcomes have been more favorable.[47,48] To compare different treatment strategies, Deal et al.[39] retrospectively investigated the outcomes of 110 severely hypertensive pediatric patients surrounding this

change in practice. The initial 57 patients were treated using bolus medications with the intent of normalizing BP in 12 to 24 hours. Of these patients, 13 (23%) developed significant complications, including acute renal failure, both transient and permanent visual loss, and transverse ischemic myelopathy. Subsequently, continuous infusions were used to treat 53 patients, with a goal of gradual BP reduction over 96 hours. Only 2 patients (4%) developed transient acute renal failure, and no neurologic complications were observed.

Thus, although patients presenting with hypertensive emergency require immediate evaluation and intervention, care should be taken not to lower BP too rapidly. Rapid lowering of BP increases the potential for complications associated with hypoperfusion, including ischemic neuropathy of the optic nerve, transverse ischemic myelopathy, and renal impairment.[49–53]

ETIOLOGY OF HYPERTENSION IN CHILDREN

Hypertension may be either primary (essential) or secondary to an underlying medical condition (Table 39.7, Table 39.8, and Table 39.9). Traditionally, most cases of childhood hypertension were considered secondary. However, the number of children with essential hypertension has risen dramatically in parallel with the obesity epidemic that has occurred since the 1990s. Despite this trend, it is important that practitioners continue to assess patients for secondary causes, particularly in patients who are very young, severely hypertensive, and of normal weight.

KEY POINTS

- Secondary hypertension is more common in young children and in those with severe hypertension.
- Renal and renovascular diseases are common secondary causes of hypertension in children.

SECONDARY HYPERTENSION

Renal Parenchymal Disease

The most common causes of secondary hypertension are related to underlying kidney disease. Up to 50% of children with chronic kidney disease have elevated BP.[54] Congenital abnormalities of the kidneys and urinary tract (CAKUT), chronic glomerulonephritides, polycystic kidney diseases, pyelonephritic renal scars, and external compression of the kidney by a tumor mass are common renal parenchymal diseases associated with hypertension (Figure 39.4).[55] The rise in BP seen in these diseases may be related to intravascular volume expansion from decreased sodium excretion, aberrant activity of the renin-angiotensin-aldosterone system, reduced production of vasodilators, activation of the adrenergic system, or a combination of these factors.[56\]

Renovascular Disease

Renovascular disease is unusual in that it may be surgically correctable. Renal artery stenosis accounts for approximately 8% to 10% of children with secondary hypertension referred to tertiary centers.[57,58] Most of these cases are caused by unilateral fibromuscular dysplasia of the main renal artery (Figure 39.5). Bilateral disease or intrarenal branch artery stenosis can also occur. More extensive involvement is more likely to be seen in children with clinical disorders associated with renal artery stenosis, including neurofibromatosis,[59–63] Marfan syndrome,[64] Takayasu disease,[65] and Klippel-Trénaunay-Weber syndrome.[66]

Coarctation of Aorta

Coarctation of the aorta is another potentially curable vascular-mediated cause of hypertension (Figure 39.6). Its reported incidence has ranged from as low as 2% to as high as 33% in case series of hypertensive infants. More than 90% of children with coarctation have narrowing of the thoracic aorta just below the origin of the left subclavian artery.[67] However, coarctation may occur at any point along the aorta. When it involves the abdominal aorta, it may extend into branching arteries such as the renal arteries, celiac artery, and mesenteric arteries.[57,68,69] This constellation, known as midaortic syndrome, may be caused by fibromuscular dysplasia or may be part of the vascular pathologic features seen in neurofibromatosis,[62] Takayasu disease,[65] or Williams syndrome.[70] Children whose coarctation goes undiagnosed beyond the first several years of life may have residual hypertension even after surgical correction of the aortic defect.

Endocrine Disorders

HYPERTHYROIDISM

Hyperthyroidism is the most common endocrine disorder that causes hypertension. Although hypertension may be an incidental finding in these patients, some may have significant symptoms of hyperthyroidism, such as tachycardia, weight loss, and anxiety. Because triiodothyronine (T_3) is a

Table 39.7 Causes of elevated blood pressure in children and adolescents

Fictitious Hypertension
- Too small blood pressure cuff
- Lower extremity measurement

Renal Diseases
- Renal dysplasia
- Hemolytic uremic syndrome
- Glomerulonephritis
  - Postinfectious glomerulonephritis
  - Rapidly progressive glomerulonephritis
  - Henoch-Schönlein purpura nephritis
  - Glomerulonephritis with systemic disease (e.g., SLE)
  - Membranoproliferative glomerulonephritis
- Tubulointerstitial nephritis
- Acute tubular necrosis
- Reflux nephropathy
- Renal trauma
- Inherited parenchymal disease (ADPKD, ARPKD)
- Obstructive uropathy (UPJ, UVJ obstruction)
- Chronic renal failure
- Nephrotic syndrome (if hypervolemic)

Vascular Disorders
- Coarctation of the aorta
- Renal artery stenosis
- Renal artery thrombosis and embolization
- Renal artery compression

Neurologic Causes
- Seizures
- Increased intracranial pressure (tumor, hydrocephalus)
- Guillain-Barré syndrome
- Poliomyelitis
- Dysautonomia
- Spinal cord injury

Low-Renin Hypertension
- Gordon syndrome
- Apparent mineralocorticoid excess
- Glucocorticoid-remediable aldosteronism
- Liddle syndrome

Endocrine Disorders
- Congenital adrenal hyperplasia
  - 11β-hydroxylase deficiency
  - 17α-hydroxylase deficiency
- Conn syndrome
- Cushing disease
- Hyperthyroidism
- Adrenal hemorrhage

Renal Tumors
- Wilms tumor
- Hamartoma
- Hemangiopericytoma

Catecholamine-Secreting Tumors
- Pheochromocytoma
- Neuroblastoma
- Paraganglioma

Neonatal Disorders
- Congenital rubella
- Bronchopulmonary dysplasia
- Birth asphyxia
- Closure of abdominal wall defects
- Maternal drug use (cocaine and heroin)
- Idiopathic arterial calcification
- Closure of abdominal wall defects
- Maternal drug use (cocaine and heroin)
- Idiopathic arterial calcification

Miscellaneous Conditions
- Prolonged TPN
- Pain
- Pneumothorax
- Sickle cell anemia
- Hypercalcemia
- Lead poisoning
- Orthopedic procedures (traction)

Diet
- Caffeine
- Alcohol
- Licorice

peripheral vasodilator, diastolic hypertension is uncommon in these patients, and isolated systolic hypertension is the usual finding.

ADRENAL DISEASES

Disorders associated with aldosterone excess are uncommon but recognizable causes of hypertension in children. Isolated overproduction of aldosterone may be seen with primary adrenal hyperplasia and aldosterone-producing adenomas. Both conditions are rare in children, however. Aldosterone indirectly activates amiloride-sensitive epithelial sodium channels (ENaC) located on the apical surface of principal cells in the renal cortical collecting duct. Activation of these channels causes sodium retention, with subsequent volume expansion, hypokalemia, and metabolic alkalosis.[71] Plasma renin activity is low to normal in these patients

Table 39.8 Common causes of hypertension by characteristic age of presentation

Neonate

- Glomerulonephritides
- Renal artery stenosis
- Wilms tumor
- Neuroblastoma

Adolescent
- Obesity or essential hypertension
- Glomerulonephritis
- Renal artery stenosis
- Endocrine disorders
- Autosomal dominant PKD
- Illicit drug use

Abbreviations: PKD, polycystic kidney disease; UAC, umbilical artery catheter.

Table 39.9 Medications associated with hypertension

Drug class	Examples
Corticosteroid	Prednisone, methylprednisolone
Nonsteroidal anti-inflammatory	Ibuprofen, naproxen
Estrogen	Oral contraceptives
Sympathomimetic	Nasal decongestants, diet pills (pseudoephedrine, phenylephrine)
Erythropoiesis-stimulating agent	Erythropoietin, darbepoetin
Illicit drug	Cocaine, amphetamines
Psychotropic	Buspirone, clozapine, fluoxetine, lithium, tricyclic antidepressants
Anticonvulsant	Carbamazepine
Herbal	Ephedra, ginseng, ma huang, ginger, St. John's wort

because of the associated volume expansion. The distinction between adrenal hyperplasia and adrenal adenoma may be difficult because most adenomas are small (less than 1 cm),[72] and hyperplasia of the remainder of the adrenal gland is also common in the presence of an adenoma.[73]

Aldosterone excess also occurs in patients with glucocorticoid-remediable aldosteronism (GRA). GRA is an autosomal dominant disorder wherein DNA encoding aldosterone synthase is coupled to the regulatory sequences conferring adrenocorticotropic hormone (ACTH) responsiveness.[74] Thus, ACTH becomes the main controlling agent of aldosterone production, rather than angiotensin II or potassium. Consequently, patients with GRA have aldosterone-mediated hypertension that can be suppressed with glucocorticoids.

Overproduction of other mineralocorticoids causes hypertension in several rare forms of congenital adrenal hyperplasia (CAH), including 11β-hydroxylase, 3β-hydroxysteroid dehydrogenase, 17β-hydroxylase, and cholesterol desmolase deficiencies.[75–77] 21-Hydroxylase deficiency, which accounts for approximately 90% of all cases of CAH, is not associated with hypertension, except as a side effect of therapy with corticosteroids and mineralocorticoids.

Cushing syndrome leads to hypertension through activation of the mineralocorticoid receptors by cortisol. Aldosterone is approximately 300 times more potent than cortisol at activating mineralocorticoid receptors. However, in high enough concentrations, cortisol can produce an aldosterone-like effect.[78,79] The specific affinity of mineralocorticoid receptors for aldosterone is provided by the enzyme 11β-hydroxysteroid dehydrogenase 2 (11β-HSD2), which is found locally at the receptor site. 11β-HSD2 breaks down cortisol to cortisone, thereby removing its ability to activate the receptor. When levels exceed the threshold concentration of this enzyme (as is seen in Cushing syndrome), cortisol is able to bind to these receptors and stimulate sodium reabsorption. Genetic deficiencies in 11β-HSD2 also lead to hypertension in the autosomal recessive disorder known as apparent mineralocorticoid excess (AME).[80,81]

Genetic Disorders

Liddle syndrome and Gordon syndrome are monogenic causes of hypertension. Liddle syndrome is an autosomal dominant condition in which a mutation in the ENaC channel leads to persistent activation and sodium reabsorption.[82,83] This creates a clinical picture similar to that of hyperaldosteronism, but plasma renin and aldosterone levels are very low.[84]

Gordon syndrome (pseudohypoaldosteronism type II) is an autosomal dominant syndrome caused by mutations in the WNK1 and WNK4 kinase family, both of which are involved in regulating the activity of the thiazide-sensitive sodium-chloride (Na-Cl) cotransporter in the distal nephron.[85,86] Hyperactivity of this receptor, as seen in Gordon syndrome, leads to a clinical picture of salt reabsorption
Figure 39.4 Renal parenchymal causes of hypertension. **(a)** Large renal pelvic diverticulum identified by magnetic resonance urography in a thin 14-year-old patient with hypertension. **(b)** Polycystic kidney disease seen on renal ultrasound in a 6-year-old child with hypertension and tuberous sclerosis. **(c)** Large retroperitoneal mass found on computed tomography in an 8-year-old child presenting with hypertension from mass effect. **(d)** Dimercaptosuccinic acid renal scan of a patient with severe hypertension. The upper pole of the right kidney shows multiple photopenic areas, representing renal scars.
Figure 39.5 Renovascular hypertension. Renal angiogram in a patient with hypertension secondary to fibromuscular dysplasia affecting the midsegment of the right renal artery. Poststenotic dilatation of the renal artery is also seen.
Figure 39.6 Severe coarctation of the descending aorta visualized on three-dimensional reconstruction images obtained with computed tomography angiography in an 11-year-old child with hypertension and diminished lower extremity pulses.

with subsequent low-renin hypertension. Unlike in other forms of monogenic hypertension, patients with Gordon syndrome develop hyperkalemia and metabolic acidosis.[84]

KEY POINTS

- Liddle syndrome is characterized by a mutation in the ENaC channel that leads to its persistent activation and sodium reabsorption.
- Gordon syndrome (pseudohypoaldosteronism type II) is caused by mutations in the WNK1 or WNK4 kinase that regulates the thiazide-sensitive Na-Cl cotransporter in the distal tubule.
- Plasma renin and aldosterone levels in Little syndrome and Gordon syndrome are low in response to excess sodium reabsorption and intravascular volume expansion.

Neoplasms

Intra-abdominal tumors may cause hypertension through compression of the renal vasculature or parenchyma, thus causing inappropriate renin release (Page kidney). Tumors may also raise BP by the direct release of vasoactive substances such as renin (Wilms tumor) or catecholamines (pheochromocytomas). Of these tumors, pheochromocytoma is the most likely to be identified when hypertension is the presenting complaint. Pheochromocytomas are uncommon in childhood; only 10% pheochromocytomas occur in this age group. These tumors are usually benign and originate in the chromaffin cell tissue in the adrenal medulla or other locations along the sympathetic chain (Figure 39.7). Rarely, they may also arise from atypical sites such as the bladder and heart.[87] The unregulated release of metanephrine or normetanephrine from these tumors leads to the classical symptoms of headaches, sweating, and palpitations with tachycardia.[88,89] Other common symptoms include anxiety, nausea and vomiting, unintentional weight loss,
Figure 39.7 Pheochromocytoma in a patient who presented with low-grade fever, weight loss, tachycardia, and hypertension. **(a)** Magnetic resonance imaging of the abdomen showing tumor in the right adrenal gland. **(b)** Meta-iodobenzylguanidine scan demonstrating radiotracer uptake in the tumor area (arrow). **(c)** Cut surface of the tumor removed surgically showing numerous necrotic areas within a yellow background of the mass. **(d)** Microscopic section (hematoxylin and eosin stain) showing tumor cells with large eccentric nuclei, arranged in rests that are surrounded by a fine fibrovascular membrane-like structure.

being excessively sensitive to warm environment, increased body temperature (low-grade fever), pallor, and acrocyanosis. Whereas symptoms in children with these tumors are often intermittent, elevated BP is more frequently sustained, with periodic spikes of severe hypertension.[88] A 24-h urine collection for determining daily catecholamines and metanephrines excretion is typically recommended for diagnostic evaluation. Serum catecholamine determination may be less accurate, especially if the secretion of these neurohormones is periodic. Plasma metanephrines, however, are more sensitive when samples are obtained correctly through an indwelling catheter.[90]

> ### KEY POINT
>
> Pheochromocytoma can occur as an isolated tumor or in association with neurofibramatosis, von Hippel-Lindau disase, or multiple endocrine neoplasia type II.

Localization of a pheochromocytoma may be challenging. A 131-iodine or 123-iodine meta-iodobenzylguanidine (MIBG) scan is the initial scan typically recommended to identify tumors of neural crest origin, but the radionuclide scan may miss even large tumors.[91,92] Labeled somatostatin is an alternate way of identifying catecholamine-secreting tumors missed by MIBG scans.[93] MRI or CT is then needed to delineate tumor borders preoperatively. Localization of a tumor with these modes of imaging should not be considered definitive because finding multiple tumor foci is not uncommon, especially with syndromes associated with pheochromocytomas such as neurofibromatosis,[94,95] von Hippel–Lindau disease,[96] and multiple endocrine neoplasia (MEN).[97,98]

Surgical removal of the tumor is the definitive treatment for pheochromocytoma. BP control initially with α blockade with phenoxybenzamine followed by β blockade if necessary, should be achieved for at least 1 week preoperatively.[99] β-Blocking agents should not be used alone in these patients because this approach results in unopposed stimulation of vascular α receptors, which can precipitate a hypertensive crisis. Calcium channel blockers may also be used safely if BP remains elevated despite α blockade.[100]

ESSENTIAL HYPERTENSION

The prevalence of essential hypertension among children and adolescents has risen dramatically since the 1990s in parallel with rising rates of obesity. Although the exact cause and mechanisms behind its development have yet to be elucidated, essential hypertension is likely the result of complex interactions between both genetic and environmental factors. Excess weight is the most strongly associated risk factor because approximately 30% of obese adolescents have elevated BP.[101] A lack of exercise and

dietary choices, independent of weight, have also been identified as risk factors for hypertension. In adults, a diet high in salt[102,103] and low in fresh fruits, vegetables, and calcium,[102] along with a sedentary lifestyle,[104] is associated with high BP. Evidence supporting the role of sodium in the development of hypertension in children is strong, although the role of other nutrients such as potassium and calcium is unclear.[105,106]

Race and ethnicity also have some influence on the incidence of hypertension. A larger percentage of African Americans in the United States have hypertension as compared with whites, Hispanics, and Native Americans.[107–109] This finding is likely related to a higher incidence of several genetic polymorphisms that have been associated with the development of essential hypertension. However, environmental factors, such as poverty or demanding environments, which have also been correlated with higher BP, may also contribute to these differences.[110]

NEONATAL HYPERTENSION

Hypertension is uncommon in infants, but it does affect 1% to 2% of newborns admitted to the neonatal intensive care unit.[111–113] Umbilical artery catheter–associated thromboembolism, which may originate from either the aorta or the renal arteries, is a unique cause of hypertension in this population (Figure 39.8). Congenital lesions of both the vasculature and renal parenchyma (e.g., coarctation of the aorta, renal artery stenosis, polycystic kidney disease, and obstructive uropathy) must also be considered in this age group. In fact, in one series approximately 50% of infants diagnosed with hypertension were found to have an underlying renal anomaly.[113] Bronchopulmonary dysplasia, extracorporeal membrane oxygenation (ECMO), patent ductus arteriosus, intraventricular hemorrhage, and acute renal failure are other well-recognized risk factors for neonatal hypertension.[111–116] Finally, iatrogenic causes of neonatal hypertension include medications, maternal drug use, and complications associated with prolonged parenteral

Figure 39.8 Computed tomography angiogram defining residual renal artery stenosis (arrow) in a 1-year-old child with a history of an umbilical artery catheter–associated thrombus.

nutrition. Close monitoring of BP at follow-up is important for all children with a complicated neonatal course because many of these children do not develop hypertension until several months after discharge from the intensive care unit.[117]

EVALUATION OF A CHILD WITH HYPERTENSION

Evaluation of a child identified as hypertensive should be aimed at identifying potential secondary causes, detecting underlying hypertensive target organ damage, and ascertaining other risk factors for cardiovascular disease. The urgency with which this evaluation is undertaken depends on the severity of the child's illness. Young patients, those with severe BP elevation, and those with symptoms related to hypertension deserve more immediate evaluation with concomitant therapeutic interventions. Less urgent evaluation is appropriate in older children and those with milder BP elevations.

KEY POINT

Evaluation of the hypertensive child should focus on identifying secondary causes, hypertensive target organ damage, and other comorbidities related to cardiovascular disease.

HISTORICAL DATA

A detailed history focused on identifying symptoms of severe hypertension, as well as clues to an underlying cause, should be obtained from all patients with hypertension (Table 39.10). A thorough past medical, family, diet, and sleep history may provide clues to the underlying cause of an individual patient's hypertension. Most patients are either asymptomatic or describe nonspecific symptoms such as mild headaches, fatigue, and sleep disturbances. Patients with severe hypertension, however, may complain of significant headaches, visual changes, and chest pain. Urinary symptoms and swelling may suggest acute glomerulonephritis, whereas weight loss and sweating may indicate an endocrine abnormality or neoplasm. Past medical history of an umbilical artery catheter or multiple urinary tract infections suggests an underlying renal abnormality. Loud snoring and sleep disturbances may be present in children with sleep apnea, a potential cause of hypertension. In addition, certain prescribed and illicit drugs may cause hypertension.

PHYSICAL EXAMINATION

A complete physical examination should be performed, with special attention to findings suggestive of an underlying hypertensive disorder or hypertensive target organ damage (Table 39.11). On initial presentation, four extremity BPs should be obtained to screen for coarctation of the aorta, which should be suspected if upper extremity BPs exceed lower extremity measurements. Lower extremity pulses are typically diminished in these children. The

Table 39.10 Historical clues in the diagnosis of hypertension

Historical finding	Possible significance
Complaint and Review of Systems	
Headaches, dizziness, epistaxis, visual changes	Nonspecific
Abdominal pain, dysuria, frequency, urgency, nocturia, enuresis	Underlying renal disease
Joint pains or swelling, edema, rashes	Autoimmune-mediated disease or glomerulonephritis
Weight loss, sweating, flushing, palpitations	Pheochromocytoma or hyperthyroidism
Muscle cramps, weakness, constipation	Hypokalemia associated with hyperaldosteronism
Delayed puberty	Congenital adrenal hyperplasia
Snoring	Sleep apnea
Prescription, over-the-counter, or illicit drug use	Drug-induced hypertension
Past Medical History	
Umbilical artery catheterization	Renal artery thrombosis/renal embolus
Thyroid cancer, neurofibromatosis, Von Hippel–Lindau disease	Pheochromocytoma
Family History	
Hypertension	Inherited forms of hypertension (AME, Gordon syndrome, Liddle syndrome, GRA), essential hypertension
Renal disease	Polycystic kidney disease, Alport syndrome
Tumors	Familial pheochromocytoma, MEN II
Early complications of hypertension or atherosclerosis	Predictive of hypertensive course

Abbreviations: AME, apparent mineralocorticoid excess; GRA, glucocorticoid-remediable aldosteronism, MEN II, multiple endocrine neoplasia type II.

Table 39.11 Physical examination abnormalities in children with hypertension

Clinical abnormality	Diagnostic implication
Vital Signs	
Bradycardia	Increased intracranial pressure
Drop in BP from upper to lower extremities	Coarctation of the aorta
Tachycardia	Hyperthyroidism, pheochromocytoma, neuroblastoma, primary hypertension
Constitutional	
Growth retardation	Chronic kidney disease
Obesity	Essential hypertension
Truncal obesity	Cushing disease, insulin resistance
Head and Neck	
Adenotonsillar hypertrophy	Sleep disorders
Elfin facies	Williams syndrome
Fundal changes (papilledema, AV nicking)	Chronic or severe hypertension
Moon facies	Cushing disease
Proptosis or goiter	Hyperthyroidism
Webbed neck	Turner syndrome
Cardiovascular	
Apical heave	Left ventricular hypertrophy
Disparity in pulses	Coarctation of the aorta
Friction rub	SLE, collagen vascular disease, uremia
Lungs	
Crackles or rales	Heart failure with chronic hypertension
Abdomen	
Bruit	Renal artery stenosis, abdominal coarctation
Hepatomegaly	Heart failure
Masses	Obstructive nephropathy, Wilms tumor, neuroblastoma, pheochromocytoma, polycystic kidney disease
Genitalia	
Ambiguous, virilized	Congenital adrenal hyperplasia
Extremities	
Edema	Acute or chronic kidney disease
Joint swelling	Autoimmune disease
Rachitic changes	Chronic kidney disease
Dermatologic	
Acanthosis nigricans	Insulin resistance or metabolic syndrome
Needle tracks	Drug-induced hypertension
Neurofibromas	Neurofibromatosis
Rashes	Vasculitis or nephritis
Striae, acne	Cushing disease
Tubers, ash-leaf spots, adenoma sebaceum	Tuberous sclerosis
Neurologic	
Encephalopathy	Severe hypertension
Cranial nerve palsy	Severe hypertension

Abbreviations: AV, arteriovenous; BP, blood pressure; SLE, systemic lupus erythematosus.

remainder of the cardiac examination, including the presence of abnormal heart sounds or an abdominal bruit, may also provide diagnostic clues. The head and neck examination may reveal proptosis, tonsillar hypertrophy, or papilledema, whereas the dermatologic examination my reveal striae, neurofibromas, or acanthosis nigricans. A neurologic examination may show signs of severe hypertension such as Bell palsy or hemiparesis.

LABORATORY AND IMAGING STUDIES

Laboratory evaluation should include electrolytes to screen for monogenic forms of hypertension, blood urea nitrogen and creatinine to assess kidney function, and a complete blood count to evaluate for anemia, which is associated with chronic kidney disease and other chronic illnesses (Table 39.12). A urinalysis to detect hematuria or proteinuria should also be performed in all patients. The urine microalbumin-to-creatinine ratio may be obtained to identify more subtle renal abnormalities. Although microalbuminuria is common in adult patients with isolated chronic hypertension, it is less common in children who do not have underlying diabetes. Plasma renin activity (PRA) levels are useful to screen patients for underlying causes of secondary hypertension. PRA levels are typically normal or mildly elevated in children with renal parenchymal or renovascular disease. They tend to be more significantly elevated in children with pheochromocytoma (increased sympathetic output directly stimulates renin release).[118] Conversely, renin levels are low in children with volume expansion and hyperaldosteronism. Specific laboratory studies, such as thyroid studies or urine catecholamines, are indicated in patients with specific symptoms or when particular diagnostic conditions are suspected. Finally, patients with essential hypertension should also be evaluated for hypercholesterolemia and metabolic syndrome.

An echocardiogram is indicated in all patients with hypertension to evaluate for congenital anomalies and left ventricular hypertrophy (LVH), a sensitive measure of target organ

Table 39.12 Clinical evaluation of confirmed hypertension

Study or procedure	Purpose	Target population
Evaluation for Identifiable Causes		
History, including sleep history, family history, risk factors, diet, and habits such as smoking and drinking alcohol; physical examination	History and physical examination help focus subsequent evaluation	All children with persistent BP ≥95th percentile
BUN, creatinine, electrolytes, urinalysis	Renal parenchymal disease; hypokalemia and alkalosis may point to mineralocorticoid excess disorders	All children with persistent BP ≥95th percentile
CBC	Anemia, consistent with chronic renal disease	All children with persistent BP ≥95th percentile
Renal ultrasound	Renal scar, congenital anomaly, or disparate renal size, polycystic kidney disease	All children with persistent BP ≥95th percentile
Evaluation for Comorbidity		
Fasting lipid panel, fasting glucose	Identify hyperlipidemia, identify metabolic abnormalities	Overweight patients with BP at 90th–94th percentile; all patients with BP ≥95th percentile; family history of hypertension or cardiovascular disease; child with chronic renal disease
Drug screen	Identify substances that could cause hypertension	History suggestive of possible contribution by substances or drugs
Polysomnography	Identify sleep disorder in association with hypertension	History of loud, frequent snoring
Evaluation for Target-Organ Damage		
Echocardiogram	Identify LVH and other indications of cardiac involvement	Patients with comorbid risk factors* and BP 90th–94th percentile; all patients with BP ≥95th percentile
Retinal examination	Identify retinal vascular changes	Patients with comorbid risk factors* and BP 90th–94th percentile; all patients with BP ≥95th percentile

Table 39.12 Clinical evaluation of confirmed hypertension (Continued)

Study or procedure	Purpose	Target population
Further Evaluation as Indicated		
Ambulatory BP monitoring	Identify white coat hypertension, abnormal diurnal BP pattern, BP load	Patients in whom white coat hypertension is suspected, and when other information on BP pattern is needed
Plasma renin determination	Identify low renin, suggesting mineralocorticoid-related disease	Young children with stage 1 hypertension and any child or adolescent with stage 2 hypertension; positive family history of severe hypertension
Renovascular imaging: Isotopic scintigraphy (renal scan) Magnetic resonance angiography Duplex Doppler flow studies Three-dimensional CT Arteriography: DSA or classic	Identify renovascular disease	Young children with stage 1 hypertension and any child or adolescent with stage 2 hypertension
Plasma and urine steroid levels	Identify steroid-mediated hypertension	Young children with stage 1 hypertension and any child or adolescent with stage 2 hypertension
Plasma and urine catecholamines	Identify catecholamine-mediated hypertension	Young children with stage 1 hypertension and any child or adolescent with stage 2 hypertension

Abbreviations: BP, blood pressure; BUN, blood urea nitrogen; CBC, complete blood count; CT, computed tomography; DSA, digital subtraction angiography; LVH, left ventricular hypertrophy.

* Comorbid risk factors also include diabetes mellitus and kidney disease.

damage. The presence of LVH should prompt more aggressive medical management. LVH can improve with therapy.[119–121] Thus, serial testing (annually or semiannually) may be useful for monitoring therapeutic control of hypertension.

A renal ultrasound scan should be performed in all patients with hypertension to identify parenchymal lesions, such as small scarred kidneys, polycystic kidney disease, or other structural anomalies. Compared with its use in adults, Doppler ultrasound is less sensitive in identifying subtle renal artery stenosis in children. Although both CT and MRI are reasonable secondary screening tools for renal artery stenosis, angiography remains the gold standard for diagnosis and treatment.[122–125] Other renal imaging techniques, such as dimercaptosuccinic acid (DMSA) renal scintigraphy to identify renal scarring, may also prove useful in detecting underlying renal disorders.

TARGET ORGAN DAMAGE

With the rising prevalence of hypertension among children and adolescents, concerns regarding the morbidity and ultimate mortality of this condition are becoming increasingly relevant. For adults, hypertension is an independent risk factor for myocardial infarction, heart failure, stroke, and chronic kidney disease.[126] In fact, the World Health Organization[127] reported that poor BP control was the number one attributable risk for death in the world, and it accounted for 62% of cerebrovascular disease and 49% of ischemic heart disease observed. Hypertension is also the second leading cause of end-stage renal disease among adults requiring dialysis in the United States.[128]

The long-term effects of high BP on children are difficult to define, given the long time period between diagnosis and a definable adverse event such as heart attack or stroke. However, measurable damage to the heart, blood vessels,

---

KEY POINT

Target organ abnormalities are common in children with hypertension and may include damage to the heart, vasculature, or kidneys.

retina, and kidneys has been documented in young people with elevated BP. Monitoring these subclinical changes may ultimately prove to be a better indicator of hypertension severity and BP control than periodic BP measurements, which are inherently variable.

LVH is the most commonly identified target organ abnormality among hypertensive children. Its reported prevalence has been as high as 40% among children with newly diagnosed hypertension; however, this prevalence varies significantly depending on the definition of LVH.[129–133] Although the adult cut-point of more than 51 g/m$^{2.7}$ has been recommended as a conservative definition for LVH in children and adolescents,[18] pediatric-based normal values may ultimately be more appropriate.[134] LVH is an independent risk factor for cardiovascular disease in adults, in whom it predicts both morbidity and mortality.[135,136] The process by which the increased afterload associated with hypertension increases the risk for cardiovascular disease is unknown. Several proposed mechanisms include abnormalities in diastolic function,[137] increased vulnerability of the cardiovascular system to ischemia because of increased oxygen consumption,[138] and induction of electrophysiologic abnormalities which increase the risk for arrhythmias and sudden death.[139] Subtle abnormalities in left ventricular diastolic function identified through tissue Doppler imaging have been reported in hypertensive children, thereby providing support for at least one of these mechanisms.[140] Left atrial enlargement has also been associated with hypertension in children, but its significance remains undetermined.[141]

Vascular changes have also been identified in children with hypertension. Increased carotid artery intima-medial thickness is a marker of generalized atherosclerosis in adults and correlates with incident coronary artery disease, myocardial infarction, and stroke.[142] Carotid artery intima-medial thickness is increased in hypertensive children and is independently associated with BMI and left ventricular mass index.[133,143] In addition, measures of arterial stiffness, such as pulse wave velocity, worsen in children as BP levels increase from normal to sustained hypertension.[144] Finally, hypertensive retinopathy may occur in children and occasionally produces the presenting symptom. Although estimates in children are limited, retinal abnormalities may occur in up to 50% of infants[145] and 20% of older children[146] with hypertension.

Microalbuminuria (30 to 300 mg albumin/g creatinine in a first morning urine specimen) is indicative of early renal damage in adults with hypertension, and it is independently associated with adverse cardiovascular events.[147–149] However, this association with hypertension has not been shown in children without underlying diabetes or chronic kidney disease.[150] The reason may be an increased prevalence of proteinuria in children or a decreased sensitivity of the test to detect lower levels of injury. Children found to have microalbuminuria should be considered at risk for progression of hypertensive renal disease. Further research

is needed, however, to identify more sensitive markers of hypertensive nephropathy and effective intervention strategies to prevent the development of end-stage renal disease.

SUMMARY

The prevalence of hypertension in children and adolescents has risen significantly since the 1990s. The diagnosis requires attention to proper measurement techniques, consideration of underlying causes, and evaluation of target-organ damage and other cardiovascular risk factors. Early detection is essential to minimize the long-term health consequences of hypertension. Clinical Vignette 39.1 describes an adolescent patient with hypertension.

Clinical Vignette 39.1

A 14-year-old African-American male patient presented to his pediatrician's office for his annual physical examination before joining the junior varsity football team. He denied any current concerns, although his mother reported that she thought he was overly tired and remembered that he complained of some dizziness during football practice toward the end of the season last year. He was born at term and had otherwise been relatively healthy for most of his life except for being slightly overweight. He was not taking any medications and denied any illicit drug use. He ate a "typical teenage" diet, and his favorite foods were pizza, nachos, and fried chicken. He ate few fresh fruits and vegetables and consumed approximately three caffeinated beverages a day. Both his father and paternal grandfather had hypertension diagnosed in their 40s and 60s, respectively. His mother was recently diagnosed with diabetes mellitus.

Physical examination revealed a moderately overweight male patient in no distress. His height was at the 75th percentile for age, and his body mass index was 29. Vital signs were temperature 98.6° F, pulse 85/min, respiration 20/min, and blood pressure (BP) 142/86 mm Hg. He had mild acanthosis nigricans on the back of his neck, but the remainder of his physical examination was normal. BP in four extremities was as follows:

Right upper extremity: 140/76 mm Hg
Left upper extremity: 132/86 mm Hg
Right lower extremity: 143/82 mm Hg
Left lower extremity: 146/88 mm Hg

Ninety-fifth percentile and 99th percentile of BP for height, age, and gender for this patient were 130/83 mm Hg and 138/91 mm Hg, respectively.

TEACHING POINTS

Because the patient in Clinical Vignette 39.1 was asymptomatic, he was instructed to return to the office for blood pressure checks two more times over the next month. His average blood pressure over all these readings was 136/78 mm Hg. He was diagnosed with stage 1 hypertension. Serum electrolytes, renal function, complete blood count, urinalysis, urine microalbumin, insulin, and renal ultrasound findings were normal. His fasting triglycerides were elevated, and an echocardiogram showed left ventricular hypertrophy (LVH). A dilated retinal examination by an ophthalmologist was normal. No underlying cause for his hypertension was discerned, and the diagnosis of essential hypertension was made. The presence of LVH suggests an increased risk for cardiovascular disease in the future and is an indication for pharmacologic therapy in addition to lifestyle modifications.

REVIEW QUESTIONS

1. According to current guidelines, the initial evaluation of all children with confirmed hypertension should include all of the following *except*:
   a. Renal ultrasound
   b. Electrocardiogram
   c. Urinalysis
   d. Complete history and physical
   e. Echocardiogram

2. All of the following low-renin hypertensive disorders are associated with hypokalemia *except*:
   a. Liddle syndrome
   b. Adrenal hyperplasia
   c. Apparent mineralocorticoid excess
   d. Glucocorticoid-remediable aldosteronism
   e. Gordon syndrome

3. Renin secretion is increased by all of the following *except*:
   a. Decreased intravascular volume
   b. Activation of the sympathetic nervous system
   c. Increased aldosterone secretion
   d. Hypotension
   e. Renal artery stenosis

4. Oscillometric blood pressure monitors directly measure:
   a. Pulse pressure
   b. Systolic blood pressure
   c. Diastolic blood pressure
   d. Mean arterial pressure
   e. Diurnal blood pressure variation

5. A previously healthy 14-year-old male patient is seen for a routine school physical examination. His blood pressure at this visit is 132/70 (95th percentile: 130/83). He is asymptomatic, and the rest of his physical examination is normal. The *next* step in his evaluation and management should be:
   a. Urinalysis
   b. Renal ultrasound.
   c. Repeat blood pressure in 1 to 2 weeks.
   d. Reassurance that his blood pressure is normal
   e. Initiation of antihypertensive medication

6. All of the following are associated with a higher risk for hypertension in the neonatal period *except*:
   a. Umbilical artery catheterization
   b. Large for gestational age
   c. Bronchopulmonary dysplasia
   d. Patent ductus arteriosus
   e. Maternal drug use

7. CT imaging of a child with hypertensive encephalopathy will *most commonly* show changes in the:
   a. Parieto-occipital white matter
   b. Hypothalamus
   c. Pituitary gland
   d. Prefrontal cortex
   e. Optic nerve

8. All of the following may raise the blood pressure of a child with chronic hypertension who is being treated for an acute asthma exacerbation and allergy symptoms *except*:
   a. Prednisone
   b. Albuterol
   c. Phenylephrine
   d. Ibuprofen
   e. Cetirizine

9. Normal blood pressure levels in children are based on the child's:
   a. Age
   b. Gender
   c. Body mass index
   d. Height
   e. a, b, and d

10. Children whose BP is greater than the 90th percentile (or greater than 120/80 mm Hg) but less than the 95th percentile should be classified as prehypertensive. However, these children should be treated as if they were hypertensive if they have any of the following conditions *except*:
    a. Left ventricular hypertrophy
    b. Diabetes mellitus
    c. Renal dysplasia
    d. Short stature
    e. Retinopathy

Management of hypertension

JOSEPH T. FLYNN

Management of hypertension in adults is guided by evidence derived from the results of large-scale clinical trials that have examined the Beffects of specific antihypertensive agents on cardiovascular morbidity and mortality.[1] In contrast, the management of hypertensive children and adolescents is still largely empiric. This is mainly because of the lack of long-term outcome data regarding the efficacy and safety of nonpharmacologic and pharmacologic approaches to treatment of hypertension in children and adolescents.[2]

Even though a rigorous evidence base is missing, the question of how to manage a child or teen with hypertension is one faced by pediatric nephrologists and other practitioners every day. The purpose of this chapter is to update the reader on current approaches to the treatment of hypertensive children and adolescents, including the special cases of hypertensive neonates, hypertensive urgencies and emergencies, pheochromocytomas, and renal artery stenosis.

MANAGEMENT APPROACH BY STAGE OF HYPERTENSION

Staging of hypertension is a concept well known to those who care for hypertensive adults,[3] but has only been applied to the management of hypertensive children and adolescents since publication of the 2004 "Fourth Report" from the National High Blood Pressure Education Program.[4] It is now recommended that, as in adults, elevated blood pressure in children and adolescents be staged to help guide the evaluation and management of pediatric patients with hypertension. Table 40.1 gives the pediatric staging criteria and the recommended management approaches for each stage.

As can be seen in Table 40.1, intervention is recommended even for children or adolescents with blood pressures that fall into the prehypertensive range. Such children should be counseled regarding lifestyle changes (weight loss, exercise, and dietary modification as appropriate) and should be seen within 6 months for a repeat blood pressure check and assessment of how well they are adhering to the recommended measures. At the other end of the scale, children or adolescents with stage 2 hypertension should have their blood pressure checked and a workup initiated within a week and are candidates for immediate institution of pharmacologic therapy. This staging system should be viewed as a framework within which to apply the specific approaches discussed in subsequent sections of this chapter.

KEY POINT

A patient's blood pressure elevation should be staged according to Fourth Report criteria to help guide evaluation and management.

NONPHARMACOLOGIC MANAGEMENT

Nonpharmacologic interventions have long been emphasized in consensus recommendations as the starting point for treatment of hypertension in children and adolescents. This is reflected in the recently issued "Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents" from the National Heart, Lung and Blood Institute,[5] which emphasizes the potential benefits of nonpharmacologic measures in not only reducing blood

TABLE 40.1 Classification of hypertension in children and adolescents, with measurement frequency and therapy recommendations

Stage	SBP or DBP percentile*	Frequency of BP measurement	Therapeutic lifestyle changes	Pharmacologic therapy
Normal	<90th	Recheck at next scheduled physical examination	Encourage healthy diet, sleep, and physical activity	—
Prehypertension	90th to < 95th or if BP exceeds 120/80 mm Hg even if below 90th percentile up to < 95th percentile†	Recheck in 6 mo	Weight management counseling if overweight, introduce physical activity and diet management§	None unless compelling indications such as CKD, diabetes mellitus, heart failure, LVH
Stage 1 hypertension	95th percentile to the 99th percentile plus 5 mm Hg	Recheck in 1–2 wk or sooner if the patient is symptomatic; if persistently elevated on two additional occasions, evaluate or refer to source of care within 1 mo	Weight management counseling if overweight, introduce physical activity and diet management§	Initiate therapy based on indications in Table 40.2 or if compelling indications, as above
Stage 2 hypertension	>99th percentile plus 5 mm Hg	Evaluate or refer to source of care within 1 wk or immediately if the patient is symptomatic	Weight management counseling if overweight, introduce physical activity and diet management§	Initiate therapy‡

Abbreviations: BP, blood pressure; CKD, chronic kidney disease; DBP, diastolic blood pressure; LVH, left ventricular hypertrophy; SBP, systolic blood pressure.

* For sex, age, and height measured on at least three separate occasions; if systolic and diastolic categories are different, categorize by the higher value.

† This occurs typically at 12 years old for SBP and at 16 years old for DBP.

‡ More than one drug may be required.

§ Parents and children trying to modify the eating plan to the DASH eating plan could benefit from consultation with a pediatric dietitian to get them started.

pressure in children with prehypertension or hypertension but also in improving the overall cardiovascular health in children with one or more risk factors for cardiovascular disease.

Weight loss and exercise

Although the magnitude of change in blood pressure may be modest, weight loss, aerobic exercise, and dietary modifications have been shown to successfully reduce blood pressure in children and adolescents. Tracking studies provide the first line of evidence supporting the concept that weight reduction has the potential to control blood pressure in children. Blood pressure clearly tracks from childhood through adolescence and into adulthood,[6] and the rise in blood pressure in these studies is typically associated with an increase in body mass index (BMI).[7] Because of the strong correlation between weight and blood pressure, excessive weight gain is likely to be associated with elevated blood pressure over time. This can be seen in data linking increased blood pressure in American children over the past decade with the

increase in childhood obesity.[8] It then follows that maintenance of normal weight in childhood should prevent the development of hypertension in adulthood.

Several studies have demonstrated that weight loss in obese adolescents lowers blood pressure.[9,10] Weight loss not only decreases blood pressure but also improves other cardiovascular risk factors such as dyslipidemia and insulin resistance.[11,12] In studies in which a reduction in BMI of approximately 10% was achieved, short-term reductions in blood pressure were in the range of 8 to 12 mm Hg. Unfortunately, weight loss is notoriously difficult and usually unsuccessful, especially in the primary care setting.[13] However, identifying a medical complication of obesity such as hypertension can perhaps provide the necessary motivation for patients and families to make appropriate lifestyle changes. This need for family-based intervention was recognized by the authors of the Fourth Report[4] and has been repeated by others.

With respect to exercise, sustained training over 3 to 6 months has been shown to result in a reduction of 6 to 12 mm Hg for systolic blood pressure and 3

KEY POINT

Although difficult to achieve, weight loss can improve blood pressure and other cardiovascular risk factors.

to 5 mm Hg for diastolic blood pressure.[14] However, cessation of regular exercise is generally promptly followed by a rise in blood pressure to pre-exercise levels. Aerobic exercise activities such as running, walking, or cycling are usually preferred to static forms of exercise in the management of hypertension.[15] Many children already may be participating in one or more appropriate activities and may need only to increase the frequency, intensity, or both of these activities (usually to at least 40 to 60 minutes per session, 4 or 5 times per week) to produce a reduction in their blood pressure.

It is important to emphasize that hypertension is not considered a contraindication to participation in competitive sports, so long as the child's blood pressure is "controlled."[16] Anecdotal experience suggests that treatment of hypertension in the competitive teen athlete may actually improve performance. However, it may be appropriate to restrict participation while the child's or adolescent's hypertension is being evaluated. Once a diagnosis has been made and treatment initiated, sports participation can be allowed. Indeed, the potential long-term benefits in terms of blood pressure reduction and weight control probably outweigh any possible risks of participation.

Diet

The role of dietary changes in the management of hypertension has received a great deal of attention, most of which has focused on sodium. Although it is controversial whether excessive sodium intake may cause hypertension,[17] once hypertension has been established, "salt sensitivity" becomes more common and reduction in sodium intake is likely to be of benefit.[17-19] Other nutrients that have been examined in patients with hypertension include potassium and calcium, both of which have been shown to have antihypertensive effects.[19,20] Therefore, a diet low in sodium and enriched in potassium and calcium may be more effective in reducing blood pressure than a diet that restricts sodium only. An example of such a diet is the DASH diet (Dietary Approaches to Stop Hypertension), which has been shown to have an antihypertensive effect in adults with hypertension, even in those receiving antihypertensive medication.[21] The DASH diet was studied in a group of hypertensive adolescents, and was found to successfully lower systolic blood pressure when combined with counseling from a pediatric dietitian.[22] The DASH diet also incorporates measures designed to reduce dietary fat intake, an important strategy given the frequent presence of both hypertension and

elevated lipids in children and adolescents and the imperative to begin prevention of adult cardiovascular disease at as an early an age as possible.[5,11,23]

KEY POINT

Dietary changes to consider in hypertensive children include sodium restriction in combination with the "DASH" diet.

PHARMACOLOGIC MANAGEMENT

Historical perspective

The number of antihypertensive medications that have been systematically studied in children has increased markedly over the past two decades as a result of financial incentives provided to the pharmaceutical industry under the auspices of the 1997 *Food and Drug Modernization Act* (FDAMA) and successive legislation.[24] Thus, although the 2000 *Physicians' Desk Reference* contained pediatric dosing information approved by the U.S. Food and Drug Administration (FDA) for a minority of antihypertensive medications commonly used in children,[25] numerous antihypertensive medications are available now that have FDA-approved pediatric labeling. Although some antihypertensive medications continue to be used off label in children,[24] today's clinician should be able to prescribe agents with evidence-based dosing recommendations for most hypertensive youth.

Indications for pharmacotherapy

Experience in adults indicates that although blood pressure in some hypertensive patients may decline without treatment, in most it will likely persist and even progress over time.[26] This implies that once a hypertensive patient has started medication, lifetime treatment is likely necessary. This is readily accepted for adults given the known long-term adverse consequences of untreated or undertreated hypertension. However, because the long-term consequences of untreated hypertension in an asymptomatic, otherwise healthy child or adolescent remain unknown,[2] the decision to prescribe antihypertensive medications in a child or adolescent should not be made lightly. Some have even questioned whether antihypertensive medications

KEY POINT

Antihypertensive medication use in hypertensive children and adolescents should be limited to a few select indications because of the lack of evidence of long-term benefit.

should be prescribed for children and adolescents at all.[27] Therefore, a clear-cut indication for initiating pharmacotherapy should be established before commencing such treatment in children and adolescents.

Indications for use of antihypertensive medications in children and adolescents are listed in Table 40.2. Other indications for use of antihypertensive medications based on the premise of reducing future risk for developing cardiovascular disease or end-stage renal disease also have been proposed. For example, the presence of multiple cardiovascular risk factors (elevated blood pressure, hyperlipidemia, tobacco use, etc.) increases cardiovascular risk in an exponential rather than additive fashion.[23,28] Thus, antihypertensive therapy might be initiated if the hypertensive child or adolescent is known to have dyslipidemia or impaired glucose tolerance. Similarly, elevated nocturnal blood pressure, blunted nocturnal dipping on ambulatory blood pressure monitoring, or both increase the likelihood of developing hypertensive target-organ damage and other adverse cardiovascular outcomes,[29,30] so nocturnal hypertension also might be considered by some as a reasonable indication for pharmacologic therapy.

Choice of antihypertensive agent

Recommendations for choice of antihypertensive medications in adults are based on evidence from large-scale studies of hypertension treatment.[1] Many of these studies have compared the effects of different classes of antihypertensive agents on cardiovascular morbidity and mortality. Fortunately, traditional "hard" cardiovascular end points such as myocardial infarction are exceedingly rare in the pediatric age group, making it unlikely that similar studies will ever be conducted in children. Given this, the choice of initial antihypertensive agent for use in children remains empiric. Consideration for selection of antihypertensive medications has been summarized and includes the underlying cause of hypertension and the presence or absence of concurrent medical conditions.[31]

Diuretics and β-adrenergic blockers, which were recommended as initial therapy in the First and Second Task Force reports,[32,33] have a long track record of safety and efficacy in hypertensive children and are still appropriate for pediatric use, although they are now mostly used as second-line

Table 40.2 Indications for antihypertensive drug therapy in children

- Stage 2 hypertension
- Symptomatic hypertension
- Secondary hypertension
- Hypertensive target-organ damage
- Diabetes (types 1 and 2)
- Persistent hypertension despite nonpharmacologic measures

agents. Similarly, newer classes of agents, including angiotensin-converting enzyme inhibitors (ACEIs), calcium channel blockers, and angiotensin receptor blockers (ARBs), have now been shown to be safe and well tolerated in hypertensive children in industry-sponsored trials and may be prescribed if indicated.[31] As noted in a survey of North American pediatric nephrologists, these newer agents, particularly calcium channel blockers and ACE inhibitors, have become the most widely used initial agents in the pediatric age group.[34]

KEY POINT

All classes of antihypertensive agents may be considered for use in hypertensive children and adolescents when medications are indicated.

A notable point to make here is the importance of using ACEIs or ARBs in children with hypertensive chronic kidney disease (CKD). These classes of agents have been shown to result in better BP control than use of other drugs[35] and have the potential to reduce the rate of progression of CKD, especially if used in a regimen that includes lower blood pressure targets.[36] For these reasons, the most recent Kidney Disease Improving Global Outcomes (KDIGO) recommendations for treatment of hypertension in nondialysis CKD state that "We suggest that an ARB or ACE-I be used in children with ND [nondialysis] CKD in whom treatment with BP-lowering drugs is indicated."[37]

Approach to prescribing

As illustrated in Figure 40.1, antihypertensive drugs in children and adolescents are generally prescribed in a stepped-care manner. The patient is started on the lowest recommended dose of the initial agent, and the dose is increased until the highest recommended dose is reached or the child experiences adverse effects from the medication. At this point a second drug from a different class should be added, until the desired goal blood pressure is reached. Many antihypertensive drugs now have specific FDA-approved pediatric labeling, so generalists should restrict their choices to those agents. Recommended doses for selected antihypertensive agents for use in hypertensive children and adolescents are given in Table 40.3.

Our usual approach is to begin with a long-acting calcium channel blocker or ACEI and then add either a diuretic or β-blocker as the second agent. Many children and adolescents with "uncomplicated" primary hypertension may require two or more drugs to achieve target blood pressure. Children with secondary hypertension, particularly those with renal disease, almost always require multidrug regimens to achieve adequate blood pressure control. Combination antihypertensive preparations are widely available and offer advantages that may improve adherence

Step 1	Begin with the recommended initial dose of desired medication

If BP control is not achieved:

Step 2	Increase dose until desired BP target is reached, or maximum dose is reached

If BP control is not achieved:

Step 3	Add a second medication with a complementary mechanism of action

Proceed to highest recommended dose if necessary and desirable

If BP control is not achieved:

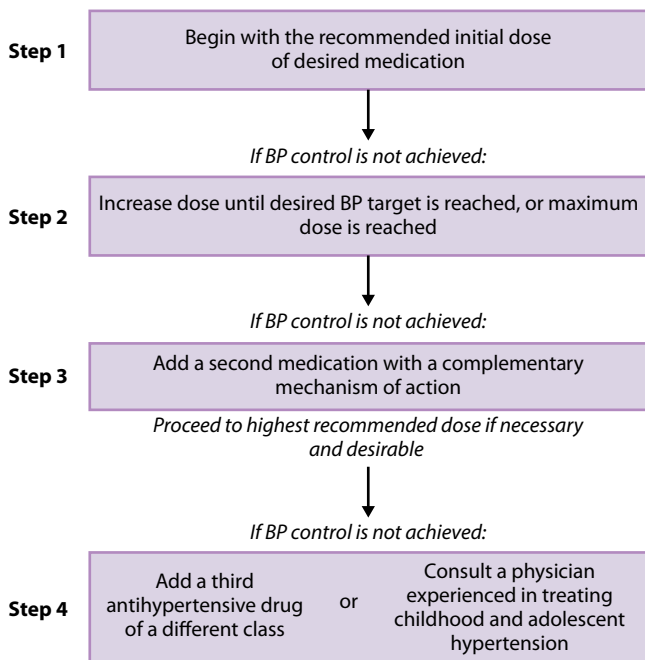
Step 4	Add a third antihypertensive drug of a different class	**or**	Consult a physician experienced in treating childhood and adolescent hypertension


Figure 40.1 Stepped-care approach to prescribing antihypertensive drugs in children.

to treatment.[38] Thus far, only one such preparation has been studied in children,[39] so it is difficult to recommend their widespread use at this time. However, they may be very useful in certain children, particularly those who require an ACEI or angiotensin receptor antagonist plus a diuretic; many preparations offering this combination are available.[38]

Goals of therapy

There are no clinical trial data available to guide the therapy of childhood hypertension; therefore, treatment goals issued by consensus organizations have been based on expert opinion. The 2004 Fourth Report recommended that for children with uncomplicated primary hypertension and no hypertensive target-organ damage, the target blood pressure should be below the 95th percentile for age, gender, and height, whereas for children with secondary hypertension, diabetes, or hypertensive target-organ damage, target blood pressure should be below the 90th percentile for age, gender, and height.[4] The 2009 European Society of Hypertension (ESH) pediatric guidelines recommended a goal of less than the 90th percentile for primary hypertension and less than the 75th percentile for nonproteinuric CKD and less than the 50th percentile for proteinuric CKD.[40] It should be noted that the Fourth Report goals are based on casual BP readings, whereas the ESH goals are based on mean ambulatory blood pressure. To further complicate matters, the KDIGO blood pressure guideline[37] endorsed a goal of below the 50th percentile for proteinuric CKD based on casual blood pressure measurements. How to reconcile these different recommendations is currently unclear. It does seem reasonable to try to achieve a blood pressure between the 90th and 95th

percentiles for patients with primary hypertension, and the ESCAPE trial results[36] certainly suggest that a lower blood pressure goal is appropriate for children with CKD.

LONG-TERM ISSUES IN HYPERTENSION TREATMENT

Treatment of childhood hypertension obviously does not end with the decision to prescribe antihypertensive medication. Ongoing monitoring of blood pressure, surveillance for medication side effects, periodic monitoring of electrolytes (in children treated with ACEIs, ARBs, or diuretics), counseling regarding other cardiovascular risk factors, and continued emphasis on therapeutic lifestyle changes also should be incorporated into the management plan. Home blood pressure measurement can be helpful in ensuring that blood pressure control has been achieved. In some patients, repeat ambulatory blood pressure monitoring (ABPM) may be necessary if office blood pressure measurements appear to indicate "resistant hypertension." ABPM also should be performed periodically in children with hypertensive CKD to assess for nocturnal or masked hypertension or both. Hypertensive target organ damage such as left ventricular hypertrophy, if present, should be reassessed periodically.[4]

It may be appropriate to consider withdrawal of drug therapy in selected children and adolescents. This involves an attempt at gradual reduction in medication after an extended course of good blood pressure control, with the eventual goal of completely discontinuing drug therapy. Although no comparable studies have been performed yet in children, experience in adults suggests that a substantial percentage of patients may remain normotensive for a time after withdrawal of active treatment.[26] Children with uncomplicated primary hypertension, especially obese adolescents who successfully lose weight and maintain their weight loss, are the best candidates for this "step-down" approach. These children should receive continued blood pressure monitoring after drug therapy is withdrawn and should continue nonpharmacologic treatment.

KEY POINT

In patients with chronic kidney disease, a lower achieved blood pressure may slow progression, so lower treatment goals have been recommended.

SPECIAL CLINICAL ISSUES

Hypertension in infancy

Even fewer data are available on the efficacy and safety of antihypertensive agents in infants than for older children. Although some recent industry-sponsored clinical trials have been extended to children younger than 6 years of age,[41] no industry-sponsored trial has included infants

Table 40.3 Recommended doses for selected antihypertensive agents for use in hypertensive children and adolescents

Class	Drug	Starting dose	Interval	Maximum dose*
Aldosterone receptor antagonists	Eplerenone	25 mg/day	QD–BID	100 mg/day
	Spironolactone†	1 mg/kg/day	QD–BID	3.3 mg/kg/day up to 100 mg/day
Angiotensin receptor blockers	Candesartan†	1–6 yr: 0.2 mg/kg/day;	QD	1–6 yr: 0.4 mg/kg/day
		6–17 yr: <50 kg 4–8 mg QD		>50 kg: 8–16 mg QD
		>50 kg: 8–16 mg QD		>50 kg: 32 mg/daily
	Losartan†	0.75 mg/kg/day (up to 50 mg QD)	QD	1.4 mg/kg/day (maximum, 100 mg QD)
	Olmesartan†	20–35 kg: 10 mg QD	QD	20–35 kg: 20 mg QD
		≥35 kg: 20 mg QD		≥35 kg: 40 mg QD
	Valsartan†	<6 yr: 5–10 mg/day	QD	<6 yr: 80 mg QD
		6–17 yr: 1.3 mg/kg/day (up to 40 mg QD)		6–17 yr: 2.7 mg/kg/day (up to 160 mg QD)
ACEIs	Benazepril†	0.2 mg/kg/day (up to 10 mg/day)	QD	0.6 mg/kg/day (up to 40 mg/day)
	Captopril+	0.3–0.5 mg/kg/dose	BID–TID	0.6 mg/kg/day (up to 450 mg/day)
	Enalapril‡	0.08 mg/kg/day	QD–BID	0.6 mg/kg/day (up to 40 mg/day)
	Fosinopril	0.1 mg/kg/day (up to 10 mg/day)	QD	0.6 mg/kg/day (up to 40 mg/day)
	Lisinopril†	0.07 mg/kg/day (up to 5 mg/day)	QD	0.6 mg/kg/day (up to 40 mg/day)
	Quinapril	5–10 mg/day	QD	80 mg/day
α- and β-Adrenergic antagonists	Carvedilol†	0.1 mg/kg/dose (up to 6.25 mg BID)	BID	0.5 mg/kg/dose up to 25 mg BID
	Labetalol†	2–3 mg/kg/day	BID	10–12 mg/kg/day (up to 1.2 g/day)
β-Adrenergic antagonists	Atenolol†	0.5–1 mg/kg/day	QD	2 mg/kg/day up to 100 mg day
	Bisoprolol/HCTZ	2.5/6.25 mg daily	QD	10/6.25 mg daily
	Metoprolol	1–2 mg/kg/day	BID	6 mg/kg/day (up to 200 mg/day)
	Propranolol‡	1 mg/kg/day	BID–QID	8 mg/kg/day (up to 640 mg/day)
Calcium channel blockers	Amlodipine†	0.06 mg/kg/day	QD	0.3 mg/kg/day (up to 10 mg/day)
	Felodipine	2.5 mg/day	QD	10 mg/day
	Isradipine†	0.05–0.15 mg/kg/dose	TID–QID	0.8 mg/kg/day up to 20 mg/day
	Extended-release nifedipine	0.25–0.5 mg/kg/day	QD–BID	3 mg/kg/day (up to 120 mg/day)
Central α-agonist diuretics	Clonidine†	5–20 mcg/kg/day	QD–BID	25 mcg/kg/day (up to 0.9 mg/day)
	Amiloride	5–10 mg/day	QD	20 mg/day
	Chlorthalidone	0.3 mg/kg/day	QD	2 mg/kg/day (up to 50 mg/day)
	Furosemide‡	0.5–2 mg/kg/dose	QD – BID	6 mg/kg/day
	HCTZ	0.5–1 mg/kg/day	QD	3 mg/kg/day (up to 50 mg/day)
Vasodilators	Hydralazine	0.25 mg/kg/dose	TID – QID	7.5 mg/kg/day (up to 200 mg/day)
	Minoxidil	0.1–0.2 mg/kg/day	BID – TID	1 mg/kg/day (up to 50 mg/day)

Abbreviations: ACEI, angiotensin converting enzyme inhibitor; BID, twice daily; HCTZ, hydrochlorothiazide; QD, once daily; QID, four times daily; TID, three times daily.

* The maximum recommended adult dose should not be exceeded.
† Information on preparation of a stable extemporaneous suspension is available for these agents.
‡ Available as a FDA approved commercially supplied oral solution approved by the U.S. Food and Drug Administration.

younger than 1 year of age. Therefore, use of antihypertensive medications in infants is by necessity based on expert opinion and data derived from experience in older patients.

Indications for starting antihypertensive drugs in infants are driven by clinical circumstances. In general, critically ill premature infants with persistent blood pressure elevation substantially above published normative values should be promptly treated. More stable neonates should probably be treated if the majority of blood pressure readings over a 24- to 36-hour period are elevated. Recently compiled normative data for preterm infants may be useful in determining which infants should be treated.[42,43] For older infants, particularly those who have been discharged from the nursery and are being followed as outpatients, blood pressure should be confirmed to be elevated over several weeks before drug treatment is initiated.

> ## KEY POINT
>
> Given the uncertainties regarding diagnosis thresholds for hypertension in infants, it is recommended to defer treatment in asymptomatic patients until sustained blood pressure elevation has been demonstrated.

As in older patients, therapy of hypertensive infants should be tailored to the severity of the hypertension and the infant's overall clinical status.[42] For example, critically ill infants with severe hypertension should be treated with an intravenous agent administered by continuous infusion, because this will allow the greatest control over the magnitude and rapidity of the blood pressure reduction. On the other hand, relatively well infants with mild hypertension may be treated with oral antihypertensive agents. Recommended doses for both intravenous and oral antihypertensive drugs in infants can be found in Table 40.4.

Most classes of antihypertensive drugs that are used in older children have been applied to the treatment of hypertensive infants,[44] and probably most can be safely used when treatment is indicated. The exceptions to this, at least on theoretical grounds, are probably ACEIs. The renin-angiotensin system is crucial to normal renal development both prenatally and postnatally. Experimental data indicate that exposure of the immature kidney to ACE inhibition may impair the completion of normal development and even cause histopathologic lesions.[45,46] Thus, it may be appropriate to avoid ACEIs in infants until they have reached a corrected post-menstrual (post-conceptual) age of 44 weeks.

Severe acute hypertension

The pathophysiology, management, and outcome of severe acute hypertension in children and adolescents have been reviewed in detail elsewhere.[47] Perhaps the most important aspect to highlight here is that hypertensive encephalopathy occurs frequently in children and adolescents with severe hypertension, particularly in younger children. Given this, it is clear that blood pressure reduction in such patients should be performed in a slow, controlled fashion to prevent ischemic strokes and other complications arising through loss of normal autoregulatory processes.[47–49]

Although evidence-based recommendations are lacking, the usual goal in treatment of a hypertensive emergency is to reduce the blood pressure by no more than 25% over the first 8 hours, with a gradual return to normal or goal blood pressure over 24 to 48 hours.[47] Given the need for controlled blood pressure reduction, treatment of hypertensive emergencies in children and adolescents should be initiated with a continuous infusion of an intravenous antihypertensive, with nicardipine and labetalol finding the greatest popularity in many centers.[50–52] Other commonly used intravenous agents given by infusion include esmolol and sodium nitroprusside; use of the latter agent is limited by the accumulation of thiocyanide.[48]

> ## KEY POINT
>
> Intravenous antihypertensive medications are preferred in most patients with severe acute hypertension.

For less severe degrees of blood pressure elevation, or if the child's symptoms permit, oral antihypertensive agents can be used. Options include isradipine, hydralazine, and clonidine, among others. Short-acting nifedipine has fallen out of favor because of safety concerns,[53] and its use was not endorsed in the Fourth Report. Recommended doses for drugs used to treat severe hypertension in children and adolescents can be found in Table 40.5.

Pheochromocytoma

Although rare as a cause of hypertension in childhood,[54] pheochromocytomas present a unique set of management challenges. Many children with pheochromocytomas initially present with severe, symptomatic hypertension of unknown cause.[55] Such children require careful immediate stabilization and gradual blood pressure reduction, as described in the preceding section, until such time as the necessary studies can be obtained to establish the diagnosis. Although theoretically the α- and β-blocking agent labetalol may seem uniquely well suited for treatment of hypertension caused by a pheochromocytoma, in practice a continuous infusion of any of the intravenous antihypertensives listed in Table 40.4 could be used for initial blood pressure management. Phentolamine has also been advocated in such patients,[56] although pediatric experience with this agent is extremely limited.

Table 40.4 Recommended doses for selected antihypertensive agents for treatment of hypertensive infants

Class	Drug	Route	Dose	Interval	Comments
ACE inhibitors*	Captopril	Oral	<3 m: 0.01–0.5 mg/kg/dose	TID	1.First dose may cause rapid drop in BP, especially if receiving diuretics
			Max 2 mg/kg/day > 3m: 0.15–0.3 mg/kg/dose Max 6 mg/kg/day		2. Monitor serum creatinine and K+
	Enalapril	Oral	0.08–0.6 mg/kg/day	QD–BID	
	Lisinopril	Oral	0.07–0.6 mg/kg/day	QD	
α-and β-Antagonists	Labetalol	Oral	0.5–1 mg/kg/dose	BID–TID	Heart failure, BPD relative contraindications
		IV	up to 10 mg/kg/day 0.20–1 mg/kg/dose (bolus)	Q4-6 hr	
		IV	0.25–3 mg/kg/hr	Infusion	
	Carvedilol	Oral	0.1 mg/kg/dose up to 0.5 mg/kg/dose	BID	May be useful in heart failure
β-Antagonists	Esmolol	IV	100–500 mcg/kg/min	Infusion	Very short-acting, constant infusion necessary.
	Propranolol	Oral	0.5–1 mg/kg/dose	TID	Monitor heart rate; avoid in BPD
			Max 8–10 mg/kg/day		
Calcium channel blockers	Amlodipine	Oral	0.05–0.3 mg/kg/dose up to 0.6 mg/kg/day	QD	All may cause mild reflex tachycardia
	Isradipine	Oral	0.05–0.15 mg/kg/dose up to 0.8 mg/kg/day	QID	
	Nicardipine	IV	0.5-4 mcg/kg/min	Infusion	
Central α-agonist	Clonidine	Oral	5–10 mcg/kg/day up to 25 mcg kg/day	TID	May cause mild sedation
Diuretics	Chlorothiazide	Oral	5–15 mg/kg/dose	BID	Monitor electrolytes
	Hydrochlorothiazide	Oral	1–3 mg/kg/dose	QD	
	Spironolactone	Oral	0.5–1.5 mg/kg/dose	BID	
Vasodilators	Hydralazine	Oral	0.25–1 mg/kg/dose up to 7.5 mg/kg/day	TID–QID	Tachycardia and fluid retention are common side effects
		IV	0.15–0.6 mg/kg/dose	q4 hr	
	Minoxidil	Oral	0.1–0.2 mg/kg/dose	BID–TID	Tachycardia and fluid retention common side effects; prolonged use causes hypertrichosis
	Sodium nitroprusside	IV	0.5–10 mcg/kg/min	Infusion	Thiocyanate toxicity can occur with prolonged (>72 h) use or in renal failure

Abbreviations: BID, twice daily; BPD, bronchopulmonary dysplasia; IV, intravenous; Q, every; QD, once daily; QID, four times daily; TID, three times daily

Table 40.5 Antihypertensive drugs for management of acute severe hypertension in children

Useful for severely hypertensive patients with life-threatening symptoms				
Drug	Class	Dose	Route	Comments
Esmolol	β-Adrenergic blocker	100–500 mcg/kg/min	IV infusion	Very short-acting—constant infusion preferred. May cause profound bradycardia.
Hydralazine	Direct vasodilator	0.2–0.6 mg/kg/dose	IV, IM	Should be given q4hr when given IV bolus.
Labetalol	α- and β-Adrenergic blocker	*Bolus:* 0.20–1.0 mg/kg/dose, up to 40 mg/dose *Infusion:* 0.25–3.0 mg/kg/hr	IV bolus or infusion	Asthma and overt heart failure are relative contraindications.
Nicardipine	Calcium channel blocker	*Bolus:* 30 mcg/kg up to 2 mg/dose *Infusion:* 0.5–4 mcg/kg/min	IV bolus or infusion	May cause reflex tachycardia.
Sodium nitroprusside	Direct vasodilator	0.5–10 mcg/kg/min	IV infusion	Monitor cyanide levels with prolonged (>72 hr) use or in renal failure; or coadminister with sodium thiosulfate.
Useful for severely hypertensive patients with less significant symptoms				
Drug	Class	Dose	Route	Comments
Clonidine	Central α-agonist	0.05–0.1 mg/dose, may be repeated up to 0.8 mg total dose	po	Side effects include dry mouth and drowsiness.
Enalaprilat	ACE inhibitor	5–10 mcg/kg/dose up to 1.25 mg/dose	IV bolus	May cause prolonged hypotension and acute renal failure, especially in neonates.
Fenoldopam	Dopamine receptor agonist	0.2–0.8 mcg/kg/min	IV infusion	Produced modest reductions in BP in a pediatric clinical trial in patients up to 12 years.
Hydralazine	Direct vasodilator	0.25 mg/kg/dose up to 25 mg/dose	PO	Extemporaneous suspension stable for only 1 week
Isradipine	Calcium channel blocker	0.05–0.1 mg/kg/dose up to 5 mg/dose	PO	Stable suspension can be compounded.
Minoxidil	Direct vasodilator	0.1–0.2 mg/kg/dose up to 10 mg/dose	PO	Most potent oral vasodilator; long-acting.

Abbreviations: ACE, angiotensin-converting enzyme; BP, blood pressure; M, intramuscular; IV, intravenous; kg, kilogram; mcg, microgram; mg, milligram; PO, oral.

Once the diagnosis of pheochromocytoma has been made, the child's blood pressure should be stabilized until the tumor can be surgically removed. Phenoxybenzamine, a potent α-adrenergic blocker, is usually recommended as the primary agent for this phase of management.[56,57] The phenoxybenzamine dose is increased gradually (every 48 hours) until the desired blood pressure is achieved. β-Adrenergic blockade is frequently advocated as adjunctive therapy to counter tachycardia in patients treated with phenoxybenzamine. Recently, some authors have recommended use of the peripheral α-blocker doxazosin because of a more favorable side-effect profile compared to phenoxybenzamine.[58]

KEY POINT

Medical management of pheochromocytoma-related hypertension should begin with α-blockade, with β-blockade added later.

Definitive treatment of pheochromocytoma requires either open or laparoscopic removal of the tumor. In addition to strict blood pressure control, as discussed earlier, preoperative management also includes volume replacement and monitoring for arrhythmias produced by surges of catecholamine release from the tumor.[55–58] Intraoperatively,

blood pressure surges and arrhythmias may occur as a result of manipulation of the tumor. These complications can be treated with use of rapidly acting intravenous antihypertensive agents and β-adrenergic blockade. Volume resuscitation may be required immediately following removal of the tumor.[57] Although successful tumor removal should result in cure of the child's hypertension, periodic monitoring of plasma catecholamines and metanephrines should be performed to detect potential tumor recurrence.

Renovascular hypertension

Although the term renovascular hypertension can be used to describe hypertension caused by a variety of conditions, it most often implies hypertension secondary to renal artery stenosis (RAS). Children with RAS may have acute presentations with severe, symptomatic hypertension, or they may be asymptomatic.[59] As in other forms of secondary hypertension, initial BP control can be achieved with any of a variety of nonspecific agents, particularly vasodilators. Addition of a diuretic can greatly improve blood pressure control, because a component of volume overload is usually present in patients with RAS, especially with unilateral disease.

The use of ACEIs in patients with RAS is controversial. They are clearly contraindicated in bilateral RAS and or in RAS with a single kidney (including RAS in transplanted kidneys) because of the likelihood of provoking acute kidney injury.[60] However, they may be very effective in cases in which RAS is unilateral and surgery or angioplasty is unable to be performed, or when intrarenal stenoses are present that are not amenable to surgery or angioplasty. In such cases, serial ultrasonography to follow renal growth, serial nuclear scans, or both to follow renal perfusion may be helpful in determining whether to continue ACE inhibition.

KEY POINT

In patients with renovascular hypertension, antihypertensive medications are used frequently—in the initial management until anatomic correction is achieved and long term when there is residual hypertension or vascular lesions that cannot be corrected.

As hypertension caused by RAS is potentially curable, the chief issue in managing children with renovascular hypertension is whether and when they should undergo angioplasty or surgical revascularization.[59] Although percutaneous transluminal angioplasty (PCTA) offers the advantage of being less invasive than surgical revascularization, results in children with renovascular hypertension may not be as good as in adults, primarily because RAS in children is typically caused by fibromuscular dysplasia and may be associated with either multiple stenoses or intrarenal branch vessel stenoses. This contrasts with RAS in adults, which is typically related to buildup of atherosclerotic plaque at the origin of the renal arteries. In a series of 48 PCTA procedures performed in 33 children, some of whom required multiple procedures because of restenosis or bilateral disease, most children had improvement of blood pressure following PCTA, although only 9 were normotensive off all medications.[61]

Surgical revascularization, while admittedly more invasive than PCTA, seems to offer a greater likelihood of complete cure of the child's hypertension. At the University of Michigan, for example, 79% of children who underwent various revascularization procedures were considered cured.[62] Surgery is preferred to PCTA in children with multiple stenoses and also can be successful when PCTA has failed.

Finally, although PCTA and surgery for RAS have been performed in very young children[63,64] when renovascular hypertension is diagnosed in infants or toddlers, it may be prudent to manage these children medically until they have grown sufficiently so that a definitive procedure can be safely performed. In such children, careful follow-up with serial renal ultrasonography to assess renal growth and serial echocardiograms to monitor for the development of left ventricular hypertrophy can be crucial in determining when surgery or PCTA should be undertaken.

SUMMARY

The management of pediatric hypertension begins by staging the hypertension based on standard tables, evaluating the patient for the presence of symptoms or target organ damage, and determining if there is an underlying medical condition that warrants more aggressive treatment. Most patients are initially treated with nonpharmacologic intervention initially, although severe, symptomatic hypertension may warrant intravenous medications in an intensive care unit. There are increasing data on the safety and efficacy of antihypertensive medications in children, but few comparative or long-term data are available to guide use of a specific agent. However, in some instances a specific agent is indicated.

REVIEW QUESTIONS

1. A 16-year-old obese boy with hypertension and type 2 diabetes has been referred to you for evaluation. His office blood pressure is 145/82 mm Hg. He has LVH on an echocardiogram and a mildly elevated urinary microalbumin-to-creatinine ratio. The referring physician prescribed hydrochlorothiazide 50 mg daily. Your recommendation should be:
   a. Order ambulatory blood pressure monitoring to assess his blood pressure control.
   b. Add metoprolol 100 mg daily to further reduce his blood pressure.
   c. Start regular aerobic exercise and a low-sodium diet.
   d. Stop the hydrochlorothiazide and start lisinopril 10 mg daily.

2. An 8-year-old girl has been found to have confirmed office hypertension. Her weight and BMI are both at the 97th percentile for age, and her height is at the 40th percentile. Which of the following changes should be made to her daily routine?
   a. Restriction of caloric intake to 1500 calories/day
   b. Supplementation with potassium chloride
   c. 30 minutes of brisk walking around the block with her mother after school
   d. Scheduling for an assessment of obesity in a pediatric endocrinology clinic

3. A 12 year-old girl treated with quinapril for primary hypertension needs the following issues addressed at her quarterly follow-up appointments:
   a. Use of contraception
   b. CBC monitoring
   c. Edema assessment
   d. a and b
   e. a, b, and c

4. When deciding whether to start an antihypertensive medication, the following is the most important consideration:
   a. The age of the child
   b. The presence of obesity
   c. The presence of left ventricular hypertrophy
   d. The success of lifestyle modification

5. A 12-year-old girl with pheochromocytoma has been referred to you by the oncology service for assistance with blood pressure management until surgery, which is scheduled to take place in 2.5 weeks. Which of the following strategies should be employed to control her BP?
   a. Sodium restriction and bedrest
   b. Start treatment with oral labetalol
   c. Start treatment with oral propranolol
   d. Sodium restriction and start phenoxybenzamine
   e. Start treatment with doxazosin

6. An 8-year-old boy presents to the emergency department after having two tonic-clonic seizures. Blood pressures obtained by ambulance personnel were 150 to 168/95 to 118 mm Hg. Ativan has been given and seizures have stopped. Which of the following measures would not be appropriate?
   a. Reduction of blood pressure with sublingual nifedipine to 110/70 mm Hg
   b. Insertion of an arterial monitoring line
   c. Obtain a comprehensive medical history
   d. Order nicardipine from the pharmacy

7. A 12-year-old boy is referred from the urology department with new-onset blood pressure elevation in the setting of known reflux nephropathy. In the clinic, his blood pressure measurements fulfill criteria for stage 2 hypertension. Initial evaluations are notable for an estimated GFR of 65 mL/min/1.73 m^2 and 3+ proteinuria by dipstick. Which of the following drug classes would be considered most appropriate in this setting?
   a. Nondihydropyridine calcium channel blockers
   b. Loop diuretics
   c. Angiotensin receptor antagonists
   d. Direct-acting vasodilators
   e. β-Adrenergic blockers

8. Which of the following medication classes should be avoided as primary therapy in the hypertensive female athlete?
   a. Angiotensin-converting enzyme inhibitors
   b. Diuretics
   c. β-blockers
   d. Calcium channel blockers
   e. a and b

9. Recommendations for staging hypertension in children and adolescents provide guidance for clinicians in evaluating and managing patients with elevated blood pressure. The new staging system recommends immediate institution of antihypertensive medications for patients with blood pressure in which of the following stages?
   a. Stage 2 hypertension
   b. Normal blood pressure
   c. Stage 1 hypertension
   d. Pre-hypertension
   e. a and c

10. You receive a phone call from a neonatologist in a neighboring community. She has been caring for a now 6-week-old, former 28 weeks of gestation premature infant. She is concerned about some high blood pressure readings and wants your recommendations regarding treatment. What additional information do you need to make the *best* recommendation?
    a. The infant's current weight and length
    b. The infant's medication list
    c. Details about how the infant's blood pressure is being measured

d. a and b
d. b and c

11. An otherwise healthy 16-year-old boy presents with office blood pressure readings of 160/100 mm Hg in both upper extremities. He is not obese, but there is a strong family history of cardiovascular disease. He initially denies any symptoms, but at the end of the visit, his mother tells you that he occasionally complains of his legs aching during soccer, and that he sometimes has abdominal pain after eating. What medication should you prescribe while you are waiting for test results to come back?
    a. Lisinopril
    b. Felodipine
    c. Valsartan
    d. Metoprolol

Inherited renal disorders

Tubulopathies

DETLEF BOCKENHAUER

Assuming a glomerular filtration rate of 100 mL/min, the kidneys of an average adult each day filter approximately 150 L of plasma each day, containing approximately 20 mol of sodium (Na^+), the equivalent of more than a kilogram of table salt. Thus, without tubules, we all would have to drink 150 L a day and eat a kilogram of salt to keep up with urinary losses. The enormity of these numbers demonstrates the importance of proper tubular function. Typically, more than 99% of filtered salt and water are reabsorbed. Yet, the tubules not only need to accomplish the massive bulk transport of water and solutes, they also need to finely regulate the precise amount of reabsorption to balance variable intake and extrarenal losses, to maintain volume and electrolyte homoeostasis.

ORGANIZATION OF TUBULES

The enormous feat of complex tubular functions is accomplished by a whole orchestra of tubular transporters arranged along the entire nephron. Each transporter plays a specific role in coordinating a portion of tubular function. Much has been learned about the individual transport processes through observations of patients in whom one or more of these transport processes is defective, or patients with tubulopathies.

Both from a functional and a histoanatomic perspective, the nephron can be divided into four different segments (Figure 41.1):

1. Proximal tubule (PT)
2. Loop of Henle
3. Distal convoluted and connecting tubule (DCT)
4. Collecting duct (CD)

Disorders of the loop of Henle are mainly restricted to the thick ascending limb (TAL). In general, high-capacity bulk transport occurs in the PT, whereas the fine tuning of reabsorption occurs mostly in the distal end, the CD. Disorders of each segment tend to have a distinctive "fingerprint" of clinical and biochemical abnormalities that informs the diagnosis (Table 41.1).

KEY POINT

The renal tubule can be separated morphologically and functionally into four main segments: PT, loop of Henle, DCT, and CD.

DISORDERS OF THE PROXIMAL TUBULE

PHYSIOLOGY

The PT is not only the site of high-capacity transport, but it is also the exclusive site of reabsorption for several solutes, such as low-molecular-weight (LMW) proteins, amino and organic acids, glucose, and phosphate.[1] Because a sizeable proportion of albumin is also filtered, PT dysfunction is associated with moderately elevated urinary albumin levels, which can lead to confusion with glomerular disorders.[2] Albumin, like LMW proteins and a host of other solutes, is taken up by the proximal tubular epithelial cells
Figure 41.1 Schematic of a nephron with respect to salt and water (H_2O) reabsorption. Shown is a schematic of a nephron depicting the four main segments for sodium (Na^+) reabsorption. The indicated percentages for sodium and water reabsorption are rough estimates and may vary with clinical conditions.

through the promiscuous receptors megalin and cubilin, which are then internalized with the cargo into endosomes (Figure 41.2).[3]

Defects in PT can range from very specific dysfunction, such as isolated renal glucosuria, caused by impaired function of the Na^+-glucose cotransporter SGLT2 (SLC5A2),[4] to a generalized dysfunction of the PT. Clinically, cases of generalized PT dysfunction with glucosuria, acidosis, and hypophosphatemic rickets were first described in the 1930s by De Toni,[5] Debre et al.,[6] and Fanconi,[7] and consequently this constellation of symptoms is referred to as De Toni–Debre-Fanconi syndrome, or just renal Fanconi syndrome. It can be acquired or inherited, either isolated or in the context of systemic disorders, such as mitochondrial cytopathies or nephropathic cystinosis (Table 41.2).[8]

CYSTINOSIS

Cystinosis, albeit a rare disorder with an estimated incidence of approximately less than 1 in 100,000, is the most common inherited cause of renal Fanconi syndrome in children.[9] The underlying gene, *CTNS,* encodes a transporter involved in exporting cysteine from lysosomes.[10]

Consequently, impaired CTNS function leads to intracellular cystine accumulation.[11] However, how exactly this accumulation leads to cellular damage has yet to be clarified, although several hypothesis have been proposed, such as increased apoptosis, impaired energy production, and altered glutathione metabolism.[12]

Clinical features and diagnosis

Although cystinosis is a multiorgan disorder, the renal manifestations initially dominate, potentially because of the high cystine turnover in the PT from amino acid and LMW protein reabsorption. Measurement of urinary excretion of several LMW proteins, such as α_1- and β_2-microglobulins, can be used as markers for LMW proteinuria, but retinol-binding protein has been shown to have the highest sensitivity and specificity[13] for proximal tubular proteinuria.

Presentation is usually in the first 2 years of life with polyuria or polydipsia, failure to thrive, and rickets. Biochemical testing reveals the typical features of renal Fanconi syndrome (Table 41.3). However, because cystinosis affects most cells, other renal segments can be affected: glomerular

Abbreviations: AD, autosomal dominant; AME, apparent mineralocorticoid excess; AR, autosomal recessive; CD, collecting duct; DCT, distal convoluted tubule; GRA, glucocorticoid-remediable hypertension; HEP, hypertension with exacerbation in pregnancy; PHA, pseudohypoaldosteronism; PT, proximal tubule; TAL, thick ascending limb of the loop of Henle.

Note: [↑], level elevated; [↓], level decreased; [→], normal; combination of [↑] and [→], level normal or elevated; combination of [↓] and [→], level normal or low.

[*] The upper eight rows (un-bold) list disorders of salt wasting (hypovolemia, low/normal blood pressure), whereas the lower five rows (**bold**) list disorders of salt retention (hypervolemia, hypertension). Bartter type 1 and 2 (TAL) and AME (CD) have identical biochemical profiles, but Bartter syndrome is associated with hypovolemia, whereas AME is associated with hypervolemia and hypertension.
Figure 41.2 Uptake of low-molecular-weight protein in the proximal tubule. Low-molecular-weight proteins and many other solutes bind to the receptors megalin or cubilin and are subsequently incorporated into endosomes. The proteins are degraded in lysosomes, a process that involves CLCN5. The receptors (megalin and cubilin) are recycled back to the apical membrane. OCRL is involved in regulation of the endosomal trafficking. AMN, amnionless.

function deteriorates with time, and other tubular features, such as secondary nephrogenic diabetes insipidus, have also been reported.[14]

Once suspected, the diagnosis is easily established by slit-lamp examination of the eyes, which demonstrates characteristic cystine crystals in virtually all children older than 16 months of age.[15] The absence of crystals before this age does not exclude the diagnosis. The diagnosis can be confirmed by measurement of an increased leukocyte cystine content or genetic testing, or both. Most children with typical clinical features of cystinosis have identifiable biallelic mutations in *CTNS*.[16]

Later in life, other types of organ dysfunction can become apparent, such as hypothyroidism, myopathy with swallowing dysfunction, retinal blindness, diabetes mellitus, male hypogonadism, and pulmonary and central nervous system dysfunction.[9]

Table 41.2 Causes of renal Fanconi syndrome

Isolated Inherited Renal Fanconi syndrome
- Autosomal dominant
- Autosomal recessive
- X-linked

Multiorgan Disorders
- Cystinosis
- Tyrosinemia
- Lowe syndrome
- Galactosemia
- Fructosemia
- Wilson disease
- Mitochondrial cytopathies
- Fabry disease (in addition to glomerular involvement)

Acquired Fanconi Syndrome
- Antiretroviral agents (tenofovir)
- Chemotherapy (ifosfamide, cisplatin)
- Cyclosporine
- Valproic acid
- Aminoglycosides
- Heavy metal poisoning
- Glue sniffing
- Aristolochic acid (Chinese herb nephropathy)

Treatment and prognosis

Treatment used to be just supportive, by replacing renal fluid and solute losses, enhancing nutrition, and treating the rickets. Patients developed end-stage renal disease (ESRD) in the

Table 41.3 Clinical and biochemical features of renal Fanconi syndrome

Clinical Features
- Polyuria or polydipsia
- Rickets
- Failure to thrive

Biochemical Features
- Hypokalemia
- Hypophosphatemia with renal phosphate wasting (low TMP/GFR)
- Metabolic non-anion gap acidosis
- Elevated parathyroid hormone
- Hypercalciuria
- Glucosuria
- Low-molecular-weight proteinuria
- Amino aciduria
- Organic aciduria

Abbreviations: TMP/GFR, tubular maximum reabsorption for phosphate

first or second decade of life, along with other organ manifestations. Death typically occurred before the third decade of life. The prognosis, however, was transformed with the introduction of cysteamine treatment in the 1980s. Cysteamine acts by entering the lysosomes and reducing cystine to cysteine, which can then exit the lysosome through a different transporter.[17]

KEY POINTS

- Cystinosis manifests clinically with failure to thrive, features of Fanconi syndrome, and photophobia.
- Leukocyte cysteine level and gene testing establish the diagnosis.
- Cysteamine treatment delays ESRD and other complications and prolongs life expectancy.

Cysteamine is prescribed in a dose of 60 to 90 mg/kg/day, or 1.3 to 1.95 g/m^2/day, given in divided in 6-hourly doses. With appropriate cysteamine treatment early in life, growth is improved, ESRD can often be deferred into the third decade of life or beyond, and other organ manifestations can be similarly delayed.[18] Side effects include a thiol-like taste and odor, which can induce vomiting. Dosage should be gradually increased so that the patient can become used to it. In rare instances, vascular elbow lesions, consistent with angioendotheliomatosis, have been reported; these lesions appear to be associated with excess cysteamine administration and improve with dose reduction.[19] The eye crystals, which can cause photophobia and pain, are not affected by systemic cysteamine treatment, but they dissolve with long-term topical application of cysteamine eye drops (6 to 12 times per day).[15] Clinical Vignette 41.1 describes a case of cystinosis in a young child.

Clinical Vignette 41.1

A 2-year-old boy presented with a several-month history of failure to thrive and bowing of his legs. The parents reported that he had little interest in food, but he constantly drank water.

Physical examination revealed a malnourished child with height below the third percentile and weight well below the third percentile. Vital signs were normal. He had clinical signs of rickets with widened wrists, a rickety rosary, and tibial bowing. Laboratory studies revealed metabolic acidosis, hypokalemia, hypophosphatemia, and elevated creatinine. Urine tests showed glucosuria, phosphate wasting, highly elevated levels of retinol-binding protein, albuminuria, and generalized aminoaciduria. Slit-lamp examination of his eyes showed corneal crystals, suggesting the diagnosis of cystinosis. The diagnosis of cystinosis was confirmed by an elevated leukocyte cystine content and genetic testing.

LOWE SYNDROME

Lowe syndrome is a rare multiorgan disorder with an estimated prevalence of less than 1 in 500,000.[20] It was first described in 1952 by Charles Lowe et al.[21] as the combination of "organic-aciduria, decreased renal ammonia production, hydrophthalmos, and [intellectual impairment]." It is an X-linked recessive disorder, and in 1992 the underlying gene was cloned and named *OCRL*.[22] *OCRL* encodes a phosphatidylinositol 4,5-bisphosphate 5-phosphatase located in the Golgi apparatus.[23] Phosphatidylinositol phosphates (PIPs) serve as important recognition molecules for intracellular membranes and thus are important for intracellular trafficking.[24] In addition to the phosphatase domain, the OCRL protein contains several other domains involved in endosomal trafficking by protein-protein interactions.[25] This protein has been shown to interact directly with clathrin[26,27] and IPIP[27] (inositol phosphatase interacting protein of 27 kDa) A and B (also referred to as Ses1 and 2), two important regulators of endosomal trafficking.[28,29]

KEY POINTS

- Lowe syndrome is characterized by congenital cataracts, intellectual impairment, and selective proximal tubular dysfunction.
- LMW proteinuria (retinol-binding protein and β$_2$-microglobulin) is common.
- Hypercalciuria is common.

Clinical features and diagnosis

Lowe syndrome is characterized by the triad of congenital cataracts, mental impairment, and proximal tubular dysfunction, yet incomplete phenotypes are increasingly recognized in patients without obvious eye findings or mental impairment.[30,31] Clearly, there is overlap with Dent disease (see later).

Patients are typically recognized at birth because of the cataracts, the muscular hypotonia, and, if tested, the LMW proteinuria. The developmental delay becomes apparent later. The diagnosis can be confirmed by genetic testing.

Lowe syndrome is often cited as a cause of renal Fanconi syndrome; however, although proximal tubulopathy is clearly part of the syndrome, it is usually selective.[32] Given the importance of endosomal trafficking for proximal tubular uptake of LMW proteins and a host of other solutes, it is not surprising that LMW proteinuria (retinol-binding protein and β$_2$-microglobulin) is the predominant renal feature in Lowe syndrome. Hypercalciuria with or without nephrocalcinosis is also typically present. In contrast, phosphate wasting and metabolic acidosis are inconsistent features, and glucosuria is rarely seen.[33]

Other clinical features may include glaucoma, seizures, growth retardation, areflexia, nontender joint swelling and arthropathy, subcutaneous nodules, and platelet dysfunction with increased risk for hemorrhage.[20,34,35] Because circulating vitamin D is bound to an LMW binding protein and is taken up into the proximal tubular epithelial cell through megalin-dependent endocytosis before 1-α-hydroxylation, this process is impaired in Lowe syndrome, as in all other diseases with LMW proteinuria, and rickets can develop.[36]

Behavioral abnormalities within the autistic spectrum are also frequently seen and can be very stressful to the families.[37] Cryptorchidism is seen in approximately one-third of patients, but usually testes descend without medical intervention.[34]

How exactly mutations in *OCRL* cause these variable symptoms is not fully clear. Beyond the role in endocytosis and intracellular trafficking, *OCRL* has also been implicated in a wide range of cellular processes, including regulation of the actin skeleton, cell migration, cell polarity, cell-cell interaction, cytokinesis, mitochondrial function, and cilia formation.[38,39]

Treatment and prognosis

No specific treatment is available for Lowe syndrome, and management is entirely supportive. In those patients with evidence of acidosis or phosphate wasting, bicarbonate and phosphate supplementation is indicated. Parathyroid hormone (PTH) levels should be checked and, if elevated, treated carefully with 1-α-hydroxylated forms of vitamin D. Oversupplementation could, of course, worsen the hypercalciuria. In those patients with nephrocalcinosis or stones, citrate supplementation should be considered.

The bleeding diathesis can be ameliorated by tranexamic acid (Lysteda), and this should be considered prophylactically before surgical interventions. Carnitine is also lost in the urine, and supplementation in deficient patients can restore normal levels.[40] Lowe syndrome is associated with progressive impairment of kidney function, and ESRD typically occurs in the fourth to fifth decade of life.

DENT DISEASE

Dent disease is an X-linked recessive disorder characterized by LMW proteinuria (e.g., retinol-binding protein and β$_2$-microglobulin) and hypercalciuria, with or without nephrocalcinosis and development of renal stones. Like Lowe syndrome, Dent disease is definable as a selective proximal tubulopathy. Metabolic acidosis is not present, and, indeed, patients have been shown to have normal urinary acidification.[41] Phosphate wasting, aminoaciduria, and glucosuria are rarely present.

Genetics

The first causative gene was identified as *CLCN5* in 1996.[42] *CLCN5* encodes a chloride (Cl^-)–proton antiporter expressed in the PT and involved in endosomal acidification.[43] This likely explains the LMW proteinuria (see Figure 41.2). The hypercalciuria is more difficult to explain. Some evidence suggests that hypercalciuria is partly enteral, rather than being caused by direct impairment of proximal calcium (Ca^{2+}) reabsorption:

- Adults are normocalciuric when fasting.[44,45]
- Thiazides, which stimulate proximal tubular Ca^{2+} reabsorption, can lower urinary Ca^{2+} excretion in patients with Dent disease.[46,47]
- Circulating levels of PTH are typically below the mean of the normal range.

Consistent with this evidence, sophisticated observations in a mouse model of Dent disease identified low total levels of vitamin D, yet with an increased ratio of fully hydroxylated vitamin D compared with 25-OH vitamin D.[43] This mouse model did not actually exhibit hypercalciuria, so these results must be interpreted with caution. However, although hypercalciuria is a defining criterion of Dent disease, it can be absent in some patients.[48]

Mutations in *CLCN5* are found in approximately 60% of patients with the clinical features of Dent disease, and in 2004, a second gene was identified in a pedigree in whom linkage to the *CLCN5* locus had been excluded.[49] Surprisingly, affected members of this family were found to have mutations in *OCRL,* the gene responsible for Lowe syndrome (see earlier).[49] Mutations in *OCRL* have since been found in several other affected families, including one of the two boys originally described by Dent and Friedman,[50] and *OCRL* mutations account for approximately 15% of all cases with the clinical diagnosis of Dent disease.[31] These patients are often referred to as having Dent2 disease.

KEY POINTS

- Dent disease is characterized by LMW proteinuria (e.g., retinol-binding protein and β$_2$-microglobulin) and hypercalciuria.
- PTH level is typically suppressed.
- Thiazide diuretics may improve hypercalciuria.

KEY POINTS

- *CLCN5* gene mutations account for majority of patients with Dent disease.
- *OCRL* gene mutation, which causes Lowe disease, is seen some (15%) patients with Dent disease (known as Dent2).

The identification of *OCRL* mutations in Dent disease created a genetic dilemma: how can mutations in one gene cause two different diseases? Mutation analysis does not provide an immediate answer. Although there is some clustering of mutations, in that frameshift and nonsense mutations underlying Dent disease are found in the first 7 exons, whereas those associated with the clinical phenotype of Lowe syndrome are usually in exons 8 to 23. This does not provide an obvious explanation because these mutations should lead to complete loss of function.[31] Use of an alternative start methionine in exon 8 has been hypothesized, but such variants have not actually been demonstrated, neither on the mRNA nor the protein level.[51]

Clinical observations suggest a spectrum of severity associated with *OCRL* mutations that can range from isolated renal involvement consistent with Dent disease to the multiorgan disorder of Lowe.[52] Thus, patients classified as having Dent2 disease can have some mental impairment, as well as growth failure and elevated muscle enzymes.[52] This finding has been further supported by the report of two brothers with the same mutation, one diagnosed with Dent2 disease and the other with Lowe syndrome.[31]

Treatment and prognosis

No specific treatment of Dent disease exists. A low-Na^+ diet is recommended to minimize hypercalciuria. Thiazides should be considered in patients with nephrocalcinosis and stones. Even though intestinal Ca^{2+} absorption clearly contributes to the hypercalciuria, calcium intake should not be restricted because this is associated with higher oxalate absorption and increased stone risk.[53,54] Citrate supplementation can decrease the tendency for Ca^{2+} precipitation.[55]

Severe stone disease is extremely rare in childhood and should be managed in conjunction with a urologist.

Progression to ESRD occurs in a large subset of patients with Dent disease, typically in the fourth to fifth decade of life. The mechanism is unclear and not necessarily related to the stone burden because progressive decline in kidney function has also been observed in patients without nephrocalcinosis.[56]

DISORDERS OF THICK ASCENDING LIMB OF LOOP OF HENLE

PHYSIOLOGY

The TAL is involved in three key functions:

1. Salt reabsorption
2. Urinary dilution or generation of the interstitial concentration gradient
3. Ca^{2+} and magnesium (Mg^{2+}) reabsorption
Figure 41.3 Molecular pathogenesis of Bartter syndrome types. Schematic of an epithelial cell in the thick ascending limb of Henle. Apical sodium (Na^+) uptake is mediated by the furosemide-sensitive Na^+, potassium (K^+), 2 chloride (Cl^-) cotransporter NKCC2 (SLC12A1), which is mutated in Bartter syndrome type 1. This transporter can function only when it is fully loaded (i.e., it has bound 1 Na^+, 1 K^+, and 2 Cl^- ions). Because the concentration of these electrolytes is similar to those in plasma (given that absorption in the preceding proximal tubule is isotonic), the availability of K^+ becomes rate limiting. To ensure an adequate supply, K^+ is recycled by the apical K^+ channel ROMK (KCNJ1), mutated in Bartter syndrome type 2. Together, these two transporters contribute to a transepithelial voltage gradient (indicated by the unequal number of plus signs), which drives paracellular reabsorption of calcium (Ca^{2+}) and magnesium (Mg^{2+}). Basolateral exit of Cl^- is mediated by the Cl^- channel CLCKNB, mutated in Bartter syndrome type 3 and probably CLCKNA, both of which require the subunit Barttin, which is mutated in Bartter syndrome type 4. ATPase, adenosine triphosphatase. (Adapted from Kleta R, Bockenhauer D. Bartter syndromes and other salt-losing tubulopathies. Nephron Physiol. 2006;104:73–80.)

Molecularly, these three functions are all linked (Figure 41.3). Because the TAL is water impermeable, salt reabsorption through the furosemide-sensitive cotransporter NKCC2 (SLC12A1) leads to urinary dilution and generates the interstitial concentration gradient needed for urinary concentration in the CD. Although NKCC2 transport is electroneutral (1 Na^+, 1 potassium [K^+], 2 Cl^-), recycling of K^+ through the K^+ channel ROMK (KCNJ1) generates the electrical gradient that drives paracellular

reabsorption of Ca^{2+}, Mg^{2+}, and Na^+. Na^+ and Cl^- can exit the cell on the basolateral side through the Na^+/K^+–adenosine triphosphatase (ATPase) and the Cl^- channel CLCNKB, respectively, thereby completing the transcellular salt reabsorption. Defects in this transcellular transport lead to Bartter syndrome, whereas defects in the paracellular transport lead to familial hypomagnesemia with hypercalciuria and nephrocalcinosis (see Chapter 13).

KEY POINTS

Disorders of TAL transport are:
- Bartter syndrome
- Familial hypomagnesemia with hypercalciuria

Importantly, the macula densa is part of the TAL, and thus tubuloglomerular feedback is impaired in Bartter syndrome, with resultant elevated levels of prostaglandin, especially prostaglandin E_2, renin, and aldosterone.[57] This situation is further compounded by the hypovolemia secondary to the renal salt losses.

BARTTER SYNDROME

The incidence of Bartter syndrome is not fully known, but it has been estimated to be approximately 1 in 1,000,000.[58] However, based on the frequency of mutations in two of the known underlying genes (*SLC12A1* and *KCNJ1;* see later) in members of the Framingham Heart Study, the incidence would be estimated to be approximately 1 in 100,000.[59] Some of the difference may reflect the early lethality of the disease.

So far, four different genes have been shown to cause Bartter syndrome independently (see Table 41.1). All these gene defects are directly involved in the transcellular salt reabsorption in TAL (see Figure 41.3) and lead to four different clinical variants of Bartter syndrome, designated types 1 to 4.

1. **Type 1 Bartter syndrome:** *NKCC2 (SLC12A1),* the apical furosemide-sensitive Na^+-K^+-2 Cl^- cotransporter.[60]
2. **Type 2 Bartter syndrome:** *ROMK (KCNJ1),* the apical K^+ channel that recycles K^+ back into the tubular lumen. This channel is also expressed in the CD (see later), where it mediates K^+ secretion.[61]
3. **Type 3 Bartter syndrome:** *CLCNKB,* the basolateral Cl^- channel that mediates Cl^- exit from the epithelial TAL cell into the interstitium.[62]
4. **Type 4 Bartter syndrome:** *BSND,* a necessary subunit for *CLCNKB,* as well as for the related Cl^- channel CLCNKA. *BSND,* together with the 2 Cl^- channels, is also expressed in the inner ear.[63]

Clinical features and diagnosis

Because salt transport in this segment involves the furosemide-sensitive transporter NKCC2, Bartter syndrome clinically resembles the effects of loop diuretic administration.

Hyperreninemia and hyperaldosteronism are universally seen in all patients because of associated volume depletion, and hypertrophy of the juxtaglomerular apparatus is evident on renal biopsy. Even so, blood pressure is normal or even low. Salt craving is commonly seen in these patients. Often these patients prefer to eat potato chips and salted pickles. Each of the four types of Bartter syndrome has typical clinical characteristics, which can direct diagnosis and genetic testing. Nevertheless, the severity and spectrum of symptoms can be quite variable.[64–68]

BARTTER SYNDROME TYPES 1 AND 2

Bartter type 1 and type 2 are typically associated with the antenatal form of the disease, manifesting with polyhydramnios and prematurity. However, gene mutations associated with these two types have also been identified in patients presenting later in life. Because ROMK is also mediating K^+ secretion in the CD, these patients typically present with hyperkalemia initially, until other K^+ channels can compensate, and then hypokalemia ensues. The patient discussed later in Clinical Vignette 41.2 has a typical case of Bartter syndrome type 2. The excretion of K^+ in these patients can be markedly impaired, sometimes resulting in the misdiagnosis of these patients as having pseudohypoaldosteronism type 1.[69]

Because the combination of electroneutral Na^+-K^+-2Cl^- cotransport through NKCC2 and recycling of K^+ through ROMK establishes the electrical gradient that drives paracellular transport of Ca^{2+} and Mg^{2+}, patients with type 1 and 2 Bartter syndrome typically have hypercalciuria, hypermagnesuria, and nephrocalcinosis. Polyuria is most pronounced in these two forms of Bartter syndrome. Often, patients have markedly impaired urinary concentrating ability consistent with a secondary form of nephrogenic diabetes insipidus.[14,70] Indeed, some of these patients are initially misdiagnosed as having nephrogenic diabetes insipidus.[71,72]

BARTTER SYNDROME TYPE 3

Bartter syndrome type 3 is the cause of what is sometimes called "classical Bartter syndrome," with onset during childhood and matching the initial description of the syndrome by Frederick Bartter.[73] Nevertheless, patients are born with a history of polyhydramnios and prematurity, rarely needing amniocentesis. Patients with Bartter syndrome type 3

KEY POINTS

- Bartter types 1, 2, and 4 usually have antenatal or neonatal presentation of the disease.
- Bartter type 2 may be characterized by hyperkalemia, rather than hypokalemia, in the neonatal period.
- Bartter type 3 is the "classic Bartter syndrome."
- Bartter 4 has associated deafness.
- Gene defects in a significant minority of patients with Bartter syndrome have yet to be identified.

typically have the most marked serum electrolyte abnormalities.[64] The reason may be the expression of the channel also in the DCT, thus affecting salt reabsorption in this segment. Indeed, some patients with Bartter syndrome type 3 can have a clinical picture closely resembling Gitelman syndrome, with marked hypomagnesemia.[65]

BARTTER SYNDROME TYPE 4

Bartter syndrome type 4 has usually severe antenatal onset, and because of the expression of *BSND* in the inner ear, these patients also have profound congenital deafness. Nevertheless, milder variants associated with mutations that likely provide residual function have been described.[74] Although *CLCKNB* is also expressed in the inner ear, it is not associated with deafness, presumably because of compensation from *CLCNKA*. Similar compensation in the kidney may also explain the usually milder phenotype of type 3 Bartter syndrome compared with type 4. This notion is supported by the finding of a severe type 4–like form of Bartter syndrome in a child with homozygous mutations in both *CLCNKA* and *CLCNKB*.[75]

Despite the identification of the four genes, a substantial minority of patients with a clinical diagnosis of Bartter syndrome will not have causative mutations identified, thus suggesting further genetic heterogeneity. However, not all patients with hypokalemic, hypochloremic alkalosis and low blood pressure have Bartter syndrome. A similar clinical picture can sometimes be seen in autosomal dominant hypocalcemia caused by heterozygous gain-of-function mutations in the Ca^{2+}-sensing receptor CaSR,[76] a finding demonstrating the importance of the CaSR in the regulation of TAL activity.[76,77]

Mitochondrial cytopathies have also been reported rarely to phenocopy Bartter syndrome.[78–80] Persistent furosemide intake obviously mimics Bartter syndrome. More commonly, however, the plasma biochemical profile of Bartter syndrome is seen in nonrenal salt-wasting states, so-called pseudo-Bartter syndromes (Table 41.4).[81–84.] The distinction can easily be made by assessing urinary Cl⁻ excretion, which is elevated in renal salt wasting, but very low with extrarenal salt wasting. This can be difficult sometimes in babies with congenital Cl⁻ diarrhea, when the clear diarrheal fluid in the diaper is confused with urine.[85]

Treatment and prognosis

The mainstays of treatment are prostaglandin synthesis inhibition and electrolyte supplementation. Indomethacin is commonly used for the former, as well as other nonsteroidal agents, such as ibuprofen.[86,87] The main complications are gastric ulcer and bleeding, and coadministration of inhibitors of gastric acid production should always be considered. Selective cyclooxygenase-2 (COX-2) inhibitors have been used successfully to avoid these gastrointestinal complications, but their adoption into routine practice has been hindered by the withdrawal of most of these agents from the market because of increased cardiovascular complications.[88–90] Antenatal

Table 41.4 Causes of pseudo-Bartter syndrome in children

- Cystic fibrosis
- Persistent vomiting (infantile hypertrophic pyloric stenosis)
- Eating disorders (induced vomiting)
- Neonates of mothers with eating disorders
- Congenital chloride diarrhea
- Mitochondrial cytopathies
- Diuretic overuse and surreptitious intake
- Long-standing laxative use
- Prostaglandin use in neonates with patent ductus arteriosus
- Aminoglycoside use and toxicity
- Magnesium depletion

administration of indomethacin has been described in cases of severe polyhydramnios, but it should be considered carefully with respect to potential complications (e.g., closure of the ductus arteriosus).[91] Similarly, early administration in premature infants can be associated with severe complications, such as necrotizing enterocolitis.[92,93]

Hypokalemia is part of the syndrome and can be marked (K^+ less than 2.0 mmol/L), especially in Bartter syndrome types 3 and 4. The relevance and treatment of this hypokalemia are controversial: long-term electrocardiographic monitoring in patients with Bartter syndrome revealed few potentially dangerous abnormalities in one study, yet there are several anecdotal reports of sudden cardiac death and rhabdomyolysis in children with hypokalemic tubulopathies.[94–96] In an attempt to normalize plasma K^+ levels, often enormous doses of K^+ supplements are prescribed; these can be difficult to manage for the patient and lead to gastrointestinal problems, such as vomiting and ulcers.

The primary defect in Bartter syndrome is impaired Na^+ reabsorption, and K^+ wasting reflects the renal response to maintain volume homeostasis. Consequently, generous salt supplementation (up to 10 mmol/kg) can help ameliorate the hypokalemia.[86,88] Indeed, most patients with this syndrome have a craving for salty foods, but even with a high-salt Western diet, it is difficult to achieve the necessary supplementation with food alone. Recognizing the importance of volume homeostasis, the use of K^+-sparing diuretics and inhibitors of the renin-angiotensin system to increase K^+ levels may lead to serious hypovolemia, especially when there are extra volume losses, such as during a gastrointestinal illness.

KEY POINTS

- Na^+ supplementation is key in the treatment of Bartter syndrome.
- Treatment with adequate salt intake may help in the management of hypokalemia.

Prognosis

The overall prognosis for Bartter syndrome itself is good, although those patients with the antenatal form may have complications of the prematurity.[64,97] Some patients, especially those with Bartter syndrome type 3, develop proteinuria and focal glomerulosclerosis later in life, with progressive chronic kidney disease.[98,99] Associated growth hormone deficiency has also been reported in Bartter syndrome type 3, and it may be related to the severe electrolyte imbalance.[99,100] Clinical Vignette 41.2 describes a case of Bartter syndrome type 2 in a neonate.

Clinical Vignette 41.2

A 3-day-old newborn boy in the neonatal intensive care unit was noted to have large urine output of 250 to 300 mL/kg/day, with concomitant weight loss of more than 15% of the birth weight. The baby was born at 25 weeks of gestation as a result of premature contractions, which occurred during an amniocentesis procedure. The pregnancy had been complicated by severe polyhydramnios, and there had been two previous amniocentesis procedures performed, each draining between 3 and 5 L. Serum chemistry studies revealed hypernatremia (Na$^+$, 151 mmol/L), hyperkalemia (K$^+$, 6.4 mmol/L), metabolic alkalosis (HCO$_3^-$, 28 mmol/L), and elevated creatinine (58 mmol/L, or 0.65 mg/dL).

Intravenous fluids were administered to maintain fluid balance, and serum plasma sodium levels were normalized. The baby failed to gain weight adequately, and over the following weeks a gradual correction of hyperkalemia was noted; eventually, he developed hypokalemia (K$^+$, 3.1 mmol/L). A diagnosis of Bartter syndrome type 2 was made, and treatment with indomethacin and salt supplementation was commenced. This led to a substantial reduction in urine output and an improvement in weight gain. An ultrasound scan of the kidney revealed marked nephrocalcinosis.

DISORDERS OF DISTAL CONVOLUTED TUBULE

PHYSIOLOGY

The DCT is involved in two key functions:

1. Salt reabsorption
2. Ca^{2+} and Mg^{2+} reabsorption

As in all the other nephron segments, the molecular basis for transport of these three ions is linked (Figure 41.4). All these ions are transported transcellularly (i.e. across the epithelial cell). Na$^+$ and Cl$^-$ are transported across the apical membrane by the thiazide-sensitive Na$^+$Cl$^-$ cotransporter
Figure 41.4 Schematic of the distal convoluted tubule epithelial cell ion transport. Na$^+$ is reabsorbed by the apical thiazide-sensitive Na$^+$-Cl$^-$ cotransporter NCC, mutations in which cause Gitelman syndrome. The driving force for Na$^+$ uptake is generated by the basolateral Na$^+$-K+–adenosine triphosphatase (Na$^+$-K$^+$-ATPase), as in all other segments, and this transporter also provides a basolateral exit pathway. The function of this pump is critically dependent on an adequate supply of K$^+$. This is provided by the basolateral K$^+$ channel KCNJ10, mutated in EAST syndrome. Recycling of K$^+$ through this channel also provides the voltage gradient for basolateral Cl$^-$ exit through CLCNKB, mutated in Bartter syndrome type 3. Because of this expression in the distal convoluted tubule, Bartter syndrome type 3 can mimic Gitelman syndrome. Apical entry for Mg^{2+} and Ca^{2+} is provided by the ion channels TRPM6 and TRPV6 and 7, respectively. The necessary voltage gradient is provided by apical K$^+$ exit through K$^+$ channels, such as KCNA1. (Adapted from Kleta R, Bockenhauer D. Bartter syndromes and other salt-losing tubulopathies. Nephron Physiol. 2006;104:73–80.)

NCC (SLC12A3) and exit the cell by the basolateral Na$^+$/K$^+$-ATPase and Cl$^-$ channel CLCNKB. Apical K$^+$ channels including KCNA1 provide the electrical gradient, which enables Mg^{2+} and Ca^{2+} uptake through TRPM6/7 and TRPV5, respectively. Basolateral exit for Ca^{2+} is provided by an Na$^+$/Ca^{2+} exchanger NCX1 and a Ca^{2+} pump PMCA1b.[101] Exit for Mg^{2+} occurs through CNNM2.[102] Most of these molecular players have been identified through genetic investigations of inherited disorders, and more genes may be discovered in the future, thereby identifying additional transport molecules.

GITELMAN SYNDROME

Gitelman syndrome is a recessive disease caused by inactivating mutations in NCC.[103] Not surprisingly, because *CLCKNB*

is also expressed in DCT, it is a rare disorder, with an estimated incidence based on the frequency of heterozygous mutations in NCC in the general population of approximately 1 in 10,000 to 1 in 50,000, although the incidence may be higher in some populations.[59,104,105] Bartter syndrome type 3 can often resemble the clinical picture of Gitelman syndrome.

Clinical features and diagnosis

Gitelman syndrome is characterized by the combination of hypokalemic, hypochloremic alkalosis with hypomagnesemia and hypocalciuria (see Table 41.1), and the diagnosis can be confirmed by genetic testing. Gitelman syndrome is often described as the benign variant of Bartter syndrome, and many patients are discovered incidentally because of cramps, dizziness, aches, and fatigue.[107] Moreover, severe complications such as rhabdomyolysis and cardiac arrhythmias have been reported.[95,96,108] In later adult years, systemic calcifications, such as chondral and scleroidal calcinosis, may occur.[109,110]

KEY POINTS

- Gitelman syndrome resembles Bartter syndrome and is characterized by hypochloremic metabolic alkalosis and hypokalemia.
- Gitelman syndrome is characterized by hypomagnesemia and hypocalciuria.
- Bartter syndrome, on the other hand, has normal magnesium level and hypercalciuria or normocalciuria.

Treatment and prognosis

The mainstay of treatment of Gitelman syndrome is electrolyte supplementation. As in the case of Bartter syndrome (see earlier), it is important to recognize that the hypokalemia is a secondary consequence of impaired salt reabsorption, and consequently NcCl supplementation is important. In addition, K^+ and Mg^{2+} supplementation are used, but normal plasma levels are difficult to achieve, and blood results obviously vary with respect to timing after the last dose.

The use of prostaglandin synthesis inhibitors in Gitelman syndrome has not been well established, and indeed urinary prostaglandin values are usually normal or only moderately elevated.[111,112] As in Bartter syndrome, the use of K^+-sparing diuretics and inhibitors of the renin-angiotensin system should be carefully considered with respect to the risk of hypovolemia. Clinical Vignette 41.3 describes a case of Gitelman syndrome in a young child.

Clinical Vignette 41.3

A 5-year-old boy was referred for persistent and unexplained hypokalemia. This was first noted during a diarrheal illness 1 month earlier and was confirmed twice in

absence of diarrhea. A subsequent aldosterone level was elevated at 1280 pmol/L. Past medical history and family history were unremarkable. Physical examination revealed a well-appearing boy with a weight and height in the 75th percentile for age and blood pressure of 90/60 mm Hg. Plasma biochemistry studies revealed hypokalemia (K^+, 2.8 mmol/l), hypochloremia (Cl^-, 97 mmol/L), metabolic alkalosis (HCO_3^-, 30 mmol/L), and hypomagnesemia (Mg^{2+}, 0.56 mmol/L, or 1.36 mg/dL). A 24-h urine collection demonstrated Ca^{2+} excretion of less than 0.025 mmol/kg/day (less than 1 mg/kg/day) of Ca^{2+}.

The diagnosis of Gitelman syndrome was based on the findings of hypokalemic metabolic alkalosis, hypomagnesemia, and hypocalciuria and confirmed by genetic testing.

EPILEPSY, ATAXIA, SENSORINEURAL DEAFNESS, AND A RENAL SALT-LOSING TUBULOPATHY (EAST) SYNDROME

EAST syndrome is a recessive disorder caused by mutations in the K^+ channel KCNJ10 (Kir4.1); EAST is an acronym for epilepsy, ataxia, sensorineural deafness, and tubulopathy.[113] The disorder has also been described as SeSAME syndrome.[114] It is an extremely rare disorder, with fewer than 50 patients worldwide described in the literature.

Clinical features and diagnosis

Patients exhibit the typical biochemical profile of impaired salt reabsorption in DCT (i.e., a Gitelman-like tubulopathy). However, the neurologic symptoms dominate, and most patients present in the first year of life with generalized seizures.[115] Later, ataxia and developmental delay are noted. The severity of all cardinal symptoms can vary markedly, even within families, with some patients confined to wheelchairs because of the movement disorder.

Treatment and prognosis

Treatment is entirely supportive and involves antiepileptic medications, as well as electrolyte supplementation. The neurologic symptoms are independent of the electrolyte imbalance, and thus attempts to normalize plasma electrolytes have no apparent influence on seizure frequency.[115]

PSEUDOHYPOALDOSTERONISM TYPE 2: GORDON SYNDROME

Pseudohypoaldosteronism type 2 (PHA2) is a rare inherited disorder of Na^+ retention in the DCT. So far, four causative genes have been identified. The first two to be reported were the WNK kinases 1 and 4, which regulate the activity of the thiazide-sensitive Na^+Cl^- cotransporter NCC.[116]

Subsequently, two further genes, *CUL3* and *KLHL3*, have been described, which are likely involved in ubiquitination of either the WNK kinases or NCC.[117] Mutations in all four genes are dominantly inherited, although *KLHL3* is also associated with recessive inheritance.

Clinical features and diagnosis

PHA2 is often referred to as the "mirror image of Gitelman syndrome" because patients exhibit the opposite symptoms.[118] Physiologically, this makes sense, given that Gitelman syndrome is caused by impaired function of NCC, whereas PHA2 is caused by overactivity of the transporter. Thus, patients have hypertension and hyperkalemic, hyperchloremic metabolic acidosis with hypercalciuria. Renin is typically suppressed, and aldosterone levels can vary, but they are usually low with respect to the degree of hyperkalemia. Symptoms may not be obvious in younger children, and the diagnosis should not be excluded in at-risk children before they have reached adolescence, unless it is confirmed by genetic testing.

Treatment and prognosis

Once the diagnosis is established, treatment with thiazide diuretics is indicated. This treatment normalizes all symptoms and thus reduces the risk of the hypertension-related complications.

DISORDERS OF COLLECTING DUCT

PHYSIOLOGY

Although only approximately 5% of filtered Na^+ is reabsorbed in this segment, the CD is critically important because this is the segment were salt reabsorption is highly regulated to adjust urine composition to physiologic needs. Na^+ is reabsorbed transcellularly, first entering the principal cell on the apical side through the epithelial Na^+ channel ENaC and exiting on the basolateral side through Na^+/K^+-ATPase (Figure 41.5). The charge movement from Na^+ uptake can be balanced by K^+ secretion via the K^+ channel ROMK (also expressed in TAL; see earlier), paracellular Cl^- reabsorption, and proton secretion from the intercalated cells. In this way, volume, K^+ and acid-base balance are all molecularly linked in this segment.

PSEUDOHYPOALDOSTERONISM TYPE 1

Pseudohypoaldosteronism type 1 (PHA1) is a very rare disorder. Clinically and molecularly, it is separated into two distinct entities: the severe autosomal recessive form caused by loss-of-function mutations in one of the subunits of ENaC[119]; and the milder dominant form, caused by heterozygous loss-of-function mutations in the mineralocorticoid receptor (see Table 41.1).[119,120]
Figure 41.5 Schematic of the collecting duct epithelial cell ion transport. Na+ is reabsorbed in the collecting duct by the epithelial Na+ channel, ENaC. ENaC can be blocked by the diuretic amiloride and is mutated in the recessive form of pseudohypoaldosteronism type 1 (PHA1). Uptake of Na+ creates a favorable gradient for K+ secretion (by ROMK) and proton secretion (from the adjacent intercalated cells; not shown). Expression of ENaC in the membrane is controlled by the mineralocorticoid receptor (MRCR), which is mutated in the dominant form of PHA1. Gain-of-function mutations in this pathway lead to low-renin forms of hypertension, such as Liddle syndrome (ENaC) or hypertension with exacerbation in pregnancy (MRCR). Specificity of the MRCR for mineralocorticoids is provided by HSD11B2, which metabolizes cortisol, which can activate MRCR to cortisol. Loss of function of HSD11B2 leads to apparent mineralocorticoid excess with pathologic activation of MRCR by cortisol. ATPase, adenosine triphosphatase. (Adapted from Kleta R, Bockenhauer D. Bartter syndromes and other salt-losing tubulopathies. Nephron Physiol. 2006;104:73–80.)

Clinical features and diagnosis

Patients with the recessive form usually present in the neonatal period or early in infancy with severe dehydration and failure to thrive. Laboratory investigations reveal hyponatremia and marked hyperkalemic acidosis, with dramatically elevated renin and aldosterone levels.[121] In some instances, even antenatal presentation with polyhydramnios has been reported.[122,123] Because ENaC mediates salt reabsorption not only in the kidney, but also in the skin, colon, and tracheal and oropharyngeal epithelium, patients have increased salt losses from sweat, skin, saliva, and the gut. Moreover, cystic fibrosis–like pulmonary involvement from impaired Na^+-dependent liquid reabsorption in the trachea can be seen.[124] The high salt content of the sweat can cause skin inflammation resembling miliaria rubra.[125]

In contrast to the systemic manifestations seen in recessive PHA1, the dominant form manifests only with renal involvement, reflecting the restricted expression of the underlying mineralocorticoid receptor. Patients typically present in infancy with failure to thrive, and biochemical investigations reveal the typical electrolyte profile of PHA1 (see earlier and Box 41.2). Symptoms typically improve with time, and in adulthood, even aldosterone levels may have normalized.[121]

Treatment and prognosis

The treatment of PHA1 hinges on salt replacement. In the dominant form, supplementation with NaCl is usually sufficient to normalize electrolytes and allow the child to thrive, and treatment can usually be stopped after a few years. Consequently, the prognosis for the dominant form is excellent. In contrast, the recessive form is often characterized by life-threatening episodes of severe hypovolemia and hyperkalemia. Mortality rates are high, if these episodes are not recognized early and treated aggressively by volume supplementation with normal saline. Hyperkalemia can be dramatic (K^+ greater than 10 mmol/L), but the condition responds well to volume expansion. Baseline supplementation with large doses (10 to 20 mmol/kg/day each) of NaCl and $NaHCO_3$ is often needed. NaCl supplementation with doses as high as 50 mmol/kg/day has been reported, but it may be difficult to administer orally.[126] Na^+/K^+ exchange

---

KEY POINT

Early diagnosis and treatment of disorders of excess sodium reabsorption are critical to avoid potentially devastating consequences of uncontrolled and severe hypertension.

---

resins, such as sodium polystyrene sulfate, can provide a steady source of Na^+ and help stabilize K^+ levels.

The diagnosis of PHA1 is easily made by the typical biochemical profile, with inappropriately high Na^+ and low K^+ excretion in the urine. The systemic (recessive) form can be confirmed by the high Na^+ and Cl^- content of the sweat. Genetic testing demonstrating either recessive mutations in one of the ENaC subunits or a heterozygous mutation in *NR3C2* will help establish a definitive diagnosis. Clinical Vignette 41.4 illustrates a case of recessive PHA1 in a neonate.

Clinical Vignette 41.4

A 6-day-old girl presented acutely with irritability, vomiting, and lethargy. Pregnancy was uncomplicated, and the child was born at term with a birth weight of 2.66 kg. Parents were first cousins, and there is a history of early child loss in the extended family. Physical examination: weight, 2.35 kg; blood pressure, 56/palpation; poor skin turgor.

Serum chemistry studies revealed moderate hyponatremia (Na^+, 128 mmol/L), severe hyperkalemia (K^+, 8.8 mmol/L), and metabolic acidosis (HCO_3^-, 12 mmol/L), with severely elevated levels of renin and aldosterone. After repeated normal saline boluses and bicarbonate administration, her clinical status and her serum chemistry results improved. She received oral supplementation with sodium chloride, sodium bicarbonate, and sodium polystyrene sulfonate. However, she had repeated hospitalizations for respiratory infections. Bronchoalveolar lavage revealed colonization with *Pseudomonas aeruginosa*. A sweat test showed elevated sweat Na^+ concentration (135 mmol/L).

MISCELLANEOUS TUBULOPATHIES

Glucocorticoid-remediable aldosteronism (GRA), Liddle syndrome (LS), hypertension with exacerbation in pregnancy (HEP), and apparent mineralocorticoid excess (AME) are all very rare disorders. All these disorders represent mirror images of PHA1 and are characterized by overactive Na^+ reabsorption by ENaC in the CD, thus leading to hypervolemia with hypertension. As discussed earlier, PHA1 is caused by loss-of-function mutations in the mineralocorticoid receptor or ENaC, whereas HEP and LS are caused by gain of function in these proteins.[127,128] In GRA, unequal meiotic crossover results in a chimeric gene that fuses regulatory sequences of steroid 11β-hydroxylase to coding sequences of aldosterone synthase.[129] Consequently, adrenocorticotropic hormone (ACTH) then drives aldosterone production. As expected for these gain-of-function disorders, LS, HEP, and GRA are inherited dominantly, whereas AME, representing loss of function of the

11β-hydroxysteroid dehydrogenase type 2 *(HSD11B2),* is autosomal recessive.[130]

The study of AME has provided interesting insights: the mineralocorticoid receptor itself is not specific for mineralocorticoids, but it is also sensitive to glucocorticoids, such as cortisol. To establish specificity, cortisol is metabolized in the principal cells of the CD by HSD11B2 and consequently, impaired function of this enzyme leads to pathologic activation of the receptor by cortisol, which is present in plasma at roughly 1000-fold the concentration of aldosterone.[131] A similar problem with specificity of the receptor is seen in HEP, in which the mutation makes the mineralocorticoid receptor more susceptible to activation by progesterone, thus explaining the exacerbation in pregnancy.

Clinical features and diagnosis

The clinical picture of these disorders is dominated by hypertension with the biochemical picture of hypokalemic, hypochloremic metabolic alkalosis (hypermineralocorticoid state). Hypertension may be mild or even absent during early childhood in the dominant disorders, but it is usually severe in AME, in which it is associated with early and severe complications, such as stroke and death. *HSD11B2* is also important in the placenta, and AME thus typically manifests antenatally, with the fetus being small for gestational age. Renin levels are suppressed in all four disorders, as is aldosterone, except for GRA, which manifests with excess aldosterone. The hypervolemia leads to decreased Na$^+$ reabsorption in the PT with consequent hypercalciuria and is associated with a urinary concentrating defect and polyuria.[14,71]

The presence of hypertension with the biochemical profile of hypokalemic, hypochloremic metabolic alkalosis and suppressed renin should always prompt consideration of any of these disorders. Even in the dominantly inherited forms, the diagnosis may not have been established despite a strong family history of hypertension, early cardiovascular complications, or unexplained early death. Genetic testing can confirm the diagnosis.

Treatment and prognosis

Because all four disorders ultimately lead to excess Na$^+$ reabsorption by ENaC, treatment concentrates on blockade of this pathway by ENaC blockers, such as amiloride. Antagonists of the mineralocorticoid receptor may also be helpful, except in LS, because the defect in LS is downstream of the receptor. GRA, as the name implies, can also be treated by glucocorticoid administration, which suppresses ACTH, the driver of the excess aldosterone production in this disorder.

The prognosis depends mostly on timely establishment of the diagnosis and initiation of the correct treatment. Without this treatment, patients are liable to experience the potentially severe cardiovascular consequences of uncontrolled hypertension.[132]

SUMMARY

Disorders of renal tubules, or tubulopathies, comprise a diverse group of conditions that are characterized by defects in the transport of water and electrolytes. Bartter syndrome and Fanconi syndrome are examples of tubulopathies seen in infants and children. Clinical suspicion of a tubulopathy in a child can involve a variety of symptoms, including failure to thrive, polyuria, and severe abnormalities of electrolytes and acid-base metabolism. Characterization of the gene defects involved in the pathogenesis of various tubulopathies since the 1990s has led to a better understanding of the clinical and biochemical abnormalities seen in these patients. Although treatment of these patients is characteristically simple, relief of the electrolyte abnormalities may be difficult to achieve because of massive urinary losses of specific electrolytes. Development of targeted therapies that influence various channel transports in the nephron may provide therapeutic alternatives in these patients.

REVIEW QUESTIONS

1. Hyperkalemia can be associated in the newborn period in which of the following types of Bartter syndrome?
   a. Type 1
   b. Type 2

c. Type 3
d. Type 4
2. Which type of Bartter syndrome is associated with hearing loss?
   a. Type 1
   b. Type 2
   c. Type 3
   d. Type 4
3. Barter syndrome is associated with:
   a. Normocalciuria
   b. Hypercalciuria
   c. Hypocalciuria
   d. a or b
   e. a or c
4. Gitelman syndrome is characterized by:
   a. Hypocalciuria
   b. Hypercalciuria
   c. Normocalciuria
   d. None of the above
5. Hypomagnesemia is a feature of:
   a. Bartter syndrome
   b. Gitelman syndrome
   c. Both Bartter syndrome and Gitelman syndrome
   d. Neither Bartter syndrome nor Gitelman syndrome
6. Gordon syndrome or pseudohypoaldosteronism-2 is a mirror image of Gitelman syndrome. Both these defects result from a malfunction or disregulation in which of the following transport channels?
   a. CLCNKB
   b. ENaC
   c. ROMK
   d. NCC
7. Pseudohypoaldosteronism 1 (PHA1) results from loss-of-function mutations in:
   a. The mineralocorticoid receptor or ENaC
   b. CLCNKB
   c. NKCC2
   d. CLCN5

8. Liddle syndrome results from:
   a. Loss-of-function mutation of ENaC
   b. Gain-of-function mutation of HSD11B2
   c. Gain-of-function mutation of ENaC
   d. Loss-of-function mutation of TRPM6
9. Transport of low-molecular-weight protein from the tubular lumen in the proximal tubules is facilitated by binding to apical receptors megalin and cubilin.
   a. True
   b. False
10. Which of the following are features of renal Fanconi syndrome?
    a. Hypercalciuria
    b. Glucosuria
    c. Low-molecular-weight proteinuria
    d. Albuminuria
    e. All of the above

Renal tubular acidosis

JOHN W. FOREMAN

In renal tubular acidosis (RTA), defective renal tubular function leads to metabolic acidosis, despite normal daily acid production from metabolism and dietary intake. RTA is typically characterized by hyperchloremic metabolic acidosis (HCMA). It can occur sporadically or as a heritable disorder, either as an autosomal dominant or recessive trait, or as part of a more generalized tubular disorder, such as Fanconi syndrome. In its early descriptions, RTA was defined by numerous terms, such as *Lightwood disease* and *infantile tubular acidosis.* Consensus around the classification of RTA into distal and proximal types emerged only after demonstration of defects in urinary acidification and bicarbonate reabsorption in such patients.[1]

KIDNEY IN ACID-BASE BALANCE

The typical Western diet generates approximately 1 mmol/kg/day of H^+ in an adult, and 1 to 3 mEq/kg/day in children and infants.[2,3] Infants and young children generate more daily acid than adults, in part because laying of new bone consumes the buffers (hydroxyl ion) OH^- and phosphate to make hydroxyapatite.[3] Three sequentially acting mechanisms eliminate the new acid generated by daily metabolic activity. The first line of buffering is accomplished by the circulating bicarbonate (HCO_3^-) to form carbonic acid (H_2CO_3), which is converted to water (H_2O) and carbon dioxide (CO_2) by erythrocyte carbonic anhydrase (CA). The CO_2 is eliminated by the second line of buffering process via the lungs. However, to continue the above two processes, the kidney must regenerate an equivalent amount of HCO_3^-, without which the internal milieu will be depleted of bicarbonate reserves (Figure 42.1). In addition, some acids (inorganic acids) must be excreted by the kidney, because these cannot be completely metabolized to CO_2 and undergo pulmonary elimination. The renal tubular acid excretion, or net acid excretion (NAE), is composed of (1) titratable acid (TA) production, mainly in the form of monobasic phosphate ($H_2PO_4^-$) and (2) ammonium ions (NH_4^+). This relationship in is shown as:

$$NAE = TA + NH_4^+ \qquad (42.1)$$

KEY POINTS

- Dietary intake generates approximately 1 mEq/kg of hydrogen ions daily in adults.
- Infants and children produce more acid (1 to 3 mEq/kg/day)

However, any HCO_3^- lost in urine reduces the NAE as represented in Equation 42.2.

$$NAE = TA + NH_4^+ - HCO_3^- \qquad (42.2)$$

Organic anions are potential sources of HCO_3^- when completely metabolized. However, if these organic acids are
Figure 42.1 Buffering mechanisms involved in elimination of daily metabolic acid load (H+). Kidneys play an important role in the homeostasis by generating new bicarbonate and also elimination of hydrogen ions.

lost in the urine, such as in metabolic disorders, the NAE by the kidney is diminished. This relationship can be expressed by the following equation:

$$NAE = TA + NH_4 - HCO_3^- - \text{Metabolizable anions} \quad (42.3)$$

At a urine pH of less than 6.5, little to no HCO_3^- is present in the urine. Organic acids are not routinely assayed in urine, but their presence can be suspected if there is a significant difference (greater than 100 mOsm/L) between the measured urine osmolality and the calculated osmolality, using the following equation:

$$\text{Calculated } U_{osm} = 2 \times U_{Na} + 2 \times U_K + U_{Urea}/2.8 + U_{Glucose}/18 \quad (42.4)$$

Kidneys generate new bicarbonate ions by recombining CO_2 with H_2O in the renal tubular cell (proximal and distal) cytoplasm to form H^+ and HCO_3^-, a process that is catalyzed by carbonic acid II (CA II). The newly generated HCO_3^- is transported into the blood, replacing the lost HCO_3^- in the initial buffering process. The H^+ thus formed is eliminated as buffered monobasic phosphate ($H_2PO_4^-$), or TA, and

KEY POINTS

- Generated H^+ is initially buffered by circulating bicarbonate and bone.
- Eventual elimination of daily acid load occurs via lungs as CO_2 and the kidneys via ammonium and as titratable acidity.
- Kidneys also perform the important task of reabsorbing filtered bicarbonate, mainly in the proximal tubules.
- Kidneys also help generate new bicarbonate molecules that replenish the serum bicarbonate lost in initial buffering of H^+

as ammonium (NH_4^+). The urinary concentration of monobasic phosphate can be modulated over a small range, but NH_4^+ generation and excretion can increase by several-fold, especially under the conditions of acidosis. Therefore, the dominant response of the kidneys to acidosis is characterized by an increased NH_4^+ production and elimination.

RENAL HANDLING OF BICARBONATE

In a normal adult, approximately 4500 mEq of bicarbonate is reclaimed daily from the glomerular filtrate (180 L/day glomerular filtrate × 25 mEq/L plasma bicarbonate concentration = 4500 mEq). Approximately 80% to 90% of the filtered load of bicarbonate is reabsorbed in the proximal tubule (Figure 42.2). This is accomplished by the secretion of H^+ into the tubular lumen, in exchange for Na^+, via the luminal membrane sodium/hydrogen exchanger (NHE_3), and to a minor extent by the H^+-ATPase pump (Figure 42.3).[4,5] The H^+ ion transported into the proximal tubule lumen combines with the filtered bicarbonate to form carbonic acid (H_2CO_3). Carbonic acid is further catalyzed to CO_2 and H_2O, a reaction that is rapidly catalyzed by the luminal carbonic anhydrase IV (CA IV) present on

Figure 42.2 Nephron sites of bicarbonate reabsorption. Most filtered bicarbonate is reabsorbed in the proximal nephron, leaving little to none in the excreted urine. CCT, cortical collecting tubule; PCT, proximal convoluted tubule; TAL, thick ascending limb of loop of Henle.

Figure 42.3 A diagrammatic representation of the metabolic process of recapturing filtered bicarbonate in the proximal tubular cells. In the first step, H^+ generated in the proximal tubular cell is transported into the tubular lumen via the Na^+/H^+ exchanger 3 (NHE3) and the H^+-ATPase. In the second step, H^+ combines with the filtered HCO_3^- to form CO_2 and water (facilitated by apical carbonic anhydrase (CA IV). CO_2 diffuses back into the proximal tubular cell, where it recombines with H_2O in step three to reform HCO_3^-. Carbonic anhydrase II (CA II) in the cytosol facilitates these steps. In the fourth step, HCO_3^- exits the cell and into the blood via basolateral surface through the Na^+-HCO_3^- cotransporter (NBC1).

the apical membrane of the proximal tubule and thick ascending limb of the loop of Henle (TAL). CO_2 diffuses into the tubular cell and recombines with H_2O, to form bicarbonate, a reaction that is catalyzed by CA II in the cytosol. The HCO_3^- generated in this process exits the tubular cell via the Na^+, HCO_3^- exchanger (NBC1), which is coded for by the gene *SLC 4A4*. Three molecules of bicarbonate and one molecule of sodium (Na) are driven out of the tubular cell at this location by NBC1. Additionally, the Na,K-ATPase on the basolateral membrane transports three Na^+ ions out of the cell in exchange for two K^+ ions, leading to an electrochemical gradient with a negative potential charge relative to the lumen. This electrical gradient favors Na^+ entry into the cell from the tubular luminal fluid.[6] Factors that enhance proximal tubular HCO_3^- reabsorption include increased filtered bicarbonate load, low peritubular pH, high pCO_2, angiotensin II (ATII), extracellular volume contraction, and potassium depletion.

The TAL reabsorbs the majority of HCO_3^- escaping the proximal tubule. Apical Na^+/H^+ exchange (NHE3) mediates most of H^+ secretion into the lumen in this nephron segment. The HCO_3^- regenerated in the TAL cell can exit via several transporters including Na^+/HCO_3^- and K^+/HCO_3^- cotransporters and the Cl^-/HCO_3^- exchanger on the basolateral surface. (Figure 42.4). The distal nephron is responsible for reabsorption of the remainder of the filtered HCO_3^- still present (less than 5%) in the tubular fluid (urine).

KEY POINTS

- Filtered bicarbonate is predominantly reabsorbed in the proximal tubule (approximately 90%).
- Remainder of bicarbonate (approximately 10% to 15%) is reabsorbed in the thick ascending limb of the loop of Henle.
- NCB1 transports bicarbonate across the basolateral surface from the proximal tubular cell.
- CA IV present in the luminal brush border facilitates bicarbonate reabsorption into the tubular cells from the lumen.

DISTAL TUBULAR ACIDIFICATION

The distal nephron dominantly participates in the acidification of urine, in addition to mopping up any filtered bicarbonate still present in the tubular fluid. Elimination of hydrogen and potassium ions occurs in an integrated manner in this nephron segment. The distal nephron consists of three distinct functional segments: the cortical collecting tubule (CCT), the outer medullary collecting tubule (OMCT), and the inner medullary collecting tubule (IMCT).[7] Two distinct types of cells that have been identified in the distal collecting
Figure 42.4 Electrolyte transport processes in the thick ascending limb (TAL) of the loop of Henle involved in recapture of the filtered bicarbonate that escapes the proximal tubule. The filtered HCO_3^- is reabsorbed by combining with the H^+ secreted into the tubular lumen via the Na^+/H^+ exchanger 3 (NHE3). Re-synthesis of bicarbonate occurs in the tubular cells from CO_2. HCO_3^- exits the cell along the basolateral surface via multiple transporters: Na^+/HCO_3^- cotransporter, K^+/HCO_3^- cotransporter, and the Cl^-/HCO_3^- exchanger. NH_4^+ can enter the tubular cell in place of K^+ on the $2Cl^-/Na^+,K^+$ transporter for recycling in the medullary interstitium.

tubule have been assigned specific functional roles. Principal cells deal with Na^+ reabsorption and K^+ secretion into the tubular ultrafiltrate, and α-intercalated cells found exclusively in the CCT are involved in urinary acidification by H^+ secretion. However, this traditional concept has been challenged. It has been suggested that the separation of function between these two cell types in the distal tubule may not be as clearly defined as previously thought.[8,9] Both cell types are believed to be crosstalking and are involved in transport of electrolytes, as well as hydrogen ions.[10]

The CCT is a low-capacity segment in which acidification is regulated by Na^+ reabsorption that generates a lumen negative membrane potential. The OMCT, on the other hand, has a high-capacity for H^+ secretion but does not transport Na^+. The IMCT has a low capacity for H^+ secretion and is regulated by systemic acid-base status and K^+ balances both in terms of net H^+ secretion and NH_4^+ transport. Most H^+ secretion in this nephron segment occurs via the H^+-ATPase pump and to a smaller extent by the H^+/K^+-ATPase pump (Figure 42.5). Residual bicarbonate reabsorption from the tubular lumen occurs by a mechanism that is similar to one seen in the proximal tubule. Bicarbonate reformulated in the tubular cells exits via the basolateral anion exchanger
Figure 42.5 H^+ ion excretion process in the cortical collecting tubular (CCT) segment of distal nephron. H^+ is generated from CO_2 by carbonic anhydrase II (CA II) in the α-intercalated cell and exits towards the tubular lumen via the H^+-ATPase pump, or the H^+/K^+ exchanger. HCO_3^- exits the cell via the anion exchanger 1 (AE1). Na^+ enters the cell via the epithelial sodium channel (ENaC) generating a lumen to cell negative gradient.

(AE1) that transports the Cl^- ion for the HCO_3^- ion leaving tubular cells.

KEY POINTS

- H^+ ion secretion occurs in the α-intercalated cells in the cortical collecting tubule.
- H^+ primarily exits from the tubular cells into the lumen via H^+-ATPase pump. Some is transported via the H^+/K^+-ATPase pump.
- Aldosterone plays a vital role, via its receptors in the distal tubule to enhance H^+ and K^+ secretion in the outer and inner medullary collecting tubules.

Mineralocorticoids (aldosterone) play a central role in H^+ secretion in the distal nephron by Na^+-dependent and Na^+-independent mechanisms. Mineralocorticoids exert their tubular effects through the mineralocorticoid receptor present in the distal collecting tubules. The downstream targets of mineralocorticoid receptor activation by aldosterone are the epithelial Na^+ channel (ENaC), the renal outer medullary K^+ channel (ROMK), and the serum and glucocorticoid–regulated kinase (SGK).[11] In the CCT, aldosterone increases Na^+ absorption and H^+ secretion. Mineralocorticoids also directly stimulate H^+ secretion in the OMCT and IMCT. Low systemic pH and high pCO_2 augment H^+ secretion in the distal nephron.

AMMONIA PRODUCTION AND EXCRETION

H^+ ion secreted by the distal nephron is buffered by NH_3 (ammonia) in the tubular lumen to form NH_4^+ (ammonium). NH_3 serves as an important buffer system in this location. Most ammonia is synthesized in the proximal tubular cells from the amino acid glutamine (Figure 42.6). The end products of glutamine metabolism are two NH_3^+ ions and α-ketoglutarate (α-KG). Further metabolism of α-KG yields two "new" HCO_3^- ions that are transported out of the cell across the basolateral membrane into the systemic circulation.[12]

Ammonia formed in the proximal tubular cells is highly permeable across cell membranes and can diffuse into the tubular lumen. Conventional thinking has been that NH_3, being noncharged, moves from the cytosol to the tubular lumen passively across the apical border. In this line of thinking, luminal NH_3 is thought to combine with secreted H^+ to form NH_4^+. Being charged, NH_4^+ is relatively impermeate across the lipid bilayer of the tubular cells and is trapped within the tubular luminal fluid (urine). More recent observations suggest that both NH_3 and NH_4^+ are preferentially moved from the proximal tubular cell into the tubular lumen via Na^+/H^+ exchanger, NHE3.[13] Any NH_4^+ that enters systemic circulation is metabolized in the liver to urea.

As tubular fluid leaves the proximal tubule, a number of processes lead to high medullary ammonia-ammonium concentrations. First, with the abstraction of H_2O from the thin descending limb of the loop of Henle, the tubular fluid becomes alkalinized by concentrating luminal HCO_3^-, which favors NH_3 efflux into the interstitium. Second, in the TAL, most of the tubular NH_4^+ is actively reabsorbed into the tubular cells from the luminal fluid by the $Na^+/2Cl^-/K^+$ cotransporter by substituting for K^+. Third, negative charge in the tubular lumen facilitates NH_4^+ movement into the interstitium. Fourth, similar to the proximal tubular mechanism, NH_4^+ transport across the basolateral surface is facilitated by Na^+/H^+ exchanger, NHE4.[13] The consequences of these complicated biologic maneuvers are twofold: (1) tubular fluid reaching the distal nephron has very little NH_3 or NH_4^+, and (b) the renal interstitium has a high concentration of NH_4^+, mirroring the concentration gradient observed in the medulla with urea.

The high interstitial NH_4^+ and NH_3 concentration facilitates its diffusion into the collecting duct, especially the IMCT, where it is "trapped" by the secretion of H^+ to form NH_4^+. NH_4^+ also can enter the collecting tubule lumen by substituting for K^+ on the Na^+/K^+-ATPase. This interaction of K^+ and NH_4^+ on the $Na^+/2Cl^-/K^+$ cotransporter and Na^+/K^+-ATPase is another mechanism by which plasma K^+ regulates
Figure 42.6 Renal ammonia metabolism. NH_4^+ is generated from glutamine in the proximal tubule cell. As the tubular fluid travels down the thin limb of the loop, water abstraction concentrates the luminal HCO_3^-, increasing the luminal pH favoring NH_3. NH_3 diffuses out of the lumen and into the medullary interstitium. The $2Cl^-$, Na^+, K^+ transporter can also actively transport NH_4^+ out of the lumen. Both of these processes lead to NH_4^+/NH_3 accumulation in the medulla and an increasing concentration favors ammonia entry into the medullary collecting duct. TAL, thick ascending limb.

<div style="border:1px solid #999;padding:8px">

KEY POINTS

- Ammonia (NH_3) formed in the proximal tubule reaches the distal tubule via the lumen, as well as from diffusion from the renal medullary interstitium.
- NH_3 traps H^+ in the distal tubule to form NH_4, which is excreted in urine.

</div>

NH_4^+ excretion. In summary, the net excretion of NH_4^+, and thus acid excretion, depends on NH_3 formation in the proximal tubule lumen, the development of the high interstitial medullary NH_3 gradient, and its trapping as NH_4^+ in the collecting duct by H^+ secretion.

Acidosis stimulates glutamine release from muscles, uptake by the proximal tubule cells, and metabolism to NH_4^+. Acidosis also increases glucocorticoid levels, which in turn stimulates ammoniagenesis. Hypokalemia also stimulates ammoniagenesis and hyperkalemia inhibits it. ATII increases proximal tubule secretion of NH_4^+.

CLASSIFICATION AND CLINICAL SPECTRUM OF RENAL TUBULAR ACIDOSIS

For clinical purposes, RTA is classified into four subtypes listed in Table 42.1. Distal RTA (DRTA) was the first one to be distinctly identified and is termed RTA type 1, and proximal RTA (PRTA), which is less commonly encountered, is known as RTA type 2. RTA type 3 has pathophysiologic and clinical features of both PRTA and DRTA, and RTA type 4 is associated with hyporeninemic-hypoaldosteronemic states, or associated with distal tubular resistance to aldosterone. Genetically inherited forms of RTA, with specific and recognizable phenotypes are increasingly being identified (Table 42.2), and these will continue to constitute an increasing clinical subgroup of RTA.

Clinical presentation of RTA in children is often protean and nonspecific. These manifestations include anorexia, vomiting, constipation, polyuria, and polydipsia. Failure to thrive is commonly present in infants and younger children.w HCMA, or normal anion gap metabolic acidosis, is the hallmark of all forms of untreated RTA. Normal anion metabolic acidosis also can be seen in clinical conditions other than RTA, and these need to be considered in the evaluation process (Table 42.3).

Table 42.1 Classification of renal tubular acidosis based on site and type of acidification defect

	RTA type 1 (Distal)	RTA type 2 (Proximal)	RTA type 3 (Mixed)	RTA type 4 (Hyperkalemic)
Defect site	Distal tubule	Proximal tubule	Proximal and distal tubule	Distal tubule and proximal tubule
Type of defect	Distal tubular H^+ excretion	Filtered HCO_3^- reabsorption defect	Distal tubular H^+ excretion. Proximal tubular filtered HCO_3^- reabsorption	Distal tubular H^+ and K^+ excretion Proximal tubular NH_3 synthesis secondary to hyperkalemia
Age of onset	Early infancy	Early infancy	Variable	Variable
Growth retardation	Yes	Yes	Yes	Uncommon, may be part of underlying disease
Bone disease	Osteopenia	Rickets common	Osteopetrosis in inherited form	Absent
Nephrocalcinosis	Common	No	No	No
Serum bicarbonate (mmol/L)	Low (15–19)	Low (10–15)	Low (15–19)	Low (15–19)
Serum potassium	Very low to low	Low to normal	Low to normal	High
Urine pH	>5.5	<5.5, untreated or severe acidosis. > 5.5 if treated or modest acidosis.	>5.5	<5.5
FE HCO_3	≤5%	>10%–15%	5%–15%	5%–10%
Ammonium excretion	Decreased	Normal	Decreased	Decreased
Urine anion gap	Positive	Negative	Positive	Positive

Abbreviations: FE, fractional excretion; RTA, renal tubular acidosis.

Table 42.2 Inherited forms of renal tubular acidosis

	OMIM	Gene product and gene	Distinctive clinical features
RTA type 1 (DRTA)			
Autosomal dominant	179800	AE1 *(SCL4A1)*	• Nephrocalcinosis • Nephrolithiasis • Older age of onset • RTA can be incomplete
Autosomal recessive	267300	β₁ subunit of H⁺-ATPase *(ATP6V1B1)*	• Deafness in early infancy • Nephrocalcinisis is prominent • Profound hypokalemia
Autosomal recessive	602722	α4 subunit of H⁺-ATPase *(ATP6V0A4)*	• Growth retardation • Deafness with later onset • Other features as noted in above *(ATP6V1B1)*
RTA type 2 (PRTA)			
Autosomal recessive	604278	NBC1 *(SLC4A4)*	• Ocular abnormalities (glaucoma, band keratopathy) • Mental retardation • Basal ganglia calcification • Enamel defects
Autosomal dominant or pseudodominant	179830	Not established yet	• Only one family described • Most have only short stature
RTA Type 3			
Autosomal recessive	259730	CA II *(CA2)*	• Osteopetrosis • Blindness • Deafness (conductive)
RTA Type 4			
Disorders of adrenal steroid biosynthesis			• Discussed in the text

Table 42.3 Causes of non–anion gap metabolic acidosis

Associated with hypokalemia

- Distal RTA
- Proximal RTA
- Diarrheal losses of bicarbonate
- Ureteroileostomy
- Ureterosigmoidostomy
- Toluene abuse (glue sniffing)
- Sjögren syndrome
- Drugs
  - Amphotericin B
  - Acetazolamide
  - Aminoglycosides
  - Sodium valproate,
  - Topiramate
  - Zonisamide
  - 6-Mercaptopurine
  - Ifosfamide
- Heavy metals (lead, cadmium, mercury)

Associated with normokalemia
- TPN use with amino acids
- Diagnostic or therapeutic intake of ammonium chloride or hydrochloric acid

Associated with hyperkalemia

- RTA type 4
- Sickle cell disease
- Obstructive uropathy
- Systemic lupus erythematosis
- Gordon syndrome
- Chronic interstitial nephritis
- Drugs
  - Cyclosporine
  - Tacrolimus
  - Spironolactone
  - Triamterene
  - Trimethoprim
  - Angiotensin-converting enzyme inhibitors
  - Angiotensin receptor blocker
  - Nonsteroidal anti-inflammatory drugs
  - Amiloride
  - Pentamidine

KEY POINTS

- For clinical purposes, RTA is classifiable into four subtypes.
- Clinical manifestations of all forms of RTA are nonspecific. Failure to thrive, especially poor weight gain, is common.
- Other conditions that cause non–anion gap metabolic acidosis need to be considered in the evaluation process.

Nephrocalcinosis, nephrolithiasis, and musculoskeletal pain are more commonly seen in older children and adults with RTA type 1. Patients with RTA, especially type 1, can present with life-threatening metabolic acidosis and hypokalemia. Rickets may be seen in DRTA but are more common in patients with Fanconi syndrome associated with PRTA. Genetically inherited variants of RTA may be seen in the context of other organ dysfunction, such as nerve deafness or osteopetrosis. RTA can be a feature of aldosterone deficiency and hyporeninemia from diabetes mellitus with renal insufficiency and a variety of interstitial diseases (RTA type 4).

RENAL TUBULAR ACIDOSIS TYPE 1

DRTA was the first to be recognized, and has been historically named RTA type 1.[14–16] Childhood presentation of RTA type 1 includes vomiting, failure to thrive, life-threatening metabolic acidosis, and hypokalemia. Less commonly, children with RTA type 1 present with nephrocalcinosis, renal calculi (at times as staghorn calculi), or bone disease. Children can develop rickets and in adults may have osteomalacia. Adults with RTA type 1 commonly present with renal calculi or with musculoskeletal complaints. Causes of RTA type 1 are listed in Table 42.4.

Inherited forms

RTA type 1 can be inherited as an autosomal dominant or recessive trait. Autosomal recessive form is the most common form of inherited RTA type 1. Mutations affecting the β_1 and α_4 subunits of the H^+-ATPase pump on the α-intercalated cell (Figure 42.7) result in autosomal recessive RTA type 1.[17–19] The *ATP6V1B1* gene on chromosome 2 encodes the β_1 subunit. The β_1 subunit of the H^+-ATPase pump is also important in maintaining the cochlear endolymph pH at 7.4, and patients with this genetic defect usually have early onset of severe bilateral sensineural hearing loss. Other features include profound hypokalemia, growth

---

Table 42.4 Causes of renal tubular acidosis type 1 or distal renal tubular acidosis

Genetic

- Autosomal dominant (AE1 deficiency)
- Autosomal recessive
- With deafness (β_1 subunit of H^+-ATPase)
- Without deafness (α_4 subunit H^+-ATPase)
- Ovalocytosis with AE1 mutation (Thailand)

Hereditary diseases

- Ehlers-Danlos syndrome
- Sickle cell disease
- Familial hypercalciuria
- Type 1 glycogen storage disease
- Carnitine palmitoyl transferase deficiency
- Medullary cystic disease
- Nephronophthisis

Hypercalciuria with nephrocalcinosis

- Primary hyperparathyroidism
- Hyperthyroidism
- Medullary sponge kidney
- X-linked hyperphosphatemia
- Fabry disease
- Vitamin D intoxication
- Wilson disease
- Hereditary fructose intoxication
- Idiopathic hypercalciuria

Autoimmune disease

- Sjögren syndrome
- Hyperglobulinemic purpura
- Systemic lupus erythematosus

Drug- and toxin-induced DRTA

- Amphotericin
- Cyclamate
- NSAIDs nephropathy
- Lithium
- Foscarnet

Tubulointerstitial disease

- Chronic pyelonephritis
- Obstructive nephropathy
- Acute and chronic renal transplant rejection
- Leprosy
- Hyperoxaluria
- Vesicoureteral reflux nephropathy

Functional (Decreased sodium delivery)

- Volume contraction (UNa <10 mEq/L)
- Edema forming states
- Nephrotic syndrome
- Cirrhosis
- Congestive heart failure

failure, and nephrocalcinosis, which can be seen even in neonates. Mutation affecting *ATP6V0A4* gene on chromosome 7 that encodes the α_4 subunit of the H^+-ATPase pump also causes autosomal recessive form of RTA type 1. Children with this gene mutation have preserved hearing during early childhood, but mild-to-moderate hearing impairment becomes evident as children get older.

Autosomal dominant RTA type 1 is the result of a defect in the HCO_3^-/Cl^- exchanger AE1 because of the mutations in the *SLC4A1* gene, located on chromosome 17.[20–22] These patients often present with renal stones, nephrocalcinosis, and incomplete RTA type 1.[19] Apart from the distal nephron, the AE1 exchanger is also expressed in the red blood cells. Some patients with the autosomal dominant form of RTA type 1 secondary to the *AE1* gene mutation may also have hemolytic anemia due to of spherocytosis.

A few studies from Thailand have reported the recessive form RTA type 1 and ovalocytosis with mutations in AE1 that facilitates bicarbonate-chloride transport in the α-intercalated cells of the distal collecting duct cells.[22,23] This disorder has been exclusively reported only from Southeast Asia. Other genetically transmitted diseases associated with RTA type 1 include Ehlers-Danlos syndrome,[24] hereditary elliptocytosis,[25] sickle cell disease,[26] familial hypercalciuria,[27,28] type 1 glycogen storage disease,[29] carnitine palmitoyltransferase type I deficiency,[30] and medullary cystic disease.[31]

Pathophysiology

Impaired H^+ ion secretion in the CCT and MCT leads to decreased ammonium and titratable acid excretion and an increased bicarbonate excretion (not reabsorbed in distal nephron), all of which cause metabolic acidosis. The hallmark of RTA type 1 is the inability to excrete appropriate amounts of H^+ and an inability to lower urine pH below 5.5 in face of systemic acidosis. In young children with RTA type 1, the fractional excretion (FE) HCO_3^- may be higher than usually seen in adults and can range from 5% to 15%, leading to potentially life-threatening acidosis.[14,16] Because of higher FE HCO_3^- in children compared to adults, treatment of RTA type 1 requires a larger dose in children, especially to maintain normal growth. After age 4 to 5 years, there is usually a decrease in the alkali requirement to levels seen in adults. Acidosis in RTA type 1 is associated with significant renal sodium wasting, leading to increased renin and aldosterone secretion, and hypokalemia that can be profound. Correction of the acidosis usually leads to a reduction in these electrolyte losses. Volume contraction and salt wasting are especially common in patients with nephrocalcinosis and tubulointerstitial disease.

The chronic metabolic acidosis leads to buffering of H^+ by the bone and impaired bone mineralization. This causes rickets in children and osteomalacia in adults.[14–16,32] Correction of the metabolic acidosis reverses this type of bone disease.[33] Chronic acidosis in RTA type 1 is also associated with decreased renal citrate production and hypocitraturia.[34] Combined with increased urinary calcium, hypocitraturia in these patients predisposes to nephrocalcinosis and nephrolithiasis (Figure 42.8).[14,16] Nephrocalcinosis further worsens NAE by impairing transfer of NH_4^+ from the loop of Henle into the collecting duct. Ongoing nephrocalcinosis and recurrent calcium phosphate and calcium oxalate stone disease can cause progressive loss of renal function. Alkali therapy decreases urinary calcium excretion and increases citrate excretion, reducing the risk for further nephrocalcinosis and stone formation. However, nephrocalcinosis, if present before alkali therapy is instituted, does not resolve with correction of acidosis. Chronic metabolic acidosis also interferes with growth, and failure to thrive and short stature are common findings in children with untreated RTA-type 1.[14–16]

Autoimmune disorders, especially Sjögren syndrome, have been associated with RTA type 1.[36–38] Nephrocalcinosis from any cause also can also lead to RTA type 1, by itself.

KEY POINTS

- Most cases of RTA type 1 have no clearly identifiable cause and are considered idiopathic.
- Genetic defects causing RTA type 1 are being increasingly recognized.
- Some inherited forms of RTA type 1 have associated sensorineural deafness.
- Hypercalciuria and nephrocalcinosis are common in RTA type 1.
Figure 42.7 Inherited defects in distal tubular hydrogen ion transport that result in renal tubular acidosis (RTA) type 1.
Figure 42.8 **(a)** Abdominal radiograph of a 17-year-old male patient with renal tubular acidosis type 1 demonstrating nephrocalcinosis affecting the renal pyramids. **(b)** CAT scan of the abdomen demonstrating medullary site of nephrocalcinosis in the same patient.

Buckalew et al.[27] described a large family in which the hypercalciuria and nephrocalcinosis preceded the development of RTA type 1. Medullary sponge kidney is associated with RTA type 1, suggesting that cystic dilatation of the collecting tubules can impair acid excretion.[31] Chronic medullary injury from sickle cell disease is also associated with RTA type 1.[26]

A functional defect and transient RTA type 1 may be observed in clinical states with markedly reduced distal Na^+ delivery. In conditions such as nephrotic syndrome, congestive heart failure, or cirrhosis, urine Na^+ concentration is below 10 mmol/L, resulting in impairment of voltage-dependent H^+ secretion in the CCT and an inability to lower the urine pH below 5.5.[39–41] Expanding volume in such patients, or increasing distal sodium delivery with furosemide or a nonreabsorbable anion-like sulfate restores the distal nephron's ability to acidify and excrete ammonium.

Strife et al.[41] described a group of young children who had a transient mild HCMA but were able to lower their urine pH below 5.5. Most had poor linear growth, and two of the seven patients described also had nephrocalcinosis. Although they could generate a low urine pH, they were unable to raise their urine pCO_2 above blood pCO_2, indicating rate-dependent RTA as proposed by Batlle at al.[42] On follow-up, none of these patients with rate-dependent RTA progressed to more severe RTA, and a number have been able to discontinue alkali supplementation altogether.

A number of medications have been implicated in impaired distal H^+ excretion. Amphotericin B alters the permeability of the distal nephron, allowing back-leak of H^+ from lumen to blood.[43] This dissipates the H^+ gradient (gradient defect RTA) and limits H^+ excretion. Lithium carbonate impairs H^+ secretion, but this usually does not result in disease.[44] Large doses of cyclamate and nonsteroidal anti-inflammatory drugs (NSAIDs) impair distal tubular H^+ secretion.[45,46] Foscarnet also has been shown to decrease distal acidification.[47] Tubulointerstitial diseases also can cause RTA type 1. These include transplant rejection,[48–50]

obstructive uropathy,[51,52] vesicoureteral reflux,[53] hyperoxaluria,[54] leprosy,[55] and pyelonephritis, especially if associated with urolithiasis.[56]

Treatment

Patients with RTA type 1 usually require 1 to 3 mEq/kg/day of alkali supplementation to correct the metabolic acidosis, often also resolving kaliuresis and naturesis, as well.[15,16] Infants and young children require larger doses of alkali supplementation for optimal growth, usually 2 to 4 mEq/kg/day, but at times more than 5 mEq/kg/day.[14–16,57] Larger doses are needed because of increased endogenous acid production and bicarbonate loss in young children with RTA type 1. Some patients require potassium supplementation, in addition to alkali therapy. When patients with RTA type 1 present with severe metabolic acidosis and hypokalemia, initial therapy should be directed at correcting hypokalemia before treating acidosis. Correcting the acidosis first may worsen hypokalemia and cause respiratory depression.

Prognosis

With adequate treatment, normal growth can be achieved and bone disease prevented or reversed. Early treatment is necessary to prevent nephrocalcinosis that can lead to renal insufficiency. After age 4 to 5 years, there is less bicarbonate loss and lower doses of alkali become necessary to correct metabolic acidosis (1 to 2 mmol/kg/day).

RENAL TUBULAR ACIDOSIS TYPE 2

Patients with RTA type 2, or PRTA, may present with an isolated defect of bicarbonate reabsorption, or as a generalized proximal tubular dysfunction (Fanconi syndrome) characterized by aminoaciduria, phosphaturia, and glycosuria, in addition to bicarbonaturia. Common causes of RTA

type 2 are listed in Table 42.5. Fanconi syndrome can result from inherited error of metabolism, such as cystinosis, tyrosinemia, galatosemia, Wilson disease, Lowe syndrome, and mitochondrial myopathies, as well as many drugs and toxins. Transient isolated RTA type 2 also has been described in newborns, especially in premature and extremely premature infants.[58,59]

Inherited forms

An autosomal recessive RTA type 2 has been well described. In addition to the features of RTA type 2, these patients also have mental retardation and ocular abnormalities, such as glaucoma and corneal opacities. It is caused by a genetic defect in defect in the NBC1 cotransporter (sodium-bicarbonate cotransporter 1) (Figure 42.9).[61–63] The *SLC4A4* gene, which encodes for NBC1, is located on chromosome 4. A much less common autosomal dominant form of RTA type 2 has been described by Brenes et al.[60] All patients in this group were asymptomatic, other than having short stature. A genetic defect in these patients has not been clearly identified.

CA II is essential for both bicarbonate reabsorption and hydrogen ion secretion in the renal tubules. Deficiency of CA II results in a unique disorder consisting of osteopetrosis and RTA with features of both RTA type 2 and RTA type 1.[64] These patients also may have brain ventricular fluid or cerebrospinal fluid abnormalities or both, since CA II also plays a role in cerebrospinal fluid turnover in the lateral ventricles.

- Leigh syndrome
- Metachromatic leukodystrophy

Carbonic anhydrase inhibition
- Topiramide (Topamax)
- Acetazolamide
- Sulfanilamide
- Mafenide

Pathophysiology

The pathophysiology of RTA type 2, except in the inherited variants of CA II and NBC1 deficiency, remains unclear. In the autosomal recessive form of RTA type 2, the basolateral NBC1 cotransporter is deficient.[63] This exchanger is necessary for transporting HCO_3^- out of the proximal tubule cell in exchange for Cl^- and its impaired activity inhibits luminal reabsorption of filtered HCO_3^-. NBC1 is also highly expressed in corneal endothelium, and its defective function
Figure 42.9 Site of defect in recessive form of renal tubular acidosis (RTA) type 2. CA II, carbonic anhydrase II. CA IV, carbonic anhydrase IV; NHE3, sodium-hydrogen ion exchanger 3 (also known as sodium-hydrogen antiporter 3); NBC1, sodium-bicarbonate cotransporter 1.

is associated with corneal opacities, cataracts, and glaucoma.[26] In CA II deficiency, cytosolic carbonic anhydrase is defective and unable to generate adequate H^+ and HCO_3^- for transepithelial transport of the filtered HCO_3^-.[21,25] CA II is also present in the α-intercalated cell in the CCT leading to impaired generation of H^+ for transport into the distal nephron leading to RTA type 1 as well.

Other possible mechanisms for RTA type 2 include an abnormality in the Na^+/H^+ exchanger on the lumen membrane or CA IV on the luminal membrane. An abnormality at either of these sites would impair reclamation of the filtered bicarbonate, causing excessive amounts of HCO_3^- to escape the proximal tubule. This excess HCO_3^- would overwhelm the limited capacity of distal nephron, which is able to reclaim only up to 15% of the filtered load, leading to bicarbonaturia along with the loss of Na^+ and K^+. The bicarbonaturia leads to a fall in plasma HCO_3^- and thus a fall in the filtered load. At some point the filtered load decreases to the extent that the nephron is able to reclaim virtually the entire filtered load of bicarbonate. The serum HCO_3^- concentration at which this occurs is termed the *renal threshold* for bicarbonate. In such a steady-state, the distal nephron is now able to acidify urine and the urine pH can be <5.5.

> ### KEY POINTS
>
> - Most cases of RTA type 2 have no clearly identifiable cause and are considered idiopathic.
> - Genetic defects in the NCB1 exchanger have been shown to cause RTA type 2.
> - Bicarbonaturia is the hallmark of RTA type 2.
> - Fanconi syndrome is characterized by glucosuria, phosphaturia, aminoaciduria, and bicarbonaturia.

Clinical manifestations

RTA type 2 usually manifests with clinical features of growth failure in infants and children.[58] Recurrent vomiting is another common symptom. Untreated patients have severe metabolic acidosis with serum HCO_3^- in the range of 10 to 15 mMol/L, mild hypokalemia, and the urine pH is often below 5.5. This paradoxical finding results from the fact that as serum bicarbonate declines during severe metabolic acidosis, filtered bicarbonate load diminishes to within the range of proximal tubular threshold for bicarbonate. This results in reabsorption of most of the filtered bicarbonate, leaving little of it in the tubular fluid. Since the distal tubular hydrogen ion secretion is intact in such patients, urine can be adequately acidified and urine pH can be lowered to < 5.5. However, once patients receive alkali supplementation and serum bicarbonate level improves, filtered bicarbonate load again increases and exceeds the proximal tubular bicarbonate reabsorptive threshold, resulting in an alkaline urine pH (often >7). Polyuria resulting from solute diuresis is

common. Aldosterone and renin levels are elevated because of the associated renal sodium and water loss, and intravascular volume depletion. Hypokalemia in RTA type 2 results from potassium secretion by the principal cells in the CCT secondary to elevated aldosterone levels. Metabolic acidosis often causes vomiting, decreased appetite, and caloric intake, eventually leading to failure to thrive. With the correction of metabolic acidosis, failure to thrive can be reversed. Isolated RTA type 2 is not associated with abnormalities of serum calcium, phosphorus, or vitamin D. Nephrolithiasis and nephrocalcinosis are absent in RTA type 2, because citrate excretion is unaffected or may even be increased.

RTA type 2 may be associated with a more global disorder of proximal tubule functions, known as Fanconi syndrome. Fanconi syndrome is characterized by glucosuria, aminoaciduria, and phosphaturia, in addition to bicarbonaturia.[59] Rickets and osteomalacia secondary to renal phosphate losses and abnormal vitamin D metabolism are common in patients with Fanconi syndrome. A number of inborn errors of metabolism are associated with Fanconi syndrome, including cystinosis, tyrosinemia, hereditary fructose intolerance, Wilson disease, galactosemia, and Lowe syndrome (Table 42.6). Several drugs can result in Fanconi syndrome (Table 42.7).

Treatment

The goal of RTA type 2 treatment is the normalization of serum HCO_3^-. However, as serum HCO_3^- is corrected, urinary HCO_3^- losses also increase. Thus, 2 to 20 mEq/kg/day of alkali supplementation, either as bicarbonate or as an anion that can be metabolized to form bicarbonate, is necessary for

correction of metabolic acidosis in RTA type 2 (Table 42.8). Given that the ability of the nephron to reabsorb bicarbonate is impaired, it may not be possible to fully overcome the effect of bicarbonate losses. Alkali administration should be divided into multiple, frequent doses. Sodium restriction or hydrochlorothiazide (1.5 to 2 mg/kg/day) may decrease alkali requirements by increasing proximal HCO_3^- reabsorption. Potassium losses often increase with alkali replacement. Therefore, some or all of the replacement alkali should be given as the potassium salt, such as potassium citrate.

The primary treatment of Fanconi syndrome is to treat the underlying cause with available specific therapies. This would include cysteamine for cystinosis, 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC) for tyrosinemia, penicillamine for Wilson disease, avoidance of galactose in galatosemia, and avoidance of fructose in hereditary fructose intolerance. In patients in whom the primary disease cannot be corrected, supplemental phosphate (Neutra-Phos or Phospha 250 Neutral), vitamin D (calcitriol), sodium, and potassium supplements must be given in addition to bicarbonate.

Prognosis

Isolated RTA type 2 can be transient, and supplemental alkali for a period to preserve growth is all that is necessary. In others, the RTA type 2 is life-long disorder, and supplemental alkali is necessary to preserve bone mineralization. The prognosis of children with Fanconi syndrome depends on the underlying cause. Wilson disease, tyrosinemia, galatosemia, and hereditary fructose intolerance can have a relatively good prognosis with early intervention. Early therapy with cysteamine in children with cystinosis is beneficial, although the long-term prognosis for preservation of renal function is unclear.[64] To date, there is no, or only incomplete, therapy, directly aimed at patients with Lowe syndrome or mitochondrial myopathies. Patients with acquired Fanconi syndrome have an outcome dependent on the extent of injury at the time the disorder is discovered, with some patients having only transient disease and others permanent.

Table 42.8 Commonly available alkali replacements

Name	Composition	Amount of alkali
Sodium bicarbonate tablets	Sodium bicarbonate	
325 mg		4 mEq
650 mg		8 mEq
Bicitra, Oracit, Cytra-2, Shohl solution	Sodium citrate	1 mEq/mL
Citra-K solution	Potassium citrate	2 mEq/mL
Citra-3 solution	Sodium and potassium citrate	2 mEq/mL
Cytra-K packet	Potassium citrate	30 mEq/packet
Urocit-K tablet	Potassium citrate	5- and 10-mEq tablets

RENAL TUBULAR ACIDOSIS TYPE 3

After the description of RTA types 1 and 2, it was recognized that some infants and young children had inability to acidify their urine in the face of severe acidosis and also had significant urinary bicarbonate losses, in the range of 5% to 10% of the filtered load.[14,16,65] A few of these infants had a fractional bicarbonate loss as high as 15%. This combined pattern suggesting a proximal and distal nephron dysfunction, and was termed RTA type 3. It was recognized later that the bicarbonate loss improved after the child was 4 to 5 years old and the abnormality was then consistent with RTA

type 1 or DRTA. Whether this disorder primarily reflects proximal or distal tubular dysfunction is still unclear, and its existence has been questioned by some.

An autosomal recessive disorder characterized by osteopetrosis, mental retardation, cerebral calcifications (marble brain disease), and metabolic acidosis has been described in association with deficiency of cytosol CA II and is caused by loss of function mutation in *CA2* gene.[66] CA II is in the cytoplasm of a number of cells, including proximal and distal tubule cells, as well as osteoclasts. Defective CA II function impairs the ability of these cells to form HCO_3^- and H^+ from H_2O and CO_2, a process that facilitates reclamation of filtered bicarbonate in the proximal tubule. In the distal tubular cells, absence of CA II impairs acidification and bicarbonate regeneration (Figure 42.9). H^+ secretion by the osteoclast is also important for bone remodeling and may be an important pathogenic factor in the development of the bone disease in osteopetrosis (Figure 42.10). These patients can have conductive nerve deafness. Metabolic acidosis in these patients is a combination of defective HCO_3^- reclamation and H^+ excretion—RTA type 3.

KEY POINTS

- RTA type 3 has features of both RTA types 1 and 2.
- Some have questioned the existence of clinically distinct RTA type 3.
- Osteopetrosis and RTA type 3 resulting from a genetic defect in intracellular CA II are well recognized.

RENAL TUBULAR ACIDOSIS TYPE 4

RTA type 4 or hyperkalemic RTA is an uncommon form of RTA that can be seen in diverse clinical disorders. The distinguishing feature of RTA type 4 is the presence of hyperkalemia, in addition to a mild normal anion gap metabolic acidosis. These patients are able to acidify the urine pH below 5.5. Patients with RTA type 4 have underlying aldosterone deficiency or tubular resistance to it. Infants with RTA type 4 often present with failure to thrive. Causes of RTA type 4 are listed in Table 42.9.

KEY POINTS

- RTA type 4 results from hyporeninemia and hypoaldosteronemic states.
- Hyperkalemia is the hallmark of RTA type 4.
- Hyperkalemia reduces proximal tubular NH_3 generation, leading to decreased acid excretion.

Pathophysiology

RTA type 4 is caused by hyperkalemia associated with aldosterone deficiency or tubular resistance (Figure 42.11). Hyperkalemia decreases proximal tubule ammonia production and competes with NH_4^+ for the $Na^-/2Cl^-/K^+$ transporter in the ascending limb of the loop of Henle, reducing the medullary ammonium gradient. Hyperkalemia also impairs the entry of NH_4^+ into the MCT cell from the
Figure 42.10 Skeletal radiographs of a 10-day-old newborn with loss of function carbonic anhydrase (CA) mutation leading to renal tubular acidosis (RTA) type 3 and osteopetrosis. **(a)** There is a generalized increase in bone density. Typical features of osteopetrosis are the "bone in bone" appearance seen in the left humerus and iliac crests (a, arrows), and the severely sclerotic appearance of the skull base relative to the calvarium **(b)**. Soft tissue calcification is evident in **(c)**. (Reproduced with permission from: Borthwick KJ, Kandemir N, Topaloglu R, et al. J Med Genet. 2003;40:115–21.)

medullary interstitium via the K^+ secretory site on the basolateral membrane Na⁺,K⁺-ATPase. The net effect is decreased NH_4^+ and NAE.[67] Aldosterone deficiency or resistance decreases H^+ secretion in the collecting duct by decreasing the number and function of H^+-ATPase pumps. Aldosterone is also important for increasing the negativity of the lumen of the CCT by enhancing the absorption of Na^+ via the apical membrane epithelial sodium channel (ENaC) and the basolateral membrane Na⁺,K⁺-ATPase. The increased lumen negativity facilitates H^+ secretion into the lumen of CCT.

Inherited forms

STEROID BIOSYNTHESIS DEFECTS

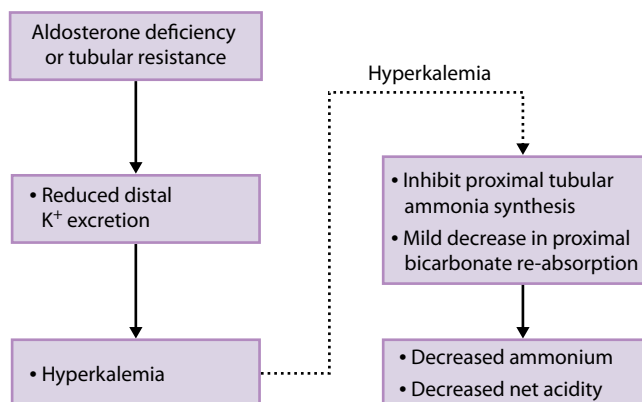
Several autosomal recessive genetic disorders of adrenal steroid synthesis leading to decreased or absent aldosterone synthesis can result in RTA type 4 in infants and children. The most common defect of adrenal steroid synthesis is 21-hydroxylase deficiency (CYP21), coded for by the genes on chromosome 6 (Online Mendelian Inheritance in Man [OMIM] #613815).[68,69] Rarely, the cortisol and sex steroid pathways are entirely normal and there is an isolated aldosterone deficiency. This results from the defect in the enzyme aldosterone synthase (CYP11B2) also known as corticosterone methyloxidase, which is involved in the final step of aldosterone synthesis and converts deoxycorticosterone to aldosterone. Two distinct subtypes of aldosterone synthase deficiency have been characterized and are known as type I (OMIM #124080) and type II (OMIM #124080) defects. These enzymatic defects have similar phenotypic expression but have varied biochemical identifiers. Other rare defects in steroid biosynthesis involve 3β-hydroxysteroid dehydrogenase, coded on chromosome 1 and congenital lipoid adrenal hyperplasia or StAR deficiency, coded on chromosome 8.[70,71]


Figure 42.11 Pathophysiology of renal tubular acidosis (RTA) type IV (hyporeninemia-hypoaldosteronemia).

PSEUDOHYPOALDOSTERONISM

Autosomal dominant pseudohypoaldosteronism I (PHA I) is associated with hyperkalemia, salt wasting, elevated renin and aldosterone levels, and hypotension. Autosomal dominant PHAI is caused by a mutation in the mineralocorticoid receptor in the collecting tubule.[72] The mutant mineralocorticoid receptor is unable to respond to aldosterone properly, and this leads to a decrease in the activity of the ENaC. This in turn decreases luminal Na^+ absorption and the transepithelial potential difference. The decreased potential difference reduces K^+ and H^+ secretion.[72] Supplemental mineralocorticoid therapy will not correct the defect. However, carbenoxolone, an 11 β-hydroxysteroid dehydrogenase inhibitor, can raise intracellular cortisol levels and overcome the functional defect in the mineralocorticoid receptor. The clinical features become less severe as the child ages.

Autosomal recessive PHAI is caused by a defective ENaC.[72,73] Infants with recessive PHAI have severe hyperkalemia, salt wasting, RTA type 4, and hypotension. Renin and aldosterone levels are elevated. Newborns with recessive PHAI may have respiratory distress due to impaired Na^+ and water reabsorption from the alveoli resulting from defective ENaC in the alveolar membranes.[74]

Gordon syndrome, or pseudoaldosteronism II (PHAII), is a rare autosomal dominant disorder characterized by hypertension, hyperkalemia, low renin, low aldosterone levels, RTA type 4, and mild volume expansion.[75] Previously, PHAII was thought to result from an early distal tubule "chloride shunt." It is now known to be caused by mutations in WNK4, Kelch-like 3, and Cullin 3 proteins.[76] WNK4, coded on chromosome 17, inhibits the NaCl cotransporter in the DCT and the ROMK channel, and the paracellular permeability of Cl^-. Mutations in WNK4 increase the activity of the NaCl cotransporter and paracellular Cl^- permeability, but inhibit ROMK activity, leading to volume expansion, hyperkalemia, and voltage dependent type IV RTA. Abnormalities in Kelch-like 3 and Cullin 3 proteins may interfere with the ubiquitination and degradation of distal nephron proteins involved with NaCl absorption and K secretion.[77] How WNK1 mutations cause Gordon syndrome is unclear. Thiazide diuretics correct the hyperkalemia, acidosis, and hypertension.

Acquired hypoaldosteronism and aldosterone resistance

Acquired diseases of the adrenal gland can lead to RTA type 4, including autoimmune adrenal failure, tuberculosis, fungal infection, or acquired immunodeficiency syndrome (AIDS). Isolated hypoaldosteronism can occur in critically ill patients and is thought to be related to inhibition of aldosterone synthetase by hypoxia, cytokines, atrial natriuretic peptide, and heparin.[78] Hypoaldosteronism leads to hyperkalemia and RTA type 4. Hyporeninemic, hypoaldosteronism typically occurs in older patients with renal insufficiency from diabetic nephropathy, AIDS, systemic lupus erythematosus (SLE) and tubulointerstitial nephritis.[79] The hyporeninemia does not respond to the usual measures to stimulate renin secretion, but low aldosterone levels increase with the infusion of angiotensin II.

Tubulointerstitial diseases may also cause unresponsiveness to aldosterone, leading to hyperkalemia and metabolic acidosis from decreased ammonium excretion. Such tubulointerstitial diseases include analgesic abuse, sickle cell disease, nephrolithiasis, nephrocalcinosis, acute and chronic transplant rejection, and SLE. Infants with fetal alcohol syndrome may have mild RTA type 4.[80] Obstructive uropathy and renal dysplasia are also common causes of RTA type 4 and relative tubular unresponsiveness to aldosterone in children.[52,53,81,82]

A number of drugs can cause RTA type 4. NSAIDs can cause hyperkalemia and metabolic acidosis by inhibiting renin release.[83] β-Blockers similarly inhibit renin release and alter potassium distribution. Heparin can be directly toxic to the zona glomerulosa and inhibit aldosterone synthase.[84] Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers lead to hypoaldosteronism and can cause hyperkalemia and acidosis, especially in patients with renal insufficiency. Spironolactone is a competitive inhibitor of aldosterone and also can cause hyperkalemia and metabolic acidosis.[85] Amiloride, triamterene, trimethoprim, and pentamidine inhibit the ENaC channel in the collecting duct principal cell.[86–88] This lowers the transepithelial potential difference reducing the secretion of H^+ and K^+. The resulting hyperkalemia reduces ammonium production and excretion. Cyclosporine and tacrolimus cause hyperkalemia and metabolic acidosis through inhibition of basolateral Na^+,K^+-ATPase.[89,90] This decreases intracellular K^+ concentration and the transepithelial potential, lowering the driving force for K^+ secretion in the CCT.

Diagnosis of renal tubular acidosis type 4

The responsiveness of the CCT to aldosterone in the setting of hyperkalemia can be evaluated by the transtubular gradient for potassium (TTKG), that is the potassium gradient between the peritubular capillary and the CCT lumen.[91] The TTKG is defined as:

$$TTKG = \frac{UrineK \times Serum\ Osmolality}{Serum\ K \times Urine\ Osmolality} \qquad (42.5)$$

A TTKG of 8 or greater indicates that adequate aldosterone is present and that the CCT is responding appropriately in the hyperkalemic patient. A value less than 8 suggests aldosterone deficiency or tubular unresponsiveness. Patients with aldosterone deficiency will increase their TTKG after several days of therapy with fludrocortisone, whereas those with tubular insensitivity fail to do so. Although the TTKG is a useful clinical test, it tends to underestimate the K^+ secretory capacity in the hyperkalemic patient with dilute urine.

Treatment of renal tubular acidosis type 4

Treatment in RTA type 4 is based on the underlying cause. A careful history of drug use is important to identify potential

offending pharmaceutical or toxic agents. Evaluation of plasma renin activity, aldosterone secretion, and TTKG is useful to distinguish aldosterone deficiency from tubular unresponsiveness. Patients with glucocorticoid and mineralocorticoid deficiency need replacement steroids. Patients with hyporeninemic, hypoaldosteronism may benefit from a loop diuretic and cation exchange resin to increase potassium excretion. Supraphysiologic doses of fludrocortisone may be helpful, but can cause volume overexpansion and hypertension.

Infants with PHAI should get salt supplements to correct the volume depletion. In contrast, patients with PHAII should be treated with thiazide diuretics and salt restriction. Patients with tubular resistance to aldosterone and hyperkalemia should be treated with dietary K^+ restriction and loop diuretics to increase K^+ secretion and augment transepithelial potential difference. Cation exchange resins to decrease the hyperkalemia also may be helpful. Supplemental alkali should be used to treat the acidosis as discussed previously.

CLINICAL TOOLS FOR EVALUATION

Anion gap

The first step in evaluating a patient for RTA is to look for HCMA by determining the anion gap (AG) in the serum of patients with acidosis.

$$AG = Na^+ - (HCO_3^- + Cl^-) \qquad (42.6)$$

AG between 6 and 16 is normal; AG exceeding 16 is elevated.

Normal serum AG varies over a wide range because of the large span of normal values of electrolytes used in this calculation. Whether or not serum potassium is used in this calculation also determines the normal value of serum AG. Most laboratories, however, do not include potassium in this calculation. Readers should familiarize themselves with normal values in their clinical laboratory. The serum HCO_3^- should be measured soon after obtaining the serum. Factors that can lead to a falsely low HCO_3^- concentration include allowing the sample to remain in contact with red cells for a prolonged period, obtaining the blood by "heel prick," and a prolonged tourniquet time. Serum albumin accounts for the bulk of the anion gap, therefore changes in the serum albumin should be taken into consideration when calculating anion gap. For every 1 g/dL decrease in the serum albumin below normal, the anion gap will decrease by approximately 2.5 mEq/L.[92]

Urine pH

Measuring urine pH is the traditional method for initial evaluation of patients suspected to have RTA. Urine pH >6.5 in face of metabolic acidosis is considered as a presumptive evidence of RTA. Some authors have, however, downplayed the importance of urine pH in the diagnosis of RTA.[93] These investigators have argued that ammonium generation is a better index for understanding the pathophysiology as well as diagnosis of RTA. It is important to note that the normal urine pH varies quite widely, depending on diet consumed. Furthermore, patients with chronic acidosis and normal renal tubular function can have a low urine pH between 5.4 and 6.4.[94,95] Therefore, an elevated urine pH (>6.5) should be considered abnormal only if associated with metabolic acidosis. Urine pH is measured ideally by glass electrode, since urine dipsticks are relatively inaccurate.

Urine anion gap

As mentioned previously, urinary ammonium excretion is the prime renal defense against an acid load. Therefore, determining the rate of urine NH_4^+ excretion is the next critical step in deciding whether there is a renal tubular acidification defect. Direct measurements of urine ammonium generally are not available to the clinician. Carlisle et al.[93] have shown that an estimate of urine ammonium can be made by determining the urine net charge or urine anion gap (UAG). The urine cations, Na^+, K^+, NH_4^+, calcium (Ca^{2+}), and magnesium (Mg^{2+}), must balance the urine anions, which are Cl^-, HCO_3^-, PO_4^-, SO_4^-, and organic anions. Urine Ca^{2+}, Mg^{2+}, PO_4^-, and SO_4^- usually are in relatively low and fixed concentrations such that they can be ignored. If the urine pH is below 6.5, the urine HCO_3^- concentration will be very low. In absence of an inborn error of metabolism, urine organic acid concentration will also be very low. Therefore, under most circumstances, the major ions in urine are Na^+, K^+, NH_4^+, and Cl^-, all of which can be easily measured and UAG calculated as follows:

$$\text{UAG or Urine net charge} = Na^+ + K^+ - Cl^- \qquad (42.7)$$

Carlisle et al.[93] demonstrated that when the concentration of Cl^- exceeds that of $Na^+ + K^+$, then NH_4^+ concentration must be high and the renal tubule is responding appropriately to the acidosis. Therefore, under normal circumstances, UAG is either zero or slightly positive (less than 10 mmol/L). The expectation is that with metabolic acidosis, ammonium excretion will increase and will be excreted as ammonium chloride, increasing urine chloride concentration. This would make the UAG negative (–10 to –20). In case of RTA type 1, in which H^+ secretion by the distal nephron is defective, UAG remains positive, despite presence of metabolic acidosis. This contrasts with extrarenal losses of bicarbonate, such as in diarrheal disorders, in which renal ammonium generation is normal and therefore UAG is negative.

Another indirect method of assessing renal ammonium excretion is by assessing the urinary osmolal gap.[96] Urinary osmolal gap is calculated by subtracting calculated urine osmolality from measured urine osmolality (See Equation 42.4). Urine osmolal gap divided by 2 (to account for accompanying anion) approximates urinary ammonium excretion (in milliequivalents/L). Normal urinary ammonium excretion varies from 5 to 50 mEq/L. If this result is greater than 75 mEq/L, the kidney is responding appropriately to metabolic acidosis by generating significant

amounts of ammonium. Urinary ammonium of less than 25 mEq/L in face of metabolic acidosis should be considered evidence of an inappropriately poor renal response and suggestive of the diagnosis of RTA type 1. Estimating ammonium excretion using the urine urinary osmolal gap is especially helpful in situations where a large amount of unmeasured organic anion present, such as hippurate to (glue-sniffing) or β-hydroxybutyrate (diabetic ketoacidosis) are present in urine. In these situations the UAG may be positive, even though the kidney is excreting appropriate amounts of ammonium that can be detected by the calculating the urine osmolal gap.

Fractional excretion of bicarbonate

To test the tubular ability to reclaim the filtered load of HCO_3^-, the fractional excretion of HCO_3^- can be determined after the serum HCO_3^- has been restored to normal (22 to 25 mEq/L) by simultaneously measuring the serum creatinine and HCO_3^- and the urine creatinine and HCO_3^-.

$$FE\ HCO_3^- \frac{U_{HCO_3^-}}{U_{creatinine}} \times \frac{P_{creatinine}}{P_{HCO_3^-}} \times 100 \qquad (42.8)$$

Normally this value should be less than 5%. With RTA type 2, the FE HCO_3^- exceeds 15%, and in the RTA type 1 FE HCO_3^- is less than 15%, usually 5% to 10%.[1] Urine HCO_3^- is calculated by measuring the urine pH and pCO_2 on a standard blood gas analyzer. Bicarbonate is calculated from the Henderson-Hasselbalch equation as follows:

$$HCO_3^- = 10^{(pH-pK)} \times 0.03 \times pCO_2 \qquad (42.9)$$

In the above formula one can assume the pK to be close to 6.1. Most blood gas analysis machines can provide calculated urine HCO_3^- values directly, without the need to calculate it from Equation 42.9.

Urine-blood pCO_2

The urine pCO_2 concentration in alkaline urine has been used to test the distal nephron's ability to secrete H^+.[97] In the distal tubular lumen, the H^+ combines with HCO_3^- and the resulting H_2CO_3 only slowly decomposes into H_2O and CO_2 because carbonic anhydrase IV absent from the luminal membrane, unlike in the proximal tubule. This slow decomposition means that CO_2 remains in urine where it can be measured. The countercurrent system in the medulla also helps maintain a high urine pCO_2.

To perform this test, the urine pH and HCO_3^- concentration are raised to greater than 7.5 and 85 mEq/L, respectively by infusing HCO_3^- (2.5 mEq/Kg) or administering acetazolamide 17 mg/kg. Urine and blood pCO_2 is then measured.[98] A normal response is that urine pCO_2 that exceeds the blood pCO_2 by 30 mm Hg. If this difference is less than 30 mm Hg, distal hydrogen ion pumping is defective and is suggestive of RTA type I or DRTA. In contrast, urine pCO_2 exceeds the blood pCO_2 by 30 mm Hg in patients with RTA type II (PRTA), since distal hydrogen ion secretion is intact in these patients.

Acid loading

The classic test for RTA is to determine the NAE (see Equation 42.1) during spontaneous acidosis or after acid loading. Most children with untreated RTA have metabolic acidosis, making acid loading unnecessary. Acid loading can be useful in equivocal cases. Traditionally, ammonium chloride (NH_4Cl) is given orally in a dose of 150 to 300 mg/kg.[99,100] The urine is then collected for 4 to 8 hours and the urine pH, titratable acid (defined as the amount of NaOH need to raise the urine pH to 7.4), and urine ammonium are measured. Oral $CaCl_2$ (2 mg/kg) and intravenous arginine hydrochloride (150 mEq H^+/m^2 or 300 mL/m^2 of a 10% arginine solution) have also been used for acid loading.[101,102] A normal response is a lowering of urine pH to less than 5.2 and an increase of TA to above 33 μEq/min/1.73 m^2, and ammonium to above 46 μEq/min/1.73 m^2.

Furosemide and sodium sulfate challenge test

A simple way of testing the distal tubule's ability to acidify the urine is to give 1 to 2 mg/kg of furosemide orally or intravenously, especially in combination with fludrocortisone. Furosemide causes an increase in distal Na^+ and Cl^- delivery.[103] The Na^+ is reabsorbed but the poorly reabsorbed Cl^- causes a lumen negative transepithelial potential difference and increased H^+ secretion.[11] Expected normal response is a fall in urine pH to below 5.5 and a doubling of the urinary excretion of net acid and potassium 2 to 5 hours after administration

Sodium sulfate infusion (¼ to ½ g/kg) also can be used to assess distal H^+ secretion. Sulfate is poorly reabsorbed in the distal nephron, increasing the lumen negative, transepithelial potential difference. This facilitates H^+ secretion and a fall in urine pH below 5.[104] An abnormal response to either sodium sulfate or furosemide suggests either a secretory (hydrogen pump) or voltage-dependent defect.

Approach to evaluation of a child for possible renal tubular acidosis

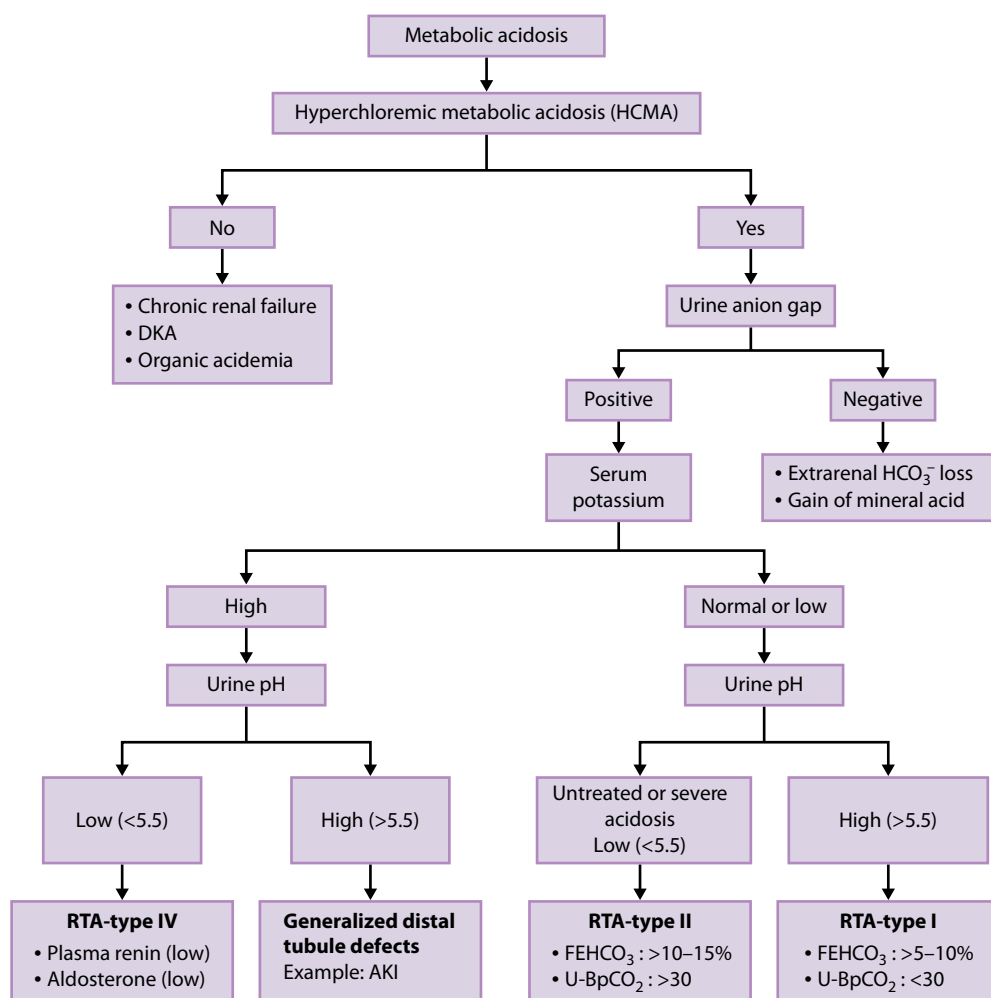
The initial step in the evaluation of a child suspected to have RTA is to document the presence of hyperchloremic normal anion gap metabolic acidosis (Figure 42.12). The history and physical examination should also be supportive of the diagnosis, and extrarenal bicarbonate loss, such as with ongoing diarrhea, should be ruled out. Arterial blood gas analysis is generally not necessary in most patients with suspected RTA. But if obtained, the test would document a low blood pH and CO_2. Next, the serum electrolytes should be obtained to document evidence for low bicarbonate, hyperchloremia, hypokalemia, and anion gap should


Figure 42.12 Algorithm for evaluation of a child suspected to have RTA. HCMA, hyperchloremic metabolic acidosis. DKA, diabetic ketoacidosis.

be determined and corrected for serum albumin. Urine pH should be obtained order to document an inappropriately elevated urine pH in face of metabolic acidosis. If the anion gap is between 6 and 16 mEq/L (normal anion gap metabolic acidosis), RTA is a diagnostic possibility. If the anion gap is elevated, some other cause of metabolic acidosis must be sought, such as renal failure, diabetic ketoacidosis, or another organic acidosis.

The next step in the evaluation of normal anion gap acidosis, or hyperchloremic metabolic acidosis (HCMA), is to measure the urine net charge (urine anion gap) to determine if there is an appropriate increase in urine ammonium excretion. If the net charge is negative, then the cause of the acidosis is extrarenal, such as gastrointestinal loss of HCO_3^-. If the anion gap is positive, the patient has RTA.

To determine the type of RTA, the following steps are helpful. Measure serum K^+. If the serum K^+ is high, the low urine NH_4^+ concentration is a consequence of hyperkalemia and the patient can be diagnosed to have RTA type 4. Measurement of serum renin and aldosterone and the TTKG are useful to determine whether the hyperkalemia is from hypoaldosteronism or distal tubular resistance to the hormone. Metabolic

acidosis in RTA type 4 is usually modest, with serum bicarbonate is the range of 16–18 mEq/L. Urine pH is <5.5, since urinary acidification is normal in these patients.

If the serum K^+ is low, the next step is to determine the urine pH and fractional excretion of HCO_3^- with alkali loading. Urine pH in RTA II or PRTA can be variable, being low (<5.5) during severe and spontaneous metabolic acidosis. This results from the fact that filtered bicarbonate load decreases as acidosis becomes more severe, and the proximal tubules are able to reabsorb most of the tubular load of bicarbonate. As patients are treated with alkali and serum bicarbonate level rises, filtered bicarbonate load increases and urine pH rise to >5.5, and is often >6.5. A low urine pH during spontaneous acidosis along. A high urinary fractional excretion of HCO_3^- (greater than 10% to 15%) is another important feature of RTA II. The presence of glucosuria, hypophosphatemia, and aminoaciduria, along with the HCMA and hypokalemia, suggests a global proximal tubule disorder, Fanconi syndrome. A urine pH greater than 5.5 in the face of metabolic acidosis, hyperchloremia, hypokalemia, and $FEHCO_3^-$ of 5% to 10% is suggestive of RTA type I, or DRTA. suggests DRTA. An FE HCO_3^- above

10% is common in infants and young children with DRTA. Further confirmation of RTA type I or DRTA can be made by demonstrating a low urine-blood (U-B) pCO_2 during HCO_3^- loading or after acetazolamide.

CLINICAL VIGNETTES

Clinical Vignette 42.1

An 8-month-old infant was noted to be failing to thrive. Serum electrolytes showed a Na+, 140; K+, 3.5; Cl–, 114; and HCO_3^-, 14 mEq/L. The urinalysis had no glucosuria or proteinuria. Urine amino acids were normal. He was started on supplemental alkali and his serum HCO_3^- rose to 24 mEq/L after giving him 8 mEq/kg/day. His urine pH rose to 8, and his urinary fractional HCO_3^- excretion was 18%.

TEACHING POINTS

- This patient had HCMA with a normal anion gap. During spontaneous acidosis, the urine pH was low.
- With correction of the acidosis the fractional HCO_3^- excretion was very high, suggesting PRTA. The lack of aminoaciduria, glucosuria, and proteinuria indicates that this is isolated PRTA.

Clinical Vignette 42.2

A 6-year-old presents to the emergency room with a blood pH of 7.10. His serum electrolytes are Na+, 136; K+, 2.5; Cl–, 116; and HCO_3^-, 8 mEq/L. His urine electrolytes are Na+, 72; K+, 31; Cl–, 70 mEq/L; and urine pH, 6.2. A renal ultrasound showed nephrocalcinosis. He required 3 mEq/kg/day of alkali to maintain a normal serum HCO_3^- and at this point his urinary fractional HCO_3^- excretion was 3%. A U-B pCO_2 test showed a difference of only 2 mm Hg.

TEACHING POINTS

- This patient again had HCMA with a normal anion gap. The positive net urine charge indicates RTA.
- The alkaline urine pH in the face of marked acidosis suggests DRTA and the low U-B pCO_2 confirms it.
- Nephrocalcinosis is common in untreated DRTA.

Clinical Vignette 42.3

A 3-month-old infant presents to the emergency room with dehydration from diarrhea and a blood pH of 7.2. The serum electrolytes show Na+, 135 mEq/L; K+, 3.5 mEq/L; Cl–, 110 mEq/L; and HCO_3^-, 11 mEq/L. His urine electrolytes were Na+, 3 mEq/L; K+, 6 mEq/L; Cl–, 16 mEq/L; and urine pH, 6.0.

TEACHING POINTS

- Again this patient had normal anion gap acidosis. The urine pH was relatively alkaline in the face of significant acidosis.
- However, the urine net charge was negative indicating increased ammonium excretion and an appropriate response to the acidosis. The alkaline urine is secondary to decreased Na+ delivery to the CCT for H+ excretion.
- With restoration of the extracellular volume, a U-B pCO_2 test was normal with a difference of 30 mm Hg.

SUMMARY

- The human kidney maintains aid-base balance by excreting acid generated from the diet and absorbing the bicarbonate filtered by the glomerulus. In the average adult the acid production is 1 mEq/kg/day, but it is higher in children, averaging 1 to 3 mEq/kg/day. It also can respond to increases in acid production by increasing acid excretion, mainly as ammonium.
- RTA occurs when the kidney fails to excrete the normal acid load or reabsorb the filtered bicarbonate. Type I RTA arises from an abnormality in the distal nephron that impairs acid excretion and is characterized by the inability to lower the urine pH. In type II RTA, the proximal tubule incompletely reabsorbs the filtered bicarbonate and is characterized by a high FE HCO_3^- when the serum HCO_3^- is normal. Type III is a combination of types I and II. Type IV is caused by hyperkalemia that decreases ammonia production and excretion. The first line of treatment for all types of RTA is treatment of the underlying disease or stopping the offending medication. If that is not possible, administration of bicarbonate to restore the serum bicarbonate to normal and preventing secondary impacts of metabolic acidosis should be the clinical goal. Patients with proximal renal tubular acidosis Type II RTA may require phosphate supplementation to prevent bone disease associated with hypophosphatemia.

REVIEW QUESTIONS

1. The normal acid production of children is:
   a. <1 mEq/kg/day
   b. 1 to 3 mEq/kg/day
   c. 4 to 6 mEq/kg/day
   d. >6 mEq/kg/day
2. The *most* important way of excreting acid during increased acid production is:
   a. Increased ammonium excretion
   b. Increased phosphate excretion
   c. Increased urea excretion
   d. Decreased bicarbonate excretion
3. Proximal tubule bicarbonate reabsorption occurs because of which of the following?
   a. Ammonia generation from glutamine
   b. Hydrogen ion excretion by the K^+/H^+ ATPase
   c. AE1 in the basolateral membrane
   d. Carbonic anhydrase on the brush border membrane
4. For adequate distal tubule acid excretion, there must be adequate:
   a. Sodium reabsorption
   b. Potassium absorption
   c. Ammonium absorption
   d. Sodium excretion
5. Ammoniagenesis occurs in the:
   a. Thick ascending limb
   b. Cortical collecting tubule
   c. Medullary collecting tubule
   d. Proximal tubule
6. Fanconi syndrome involves RTA type:
   a. Type I
   b. Type II
   c. Type III
   d. Type IV
7. In RTA, the urine anion gap is:
   a. Positive
   b. Negative
   c. Neutral
8. Type 1 is associated with a mutation in the gene coding for:
   a. NBC1
   b. 2Cl/Na/K
   c. AE1
   d. CA
9. An abnormal β_1 subunit of H^+-ATPase is associated with:
   a. Skeletal dysplasia
   b. Early onset deafness
   c. Cardiac defect
   d. Mental retardation
10. The *main* abnormality of RTA type 4 is:
    a. Hyperkalemia causing decreased ammoniagenesis
    b. Hypokalemia causing decreased ammoniagenesis
    c. Hyperkalemia causing increased ammoniagenesis
    d. Hypokalemia causing increased ammoniagenesis
11. Nephrocalcinosis is associated with:
    a. Type I RTA
    b. Type II RTA
    c. Type IV RTA
    d. None of above
12. The anticonvulsant medication, topiramate, is associated with:
    a. Type I RTA
    b. Type II RTA
    c. Type III RTA
    d. Type IV RTA
13. The type of RTA requiring the largest dose of supplemental alkali to correct the acidosis is:
    a. Type I
    b. Type II
    c. Type IV
14. The *major* urinary buffer of titratable acid is:
    a. Citrate
    b. Phosphate
    c. Urate
    d. Creatinine
15. A simple way of testing the distal nephron's ability to acidify the urine is to administer orally:
    a. Phosphate
    b. Citrate
    c. Furosemide
    d. Hydrochlorothiazide

Cystic kidney disease

LISA M. GUAY-WOODFORD

Renal cysts are observed in a variety of kidney diseases. Many of these disorders are inherited as single gene defects, and some are associated with extrarenal manifestations or represent manifestations of syndromes. Different ages of onset, variability in kidney disease progression, and a diverse array of extrarenal manifestations help distinguish these disorders. On the whole, renal cystic disorders are relatively rare diseases, although a few, such as autosomal recessive polycystic kidney disease (ARPKD), juvenile nephronophthisis (NPHP), and hepatocyte nuclear factor-1β (HNF1B)–related renal disease, are common enough to cause considerable pediatric morbidity and mortality. In contrast, autosomal dominant polycystic kidney disease (ADPKD), one of the most common human genetic diseases, typically has relatively mild clinical manifestations during childhood. Table 43.1 provides a clinicopathologic classification of the cystic renal diseases.

CELLULAR MECHANISM OF CYST FORMATION

With the identification of disease-causing genes, proteins involved in renal cystic diseases have been localized, often in multimeric complexes, at discrete subcellular locations in renal epithelial cells, including the primary apical cilium, intercellular junctions, and focal adhesions.[1] In addition, defects in several common signaling pathways have been defined in renal cystic epithelia. Taken together, these data suggest that cyst formation may involve the abnormal integration of signal transduction pathways that lead to altered cell proliferation and apoptosis.[2]

> **KEY POINT**
>
> Renal cysts result from abnormal integration of signal transduction in the epithelial cells that alters cell proliferation and apoptosis.

AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE

ARPKD is one of the most common form of renal cystic disease encountered in children. It was previously known as infantile polycystic kidney disease, a term no longer in use. With the advent of high-resolution ultrasound, many cases of ARPKD are diagnosed prenatally. While the true incidence of the disease is not certain because many patients die in the neonatal period, ARPKD is estimated to occur in 1 in 20,000 live births.

Table 43.1 Classification of cystic kidney diseases

Disorder	Affected genes
Nongenetic renal cystic disease	
Simple renal cysts	NA
Multilocular cysts	NA
Polycystic kidney disease	
Autosomal recessive polycystic kidney disease	*PKHD1*
Autosomal dominant polycystic kidney disease	*PKD1, PKD2*
Cystic diseases of the renal medulla	
Juvenile nephronophthisis	*NPHP1-NPHP18*
Medullary cystic kidney disease	*MUC1, UMOD*
Medullary sponge kidney	*NA*
Other renal cystic diseases	
HNF1B-related renal cystic disease	*TCF2*
Glomerulocystic kidney disease	*PKD1, TCF2, UMOD*

Abbreviation: NA, not applicable.

CLINICAL MANIFESTATIONS

ARPKD (Mendelian Inheritance in Man [MIM] 173900) is a severe, typically early-onset form of cystic disease. Patients with ARPKD have a spectrum of clinical phenotypes that depend in part on the age at presentation.[3] Most patients are identified either in utero or at birth with enlarged echogenic kidneys and oligohydramnios. At birth, the most severely affected neonates have a critical degree of pulmonary hypoplasia that may be incompatible with survival. The estimated perinatal mortality rate is 30%. In patients who survive the first month of life, 1-year survival rates of 92% to 95% have been reported.[3,4] Renal function, although frequently compromised, is rarely a cause of neonatal death.

KEY POINTS

- ARPKD is the most common inherited renal cystic disease encountered in children.
- Oligohydramnios and large kidneys are common manifestations of ARPKD in neonates.
- Pulmonary hypoplasia is a cause of neonatal morbidity and mortality in ARPKD.
- Some ARPKD patients may manifest Potter syndrome.

For those patients who survive the first few weeks of life, the major morbidities include severe systemic hypertension,

Table 43.2 Clinical manifestations of autosomal recessive polycystic kidney disease in children

Prenatal
- Abnormal prenatal ultrasound scan, large kidneys with increased echogenicity

Postnatal
- Respiratory distress
- Enlarged kidneys
- Hyponatremia
- Systemic hypertension
- Renal failure
- Pyuria
- Urinary tract infection
- Proteinuria
- Failure to thrive
- Hepatomegaly
- Portal hypertension
- Esophageal varices

Family History
- Renal cystic disease in a sibling
- Normal renal ultrasound scan in parents

renal impairment, and portal hypertension (Table 43.2).[3,5,6] Hyponatremia occurs in a subset of neonates, presumably secondary to defects in free water excretion.[3] Systemic hypertension usually develops during the first 6 months of life, often associated with a transient improvement in glomerular filtration rate (GFR) resulting from renal maturation. Subsequently, there is a progressive, but variable decline in renal function.[7]

A subset of patients with late-onset ARPKD has a liver-predominant phenotype with few or no manifestations of kidney disease.[6] These patients present with portal hypertension, hepatosplenomegaly, esophageal or gastric varices, and hypersplenism with associated thrombocytopenia, anemia, and leukopenia. Hepatocellular function is usually preserved. Ascending suppurative cholangitis, a serious complication, can cause fulminant hepatic failure in such patients.[8,9]

Other associated features of ARPKD include an increased incidence of culture-confirmed urinary tract infections,

KEY POINTS

- Hyponatremia is common in ARPKD neonates.
- Hypertension and chronic kidney disease (CKD) evolve over time in ARPKD.
- Liver disease (hepatic fibrosis) can be a prominent clinical finding in some patients.

very rare occurrence of intracranial aneurysms (ICAs), and growth retardation, although the pathophysiology of the growth retardation is poorly defined.[3,10]

GENETICS

All typical forms of ARPKD are caused by mutations in a single gene, *PKHD1,* which encodes multiple alternatively spliced isoforms predicted to form both membrane-bound and secreted proteins.[11] To date, more than 700 pathogenic mutations have been catalogued in the ARPKD Mutation Database,[12] of which approximately half are missense changes. Although a missense mutation in exon 3, c.107C>T (p.Thr36Met), accounts for approximately 20% of all mutant alleles,[5] no other mutational hotspots have been described. Indeed, ARPKD mutations have been identified along the entire length of the *PKHD1* gene, and many of these mutations are unique to single families.[13]

MOLECULAR PATHOGENESIS

The largest protein product of *PKHD1,* termed the fibrocystin-polyductin complex (FPC), localizes, at least in part, to the primary cilium and the centrosome in renal epithelial cells.[14] The basic defects observed in ARPKD suggest that the FPC mediates the terminal differentiation of the collecting duct and the biliary tract. However, the exact function of the numerous isoforms has not been defined, and the widely variable clinical spectrum may partially depend on the nature and number of splice variants that are disrupted by specific *PKHD1* mutations.

KEY POINTS

- ARPKD involves dysfunction of the cilia-centrosome complex, and is classified under the group of conditions designated as ciliopathies.
- Because of associated congenital hepatic fibrosis, ARPKD is often grouped under the disorders known as hepatorenal fibrocystic diseases.

ARPKD is one of several renal cystic diseases that are associated with congenital hepatic fibrosis, thus prompting these disorders to be described as hepatorenal fibrocystic diseases[15] (Table 43.3). The primary cilium appears to play a central role in the pathogenesis of ARPKD and other hepatorenal fibrocystic diseases.[16] Hence this subset of clinical disorders is now grouped under the broader term of "ciliopathies," in which dysfunction of the cilia-centrosome complex appears to underpin the development of a wide array of phenotypes, including renal cystic disease.[17]

ANATOMIC PATHOLOGY

Kidneys in ARPKD are grossly enlarged, but they usually retain their reniform appearance. These enlarged kidneys may appear to occupy the entire abdominal cavity in the affected neonates. The outer surface of the kidneys demonstrate cysts that are usually small. The cysts in ARPKD represent fusiform dilatation of the collecting tubules (Figure 43.1). These dilated collecting tubules (cysts) run perpendicular to the cortical surface (Figure 43.2) in cut section of the kidney.

DIAGNOSTIC EVALUATION

Imaging

In utero ARPKD kidneys are hyperechogenic by ultrasound evaluation and display decreased corticomedullary differentiation as a result of the hyperechogenic medulla (Figure 43.3A). These ultrasound findings are generally observable by the mid-second trimester. With high-resolution ultrasound, the radial array of dilated collecting ducts may be observed. A hypoechoic cortical rim may be seen many infants (Figure 43.3B). In comparison, autosomal dominant polycystic kidney disease (ADPKD) kidneys tend to be moderately enlarged in utero, with a hyperechogenic cortex and relatively hypoechogenic medulla resulting in increased cortico-medullary differentiation.

Kidney size in ARPKD typically peaks at 1 to 2 years of age, then gradually declines relative to the child's body size, and stabilizes by 4 to 5 years.[18] As patients age, medullary echogenicity increases, with scattered cysts that are smaller than 2 cm, and progressive interstitial fibrosis. A hypoechoic cortical rim may be seen many infants (Figure 43.3B). The resulting sonographic pattern may be confused with ADPKD, and contrast-enhanced computed tomography (CT) can better delineate the renal architecture. Bilateral pelvicaliectasis (Figure 43.3C) and renal calcifications have been reported.[6,19] In adults with medullary ectasia alone, the cystic lesion may be confused with medullary sponge kidney (MSK).

By ultrasound evaluation, liver may be either normal in size or enlarged. It is usually less echogenic than the kidneys. Presence of prominent intrahepatic bile duct dilation suggests associated Caroli syndrome (Figure 43.4). With age, the portal fibrosis tends to progress, and in older children, ultrasound typically shows hepatosplenomegaly and a patchy increase in hepatic echogenicity.[20,21]

Genetic testing

Gene-based testing is clinically available. At present, the mutation detection rate is only 80% to 87%.[5,22] Therefore, sequence analysis is largely reserved for prenatal testing and preimplantation genetic diagnosis.[23]

Table 43.3 Hepatorenal fibrocystic diseases

Disease	Gene(s)	Renal disease	Hepatic disease	Associated features
ARPKD	*PKHD1*	Collecting duct dilatation	CHF, Caroli disease	Growth retardation
ADPKD	*PKD1, PKD2*	Cysts along entire nephron	Biliary cysts, CHF	Minimal in children
Nephronophthisis (NPHP)	*NPHP1-NPHP18*	Cysts at the corticomedullary junction	CHF	Tapetoretinal degeneration, situs inversus
Joubert syndrome (JBTS)	*JBTS1-JBTS22*	Cystic dysplasia, NPHP	CHF, Caroli disease	Cerebellar vermis hypoplasia or aplasia with episodic hyperpnea, abnormal eye movements, intellectual disability
Bardet-Biedl syndrome (BBS)	*BBS1-BBS19*	Cystic dysplasia, NPHP	CHF	Retinal degeneration, obesity, postaxial polydactyly, hypogonadism in male patients, intellectual disability
Meckel-Gruber syndrome (MKS)	*MKS1-MKS11*	Cystic dysplasia	CHF	Occipital encephalocele, polydactyly
Oral-facial-digital syndrome, Type I	*OFD1*	Glomerular cysts	CHF (rare)	Malformations of the face, oral cavity, and digits
Glomerulocystic disease	*PKD1, HNF1B(TCF2), UMOD*	Enlarged; normal or hypoplastic kidneys	CHF (with *PKD1* mutations)	Diabetes, hyperuricemia
Jeune syndrome (asphyxiating thoracic dystrophy [ATD])	*IFT80 (ATD2) DYNC2H1 (ATD3) ATD1, ATD4, ATD5*	Cystic dysplasia	CHF, Caroli disease	Short stature, skeletal dysplasia, small thorax, short limbs; polydactyly, hypoplastic pelvis
Renal-hepatic-pancreatic dysplasia	*NPHP3, NEK8*	Cystic dysplasia	Intrahepatic biliary dysgenesis	Pancreatic cysts, dysplasia, or fibrosis; splenic abnormalities, situs inversus
Zellweger syndrome	*PEX1-3, 5-6, 10-11, 13, 14, 16, 19, 26*	Renal cortical microcysts	Intrahepatic biliary dysgenesis	Hypotonia, seizures, agenesis or hypoplasia of corpus callosum, characteristic facies, skeletal abnormalities, neonatal death

GENETIC COUNSELING

Most patients with ARPKD are compound heterozygotes, and the functional effect of any particular mutant allele can be difficult to define. In general, patients with two truncating mutations have a severe phenotype, leading to perinatal demise.[13] However, there are notable exceptions, such as a child homozygous for a large *PKHD1* deletion who survives well past the neonatal period.[24] Although
Figure 43.1 Mechanisms of cyst formation in polycystic kidney disease. (a) Normal nephron. (b) In autosomal dominant polycystic kidney disease, cystic outgrowths arise in every segment of the tubule and rapidly close off from the nephron of origin. (c) In autosomal recessive polycystic kidney disease, cysts are derived from collecting tubules, which remain connected to the nephron of origin. (Redrawn with permission from Wilson PD. Polycystic kidney disease. N Engl J Med. 2004;350:151–64.)

most missense mutations are associated with milder disease, some missense mutations result in severe phenotypes when combined with a truncating mutation, or occurring in the homozygous state.[13] In addition, significant phenotypic variability in a subset of families suggests that genetic modifiers modulate disease expression. These data can complicate genetic counseling, and caution must be exercised in predicting the clinical outcome of future affected children.[25]

MANAGEMENT AND PROGNOSIS

Neonatal pulmonary hypoplasia, often complicated by pneumothoraces, is a major cause of neonatal mortality in ARPKD.[26] Aggressive interventions such as unilateral or bilateral nephrectomies and continuous hemofiltration have been advocated for neonatal management. However, these recommendations are based on limited set of small case reports and case series. Evidence-based clinical practice will require prospective, controlled studies.

For those children who survive the perinatal period, hypertension is a dominant clinical issue, with a prevalence of 55% to 75% and an onset that typically precedes the decline in GFR. Angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARB), adrenergic antagonists, and loop diuretics are effective antihypertensive agents. The management of children with ARPKD who have a declining GFR should follow the standard guidelines established for chronic kidney disease in the pediatric patients.[27] Given the relative urinary concentrating defect, children with ARPKD should be monitored for dehydration during intercurrent illnesses associated with fever, tachypnea, nausea, vomiting, or diarrhea.
Figure 43.2 Autosomal recessive polycystic kidney disease. (From Kissane JM. Renal cysts in pediatric patients. Pediatr Nephrol. 1990;4:69–77.)

Most patients with ARPKD progress to end-stage renal disease (ESRD), but the age at onset is highly variable, and partly depends on the age at initial presentation. For example, 25% of patients diagnosed in the perinatal period required renal replacement therapy by 11 years, whereas only 25% of those who presented after 1 month of age required renal replacement therapy by age 32 years.[7]
Figure 43.3 Autosomal recessive polycystic kidney disease (ARPKD). **(a)** Renal sonogram of a fetus at 34 weeks demonstrating large kidneys bilaterally, almost filling the entire abdomen. Echogenicity of the kidneys is increased. **(b)** Renal ultrasound scan of a 6-month-old infant showing increased echogenicity of the medullary cortex. The arrow points to the hypoechoic cortical rim. **(c)** Hydronephrosis seen in the transverse section of the right kidney in a 3-year-old girl with ARPKD.

A subset of ARPKD patients develop portal hypertension and the associated complications of hypersplenism and esophageal varices.[20] Platelet counts, serial abdominal ultrasound scans (assessing liver and splenic size), and Doppler flow studies provide surrogate markers for portal hypertension severity.[21] Medical management includes sclerotherapy or variceal banding; whereas surgical approaches such as portocaval or splenorenal shunting may be indicated in some patients.[20] Ascending cholangitis is a leading cause of morbidity and mortality in patients with ARPKD.[28] Meticulous evaluation is required for suspected bacterial cholangitis, and if indicated, aggressive antibiotic therapy should be initiated.

KIDNEY TRANSPLANTATION

Because ARPKD is a recessive disorder, either parent may be a suitable kidney donor. However, subtle renal and liver sonographic abnormalities have been described in ARPKD parents,[29] thus warranting particular caution in donor evaluation. Native nephrectomies may be indicated in patients

> ### KEY POINTS
>
> - Because ARPKD is a recessive disorder, either parent can be considered as a renal transplant donor for the affected child.
> - Liver disease in the recipient and in the organ donors should be carefully investigated.
> - Liver-kidney transplant may be appropriate in patients with significant liver disease, in addition to ESRD.

with massively enlarged kidneys in order to allow space for allograft placement within the abdominal cavity.

In some patients, combined kidney-liver transplantation may be appropriate.[30] Indications include the combination of renal failure and either recurrent cholangitis or significant complications of portal hypertension (e.g., recurrent variceal bleeding, refractory ascites, and the hepatopulmonary syndrome).[20]
Figure 43.4 Caroli syndrome. **(a)** Axial T2-weighted MRI scans showing intrahepatic biliary dilatation (arrow). **(b)** Coronal T2-weighted MRI scans showing bilaterally enlarged kidneys with extensive cystic disease (white arrow) that simulate findings in ARPKD. (Reproduced with permission from from Kurschat CE, Müller RU, Franke M, et al. An approach to cystic kidney diseases: the clinician's view. Nat Rev Nephrol. 2014;10:687–99.)

Effective management of systemic and portal hypertension, coupled with successful renal replacement therapy and transplantation options, has allowed for long-term patient survival. Therefore, the prognosis in ARPKD, particularly for those children who survive the first month of life, is far less bleak than previously thought, and aggressive medical therapy is warranted.

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

CLINICAL MANIFESTATIONS

ADPKD (MIM 173900) is a multisystem disorder characterized by bilateral and multiple renal cysts, as well as a variety of extrarenal manifestations. These extrarenal features include cysts in the bile ducts, pancreatic ducts, seminal vesicles, and arachnoid membrane, as well as noncystic abnormalities, such as ICAs and elongation and dilatation of intracranial arteries (dolichoectasia) aortic root dilatation and aneurysms, mitral valve prolapse, and abdominal wall hernias.[31]

KEY POINTS

- ADPKD is a multisystem disorder. Cystic lesions can be seen in multiple organs.
- 1% to 2% patients may present early in infancy with features that are indistinguishable from those of ARPKD.
- Incidental finding of renal cysts is a common presentation during childhood.

The typical symptomatic presentation of ADPKD and major morbidities occur in adults. However, ADPKD is also diagnosed in fetuses, infants, children, and adolescents. Most of the time, the diagnosis is made in the at-risk children as an incidental imaging finding, or by presymptomatic sonographic screening. However, renal manifestations and limited extrarenal manifestations do occur in children with ADPKD (Table 43.4).[32] In addition, a form of very early-onset ADPKD occurs in 1% to 2% of affected children and may be clinically indistinguishable from ARPKD.[33]

GENETICS

Mutations in *PKD1* account for approximately 85% of ADPKD cases, and mutations in *PKD2* account for the remainder.[34] De novo mutations account for up to 10% of cases. The high mutability of *PKD1* likely explains why de novo mutations arise much more frequently in this gene and why private mutations (i.e., unique to a single family) are more common in *PKD1*.[22,35]

Although the disease is transmitted as an autosomal dominant trait, it is recessive on a cellular level[36]; that is, ADPKD is genetically a "two-hit" disease, analogous to what has been described for tumor suppressor genes. Cysts form only when both copies of the gene are mutated and *PKD* gene activity is reduced below a cellular threshold. Although not precisely defined, this threshold likely differs in cells of different nephron segments and may even change over time depending on developmental stage.

KEY POINTS

- Mutations in the *PKD1* gene comprise approximately 85% cases of ADPKD, and *PKD2* gene mutation accounts for 15% cases.
- De novo mutations are relatively common in ADPKD, and are seen in up to 10% cases..
- Pathogenesis of ADPKD is considered to be a "two-hit" disease.

MOLECULAR PATHOGENESIS

After decades of investigation, it is well established that increased cell proliferation, fluid secretion, and loss of normal renal parenchyma are the key elements that cause loss of renal function in ADPKD. The identification of the disease-causing genes and of the proteins they encode has provided key pathogenic insights. The *PKD1* gene encodes a membrane receptor polycystin-1 (PC1), and *PKD2* encodes a nonselective cation channel permeable to calcium designated polycystin-2 (PC2). Together, these proteins function as a receptor-channel complex on the cell surface.[37] The complex, as well as virtually every other cystoprotein (i.e., a protein encoded by a gene whose mutation results in renal cystic disease), localizes to the primary apical cilium. The PC1/PC2 complex has been postulated to function as a flow sensor that triggers the release of intracellular calcium stores[38] and regulates a cascade of integrated signaling pathways that regulate cellular growth, fluid secretion, and tubular morphology.

ANATOMIC PATHOLOGY

The kidneys in ARPKD can be normal to very large in size. In advanced cases, the cysts are large and conspicuous in the cut section of the kidney, giving it a "Swiss cheese" appearance (Figure 43.5). The cysts in ADPKD arise from every segment of the nephron (see Figure 43.1b) and have a narrow attachment to the nephron, from which the cysts eventually lose communication.[1]

Table 43.4 The incidence of renal and extrarenal manifestations of autosomal dominant polycystic kidney disease in adults and children

Manifestation	ADPKD in adults	ADPKD in children
Hematuria (micro and macro)	35%–50%	10%
Concentrating defects	100%	60%
Proteinuria	18%	14%
Microalbuminuria	25%	30%
Nephrolithiasis	20%	Unknown
Flank or abdominal pain	60%	10%
Hepatic cysts revealed by MRI	83%	55% by age 25 yr
Colonic diverticula	82%	Unknown
Cerebral aneurysms	5%–7%	Rare
Prolapse of the mitral valve	26%	12%
Hypertension before eGFR decline	60%	22%
Hyperlipidemia	Unknown	54%

DIAGNOSTIC EVALUATION

A screening algorithm for children at risk for ADPKD and for patients with confirmed ADPKD is provided in Figure 43.6.

KEY POINTS

- The membrane receptor PC1/PC2 complex on the primary apical cilium of the epithelial cell is a flow sensor and facilitates intracellular calcium release.
- Intracellular calcium release triggers signal pathways that regulate cell growth, fluid secretion, and morphology of renal tubules.
- Defective function of the PC1/PC2 complex contributes to tubular cell abnormalities in ADPKD.

Imaging

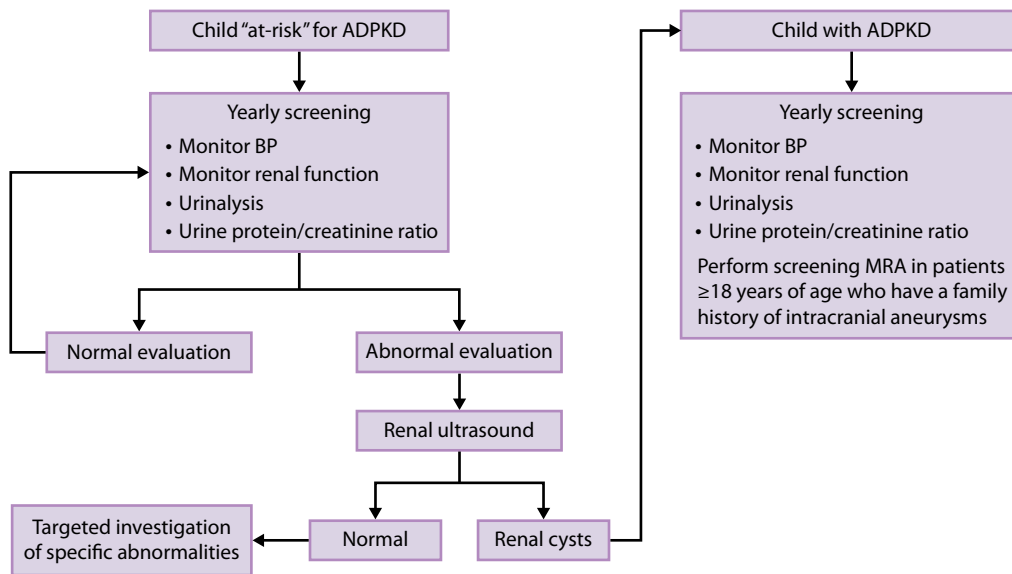
Renal sonography is the main diagnostic tool in ADPKD. It is widely available, has a relatively low cost, is well tolerated by patients, and lacks known adverse effects. Sonographic imaging shows increased echogenicity of the renal parenchyma with many cysts distributed throughout (Figure 43.7). Magnetic resonance imaging (MRI) may provide better delineation of renal cysts, especially if hemorrhage within the cysts needs to be confirmed (Figure 43.8). Sonographic screening in asymptomatic children is controversial because of the limited sensitivity of ultrasonography, particularly in children younger than 5 years of age.[39] A study involving sonographic analysis of 420 at-risk children 15 years or younger demonstrated this point. Investigators detected bilateral renal cysts in 193 (46%) and cysts were


Figure 43.6 Algorithm for screening and monitoring of children with autosomal dominant polycystic kidney disease (ADPKD). BP, blood pressure; MRA, magnetic resonance angiography.

absent in 227 (54%) of participants.[39] Of these, bilateral cysts were evident in 150 out of 193 (77%) and unilateral cysts observed in 43 out of 193 (22%) subjects (Figure 43.9).[39]

In another single-center study, the manifestations of ADPKD in cohorts of children whose disease was diagnosed by screening ultrasound were compared with disease manifestations in children presenting with symptoms. The proportions of children with nephromegaly, hypertension, microalbuminuria, and decreased estimated GFR (eGFR), were similar in both groups.[40] These data reinforce the prevailing wisdom that at-risk children should have regular surveillance for hypertension and urinary abnormalities.
Figure 43.7 Renal ultrasound scan in a 17-year-old patient with autosomal dominant polycystic kidney disease. Numerous cysts are evident in the parenchyma, and the echogenicity of the kidney tissue is increased.
Figure 43.8 Autosomal dominant polycystic kidney disease. Coronal T2-weighted magnetic resonance imaging (MRI) scans showing renal (K) and liver (L) cysts (arrows). One renal cyst in the left kidney is hemorrhagic (arrowhead). (Reproduced with permission from Kurschat CE, Müller RU, Franke M, et al. An approach to cystic kidney diseases: the clinician's view. Nat Rev Nephrol. 2014;10:687–99.)

New onset of flank or abdominal pain, hypertension, or urinary abnormalities in these at-risk children should prompt sonographic evaluation. Screening for extrarenal features of the disease is not recommended during childhood.

Genetic testing

Several key caveats merit consideration before undertaking gene-based testing, including the current expense of sequencing *PKD1*, a large, complex gene with multiple *PKD1*
Figure 43.9 Distribution of renal cysts by age in 420 children at risk for autosomal dominant polycystic kidney disease. The data compiled from the initial ultrasonographic examination. Distribution within each age group are as follows: age 0 to 4 years, 59% with no cysts, 9% with unilateral cysts, 33% with bilateral cysts; age 5 to 8 years, 57% with no cysts, 15% with unilateral cysts, 30% with bilateral cysts; age 9 to 13 years, 50% with no cysts, 10% with unilateral cysts, 40% with bilateral cysts; and age 13 to 15 years, 50% with no cysts, 8% with unilateral cysts, 42% with bilateral cysts. Am J Kidney Dis. 2010;56:50–6.)

homologues (i.e., pseudogenes that must be distinguished from the actual gene)[41], the limited detection rate for *PKD1* mutations (approximately 85%), imprecision in predicting the pathogenicity of missense variants,[22,35] and the minimal predictive value of a specific sequence variation.

Despite these limitations, under certain circumstances a DNA-based diagnosis may be informative. For example, very early-onset ADPKD can result from a combination of mutations in *PKD1* and hypomorphic (limited loss-of-function) alleles of other genes that cause cystic kidney disease.[42] Therefore, genetic testing should be considered to evaluate the contribution of other "cystogenes" to the clinical disease expression. In

KEY POINTS

- Gene testing may be helpful in the diagnosis of early-onset ADPKD in neonates and infants.
- *PKD1* and the tuberous sclerosis 2 (*TSC2*) genes are adjacent to each other. Deletions in both genes may be detected in some patients with tuberous scle-rosis who may have large cystic kidneys.

addition, limited numbers of pedigrees have been described in which an affected child presented with an ARPKD-like phenotype resulting from the inheritance of incompletely penetrant *PKD1* alleles from each parent.[43] Finally, in children with massively enlarged kidneys and associated neurologic deficits, genetic testing may identify deletions involving both the *PKD1* gene and the adjacent tuberous sclerosis 2 (*TSC2*) gene, the *TSC2/PKD1* contiguous gene syndrome, which is associated with a much poorer renal outcome.[44]

GENETIC COUNSELING

Genetic counseling in childhood is limited. Prenatal screening, albeit feasible, is not often requested, and in the one study that examined family attitudes, less than 5% would terminate a pregnancy for ADPKD.[45] Therefore, genetic counseling must be tailored to the specific patient and family, be directed toward explaining genetic risk and genetic tests, and discuss when to test (e.g., for interested adolescents before transitioning to adult care).

MANAGEMENT AND PROGNOSIS

Most children with ADPKD are asymptomatic throughout childhood, and even in adulthood, clinical issues may arise only intermittently. Management in pediatric patients focuses on five principal issues.

First, hypertension and cardiovascular health are foremost longterm clinical concerns in these patients. Most patients with ADPKD develop hypertension, and cardiovascular disease is the leading cause of death in adults. One study demonstrated that children with ADPKD and hypertension have larger kidney volumes and higher left ventricular mass indices as compared with their normotensive counterparts.[46] Therefore, blood pressure control in children with ADPKD is of paramount importance. ACE inhibitors and ARBs are the therapeutic mainstays, with treatment goals the same as for other hypertensive patients.[47]

The second issue involves renal function. Although decline in renal function is uncommon during childhood,

KEY POINTS

- Most children with ADPKD are asymptomatic.
- Hypertension is common in patients with ADPKD and can lead to cardiovascular morbidity and mortality in adulthood.
- Back pain in ADPKD results from large kidneys and may be the earliest presenting symptom in some patients.
- Urinary tract infection with localization in a cyst can be difficult to treat. Drugs that penetrate ADPKD cysts need to be selectively used.
- ICAs occur but tend to cluster in 5-10% of ADPKD families.

glomerular hyperfiltration (GH) is prevalent and is associated with more rapid disease progression.[48] A few small studies suggest that ACE inhibitor therapy reduces GH, but the long-term impact has yet to be determined.[49]

The third issue focuses on evaluation and management of abdominal or back pain, which can be challenging, particularly in adolescents with ADPKD.[50,51] For acute episodes, diagnostic considerations should include cyst infection, rupture, or hemorrhage; and renal stones. Treatment is directed at the underlying diagnosis. Chronic pain is much more vexing; it correlates poorly with renal size and, like most other types of chronic pain, can be difficult to manage. After excluding acute events, non–narcotic-based treatments are the preferred approach; acupuncture and other nonpharmacologic approaches can provide reasonable relief. Early referral to pain management specialists also may be helpful.

The fourth issue involves urinary tract infections. Most are easily treated, but cyst infections can be particularly difficult to diagnose and treat. Often, persistent fever or high clinical suspicion may provide the only clues.[52] Positron emission tomography (PET) scan may be helpful in establishing cyst infection in ADPKD. Antibiotics that penetrate cysts well include trimethoprim-sulfamethoxazole, fluoroquinolones, clindamycin, vancomycin, and metronidazole.

The fifth issue relates to ICAs, one of the most feared extrarenal manifestations of ADPKD.[53] ICAs often manifest at an earlier age in patients with ADPKD than in the general population. These aneurysms are reported to rupture at a smaller size, and ICA rupture can sometimes be the presenting symptom in otherwise asymptomatic individuals.[54] Fortunately, only a small fraction (approximately 8%) of patients with ADPKD develop this problem, so standard practice is to reserve screening for a small subset of patients. Among pediatric patients with ADPKD, screening candidates include those with symptoms suggestive of ICA (unusual, but reported in patients with ADPKD who are less than 18 years of age) and 18-year-old patients from families with a known history of ICA and ADPKD.

CYSTIC DISEASES OF RENAL MEDULLA

Renal cysts that primarily affect renal medulla can be seen in association with several disorders (see Table 43.1), many of which are syndromic or multisystem conditions.

JUVENILE NEPHRONOPHTHISIS

Juvenile nephronophthisis (NPHP; MIM 256100) comprises a group of autosomal recessive tubulointerstitial diseases associated with renal cysts.[55] At least in some reports, it is one of the most frequent inherited causes of ESRD in children and adolescents.[56]

Clinical manifestations

Initial reports described three distinct forms of NPHP (infantile, juvenile, and adolescent), based on the age of onset of ESRD. In the infantile form, the age of onset of ESRD consistently occurs before 5 years of age, whereas in juvenile NPH (the most common form), ESRD occurs at a mean age of 13 years. However, more recent studies have demonstrated no clear genotype-phenotype correlation for this spectrum of presentations, and these disorders should be referred to with the single designation, NPHP.[57,58]

KEY POINTS

- NPHP is a common cause of ESRD in children.
- Clinical presentation can occur early in infancy, but onset of the disease during early adolescence is most common.
- Persistent nocturnal enuresis and polyuria are well-known presenting manifestations.
- Renal dysfunction, hypertension, growth retardation, and anemia out of proportion to renal dysfunction are usual at onset.
- Hypertension is not a common presenting feature of NPHP, save in the small subset of infantile variety.

Decreased urinary concentrating capacity is quite common in NPHP and usually precedes the decline in renal function, with typical onset between 4 and 6 years of age. Polyuria and polydipsia are common, often resulting in night-time and even day-time wetting. Salt wasting develops in most patients with renal impairment, and sodium supplementation is often commonly required until the onset of ESRD. One-third of patients become anemic before the onset of renal impairment, and this has been attributed to a defect in the functional regulation of erythropoietin production by peritubular fibroblasts.[59] Growth retardation, out of proportion to the degree of renal impairment, is a common finding.

Slowly progressive decline in renal function is typical of NPHP. Although symptoms can be detected after the age of 2 years, they may progress insidiously, such that 15% of affected patients are recognized as having NPHP only after ESRD has developed. The disease is not known to recur in renal allografts.

Children with the infantile variant, which results primarily from mutations in *NPHP2* or *NPHP3,*[57] develop symptoms in the first few months of life and rapidly progress to ESRD, usually before the age of 2 years, but invariably by 5 years of age. Severe hypertension is common in this subset of patients with NPHP. In general, patients with NPHP rarely develop flank pain, hematuria, hypertension, urinary tract infections, or renal calculi.

Associated extrarenal abnormalities

Extrarenal abnormalities have been described in approximately 10% to 15% of patients with NPHP.[60] The most frequently associated anomaly is retinal dystrophy secondary to tapetoretinal degeneration (Senior-Loken syndrome). Severely affected patients present with coarse nystagmus, early blindness, and a flat electroretinogram (Leber amaurosis). Patients with moderate retinal dystrophy typically have mild visual impairment and retinitis pigmentosa. Other extrarenal anomalies include oculomotor apraxia (Cogan syndrome), cerebellar vermis aplasia (Joubert syndrome), and cone-shaped epiphyses of the bones. Congenital hepatic fibrosis occurs in some NPHP patients, but the associated bile duct proliferation is mild and qualitatively different from that found in ARPKD.

Genetics

Mutations in 18 distinct genes have been identified in patients with NPHP. Defects in *NPHP1* account for 21% of NPHP cases with large, homozygous deletions detected in 80% of affected family members and in 65% of sporadic cases. Mutations in each of the remaining *NPHP* genes cause no more than 3% of NPHP-related disease.[56] Clinical disease expression seems to be exacerbated by oligogenic inheritance (i.e., patients carrying two mutations in a single *NPHP* gene, as well as a single-copy mutation in an additional *NPHP* gene).[61] In addition, multiple allelism, or distinct mutations in a single gene, appears to explain the continuum of multiorgan phenotypic abnormalities observed in NPHP, Meckel syndrome, and Joubert syndrome.[62] Most of the protein products of the NPHP-associated genes are expressed in the cilia-centrosome complex.[56,63] NPHP is included among the hepatorenal fibrocystic disease subset of the ciliopathies.

KEY POINTS

- NPHP is an autosomal recessive disorder.
- Most of the proteins associated with NPHP-related genes are expressed in the cilia-centrosome complex.
- *NPHP1* gene defects account for about 20% of the cases of NPHP. Homozygous deletions are common in *NPHP1* families (80%). This information can be useful in genetic counseling.
- Known defects in NPHP-related genes account for only about 35% to 40% cases.

Diagnostic evaluation

IMAGING

In a child with NPHP and renal impairment, ultrasound examination typically reveals normal-sized or small kidneys with increased echogenicity and loss of corticomedullary differentiation.[58] On occasion, cysts can be detected at the corticomedullary junction or in the medulla. Thin-section CT scanning may be more sensitive than ultrasound in detecting these cysts.

GENETIC TESTING

Molecular testing can be useful in establishing the diagnosis of *NPHP1*-related disease.[64] However, to date defects in 18 different genes have been described in patients with NPHP, but these defects together account for the disease in only 30% to 40% of patients with NPHP.[65] Newer strategies using next-generation sequencing technologies should allow high-throughput mutation detection for known *NPHP* genes, as well as facilitate the identification of new NPHP-associated genes.

Genetic counseling

For those patients with *NPHP1*-related disease, identification of a homozygous deletion in the index child can be quite useful in genetic counseling regarding future pregnancies. Otherwise, the large number of disease-associated genes and their contribution in the aggregate to less than 50% of the observed NPHP cases limit the utility of genetic testing in clinical diagnosis. In these families, genetic counseling relies on the probability that for a recessive trait, each fetus has a 25% of being affected.

Management and prognosis

Current treatment of NPHP is entirely supportive. With progressive decline in renal function, treatment should follow standard guidelines for chronic kidney disease. Renal replacement therapy, including transplantation, is indicated for patients who progress to ESRD. A 2006 report from the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) group revealed that NPHP renal transplant recipients have excellent outcomes when compared with all other patients registered in the NAPRTCS database.[66]

MEDULLARY CYSTIC KIDNEY DISEASE

Medullary cystic kidney disease (MCKD) is a rare an autosomal dominant disorder that is histopathologically indistinguishable from NPHP.

Clinical features

Key features of MCKD include formation of renal cysts at the corticomedullary junction, a urinary concentrating defect, salt wasting, and a progressive decline in renal function. Two distinct forms of MCKD have been described: MCKD type 1 (MCKD1; MIM 174000), which is a renal-specific disorder, and MCKD type 2 (MCKD2; MIM 603860), which is also associated with hyperuricemia and gout. In both disorders, hypertension appears to be a sequela of the disease, and it occurs after the onset of kidney failure. Progression to ESRD typically occurs in adulthood in both disorders, although the onset can range from 20 to 70 years of age, and patients with MCKD1 typically have a later onset of ESRD.

Genetics

MCKD1 results from variants in the mucin *(MUC1)* gene, whereas defects in the uromodulin *(UMOD)* gene account for most cases of MCKD2. *UMOD* mutations have also been identified in families with the following: (1) familial juvenile hyperuricemic nephropathy (FJHN; MIM 162000), a dominantly transmitted disorder characterized by MCKD, hyperuricemia, and gout; and (2) familial glomerulocystic disease with hyperuricemia (MIM 609886).

KEY POINTS

- MCKD is an autosomal dominant disorder.
- MCKD1 is caused by a mucin gene *(MUC1)* defect.
- MCKD2 is caused by defect in the uromodulin *(UMOD)* gene.
- *UMOD* gene defects have also been noted in patients with familial juvenile hyperuricemic nephropathy and familial glomerulocystic disease with hyperuricemia.

Diagnostic evaluation

The diagnosis is suspected in patients with a positive family history of kidney disease and the clinical features described earlier. Renal ultrasound examination may reveal normal or small kidneys, but medullary cysts are typically not observed. Genetic testing can confirm the diagnosis.

Genetic counseling

MCKD is inherited as an autosomal dominant trait. Therefore, each child of an affected patient has a 50% chance of inheriting the mutation. Asymptomatic siblings of an affected child should be considered at 50% risk during childhood and should undergo annual surveillance for hypertension and renal dysfunction. If the disease-causing mutation has been identified in an affected family member, diagnostic testing can be offered to other at-risk family members, including at-risk siblings and in the prenatal context. However, prenatal testing of at-risk pregnancies is not commonly practiced.

Management and prognosis

Treatment follows standard guidelines for managing chronic kidney disease and its sequelae, which can include hypertension, anemia, and gout. Annual surveillance of blood pressure and renal function is advised for affected patients. With progression to ESRD, renal replacement therapy becomes the mainstay of management. All related potential kidney donors should be evaluated to identify the family-specific *MUC1* or *UMOD* mutation. Only those persons without the mutation are suitable candidate donors. Based on small

cohort studies, it appears that these patients do well after transplantation, and the disease does not recur.[67]

MEDULLARY SPONGE KIDNEY

Medullary sponge kidney (MSK) is a relatively common disorder in adults that occasionally manifests in adolescents. It is typically asymptomatic unless it is complicated by nephrolithiasis, hematuria, or infection. Renal stones and granular debris are composed of either pure apatite (calcium phosphate) or a mixture of apatite and calcium oxalate. Several factors contribute to stone formation, including urinary stasis within the ectatic ducts, hypercalciuria, and hypocitraturia.

KEY POINTS

- MSK is commonly seen in adults but can be detected in adolescents.
- Although MSK is often asymptomatic, renal stones, (calcium phosphate) may be manifest.
- MSK is believed to be a developmental disorder affecting the renal pyramids.

Hematuria, unrelated to either coexisting stones or infection, may be recurrent. It is usually asymptomatic, unless extensive bleeding causes clot-induced colic. Urinary tract infection may occur in association with nephrolithiasis or as an independent event. In those patients with stones, infections are more likely to occur in female patients than in male patients.

Decreased renal concentrating ability and impaired distal urinary acidification are common clinical features. Although the acidification defect is not associated with overt systemic acidosis, bone mineralization defects are well described.[68]

Molecular pathogenesis

The occasional presence of embryonal tissue in the affected papillae and the coexistence of other urinary tract anomalies suggest that MSK results from a developmental defect in the medullary pyramids, with more recent data suggesting that MSK is caused by a disruption at the "ureteric bud-metanephric mesenchyme" interface.[69] In addition, MSK occurs more frequently in patients with other developmental anomalies or tumors (e.g., congenital hemihypertrophy, Beckwith-Wiedemann syndrome, CAKUT [congenital abnormalities of the kidneys and urinary tract] syndrome, and Wilms tumor).[68]

Diagnostic evaluation

In patients with MSK, abdominal plain radiographs often reveal radiopaque concretions in the medulla. Historically, the diagnosis has been established by excretory urography, with the "bouquet of flowers" or "paintbrush" sign reflecting retention of contrast media in the ectatic collecting ducts. However, CT has been almost completely supplanted urography for

routine clinical imaging.[70] Nonenhanced CT may help distinguish MSK from papillary necrosis or even ADPKD.

Genetic counseling

MSK is generally considered to be a sporadic disorder, but more recent studies have provided evidence for familial clustering involving autosomal dominant inheritance with reduced disease penetrance and variable disease expression.[71] In addition, genetic analyses of 55 patients with MSK identified 2 novel variants in the glial cell–derived neurotrophic factor *(GDNF)* gene, a finding suggesting a role for this gene in MSK pathogenesis.[72] The implications of these data for genetic counseling are currently unclear.

Management and prognosis

No therapy is indicated for asymptomatic patients with MSK or for those patients with hematuria in the absence of stones or infection. If the tubular ectasia is unilateral and segmental, partial nephrectomy may alleviate recurrent nephrolithiasis and urinary tract infection.

Given that hypercalciuria and hypocitraturia are key factors contributing to nephrolithiasis, potassium citrate and high fluid intake are the mainstays of treatment for patients with stones. Recurrent stone formers may benefit from thiazide diuretics or inorganic phosphate therapy. However, oral phosphates should not be used in patients with previous urinary tract infections caused by urease-producing organisms. Patients who form and pass stones recurrently may require lithotripsy or surgical intervention.

Urinary tract infection should be treated with standard antibiotic regimens, and for some patients, prolonged therapy may be warranted. Urease-producing organisms, such as coagulase-negative staphylococci, are particularly problematic as urinary pathogens in MSK. Positive urine culture results, even with relatively insignificant colony counts, should be vigorously pursued. With proper management of the clinical complications, the long-term prognosis is excellent. Progression to renal impairment is unusual.

HEPATOCYTE NUCLEAR FACTOR-1B–RELATED RENAL DISEASE

Hepatocyte nuclear factor-1β (HNF1B), a transcription factor encoded by the *HNF1B* (or *TCF2*) gene, is involved in the early development of the kidney, pancreas, liver, and genital tract. HNF1B-related disease is pleiotropic, with expression sometimes restricted to the kidney and sometimes involving both renal and nonrenal manifestations.[73] There is a striking phenotypic heterogeneity within families.

CLINICAL MANIFESTATIONS

Renal involvement in *HNF1B*-related disease is quite heterogeneous. During fetal life and childhood, the predominant phenotype is characterized by either hyperechogenic kidneys or bilateral renal cystic hypodysplasia. In adults, renal involvement is widely variable, including renal cysts (mostly few cortical cysts), a solitary kidney, pelvicaliceal abnormalities, hypokalemia and hypomagnesemia from tubular dysfunction, and, more rarely, Fanconi syndrome and chromophobe renal carcinoma. Adult-onset disease is associated with slowly progressive renal decline.

The extrarenal phenotype consists of maturity-onset diabetes of the young, type 5 (MODY5), exocrine pancreas failure and pancreatic atrophy, diverse genital tract abnormalities in female patients or infertility in male patients, and, rarely, mild mental retardation. HNF1B-related disease is now recognized as the second most prevalent dominantly inherited kidney disease,[73] and *HNF1B* mutations are among the most common causes of bilateral hyperechogenic kidneys in the fetus.[74]

GENETICS

The HNF1B transcription factor regulates several renal cystogenes, including *PKHD1, PKD1, PKD2,* and *UMOD.* In addition, *HNF1B* modulates expression of three genes involved in magnesium homeostasis: *ATP1A1, FXYD2,* and *CLDN16.*[75] In mice, antenatal *HNF1B* inactivation causes downregulation of all these genes, suggesting mechanisms that contribute to the observed renal cystic disease and hypomagnesemia. In contrast, when compared with controls, human patients had no significant difference in the urinary mRNA levels of *HNF1B* or other renal cystic genes. Thus, the pathogenesis of the human renal cystic disease phenotype remains unclear. However, a significant alteration in *ATP1A1* expression was observed in patients with HNF1B-related disease, consistent with its role in magnesium homeostasis.

KEY POINTS

- *HNF1B*-related disease is the second most common form of dominantly inherited renal disease
- *HNF1B*-related disease can be detected in fetuses and neonates and can mimic ARPKD
- *HNF1B* defects can result in diverse manifestations, which can include renal multicystic dysplastic kidneys, and solitary kidneys.

DIAGNOSTIC EVALUATION

Mutations in *HNF1B* are dominantly inherited and typically involve complete heterozygous deletion of the *TCF2* gene.[74] De novo mutations occur in more than one-half of tested kindreds.[73,76] The diagnosis of HNF1B-related renal disease requires a high index of suspicion.

GENETIC COUNSELING

Effective genetic counseling must take into consideration the striking phenotypic heterogeneity within families and the high rate of spontaneous mutations in the *HNF1B* gene.

MANAGEMENT AND PROGNOSIS

Management is directed toward the specific clinical manifestations. For patients who progress to ESRD, renal replacement therapy becomes the primary therapeutic option. In individuals with ESRD and diabetes (MODY5) combined kidney-pancreas transplantation should be considered.

GLOMERULOCYSTIC KIDNEY DISEASE

Glomerulocystic kidney disease (GCKD) consists of diverse clinical disorders with unifying pathologic findings of Bowman space dilatation (Figure 43.10). These dilated Bowman capsules are widely distributed throughout the renal cortex, and glomeruli within them may appear rudimentary or even collapsed by light microscopy.

CLINICAL FEATURES

Cystic glomeruli are evident in five different clinical contexts (Table 43.5): (1) isolated, nonsyndromic GCKD; (2) associated with single-gene disorders, such as ADPKD; (3) associated with heritable malformation syndromes, such as tuberous sclerosis, Meckel-Gruber syndrome, oral-facial-digital syndrome type I (OFD1), the short-rib polydactyly syndromes, and Zellweger cerebrohepatorenal syndrome;
Figure 43.10 Glomerulocystic kidney disease in a patient with multicystic dysplastic kidney. Histologic sample demonstrating glomerular cysts (arrow) and a focus of cartilage (asterisk). (Reproduced with permission from Bissler JJ, Siroky BJ, Yin H. Glomerulocystic kidney disease. Pediatr Nephrol. 2010;25:2049–56.)

(4) associated with trisomies 9, 13, and 18; and (5) dysplastic kidneys or urinary tract obstruction.[77]

GENETICS

Isolated GCKD can occur as a sporadic condition, as a familial disorder, or as the infantile manifestation of ADPKD. Glomerular cysts can be distributed from the subcapsular zone to the inner cortex.[78] Familial hypoplastic GCKD (also called the renal cysts and diabetes syndrome; MIM 137920) appears to be a distinct form of GCKD caused by mutations in *HNF1B*.[79] As noted earlier, intrafamilial disease expression is widely variable with variable associations of hypoplastic GCKD, gynecologic abnormalities, and MODY5.

DIAGNOSTIC EVALUATION

The typical ultrasound pattern in GCKD involves increased echogenicity of the renal cortex with minute cysts, smaller than those evident in ADPKD. The appearance and distribution of the renal cysts by MRI may further validate the diagnosis of GCKD.[80] Young infants with either familial or sporadic forms of GCKD may also have renal medullary dysplasia and biliary dysgenesis.[77]

KEY POINTS

- GCKD is characterized by microcysts in the subcortical region.
- Enlarged Bowman capsules with rudimentary or collapsed glomeruli are the pathologic hallmarks.
- GCKD is a diverse disorder that can be sporadic, familial, or associated with syndromic malformations or urinary tract obstruction.

GENETIC COUNSELING

GCKD is typically transmitted as an autosomal dominant trait, save for when associated with rare, recessive syndromic disorders. In addition, several sporadic cases of nonsyndromal GCKD have been described, suggesting either new spontaneous mutations or a recessively transmitted disorder.[77]

MANAGEMENT AND PROGNOSIS

Management is directed toward the specific underlying disorder and its associated clinical manifestations.

NONGENETIC RENAL CYSTIC DISEASE

SIMPLE RENAL CYSTS

Simple renal cysts (SRCs) are the most commonly acquired renal cystic lesion. They occur rarely in children (less than 1.0%), but become increasingly frequent with age. Men are

Table 43.5 Disorders associated with glomerular cysts

	Disorder	Gene
Single gene disorders		
	Autosomal dominant polycystic kidney disease	*PKD1*
	Autosomal dominant glomerulocystic kidney disease	*UMOD*
	Familial hypoplastic glomerulocystic kidney disease	*HNF1B*
Syndromic disorders

Urinary tract obstruction		

affected more commonly than women.[81,82] In children, SRCs are usually asymptomatic; although in some children they cause flank or abdominal pain. In some adolescents, there appears to be a relationship between SRCs and hypertension.[83]

Molecular pathogenesis

SRCs likely originate from the distal convoluted tubule or collecting ducts and may arise from renal tubular diverticula, but the pathogenic mechanisms are unknown. They are usually spherical and unilocular. They can occur in the cortex, where they can protrude from the cortical surface (exophytic cysts), in the corticomedullary junction, or in the medulla. By definition, they do not communicate with the renal pelvis. The cyst walls are lined with a single layer of flattened epithelium, and cyst fluid is essentially an ultrafiltrate of plasma.

Diagnostic evaluation

SRCs are usually discovered as an incidental finding during radiologic evaluation of the abdomen. The critical clinical issue in children is to distinguish single or multiple SRCs from cysts associated with ADPKD and other cystic diseases. This distinction can usually be made on the basis of the patient's age, family history, and renal imaging patterns.[81,84] The ultrasound features of SRCs include smooth walls, no septa, and no intracystic debris (Figure 43.11A). If the ultrasound pattern is indeterminate, CT scanning should be performed.

A classification system for renal cysts based on their appearance and enhancement on CT was described by Bosniak and is widely used (Table 43.6).[85] SRCs or benign cysts (class I) have homogeneous attenuation, no contrast enhancement,

thin and smooth cyst walls, and no associated calcifications, unless earlier infection has occurred (Figure 43.11C).

Management and prognosis

In children, SRCs are rarely symptomatic. Rarely, SRCs occasionally can be associated with flank pain or renin-dependent hypertension. Such symptomatic cysts can be effectively treated by ultrasound-guided percutaneous puncture, drainage, and instillation of a sclerosing agent into the cyst cavity.[86,87] The prognosis is excellent.

MULTILOCULAR CYSTS

Solitary multilocular cysts are generally benign neoplasms that arise from the metanephric blastema. These solitary cysts have also been termed multilocular cystic nephroma (CN), benign cystic nephroma, and papillary cystadenoma. By definition, the cystic structures are unilateral, solitary, and multilocular. The cystic locules do not communicate with each other or with the renal pelvis. These locules are lined with a simple epithelium, and the interlocular septa do not contain differentiated renal epithelia structures.[18]

Molecular pathogenesis

Multilocular cysts represent a spectrum,[88] from CN to cystic partially differentiated nephroblastoma (CPDN), in which the septa contain foci of blastemal cells. It is not clear whether a multilocular cyst represents a congenital abnormality in nephrogenesis, a hamartoma, a partially or completely differentiated Wilms tumor, or a benign variant of Wilms tumor.

A bimodal age distribution has been described, with approximately half the cases occurring in children less than
Figure 43.11 **(a)** Ultrasound scan of a simple renal cyst showing a smooth-walled outline and no echogenic focus in the cyst itself (Bosniak category I). **(b)** Computed tomography (CT) scan of the same patient as in (a) showing the smooth-walled cyst posteriorly projecting slightly from the cortical surface (arrow). **(c)** Ultrasound scan of the kidney showing a renal cyst with an irregular but sharply marginated outline (arrow). An echogenic focus exists within the cyst itself (Bosniak category II). The CT scan did not demonstrate any lesion or growth within the cyst. During 5 years of follow up, the patient's ultrasound findings have remained unchanged.

4 years of age and the remaining cases detected in adults.[89] The childhood-onset disease (mostly CPDN) is usually found in boys, whereas multilocular cysts presenting in adulthood (mostly CN) occur more commonly in women.

KEY POINTS

- SRCs are less common in children and increase in occurrence with age.
- The contour of the cysts is thin walled on ultrasound or CT scan.
- Multilocular cysts are large and can occupy the entire pole of the kidney. The cystic lobules do not communicate with each other or with the renal pelvis.
- Multilocular cysts need to be differentiated from a renal neoplasm.

Diagnostic evaluation

An abdominal or flank mass is the most common clinical presentation because these cysts are typically quite large and often replace an entire pole. Associated hematuria, calculi, urinary tract obstruction, and infection occur in rare instances. The diagnosis can be made either by ultrasonography or with CT.

Management and prognosis

Almost all multilocular cysts are complex renal cysts, which in adults are suspicious for malignancy (Bosniak class III).[84] CPDNs in children may contain blastema and incompletely differentiated metanephric tissue, but usually they have a benign course. In adults, associated foci of renal cell carcinoma or sarcoma must be excluded.[90] For diagnostic accuracy, as well as treatment, enucleation or partial surgical resection is recommended.[91] The typical prognosis of solitary multilocular cysts is excellent.

Table 43.6 Bosniak classification of renal cysts for neoplastic risk

Bosniak category	Ultrasound and CT cyst features
I	Simple benign cyst with a hairline thin wall that does not contain septa, calcification, or solid components; measures as water density and does not enhance with contrast material.
II	Benign cyst that may contain a few hairline thin septa. Fine calcification may be present in the wall or septa; high-attenuation lesions of <3 cm that are sharply marginated and do not enhance
IIF	Cysts containing more hairline thin septa; minimal enhancement of a hairline thin septum or wall visible, minimal thickening of the septa or wall. Cyst containing calcification that could be nodular and thick but there is no contrast enhancement. Entirely intrarenal nonenhancing high-attenuation renal lesions of ≥3 cm that are well marginated are also included in this category. Malignant potential higher than Bosniak category II.
III	Indeterminate cystic masses that have thickened irregular walls or septa in which enhancement can be seen. Should be considered potentially malignant.
IV	Clearly malignant cystic lesions that contain enhancing soft tissue components.

DIAGNOSTIC EVALUATION OF RENAL CYSTIC DISORDERS

As described earlier, disorders associated with renal cysts may be inherited or acquired. Their manifestations may be confined to the kidney or expressed systemically. Renal cysts may be single or multiple, and the associated renal impact may range from clinical insignificance to progressive parenchymal destruction with resultant renal insufficiency. For those disorders associated with systemic manifestations, such as oral-facial-digital syndrome, type 1 (OFD1) and ADPKD, the associated extrarenal features may provide other important differential diagnostic clues. However, in some patients with atypical presentations, more extensive imaging studies or genetic testing may be required to establish the diagnosis.

The algorithm provided in Figure 43.12 outlines an initial guide to diagnosis, based on family history, the laterality of the cystic findings, and kidney size on renal imaging (Figure 43.13). Distinguishing features of key pediatric renal cystic diseases are provided in Table 43.7. Genetic testing resources for inherited renal cystic diseases are available at GeneTests (http://www.genetests.org) and at the National Institutes of Health (NIH) Genetic Testing Registry (http://www.ncbi.nlm.nih.gov/gtr).

* Joubert syndrome (JBTS; MIM 213300) is a genetically heterogeneous (JBTS 1–22), autosomal recessive disorder characterized by developmental defects in the cerebellum (cerebellar vermis aplasia) and the eye (coloboma), as well as retinitis pigmentosa, congenital hypotonia, and either ocular motor apraxia or irregularities in breathing patterns during the neonatal period. The disease can be associated with NPHP, and mutations in several *NPHP* genes have been described in patients with JBTS.

† Genetic testing: listed at GeneTests (http://www.genetests.org) and the NIH Genetic Testing Registry (http://www.ncbi.nlm.nih.gov/gtr).

FUTURE THERAPEUTIC DIRECTIONS

The discovery of the single-gene defects that cause renal cystic diseases and the generation of corresponding animal models have provided important insights into disease pathobiology. Preclinical studies in animal models have implicated a central role for primary apical cilium signaling in suppressing cell proliferation, cyst formation, and progression (Figure 43.14). Ciliary dysfunction contributes to increased intracellular accumulation of cyclic adenosine monophosphate (cAMP) and activation of mammalian target of rapamycin (mTOR), key signatures of renal cystic epithelia. These insights have spurred the identification of potential molecular targets for therapeutic intervention within these pathways, as well as other signaling pathways.

The ultimate goal of preclinical studies is to translate knowledge of disease mechanisms into effective therapy. However, the ability to assess clinically significant changes in outcome is predicated on having defined predictive and prognostic endpoints for disease progression. In experimental animals, renal cystic disease progression can be quantitated by serial histologic examination, and more recently, by serial live animal imaging.[92] However, for most human renal cystic diseases, clinical trial design has been hampered by the lack of defined biomarkers to track disease progression meaningfully. Therefore, imperatives for designing clinical translational studies in ARPKD, NPHP,
Figure 43.14 Ciliary dysfunction in the pathogenesis of renal cysts. The cilium concentrates and organizes numerous channels, receptors, and effectors, such as transcription factors and proteolytic fragments of cystoproteins. Cilia play a critical role in transmitting information on the external milieu back into the cell and ultimately regulating cellular and tubular differentiation and homeostasis. Cilia appear to play a role in maintaining this balance through sensing the extracellular milieu, by responding to mechanical cues and modulating different signaling cascades. Ciliary dysfunction contributes to increased intracellular accumulation of cyclic adenosine monophosphate (cAMP) and activation of mammalian target of rapamycin (mTOR), features common to cystic epithelia in human and rodent models of renal cystic disease. Almost all cystoproteins, including (but not limited to) the polycystins, fibrocystin/polyductin (FPC), the nephrocystins, uromodulin, and the OFD1 protein, localize to the cilia-centrosome complex, a finding suggesting that this complex is critical in the pathogenesis of renal cystic disease. ACVI, Adenylate cyclase VI; ATP, adenosine triphosphate; Ca2+, calcium; V2R, V2 receptor.

and other renal cystic disorders are the identification and validation of reliable, noninvasive biomarkers to monitor the effectiveness of potential therapies.

ADPKD is the one renal cystic disease for which an early predictive marker has been defined. Specifically, total kidney volume (TKV) is now widely accepted as an early predictor of ADPKD progression, based on the findings of the NIH-sponsored Consortium for Radiologic Imaging Studies of Polycystic Kidney Disease (CRISP) study.[93,94] This longitudinal study developed a highly reproducible, MRI-based imaging protocol that demonstrated that rates of increase in kidney volume correlated with changes in renal function. Several trials directed at slowing disease progression have used TKV measurements as a surrogate for ADPKD progression.

Three randomized, controlled, blinded trials have been reported. The first two tested rapamycin analogues (inhibitors of the mTOR signaling pathway) in ADPKD.[95,95] In

the first study,[95] no benefit was observed with respect to renal volume or function in subjects with well-preserved function. In the second study, renal volumes were better preserved in subjects taking the study drug, but renal function was not, a finding suggesting that changes in volume and function may be disassociated.[96] The third study tested tolvaptan, an inhibitor of the vasopressin-2 receptor.[97] Tolvaptan slowed the rate of cyst growth; it had a modestly positive effect on renal function, and treated subjects experienced fewer and less severe pain episodes. Although these data are encouraging, several issues prompted the US Food and Drug Administration (FDA) to defer approval of tolvaptan for ADPKD treatment.[98] These issues included (1) rodent studies demonstrating that the drug benefits attenuate over time,[99] (2) the development of liver enzyme abnormalities in a small but significant fraction of patients taking tolvaptan, and (3) dropout of approximately 25% of the treatment group (twice the placebo rate) because of

side effects. Although the outcomes of these initial clinical trials are disappointing, the data suggest that additional, well-designed studies of targeted therapies, perhaps using composite clinical outcome markers that include TKV, may be able to demonstrate a positive impact on attenuating the disease course in ADPKD.

SUMMARY

Cystic renal diseases are diverse disorders, many of which are genetically transmitted. These disorders are also diverse in their age of presentation, clinical manifestations, and progression to ESRD. With the growing use of fetal ultrasound evaluation, these disorders are increasingly diagnosed prenatally. Although ARPKD is the most common genetically inherited cystic disorder in children, ADPKD can also be clinically significant during childhood. Several syndromes are associated with renal cysts and must be considered in the evaluation of children found to have cysts on ultrasound evaluation. Cystic diseases are now classified as ciliopathies because ciliary dysfunction in renal eipthelia is a major contributor to disease pathogenesis in most of these conditions. Treatment modalities for most renal cystic diseases are limited at the present time, and these disorders often progress to ESRD. Future development of drugs that reduce cyst size, attenuate interstitial fibrosis, and prevent progressive decline in renal function could reduce the evolution of ESRD in these patients.

REVIEW QUESTIONS

1. Extrarenal complications of ARPKD can include:
   a. Congenital hepatic fibrosis
   b. Caroli syndrome
   c. Growth retardation
   d. Intracranial aneurysms
   e. All of the above

2. All of the conditions below are included in hepatocellular fibrocystic disorders, *except*:
   a. ARPKD
   b. ADPKD
   c. Multicystic dysplastic kidney (MCDK)
   d. Nephronophthisis (NPHP)
   e. Joubert syndrome (JBTS)

3. In which of the pediatric age groups can ADPKD manifest?
   a. Fetus
   b. Infant
   c. Child
   d. Adolescent
   e. All of the above

4. Small, contracted kidneys are characteristically seen in seen in which of the following cystic disease(s)?
   a. HNF1B-related disease
   b. ARPKD
   c. Nephronophthisis
   d. Medullary sponge kidney
   e. None of the above

5. A causal relationship between hypertension and renal cystic disease has been proposed in each of the following disorders *except*:
   a. ARPKD
   b. ADPKD
   c. NPHP
   d. MCKD
   e. Simple cysts

6. Gene-based testing is a clinically informative tool for which disorder?
   a. ARPKD
   b. ADPKD
   c. NPHP
   d. MCKD
   e. All of the above

7. Medullary sponge kidney is a single-gene disorder in a subset of patients.
   a. True
   b. False

8. Which disorder is the *most common* cause of hyperechoic kidneys in a fetus?
   a. ARPKD
   b. ADPKD
   c. NPHP

d. HNF1B-related disease
e. Glomerulocystic kidney disease

9. Glomerular cysts can be observed in which disorders?
   a. ADPKD
   b. MCKD2
   c. HNF1B-related disease
   d. Trisomy 18
   e. All of the above

10. Simple cysts can lead to clinical symptoms in childhood.
    a. True
    b. False

Ciliopathies and nephronophthisis

JOHN SAYER, SHREYA RAMAN, AND SHALABH SRIVASTAVA

Nephronophthisis (NPHP), which literally means "disappearance of nephrons," is an autosomal recessively inherited renal disease leading to end-stage renal disease (ESRD). NPHP belongs to a group of disorders that are now classed as *ciliopathies* with the underlying morphologic and functional defect in the primary cilium, basal body, or centrosome.

Ciliopathies are a relatively new class of disorders, in which the pathologic process lies in the cilium and basal body complex. They encompass a wide spectrum of diseases involving almost any organ system. Interest in the cilium as an organelle, described in 1675 by Anthony van Leeuwenhoek, has gathered such momentum that a new journal dedicated to the cilia and its associated diseases was launched in 2012.[1,2] The primary cilium is a hairlike organelle that is present on virtually all somatic cells. It functions as a cellular antenna through which it allows the cell to remain constantly in contact with its environment.

Ciliopathies result from mutation in genes encoding component proteins of the basal body, transition zone, or ciliary axoneme. Table 44.1 lists examples of the diseases caused by such mutations and the proposed consequent functional defect in the cilium and basal body. In its most severe form, the loss of ciliary structure may cause the loss of planar cell polarity (PCP) in renal tubular cells and in less severe case result in cellular disruption and disordered signal transduction. The various signaling cascades intimately related to the primary cilium are discussed later. The result of these abnormalities is not only renal tubular cell dysfunction and renal cyst formation, but also abnormal development and organ function throughout the body.

Table 44.1 Examples of ciliopathy diseases, their genes, and their proposed functional role

Disease	Gene(s)	Affected function
Bardet-Biedl syndrome	BBS1/BBS2/ BBS5/BBS7/ BBS8	Ciliary function
	BBS3	Vesicle trafficking
	BBS4	Microtubule transport
	BBS6	Cilia/chaperone
Alström syndrome	ALMS1	Ciliogenesis
Joubert syndrome	AHI1	Ciliogenesis
Meckel-Gruber syndrome	MKS1	Ciliogenesis
	MKS2/MKS3	Transmembrane/ ciliary protein
	MKS4	Basal body function
Nephronophthisis	NPHP1	Ciliary function
Short-rib thoracic dysplasia (Jeune asphyxiating thoracic dystrophy)	IFT80	IFT subcomplex B
Ellis–van Creveld	EVC1/EVC2	Ciliary

CILIARY STRUCTURE

The primary cilium has a 9 + 0 microtubular structure and arises from the mother centriole, the older of the two centrioles (Figure 44.1). Centrioles are microtubule-based cylindrical structures surrounded by pericentriolar material (PCM). The PCM forms a scaffold around the centriole and has been shown to be involved in intracellular transport to the ciliary base. The cilium is assembled by the transfer of actin subunits from the cytoplasm by transport proteins. After assembly, the cilium is in contact with the cellular cytoplasm via a specialized transition zone, which along with transition fibers acts as a gatekeeper to the cilium (see Figure 44.1). There are approximately 600 proteins within the cilium and their transport in and out of the cilium is closely regulated by specific ciliary localization sequence.[3,4] Intraflagellar transport (IFT) of proteins is mediated by kinesin 2 and IFT B motor complexes involved in the anterograde movement of molecules and dynein and IFT A complexes and is involved in the retrograde movement of proteins.[5]

It is important to understand that the cilium consists of clearly defined subciliary compartments that are anatomically and functionally distinct. The ciliary axoneme is separated from the cell by a transition zone. The component proteins of the transition zone are organized into modules.[6] The interaction of transition zone proteins between and within these modules defines its function and allows prediction of disease phenotypes. Even within the NPHP ciliopathy, there is a significant degree of genetic heterogeneity.[7] The role of modifier genes, oligogenicity, and mutation load is an area of intense research and may be responsible for the huge phenotypic variability seen in certain ciliopathies.[8,9]

CILIARY SIGNALING CASCADES

Hedgehog signaling

The Hedgehog (Hh) signaling pathway (Figure 44.2) is an ancient signaling cascade that is involved in development, organogenesis, growth, and intracellular and intercellular

> **KEY POINTS**
>
> - The primary cilium is a complex organelle that senses the cellular microenvironment to regulate cell function.
> - The cilium transduces signals into the cell by the Sonic hedgehog and Wnt signaling pathways.

Figure 44.1 Structure of the cilium. The ciliary axoneme comprises nine microtubule doublets. The mother centriole comprises nine microtubule triplets, arranged in a cylinder. Cells contain two centrioles, the mother and the daughter. The mother centriole is the older of the two and provides a template for the nine microtubule doublets to form the ciliary axoneme. The transition fibers and transition zone form a ciliary gate that mediates entry and exit of molecules into the cilium.

Figure 44.2 Ciliary Hedgehog signaling. The cilia mediate Hedgehog (Hh) signaling. In the absence of the ligand Sonic hedgehog (Shh), Patched (Ptch) represses the function of Smoothened (Smo) and there is no activation of Gli transcription factor. In the presence of Hh, Smo is released and moves into the cilium. At the ciliary tip, Smo promotes activation of Gli (GliA), which enters the nucleus and promotes Hh-dependent gene transcription.

signaling. Excess Sonic hedgehog (Shh) pathway activation can lead to severe developmental defects, extra digits, and tumor formation.[10] The Glioma (Gli) family of proteins are the terminal mediators of the Shh, and they localize to the primary cilia.[11] In the absence of Shh, Patched (Ptch) inhibits Smoothened (Smo) and there is no Gli3 activation. When Shh binds to its receptor Ptch, Smo enters the cilium and induces activation of Gli3, which then translocates to the nucleus, where it regulates gene expression.[5] The transport of the Shh pathway proteins within the cilium depends on the IFT machinery.[12,13]

Wnt signaling

The noncanonical PCP pathway is a Wnt signaling pathway that is responsible for targeted cell migration, mitotic spindle orientation, and PCP.[14] Mutations in the components of the Wnt pathway lead to neural tube defects and have been implicated in the development of a cystic kidney phenotype.[15] May-Simera and Kelly[16] published an excellent review exploring the role of this pathway in ciliopathies.·

Platelet-derived growth factor receptor-alpha (PDGFR-α)

The cilium responds to chemosensory and mechanosensory stimulus by multiple signaling pathways involving PDGFR-α and its downstream effectors of the MEK/ERK cascade. A review of the ciliary signaling pathways mentioned previously and novel pathways such as the Hippo pathway can be found in a recent paper by Basten and Giles.[17]

CLASSIFICATION OF NEPHRONOPHTHISIS

Historically, NPHP was classified by its clinical presentations and was also based on the age of onset of ESRD (Table 44.2). Modern-day molecular genetics allows a more precise diagnosis to be made.[18] It is now clear that single-gene disorders leading to NPHP may have a spectrum of presentations and

Table 44.2 Clinical classification of nephronophthisis

Type	Median age of onset of ESRD	Most frequent genetic correlate
Infantile	<1 yr	*NPHP2* and *NPHP3*
Juvenile	13 yr	*NPHP1*
Adolescent	19 yr	*NPHP3* originally described
Late onset	3rd to 6th decade	*NPHP1* and others

Abbreviation: ESRD, end-stage renal disease.

disease severity. Indeed, mutations in NPHP genes may give rise to isolated NPHP or to overlapping syndromes, including Senior-Loken syndrome (SLS), Joubert syndrome (JBTS), and Meckel-Gruber syndrome (MKS) (Table 44.3). Mutations in *NPHP6* may even cause Bardet-Biedl syndrome (BBS) phenotype.[19]

Abbreviations: BBS, Bardet-Biedl syndrome; JATD, Jeune asphyxiating thoracic dystrophy; JBTS, Joubert syndrome; LCA, Leber congenital amaurosis; MKS, Meckel-Gruber syndrome; OFD, oral-facial-digital syndrome; SLS, Senior-Loken syndrome.

Table 44.4 Nephronophthisis may be associated with extrarenal manifestations and various eponymous syndromes

NPHP-associated syndrome	Extrarenal features
Arima syndrome	Agenesis of the cerebellar vermis, ocular abnormalities, variable liver disease
COACH syndrome	Cerebellar vermis hypo/aplasia, oligophrenia (mental retardation), ataxia, ocular coloboma, and hepatic fibrosis
Cogan oculomotor apraxia	Defective or absent horizontal voluntary eye movements
Jeune asphyxiating thoracic dystrophy (JATD) (short-rib thoracic dysplasia)	Chondrodysplasia characterized by a severely constricted thoracic cage, short-limbed short stature, and polydactyly. Variable hepatic disease, retinal degeneration, pancreatic cysts
Joubert syndrome (JBTS)	Hypoplasia of the cerebellar vermis; neurologic symptoms, including dysregulation of breathing pattern and developmental delay. Variable retinal dystrophy, renal anomalies
Meckel-Gruber syndrome (MKS)	CNS malformation (including occipital encephalocele) and hepatic abnormalities, including portal fibrosis or ductal proliferation. Variable polydactyly, most often postaxial
RHYNS syndrome	Retinitis pigmentosa, hypopituitarism and mild skeletal dysplasia
Senior-Loken syndrome (SLS)	Leber congenital amaurosis
Sensenbrenner syndrome (cranioectodermal dysplasia)	Skeletal abnormalities, including craniosynostosis, narrow rib cage, short limbs, brachydactyly, and ectodermal defects. Variable hepatic fibrosis, heart defects, and retinitis pigmentosa

CLINICAL PRESENTATION

NPHP is a clinically and genetically heterogeneous disease (see Tables 44.2 and 44.3). The clinical presentation can vary from a very mild urinary concentrating defect to intrauterine death. The average age of presentation is approximately 6 years. The child usually presents with polydipsia, polyuria, secondary enuresis or nocturia, and generalized lethargy.[20] An inability to concentrate the urine usually precedes renal dysfunction, and ESRD ensues usually under the age of 25 years. The diagnosis of NPHP should be questioned if ESRD has not developed by the age of 25 years.[21] However, late adulthood presentation is possible

Table 44.5 Demographics and pathology of nephronophthisis

Inheritance	Autosomal recessive
Incidence	1:50,000 to 1:900,000
Geographic distribution	Worldwide
Macroscopic renal pathology	Normal or reduced kidney size with corticomedullary cysts arising from collecting ducts and distal tubule
Renal microscopy	Corticomedullary cysts, tubulointerstitial nephritis, and tubular basement membrane disruption

(see later). Extrarenal manifestations occur in 15% of cases and may help determine a clinical diagnosis of the disease (Table 44.4). Although NPHP is the most common genetic cause for ESRD in children and young adults, its reported incidence is widely variable (Table 44.5).[22–25]

Infantile nephronophthisis

The rare infantile form of NPHP is characterized by early and widespread development of tubulointerstitial nephritis with cortical cysts, enlarged kidneys, and ESRD before 2 years of age. It is histologically distinct from juvenile NPHP.[26] Genetically, *NPHP2* and *NPHP3* are the most common causes of infantile NPHP. *NPHP2* encodes for inversin, and *NPHP3* encodes for nephrocystin-3.[27–29] Situs inversus and other cardiac defects may be associated with infantile NPHP.

Juvenile nephronophthisis

Juvenile NPHP is the most common form of inherited kidney disease leading to chronic kidney disease in children.[30] Mutations in *NPHP1* account for approximately 20% of cases of NPHP.[7] *NPHP1* encodes for the primary ciliary protein nephrocystin-1 and is expressed in the human collecting duct.[31]

Adult-onset nephronophthisis

There are a few case reports of onset of renal failure in the 3rd to 6th decade of life along with extra renal manifestations of NPHP.[32–34] It is important to perform accurate assessment of a patient's vision and neurologic status to

KEY POINTS

- NPHP may present as an isolated lesion or as a part of a complex of symptoms involving multiple organs.
- Common findings of NPHP include a urine concentrating defect, normal to small kidneys on ultrasound, and anemia more severe than would be expected by the degree of renal impairment.

assess for the extrarenal manifestations of NPHP. These patients have been reported to have pendular nystagmus, retinal degeneration, and a reduction in vision. They have also been reported to have ataxia. These features along with chronic interstitial nephritis should lead the physician toward a genetic analysis for NPHP mutations.

DIAGNOSIS

CLINICAL EVALUATION

To establish a clinical diagnosis of NPHP, a detailed history and clinical examination including looking for extrarenal associations (abnormal eye movements, retinopathy, ataxia, polydactyly, cardiac malformations) is necessary. A detailed family history must be obtained.[18] Fundoscopic evaluation should be performed by an ophthalmologist. The majority of patients with NPHP present with renal disease and its manifestations. However, as described earlier, ciliary dysfunction may lead to multiorgan involvement. Patients with extrarenal manifestations require referral to appropriate specialists for management.

RENAL FUNCTION AND ANCILLARY DATA

Investigations should include renal and liver function tests, hemoglobin determination, and urine concentration ability. Key diagnostic features are elevated serum creatinine level with reduced urine osmolarity (typically < 400 mOsm/kg). Anemia that is out of proportion to the degree of chronic kidney disease (CKD) is a frequent finding in patients with NPHP. Regular review is required to appropriately manage CKD and ESRD.

RADIOLOGIC INVESTIGATIONS

The most informative and practical modality for radiologic assessment is ultrasound of the kidney. The important features are loss of corticomedullary differentiation, presence of corticomedullary cysts, and reduced or normal renal size (Figure 44.3). Indeed, a patient with previously undetected CKD, small kidneys on ultrasound, and anemia that is disproportionate to the degree of renal dysfunction may be

Figure 44.3 Renal ultrasound appearance of nephronophthisis (NPHP). Renal ultrasound scan of a patient with NPHP showing loss of corticomedullary differentiation, normal renal size, and few corticomedullary cysts.

presumed to have NPHP until proved otherwise. Hepatic ultrasound may provide information about extrarenal involvement.

Brain magnetic resonance imaging (MRI) may be performed, if indicated, to assess for intracranial abnormalities. The pathognomonic "molar tooth sign" (Figure 44.4) is seen in JBTS and represents a deep interpeduncular fossa; narrow isthmus; thickened, elongated, and maloriented superior cerebellar peduncles; and cerebellar vermis hypoplasia.[35]
Figure 44.4 Molar tooth sign (within arrowheads). This finding is strongly associated with Joubert syndrome. (Reproduced with permission from: Brancati F, Dallapiccola B, Valente EM. Joubert syndrome and related disorders. Orphanet J Rare Dis. 2010;5:20. doi:10.1186/1750-1172-5-20.)

GENETIC TESTING

After genetic counseling, genetic testing to seek a molecular diagnosis should be undertaken, and this may avoid the need for renal biopsy. Targeted *NPHP1* mutational analysis (including searching for whole gene deletion) will detect approximately 20% of cases.[36] However, given the huge genetic heterogeneity, high-throughput polymerase chain reaction (PCR), and next-generation sequencing and whole exome approaches are providing a more efficient means of genetic diagnosis than individual gene sequencing.[27,37–39] At this point, however, more than half of NPHP cases remain unsolved in terms of a molecular genetic defect.[27]

RENAL PATHOLOGIC FINDINGS

Traditionally, a diagnosis of NPHP has relied on a pathologic evaluation (Table 44.5 and Figure 44.5). Typically, the kidneys are normal or reduced in size. This is in contrast to autosomal dominant polycystic kidney disease, in which there are grossly enlarged kidneys and predominantly cortical cysts. In NPHP, the presence of corticomedullary cysts is not universal and depends on the underlying genetic defect. In NPHP, the histopathologic changes are characterized by diffuse interstitial fibrosis, tubular basement membrane thickening, tubular atrophy, corticomedullary cyst formation, and periglomerular fibrosis.[24,28] Karyomegalic interstitial nephritis described by Mihatsch et al.[40] has histopathologic features similar to those of NPHP, apart from the presence of karyomegaly. The autosomal dominant condition medullary cystic kidney disease also may mimic NPHP histologically.[36]

TREATMENT

Presently there is no cure for NPHP and related ciliopathies. Clinicians must focus on optimizing the delivery of renal replacement therapy, ideally with renal transplantation where possible. However, with a growing understanding of the pathophysiology of NPHP, therapeutic interventions are possible in the future. Management of extrarenal manifestations requires input from specialists and multidisciplinary care teams, to ensure the best possible quality of life for these patients.

PROGNOSIS

Infantile forms of NPHP have a guarded prognosis, given the challenges and difficulties of managing ESRD, especially if it occurs before 5 years of age. The prognosis for children and young adults with other forms of NPHP is variable, depending on the age of onset of CKD or ESRD and presence of extrarenal manifestations. Following transplantation, there is no recurrent disease in the allograft and patients with nonsyndromic forms of NPHP do well. Where severe extrarenal manifestations are present, such as in JBTS, the prognosis largely depends on the degree of associated brain anomalies.

SUMMARY

The nephronophthises are a group of diseases that result from abnormal function of the primary cilium. This structure is essential for transducing environmental signals into the cell, and its disruption results in organ maldevelopment and malfunction. Although the primary manifestations in the kidney are renal concentrating defects and cyst formation, systemic loss of cilia can affect the form and function of many organs. Further, the mutation of different proteins in the cilium may have different effects, so that multiple mutations have been identified, each of which causes a unique pattern of systemic pathologic processes. Given that NPHP is a genetically determined disease, treatment is directed entirely toward ameliorating symptoms.

Clinical Vignette 44.1

A 5-year-old girl presented to the nephrology department with symptoms of being tired and lethargic. Her medical history revealed developmental delay and possible seizures as a neonate. She had no breathing abnormalities during the perinatal period and no history of gaze palsy. She was still wearing diapers at night because of nocturnal enuresis, and the mother reported polydipsia from an early age. Her parents were consanguineous (first-degree cousins). She had one healthy sibling 7 years of age, and there was no other family history of renal disease. Fundoscopic examination was normal and showed no coloboma or retinal dystrophy. Her serum creatinine level was 4 mg/dL and hemoglobin was 7 g/dL. MRI of the brain revealed hypertrophy of the superior cerebellar peduncles and dysplasia of the cerebellar vermis. Renal ultrasound showed small kidneys bilaterally with loss of corticomedullary differentiation. No renal cysts were seen. Urine biochemistry revealed a urine osmolarity of 320 mOsm/kg and serum biochemistry confirmed CKD stage 5 (eGFR 12 mL/min).

TEACHING POINTS

- This child presented with a cerebral-renal syndrome. She had evidence of CKD and severe anemia, in addition to neurologic symptoms.
- A search for additional clinical features suggestive of a ciliopathy should be performed. These include documenting polydactyly (may be already corrected surgically) and other skeletal abnormalities, ataxia, cardiac malformations, and liver dysfunction.
- A formal ophthalmologic examination should be performed, because retinal changes may be subtle.
- A detailed family history may reveal other family members at risk.
- An obstetric history from the mother (oligohydramnios, miscarriages, etc.) may be informative.
- Baseline investigations should include renal and liver function tests, hemoglobin determination, urine concentrating ability, renal and hepatic ultrasound scans, and cerebral imaging.
- Brain imaging should be reviewed to look for the pathognomonic "molar tooth" sign of JBTS syndrome.
- A renal biopsy should be withheld in cases in which there is evidence of CKD or ESRD. Instead, genetic testing should be performed. Mutations in *NPHP1* are the most common molecular genetic findings in NPHP and may be associated with both brain and eye phenotypes.
- Whole exome sequencing approaches may be the most efficient way of obtaining a definitive molecular genetic diagnosis if the *NPHP1* gene testing is negative.

- Clinical management should focus on the treatment of CKD and impending ESRD, with optimization of blood pressure, anemia, and bone health.
- Assessment and preparation for dialysis and transplantation are important needs to be addressed. Extrarenal clinical manifestations should be managed by referral to appropriate specialists.

REVIEW QUESTIONS

1. Clinical features of a ciliopathy may include:
   a. Renal cysts
   b. Retinal disease
   c. Cerebral malformations
   d. All of above
   e. None of above
2. Nephronopthisis may be associated with which of the following syndromes?
   a. Joubert syndrome
   b. Long QT syndrome
   c. Medullary cystic kidney disease
   d. Senior-Loken syndrome
   e. a and d
   f. b and c
3. The most common genetic cause of nephronophthisis is:
   a. *NPHP1*
   b. *NPHP4*
   c. *SDCCAG8*
   d. *NPHP5*

4. A molecular genetic diagnosis can be made in what percentage of cases of NPHP?
   a. 25%
   b. 40%
   c. 60%
   d. 10%
5. The histologic features of nephronophthisis may include:
   a. Glomerular basement membrane thinning
   b. Interstitial fibrosis
   c. Karyomegaly
   d. Cortical microcysts
   e. b and d
   f. a and c

Alport syndrome and thin basement membrane nephropathy

MICHELLE N. RHEAULT AND CLIFFORD E. KASHTAN

Alport syndrome (AS) and thin basement membrane nephropathy (TBMN) are related inherited disorders of glomerular basement membranes (GBMs) that manifest with hematuria in childhood. AS is characterized clinically by progressive deterioration of kidney function with cochlear and ocular involvement, leading to end-stage renal disease (ESRD) and deafness in many affected individuals.

Familial hematuria associated with renal disease was described by several English investigators in the early 20th century. Cecil Alport recognized that these patients also exhibited deafness and that symptoms were more severe in the affected males.[1] The underlying genetic cause was identified in 1990 when Barker et al.[2] discovered mutations in *COL4A5*, the gene encoding the α5 chain of type IV collagen, in several kindreds affected by X-linked Alport syndrome (XLAS). In 1994, mutations in both alleles of the related type IV collagen genes *COL4A3* and *COL4A4* were identified as causative for autosomal recessive Alport syndrome (ARAS).[3]

TBMN, formerly known as benign familial hematuria, has been recognized since the early 1970s as a cause of familial hematuria.[4] TBMN is usually not associated with extrarenal clinical manifestations and is generally a nonprogressive disorder. However, a subset of patients have been found to develop overt proteinuria and hypertension.[5] Heterozygous mutations in *COL4A3* and *COL4A4* were identified in some patients with TBMN in 1996, but the genetic basis in others remains unclear.[6]

ALPORT SYNDROME

EPIDEMIOLOGY

The prevalence of AS has been estimated at 1:50,000 live births.[7] The prevalence of TBMN is estimated at 1% to 2% of the population.[8] There does not appear to be an ethnic predisposition to development of AS or TBMN. In children undergoing kidney biopsy for persistent microscopic hematuria, approximately 12% to 27% are diagnosed with AS and 15% to 50% are diagnosed with TBMN.[9–11] According to the US Renal Data System (USRDS), 1.3% of pediatric ESRD patients and 0.4% of adult ESRD patients have a primary diagnosis of AS.[12]

> ### KEY POINTS
>
> - AS and TBMN are common causes of persistent microscopic hematuria in childhood.
> - TBMN is estimated to affect 1% to 2% of the population.

GLOMERULAR BASEMENT MEMBRANE COLLAGEN NETWORK

Transmission electron microscopy of the normal GBM exhibits an electron-dense lamina densa surrounded on

each side by more electron-lucent layers known as the lamina rara interna and externa. Both podocytes and endothelial cells secrete components of the GBM during glomerulogenesis and are responsible for maintenance of its structure and function.[13,14] Similar to other basement membranes, the GBM is composed of type IV collagen, laminin, entactin/nidogen, and heparan sulfate proteoglycan. However, the isoforms of each protein class that are present in the GBM are often unique compared to those in other basement membranes in the body.[15]

There are six isoforms of type IV collagen, α1(IV)-α6(IV), encoded by six genes, *COL4A1 to COL4A6*. The type IV collagen genes are arranged in pairs on three chromosomes: *COL4A1 to COL4A2* on chromosome 13, *COL4A3 to COL4A4* on chromosome 2, and *COL4A5 to COL4A6* on the X chromosome. Each gene pair is oriented in a head-to-head manner with intervening promoter and transcriptional regulatory sites allowing for coordinated transcription.[16,17] All α(IV) chains share similar structural features, including a noncollagenous aminoterminal sequence of approximately 20 amino acids (7S), a collagenous domain of approximately 1400 amino acids with multiple Gly-X-Y repeats, and a noncollagenous carboxyterminal (NC1) domain of approximately 230 amino acids. The type IV collagen α chains wind around one another to form triple helixes or trimers. Despite multiple combinatorial possibilities, only three type IV collagen trimers are found in mammalian basement membranes: α1α1α2(IV), α3α4α5(IV), and α5α5α6(IV). Trimer formation is directed by sequence and structure within each NC1 domain.[18] The 7S and NC1 domains are then responsible for linking trimers together to form three-dimensional collagen IV networks.[19] The α1α1α2(IV) network is found in all basement membranes, whereas the α3α4α5(IV) network has a more limited distribution in GBM, Bowman capsule, distal and collecting tubules, alveoli, inner ear, and eye, and some other basement membranes.[20,21] The α5α5α6(IV) trimer is present in the Bowman capsule and distal and collecting tubule basement membranes, as well as some skin, alimentary canal, and vascular basement membranes, but is not present in GBM.

During glomerulogenesis, the primary type IV collagen network switches from a predominantly α1α1α2(IV) network in GBM of primitive glomeruli to a predominantly α3α4α5(IV) network in the mature GBM.[22] The α3α4α5(IV) network is more highly cross-linked and may be more resistant to proteases than the α1α1α2(IV) network, which may account for some of the unique properties of the GBM.[23,24] Absence or disruption of the α3α4α5(IV) network with persistence of the embryonal α1α1α2(IV) network is the primary abnormality in AS.

COLLAGEN DEFECT IN ALPORT SYNDROME

The α3(IV), α4(IV), and α5(IV) chains must associate into trimers to be deposited into basement membranes. If any one of the chains is absent, the other collagen chains are degraded, and α3α4α5(IV) network is not deposited in basement membranes.[23] If the α3α4α5(IV) network is absent, α1α1α2(IV) network remains as the dominant collagen network. This has significant consequences for the composition, structure, and function of the GBM and other affected basement membranes in individuals with mutations in any of the associated genes. For example, severe *COL4A5* mutations that result in failure to synthesize α5(IV) chains (deletions, frame shift mutations, premature stop codons, etc.) prevent the formation of α3α4α5(IV) trimers (Figure 45.1). The α3(IV) and α4(IV) chains are then degraded before deposition in the basement membrane and α3α4α5(IV) network is absent. Similarly, severe mutations in *COL4A3* or *COL4A4* lead to absence of the entire α3α4α5(IV) network in the basement membranes. Mutations in the collagenous domain of *COL4A3 to COL4A5,* particularly the glycine residues that allow for triple helix formation, lead to the formation of abnormally folded trimers that are susceptible to degradation before being incorporated into basement membranes. Finally, minor missense mutations may allow for abnormal α3α4α5(IV) network formation that is deposited into basement membranes.

GENETICS OF ALPORT SYNDROME AND THIN BASEMENT MEMBRANE NEPHROPATHY

There are three distinct genetic forms of AS that are clinically similar: X-linked, autosomal recessive, and autosomal dominant. XLAS is caused by mutations in *COL4A5* on the X-chromosome and has been known to account for approximately 80% of the affected patients. ARAS is caused by mutations in *COL4A3 or COL4A4*. Autosomal dominant Alport syndrome (ADAS) rarely has been reported in the literature and is caused by heterozygous mutations in *COL4A3 or COL4A4*.[25] With the advent of next-generation sequencing, recent studies are finding a much higher percentage of patients with AS who demonstrate autosomal dominant inheritance than was previously recognized, with

---

KEY POINTS

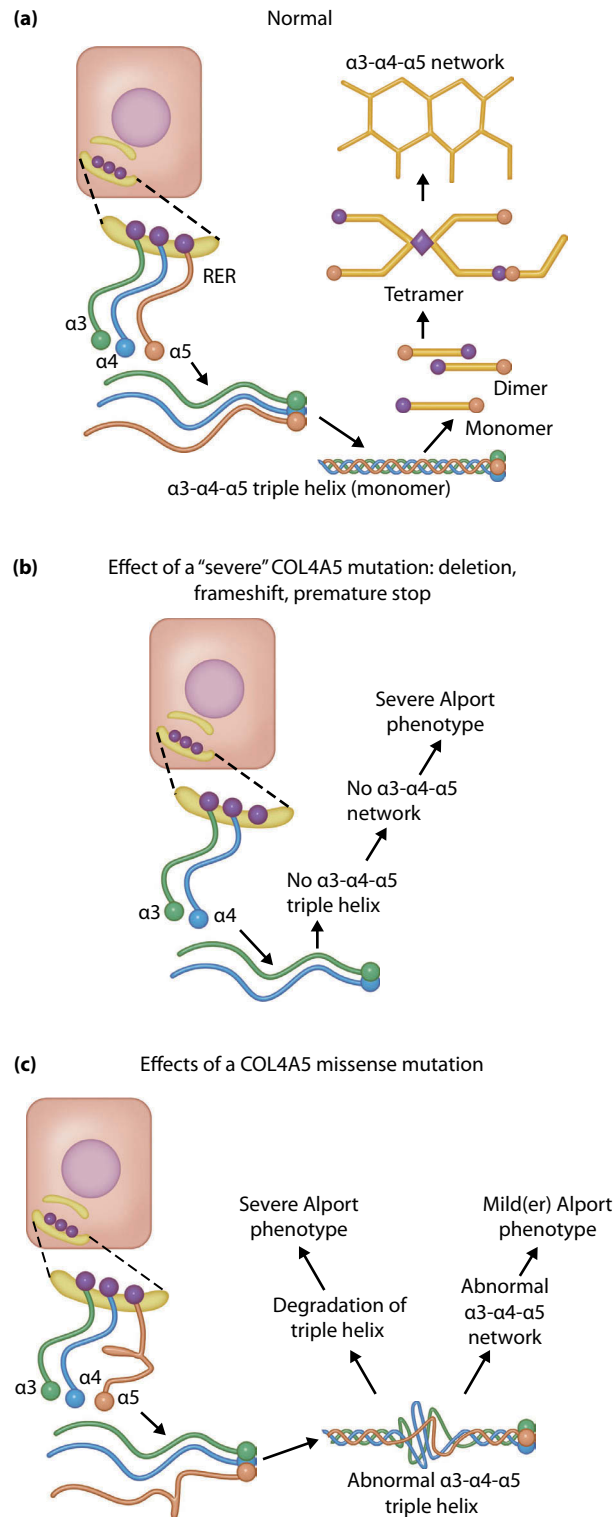
- AS is most often inherited as an X-linked disorder, but autosomal recessive and autosomal dominant forms also can be observed.
- Affected individuals with AS demonstrate absence or dysfunction of the normal α3α4α5(IV) network within the GBM.
- Mutations that block synthesis of a full-length α5(IV) chain prevent α3(IV) and α4(IV) from forming trimers, resulting in their degradation. The α3α4α5(IV) GBM network cannot be formed, causing a severe Alport phenotype.


Figure 45.1 Models of assembly of collagen IV α3α4α5 networks. **(a)** In normal individuals, α3(IV), α4(IV), and α5(IV) chains form trimers, which then self-associate through carboxyterminal and aminoterminal interactions to form networks. **(b)** Mutations that block synthesis of a full-length α5(IV) prevent α3(IV) and α4(IV) from forming trimers, resulting in their degradation. The α3α4α5(IV) network cannot be constructed, and the result is a severe Alport phenotype. **(c)** The effect of missense *COL4A5* mutations is variable. Formation of abnormal α3α4α5(IV) trimers can result in their degradation, causing a severe Alport phenotype. Some missense mutations are compatible with formation of α3α4α5(IV) trimers that can self-associate into networks. Partial degradation may result in basement membranes that are relatively deficient in their content of this network or the network may function abnormally, resulting in a milder Alport phenotype. (Reprinted with permission from: Kashtan, CE. Alport syndrome and thin basement membrane disease. Curr Diagn Pathol. 2000;8:349–60.)

up to 31% in one report.[26] Future large studies using this technique will likely help to clarify the population genetics of this disorder. Over 600 pathogenic mutations in *COL4A5* have been identified in families with XLAS, and these span the entire 51 exons of the gene with no identified hot spots.[27] Approximately 10% to 15% of *COL4A5* mutations occur as spontaneous events in the proband and these patients have a negative family history of the disease. All males with pathogenic *COL4A5* mutations are affected with the disease, and clinical expression in heterozygous females is variable. Unlike XLAS, ARAS affects males and females equally. Affected patients may be homozygous or compound heterozygous for their mutations.

TBMN and ADAS are both caused by heterozygous mutations in *COL4A3* or *COL4A4*.[28,29] It is not clear why some individuals with these mutations have asymptomatic hematuria whereas others have progressive and multisystem disease. TBMN is not always linked to *COL4A3* and *COL4A4* mutations, and other causative genetic loci may be identified in the future.[30]

CLINICAL FEATURES OF ALPORT SYNDROME

Renal manifestations

Microscopic hematuria is the hallmark finding in AS and is present in 100% of males and more than 90% of heterozygous females with XLAS and all males and females with ARAS.[31,32] Intermittent gross hematuria is not unusual, particularly in affected children with XLAS and ARAS. Untreated affected males with XLAS, some females with XLAS, and both males and females with ARAS, exhibit progression of kidney disease from isolated microscopic hematuria to microalbuminuria, overt proteinuria, progressive renal dysfunction, and eventual ESRD.[33]

Large deletions, nonsense mutations, and frame shift mutations in *COL4A5* are associated with more rapid progression to ESRD. Affected males with such mutations have a 90% probability of ESRD by age 30 years.[31] Missense mutations are associated with less severe disease with only a 50% probability of ESRD by age 30.[31] There is no genotype-phenotype correlation for females with heterozygous *COL4A5* mutations, and disease severity appears to be influenced by X-inactivation and other yet unknown factors.[32,34] The risk for ESRD for heterozygous females is 12% by age 40 and approximately 30% by age 60.[32]

KEY POINT

Heterozygous females with *COL4A5* mutations (carriers) are at risk for developing proteinuria, sensorineural hearing loss, and ESRD.

Cochlear manifestations

The α3α4α5(IV) network is normally found in the cochlea in the basement membrane between the organ of Corti and the basilar membrane and within the spiral ligament.[35] The mechanism of hearing loss in AS is unknown but may be related to dysfunction of the spiral ligament or alterations in cochlear micromechanics.[37,36]

Audiologic abnormalities in AS are typically apparent by late childhood as high tone (2000- to 8000-Hz range) hearing loss detectable by audiometry. Newborn hearing screening is normal. Hearing loss is progressive over time with 80% to 90% of XLAS males demonstrating sensorineural deafness by 40 years of age.[31] Heterozygous females with *COL4A5* mutations have a 10% risk for sensorineural deafness by age 40 and 20% by age 60.[32] Sensorineural hearing loss is common in ARAS as well, with 66% of individuals affected in a recent study.[37] Similar to the case in kidney disease, affected individuals with severe mutations such as large rearrangements, nonsense mutations, splice site mutations, or frameshift mutations have more severe hearing loss at earlier ages.[31]

Ocular manifestations

The α3α4α5(IV) network is present in the lens capsule, retina, and cornea of the eye.[38] Ocular findings resulting from absence or dysfunction of the α3α4α5(IV) network in these locations are present in 40% to 60% of patients with AS, and the spectrum of disease appears to be similar in XLAS and ARAS.[31,37] Findings in affected patients include anterior lenticonus, dot and fleck maculopathy, or posterior polymorphous dystrophy. Anterior lenticonus, the protrusion of the central portion of the lens into the anterior chamber, is pathognomonic of AS.[38,39] Lenticonus is absent at birth and manifests during the second and third decades of life in approximately 13% to 25% of affected individuals.[31,38] Anterior lenticonus has been described only rarely in heterozygous females with *COL4A5* mutations.[32] A maculopathy consisting of whitish or yellowish flecks in a perimacular distribution, likely because of abnormality of the internal limiting membrane, is found in 14% to 85% of affected individuals and does not appear to be associated with any abnormality in vision.[38,40] Posterior polymorphous dystrophy has been more rarely observed in individuals with AS and may be due to abnormalities in the Descemet membrane.[41] Recurrent corneal erosions also have been described, likely secondary to abnormalities in the corneal basement membrane.[42]

Renal pathology

There are no pathognomonic abnormalities present on kidney biopsy by light microscopy or routine immunofluorescence microscopy. Electron microscopy (EM) in young children typically shows diffuse thinning of the glomerular capillary wall. The glomerular capillary walls of older children and adolescents exhibit areas of diffuse thickening and splitting of the basement membrane with a "basket-weave" appearance
Figure 45.2 Electron micrographs from patients with hematuria. Magnifications are similar, but not identical. **(a)** Normal glomerular basement membrane (GBM). **(b)** Attenuated GBM in a patient with thin basement membrane nephropathy. **(c)** This female with a heterozygous *COL4A5* mutation exhibits both thin and split lamellated GBM. **(d)** This male with XLAS shows diffuse thickening and lamellation of GBM. (Reprinted with permission from: Kashtan, CE. Alport syndrome and thin basement membrane disease. Curr Diagn Pathol. 2000;8:349–60.)

of the lamina densa (Figure 45.2). The subepithelial aspect of the GBM frequently appears irregular or scalloped. Areas of thickening and basket weaving are usually associated with overlying effacement of foot processes. By immunohistology, approximately 80% of affected males with XLAS demonstrate absence of the α3(IV), α4(IV), and α5(IV) chains from the GBM, Bowman capsules, and distal/collecting tubule basement membranes (Figure 45.3).[43] Females with heterozygous mutations in *COL4A5* may demonstrate a patchy or mosaic expression pattern for α3α4α5(IV) in the GBM consistent with X-inactivation. The GBM of males and females with ARAS typically lacks the α3(IV), α4(IV), and α5(IV) chains. Bowman capsules and distal/collecting tubule basement membranes lack the α3(IV) and α4(IV) chains, but the α5(IV) chain is present in Bowman capsules and distal/collecting tubule basement membranes as part of the α5α5α6(IV) network. Thus, immunostaining of kidney biopsy specimens for type IV collagen can be used to distinguish XLAS and ARAS. Patients with ADAS typically show normal renal basement membrane expression of the α3α4α5(IV) network.

Skin biopsy shows absence of the α5α5α6(IV) network in approximately 80% of males with XLAS, and mosaic expression of this network in 60% to 70% of XLAS females. For individuals with ARAS or ADAS, α5(IV) will be present in skin as part of the α5α5α6(IV) network.[44]

THIN BASEMENT MEMBRANE NEPHROPATHY

TBMN is the most common cause of persistent microscopic hematuria in children and adults.[45] Affected individuals typically demonstrate persistent microscopic hematuria with rare episodes of gross hematuria, although for some the hematuria may be intermittent. The penetrance of hematuria is only approximately 70%.[46] Proteinuria is rare in childhood but is observed in a significant proportion of adult patients, up to 63% in one series.[47] Chronic kidney disease (CKD) or ESRD is observed in fewer than 5% of affected adults.[47] The presence of proteinuria and CKD in
Figure 45.3 Glomerular immunofluorescence microscopy in X-lined Alport syndrome (XLAS) and autosomal recessive (ARAS). α3(IV), α4(IV), and α5(IV) chains are expressed in the glomerular basement membrane in patients with normal glomeruli and thin basement membrane nephropathy. All three chains are missing in affected males with XLAS. A mosaic pattern is present for heterozygous females with XLAS secondary to X-inactivation. In ARAS, α3(IV), α4(IV), and α5(IV) chains are absent from the glomerulus; however, α5(IV) is visible in the Bowman capsule as part of the α5α5α6(IV) network. (Reprinted with permission from: Kashtan, CE. The nongenetic diagnosis of thin basement membrane nephropathy. Semin Nephrol. 2005;25:159–62.)

individuals diagnosed with TBMN may represent misclassification of patients who more accurately should be designated as having ADAS or XLAS. Future large genetic and natural history studies will hopefully clarify the prognosis for affected patients. Extrarenal manifestations are only sporadically reported.

Kidney biopsy in patients with TBMN demonstrates normal light and immunofluorescence microscopy, including immunostaining for type IV collagen chains. EM shows diffuse thinning of the GBM that may be identical in appearance to that seen in early stages of AS. The thickness of the GBM varies with age, gender, and EM technique and should be interpreted based on individual criteria for each histologic laboratory.[48,49]

DIAGNOSTIC CONSIDERATIONS

The diagnosis of AS or TBMN is often suspected in patients with persistent microscopic hematuria and a family history of hematuria. Although difficult to distinguish at times,

features that may help in differentiating these two disorders are listed in Table 45.1. The likelihood of AS increases with a family history of AS or renal failure; the presence of sensorineural hearing loss; the presence of anterior lenticonus, maculopathy, or both; and lamellation of the GBM or abnormalities of type IV collagen immunostaining on kidney or skin biopsy.[50] The diagnosis of AS can be confirmed by genetic testing that demonstrates a pathogenic mutation(s) in *COL4A3, COL4A4,* or *COL4A5.* The results of genetic studies can improve the accuracy of genetic counseling and provide prognostic information. Genetic testing is at least 90% sensitive for XLAS.[51] All at-risk family members of a patient with a new diagnosis of XLAS, including females, should be screened for hematuria on at least two occasions and offered genetic testing to confirm their disease status.[50] Genetic counseling is recommended for the affected families.

Genetic confirmation in patients with TBMN is generally not necessary, unless the clinical course is atypical. Genetic testing for mutations in *COL4A3 to COL4A5* should be considered in individuals with proteinuria or renal impairment or when AS cannot be excluded based on family history.

Table 45.1 Alport syndrome versus thin basement membrane nephropathy

	XLAS		ARAS	ADAS	TBMN
	Males	Females			
Gene	COL4A5		COL4A3 or COL4A4	COL4A3 or COL4A4	COL4A3 or COL4A4, other
Clinical findings					
Hematuria (%)	100	>90	100	100	100
ESRD	100%	~30% by age 60	100%	?	Rare
Sensorineural deafness	80%–90%	20% by age 60	?	?	None
Ocular findings	~40%	~15%	~40%	?	None
Biopsy findings

Lamellated GBM	Diffuse*	Focal†	Diffuse*	Diffuse*	Focal or absent
α5(IV) chains in GBM	Absent‡	Mosaic‡	Absent	Present	Present
α5(IV) chains in Bowman capsule and dTBM	Absent‡	Mosaic‡	Present	Present	Present
α5(IV) chains in skin BM	Absent§	Mosaic§	Present	Present	Present

ADAS, autosomal dominant Alport syndrome; ARAS, autosomal recessive Alport syndrome; dTBM, distal tubular basement membranes; ESRD, end-stage renal disease; GBM, glomerular basement membrane; TBMN, thin basement membrane nephropathy; XLAS, X-linked Alport syndrome.

* In young children with AS, GBM width may initially be diffusely thinned with only rare or focal areas of lamellation, whereas older children and adults will demonstrate diffuse lamellation and thickening of the GBM.

† Females with XLAS often demonstrate thin or lamellated GBM interspersed with areas of normal-appearing GBM. They may, however, have GBM that appears identical to individuals with TBMN.

‡ Approximately 20% of males with XLAS, 30% to 40% of females with XLAS, and some patients with ARAS have normal type IV collagen immunostaining on renal biopsy. Normal renal immunostaining for type IV collagen cannot by itself exclude a diagnosis of AS.

§ Approximately 20% of males with XLAS and 30% to 40% of females with XLAS have normal α5(IV) expression in skin basement membranes.

MONITORING AND TREATMENT

Individuals with AS should have formal ophthalmologic and hearing examinations performed at the time of diagnosis and at regular intervals thereafter to ensure early detection of extrarenal abnormalities. They should be monitored regularly for the presence of microalbuminuria, overt proteinuria, hypertension, and renal dysfunction. The goal of treatment in AS is to slow the progression of kidney disease and delay the need for renal replacement therapy. Treatment with an angiotensin-converting enzyme inhibitor (ACEI) is recommended for affected individuals with proteinuria, including heterozygous females (Table 45.2).[33,52] ACEI therapy should be considered for those with microalbuminuria and a family history of ESRD younger than 30 years of age or a severe COL4A5 mutation (deletion, splice site, or nonsense mutation).[33] Data are insufficient to recommend treatment for individuals with microscopic hematuria only. Retrospective data from a large European database suggests that treatment of AS with ACEIs is associated with a significant delay in the need for renal replacement therapy.[53] Early treatment with ACEIs also has been shown to improve lifespan in a mouse model of ARAS by more than 100%.[54] A prospective clinical trial of ACEIs in patients with AS is underway.[55]

KEY POINT

Treatment of proteinuric AS patients with ACEIs may slow the progression of the disease and delay renal replacement therapy.

Individuals with TBMN should be monitored yearly for disease progression, including evaluation for proteinuria, hypertension, and renal impairment. The presence of proteinuria should prompt treatment with an ACEI, similar to treatment in patients with AS.[33,50]

TRANSPLANTATION IN ALPORT SYNDROME

Patients with AS have graft survival rates as good as or better than those with other inherited renal diseases.[56] Females

† Missense mutation.

with heterozygous mutations in *COL4A5* should be discouraged as living donors because of the risk for progressive kidney disease.[50,57] Of males with XLAS, 3% to 5% develop anti-GBM disease after transplantation secondary to the presence of antibodies predominantly against the α5(IV) NC1 domain.[58,59] Anti-GBM disease following transplantation is associated with rapid allograft loss and is likely to recur in subsequent grafts.[58]

SUMMARY

Both AS and TBMN can manifest clinically with persistent microscopic hematuria and, in the case of AS, progress to proteinuria and ESRD. The past two decades have seen enormous developments in understanding the genetic defects that lead to AS and TBMN. Research efforts in the future will continue to focus on delaying or preventing ESRD in AS by two general approaches: (1) Correction of the underlying defect by gene or cell therapy and (2) interference with downstream events that promote cell injury and fibrosis. The demonstration that renal manifestations of AS can be ameliorated by nonspecific therapies such as angiotensin blockade is likely to stimulate investigation of novel antifibrotic agents in this disorder. Clinical evaluation of new therapies will require collaborative networks built on national registries and patient advocacy groups, combined with support from government, industry, and philanthropic sources.

Clinical Vignette 45.1

An otherwise healthy girl presented with gross hematuria and dysuria at the age of 2 years. Urinalysis demonstrated 3+ blood, trace protein, and packed red blood cells on microscopic examination. Urine culture was negative. Blood pressure, physical examination, and renal ultrasound were all normal. Family history was negative for hematuria, chronic kidney disease, dialysis, kidney transplant, consanguinity, or deafness. She had normal values for blood urea nitrogen and creatinine (0.4 mg/dL), albumin, electrolytes, complete blood count, complement C3, complement C4, antistreptolysin O antibody titer, anti-DNAse B antibody titer, antinuclear antibody screen, and antineutrophil cytoplasmic antibody titer. Urine calcium-to-creatinine ratio also was normal (0.06 mg/mg). She continued to have intermittent grossly bloody urine with persistent microscopic hematuria over the next 3 months, and a kidney biopsy was performed. Light microscopy demonstrated three fetal-appearing glomeruli with otherwise normal-appearing tissue. EM demonstrated thin GBMs diffusely with no evidence for splitting, thickening, or basket weaving. No immune deposits were identified. Unfortunately, no tissue was available for immunofluorescence examination. Because of the inconclusive biopsy findings, genetic testing was sent to evaluate for mutations in *COL4A3, COL4A4,* and *COL4A5.* She was found to have a homozygous mutation in *COL4A3* with transition C*T at nucleotide 4981 with an amino acid change of arginine to cysteine at codon 1661 in a conserved residue in the NC1 domain, confirming a

diagnosis of autosomal recessive AS. Formal hearing and vision screening were normal. She was started on an ACEI after she developed mild proteinuria at the age of 5 years (ratio of urine protein to creatinine, 0.57 mg/mg).

TEACHING POINTS

- This case highlights the importance of keeping AS in the differential diagnosis for girls who present with hematuria. Both X-linked and autosomal recessive AS were possible diagnoses in this case. Autosomal dominant AS is an unlikely cause of gross hematuria in a child.
- Confirmation of a genetic diagnosis allows for informed counseling of the family about the possibility of disease in other family members and in subsequent pregnancies.
- Another important highlight of this case is that children affected with autosomal recessive AS may not have a family history of hematuria or kidney disease that would be more typically seen in children with X-linked AS.

REVIEW QUESTIONS

1. In a patient with persistent microscopic hematuria, which of the following findings is suggestive of a diagnosis of Alport syndrome rather than thin basement membrane nephropathy?
   a. Male gender
   b. Family history of hematuria
   c. Failed newborn hearing screen
   d. Anterior lenticonus
   e. Elevated cholesterol

2. X-linked Alport syndrome is caused by mutations in which gene?
   a. COL4A3
   b. COL4A4
   c. COL4A5
   d. MYH9
   e. PAX2

3. Heterozygous females with *COL4A5* mutations are at risk for:
   a. Microscopic hematuria
   b. Proteinuria
   c. End-stage renal disease
   d. Deafness
   e. All of the above

4. ACEIs are NOT indicated for treatment of which patient?
   a. Male with XLAS and proteinuria
   b. Male with XLAS and microalbuminuria with family history of ESRD at age 20
   c. Male with XLAS and microalbuminuria with family history of ESRD at age 50
   d. Female with XLAS and proteinuria
   e. Female with ARAS and proteinuria

5. This type of mutation in *COL4A5* is associated with a milder Alport phenotype:
   a. Missense mutation
   b. Large deletion
   c. Splice site mutation
   d. Nonsense mutation
   e. Large rearrangement

6. The following ophthalmologic findings are frequently observed in patients with Alport syndrome, *except*:
   a. Anterior lenticonus
   b. Myopia
   c. Corneal erosion
   d. Maculopathy
   e. Posterior polymorphous dystrophy

7. α5(IV) may be absent from the GBM and present in the Bowman capsule in which disorder?
   a. Males with XLAS
   b. Females with XLAS
   c. TBMN
   d. ARAS
   e. ARAS and ADAS

8. TBMN can be caused by mutations in:
   a. COL4A3
   b. COL4A4
   c. COL4A5
   d. Both a and b
   e. Both a and c

ANSWERS

1. d
2. c
3. e
4. c
5. a
6. b
7. e
8. d

Renal disease in syndromic disorders

PATRICK NIAUDET

Renal disease occurs in a very large number of syndromic disorders in which anomalies involving other organs are also present. More than 500 such syndromes have been described. Congenital renal anomalies, such as renal hypoplasia, renal dysplasia, renal cysts, or congenital abnormalities of the urinary tract, accompany many syndromic disorders. Other kidney-related symptoms, such as nephrotic syndrome or hematuria, may also be observed in the syndromic disorders.

Syndromic disorders with renal disease may have a genetic basis. Mutated genes expressed in different organs and tissues, correspondingly, give rise to diverse clinical manifestations in these organs. The proteins encoded by these genes have many functions, including structural, signaling, and regulation. As an example, mutations of some type-IV collagen genes that are involved in the structure of basement membranes in the kidney and cochlea lead to the Alport syndrome, a progressive hematuric nephropathy associated with sensorineural hearing loss. Another example concerns the ciliopathies, wherein the genes coding for proteins expressed in the primary cilia may lead to different clinical entities such as Jeune, Joubert, Bardet-Biedl, or Meckel-Gruber syndromes, as well as nephronophthisis and polycystic kidney diseases.

Some of the selected syndromes that are observed more frequently by pediatric nephrologists are discussed in this chapter (Tables 46.1 and 46.2). For more details on the subject, the reader may refer to other references.[1–3]

ALAGILLE SYNDROME

Alagille syndrome (Online Mendelian Inheritance in Man [OMIM] 118450, 610205), also called arteriohepatic dysplasia, is characterized by a paucity of interlobular bile ducts with chronic cholestasis present in the neonatal period or during the first months of life and various other congenital malformations.[4] The prevalence is approximately 1 in 70,000. Alagille syndrome is an autosomal dominant disorder with incomplete penetrance and variable expressivity. Liver disease is present in 95% of cases of Alagille syndrome. Other manifestations include the following: heart anomalies, most commonly pulmonary artery stenosis and tetralogy of Fallot; skeletal anomalies such as butterfly vertebrae; eye anomalies, including posterior embryotoxon (prominent Schwalbe line) and dysmorphic facies, consisting of prominent forehead, broad nasal bridge, straight nose, triangular facies, and

Table 46.1 Syndromes associated with renal disease

Syndrome	Mutated gene	Renal and urologic anomalies	Extrarenal anomalies
Alagille syndrome	JAG1	Renal dysplasia, mesangiolipidosis	Paucity of intrahepatic bile duct, cardiac defect, vertebral anomalies
Bardet-Biedl syndrome	BBS1 to BBS14	Renal dysplasia, calyceal malformations	Retinopathy, polydactyly, obesity, diabetes, male hypogonadism
Beckwith-Wiedemann syndrome	p57KIP2	Large kidneys, cysts, dysplasia	Somatic overgrowth, embryonal tumors
Branchio-oto-renal syndrome	EYA1	Renal agenesis, dysplasia	Deafness, branchial arch defects
CHARGE syndrome	CHD7 and SEMA3E	Solitary kidney, duplex kidneys, renal hypoplasia, nephrolithiasis, ureteropelvic junction obstruction, vesicoureteral reflux	Coloboma, heart malformation, choanal atresia, mental retardation, genital anomalies
Di George syndrome	Microdeletion at 22q11	Renal agenesis, dysplasia, and vesicoureteric reflux	Heart anomalies, branchial arch defects
Fraser syndrome	FRASI	Renal agenesis, dysplasia	Digital and ocular malformations
Kallmann syndrome	KAL1	Renal agenesis, dysplasia	Hypogonadotropic hypogonadism, anosmia
Meckel syndrome	MKSI-6	Cystic renal dysplasia	Central nervous system malformations, polydactyly
Oral-facial-digital syndrome	OFD1	Glomerular cysts	Facial and digital anomalies
Renal-coloboma syndrome	PAX2	Renal hypoplasia, vesicoureteral reflux	Coloboma of the optic nerve
Renal cyst and diabetes	TCF2	Renal cysts, dysplasia, hypoplasia	Diabetes, genital anomalies
Simpson-Golabi-Behmel syndrome	GPC3	Renal cysts, dysplasia	Somatic overgrowth, craniofacial and vertebral anomalies, cardiac defect, cryptorchidism
Smith-Lemli-Opitz syndrome	DHCR7	Renal cysts, dysplasia, urinary tract obstruction, vesicoureteral reflux	Failure to thrive, craniofacial malformations
Townes-Brocks syndrome	SALL1	Renal hypoplasia, dysplasia, agenesis, vesicoureteric reflux, posterior urethral valve	Limb malformation, hearing loss, imperforate anus
VACTERL association	?	Renal dysplasia	Vertebral defects, anal atresia, tracheoesophageal fistula, esophageal atresia, limb anomalies

deep-set eyes (Figure 46.1). Systemic vascular abnormalities have been reported, including carotid and cerebral arteries and moyamoya syndrome predisposing to stroke. The mid-aortic syndrome and renal artery stenosis may be responsible for severe hypertension and renal failure.[5,6] Renal and urologic anomalies, such as cysts and ureteropelvic obstruction, have been reported. Mesangiolipidosis, with accumulation of lipid vacuoles in the mesangial matrix, in mesangial cells and in the glomerular basement membranes have been reported (Figure 46.2).[7]

Alagille syndrome results from defects in the Notch signaling pathway, which is important in angiogenesis. Mutations in the JAG1 gene are responsible for the disease in more than 90% of patients. JAG1 encodes the JAGGED1 cell surface protein, a ligand for the Notch receptors. Knockout mice for JAG1 die early from vascular defects. More than 400 mutations have been reported in the JAG1 gene, which consists of 26 exons on chromosome 20p12. Approximately 60% are de novo mutations, and germline mosaicism has been observed in 8% of cases. Mutations in the NOTCH2

Table 46.2 Syndromic disorders associated with nephrotic syndrome

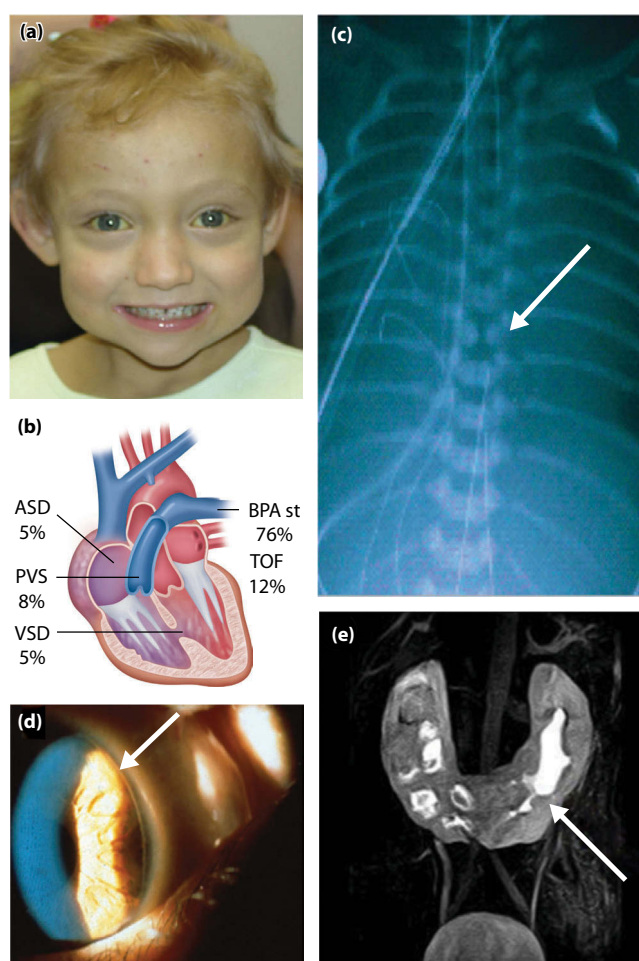
Syndrome	Mutated gene	Renal anomalies	Extrarenal anomalies
Pierson syndrome	LAMB2	Renal failure, diffuse mesangial sclerosis	Microcoria, neurologic anomalies
Denys–Drash syndrome	WT1	Renal failure, diffuse mesangial sclerosis	Wilms tumor, pseudohermaphroditism
Frasier syndrome	WT1	Renal failure in adult life, focal segmental glomerulosclerosis	Male pseudohermaphroditism with normal female external genitalia
Nail-patella syndrome	LMX1B	Progression to renal failure in 30% of cases with nephropathy	Nail dysplasia, hypoplastic or absent patellas
Schimke immuno-ossous dysplasia	SMARCAL1	Progression to renal failure, focal segmental glomerulosclerosis	Spondyloepiphyseal dysplasia, T-cell deficiency, cerebral ischemic lesions
Mitochondrial cytopathies	Mitochondrial DNA or nuclear DNA	Proximal tubulopathy, nephrotic syndrome	Myopathy, hearing loss, neurologic deterioration, diabetes mellitus
Galloway syndrome	WDR73	Renal failure, focal and segmental glomerulosclerosis or diffuse mesangial sclerosis	Microcephaly with psychomotor retardation, ocular abnormalities, hiatal hernia


Figure 46.1 Alagille syndrome. (a) Characteristic facies in a patient with Alagille syndrome: broad forehead, pointed chin, and deep-set eyes. Note also the scleral icterus and excoriations on the forehead. Written consent for publication of this image was obtained from the patient's responsible relative by the original authors. (b) Diagram of classic cardiac abnormalities and their frequency in Alagille syndrome. ASD, atrial septal defect; BPA st, branch pulmonary artery stenosis; PVS, pulmonary valve stenosis; TOF, tetralogy of Fallot; VSD, ventricular septal defect. (c) Radiograph showing butterfly vertebra (arrow). (d) Slit-lamp examination of the eye revealing posterior embryotoxon (arrow). (e) Magnetic resonance imaging scan showing the fused poles of a horseshoe kidney (arrow) in a patient with Alagille syndrome. (From Kamath BM, Spinner NB, Rosenblum ND. Renal involvement and the role of Notch signaling in Alagille syndrome. Nat Rev Nephrol. 2013;9:409–18.)
Figure 46.2 Renal pathology in Alagille syndrome. **(a)** Mesangiolipidosis, characterized by an increase in the mesangial matrix and the presence of mesangial foam cells (hematoxylin-eosin-safran stain, 400×). **(b)** Lipid deposits were confirmed by Sudan black stain (400×). **(c)** Electronic microscopy showed numerous clear vacuoles containing osmiophilic lamellated inclusions in the mesangial cells and matrix (5000×). **(d)** Higher magnification electron microscopy image of mesangial cell cytoplasm showed lipid vacuoles (arrow) with a mean diameter of 46 nm (44,000×). (From Benoit G, Sartelet H, Levy E, et al. Mesangiolipidosis in Alagille syndrome: relationship with apolipoprotein A-I. Nephrol. Dial Transplant. 2007;22:2072–5.)

gene that encodes the NOTCH2 transmembrane protein have been reported in two families.

BARDET-BIEDL SYNDROME

The Bardet-Biedl syndrome (OMIM 209900) is an autosomal recessive disorder characterized by retinal dystrophy, truncal obesity, hypogenitalism in men or genital abnormalities in women, learning disabilities, postaxial polydactyly, and renal anomalies (Figure 46.3).[8] Retinal dystrophy leads to a progressive decline of visual acuity and blindness at a mean age of 15 years.[9] Learning disabilities may be in part explained by visual impairment, and less than half of the patients are mentally retarded. Some patients show speech disorders or behavior problems. Other signs and symptoms may be present such as anosmia, dental anomalies, congenital heart defects, and diabetes mellitus.

Renal symptoms are nonspecific.[10] Polyuria and polydipsia, related to a concentrating defect, are present in one-third of cases. Urinary tract infections are frequent. Tubular defects may be observed, such as tubular acidosis, glucosuria, or hyperaminoaciduria. Chronic renal failure is a major complication, and 10% of patients progress to end-stage renal disease (ESRD) during childhood. Blood hypertension is frequently observed, sometimes early in life.

Ultrasonography shows enlarged hyperechogenic kidneys after birth.[11,12] Cysts may be present. Later in life, an inversion of corticomedullary differentiation may be observed. These anomalies tend to disppear after age 2 years. Renal histologic examination shows nonspecific tubulointerstitial changes, cysts, and dysplasia. Glomerular lesions may appear later as a consequence of nephron reduction.

Mutations in at least 14 genes have been described in patients with this syndrome.[13] The genes most frequently involved are *BBS1* on chromosome 11q13, *BBS10* on chromosome 12q, *BBS2* on chromosome 16q21, and *BBS9* on chromosome 7p14.[14] Disordered function of the cilia is a fundamental defect in this syndrome. Indeed, BBS genes code for proteins of the primary cilia, basal body, or centrosome. The age of first symptoms and the severity of symptoms are not related to the genotype. Furtheremore, there is a high variability of symptoms within and among affected families.[15]

BECKWITH-WIEDEMANN SYNDROME

The Beckwith-Wiedemann syndrome (BWS) (OMIM 130650) is a congenital overgrowth syndrome with a predisposition to tumor development. The estimated prevalence is 1 in 13,700, and it affects female and male patients equally.[16]
Figure 46.3 Bardet-Biedl syndrome. Images of patients demonstrating the dysmorphic features associated with this syndrome. **(a)** to **(d)** Typical facial features. These are often subtle and are not always present. Features include deep-set eyes, hypertelorism, downward-slanting palpebral fissures, a flat nasal bridge, small mouth, malar hypoplasia, and retrognathia. **(e)** Brachydactyly and scars from excision of accessory digits. **(f)** Dental crowding. **(g)** High-arched palate. **(h)** Funduscopy demonstrating rod-cone dystrophy. (From Forsythe E, Beales PL. Bardet-Biedl syndrome. Eur J Hum Genet. 2013;21:8–13.)

Most cases are sporadic, but autosomal dominant transmission with variable expressivity and incomplete penetrance is observed in 15% of cases. Clinical features include omphalocele, macroglossia, and macrosomia, with height and weight greater than the 97th percentile, asymmetric overgrowth of certain regions of the body, visceromegaly, and tumors (Figure 46.4).[17] Neonatal hypoglycemia may be observed. Patients develop embryonic tumors such as Wilms tumor, hepatoblastoma, neuroblastoma, or rhabdomyosarcoma. Renal symptoms consist of nephromegaly, duplicated collecting system, nephrocalcinosis, renal cysts, and medullary sponge kidney.

KEY POINTS

- Patients with BWS present with omphalocele, macroglossia, macrosomia, and visceromegaly.
- They are at high risk of embryonic tumors.

Dysregulation of the expression of multiple imprinted growth regulatory genes in the chromosome 11p15.5 region has been reported.[18] Epigenomic or genomic alterations in this 11p15.5 region are detected in most patients. The distal domain I contains the imprinted genes *IGF2* (paternal monoallelic expression) and *H19* (maternal monoallelic expression), which play important roles in growth and development. The proximal domain 2 contains two genes, *KCNQ10T1* and *CDKN1C* that are both implicated in the BWS.

BRANCHIO-OTO-RENAL SYNDROME

Branchio-oto-renal (BOR) syndrome (OMIM 113650, 610896) is an autosomal dominant disorder that combines branchial defects with lateral cervical fistulas or cysts, ear pits, hearing loss, and renal anomalies (Figure 46.5).[19] The incidence of BOR syndrome is 1 in 40,000 infants. In this syndrome, penetrance is incomplete, and patients may have only one or two features of the syndrome.[20] Renal anomalies are not observed in all patients and may differ among members of the same family. Renal findings include renal agenesis or hypoplasia (which may be unilateral or bilateral), vesicoureteral reflux, ureteropelvic junction obstruction, or ureteral duplication.[21,22] If renal hypoplasia is present, it may vary in severity and may progress to end-stage renal failure. Ear abnormalities include periauricular pits, anomalies of the middle and external ear, and hypoplasia of the cochlea, resulting in hearing loss.

More than 80 mutations in the *EYA1* gene on chromosome 8q13.3 have been identified in patients with BOR syndrome.[22–24] The *EYA1* gene encodes for a transcription cofactor that is expressed in the metanephric mesenchyme during kidney development.[25] The *EYA1* gene interacts with members of the SIX family, which encodes transcription factors that control expression of *PAX2* and *GDNF* in the metanephric mesenchyme. *Eya1*[+/-] mice may show renal hypoplasia or unilateral renal agenesis, whereas *Eya1*[-/-] mice lack both ureteres and kidneys.[25] Mutations in *SIX1* (chromosome 14q23.1) and *SIX5* genes have also been reported in families with the BOR syndrome.[26–28]
Figure 46.4 Beckwith-Wiedemann syndrome. **(a)** A 1-month-old boy showing macroglossia and umbilical hernia. **(b)** Photograph taken 1 year after a tongue reduction surgical procedure. (From Weksberg R, Shuman C, Beckwith JB. Beckwith-Wiedemann syndrome. Eur J Hum Genet. 2010;18:8–14.)

CHARGE SYNDROME

Infants with the CHARGE (coloboma of the retina or the iris, heart anomalies, choanal atresia, mental retardation, and genital and ear anomalies) syndrome[29] (OMIM 214800) often have renal or urologic anomalies, such as unilateral renal agenesis, renal hypoplasia, duplex kidneys, ureteropelvic junction obstruction, or vesicoureteral reflux.[30]

Most cases of CHARGE syndrome are related to mutations of the gene coding for the chromodomain helicase DNA-binding protein-7 (CHD7).[31,32] These are heterozygous mutations, suggesting that haploinsufficiency of the gene is responsible for CHARGE syndrome. Most cases are caused

Figure 46.5 Branchio-oto-renal syndrome. Typical facial appearance. Note the cup-shaped ear deformity. Bilaterally symmetric ear deformities also can be seen. (From Smith RJ, Schwartz C. Branchio-oto-renal syndrome. J Commun Disord. 1998;31:411–21.)

by de novo mutations, although rare familial cases have been reported.[33]

COCKAYNE SYNDROME

Cockayne syndrome (OMIM 216400, 133540, 216411) is an autosomal recessive disorder characterized by neurologic anomalies with progressive dementia, microcephaly, growth retardation, premature aging, sensorineural deafness, retinopathy, cataract, and sun sensitivity.[34] There is wide variability in the severity of clinical manifestations. Renal manifestations consist of hypertension, proteinuria, and renal failure, which occurs in 10% of patients. Ultrastructural lesions include thickened glomerular basement membranes.[35]

Cockayne syndrome results from a defect in the ability to perform transcription-coupled repair of active genes after ultraviolet irradiation. Two complementation groups (CS-A and CS-B) have been identified, and 80% of patients belong to the second group.[36] The *CSA* gene encodes a WD repeat protein that interacts with the *CSB* protein and RNA polymerase II transcription factor IIH.[37] The *CSB* protein is a helicase involved in the repair of active genes.[38]

DI GEORGE SYNDROME

Di George syndrome (OMIM 188400) is characterized by conotruncal cardiac anomalies, a hypoplastic thymus, hypocalcemia secondary to parathyroid hypoplasia, and developmental disabilities, learning disabilities, or both.[39,40] The most frequent cardiac anomalies include interrupted aortic arch, truncus arteriosus, tetralogy of Fallot, atrial or ventricular septal defects, and vascular rings. The first three of them are responsible for cyanotic heart disease. The thymus may be absent or hypoplastic. The severity of the immunodeficiency is related to the size of the thymus and varies between severe combined immunodeficiency and mild recurrent infections. Hypocalcemia may be life-threatening in the newborn, who can present with tetany, seizures, and laryngospasm. This condition is accompanied by hyperphosphatemia and a low parathyroid hormone (PTH) level.

Renal and urologic anomalies are observed in 36% of patients and consist of unilateral renal agenesis, multicystic kidney, megaureter, vesicoureteric reflux, and renal ectopy.[39,41] Systematic renal ultrasound is recommended in these patients to detect such anomalies which can be asymptomatic. In the majority of cases, Di George syndrome is caused by hemizygous 22q11.2 deletion at chromosome 22q11.2 which can be detected by fluorescence in situ hybridization. The inheritance is autosomal dominant, but most cases are caused by de novo mutations.[42]

FRASER SYNDROME

Fraser syndrome (OMIMI 219000) is an autosomal recessive disease characterized by cryptophthalmos, cutaneous syndactyly, genital malformations with ambiguous genitalia, craniofacial anomalies, and malformations of the larynx (stenosis or atresia) and the kidneys. Cryptophthalmos is bilateral or less frequently unilateral. Other ocular malformations include coloboma, microphthalmia, or anophthalmia. Bilateral renal agenesis was reported in 23% of 117 cases.[43] Patients who survive may have unilateral renal agenesis or renal cystic dysplasia.

Fraser syndrome occurs in 1 in 10,000 live births. Mutations in the *FRAS1* and *FREM2* genes have been described in patients with this syndrome.[44,45] Both genes are involved in kidney development in the embryo.

GOLDENHAR SYNDROME (OCULO-AURICULO-VERTEBRAL SYNDROME)

Goldenhar syndrome (OMIM 164210), also referred to as first and second branchial arch syndrome, is characterized by unilateral craniofacial and vertebral malformations. They consist of preauricular skin tags, dermal epitubular tumors, cleft palate, mandibular hypoplasia, ear microtia, and facial asymmetry.[46] Vertebral anomalies consist of hemivertebrae or absence of vertebrae and scoliosis. The incidence of this syndrome is 1 in 5,000 to 1 in 25,000 live births. Most cases are sporadic, but an autosomal dominant mode of inheritance is possible with variable penetrance.

In addition to cardiac and pulmonary malformations, renal and urologic anomalies are observed in up to 50% of the patients: renal ectopy, unilateral renal agenesis, vesicoureteric reflux, ureteropelvic junction obstruction, and multicystic dysplasic kidney.[47]

HEPATIC NUCLEAR FACTOR-1β-- RELATED DISEASE (RENAL CYSTS AND DIABETES SYNDROME)

Heterozygous mutations of the TCF2 gene encoding the hepatic nuclear factor-1β are responsible for an autosomal dominant disease named renal cysts and diabetes (RCAD) syndrome (OMIM 137920).

The renal disease may be discovered on antenatal ultrasound examination with enlarged hyperechogenic kidneys, renal cysts, unilateral or bilateral multicystic kidney disease, or unilateral renal agenesis.[48] During childhood, kidney size decreases while renal cysts increase in size. Progression to renal failure is observed during childhood in one-half of the patients.[49] Renal histologic examination shows glomerular cysts or cysts in any part of the nephron

and often renal dysplasia. Renal cell carcinoma may develop later in life.[50]

Several extrarenal manifestations may be present. Maturity-onset diabetes of the young type 5, with slow aggravation of insulin production, no autoantibodies, and persistent C-peptide, may be the first sign before the renal disease is recognized.[51] The diabetes usually begins in adolescence but may have a neonatal onset.[52] Exocrine pancreas deficiency may also develop in adult patients. Asymptomatic cholestasis with increased gamma-glutamyl transferase but without liver histologic anomalies is observed in 40% to 80% of adult cases. Other anomalies include hypomagnesemia, hyperuricemia, and genital tract anomalies. An increased incidence of autism and schizophrenia has been reported in these patients.[53,54]

KEY POINT

Mutations of *TCF2* gene are responsible for a renal cystic disease which progresses to ESRD in 50% of cases.

TCF2 gene is located on chromosome 17q12 and codes for a transcription factor, HNF1β, that controls the expression of several genes involved in development in the liver, kidney, intestine, and pancreas. Deletion of the whole gene is observed in 50% to 60% of patients, whereas other patients show small mutations. De novo mutations occur in more than 50% of cases. The severity of the renal disease associated with *TCF2* mutations is extremely variable and is not correlated with the genotype.[55]

KALLMANN–DE MORSIER SYNDROME

Kallmann syndrome (OMIM 308700) is defined by the association of hypogonadotropic hypogonadism and anosmia or hyposmia. Some patients also present with cleft lip, heart defects, obesity, and mental retardation.[56] Renal malformations include unilateral renal agenesis and, less frequently, hydronephrosis or vesicoureteric reflux.

The association of hypogonadotropic hypogonadism and anosmia is explained by the embryologic origin of olfactory sensory neurons and gonadotropin-releasing hormone (GnRH)–producing neurons whose precursors migrate together during development from the nasal placode to the telencephalon. This migration is regulated by neurotransmitters, extracellular matrix proteins, and growth factors. Kallmann syndrome is genetically heterogeneous. Anomalies have been found in six different genes *(KAL1, FGFR1, FGF8, CHD7, PROK2, PROKR2),* explaining one-third of cases.[57,58] The *KAL1* gene is located on the X chromosome and encodes anosmin-1, an extracellular matrix protein that is involved in neuronal development, migration,

and organogenesis. Anosmin-1 was detected in the basement membranes of mesonephric tubules and duct, as well as in branches of the ureteric bud.[59] Of patients with *KAL1* gene mutations, 40% show renal anomalies, most often unilateral renal agenesis.[60]

MAYER-ROKITANSKY-KUSTER-HAUSER SYNDROME

Mayer-Rokitansky-Kuster-Hauser (MRKH) syndrome (OMIM 277000) is characterized by müllerian duct aplasia in XX individuals with female phenotype. Patients have uterovaginal atresia or hypoplasia and present with primary amenorrhea at adolescence while they have normal breast development and pubarche.[61] Some patients have renal, skeletal, and cardiac malformations, also described as MURCS association (aplasia or hypoplasia of müllerian ducts [MU], congenital renal dysplasia [R], and cervicothoracic dysplasia [CS]).

Renal malformations include unilateral renal agenesis, renal ectopy, renal hypoplasia, horseshoe kidney, and hydronephrosis. Bilateral renal agenesis associated with absence of the uterus and oviducts has been reported in a medically aborted fetus.[62] In familial cases, the syndrome appears to be transmitted as an autosomal dominant trait with incomplete penetrance and variable expressivity. At present, no specific gene has been identified in MRKH syndrome.

MECKEL-GRUBER SYNDROME

Meckel-Gruber syndrome (MKS, MIM 249000) is a rare and lethal autosomal recessive syndrome characterized by cystic dysplastic kidneys, occipital encephalocele, hepatic ductal dysplasia, and postaxial polydactyly.[63,64] Other anomalies may be observed, such as anophthalmia or microphthalmia and cardiac and genitalia malformations. Other renal anomalies include renal hypoplasia or aplasia and horseshoe kidneys.

The incidence of MKS varies from 1 in 13,250 to 1 in 140,000 live births and is higher in Belgian (1 in 3000) and Finnish (1 in 9000) populations.[63] MKS is caused by mutations in several different genes, including *B9D1, B9D2, MKS1, MKS3 (TMEM67), NPHP3, CEP290, RPGRIP1L, CC2D2A,* and *TMEM216.*[65] These genes, like other genes associated with renal ciliopathies, encode proteins that regulate ciliogenesis and control renal development and homeostasis

MITOCHONDRIAL DISORDERS

Mitochondrial disorders are genetic defects of oxidative phosphorylation that can affect different organs or tissues.[66,67] Oxidative phosphorylation takes place in the mitochondrial
Figure 46.6 Oxidative phosphorylation occurs within the respiratory chain that is composed of four protein complexes (I to IV). These proteins transfer electrons and protons through the inner mitochondrial membrane generating the electrochemical gradient for adenosine triphosphate (ATP) synthesis, which is performed by the ATP synthase (complex V). ADP, adenosine diphosphate; H+, hydrogen Ion; H_2O, water; NADH, nicotinamide adenine dinucleotide (reduced form); O_2, oxygen; Pi, inorganic orthophosphate.

inner membrane and consists of the oxidation of fuel molecules by oxygen and the concomitant energy transduction into adenosine triphosphate (Figure 46.6). The mitochondrial respiratory chain is a complex metabolic pathway. It is made of approximately 100 polypeptides, most of which are encoded in the nucleus, whereas 13 are encoded in the mitochondria. Mitochondrial DNA is maternally inherited, and its mutations are transmitted by the mother.[68] During cell division, mitochondria are randomly partitioned in daughter cells. Therefore, in cases when normal DNA and mutant DNA are present in the mother's cells, some lineages may have only mutant mitochondrial DNA or normal mitochondrial DNA, whereas others may have both mutant and normal DNA, a condition called heteroplasmy (Figure 46.7). Mitochondrial disorders have long been regarded as neuromuscular diseases. However, other organs, incuding heart, liver, pancreas, hematopoietic system, and kidney, depend on a mitochondrial energy supply and can therefore be affected during the course of these disorders (Table 46.3). Several clinical entities encompassing mitochondrial disorders have been described according to the clinical presentation (Table 46.4). Renal involvement and symptoms are more common in children than in adults.[69]

The most frequent renal manifestation of mitochondrial disorders is proximal tubulopathy resulting in a more or less complete and severe form of De Toni-Debre-Fanconi syndrome with urinary losses of amino acids, glucose, proteins, phosphate, uric acid, calcium, bicarbonate, potassium, sodium, and water.[70–73] The proximal tubulopathy is often moderate, with isolated hyperaminoaciduria in the absence of clinical manifestations. Some patients, however, have metabolic acidosis, hypophosphatemia, hypercalciuria, glycosuria, and tubular proteinuria and may develop growth
Figure 46.7 All human cells contain several mitochondria. In most cases, mitochondrial DNA (mtDNA) copies are identical, a condition called homoplasmy. When a mutation arises, it creates a mixture of normal and mutant mtDNA called heteroplasmy. During mitotic cell division, mitochondria are randomly partitioned to daughter cells. If normal DNA and mutant DNA are present in mother cells, daughter cells may drift to purely normal mtDNA or purely mutant mtDNA, or they may remain heteroplasmic.

Table 46.3 Clinical symptoms observed in patients with mitochondrial cytopathies

Affected organ or system	Symptoms
Central nervous system	Apnea, lethargy, hypotonia, coma in the neonatal period
	Hypotonia, psychomotor regression, cerebellar ataxia, strokelike episodes, myoclonus, seizures, dementia, spasticity, headache, hemiparesis in infants and children
Muscle	Myopathy, poor head control, limb weakness, myalgia, exercise intolerance
Liver	Liver enlargement, hepatocellular dysfunction
Heart	Cardiomyopathy, heart block
Kidney	Proximal tubulopathy, nephrotic syndrome, renal failure, tubulointerstitial nephritis
Gut	Vomiting, diarrhea, villous atrophy, colonic pseudo-obstruction, exocrine pancreas dysfunction
Endocrine	Diabetes mellitus, growth hormone deficiency, hypoparathyroidism, hypothyroidism
Bone marrow	Sideroblastic anemia, neutropenia, thrombocytopenia
Ear	Hearing loss
Eye	Progressive external ophthalmoplegia, pigmentary retinal degeneration, ptosis, diplopia, cataract

retardation, rickets, or dehydration. Most patients develop tubular symptoms before the age of 2 years. Renal biopsy demonstrates nonspecific abnormalities of the tubular epithelium, with dilatations and obstructions by tubular casts, de-differentiation, or atrophy of the tubular cells also seen. Giant mitochondria are often observed within the tubular cells by light and electron microscopy. Extrarenal symptoms are always present and include myopathy, neurologic symptoms, Pearson syndrome, diabetes mellitus, or cardiac problems.

Children with mitochondrial disorders may present with steroid-resistant nephrotic syndrome and focal segmental glomerular sclerosis. A triad of steroid-resistant nephrotic syndrome, hypoparathyroidism, and sensorineural deafness has been reported.[74] Some patients may even present with congenital nephrotic syndrome.[75] Coenzyme Q_{10} deficiency was reported in siblings with severe encephalopathy, nephrotic syndrome, and renal failure. Mutations of the *COQ2* gene have been found in these patients. Coenzyme Q_{10} supplementation may improve neurologic and renal symptoms.[76,77] Mutations of the *PDSS2* and *COQ6* genes involved in coenzyme Q_{10} synthesis have been reported in children with early-onset nephrotic syndrome progressing to end-stage renal failure.[78]

A tubulointerstitial nephropathy has been described in a few patients with mitochondrial disorders.[79,80] The clinical presentation is characterized by polyuria secondary to impaired urinary concentrating ability without proximal tubular defects and by progression to end-stage renal failure. These patients present with extrarenal symptoms consisting of hearing loss, cardiomyopathy, myopathy, growth retardation, mental retardation, or pigmentary retinopathy.

The defect in the respiratory chain alters the redox status in the plasma and leads to increases in the ketone bodies (α-OH butyrate–to-acetoacetate molar ratio) within the mitochondria, along with an increase in the lactate-to-pyruvate molar ratio in the cytoplasm and a secondary elevation of plasma lactate level. Therefore, screening for mitochondrial disorders includes the determination of lactate, pyruvate, ketone bodies, and their molar ratios. Gas chromatography-mass spectrometry can detect high amounts of lactate and Krebs cycle intermediates in the urine in patients with proximal tubulopathy.

Table 46.4 Clinicopathologic entities in mitchondrial cytopathies

Mitochondrial cytopathy	Clinical manifestations
Kearns-Sayre syndrome	Progressive external ophthalmoplegia, retinal pigmentary degeneration, cerebellar ataxia, heart block
Myoclonus epilepsy and ragged-red fibers (MERRF)	Encephalomyopathy with myoclonus, epilepsy, ataxia, myopathy, hearing loss, dementia
Leber hereditary optic neuropathy (LHON)	Blindness, cardiac dysrhythmia
Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS)	Headache, vomiting, lactic acidosis, myopathy with ragged-red fibers, seizures, dementia, deafness
Leigh disease	Subacute necrotizing encephalomyopathy, ataxia, respiratory troubles with weak cry, deafness, blindness
Chronic progressive external ophthalmoplegia (CPEO) and mitochondrial myopathy	Ocular myopathy, retinal pigmentary degeneration, central nervous system dysfunction
Alpers disease	Progressive infantile poliodystrophy, hepatic failure

Polarographic and spectrophotometric studies allow identification of the biochemical nature of the mitochondrial defect.[81] Polarography measures oxygen consumption by mitochondria in the presence of various oxidative substrates. The only limitation of this technique is that it requires fresh tissue. Spectrophotometric studies assess isolated or combined respiratory chain complexes. When the disease is expressed in organs difficult to access, such as the kidney, accessible peripheral tissues, including skeletal muscle, cultured skin fibroblasts, and circulating lymphocytes, should be tested.

Any mode of inheritance (autosomal recessive, dominant, X-linked, maternal, or sporadic) can be observed in mitochondrial disorders.[82] Mutations in both mitochondrial and nuclear genes have been identified in patients with mitochondrial disorders associated with renal disease. However, the molecular definition is complicated by the dual genetic control of respiratory chain proteins and by the high number of genes involved in the biogenesis and assembly of the respiratory chain. Therefore, mutations are identified in only very few cases. The A-3243-G change in the tRNALeu gene is one of the most commonly encountered mitochondrial DNA (mtDNA) mutation (MELAS mutation).[83] This mutation is maternally inherited and is heteroplasmic. It can be associated with a large variety of clinical phenotypes, including nephrotic syndrome. Large mtDNA deletions have been described in several patients with renal disease. There are only few examples of mitochondrial kidney diseases associated with nuclear gene mutations.[73]

KEY POINTS

- A mitochondrial disorder should be considered in any patient with unexplained disease, especially when two or more seemingly unrelated symptoms are present.
- Proteinuria is observed in 30% of patients with NPS. ESRD occurs in approximately 10% of cases.

NAIL-PATELLA SYNDROME

The nail-patella syndrome (NPS) or osteo-onychodysplasia (OMIM 161200) is an autosomal dominant disease characterized by hypoplastic or absent patella, dystrophic fingernails and toenails, and dysplasia of the elbows and iliac horns.[84,85] Renal symptoms are present in approximately 50% of patients. The estimated incidence of NPS is 22 per million population.[86]

Nail abnormalities are present in 80% to 90% of patients with NPS and are observed at birth.[87] The nails may be absent but more often are hypoplastic or dysplastic. Abnormalities predominate on the fingernails and consist of discoloration, longitudinal pterygium, splitting, and triangular lunulae (Figure 46.8). Abnormalities of the knees and elbows are

Figure 46.8 Nail-patella syndrome. Left hand in nail-patella syndrome showing dysplasia of the nails. The severity of dysplasia decreases from the thumb to the fifth finger. Clinodactyly of the fifth finger and triangular lunulae are also present.

found in almost all patients. The patella may be absent or hypoplastic, often with fragmentation, causing lateral slippage during knee flexion. The radial heads and the distal ends of the humerus are typically hypoplastic, leading to subluxation and limitations of extension, pronation, and supination of the forearm. Iliac horns, observed in 30% to 70% of the patients, are pathognomonic radiologic features of the disease (Figure 46.9). They consist of asymptomatic symmetric bone formations arising from the anterosuperior iliac crest.

The degree of renal involvement varies among families and also within members of the same family. The most frequent symptoms are proteinuria, sometimes with the nephrotic syndrome, hematuria, and hypertension.

Figure 46.9 Nail-patella syndrome. x-ray film of the hip and iliac bones showing the characteristic iliac horns.

Urine-concentrating ability may be impaired. ESRD develops in approximately 10% of cases.[88] Patients with heavy proteinuria or impaired renal function may show basement membrane thickening and nonspecific lesions of focal segmental glomerular sclerosis. Electron microscopy shows pathognomonic and consistent lesions of the glomerular basement membrane.[89] These lesions consist of irregular and lucent rarefactions within the lamina densa, containing clusters of cross-banded collagen fibrils.

NPS is caused by mutations of the *LMX1B* gene located on chromosome 9.[90,91] LMX1B is a transcription factor of the LIM-homeodomain type, which plays an important role for limb development in vertebrates. More than 140 mutations in this gene have been identified in patients with NPS. *LMX1B* is expressed in the podocyte. The study of homozygous knockout mice has shown that this gene regulates the transcription of four genes: *COL4A3, COL4A4, CD2AP,* and *NPHS2*.[92–94] Investigators have suggested that there may be two allelic mutations of the gene: one responsible for the NPS without nephropathy and one responsible for the NPS with nephropathy. It has been calculated that, for a parent with the NPS whose family has nephropathy, the risk of having a child with nephropathy is 24%, and the risk of having a child who will progress to ESRD is 7%.[95]

OCHOA SYNDROME (UROFACIAL SYNDROME)

Ochoa syndrome (OMIM 236730, 615112) is characterized by voiding dysfunction and an abnormal facial expression on smiling or crying.[96] The facial dysmorphism is related to an inversion of facial expression on smiling or crying (Figure 46.10). Children present with urinary incontinence and incomplete voiding of the bladder leading to urinary tract infections. Vesicoureteric reflux is frequently associated, and patients may progress to chronic renal failure. Patients may also have severe constipation.

Ochoa syndrome is inherited as an autosomal recessive trait. Most patients who have been studied carry biallelic mutations of *HPSE2* or, less commonly, of *LRIG2* genes, encoding for heparanase 2 and leucin-rich repeats and immunoglobulin-likedomains 2.[97] These two proteins are detected in the fetal bladder nerves and may facilitate neural growth in the bladder and bladder function.

ORAL-FACIAL-DIGITAL SYNDROMES

Oral-facial-digital (OFD) syndromes are characterized by malformations of the oral cavity, the face, and the digits.[98] Several different forms of the syndrome have been described.

OFD1 (OMIM 311200) is the most frequent. It is lethal before birth in males. There is a high phenotypic variability
Figure 46.10 Urofacial syndrome (Ochoa syndrome). Characteristic inversion of the facial expression with smiling. (From Stamatiou K, Tyritzis S, Karakos C, et al. Urofacial syndrome: a subset of neurogenic bladder dysfunction syndromes? Urology. 2011;78:911–3.)

in females. Female patients present with oral malformations (clefts of the palate and tongue-gingival frenulae, abnormal dentition), craniofacial anomalies (facial asymmetry, hypertelorism, micrognathia, pseudocleft upper lip), abnormal hair, and digital malformations (brachydactyly, syndactyly, clinodactyly, and polydactyly). Neurologic anomalies are observed in 40% (intracerebral cysts, agenesis of the corpus callosum, cerebellar anomalies), and variable degrees of mental retardation occur in one-half of the patients. Renal disease consists of bilateral renal cysts, mostly glomerular cysts. Patients with renal cystic disease may progress to renal failure.[99]

The *OFD1* gene is located on the Xp22 region and encodes a centrosomal protein localized in the basal body of the primary cilia.[100] Many cases result from de novo mutations.

RENAL-COLOBOMA SYNDROME

Renal-coloboma syndrome, also named papillorenal syndrome (OMIM 120330), is an autosomal dominant disorder characterized by renal hypoplasia and optic nerve coloboma.[101] Renal malformations include oligomeganephronic hypoplasia, vesicoureteral reflux, and, less often, multicystic dysplasia and ureteropelvic junction obstruction. Ophthalmologic examination shows an optic disc split and vascular anomalies associated with variable visual impairment.[102] Some patients have a large coloboma of the optic nerve, whereas other patients present with optic nerve dysplasia without visual impairement (Figure 46.11). Other
Figure 46.11 Renal-coloboma syndrome (RCS). Fundus photographs. **(a)** Normal fundus. Note that the typical optic nerve is smaller and compact, and the retinal vessels emerge from the center of the disc. **(b)** Right retinal coloboma in a patient with RCS (arrow). **(c)** Right retina from a patient with showing an optic disc coloboma in RCS (arrow). The optic disc is enlarged and excavated. The retinal vessels emerge from the edge of the disc, rather than the center. (From Schimmenti LA. Renal coloboma syndrome. Eur J Hum Genet. 2011;19:1207–12.)

features include sensorineural hearing loss, Arnold Chiari malformation, seizures, and joint laxity.[103]

More than 50 heterozygous mutations in the *PAX2* gene have been described in patients with the renal-coloboma syndrome.[104,105] Identified mutations have mostly been located in the second and third exons of the *PAX2* gene, which is located on chromosome 10q24-25.[104] The *PAX2* gene encodes a transcription factor involved in the development of the kidneys and eyes. Studies in mice found that heterozygous *PAX2* mutations (1Neu) are associated with increased apoptosis and reduced branching of the ureteric bud.[106] *PAX2* mutations have been identified in a few patients with oligomeganephronia and limited or no optic nerve anomalies.[107,108]

SIMPSON-GOLABI-BEHMEL SYNDROME

Simpson-Golabi-Behmel syndrome (SGBS, OMIM 312870) is a rare X-linked congenital syndrome characterized by prenatal and postnatal overgrowth, craniofacial anomalies, organomegaly, increased risk of tumors, moderate intellectual deficiency, and variable congenital malformations.[109] Two types of the disorder have been described: a less severe form (SGBS type I) and a severe form (SGBS type II).

The glypican 3 *(GPC3)* gene located on Xq26 encodes a heparan sulfate proteoglycan, an extracellular matrix protein, that plays an important role in cell growth during development.[110] Mutations in this gene have been identified mostly in patients with SGBS type I, the most frequent form of SGB syndrome. Renal anomalies are observed in 50% of patients with *GPC3* mutations and consist of duplicated collecting duct, megaureter, vesicoureteral reflux, and ureteropelvic junction obstruction. Patients may have renal dysplasia, renal cysts, and nephromegaly and may develop Wilms tumor.[111] A second locus on chromosome Xp22 is associated with SGBS type II.

TOWNES-BROCKS SYNDROME

Townes-Brocks syndrome (OMIM 107480), also named anus-hand-ear syndrome, is an autosomal dominant disorder characterized by the association of imperforate anus, preaxial polydactyly and triphalangeal thumbs, external ear anomalies, sensorineural hearing loss, renal and heart anomalies, and variable expressivity (Figure 46.12).[112] Most patients have normal intelligence. Renal malformations consist of unilateral or bilateral hypoplasic or dysplasic kidneys, renal agenesis, multicystic kidney, horeshoe kidney, vesicoureteral reflux, and posterior urethral valves. These
Figure 46.12 Townes-Brocks syndrome. **(a)** Dysplastic ear with a preauricular tag and a cheek tag. **(b)** Preaxial polydactyly and bifid distal phalanx of the thumb with ulnar deviation. (From Powella CM, Michaelisb RC. Townes-Brocks syndrome. J Med Genet. 1999;36:89–93.)

malformations may be responsible for renal failure, including end-stage renal failure.

Townes-Brocks syndrome occurs in 1 in 200,000 live births. More than 60 mutations have been identified in the *SALL1* gene on chromosome 16q12.1, which codes for a zinc finger transcription factor that is involved in kidney development.[113,114] *SALL1* is essential for ureteric bud invasion, the first step of metanephros development.[115] De novo mutations are observed in 50% of cases. Approximately 65% of patients have point mutations and 5% deletions.[116] A significant proportion of patients with the typical malformations does not have a *SALL1* mutation.

VATER AND VACTERL ASSOCIATIONS

VATER association, initially described in 1973, is characterized by congenital malformations including Vertebral defects, Anal atresia, Tracheo-Esophageal fistula, and Renal anomalies.[117] VACTERL association also includes Cardiac malformations and Limb abnormalities.[118] VACTERL association occurs in 1 in 10,000 to 1 in 40,000 liveborn infants. The diagnosis is made if three of the foregoing symptoms are present in early life.

Renal anomalies have been reported in 50% to 80% of cases and include unilateral or bilateral renal agenesis, horseshoe kidney, and cystic or dysplastic kidneys. Some patients may progress to renal failure.[119]

SUMMARY

Genetic and syndromic disorders can be associated renal malformations, the presence of renal cysts, hypercalciuria, nephrocalcinosis, and proteinuria. Progressive loss of renal function, chronic kidney disease, and ESRD can also result from some of these disorders. Recognition of syndromes that are associated with renal disease requires the input of a genetics team in addition to the nephrologist. Complex surgical management in disorders such as VATER or VACTERL association requires the involvement of urologic and other surgical expertise. Genetic diagnosis of many syndromic disorders is possible now, and the array of available diagnostic tests for clinical use is ever increasing. This chapter provides an overview of the common syndromes and genetic diseases associated with renal manifestations. The reader is referred to the broader literature on the subject for a deeper understanding, if needed.

REVIEW QUESTIONS

1. Children affected with *one* of the following syndromes are at higher risk of developing Wilms tumor.
   a. Branchio-oto-renal syndrome
   b. Renal-coloboma syndrome
   c. Townes-Brocks syndrome
   d. Beckwith-Wiedemann syndrome
   e. Cockayne syndrome

2. Which of the following anomalies is *not* observed in patients with HNF1B-mutation?
   a. Cholestasis
   b. Hypomagnesemia
   c. Multicystic kidney disease
   d. Vertebral malformations
   e. Diabetes mellitus

3. Children affected with *one* of the following syndromes may develop proteinuria and a nephrotic syndrome.
   a. CHARGE syndrome
   b. Nail-patella syndrome
   c. Ochoa syndrome
   d. Fraser syndrome
   e. Simpson-Golabi-Behmel syndrome

4. Concerning mitochondrial disorders, which of the following assertions is *not applicable*?
   a. They are secondary to defects of oxidative phosdphorylation.
   b. Mitochondrial DNA is inherited from the father.
   c. The most frequent renal manifestation is proximal tubulopathy.
   d. Patients may present with hyperlactatemia.
   e. Patients may develop a nephrotic syndrome.

5. All of the following are seen in patients with Alagille syndrome, *except:*
   a. Chronic cholestasis
   b. Pulmonary artery stenosis
   c. Posterior embryotoxon
   d. Hearing loss
   e. Vascular abnormalities

6. Which of the following *does not apply* to nail-patella syndrome?
   a. It is an autosomal dominant disease.
   b. Iliac horns are a pathognomonic radiologic feature of the disease.
   c. Urinary tract malformations are frequently observed in nail-patella syndrome.
   d. Nail-patella syndrome is caused by mutations of the LMX1B gene.
   e. End-stage renal disease develops in 10% to 15% of cases.

Urologic disorders

Hydronephrosis and obstructive uropathies

IHOR V. YOSYPIV

Congenital obstructive uropathy is characterized by compromised urine flow or transport that begins in utero and can impair fetal renal development and function. This group of disorders forms one of the most important and identifiable causes of chronic kidney disease (CKD) in infants and children.[1] Congenital obstructive uropathy constitutes a part of the spectrum of the congenital anomalies of the kidney and urinary tract (CAKUT), which occurs in 1 of 1000 live births and counts for 50% to 56% of CKD and end-stage renal disease (ESRD) in children of all ages.[2–4]

Because urinary tract obstruction during fetal life has serious consequences for the structural and functional development of kidneys and the urinary tract, there is a clear need for early diagnosis, for appropriate and timely interventions, and to monitor progression and response to therapy. This chapter reviews the causes and pathophysiology of urinary tract obstruction, discusses antenatal and postnatal clinical manifestations, and examines clinical management.

CLASSIFICATION

Obstructive uropathy can be classified based on the site of obstruction and whether it is acute or chronic. Because congenital obstructive uropathies are developmental in origin from fetal life, all of them can be considered to be chronic. This is in contrast to older children and adults, in whom urinary obstruction is often acute in timing and is likely to be reversible.

Based on the site of obstruction (Figure 47.1), congenital obstructive uropathies can be classified as upper urinary tract obstruction and lower urinary tract obstruction (LUTO). The upper urinary tract obstruction encompasses the renal pelvis and the upper part of the ureters. Ureteropelvic junction (UPJ) obstruction typifies this type of urinary obstruction. LUTO, on the other hand, involves lower ureters, urinary bladder, and the urethra. Ureterovesicular junction (UVJ) obstruction can be present unilaterally or bilaterally, with the corresponding side of urinary tract involvement. On the other hand, lesions of the bladder and urethra usually affect both sides of the urinary tract. Posterior urethral valves (PUVs) are common examples of LUTO that often affect both sides of the urinary tracts. Urethral stenosis and atresia also cause bilateral urinary tract effects.

KEY POINTS

- CAKUT accounts for 50% to 56% of ESRD and CKD in children.
- Congenital obstructive uropathy affects the development and functions of fetal kidneys.
- Based on the site of urinary obstruction, obstructive uropathy can be classified as upper urinary tract obstruction or (LUTO).
- Urinary obstruction may be acute or chronic.
Figure 47.1 Location of most common sites of congenital urinary tract obstruction. LUTO, lower urinary tract obstruction; PUV, posterior urethral valves. UPJ, ureteropelvic junction; UVJ, ureterovesical junction.

EPIDEMIOLOGY

The most common cause of prenatally detected hydronephrosis is UPJ obstruction, which occurs in 1 in 1500 live births.[3–5] Obstruction is bilateral in 20% to 25% of cases of UPJ obstruction, with 3:1 male predominance.[6] Ureterovesical junction (UVJ) obstruction accounts for 20% of cases of neonatal hydronephrosis, has a 4:1 male predominance and is bilateral in 25% of cases.[6] The incidence of PUV that occurs exclusively in males is 1 in 5000 to 8000.[3,7] Because both kidneys are affected, the presence of PUV carries the greatest risk for development of ESRD. Therefore, intervention is potentially most urgent in patients with PUV.[8] The prevalence of ureterocele, a cystic dilatation of the terminal ureter within the bladder, the urethra, or both, is 1 in 5000 newborns, with 3:1 female predominance.[6] Bilateral ureteroceles occur in 20% to 50% of cases.[6] Approximately 50% of all cases of congenital hydronephrosis have no evidence of physical obstruction or abnormality in the structural components of the lower urinary tract (LUT). In these cases, the presence of functional urinary tract obstruction is assumed.

PATHOPHYSIOLOGY

Obstruction of the urinary tract causes rapidly detectable changes in ureteric function and anatomy and leads to numerous closely linked cellular and molecular responses in the kidneys that result in (1) changes in developmental physiology of the kidneys, (2) induction of inflammatory and fibrosis induction pathways, and (3) apoptosis. The underlying mechanisms that account for congenital structural or functional obstructive uropathy are poorly understood. Although numerous genes have been postulated to play a

role in the normal and abnormal development of the urinary tract, none has been shown to be responsible for the common lesions associated with congenital obstructive uropathy in humans. The potential role played by some of the well-characterized mechanisms in the pathogenesis of congenital obstructive uropathy is discussed in the following section.

KEY POINTS

- Approximately 50% cases of congenital hydronephrosis have no recognizable cause.
- UPJ obstruction is the most common cause of unilateral prenatal hydronephrosis (1:5000 live births).
- PUV occurs in 1:5000 to 8000 male births.
- Patients with PUV are at the greatest risk for CKD and ESRD because of potential bilateral renal injury.

URETERAL PRESSURE AND RENAL BLOOD FLOW

The structural and functional changes occurring at the level of the ureter in the presence of obstruction depend on its extent and duration of obstruction, the rate of urine formation, and the presence or absence of infection. An acute increase in the intraluminal baseline ureteral pressure is followed, within several hours, by a decline in the intraluminal ureteral pressure to values slightly above normal.[9] The fall in ureteral pressure is attributable to decreased renal blood flow (RBF) and glomerular filtration rate (GFR). In addition, an increase in the ureteral cross-sectional muscle area, ureteral length and diameter, and an alteration of ureteral peristalsis are also observed.

RBF in the affected kidney decreases after unilateral ureteral obstruction (UUO) in experimental models.[9] In some experimental models of UUO, despite a substantial rise in the ureteral pressure, there is an initial rise in RBF that lasts up to 1½ hours. Subsequently, the renal blood flow continues to decline as the ureteric pressure rises and this decline persists even after the ureteric pressure reduces.[10] In the unobstructed contralateral kidney, however, RBF increases and is a mirror image of the changes noted in the kidney with ureteral obstruction (Figure 47.2).[10] This may represent an early hemodynamic compensatory mechanism. In experimental models, RBF and GFR have been noted to be persistently decreased by as much as 40% from baseline even after release of the obstruction, suggesting a long-lasting impact of urinary obstruction on renal structure and function.[11]

Renin-angiotensin system activation in obstructive uropathy

Numerous experimental studies have demonstrated an important role for the renin-angiotensin system (RAS) in
Figure 47.2 Ureteral pressure changes, renal blood flow, and mean arterial blood pressure changes following unilateral ureteral obstruction in lambs. Mean ureteral pressure increased from a baseline of 9 to 37 mm Hg (*P* < 0.001) 2 hours after obstruction but gradually decreased to 24 mm Hg after 24 hours and remained elevated for 5 days. Renal blood flow in the obstructed kidney remained unchanged for the first 5 hours, then there was a downward trend and it remained significantly lower for 5 days after obstruction. Blood flow in the contralateral kidney tended to increase after 5 hours and it remained above baseline for 5 days. Blood flow is represented as mean percent change ± standard error of the mean after obstruction. (Reproduced with permission from: Kim KM, Bogaert GA, Nguyen HT, et al. Hemodynamic changes after complete unilateral ureteral obstruction in the young lamb. J Urol. 1997;158:1090–3.)

modulating renal and collecting system development. Mice with angiotensinogen *(Agt), renin,* angiotensin-converting enzyme *(ACE),* or angiotensin II receptor type 1 *(AT1)* receptor gene mutations exhibit severe medullary hypoplasia and hydronephrosis.[12] Emerging evidence suggests that *RAS* gene mutations may be associated with diverse types of CAKUT in humans. Mutations in the genes encoding *Agt, renin, ACE, or AT1* receptor have been associated with renal tubular dysgenesis (RTD, Online Mendelian Inheritance in Man [OMIM] 267430) in one study.[13] These patients with RTD exhibit severe hypotension, thickening of renal arterial walls, reduced number of proximal tubules, collapsed collecting ducts, and interstitial fibrosis, but do not manifest

severe medullary hypoplasia and hydronephrosis that are observed in mice with *Agt, renin, ACE,* or *AT1* receptor mutations.[12] The reasons for different renal phenotypes observed in mice but not in humans with *RAS* gene mutations are not clear. It is possible that differences in timing for completion of nephrogenesis, unique renal morphology in mice with a single papilla, or variability in renal tissue *RAS* activity in relation to critical periods of metanephric organogenesis may contribute these species-specific phenotypic expressions. Although clinical studies have suggested an association of other types of CAKUT with mutations in components of the *RAS* in children, this has not been confirmed in others.[12,14]

Influencing genes in obstructive uropathy

Mice with targeted deletion of a disintegrin and metalloproteinase with thrombospondin motifs 1(ADAMTS1), lysosomal membrane protein LIMP-2/LGP85, calcineurin, sonic hedgehog cell surface effector smoothened (Smo) or transgenic megabladder mice develop urinary tract obstruction in the postnatal period.[15–19] Functional obstruction observed in *Smo*-deficient mice is due to ureter dyskinesia from loss

---

KEY POINTS

- RAS plays an important role in renal development.
- Genes affecting ureteral muscle development may play a role in congenital obstructive uropathy.

of ureteral pacemaker cells.[19] Targeted deletion of *Smad4*, a signaling molecule critical for transcriptional responses to transforming growth factor-β (TGF-β and bone morphogenic protein 4 (BMP4) signaling in the ureteral and bladder mesenchyme during embryogenesis, results in bilateral UPJ obstruction and hydronephrosis from functional obstruction secondary to abnormal pyeloureteral peristalsis during embryogenesis.[20] Subsequent bending and luminal constriction of the ureter at the UPJ account for the transition from a functional into a more damaging and permanent physical obstruction. These observations suggest that early intervention of milder obstruction may prevent more irreversible damage to the urinary tract.[20] Emerging evidence points to an important role for epigenetic regulators in the pathophysiology of obstructive uropathy. In this regard, conditional ablation of *Brg1*, a member of Swi/Snf transcription complex, in mouse ureter results in hydroureter as a result of reduced smooth muscle cell development.[21] These observations, furthermore, point to the critical role played by ureteral muscular development and peristalsis in the pathogenesis of some cases of congenital hydronephrosis.

Impact of obstructive uropathy on renal development

Clinical and experimental evidence indicates that urinary obstruction during early development has deleterious consequences on the structure and function of the developing kidney. Compared to the adult kidney, the developing kidney is highly susceptible to injury from obstruction to urine flow.[22] A variety of experimental models have been used to investigate the pathophysiology of congenital obstructive uropathy. UUO or urethral obstruction in fetal sheep results in hydronephrosis, renal dysplasia, and marked changes in renal growth.[23] UUO in the fetal rhesus monkey disrupts branching of the ureteric bud, an embryonic precursor of the renal collecting system (pelvis, ureter, collecting ducts).[24] Over the past two decades, much has been learned from studies of the developing rat and mouse.[25] Whereas nephrogenesis in humans is complete by the 36th week of gestation, nephrogenesis in the rat and mouse proceeds after birth.[3] Thus, surgical obstruction of the ureter in the neonatal rat or mouse is analogous to ureteral obstruction in the mid to late trimester of the human fetus.

Transient complete UUO in the neonatal rat impairs growth of the obstructed kidney, which correlates well with the duration of obstruction (Figure 47.3).[26] This suggests that a delay in the relief of severe obstruction can permanently impair the growth potential of the kidney. Chronic partial UUO in the neonatal rat also impairs renal growth, an effect that depends on the severity of obstruction.[27] There appears to be a critical reduction in ureteral diameter (65%) that, if exceeded, results in impaired renal growth. Because renal growth is a major determinant of long-term renal function, a better understanding of the "critical" ureteral stenosis in humans may permit the development of a better definition of clinically significant obstruction.

Chronic UUO delays maturation of all the major components of the nephron, from the glomerulus to the collecting duct, as well as the microvasculature and renal interstitium.[28] As a consequence of obstruction, there are also major hemodynamic changes with profound renal vasoconstriction mediated by the RAS (already highly activated in the developing kidney compared to the adult kidney).[29–34] Although the renal vasoconstriction is modulated by endogenous vasodilators such as prostaglandins and nitric oxide, the net balance favors vasoconstriction.[35,36] There is increased renin production by afferent arterioles and an upregulation of molecules induced by activation of the RAS.[32,37,38]

> ## KEY POINTS
>
> - Urinary obstruction affects renal development.
> - Tubulointerstitial fibrosis and atrophy in obstructive uropathy result from induction of numerous cytokines in response to stretch stress injury.

Chronic severe obstructive uropathy is characterized by the development of tubular atrophy and interstitial fibrosis, both of which contribute to impaired renal growth (Figure 47.4). Tubular atrophy results from progressive destruction of tubular epithelial cells by apoptosis, or programmed cell death.[39,40] Chronic partial UUO in the neonatal rat leads to apoptosis of epithelial cells in the dilated collecting ducts and the characteristic atrophic tubules with thickened basement membranes.[27] Stimuli leading to tubular apoptosis include mechanical stretch of epithelial cells in dilated tubules and altered gene expression.[28,40–44] Renal tubular expression of epidermal growth factor (EGF), which is a survival factor, is reduced by UUO, and expression of TFG-β1 (a proapoptotic factor) is increased by UUO.[28] The balance of survival and death signals is tipped in favor of cell death, leading to progressive loss of renal mass.[45]

Chronic UUO also has profound effects on the renal interstitium, leading to infiltration by macrophages and fibroblasts, which release cytokines such as TGF-β1 (Figure 47.5).[44] Activated macrophages and their products can induce both tubular apoptosis and progressive interstitial fibrosis.[46] This can involve the transformation of interstitial fibroblasts to myofibroblasts that express α-smooth muscle actin, and release additional fibrogenic molecules.[28] Most remarkable is the recent discovery that mechanical stretching of tubular cells and changes in the local production of growth factors, cytokines, and chemokines can lead to transformation of renal tubular epithelial cells to assume mesenchymal characteristics.[47,48] Tubular cells undergoing epithelial-mesenchymal transformation can differentiate into fibroblasts that augment the progression of interstitial fibrosis.[49] The multiple interacting processes depicted in Figure 47.3 are dynamic and
Figure 47.3 The ratio of kidney to body weight of obstructed (pink) and contralateral (blue) kidneys of neonatal rats 28 days following sham operation, following relief of 1 to 5 days of unilateral ureteral obstruction (UUO) and following persistent complete UUO. *$P < 0.05$ versus sham. (Reproduced with permission from: Chevalier RL, Thornhill BA, Wolstenholme JT, et al. Unilateral ureteral obstruction in early development alters renal growth: dependence on the duration of obstruction. J Urol. 1999;161:309–14.)

activated by the persistence of significant urinary tract obstruction. Recent studies demonstrate that pharmacologic antagonism of TGF-β1 receptor aggravates obstructive renal injury from UUO in neonatal mice, indicating caution for pediatric use of TGFβ1 inhibitors.[50] A more thorough understanding of these interactions may lead to improved therapies for obstructive uropathy by interfering with tubular apoptosis, macrophage infiltration, or epithelial-mesenchymal transformation. Once this process has progressed to tubular atrophy and extensive interstitial fibrosis, the impairment of renal growth becomes irreversible.

J Clin Invest. 1999;103:39–46.)

NEPHRON LOSS IN OBSTRUCTIVE UROPATHY

Even transient complete UUO during nephrogenesis or during nephron maturation can lead to a permanent loss of nephrons mass in the obstructed kidney.[51,52] Chronic partial UUO in the neonatal rat also reduces nephron number, although the loss of nephrons takes place over a longer period.[27] As with any loss of renal mass, chronic UUO leads to compensatory growth of the contralateral kidney (see Figure 47.3). This "counterbalance" is very finely tuned and develops after even short periods of ureteral obstruction.[26,53] Because the severity of urinary tract obstruction in clinical practice is usually asymmetrically distributed between the two kidneys, adaptive growth by the remaining nephrons may occur in both kidneys. Current limitations in detecting such adaptive growth lie in the relative lack of precision in imaging techniques, as well as in the measurement of differential renal function.[54]

TUBULAR DYSFUNCTION IN OBSTRUCTIVE UROPATHY

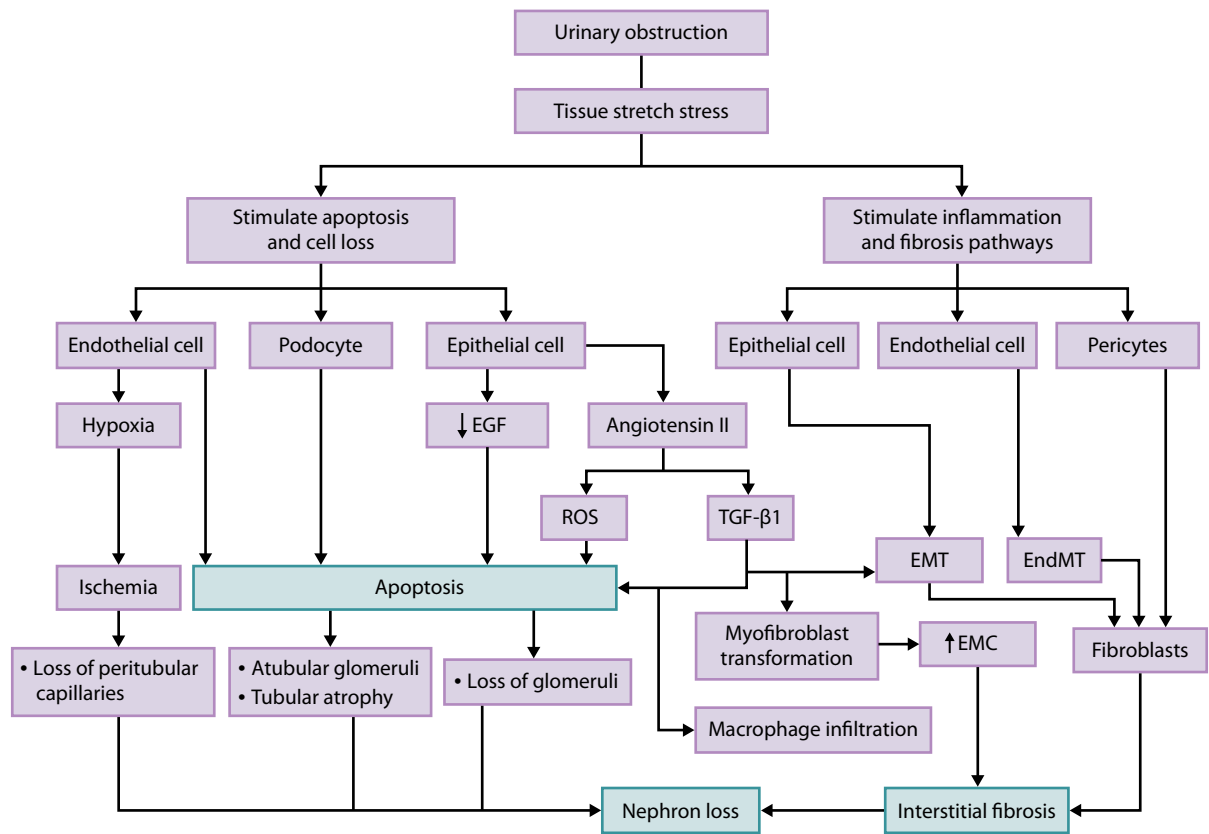
Chronic obstructive uropathy leads to impaired tubular function, which can have significant clinical implications. Downregulation of sodium transporters and aquaporins and distortion of the medullary architecture contribute to limited renal concentrating capacity.[55,56] These factors also contribute to the phenomenon of postobstructive diuresis that often follows the relief of severe bilateral urinary tract obstruction (such as PUV).[56] Because positive sodium balance is necessary for normal somatic growth in infancy, impaired growth is another consequence of reduced renal sodium reabsorption in obstructive uropathy.[57] Thus, infants may require sodium supplements to prevent volume


Figure 47.5 Schematic representation of the pathogenesis of obstructive nephropathy. Downstream obstruction to urine flow causes mechanical stretching and dilation of tubules, leading to apoptosis and epithelial-mesenchymal transition (EMT) of the tubular epithelial cells. Affected epithelial cells downregulate epidermal growth factor (EGF) and activate the local renin-angiotensin system (angiotensin II) that stimulates the expression of transforming growth factor- β_1 (TGF-β_1) and the generation of reactive oxygen species (ROS). This leads to interstitial macrophage recruitment and the generation of monocyte chemoattractant protein-1 (MCP-1), adhesion molecules, and tumor necrosis factor-α (TNFα). This contributes to apoptosis of epithelial and endothelial cells, podocytes, leading to renal hypoxia and ischemia, loss of peritubular capillaries and glomeruli, proximal tubular disruption, tubular atrophy and atubular glomeruli. Phenotypic transition occurs in EMT, endothelial cells (EndMTs), pericytes, as they become fibroblasts, which in turn develop into myofibroblasts that express α-smooth muscle actin (α-SMA). Myofibroblasts contribute to expansion of the extracellular matrix (ECM) and progressive fibrosis. The end result is progressive loss of all components of the nephron.

contraction and optimize somatic growth. Somatic growth also may be limited in obstructive uropathy by abnormal distal tubular potassium and hydrogen ion secretion as a result of type 4 renal tubular acidosis (RTA).[58] These tubular defects can lead to hyperkalemia and metabolic acidosis, even with unilateral obstruction, and may persist even after surgical relief of the obstruction.[59,60]

KEY POINTS

- Nephron loss and tubular dysfunction are common accompaniments of congenital obstructive uropathy.
- Renal salt wasting and metabolic acidosis resulting from distal RTA are common in obstructive uropathy.

CLINICAL FEATURES

PRENATAL DETECTION

Most cases of congenital obstructive uropathy are detected by prenatal ultrasonography, usually performed between 16 and 20 weeks of gestation. Measurement of the anteroposterior diameter of the renal pelvis obtained in the maximal transverse plane (usually near hilum region) in ultrasound has been used as an index of the severity of hydronephrosis (Figure 47.6). There is lack of consensus on grading the fetal and neonatal hydronephrosis, but the criteria developed by the Society for Fetal Urology (SFU) provide a clinically applicable platform (Figure 47.7).[61]

The risk for clinically significant urinary tract obstruction is increased when the fetal renal pelvic diameter exceeds 6 mm at less than 20 weeks, 8 mm at 20 to 30 weeks,
Figure 47.6 Renal ultrasound showing anatomic points used to determine the anteroposterior diameter (APD) of renal pelvis in ultrasound evaluation of hydronephrosis. The kidney is seen in a transverse image at the level of renal hilum. White bar represents the APD of pelvis.

or 10 mm at more than 30 weeks of gestation.[62] However, the diagnosis of fetal hydronephrosis based on renal pelvic dimensions can be misleading. Not only is the reliability of the measurement operator-dependent, the high urine flow of the fetus can cause relative distention of the pelvis and normal dimensions following fetal voiding, even with a partially obstructed ureter.

Equally important in the prenatal diagnosis of obstructive uropathy is to determine whether the lesion is unilateral or bilateral, the presence of ureteral dilatation, whether the bladder is dilated or has a thickened wall, and if other organ system abnormalities are present. Dilatation of renal calyces also should be looked for in the ultrasound evaluation, because greater severity of calyceal dilatation indicates a clinically significant hydronephrosis.[63] Suspected fetal hydronephrosis should be confirmed by postnatal ultrasonography. It is important to note that not all cases of fetal hydronephrosis are due to urinary obstruction. Other diagnoses that can mimic neonatal hydronephrosis include vesicoureteral reflux (VUR), megacalicosis, and multicystic dysplastic kidney (Table 47.1 and Table 47.2).

Table 47.1 Causes of dilated urinary tract in the fetus and neonates

True Hydronephrosis
- Transient
- Ureteropelvic junction obstruction
- Vesicoureteral reflux
- Ureterocele
- Posterior urethral valves
- Nonobstructive hydronephrosis

Hydronephrosis Mimickers
- Multicystic dyplastic kidney
- Megaureter
- Megacalycosis
- Large renal cysts

SFU grade 1	SFU grade 2	SFU grade 3	SFU grade 4
Urine barely splits sinus	Full pelvis, major calyces dilated	Uniformly dilated minor calyces, parenchyma spared	Parenchymal compromise

Table 47.2 Prenatal ultrasound findings of obstructive uropathies and other CAKUT disorders

Cause	Incidence (%)	Prenatal ultrasound findings
Transient/physiologic	50–70	Isolated hydronephrosis, most often mild
Ureteropelvic junction (UJP) obstruction	10–30	Moderately (10–15 mm) or severely (>15 mm) dilated renal pelvis in the absence of any dilation of ureter or bladder
Vesicoureteral reflux (VUR)	10–40	Variation in the degree of antidiuretic during the time of ultrasound evaluation (in general, there are no specific ultrasound findings that are pathognomonic)
Ureterovesical junction (UVJ) obstruction	5–15	Hydronephrosis and dilated ureter to level of the UVJ
Multicystic dysplastic kidney (MCDK)	2–5	Varying sizes of randomly located renal cysts, a large noncommunicating central cyst, and nonrenoform shape
Posterior urethral valves (PUVs)	1–5	A combination of posterior urethral dilatation (keyhole sign), a full bladder with thickened wall, oligohydramnios or anhydramnios, unilateral or bilateral hydronephrosis, increased renal echogenicity
Ureterocele	1–3	A cystic mass in the bladder, and hydroureteronephrosis to the level of the obstructing ureterocele
Less common causes: Ectopic ureter, urethral atresia, prune belly syndrome, polycystic kidney diseases, and renal cysts	<1

Radiologic findings of PUV in fetal ultrasound evaluation are characterized by a thickened bladder wall, bilaterally dilated ureters, and the so-called keyhole sign (Figure 47.8).

In addition to a direct impact on the bilateral renal development and function in the fetus, LUTO, such as PUV, also has a clinically significant impact on pulmonary development. Severe oligohydramnios resulting from reduced fetal urine output in PUV leads to pulmonary hypoplasia that can be even more life-threatening in the immediate postnatal period than renal failure itself. Therefore, estimation of amniotic fluid volume is critical in the evaluation of any fetus suspected of CAKUT. Severe cases of PUV can develop Potter syndrome, characterized by oligohydramnios, pulmonary hypoplasia, and typical facial appearance of a broad nasal bridge, low-set ears and epicanthic folds. Severe cases of LUTO also may develop fetal urinomas or urinary ascites, resulting from rupture of urinary bladder or other parts of the dilated urinary tract. In one study the incidence of urinomas in PUV was reported to be 15%.[64] Postnatally, these patients may have pseudoazotemia secondary to reabsorption of urea nitrogen present in leaked urine in the peritoneal cavity. Concurrent renal maldevelopment, such as dysplasia, is common in patients with LUTO (Figure 47.9), which leads to progressive CKD and ESRD in these children.

Fetal urinary sodium and osmolality can be used to predict fetal outcome in suspected bladder outlet obstruction. Normally, fetal urine sodium concentration is less than 90 mmol/L at 20 to 30 weeks of gestation.[65] Higher fetal urinary sodium values are indicative of deranged tubular functions associated with renal maldevelopment. Similarly, fetal urine osmolality should be less than 200 mOsm/L, and higher values are consistent with significant renal impairment.[66] The sensitivity and specificity of fetal urine chemistries are not ideal, and the results lack predictive value.

POSTNATAL PRESENTATION

A palpable abdominal mass is a common manifestation of obstructive uropathy in an infant or child. Such a mass may represent a large hydronephrotic kidney or an enlarged bladder resulting from LUTO, such as PUV. In older children, other symptoms may include flank pain, incontinence, urinary dribbling, urinary tract infection (UTI),

---

KEY POINTS

- Nephron loss and tubular dysfunction are common accompaniments of congenital obstructive uropathy.
- Renal salt wasting and metabolic acidosis secondary to distal RTA can be seen in obstructive uropathy.
- Pulmonary hypoplasia can be the consequence of fetal urinary obstruction and poor urine output into the amniotic fluid.
Figure 47.8 Fetal ultrasound showing the characteristic findings of "keyhole" sign.

or hematuria as a result of injury to the dilated urinary tract. Patients with imperforate anus or other organ system anomalies should be suspected of having obstructive uropathy. Patients with abnormalities such as preauricular tags or pits, Townes-Brocks syndrome, or branchio-oto-renal syndrome have a higher incidence of renal anomalies, including obstructive uropathy. LUTO is more common in male newborns and should be suspected in a neonate with antenatal diagnosis of bilateral hydronephrosis, or other clinical findings noted in Table 47.3.

Dietl crisis is a unique clinical presentation consisting of recurrent abdominal pain or flank pain seen in patients with undiagnosed UPJ obstruction. These painful crises are

Table 47.3 Clinical features suggestive of lower urinary tract obstruction in neonates, infants, and older children

Neonate
- Male predominance

usually precipitated by increased fluid intake, in vigorous exercise, or when the bladder is full.

DIAGNOSTIC EVALUATION

Postnatal ultrasound

Several diagnostic algorithms have been proposed for evaluation of antenatal hydronephrosis.[66] The initial diagnostic study for patients with antenatal diagnosis of hydronephrosis, or for any infant with a suspicious prenatal ultrasound, should be to obtain a postnatal ultrasound of the kidneys, ureters, and bladder. In general, ultrasonography in newborns should be performed in a well-hydrated state several days after birth, because the degree of hydronephrosis may

be underestimated if urine flow rate is low. Infants with LUTO, on the other hand, should have immediate imaging studies to determine the state of urinary dilatation and degree of hydronephrosis.

Diuretic renography

Intravenous pyelography is indicated only in a rare circumstance in an older infant or child, in whom a better definition of urinary tract anatomy may be needed in preparation for surgical intervention. Most pediatric centers use radionuclide diuretic renography in place of conventional intravenous pyelography to determine the site of urinary obstruction (Figure 47.10). An added advantage of renography is that it provides information on the relative

contribution of each kidney to total renal function. This study should be performed with a bladder catheter in place in the newborn. Unless there is an urgent need, such as in suspected LUTO, diuretic urography also should be delayed until the infant is several weeks of age, because maturation of renal concentration capacity significantly improves the imaging quality.[67]

Contrast cystogram

Contrast voiding cystourethrography (VCUG) is indicated if the diagnosis of PUV is being considered in a male new-born or VUR is suspected (Figure 47.11). Radionuclide cys-togram may provide a lesser degree of radiation to pelvic organs compared to that with contrast VCUG and may be considered in females suspected to have VUR. Interestingly, in patients with UPJ obstruction, VUR is often seen on the opposite-side urinary tract. Magnetic resonance imaging (MRI) offers some promise of enhanced resolution, bet-ter anatomic delineation, and functional information in some patients (Figure 47.12).[68] Although the combination of ultrasonography and renography provides useful diagnostic information in an infant with suspected obstructive uropa-thy, the decision for surgical correction or timing of such surgery is a clinical one that should involve the pediatric nephrologist, urologist, and radiologist.

MANAGEMENT

PRENATAL MANAGEMENT

Fetuses with unilateral hydronephrosis should be moni-tored with serial ultrasound examinations throughout pregnancy, for not only the degree of hydronephrosis but also the volume of amniotic fluid. Fetuses with bilateral hydronephrosis and oligohydramnios should be suspected to have LUTO and are at risk for the development of pulmo-nary hypoplasia. In utero fetal surgical interventions, with the aim of improving renal and pulmonary outcome, and overall fetal survival in severely affected fetuses have been attempted since early 1980s. Such interventions consist of either repeated fetal vesicocentesis procedures or placement of a vesicoamniotic shunt. The aim of such treatments is to decompress the urinary tract and increase the amniotic

fluid volume to prevent associated pulmonary hypoplasia. The results of such interventions, however, have been largely disappointing, with a high incidence of displacement of the catheter, amnionitis, and fetal loss.[69,70]

Despite prenatal vesicoamniotic shunts for LUTO, ESRD developed in 30% of patients after a mean follow-up of only 5.8 years.[71] Even in fetuses with successful retention of the diversion catheter through the pregnancy and nor-mal postnatal pulmonary functions, long-term renal func-tion may still be poor.[64] This is likely due to aberrant renal development in the first trimester, before the kidneys and urinary tract are reliably identified by maternal sonography. Unfortunately, an international prospective randomized trial on the percutaneous vesicoamniotic shunting ver-sus conservative management for fetal lower urinary tract obstruction (PLUTO) had to be terminated early for lack of adequate recruitment of patients.[70]

KEY POINT

Fetal vesicoamniotic shunt placement, although technically feasible, has not succeeded in improving renal survival in antenatal diagnosis of urinary tract obstruction.

POSTNATAL MANAGEMENT

The postnatal management of the infant with obstructive uropathy depends on the specific findings from the imag-ing evaluations described earlier. A management pathway,

based on SFU grading, has been suggested recently by Timberlake and Herndon, and is shown in Figure 47.13.[72]

Ureteropelvic junction obstruction

For the infant with unilateral UPJ obstruction, mild obstruction (without caliectasis) may be followed with sequential renal ultrasound examinations, because many of these patients will undergo progressive and spontaneous improvement of the obstruction.[73] There is considerable controversy about the management of infants with moderate-to-severe UPJ obstruction. Some centers have reported good results with close monitoring over the long term, and others recommend early surgical correction.[73–78]

Based on the principles of pathogenesis outlined earlier and to avoid ongoing renal damage, the truly "conservative" approach in significant UPJ obstruction is to consider an early pyeloplasty.[77,78] Difficulties of subjecting infants to repeated diuretic renography, noncompliance with a rigorous schedule of imaging studies, and the potential for irreversible loss of renal function should be taken into account in the clinical decision-making process.[79] Although most pediatric urologists are reluctant to postpone surgical correction in infants with bilateral UPJ obstruction, Onen et al.[80] advocated nonoperative management with close follow-up during the first 2 years of life. Significant concerns associated with observational approach in bilateral UPJ obstruction, especially the difficulty in compliance with a rigorous imaging schedule, have been stressed by Peters.[81]

Lower urinary tract obstruction

In infants with bilateral hydronephrosis, and in any male infant suspected to have LUTO, a voiding cystogram should be obtained promptly to rule out the possibility of PUV. If the diagnosis of PUV is established, the bladder should be continually drained with a sterile 5-Fr feeding tube and serial plasma creatinine concentration should be measured until it stabilizes.

Many cases of LUTO are associated with VUR or with secondary ureteral obstruction resulting from kinking of the dilated ureters. Pending a complete radiologic evaluation, it is prudent to treat infants with prophylactic antibiotics to minimize the possibility of UTI and septicemia. Oral

amoxicillin, 25 mg/kg daily, should be used in the neonate or infant (unless there are specific contraindications).

To optimize growth, infants with obstructive uropathy may require increased sodium intake or alkali therapy after surgical relief of obstruction, to manage natriuresis or distal RTA seen in these patients.[82] Hyperkalemia may be a feature of distal RTA in some patients and needs to be treated with low-potassium formula feeds and with potassium exchange resins.[58,59]

KEY POINTS

- Neonates with LUTO need relief of obstruction by either cutaneous vesicostomy or PUV ablation.
- Not all patients with unilateral UPJ obstruction need surgical relief. Many can be followed by renal ultrasound and radionuclide scans.
- Medical management includes attention to maintaining fluid, electrolyte, and acid-base balance.
- Prophylactic antibiotics to prevent UTI are generally recommended.

Primary ablation of the PUV is challenging in neonates because of the small urethral caliber, but may be possible in some centers. If valve ablation is not technically feasible in the neonate, a cutaneous vesicostomy may be the bridging drainage procedure of choice, especially in the low-birth-weight neonates. Definitive PUV ablation and closure of the vesicostomy can be attempted at a later age. Bladder dysfunction is common in older children with a history of PUV. Dysfunctional bladder and associated postvoid residual urinary volume in the bladder may lead to recurrent UTIs and persistently dilated urinary tracts. Use of α-adrenergics, has been advocated by some to decrease the postvoid residues, but pediatric use of these drugs in this indication has not yet been approved by the US Food and Drug Administration in the United States. A clean intermittent catheterization trial to keep the bladder in a decompressed state may be considered as the initial intervention in such patients. If successful, Mitrofanoff appendicovesicostomy and augmentation of the bladder may be an option for others with severe bladder dysfunction associated with PUV, especially those being considered for renal transplantation.

LONG-TERM IMPACT OF OBSTRUCTIVE UROPATHIES

Over time, some patients with UPJ obstruction often develop glomerular sclerosis, likely from ongoing hyperfiltration injury.[83,84] Similar morphologic changes have also been noted 1 year after release of transient complete UUO in the neonatal rat.[54] Immediate surgical intervention for relief of urinary obstruction is not generally necessary in most neonates, and follow-up by ultrasound and radionuclide scans is an acceptable strategy, especially in those with mild-to-moderate hydronephrosis.[72] Nevertheless, approximately 20% to 25% of babies born with UPJ require surgical intervention within the first year of life because of progressive increase in hydronephrosis. Kumar et al.[84] reported that in 762 infants with antenatally diagnosed hydronephrosis, 103 patients (13.5%) had severe hydronephrosis (anteroposterior diameter [APD] of >15 mm). UPJ obstruction was confirmed in 48 cases, of which 10 (20.8%) required surgical intervention within the first year of life.[84]

It is important to note that renal function may not normalize despite pyeloplasty in patients with severe UPJ obstruction.[86,87] In a long-term follow-up study of children after pyeloplasty for unilateral UPJ obstruction, Boubaker et al.[87] noted that despite renal function (measured by radionuclide renography) improvement in all but one patient, 14 of 33 patients developed CKD.[7]

KEY POINT

Patients with obstructive uropathy need to be monitored for evolution of CKD over the long-term horizon.

For patients with PUV and other types of bladder outlet obstruction, continued monitoring of renal function is essential. Despite surgical correction of the obstruction, many of the prenatally diagnosed PUV patients develop CKD in the second decade of life (Figure 47.14). Roth et al.[88] reported that over a mean follow up of 11.3 ± 2.1 years, 7 of the 10 (70%) patients surgically treated for PUV as infants developed ESRD. In a Finnish study, Heikkilä et al.[89] followed 193 boys treated for PUV as infants into adulthood
Figure 47.14 Progression of chronic kidney disease in a patient with posterior urethral valve (PUV). Serum creatinine concentration is plotted against time in years. After surgical relief of PUV, patient's serum creatinine remained below 1 mg/dL for a decade before he developed pyelonephritis. Despite effective treatment of infection he continued to have worsening renal function and developed end-stage renal disease. (Figure courtesy of Robert Chevalier, MD.)

(median age 31 years). Of these, 44 (22.8%) patients progressed to ESRD. Lifetime risk for ESRD in these patients was 28.5% (standard error 3.8%).

In another study of 312 children with CAKUT followed for a median of 6 years (2 to 30 years), the risk for ESRD was highest in patients with PUV (Figure 47.15).[8] Correlation of the timing of diagnosis of PUV with outcome has been evaluated in several studies. Diagnosis after age 1 year is associated with better renal function outcome and risk for ESRD.[90] It has been suggested that prenatal presentation may represent more severe form of the obstructive uropathy and this may be associated with a significant degree of renal dysplasia in these patients.[91] Some studies have noted that a nadir serum creatinine greater than 1 mg/dL after PUV surgery, presence of bladder dysfunction, and VUR may be additional factors associated with risk for ESRD.[92]

CLINICAL FOLLOW-UP

Clinical follow-up of infants and children with obstructive uropathy should include regular monitoring of blood pressure, urinalysis, renal function by plasma creatinine concentration or cystatin C, and renal ultrasound (Table 47.4). Urine culture may be considered, if clinically indicated, and individualized strategies to minimize urinary tract infections need to be considered. Renal ultrasound permits evaluation of renal growth, as well as assessing the progress of hydronephrosis. Monitoring the rate of growth of the normal contralateral kidney, representing compensatory hypertrophy, has been suggested as an index of functional impairment of the obstructed kidney.[93,94] It is important to emphasize that serial measurements are necessary to detect the subtle changes in renal dimensions over time.[95,96] Radionuclide renal scans with diuretics may be indicated for following renal function and determining the degree of urinary obstruction in some patients.

The patient family should also be counseled to maintain adequate hydration and sodium repletion in the patient, particularly during hot weather. Use of nephrotoxic drugs, such as nonsteroidal anti-inflammatory compounds, should be avoided. Likelihood of progression of renal disease and development of CKD, regardless of the time of diagnosis and surgical intervention, should be discussed with the parents of children with congenital urinary obstruction. Although patients with obstructive uropathy often suffer from urinary sodium wasting secondary to tubulointerstitial dysfunction, children with intermittent complete obstruction resulting from severe UPJ stenosis can develop hypertension.[97] Hypertension in such cases may result from progressive interstitial fibrosis or glomerular sclerosis. Hypertension is, by itself, a determinant of progression of renal disease; therefore, it is critical to monitor blood pressure and to treat hypertension appropriately.

Table 47.4 Principles of follow-up of congenital obstructive uropathy

- Monitor blood pressure and prevent hypertension
- Monitor urinary protein excretion and urinalysis
- Monitor renal function (serum creatinine or cystatin-C concentration)
- Renal ultrasound
- Prevent urinary infection
- Avoid dehydration
- Avoid use of nonsteroidal anti-inflammatory drugs
Figure 47.15 Survival probabilities by CAKUT category, adjusted for the concomitant presence of vesicoureteral reflux, time varying values of serum creatinine (mg per 100 mL) and proteinuria (X1 g/day vs. less), and referral period (before 1990 vs. 1990 and thereafter). (Reproduced with permission from: Sanna-Cherchi S, Ravani P, Corbani V, et al. Renal outcome in patients with congenital anomalies of the kidney and urinary tract. Kidney Int. 2009;76:528–33.)

PREVENTING PROGRESSION

Emerging evidence suggests that the patient's genotype is a significant determinant of renal disease progression and *ACE* gene polymorphisms can have a profound impact on the rate of renal disease progression.[98] Angiotensin II and hypertension are risk factors for proteinuria associated with progressive renal disease, and proteinuria itself may further accelerate glomerular and tubular injury.[99] Since the intrarenal RAS is highly activated in obstructive uropathy, inhibition of angiotensin by ACE inhibitors or angiotensin receptor blockers (ARBs) can have a salutary effect on both the hemodynamic and the fibrotic consequences of chronic urinary tract obstruction (Table 47.5). Inhibition of angiotensin can impair normal renal development and maturation through the period of infancy, especially in premature infants.[100,101] In addition, RAS inhibition can markedly reduce intraglomerular pressure and GFR in neonates and infants, necessitating close monitoring.[102,103]

PROTEOMIC TOOLS FOR MONITORING PROGRESSION

Renal histology and ultrasonographic findings in infants and children with obstructive uropathy correlate poorly with renal function.[104] It is also well accepted that plasma creatinine concentration and urine protein excretion are relatively insensitive markers for CKD resulting from obstructive uropathy. Abnormalities in serum concentrations in these patients are noted only with significantly advanced renal disease. Prospective urinary proteome analysis in neonates with congenital obstructive uropathy is a promising technology that may allow early detection and a more accurate follow-up of progression of CKD in these patients.[1,105]

As shown in Figure 47.5, TGF-β1 plays a central role in the pathophysiology of obstructive uropathy, and the expression of this cytokine is increased in dysplastic renal tubules.[106] Urinary excretion of TGF-β1 may be able to identify patients with early renal tissue injury secondary to urinary tract obstruction, even when it is unilateral (Figure 47.16).[107] L1 cell adhesion molecule (L1CAM) is another biomolecular marker that might be important in correlating renal injury with renal functional impairment. In boys with PUV, urinary TGF-β1 and L1CAM have been shown to be significantly increased and correlated negatively with GFR.[108] Other candidate biomarkers in the urine include monocyte chemoattractant protein-1 (MCP-1), which is increased in patients with UPJ obstruction and EGF, which is decreased in UPJ obstruction.[109] An inverse correlation of SFU grade of hydronephrosis and urinary EGF has been demonstrated, suggesting a possible use as a predictor of progression in obstruction.[110] Urinary kidney injury molecule-1 (KIM-1) and neutrophil gelatinase–associated lipocalin also may be potential predictors of progression of obstructive uropathy, even when renal function by conventional techniques is normal.[111]

Table 47.5 Therapeutic consequences of renin-angiotensin system inhibition in congenital obstructive uropathy

Advantages
- Control hypertension
- Reduce proteinuria
- Attenuate fibrosis

Disadvantages
- Impair renal development
- Reduce glomerular filtration rate
- Exacerbate sodium wasting

SUMMARY

Given the broad spectrum of CAKUT in children and the variable clinical impact of different forms of obstructive uropathy, ranging from mild clinically asymptomatic cases to severe kidney injury manifesting before or after birth, each patient with obstructive uropathy requires individualized clinical management. Because morbidity in mild cases of obstructive uropathy may not manifest until later in life, these patients should be closely followed throughout life. Medical monitoring should include diet, nutritional status, growth, blood pressure, renal function, proteinuria, and urinary tract imaging. Close partnership between the pediatric nephrologist and pediatric urologist is essential to integrating medical and surgical management, as well as transition to appropriate specialists when the patient reaches adulthood. New biomarkers are needed to better assess disease progression and therapeutic strategies to slow progression of renal injury. Genetic counseling is recommended for all patients with familial cases of isolated obstructive uropathy, obstructive uropathy associated with other types of CAKUT, or newly diagnosed forms of obstructive uropathy that suggest the presence of genetic anomalies. Introduction of more sensitive array-based methods that allow screening for multiple gene mutations and unraveling a complex network of molecular interactions will help determine and predict occurrence and consequences of obstructive uropathy. Finally, establishment of shared large biorepositories of patients with obstructive uropathy/CAKUT for molecular, genetic, and translational studies will have a major impact on designing novel strategies to predict, prevent, and manage these malformations.
Figure 47.16 Mean urinary transforming growth factor-β (TGF-β_1) concentration in children with upper tract urinary obstruction versus controls, as corrected for creatinine (Cr). Bladder urine TGF-β_1 in obstructed group was four-fold that in control group. In the obstructed group, mean renal pelvic urine TGF-β_1 was twofold that in bladder urine. Bars represent mean ± standard error of the mean SEM. (Reproduced with permission from: Furness PD, III, Maizels M, Han SW, et al. Elevated bladder urine concentration of transforming growth factor-beta1 correlates with upper urinary tract obstruction in children. J Urol. 1999;162:1033–6.)

Figure 47.17 Contrast voiding cystourethrogram (VCUG) shows **(a)** a large urinary bladder with a highly trabeculated wall and **(b)** dilated posterior urethra.

Clinical Vignette 47.1

A male infant with antenatal diagnosis of bilateral hydronephrosis and oligohydramnios was born at 37 weeks of gestation and birth weight of 2.7 kg. On day 1 of birth he developed right-sided pneumothorax and voided normally. Postnatal ultrasound demonstrated bilateral severe left hydroureter. A VCUG established the diagnosis of PUV. He also had bilateral severe VUR, grade 5/5 on the left side and 4/5 on the right side. At 2 weeks his blood urea nitrogen (BUN) was 30 mg/dL, serum creatinine 1.8 mg/dL, and serum electrolytes normal. Transurethral PUV ablation was done successfully at 2 weeks of life. He was started on Similac PM 60/40 formula, alkali supplements, and calcitriol. Prophylactic antibiotics for prevention of UTI consisted of amoxicillin initially and trimethoprim-sulfamethoxazole subsequently. The patient was followed in the outpatient clinic.

Height and weight remained at approximately the 2nd percentile. He developed one episode of UTI at 4 years of age. The patient was lost to follow-up at 5 years of age. At 8 years of age he presented with urinary incontinence at school and being "smelly" in the classroom. He also had nocturnal enuresis. Examination showed height in the 2nd percentile and weight in 4th percentile. Blood pressure was normal for age (110/67 mm Hg). A large bladder mass filling the suprapubic area up to the umbilicus was noted on abdominal palpation. A VCUG test

demonstrated a large urinary bladder with a highly trabecular wall (Figure 47.17). Severe VUR persisted bilaterally, being worse on the left side. Electrolytes demonstrated sodium, 139 mmol/L; potassium, 4.5 mmol/L; chloride, 102 mmol/L; bicarbonate, 19 mmol/L; BUN, 24 mg/dL; creatinine, 1.7 mg/dL; calcium 8.6 mg/dL; phosphorus 5.4 mg/dL; and parathyroid hormone, 294 pg/mL. Estimated GFR (using the Schwartz equation) was 38 mL/min/1.73 m^2. Urodynamic studies showed bladder capacity of 340 mm^3/mL; voiding pressure was elevated at 98 cm H$_2$O and after voiding. The patient was restarted on erythropoietin for anemia, growth hormone for poor linear growth, calcitriol, alkali supplementation, and nutritional counseling. The patient was trained to do intermittent clean urethral catheterization, which provided relief from incontinence and symptoms of being "smelly" in the classroom. Nocturnal enuresis has also improved. At 11 years of age, he underwent a Mitrofanoff appendicovesicostomy procedure to facilitate urinary catheterization. At 12.5 years of age, his GFR declined and he was started on peritoneal dialysis.

TEACHING POINTS

- This case traces the clinical course of a patient with PUV from antenatal diagnosis to the point of initiation of dialysis. The diagnosis of PUV was suspected because of bilateral hydronephrosis, and the diagnosis was confirmed postnatally by renal ultrasound and a VCUG.
- Despite a successful PUV ablation at 2 weeks of age, the patient continued to have abnormal renal function and CKD. Unfortunately, he was lost to follow-up and later presented with symptoms of bladder dysfunction (incontinence), in addition to CKD, growth failure, and anemia.
- Treatment of bladder dysfunction with intermittent catheterization resulted in improvement of clinical symptoms, but his CKD continued to progress.

- This case demonstrates the need for long-term follow-up of patients with obstructive uropathy, and interventions for treatment of CKD that may be necessary throughout the childhood and adolescence.

REVIEW QUESTIONS

1. The *most* common cause of antenatal obstructive uropathy is:
   a. Posterior urethral valves
   b. Vesicoureteric reflux
   c. Ureterovesicular junction obstruction
   d. Ureteropelvic junction obstruction

2. Routine antenatal ultrasound detects most cases of antenatal hydronephrosis.
   a. False
   b. True

3. In prenatally detected hydronephrosis, no evidence of urinary tract obstruction is seen in:
   a. 10%
   b. 90%
   c. 50%
   d. 30%

4. A prenatal ultrasound in a male fetus demonstrate bilateral hydronephrosis and a thickened bladder wall. A diagnosis of posterior urethral valves is being entertained. The most important clinical concern in the neonatal period in this patient will be:
   a. Reduced nephron mass
   b. Urinary tract infection
   c. Pulmonary hypoplasia
   d. Diaphragmatic hernia

5. Risk for CKD and ESRD risk in patients with posterior urethral valves is determined by:
   a. Severity of hydronephrosis
   b. Severity of renal dysplasia
   c. Frequency of urinary tract infections
   d. Amniotic fluid sodium concentration

6. A male baby at the age of 37 weeks of gestation is born via cesarean section delivery and requires mechanical ventilation after resuscitation. His mother had poor prenatal follow-up, and there is no record of her having had any prenatal ultrasound evaluations. The patient developed right-sided pneumothorax on day 2. He did not urinate for 12 hours, urinary bladder catheterization was done, and an

indwelling catheter was left in place. Renal ultrasound showed bilateral hydronephrosis, bilateral hydroureters and a distended urinary bladder with thickened wall. The *most* important next investigative step in this patient should be:

a. Monitor renal ultrasound for worsening of hydronephrosis
b. Monitor serum creatinine for renal function
c. A DMSA renal scan
d. A nuclear cystogram
e. A contrast vesicocystourethrogram

7. Following are the features of lower urinary tract obstruction in neonates, *except:*
a. Hematuria following birth
b. Bilateral antenatal hydronephrosis
c. Hypospadias
d. Fetal or neonatal urinary ascites

8. Urinary incontinence is a clinical manifestation of lower urinary tract obstruction:
a. True
b. False

9. Of prenatally detected cases of pyelectasis/hydronephrosis, 50% to 70% are due to:
a. Ureteropelvic junction obstruction
b. Vesicoureteric reflux
c. Transient or physiologic neonatal changes
d. Potter syndrome

10. Which of the following disorders can mimic hydronephrosis in an antenatal sonogram?
a. Multicystic dysplastic kidney
b. Megaureter
c. Large renal cysts
d. All of the above

11. A 6-year-boy complains of right-side abdominal pain every time he goes out with his parents for dinner or when parents give him a small carton of juice to drink. He was seen today in the emergency room with severe right flank pain. Because of concern about a renal colic, the staff started him on ½ normal saline an intravenous infusion at 1.5 times maintenance. Within a half-hour after infusion being started, his flank pain worsened, requiring morphine for adequate pain control. His urinalysis showed: pH 6.5, specific gravity 1.015, no protein, no blood, nitrate negative, and leukocytes negative. Renal ultrasound shows a severe right-side hydronephrosis. The child has which of the following?
a. Acute appendicitis
b. Renal colic
c. Dietl crisis
d. Recurrent colonic volvulus

12. Diagnosis of posterior urethral valves in a male after 1 year of age is associated with:
a. Better overall prognosis for renal function and ESRD compared to neonatal diagnosis
b. Worse overall prognosis for renal function and ESRD compared to neonatal diagnosis

ANSWERS

1. d

Vesicoureteral reflux

TEJ K. MATTOO

Vesicoureteral reflux (VUR) denotes the retrograde flow of urine from bladder to the kidneys, most commonly the result of anatomic abnormality of vesicoureteral junction with shortening of intravesical submucosal length of the ureter. VUR may be an isolated abnormality (primary VUR) that is diagnosed mostly after urinary tract infection (UTI). Primary VUR is predominantly seen in white children. Indeed, 81% of the 607 patients in the Randomized Intervention in Children with VUR (RIVUR) study were white.[1] Primary VUR is also diagnosed during postnatal follow-up of antenatally diagnosed hydronephrosis or screening a sibling of a patient with VUR. VUR also occurs in association with other congenital anomalies of the kidney and urinary tract, including renal dysplasia, and can occur in association with obstructive uropathy or neurogenic bladder (secondary VUR).

EPIDEMIOLOGY

The prevalence of primary VUR varies from 1.3% of healthy children to 8% to 50% of children evaluated after UTI.[2–5] In newborns and infants, the incidence of VUR diagnosed after UTI is 36% to 49%.[6–8] Children with VUR detected after UTI are predominantly females, although in some studies no gender difference or even male predominance has been reported.[3,4,9,10–12] VUR is less common in African-American children.[13,14] High prevalence of VUR in whites is well known and was also documented in the RIVUR study.[1] Moreover, only approximately one-third as many African-American as white girls with UTI have VUR, but there are no significant differences in age or mode of presentation between the two races.[13,16] Interestingly, in comparison to white children, VUR is generally less severe in African-American children.[17]

In patients with prenatally detected hydronephrosis, postnatal evaluation reveals the presence of VUR in 10% to 30% of infants and the incidence is higher in boys.[18,19] The reported incidence of VUR in asymptomatic siblings of index cases is 32% to 45%.[20,21] The incidence of VUR in the offspring of parents with known VUR in one study was 66%, suggesting high likelihood of parent-to-child transmission.[22]

KEY POINT

Vesicoureteral reflux is less common in African-American children.

DIAGNOSIS AND GRADING

The diagnosis of VUR is based on the demonstration of reflux of urine from the bladder to the upper urinary tract by either contrast voiding cystourethrogram (VCUG) or radionuclide cystogram (RNC). Contrast VCUG is preferable, particularly in males and as the initial study, because it allows more precise grading of VUR and helps evaluate lower genitourinary tract anatomy.
Figure 48.1 International Reflux Study grading system for vesicoureteral reflux. Grade I: Reflux into nondilated ureter. Grade II: Reflux into the renal pelvis and calyces without dilatation. Grade III: Mild/moderate dilatation of ureter and pelvicalyceal system. Grade IV: Dilation of the renal pelvis and calyces with moderate ureteral tortuosity, blunting of fornices. Grade V: Gross dilatation of the ureter, pelvis, and calyces; ureteral tortuosity; loss of papillary impressions. (Reproduced with permission from: Gargollo PC, Diamond DA. Therapy Insight: what nephrologists need to know about primary vesicoureteral reflux. Nat Clin Pract Nephrol. 2007;3:551–63.)

The grading system used most widely for classifying the severity of VUR was proposed by the International Reflux Study in Children (IRSC).[23] It classifies VUR into the following five grades based on appearance in contrast VCUG (Figures 48.1 and 48.2):

Grade I: Reflux into the ureter
Grade II: Reflux into the renal pelvis, without any dilation of the calyces
Grade III: Reflux to the renal pelvis with mild dilation of the renal pelvis
Grade IV: Reflux to the renal pelvis with greater dilation of the renal pelvis
Grade V: Reflux includes reflux to the renal pelvis with ureteral and pelvic dilation

Intrarenal reflux (IRR) is the condition in which the contrast flows backward from the renal pelvis into the collecting tubules (pyelotubular backflow). IRR is usually present in conjunction with high-grade VUR (Figure 48.3).

The degree of reflux seen in the VCUG may be modified by how aggressively the bladder is filled during VCUG, by both volume and as rapidity. Sometimes, ureteral dilatation may be present without calyceal dilation, leading to difficulties with grading. The severity of VUR in RNC (Figure 48.4) is usually classified as mild (grades I and II), moderate (grade III), and severe (grades IV and V).

NATURAL HISTORY

Primary VUR generally improves with time; this is attributed to the lengthening of the submucosal segment of the ureter.[24] The reported rate of improvement is not consistent because of differences in patient selection, definition of resolution, duration of follow-up, and use of single versus two negative VCUGs to confirm resolution of VUR. The Birmingham Reflux Study, which used single negative VCUG, reported approximately 50% cessation of VUR after 5-year follow-up in medically managed moderate-to-severe VUR.[25] In the International Reflux Study in Children (IRCS), which used two consecutive negative VCUGs, the corresponding number was 25.0%.[26] In a study by Wennerstrom et al.,[4] the end point of reflux grade I or less was reached in approximately 75% of children after 10 years of follow-up. The rate of resolution is higher in younger children. In a 5-year follow-up study in children younger than 5 years old, including 60% younger than 2 years, grade I VUR resolved in 82%, grade II in 80%, and grade III in 46% of the ureters.[6]

The important factors identified with resolution of VUR are nonwhite race, lower grades of reflux, absence of renal damage, and lack of voiding compared to high-grade VUR. The IRSC reported that VUR disappeared in more than 80%
Figure 48.2 VUG images showing different grades of VUR, scored by the International Reflux Study grading system. (Figures courtesy of Dr. Eglal Shalaby-Rana, Children's National Medical Center, Washington, DC.)
Figure 48.3 Intrarenal reflux. (Figure reproduced with permission from: Yüksel S. Intrarenal reflux. Clinical Kidney Journal 2008; 1: 188-189.)

of undilated and approximately 40% of dilated ureters.[3] Schwab et al.[28] reported that grades I to III VUR resolve at a rate of 13% per year for the first 5 years of follow-up and 3.5% per year during subsequent years, whereas grades IV and V VUR resolve at a rate of 5% per year. In the IRSC, resolution of VUR was significantly better in grade III versus grade IV VUR.[29] A systematic review of published literature
Figure 48.4 Radionuclide cystogram showing bilateral severe vesicoureteral reflux. (Figure courtesy of Dr. Eglal Shalaby-Rana, Children's National Medical Center, Washington, DC.)

on the resolution of VUR concluded that increasing age at presentation and bilateral VUR decrease the probability of resolution, and bilateral grade IV VUR has a particularly low chance of spontaneous resolution.[30] In one study, the mean time until spontaneous resolution in black children was 14.6 months, which was significantly shorter than the mean of 21.4 months in white children.[16]

VUR diagnosed because of antenatal hydronephrosis has a high a high rate of spontaneous resolution (59% by age 4 years), even in those with grades IV and V reflux.[31]

Review of the natural history of VUR in siblings indicated that 52% had resolution of the reflux at follow-up of 18 months, with yearly resolution rates of 28%.[32]

KEY POINT

VUR diagnosed in response to antenatal hydronephrosis has a high rate of spontaneous resolution.

CLINICAL MANIFESTATIONS

URINARY TRACT INFECTION

By itself, VUR is usually asymptomatic, but an increased risk for febrile UTI (acute pyelonephritis) in these patients is well established.[33,34] Indeed, initial discovery of VUR in many of these patients occurs after a febrile UTI. The majority of children diagnosed with VUR after UTI are girls, but there is no gender difference in infants younger than 6 months of age.[35]

DYSFUNCTIONAL ELIMINATION SYNDROME

The symptoms of dysfunctional elimination syndrome (DES) include daytime wetness, urgency, frequency, infrequency, constipation, or fecal incontinence in toilet-trained children with no underlying anatomic or neurologic abnormality.[36–38] Toilet-trained children diagnosed with VUR following a UTI have a high association (43%) with DES.[38] Voiding dysfunction in these children is likely to predispose them to recurrent UTI, worsening or delaying resolution of VUR and increasing risk for renal scarring.[39,40] In a study by Koff et al.,[38] DES, besides increasing the rate of breakthrough UTI, delayed resolution of reflux. DES also adversely affected the results of surgical ureteric reimplantation in this study. In another study that involved use of a questionnaire in 310 children enrolled in the European branch of the IRSC, a strong negative correlation was seen between recurrences of UTIs, as well as disappearance of VUR, and non-neuropathic bladder or sphincter dysfunction (equivalent of DES).[41]

Constipation, as an isolated finding or as part of the DES, results in compression of the bladder and bladder neck, increasing bladder storage pressure and postvoid

residual urine volume. Also, distended colon, soiling, or both provides an abundant reservoir of pathogens.[42–44] By these mechanisms, constipation increases the likelihood of urinary incontinence, bladder overactivity, dyscoordinated voiding, a large capacity and poorly emptying bladder, recurrent UTI, and deterioration of VUR.[45] In a study that involved 366 children, constipation, encopresis, or both was reported in 30% cases, daytime wetting in 89%, nighttime wetting in 79%, and recurrent UTI in 60% of the patients. VUR was present in 20% of the patients.

RENAL SCARRING

Renal scarring seen in conjunction with VUR is termed *reflux nephropathy* (RN). Although most commonly seen in patients with acute or chronic pyelonephritis (Figure 48.5), RN also may be of congenital origin. Differences between the two forms of RN are outlined in Table 48.1.

The risk for renal scarring following acute pyelonephritis is 5% to 10%.[46,47] In children with VUR and UTI, however, the incidence of renal scarring is significantly higher, at 30% to 56%.[48–50] A systematic review of 23 studies that included a total of 2106 children with renal scarring after pyelonephritis from across the world revealed the incidence of RN to be 48.5%.[9] The prevalence of renal scarring in healthy populations is not known. In a study in healthy children and adolescents who were evaluated for newly diagnosed hypertension, the dimercaptosuccinic acid (DMSA) renal scans revealed renal scarring in 33 (21%) of 159 patients.[51] In a study in adults with hypertension, radionuclide VCUG

KEY POINT

Reflux nephropathy may be congenital or acquired secondary to scarring from UTIs.
Figure 48.5 Dimercaptosuccinic acid (DMSA) renal scan demonstrating upper and lower pole scarring (arrows) in the right kidney (R). The left kidney (L) is normal. (Figures courtesy of Dr. Eglal Shalaby-Rana, Children's National Medical Center, Washington, DC.)

Table 48.1 Congenital versus acquired reflux nephropathy in children

	Acquired RN	Congenital RN
Time of occurrence	Postnatal	Prenatal
UTI before diagnosis	Common	Uncommon
Age distribution	All pediatric age groups	Mostly in younger children
Gender distribution	Predominantly females	Predominantly males
Grade of VUR	Mostly high-grade	Mostly high-grade
Dysplastic features on renal histopathology	No	Yes

Source: Adapted from Mattoo TK. Vesicoureteral reflux and reflux nephropathy. Adv Chronic Kidney Dis. 2011;18: 348–54.

Abbreviations: RN, reflux nephrology; UTI, urinary tract infection; VUR, vesicoureteral reflux

revealed VUR in 30 of 157 (19.1%) of the patients.[52] Of the 30 patients, 7 (23%) had bilateral VUR that was graded as severe. Congenital RN in association with VUR has been reported in 30% to 60% of such children, most of whom are diagnosed during follow-up for antenatal hydronephrosis.[53–55]

The relative risk for renal scarring in children with VUR after acute pyelonephritis is 2.6 (95% confidence interval [CI], 1.7 to 3.9) compared to those with no VUR.[33] Children with VUR grades III or higher are more likely to develop scarring than children with lower VUR grades (relative risk [RR], 2.1; 95% CI, 1.4 to 3.2]).[33] Renal injury is more common in infants because of their unique kidney papillary morphology.[56,57] The International Reflux Study reported that renal injury is more frequent in children younger than 2 years old, particularly in the presence of high-grade VUR.[58] A comprehensive literature review on febrile UTI in children by the Committee on Quality Improvement (Subcommittee on Urinary Tract Infection) of the American Academy of Pediatrics identified children younger than 2 years old as being at highest risk for renal injury with febrile UTI.[59] The risk is aggravated by diagnostic challenges, nonspecific clinical presentation, difficulties in getting urine specimens, and a higher prevalence and severity of VUR in smaller children. Other factors that affect the probability of renal scarring in children with VUR and UTI include delayed treatment of UTI, recurrent UTI, and bacterial virulence.[60–64] Finally, there is evidence that genetic factors predispose patients with VUR to scarring, as demonstrated by studies of angiotensin-converting enzyme (ACE) gene polymorphisms.[65,66]

The complications of renal scarring are well known but poorly defined because of their insidious onset, slow progression, and a lack of well-designed prospective studies in children, as well as in adults. Hypertension and proteinuria are

the most common reported complications. Other complications include focal segmental glomerulosclerosis (FSGS), urine concentration defects, hyperkalemia, and acidosis.[44,45]

HYPERTENSION

Hypertension occurs in 17% to 30% of pediatric patients and 3% to 38% of adult patients with renal scarring.[9,48,67,68] Simoes e Silva et al.[69] found that 3% of patients with VUR developed hypertension during childhood, but survival analysis of data suggested that 50% of patients with unilateral or bilateral renal damage were expected to develop sustained hypertension later in adult life. In a follow-up lasting 15 years in pediatric patients with renal scarring, approximately 13% of patients at ages 20 to 31 years were noted to be hypertensive.[70] In another 5-year prospective study of patients with long-standing RN, there was no correlation between blood pressure and plasma renin activity, plasma creatinine concentration, or degree of scarring.[71] Some studies have, however, reported no increase in BP after many years of follow-up.[72,73]

PROTEINURIA

Overt proteinuria, which has been reported in 21% of adult patients with RN, is rare in pediatric patients.[74] Significant degrees of microalbuminuria, an indicator of glomerular damage at a very early stage, have been reported in patients with renal scarring and precede the development of overt proteinuria.[75] Patients with RN also have increased urinary excretion of low-molecular-weight proteins (LMWPs) such as β_2-microglobin, retinol-binding protein, α_1-microglobin, and N-acetyl-β-D-glucosaminase. Microalbuminuria occurs around the same time or soon after the appearance of LMWPs in urine. Urinary albumin excretion increases with the severity of renal scarring.[75,76] FSGS is known to occur in patients with RN.[76] FSGS is progressive and can occur in nonscarred parts of the kidney or in the normal contralateral kidney in patients with unilateral RN.[77]

KEY POINT

Hypertension and proteinuria are the most common complications of renal scarring.

CHRONIC KIDNEY DISEASE

Renal scarring is responsible for 5% to 10% of pediatric and adult cases of end-stage renal disease. According to 2008 North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) report, RN is the fourth most common cause of chronic kidney disease (CKD) in 8.4% of the children and is present in 5.2% of transplanted patients and 3.5% of dialysis patients.[78] In the Chronic Kidney Disease in Children (CKiD) study following a cohort of 586 children aged 1 to 16 years with an estimated glomerular filtration

rate (GFR) of 30 to 90 mL/min/1.73m², RN was the underlying cause of CKD in 87 (14.8%) patients, constituting 19% of the patients with a nonglomerular etiology of CKD.[79]

ADULTS DIAGNOSED IN CHILDHOOD

Adults who develop renal scarring secondary to VUR are at risk for developing renal disease and hypertension as adults. In a study of 21 adults (mean age, 23.9 years) with gross VUR diagnosed in infancy, proteinuria and renal insufficiency were diagnosed in 3 of the 13 patients (23%) with unilateral RN and 2 of the 4 patients (50%) with bilateral RN.[80] In another study of 127 adults (mean age, 41 years) with VUR diagnosed during childhood, 44 (35%) had unilateral renal scarring and 30 (24%) had bilateral renal scarring.[81] Of these, 30 patients (24%) had albuminuria and 14 (11%) had hypertension. Of the 30 patients with bilateral renal scars, 25 (83%) had an abnormal GFR.[81] Renal scarring also may cause pregnancy-related complications such as recurrent pyelonephritis, hypertension, toxemia of pregnancy, babies with low birth weight, and miscarriage.[82–84]

MANAGEMENT

The two main treatment modalities that have been practiced for more than three decades in the management of VUR are long-term antimicrobial prophylaxis and surgical correction. A third, more recent option is surveillance, with no routine prophylaxis or surgical intervention. Surgical correction of VUR was common until the concept of antimicrobial prophylaxis for childhood UTI was introduced in 1975.[85] Numerous subsequent studies established that medical management of VUR is as good as the surgical treatment, and there is no significant outcome difference between the two treatment approaches.[25,58,86–89]

ANTIMICROBIAL PROPHYLAXIS

The antimicrobial agents most appropriate for prophylaxis include trimethoprim-sulfamethoxazole (TMP-SMX), trimethoprim alone, nitrofurantoin, and cephalexin. For infants younger than 2 months, ampicillin or amoxicillin is preferable for prophylaxis. The prophylactic dose of antimicrobials is one-fourth to half of the therapeutic dose for acute infection.[59,90] The dosage for commonly used antimicrobials is shown in Table 48.2. In toilet-trained children, the medication is generally administered at bedtime, although this recommendation is not evidence-based.

Follow-up of patients with VUR-associated UTI requires close monitoring, early detection and prompt treatment of UTI, change of antimicrobial prophylaxis if the patient has recurrent breakthrough UTI, and monitoring of the VUR by periodic VCUG or RNC examinations. The timing of follow-up VCUG is not well defined, but studies have suggested time intervals of 12 to 24 months. The duration of antimicrobial prophylaxis and the potential surgical

Table 48.2 Prophylactic antimicrobial agents

Antibiotic	Dose
Trimethoprim (TMP)-sulfamethoxazole	2 mg TMP/kg/day daily
Nitrofurantoin	1-2 mg/kg/dose daily
Cephalexin	10 mg/kg/dose daily
Amoxicillin	10 mg/kg/dose daily

Source: Adopted from Saadeh SA, Mattoo TK. Managing urinary tract infections. Pediatr Nephrol. 2011;26:1967–76.

intervention depends on the age of the patient, severity of the VUR, frequency of UTI, and degree of renal scarring, if present. Cessation of antimicrobial prophylaxis after age 5 to 7 years, even if the low-grade VUR persists, has been recommended by some.[91]

> ## KEY POINT
>
> Management options for VUR include surgical correction, antibiotic prophylaxis, and surveillance.

Limitations of prophylactic antimicrobials

Long-term antimicrobial prophylaxis has its limitations. Antimicrobial prophylaxis is not always effective, and breakthrough UTI rates in children with VUR range from 25% to 38%.[25,92] Antimicrobial resistance is a major concern with long-term antimicrobial prophylaxis. In one study, children who received the medication for more than 4 weeks in the preceding 6 months had more resistant *Escherichia coli* than those not on such treatment (odds ratio [OR], 13.9; 95% CI,

8.2 to 23.5).[93] Approximately 10% of children on long-term prophylaxis have adverse reactions, most of which occur within the first 6 months. These include gastrointestinal symptoms, skin rashes, hepatotoxicity, and hematologic complications with TMP-SMX, and mostly gastrointestinal symptoms with nitrofurantoin. More adverse reactions such as marrow suppression and rarely Stevens-Johnson syndrome also may occur with TMP-SMX.[94,95] Compliance for daily administration of the medication over a prolonged period also remains a concern. In one study, 97% of the parents reported compliance with low-dose daily antimicrobial prophylaxis and yet excretion of the antimicrobial agent in urine was found in only 31% of the patients' urine.[96]

> ## KEY POINT
>
> Antibiotic prophylaxis increases the risk for resistant organisms.

Controversies in prophylactic antimicrobial use

Systematic reviews of published literature have raised serious questions about the role of antimicrobial prophylaxis in VUR.[97–99] A Cochrane review in 2006 identified eight randomized studies (618 children) that compared antibiotics with placebo or no treatment to prevent recurrent UTI. This analysis demonstrated that prophylactic antibiotics decreased the risk for positive urine culture compared to a placebo. However, the authors concluded that more evidence in the form of properly randomized double-blind trials was necessary to support the routine use of antibiotic prophylaxis in preventing recurrent UTI.[100]

Table 48.3 Recent randomized trials on antimicrobial prophylaxis in vesicoureteral reflux with urinary tract infection

Author (yr)	Patient age	Total number of patients in study	VUR status	Number of patients with VUR	VUR grade	Follow-up (mo)
Garin et al. (2006)	1 mo–18 yr	218	±VUR	113	I–III	12
Roussey-Kesler et al. (2008)	1 mo–3 yr	225	+VUR	225	I–III	18
Pennesi et al. (2008)	0–30 mon	100	+ VUR	100	II–IV	24–48
Montini et al. (2008)	2 mo–7 yr	338	±VUR	128	I–III	12
Craig et al. (2009)	0–18 yr	576	±VUR	243	I–V	12
Swedish Reflux Trial (2010)	1–2 yr	203	+VUR	203	III–IV	24
RIVUR Study	2–71 mo (6 yr)	607	+VUR	607	I–IV	24

Several randomized trials (see Table 48.3) have investigated the utility of antimicrobial prophylaxis for UTI.[88,101–105] Overall, these studies included patients from 0–18 years of age, with grades 0-V VUR. Three studies included children with and without VUR.[101,104,105] Garin et al.[101] and Montini et al.[104] reported no benefit with prophylaxis in children with and without VUR (grades I to III), The study by Craig et al.,[105] which was placebo-controlled, showed a reduction in the absolute risk for UTI (6 percentage points) that did not vary with any stratifying variable (age, sex, reflux status, history of more than one UTI, or susceptibility of the causative organism for TMP-SMX).[105] The other randomized trials of antimicrobial prophylaxis for UTI included only patients with VUR grades I to IV, and patient age ranged from 0 to 3 years.[88,102,103] Roussey-Kesler et al.[102] did not show any benefit to antibiotic prophylaxis in low-grade VUR, except in boys with grade III reflux. Pennesi et al.[103] found no difference in UTI recurrence between prophylaxis and no prophylaxis in all patients younger than 30 months of age.[103] The Swedish Reflux Trial included 203 children (1 to 2 years of age) with grades III or IV reflux openly randomized into three groups.[88] Treatment groups were assigned to low-dose antibiotic prophylaxis, endoscopic therapy, and a surveillance group. The study demonstrated that the rate of UTI recurrence in girls older than 1 year with dilating VUR was higher than in boys and that this rate can be decreased with antibiotic prophylaxis and endoscopic treatment. There was no difference between the prophylaxis and endoscopic treatment groups. Of patients in the surveillance group, 57% had a UTI recurrence during follow-up. The study also showed that girls had a significantly higher rate of new renal damage on DMSA scan than in boys at 2 years. The renal damage was most common in the surveillance group and showed a strong association with recurrent febrile UTI.[89]

Randomized Intervention for Children with Vesicoureteral Reflux Study and antimicrobial prophylaxis

In 2011, the American Academy of Pediatrics revised its recommendations regarding investigations and use of prophylactic antibiotics after first UTI.[106] These recommendations suggested renal ultrasound be the sole investigation after first UTI. After treatment with antibiotics for 14 days, use of antimicrobial prophylaxis was not recommended for prevention of UTI. VCUG after the first UTI was also discouraged in these recommendations, unless hydronephrosis, potential scarring, high-grade VUR, or obstructive uropathy was suggested on the renal ultrasound evaluation. VCUG was, however, recommended in cases of recurrent febrile UTIs.

The Randomized Intervention for Children with Vesicoureteral Reflux (RIVUR) study recruited 607 children with VUR who were diagnosed after a first or second febrile or symptomatic UTI.[107] Efficacy of TMP-SMX prophylaxis in preventing recurrence of UTI, renal scarring, and antibiotic resistance was assessed over 2 years. The group of 302 children were assigned to the prophylaxis arm, and 305 children received placebo. Of the 302 children, 39 (12.8%) developed recurrent infections in the prophylaxis (treatment) group compared 72 of 305 (25.4%) children in the placebo group who developed recurrent infections. Renal scarring did not differ between the prophylaxis group and the placebo group, being 11.9% and 10.2%, respectively in the two groups. The investigators concluded that the data support use of antibiotic prophylaxis in children with documented VUR. The data also provide some support to the argument for obtaining VCUG in patients who have febrile UTI (acute pyelonephritis).

SURGICAL MANAGEMENT

The surgical intervention has the advantage of a "quick fix" in most cases and is recommended in patients with high-grade VUR, breakthrough febrile UTIs while on prophylaxis, allergy to prophylactic antimicrobials, poor adherence, worsening of renal scarring, and sometimes parental preference.[108] Some of the commonly used methods are described in the following section.

Endoscopic treatment

Currently, of all the surgical options, endoscopic treatment that involves subureteral or intraureteral injection of dextranomer hyaluronidase (Deflux) is offered in most cases (Figures 48.6 and 48.7). The reported success rate for this procedure is 83%, compared to 98.1% for open surgical reimplantation.[34] Meta-analysis of all of the endoscopic modalities used for VUR revealed that the cure rates per ureter for grades I and II was 78.5%, grade III was 72%, grade IV was 63%, and grade V was 51%.[109] A success rate of 68% was noted for patients failing first injection and 34% for those failing a second injection. Reduced success rates have been reported in patients with duplicated systems and those with neurogenic bladders.[109] Postoperative ureteral obstruction and calcification of the implant of dextranomer/hyaluronic acid, which mimics distal ureteral calculus, have been noted as complications of the procedure.[110,111] Improved success rate and the minimally invasive nature have led to a substantial increase in the number of endoscopic procedures.[112]

> **KEY POINT**
>
> The success rate of endoscopic repair of VUR decreases with increasing grade of VUR.
Figure 48.6 The endoscopic method currently achieving the highest success rates for treatment of vesicoureteral reflux (VUR) is the double hydrodistention implantation technique (HIT). The needle is passed into the ureteric orifice (UO) and inserted at the midureteral tunnel at the 6 o'clock position. Sufficient bulking agent is injected to produce a bulge, which initially coapts the detrusor tunnel, while a second implant within the most distal intramural tunnel leads to coaptation of the UO. Sites 1 and 2 comprise the double HIT method, and site 3 (STING) is rarely used. (Reproduced with permission from: Läckgren G, Kirsch AJ. Surgery: illustrated surgical atlas endoscopic treatment of vesicoureteral reflux. BJU Int. 2010;105:1332–47.)

Laparoscopic ureteral reimplantation

Laparoscopic ureteral reimplantation has the benefit of providing results that are less invasive than with open surgery. Overall success with correction of VUR is similar to that with the open procedures.[113] Complications include ureteral injury, ureteral leak, and ureteral stricture.[113,114]

Open surgical technique

The gold standard for the surgical management of VUR remains the open approaches. The most commonly performed open technique is the Cohen cross-trigonal reimplantation (Figure 48.8).[115] The success rates of this procedure for the correction of VUR are consistently approximately 98%, to the point that most clinicians have stopped performing follow-up studies to confirm reflux resolution.[116,117] Contralateral VUR is noted in 19% of patients who have had unilateral ureteral reimplantation, with the majority resolving over the ensuing 2 years, and are thought to be the result of trigonal changes following ureteral reimplantation.[118] Ureteral stricture resulting from ischemia of the distal ureter also has been reported in surgically corrected patients. Endoscopic access to the ureter following ureteral reimplantation can be difficult, which should be kept in mind if a patient needs the procedure for stone removal later in life. Sung and Skoog[119] extensively reviewed the open surgical techniques for ureteric reimplantation.

MANAGING VOIDING AND BOWEL DYSFUNCTION

Treatment of constipation by dietary measures, behavioral therapy, and laxatives helps reduce UTI recurrence and facilitates the resolution of enuresis and uninhibited bladder contractions.[43,120] The treatment of voiding dysfunction or DES includes the use of laxatives and timed frequent voiding, every 2 to 3 hours. Pelvic floor exercises, behavioral modification, anticholinergic medication, or a combination of these may be required. A combined conservative medical and computer game–assisted pelvic floor muscle retraining decreased the incidence of breakthrough UTI and facilitated VUR resolution in children with voiding dysfunction and VUR.[121] Similar results of improved outcome with medical management have been reported by others.[122,123]
Figure 48.7 Endoscopic injection technique developed by Kirsch et al. In most patients a combination of the intraureteric injection and the STING is used to achieve an optimal bolus. (Reproduced with permission from: Läckgren G, Kirsch AJ. Surgery: illustrated surgical atlas endoscopic treatment of vesicoureteral reflux. BJU Int. 2010;105:1332–47.)
Figure 48.8 The Cohen procedure is the most widely used technique for surgical correction of vesicoureteral reflux. **(a)** The ureters (the procedure is often bilateral) are mobilized intravesically. **(b)** Two separate submucosal tunnels are created so that each ureter opens on the opposite side from its hiatus. HYPERTENSION AND PROTEINURIA

Appropriate management of hypertension and proteinuria is important to slow progression of renal disease. Although a large number of antihypertensive drugs are available for clinical use, ACE inhibitors (ACEIs) or angiotensin II receptor blockers (ARBs) are preferred because of their renoprotective effect. Studies have revealed that ACEIs, besides lowering the blood pressure, reduce proteinuria resulting from RN.[124] Therapy with ACEI may be particularly beneficial for patients with RN, especially those born with D alleles of the ACE gene.[125] In some patients with very poorly functioning scarred kidney and a healthy second kidney, the removal of a poorly functioning kidney may help cure hypertension.

SUMMARY

VUR increases the risks for UTI and renal scarring, which can lead to CKD and hypertension. Management strategies continue to evolve, with options that include open surgical repair, endoscopic repair, antibiotic prophylaxis, and surveillance. A variety of variables influence the management strategy for the individual patient, including the severity of the VUR, the presence of UTIs and scarring, and the age of the patient. Prophylactic antibiotics have been used in prevention of UTI in patients with VUR for over three decades. For various reasons, including the risk of antibiotic resistance, the use of prophylactic antibiotics in VUR has come under increasing criticism. The RIVUR study, however, has provided support for use of prophylactic antibiotics in prevention of UTIs in patients with VUR.

REVIEW QUESTIONS

1. Which of the following is associated with a higher incidence of primary vesicoureteral reflux diagnosed after urinary tract infection?
   a. Older age
   b. Male gender
   c. African American race
   d. Family history of vesicoureteral reflux in parent or sibling

2. Which of the following is a risk factor for renal scarring after a UTI?
   a. African American race
   b. High grade vesicoureteral reflux
   c. Absence of vesicoureteral reflux
   d. Diarrhea
   e. Pyuria

3. Hypertension is most directly associated with which of the following?
   a. History of urinary tract infections
   b. Vesicoureteral reflux
   c. Use of Deflux
   d. Renal scarring

4. Which of the following is a risk factor for unsuccessful endoscopic repair of vesicoureteral reflux?
   a. Neurogenic bladder
   b. Congenital reflux
   c. History of UTI
   d. Caucasian race
   e. Grade I or II reflux
5. The success rate of open surgical repair of vesicoureteral reflux is approximately:
   a. 65%
   b. 75%
   c. 85%
   d. 90%
   e. 98%

6. Which of the following is the preferred agent for treating hypertension in a patient with reflux nephropathy?
   a. Calcium channel blocker
   b. Beta blocker
   c. ACE inhibitor
   d. Thiazide diuretic

ANSWER KEY

1. d
2. b
3. d
4. a
5. e
6. c

Urinary tract infection

BRITTANY GOLDBERG AND BARBARA JANTAUSCH

Urinary tract infection (UTI) is a common childhood infection, being second in frequency only to respiratory infections. In many children, these infections recur, causing significant morbidity, hospitalizations, and long-term health effects, such as renal scars, hypertension, and chronic kidney disease (CKD). Although bacterial UTIs are well recognized in children and adults, fungal, viral, and parasitic infections of the urinary tract are also encountered with an increasing frequency, especially in immunocompromised and susceptible subpopulations. The increasing prevalence of antimicrobial resistance in bacteria introduces an additional level of complexity to the management of patients with UTIs.

KEY POINTS

- Asymptomatic bacteriuria is more common among girls.
- Lifetime risk for symptomatic UTI is 3 to 5 times higher in girls than in boys.
- Approximately 2% of boys and 3% to 8% of girls will develop a UTI during their lifetime.
- During first 3 months of life, male infants have a higher incidence of UTI than females.

EPIDEMIOLOGY

Large-scale urinary screening studies of school children suggests the prevalence of bacteriuria in asymptomatic children to be 0.7% to 1.95% in girls and 0.04% to 0.2% in boys.[1,2] It has been estimated that 2% to 5% of girls would develop bacteriuria by the time they graduate from high school.[2,3] The American Association of Pediatrics (AAP) clinical practice guidelines estimates the prevalence of UTI to be approximately 5% in children 2 to 24 months of age.[4] The lifetime risk for symptomatic UTI is 3 to 5 times higher in girls than boys. In numerous epidemiologic studies, the overall risk for UTI has been reported as 1.1% to 1.8% in boys and 3.3% to 7.8% in girls.[5–7]

In the first 3 months of life, UTI is more common in males than in females. The male-to-female ratio of children with UTI in this age group ranges from 2:1 to 5:1.[8-10] The reasons for male predilection for UTI in neonates remains unclear, but follows a similar trend noted for other infections and sepsis in this age group. Circumcision has been noted to reduce the risk for UTI in male infants.[11] Bacteremia associated with UTI is also common in neonates and young infants. Ginsburg and McCracken[12] reported the incidence of bacteremia in hospitalized infants younger than 8 weeks with UTI to be as high as 31%. A recent study found the incidence of bacteremia in febrile infants aged 29 to 60 days with UTI to be only 6.5%.[13] Others also have reported a lower incidence (approximately 10%) of bacteremia in unselected nonhospitalized infants with UTI.[14]

BACTERIOLOGY

Gram-negative enteric bacteria of the Enterobacteriaceae family cause most UTIs in children of all ages. This includes *Escherichia coli*, which is responsible

for 80% to 85% of all UTIs in children. *Klebsiella, Proteus, Citrobacter, Enterobacter* species, and *Morganella morganii,* the other members of the Enterobacteriaceae family, are less frequent causes of UTI.[12,15-17] *Pseudomonas aeruginosa,* Gram-positive organisms such as *Enterococcus, Staphylococcus,* and *group B streptococci* also can cause UTI in children. *Group B streptococcus* is almost exclusively seen as a cause of UTI in neonates, whereas *Staphylococcus saprophyticus* is seen commonly in adolescent girls.[18,19] *Staphylococcus aureus* is an uncommon cause of UTI and may be the result of hematogenous spread to the kidney. Infection with *S. aureus* often results in focal renal lesions, such as intrarenal and perinephric abscesses.[20,21]

Since their discovery in the 1980s, bacteria that produce extended-spectrum β-lactamase (ESBL) have increased in prevalence among nosocomial and community-acquired UTIs. ESBL bacteria primarily include Gram-negative organisms, particularly *Klebsiella* and *E. coli.*[22] Prevalence of ESBL bacteria varies among geographic regions, with regional rates of resistant organisms surpassing 50% in some areas.[23] A study by Moland et al. found that 11.3% of *Klebsiella pneumoniae,* 2.6% of *E. coli,* 1.6% of *Serratia marcescens,* 1.4% of *Proteus,* and 3.5% of *Citrobacter koseri* were categorized as ESBL.[24] Another review of ESBL bacteria at a tertiary children's hospital found that 78% of ESBL bacterial cultures were isolated in urine.[25] The overall incidence of ESBL bacteria among Enterobacteriaceae was found to be 7%, with *E. coli* responsible for 78% of ESBL isolates and *Klebsiella* accounting for 12.7%.

KEY POINTS

- Ascending infection accounts for most cases of UTI.
- Most UTIs are caused by Gram-negative bacteria, such as *E. coli* and *Klebsiella.*
- *Group B streptococci* may cause UTI in neonates.
- *S. aureus* is an uncommon cause of UTI that may result in renal abscess.

PATHOGENESIS

Infection can reach the urinary tract via the ascending route or by the hematogenous route. Hematogenous spread of infection to the urinary tract accounts for fewer than 1%

of UTIs and commonly occurs in association with sepsis, particularly that caused by *S. aureus.*[20,21] Resultant infection leads to focal renal lesions, such as pyelonephritis, intraparenchymal abscess, and perinephric abscess. In most cases, UTI results from an ascending infection, where the Gram-negative enteric flora ascends via the urethra to invade the urinary tract and cause asymptomatic bacteruria, acute cystitis, or acute pyelonephritis.

Virulence of the infecting organism is an important aspect of establishing infection within the host urinary tract. Predisposition to UTIs also can result from structural abnormalities of the urinary tract, such as vesicoureteral reflux (VUR), or from functional derangements of the bladder. Identification and treatment of these underlying disorders is an integral component of the management plan for affected children.

BACTERIAL VIRULENCE FACTORS

Specific microbiologic properties of *E. coli,* known as virulence factors, are now recognized to be involved in enhancing the invasiveness of these organisms. Strains possessing these virulence factors are able to spread to the urinary tract and result in more serious infections. Interestingly, *E. coli* strains isolated from patients with asymptomatic bacteriuria have been found to carry virulence genes that are similar to pathogenic strains, but appear to downregulate expression of these genes when they establish colonization.[26]

KEY POINT

The increasing prevalence of ESBL Gram-negative bacteria is changing antibiotic resistance patterns in communities.

Adhesins or fimbriae

Adhesins, or fimbriae, are microscopic appendages present on the surface of *E. coli* that allow bacterial adherence to the uroepithelial cell.[27] Fimbriae allow *E. coli* to bind to specific glycolipid receptors on uroepithelial cells and permit evasion of host defense mechanisms for colonization of the urinary tract. Type I fimbriae, type II fimbriae (also known as *P* fimbriae), and the Dr hemagglutinin are the three types of clinically significant fimbriae expressed by uropathogenic *E. coli.*

Recent studies have demonstrated significant differences in fimbrial expression between commensal *E. coli* strains and pathogenic *E. coli.* Pyelonephritis isolates have more fimbrial types than commensal isolates.[28] Type I fimbriae exhibit mannose-sensitive hemagglutination and attach to

bladder epithelial cells.[29] *P* fimbriae demonstrate mannose-resistant hemagglutination and are associated with acute pyelonephritis.[30] *E. coli* that express the Dr hemagglutinin, a fimbria-like adhesin, are associated with the development of cystitis.[31]

Hemolysin and cytotoxic protein

E. coli strains that produce hemolysin, a cytotoxic protein that lyses erythrocytes and other cells, are associated with the development of acute pyelonephritis. The effects of hemolysin on host cells are thought to contribute to the inflammation and tissue injury associated with hemolytic *E. coli*.[32] Similarly, colicin, another cytotoxic protein, is also thought to contribute to *E. coli* virulence.[33]

Serotypes and bacterial virulence

E. coli contain three major antigens that are identified through antibody serotyping and are associated with invasiveness, virulence, and the ability to evade phagocytosis and complement-mediated lyses. These are the O antigen present in the outer membrane of the cell wall, K antigen, the capsular antigen, and H antigen, or the flagellar antigen. More than 150 O antigens and in excess of 80 K and H antigens have been identified.[32,34] *E. coli* strains with certain O antigen serogroups (1, 2, 4, 6, 7, 8, 16, 18, 25, and 75) are associated with the development of pyelonephritis.[35-37] *E. coli* strains are typically named after their O and H serotypes.

Bacterial genetics

Many of the genes encoding for the virulence factors in *E. coli* are located on distinct pieces of DNA called *pathogenicity islands* (PAIs) that are present in the genome of pathogenic bacteria and are not found in avirulent bacteria strains. Genes encoding for hemolysin or *P* fimbriae production are characteristically found in PAIs. PAIs can be deleted from the chromosome and also can be transferred to other bacteria by helper phages.[38,39] Many pathogenic strains of *E. coli* may carry more than one PAI, although the implication for virulence is unclear.[40]

HOST FACTORS

Some children are prone to developing UTI and may have frequent recurrences. Several anatomic, functional, and behavioral factors can render children prone to UTI. Although it is possible that a solitary risk factor may render many children susceptible to UTI, multiple risk factors often are operative in others.

Inflammatory response

The inflammatory response generated by the host in the kidney and the urinary tract to the invading bacteria is an essential determinant of the severity and outcome of UTI. Once uropathogenic *E. coli* attach to the uroepithelial cells, they initiate inflammation by stimulating uroepithelial cells to produce cytokines and chemokines, such as interleukin-6 (IL-6) and IL-8.[41-43] Urinary IL-6 and IL-8 concentrations are elevated in children with UTI.[44-46] IL-8 has also been found to be elevated in noninfectious renal conditions such as VUR and non-VUR congenital abnormalities, suggesting that IL-8 is a nonspecific marker of renal injury.[47] IL-8 also may provide insight into the severity of renal scarring after UTI.[48] Recent genomics studies have also identified IL-10 upregulation in response to UTI.[49]

Infection with *P* fimbriated *E. coli* is associated with the presence of elevated concentrations of these inflammatory mediators in urine and is also involved in neutrophil recruitment within the infected urinary tract.[46] *P* fimbriae activate epithelial cells to release cytokines and chemokines by using the Toll-like receptor 4 (TLR-4) pathway for signal transduction.[50] IL-8, also designated CXC chemokine, recruits neutrophils and other inflammatory cells to migrate to the site of infection within the urinary tract.[51] IL-8 orchestrates neutrophil recruitment by binding to two high-affinity IL-8 receptors, CXCR1 and CXCR2, expressed on the surface of uroepithelial cells. Expression of these receptors increases with infection, leading to higher IL-8 binding and greater neutrophil migration across infected epithelial cells. Neutrophils exit the blood vessels, cross the lamina propria and the epithelial barrier, and enter the urinary lumen, resulting in pyuria (Figure 49.1).[52] IL-8 levels have been found to be significantly elevated in patients with urosepsis, and urine samples demonstrated increased recruitment of neutrophils in chemotaxic assays, suggesting that local production of cytokines contributes to the migration of neutrophils to infected urine.[53] The overall cytokine response to UTI is complex, involves multiple different cytokines, and may reflect disease severity. Bacterial endotoxins also facilitate chemotaxis by activating the complement pathway.[54]

The neutrophils recruited by the cytokines kill bacteria and help clear the infection. Chemokine receptor CXCRI expression and CXCRI-specific mRNA were found to be low on the neutrophils of children with recurrent UTI, compared to those of matched controls.[55] CXCR1 receptor expression was also significantly lower in a cohort of UTI-prone children compared to age-matched controls without a significant history of UTIs.[56] Polymorphisms in *TLR-4* genes also have been implicated in susceptibility to UTIs.[57-59] These findings suggest that molecular factors in the host may contribute to susceptibility to acute pyelonephritis.
Figure 49.1 Host response to urinary tract infection. GSL, Glycosphingolipid.

Host response and renal scarring

Renal parenchymal scarring as a result of acute pyelonephritis is intimately related to the host response to infection. Bladder inoculation of *E. coli* in IL-8 receptor knockout (KO) mice triggered a chemokine response and neutrophil recruitment, but the neutrophils accumulated under the epithelium and failed to cross the mucosal barrier and kill bacteria.[55] Although control mice successfully cleared the infection in this study, the KO mice developed edema of kidneys, neutrophil abscesses, and subsequent renal scarring. This animal model underscores the importance of chemokine receptors in the host's ability to successfully clear infection, and suggests a potential molecular basis for the progression of acute pyelonephritis to renal scarring.

Despite encouraging data in the animal models, studies in children have provided conflicting results regarding the correlation between IL-8 levels and renal scarring. Tramma et al.[60] compared children with and without renal scars following UTI. Six months after UTI, no children had detectable levels of IL-8 in their urine. Another study performed within 3 weeks of UTI demonstrated significantly increased levels of IL-8 in patients with renal scarring.[61,62] It seems that although IL-8 may play a role in immediate inflammatory responses, it is unclear what molecular mechanisms lead to the chronic inflammatory responses that may contribute to renal scarring.

Procalcitonin is emerging as a potential marker for the diagnosis of acute pyelonephritis and renal scarring in children. A prospective study of 100 Italian children found that patients who developed renal scars on DMSA scintigraphy had significantly elevated procalcitonin levels compared to children with normal or mild renal involvement. The study concluded that procalcitonin values 0.8 ng/mL or greater had a sensitivity of 83.3% and specificity of 93.6% in predicting acute pyelonephritis.[63] Similarly, meta-analysis of procalcitonin in the pediatric literature found that procalcitonin correlated with both renal scarring and acute pyelonephritis.[64] Procalcitonin has not yet been incorporated into clinical algorithms for management decisions in pediatric patients with UTI.

> ### KEY POINTS
>
> - IL-6 and IL-8 may serve as markers of renal injury during infection.
> - Procalcitonin may be a predictive biomarker for the development of pyelonephritis and renal scarring.
> - The host chemokine response also may contribute to the development of renal scarring.

Blood group

In addition to underlying structural urogenital anomalies, an individual's blood group also may influence predisposition to UTI.[65–67] Blood group antigens are genetically

determined carbohydrate moieties present on erythrocytes and epithelial cells, including uroepithelial cells. Blood group antigens may influence the binding of fimbriated bacteria to carbohydrate receptors present on uroepithelial cell surfaces by producing a specific receptor site for bacteria or blocking an exposed receptor site. Women with recurrent UTIs have an increased frequency of Lewis blood-group nonsecretor and recessive phenotypes.[65] Jantausch et al.[66] reported that the relative risk for UTI was 3.2 in children with the Lewis (Le) (a-b-) phenotype. Sheinfeld et al.[67] in a study of children with genitourinary structural anomalies, correlated uroepithelium nonsecretor phenotype with a history of UTI. These children had low or undetectable levels of ABO and Le-b reactivity in their uroepithelium compared to children without a history of UTI, whose uroepithelium demonstrated strong ABO and/or Le-b immunoreactivity. Other studies have cast doubt on the role of blood group antigens in the pathogenesis of UTI.[68–70]

URINARY ANATOMY

Because of known predisposition of females to UTI, a short urethra in girls in comparison to boys has long been proposed to be a factor in facilitating spread of ascending infection. Although intuitively plausible, published evidence for this hypothesis is almost nonexistent. A small urethral diameter in girls has also been cited as a reason for susceptibility of some girls to UTI. Works of Graham et al.[71] and Immergut and Wahman,[72] however, convincingly demonstrated that the internal urethral diameter does not differ significantly between the bacteriuric and nonbacteriuric girls. In conclusion, although commonly cited, the role of normal urethral anatomy in facilitating movement of bacteria upstream into the urinary bladder is largely unclear.

KEY POINTS

- Most UTIs are the result of ascending infections.
- Hematogenous spread occurs in a minority of infections.
- Structural abnormalities of the urinary tract may predispose to infection.

Prepuce and circumcision

Circumcision is practiced as a religious and sociocultural ritual in many parts of the world. In the religious context, circumcision is widely practiced in the Jewish and Muslim faiths. Incidence of circumcision in the United States peaked at 85% in 1965.[73] In a cross-sectional study, the Centers for Disease Control and Prevention estimated

that the incidence of routine newborn male circumcision in the United States was between 54.7% and 56.9%.[74] The rate of circumcision in African-American neonates used to be 10% to 15% lower than in white neonates, but recent data suggest that the circumcision rate is similar in the two races.[73,75,76] Geographic variation also exists within circumcision incidence in the United States. States in which Medicaid covers routine circumcision were found to have circumcision rates that were 24% higher than states without Medicaid coverage.[74] The circumcision rate in countries outside the United States is low. In Europe, circumcision is generally practiced for medical reasons only, and rates vary from 2 percent in Denmark to about 3.1 percent in the United Kingdom.[77–79]

The role of circumcision in preventing UTI has been recognized since the 1980s. Ginsburg et al.[12] noted that 75% of boys with febrile UTI in the first 8 weeks of life were noncircumcised. In a retrospective analysis of 5261 infants younger than 1 year of age, Wiswell and Roscelli[80] showed that the incidence of UTI in females and circumcised males was 0.47 and 0.21, respectively, whereas 4.21% of uncircumcised males had a confirmed UTI. These authors subsequently expanded their studies to suggest a 20- to 29-fold increase in febrile UTI in uncircumcised males compared to circumcised infants.[80–82] Schoen et al.[83] reviewed the incidence of UTI in 28,812 neonates in the Kaiser Permanente system in California. The incidence of UTI during the first year of life in the noncircumcised infants group was 2.15% compared to 0.22% in circumcised infants—a 9.1-fold increase of UTI in noncircumcised infants. A Cochrane review of UTIs found that there were no randomized controlled trials examining the effect of circumcision on infection.[84] A meta-analysis of existing literature found the summary odds ratio to be 0.13 for the seven included studies and estimated that the number of subjects needed to treat (circumcise) to prevent one UTI was 111.[85] These authors inferred that the evidence is insufficient to support routine circumcision of all male infants, but that males at increased risk for UTI or with a history of recurrent UTI may benefit from circumcision. Over all, the incidence of UTI in uncircumcised infants is reported to be 3 to 7 times higher than in circumcised infants.[11,14,83,86–88]

The mechanism by which the intact prepuce predisposes to UTI is unclear. One possible explanation is that the prepuce allows enteropathogenic bacteria to harbor and multiply in an uncircumcised male.[89,90] Urethral swabs in male infants before and after circumcision found that 89.5% of males grew bacteria before circumcision and only 33.9% of swabs grew bacteria after circumcision.[91] Culture independent investigations of bacterial flora before and after circumcision have shown a similar decrease in the diversity of penile microbiota, although it is unclear what impact this finding may have on disease risk.[92] Enhanced adherence capability of the uropathogenic organisms to the nonkeratinized mucosa of the prepuce also has

been cited as leading to a higher incidence of UTI in uncircumcised male infants.[93] Colonization by highly virulent strains of *E.coli* appears to be facilitated by presence of the prepuce in young infants.[94] The molecular mechanism for this predisposition, especially in absence of urinary tract malformations, is unclear.

Routine neonatal circumcision: View of the American Academy of Pediatrics

The AAP's Task Force on Circumcision issued a revised policy statement on male circumcision in September 2012. This statement points out that based on available evidence, the health benefits of newborn male circumcision outweigh the risks of the procedure.[95] However, universal circumcision has not been recommended. If parents choose to have male neonates circumcised, access to the procedure has been advocated.

KEY POINTS

- The 2012 AAP statement indicates that the health benefits of newborn male circumcision outweigh the risks of the procedure, but does not recommend universal circumcision in males.
- Parental choice for access to circumcision has been advocated by AAP.
- Males at an increased risk for infection may benefit from circumcision.

ELIMINATION DYSFUNCTION

Voiding and bowel dysfunction often occur together and are usually termed *elimination dysfunction*. These children have an abnormal micturition and stooling pattern associated with normal urinary tract anatomy and intact neurogenic control of the urinary tract and bowel. The association between voiding and bowel dysfunctions and UTI is well known.[7,96–100] Patients with elimination dysfunction also have been independently noted to have a high incidence of VUR, which can also predispose to UTIs.[97–100] Clinical manifestations of elimination dysfunction in children include urinary frequency and urgency, prolonged voiding intervals, daytime wetting, perineal and penile pain, holding maneuvers, or posturing to prevent wetting, constipation, and encopresis.[99] Predisposition to UTI in these patients is thought to be due to incomplete bladder emptying, leading to accumulation and proliferation of uropathogenic bacteria in the bladder. Voiding dysfunction and its management are discussed further in Chapter 52.

Urinary obstruction

In an unselected childhood population with UTI, the incidence of urinary obstruction has been reported to be as high as 10%.[5] In the more recent literature, however, urinary obstruction accounts for fewer than 1% of children with UTI caused by *E. coli*.[9,101] On the other hand, urinary obstruction is more commonly (15%) seen in children with UTI caused by *Proteus, Enterococcus, Klebsiella,* or coagulase-negative staphylococcal infections.[102] In the era of prenatal ultrasound evaluation, most patients with obstructed urinary tracts are detected early, even before the onset of first UTI. However, children with posterior urethral valves may first come to medical attention because of febrile UTI or urosepsis. Obstruction at the ureteropelvic junction or along the ureteric length also can lead to a predisposition to UTI.

Vesicoureteral reflux

Retrograde flow of the urine from the urinary bladder into the ureters is prevented during micturition by a functional valve mechanism at the level of the ureterovesicular junction (UVJ). Incompetence of the UVJ valve leads to flow of urine upstream into the ureter and the kidney, or VUR. The association between VUR and predisposition to UTI is well established. VUR is discussed in Chapter 48.

KEY POINTS

- Voiding dysfunction and urinary obstruction predispose children to UTIs.
- VUR is an important predisposition to UTI in children.

CLINICAL MANIFESTATIONS

Manifestations of UTI vary with age, site of infection within the urinary tract, and severity of infection. From a clinical perspective, infection of the urinary tract may be discussed as a nonfebrile UTI or acute cystitis and febrile UTI or acute pyelonephritis.

CYSTITIS

Among preschoolers, cystitis is more commonly seen in girls than in boys. Of the 157 children under the age of 6 years identified with first-time symptomatic nonfebrile UTI by Marild and Jodal,[7] 130 were girls, and only 27 were boys. The peak incidence of nonfebrile UTI in preschool girls in this study was 9.4 cases per 1000 at-risk children and occurred in the third year of life. Thereafter, the incidence gradually declined to a stable level of 2.5 cases per 1000 at-risk children. In contrast, the peak incidence of nonfebrile UTI in preschool boys in this study was only was 2.8 per 1000 at-risk children and was noted during the first year of life.[7]

In children who can verbalize (usually more than 3 to 4 years of age), dysuria and suprapubic pain are common

manifestations of cystitis.[101] Symptoms of dysuria may be difficult to ascertain in younger children. In boys between 6 and 12 years of age with bacteriologically proved UTI, Hallett et al.[102] found dysuria or urinary frequency (82%), enuresis (66%), and abdominal pain (39%) to be the most common symptoms. Urinary incontinence is another common symptom of cystitis, especially in girls. Parental observations may range from a general reluctance of the child to urinate, to excessive crying and abdominal pain. Parents may report the urine to have a foul odor, but these symptoms may be subjective and not reported.

Gross hematuria has been reported to be a common manifestation of bacterial cystitis in children. Bergstrom et al.[8] noted macroscopic hematuria as a clinical symptom in 26% of children with UTI. Hematuria was more common in males (43%) than in females (9%) in this study. In another study, Ingelfinger et al.[103] reported that of the 158 children with macroscopic hematuria seen in the emergency room, UTI was the underlying cause in 26% of cases. Cystitis has been reported in children who self-inject or manipulate the urethra.[104] Hematuria is also a common manifestation (60%) in such children.

ACUTE PYELONEPHRITIS (FEBRILE URINARY TRACT INFECTION)

Association of fever in a patient with a positive urinary culture suggests renal parenchymal infection or acute pyelonephritis. Other symptoms of acute pyelonephritis include abdominal pain and costovertebral angle pain and tenderness, which are more commonly present in older children and adolescents. In younger children and infants, in addition to fever, other nonlocalizing symptoms such as excessive crying, irritability, vomiting, feeding problems, and lethargy are often present. Dysuria is an uncommon manifestation of febrile UTI in children younger than 1 year of age, but up to a quarter of older children may complain of this symptom.[105] Febrile UTI, or acute pyelonephritis associated with manifestations of sepsis is referred to as *urosepsis* and is particularly common in children with clinically significant urinary tract anomalies, such as obstructive disease, or VUR.

Bacteremia is present in 4% to 9% of infants and children younger than 1 year of age with UTI.[106,107] Fever may be the only symptom in many patients with UTI associated with bacteremia, especially early in their presentation. Symptoms of chills and rigors may also be seen in these patients, but clinical symptoms alone are poor predictors of bacteremia.[105] Meningitis may be present in patients with urosepsis, especially in those younger than 3 months of age.[107] Although ESBL-producing bacteria have come to represent an increasing percentage of community-acquired UTIs, no difference in clinical presentation has been noted in children with ESBL and non-ESBL bacterial pneumonia.[108]

Acute renal failure is an uncommon manifestation of acute pyelonephritis. Such patients may require dialysis therapy, and complete renal recovery after successful treatment of the infection is possible.[109]

URINARY TRACT INFECTION IN NEONATES AND INFANTS

The diagnosis of UTI needs to be considered in neonates and infants younger than 3 months of age with sepsis or unexplained fever. Although girls are generally at higher risk for UTI, the majority of UTIs in infants younger than 3 months of age are in males.[110–112] In infants with known urinary tract abnormalities, such as hydronephrosis, obstructive uropathy, or VUR, diagnosis of UTI should be considered and ruled out during febrile episodes. Fever may be absent in some patients, especially in neonates. Winberg et al.[5] found fever as an accompanying symptom in only 42% of neonates with acute pyelonephritis. Hypothermia, hypotension, shock, jaundice, failure to thrive, diarrhea, vomiting, feeding problems, irritability cyanosis, polyuria, and metabolic acidosis also have been reported as presenting manifestations in neonates and infants younger than 3 months of age with acute pyelonephritis.[9,113]

Febrile UTI in neonates may be associated with sterile cerebrospinal fluid (CSF) pleocytosis. A multicenter retrospective review of 1190 infants aged 29 to 60 days with febrile UTIs showed that 214 (18.0%) had CSF white blood cell (WBC) counts of 10/μL or higher.[114] The dominant risk factor associated with sterile CSF pleocytosis was elevated peripheral WBC count, leading the study authors to propose a possible inflammatory mechanism for the development of sterile pleocytosis.

RENAL ABSCESS

Renal abscesses are an uncommon complication of UTI. Two retrospective studies of pediatric patients identified only 13 patients over 20 years.[115,116] Renal abscesses can be divided into two anatomic categories: intrarenal and perirenal abscesses. Intrarenal abscesses include cortical and corticomedullary abscesses. Renal cortical abscesses are often a consequence of hematogenous spread from infection elsewhere in the body.[116,117] Corticomedullary abscesses, on the other hand, are more likely to be associated with a urinary tract abnormality and are often the result of an ascending infection. A perinephric abscess is characterized by infection between the renal capsule and Gerota fascia. These abscesses often develop after an intrarenal abscess ruptures and spreads infection into the perinephric space, but also may develop as a complication from a primary infection elsewhere in the body.

Clinical presentation of renal abscesses is often insidious, and most symptoms can be nonspecific. Fever, nausea, vomiting, abdominal pain, and localized flank pain are reported as the most common manifesting symptoms.[116,118,119] Although Wippermann et al.[116] did not find an association between renal

abscess and underlying urologic abnormalities, five of the six patients described by Angel et al.[119] were found to have abnormal anatomy that may have contributed to the development of a renal abscess. Among adults, diabetes mellitus, urolithiasis, and immunosuppression have been reported to be risk factors for renal abscesses.[120,121] Diagnosis of renal abscess can be made by renal ultrasound (Figure 49.2), or computed tomography (CT) scan of the abdomen, which may demonstrate a partially filled cystic lesion. Treatment consists of surgical drainage of the abscess under ultrasound guidance and antibiotic therapy for 3 weeks or longer, as dictated by the patient's clinical state.

DIAGNOSIS

The aims of investigation in a child with UTI are to: (1) confirm the diagnosis, (2) identify the infecting organism, (3) localize the site of infection and identify children with acute pyelonephritis, and (4) recognize patients with urinary tract malformations.

URINALYSIS

Urinalysis is often the initial laboratory study performed in patients with a presumptive diagnosis of UTI, especially in
Figure 49.2 Ultrasound of the kidney showing an intrarenal abscess. The abscess demonstrates fluid and debris within it (arrow). Aspirated fluid from the abscess grew *Escherichia coli*.

the office or emergency room setting. Collection methodology of urine for examination has significant implications for sensitivity and specificity of findings. Urinalysis can be collected by any method, including perineum bag, but the sample should be processed promptly. A specimen kept at room temperature should be analyzed within 1 hour, or in 4 hours if refrigerated.[4,122] Urine dipsticks are frequently used in the primary care setting, in which the rapid return of results is desirable for clinical decision making. Most urine dipsticks provide leukocyte esterase and nitrite values. Hematuria and proteinuria may be detected in UTI, but sensitivity and specificity are poor.[123]

URINE COLOR AND SMELL

Turbid urine may be an indication of pyuria and UTI. Clarity of urine has been shown to have a negative predictive value for absence of UTI in some reports.[124] In contrast, Bulloch et al. found that 3 of 29 children with UTI and positive urine culture were found to have clear urine.[125] In general, clarity of urine has limitations as a discerning indicator for absence of UTI.

Parents often report an abnormal smell to be suggestive of onset of UTI in children. In a study of 110 patients, 52% of parents reported that their child's urine smelled different from usual, but only 6.4% of children had a positive urine culture.[126] These observations indicate that urine smell is also a poor screening test for UTI. Neither color nor odor is taken into consideration for diagnosis in the AAP UTI Practice Guideline.[4]

URINE MICROSCOPY

Bacteriuria

Detection of any bacteria in the uncentrifuged urine slide stained by Gram stain has been used as the gold standard for the presumptive diagnosis of UTI. In a meta-analysis of published studies in children, Gorelick and Shaw[127] reported that presence of any bacteria in the Gram-stained urine slide demonstrated a true positive rate of 0.97 (high sensitivity) and false positive rate of only 0.05 (high specificity). The AAP practice guideline for UTI suggests that by combining the findings of pyuria and bacteriuria results, a greater sensitivity and specificity of the tests may be achieved.[4] The limitations of this test for a wider acceptability in clinical practice are that it is time-consuming and requires expertise in performing the Gram stain and identifying the organisms in the urine sample.

Pyuria

Pyuria or light microscopy visualization of more than 5 white blood cells per high-power field (WBCs/hpf) in

centrifuged urinary sediment is considered as presumptive evidence of UTI.[4] Presence of 10 WBCs/hpf has been noted to have a true positive rate of 0.77 and a true negative rate of 0.11.[127]

Pyuria alone cannot be used as the sole diagnostic criteria for UTI, but it is unusual to diagnose UTI in the absence of pyuria. Variables such as centrifuge speed, centrifugation time, volume of urine centrifuged, and volume of urine used for resuspension can influence the quantitation of pyuria. Sterile pyuria, or urinary WBC excretion, without concurrent evidence of bacterial infection or UTI may be seen in some clinical conditions (Table 49.1). Other limitations include neutropenia, in which the patient may not be able to mount a urinary WBC response. Infection with organisms such as *Proteus* species, that produce alkaline urine, leads to disruption of urinary WBCs in urine and an apparent absence of pyuria in the face of UTI.

KEY POINTS

- The finding of single bacteria in an uncentrifuged urine sample stained with Gram stain is presumptive of UTI with high sensitivity and specificity.
- Pyuria detection requires urine centrifugation.
- Presence of pyuria is not sufficient to diagnose UTI.
- The nitrite test has high specificity but modest sensitivity.
- The nitrite test identifies only Gram-negative bacterial UTI.

Table 49.1 Clinical conditions that may be associated with sterile pyuria

1. Partially treated urinary tract infection
2. Interstitial nephritis
3. Renal tubular acidosis
4. Glomerulonephritis, especially acute postinfectious glomerulonephritis
5. Renal cystic diseases
6. Renal stone disease
7. Hydronephrosis
8. Appendicitis
9. Dehydration
10. Meatal or urethral irritation, especially in males
11. Vaginitis in females
12. Neonates
13. Renal tuberculosis
14. Exercise
15. Kawasaki's disease

Leukocyte esterase

Testing for leukocyte esterase may overcome some of the limitations of urinary microscopy in identifying leukocyturia. Leukocyte esterase is present in the neutrophils and can be assayed in the urine by dipstick strips. For patients with a suspected UTI, the sensitivity of this test is 94%, with an average specificity of 72%.[4] False-negative tests can be caused by the presence of ascorbic acid, high urinary protein, glycosuria, presence of urobilinogen, gentamicin, nitrofurantoin, cephalexin, and boric acid. A false-positive test can result from presence of imipenem and clavulanic acid in the urine.

Nitrite test

This test is based on the fact that bacterial enzyme nitrate reductase can convert urinary nitrate to nitrite, which can be detected by several chemical methods. The nitrite test has now been incorporated in commercially available dipstick test strips. Specificity is estimated to be 90% to 100%, although sensitivity is significantly lower at 16% to 82%.[123]

Although a good screening test, nitrite testing cannot be relied on as a confirmatory test for UTI. Kunin et al.[128] found that the test was positive in 65.4% patients with culture-positive UTI if performed one time. The nitrite test does not identify patients with Gram-positive infections because they lack the nitrate reductase enzyme. Also, conversion of the urinary nitrate to nitrite requires sufficient time (usually 3 to 4 hours in the bladder) even in presence of Gram-negative infection. In patients with UTI and urinary frequency, the reaction time may be less than optimal, leading to poor conversion of nitrate and a falsely negative test. The 2011 AAP guidelines suggest that in infants with frequent urination, nitrite testing may be particularly insensitive.[4] High urine specific gravity reduces the sensitivity of this test, and high urinary ascorbic acid may also produce a negative test in the presence of a small amount of nitrite.

URINE CULTURE

Urine collection

Culturing urine remains the gold standard for confirming the diagnosis of UTI. Potential contamination of the urine sample is a well-recognized problem that can make interpretation of the culture results difficult. Collection of urine in infants by a collection device, such as the U-Bag (Hollister, Libertyville, IL), is associated with a high rate of bacterial contamination (56% to 69%) and is not an acceptable collection method for urine culture.[129] A positive culture from a bagged specimen cannot be used as confirmatory evidence of a UTI.[4]

To reduce the risk for bacterial contamination, urine for culture is collected by clean catch, catheterization, or suprapubic aspiration in neonates. The clean catch method involves cleaning the external genitalia with mild antiseptic

and collecting urine in midstream into a sterile container. This method is generally acceptable for adolescents and cooperative children. Suprapubic urine aspiration involves percutaneous insertion of a needle into the urinary bladder and aspirating urine into a sterile syringe. This method is reserved for use in neonates and infants younger than 2 months of age, when the urinary bladder is a pelvic organ. The single most important factor in success of the procedure is whether the bladder is palpable at the time of the aspiration. The success rate can be further enhanced by the use of ultrasound guidance. Catheterization of the urethra to obtain urine is the preferred method for collection in a noncooperative patient, in whom clean catch collection of urine is not possible. If a delay in the inoculation of the culture is expected, urine specimens should be refrigerated to prevent the overgrowth of bacteria at ambient temperature.

Bacterial count

> **KEY POINTS**
>
> - A positive urine culture obtained from bagged specimens is inadequate to confirm the presence of UTI.
> - Suprapubic aspiration (neonates) and catheterization are the preferred methods for urine culture.

A growth of more than 10^5 colony-forming units (CFU)/mL of a single species of bacteria in a catheterized urine sample is considered positive evidence of UTI (Table 49.2).[12] Any growth of a single organism in a sample obtained by suprapubic aspiration is regarded as a strong indication of UTI. From his study of catheterized urine cultures in patients younger than 24 months of age, Hoberman et al.[130] concluded that UTI can be diagnosed accurately by a colony count of 50,000 CFU/mL in this age group. The AAP guidelines also endorse a colony count of 50,000 CFU/mL of a single organism in association with evidence of pyuria as the cutoff for a positive culture.[4]

Colony counts lower than those listed in Table 49.2 may be considered diagnostic of UTI in some clinical circumstances. These include patients currently receiving

Table 49.2 Microbiologic criteria for positive urine culture

Method of collection	Threshold for diagnosis of urinary tract infection*
Suprapubic aspiration	1,000 CFU/mL
Catheterization of bladder	50,000 CFU/mL†
Midstream clean catch	50,000 CFU/mL†
Bagged urine culture	Unreliable

* Assumes single organism is identified.
† Presence or absence of pyuria should be used to differentiate between true infection and colonization.

antibiotic therapy, patients with complete ureteral obstruction preventing the flow of infected urine and bacteria into the bladder, patients with urinary frequency who may have a reduced dwell time of urine in the bladder, and patients infected with organisms that are well known to have lower colony counts in urine culture, such as *S. saprophyticus*.[18,19,29] On the other hand, certain organisms are not considered clinically relevant in children under 2 years of age. These include *Lactobacillus* species, coagulase-negative staphylococci, and *Corynebacterium* species.[4]

> **KEY POINTS**
>
> - *S. saprophyticus* can be pathogenic with low CFU counts, especially in a symptomatic patient (usually adolescent girls).
> - *Lactobacillus* species, *Corynebacterium* species, and coagulase-negative staphylococci are not usual urinary pathogens. These can be ignored in urine culture in otherwise healthy children.

RADIOLOGIC IMAGING

The purpose of radiologic investigations in patients with UTI is twofold: (1) to search for any malformations of the urinary tract that may predispose to UTI and (2) to establish the diagnosis of acute pyelonephritis, when other evidence may be lacking. A consensus regarding the types of imaging studies necessary in patients with first UTI is still lacking.

Ultrasound

Renal ultrasound has been considered an essential investigation in patients with first-time febrile UTI.[131] But recommendations regarding the use of renal ultrasound in the management of children with UTI continues to evolve. In a review of the radiologic investigations of 309 children younger than 2 years of age, renal ultrasound was normal in 88% and provided no additional diagnostic advantage in most patients.[132] Change in therapy as a result of ultrasound findings would have been indicated in fewer than 1% of cases. In another study of radiologic imaging in 124 children with first febrile UTI, ultrasound detected only one patient with urologic

> **KEY POINTS**
>
> - Renal ultrasound detects very few abnormalities in children with UTI.
> - Renal scarring cannot be effectively detected by renal ultrasound.
> - AAP recommends renal ultrasound in all children with UTI.

abnormality.[133] Others also have pointed out the poor performance of renal ultrasound in children with UTI to detect significant abnormalities that would alter the management course.[134,135] Additionally, renal ultrasound also performs poorly in detecting renal scars.

The guidelines from the National Institute for Health and Clinical Excellence (NICE) in the United Kingdom recommend that all infants under 6 months of age should undergo a renal ultrasound.[136] A critical appraisal of the NICE guidelines seems to indicate that limiting ultrasounds to children under 6 months of age does not significantly change patient management.[137] In contrast, the AAP guidelines make no such age differentiation and recommends that all children with a febrile UTI undergo a renal ultrasound.[4] Ultrasound may be the initial investigation of choice when suspicion of complications, such as renal or perinephric abscess are being considered in a patient with acute pyelonephritis. It is important to point out that the clinical need should guide the investigative decision regarding the use of renal ultrasound in patients with UTI, especially those with atypical manifestations or clinical courses.

Vesicocystourethrography and radionuclide cystography

Traditionally, vesicocystourethrography (VCUG) or radionuclide cystography (RNC) have been used to assess VUR. Since recent studies has cast doubt on the utility of antibiotic prophylaxis in the management of VUR, the role of the routine VCUG is also being challenged. Contrast VCUG with fluoroscopic guidance allows visualization of the anatomy of the bladder and urethra. RNC is an acceptable alternative to contrast VCUG, particularly in females, when bladder outlet and urethral obstructive lesions are unlikely. The advantage of nuclear cystogram is that it exposes children to only approximately 1% to 2% percent of the radiation dose used in contrast fluoroscopy VCUG.

KEY POINTS

- In past, VCUG has been used to detect VUR in most patients with a febrile UTI.
- Selective use of VCUG is now emerging.
- AAP recommends VCUG after a second UTI.

A growing body of evidence supports a more selective use of VCUG in the evaluation of febrile UTIs.[138-141] In a retrospective review of 2036 children who had imaging following a UTI, VCUG detected abnormalities in only 42 patients (4.9%), leading the authors to conclude that VCUG could safely be reserved for patients with additional risk factors.[138] The NICE guidelines suggest avoiding routine VCUGs for

the identification of VUR.[136] The AAP guidelines recommend that VCUG can be delayed until the second episode of UTI, because the risk for radiation exposure and discomfort from the procedure outweigh the potential benefits for the majority of patients.[4]

Timing of VCUG or RNC in a patient with newly diagnosed febrile UTI also has been recently re-evaluated. So as not to overdiagnose transient VUR associated with UTI, the general recommendation in the past has been to defer VCUG/RNC for 4 to 6 weeks after the diagnosis of UTI. In several recent studies, however, it has been shown that the incidence of VUR in cystograms obtained within 1 week of diagnosis of UTI is not different from cystograms performed later in the clinical course of febrile UTI (1 to 4 weeks).[142-145] It has also been demonstrated that the patients undergoing early VCUG evaluation (less than 1 week) did not have any worsening of their clinical condition.[142] The AAP guidelines do not comment regarding optimal timing of VCUG or RNC studies.[4]

Dimercaptosuccinic acid renal scan

Intravenous pyelography has, in the past, been used as the gold standard for detection of pyelonephritic scars following acute pyelonephritis. In the last two decades, nuclear scan, using technetium-99m–dimercaptosuccinic acid (DMSA) has evolved as an attractive alternative to intravenous pyelogram for evaluation of pyelonephritic renal scars or reflux nephropathy.[146] Furthermore, DMSA renal scan obtained early in the course of a febrile UTI also can help in the diagnosis of acute pyelonephritis, in cases in which other evidence may be lacking.[146,147] DMSA renal scan is discussed further in Chapter 7.

Preference for diagnostic use of DMSA renal scan in the investigation of febrile UTI is highly institution dependent. The AAP Subcommittee on Urinary Tract Infection has not recommended DMSA scan as a required imaging investigation of children less than 2 years.[148] Recently, a "top-down" approach replacing cystograms with DMSA renal scans as the initial investigation has been advocated for investigation of febrile UTI in children.[149,150] A meta-analysis of the top-down approach, however, concluded that the DMSA scan did not perform well in identifying VUR.[151] VUR and its management are discussed further in Chapter 48.

RECURRENT URINARY TRACT INFECTION

After the first episode of UTI, recurrent UTI may be seen in 30% to 40% of patients, especially in those with anatomic urinary tract anomalies such as VUR, urinary obstruction, or bladder divirticulum.[152-154] Female sex, age younger than 6 months, dysfunctional elimination, and bladder instability are other risk factors for recurrent UTIs.

TREATMENT OF URINARY TRACT INFECTION

The aims of antimicrobial treatment for UTI are (1) to clear the acute infection, (2) prevent urosepsis, and (3) reduce the likelihood of renal damage. The principles for selection of antibiotic therapy for UTI are similar to the guidelines used in choosing antibiotics for other serious infections, which are bacterial susceptibility, a narrow antimicrobial spectrum antibiotic selection, tolerance of therapy by patients, a low toxicity profile of therapy, and cost-effectiveness.

INITIAL THERAPY

Initial antibiotic therapy of UTI is often empiric. The susceptibility pattern of the infecting organism grown in urine culture should be used subsequently to guide transition to an appropriate antimicrobial agent. The choice of empiric antibiotics is dictated by the sensitivity pattern of the organisms in the community, especially in view of the increasing resistance of uropathogens to antimicrobial agents over the last two decades, particularly ESBL organisms.[155] Up to 40% to 58% of uropathogens are known to be resistant to ampicillin or amoxicillin, and 5% to 36% are resistant to trimethoprim-sulfamethoxazole (TMP-SMX).[156-158] Antibiotic resistance, however, varies across geographic regions, and local antibiotic resistance patterns should be considered in choice of empiric antibiotic therapy.

TMP-SMX, second- and third-generation cephalosporins, and amoxicillin/clavulanate are generally used as the initial empiric therapy for the treatment of UTI in the United States.[159] Table 49.3 details dosing regimens for commonly used antibiotics to treat UTI. The US Food and Drug Administration also has approved ciprofloxacin as an option for complicated UTI or pyelonephritis in children.[160] Antibiotics doses in children should not exceed the maximum daily adult dosage.

KEY POINTS

- Antimicrobial resistance patterns vary widely with geographic region.
- TMP-SMX, second- and third-generation cephalosporins, and Augmentin (amoxicillin) are generally the first-line agents for empiric treatment of UTI.
- Ciprofloxacin may be used in complicated urinary infections or to treat multidrug resistant organisms, but should not be routinely used as empiric therapy.

FEBRILE URINARY TRACT INFECTION

First three months

Neonates (younger than 1 month of age) with febrile UTI should be hospitalized and treated with intravenous therapy at least initially. Bacteremia and meningitis should be excluded by obtaining blood for culture and examining the CSF. Inpatient intravenous antibiotic therapy is recommended because of the inability of young infants to adequately absorb oral antibiotics, the immaturity of the young infant's immune system, and the consequent increased risk for disseminated infection.

Initial parenteral therapy is generally recommended for all infants up to 3 months of age with UTI, especially if they are ill appearing.[161] Empiric parenteral antibiotic therapy for infants younger than 3 months of age can consist of the combination of ampicillin and gentamicin, which provides coverage for *group B streptococci, Enterococcus,* and Gram-negative organisms. Alternatively, cefotaxime as a monotherapy or the combination of cefotaxime and gentamicin can be considered.[161,162] Emerging evidence suggests that infants may be safely transitioned to oral therapy without increased risk for treatment failure. Parenteral therapy should continue until the infants improve clinically (usually 3 to 7 days) before switching to oral therapy. Oral antibiotic therapy is continued to complete a total of 14 days of antibiotic treatment.[163]

Outpatient management may be considered in carefully selected 1- to 3-month-old infants with febrile UTI, provided they do not appear acutely ill, do not have bacteremia or meningitis, and are able to be followed closely.[156,161] Efficacy of oral cefixime (16 mg/kg on first day and then 8 mg/kg/day for remainder of duration) with intravenous cefotaxime (200 mg/kg/day) was compared in one study of infants with UTI.[156] The study found the two treatment regimens to be equally effective, with urine culture becoming negative after 24 hours in both treatment arms. It needs to be cautioned that the number of patients in the 4- to 7-week age group in this study was small (13 total, 4 oral, and 9 intravenous treatment). Apart from cefixime, other third-generation cephalosporins, such as cefdinir and ceftibuten, also can be antibiotic choices. Outpatient treatment with ceftriaxone or gentamicin given every 24 hours also can be an acceptable alternative in such patients.[161] Parenteral therapy should be continued until the infant is afebrile for 24 hours, with the remainder of the 14-day total course of therapy completed with oral antibiotics.

Infants and children

Although intravenous antibiotic therapy has been the standard in the 3- to 24-month-old children, oral antibiotics, particularly the third-generation cephalosporins may be equally effective in these children. Effectiveness of oral antibiotic therapy in treating febrile UTI in children 1 to 24 months of age has been well established.[156] Total duration of therapy should be between 7 and 14 days.[4]

Table 49.3 Empiric antibiotic treatment for common urinary pathogens

Organism	Oral antibiotic therapy	Intravenous antibiotic therapy
Gram-negative bacteria		
Enterobacteriaceae	Amoxicillin 30 mg/kg/day divided q 8–12 h	Cefazolin 50 mg/kg/day divided q 8 h
	Amoxicillin-clavulanate 45 mg/kg/day divided q 12 h	Cefuroxime 150 mg/kg/day divided q 8 h
	Cephalexin 50 mg/kg/day divided q 6–8 h	Cefotaxime 150 mg/kg/day divided q 8 h
	Cefprozil 30 mg/kg/day divided q 12 h	Ceftriaxone 50 mg/kg/day q 24 h
	Cefuroxime axetil 20–30 mg/kg/day divided q 12 h	Gentamicin 6 mg/kg/day divided q 8 h in children, 7.5 mg/kg/day divided q 8 h in neonates
	Cefixime 8 mg/kg/day once daily	
	TMP-SMZ 8–12 mg TMP/kg/day divided q 12 h	
ESBL organisms	Use susceptibility results to guide therapy	Meropenem 60 mg/kg/day divided q 8 h
Pseudomonas aeruginosa	Ciprofloxacin 20-40 mg/kg/day PO divided q 12 h, maximum dose 1.5 g/24 hr.	Ceftazidime 150 mg/kg/day divided q 8 h, *or* Ticarcillin-clavulanate 200–300 mg/kg/day divided q 6 h
Gram-positive bacteria		
Enterococcus	Ampicillin 200 mg/kg/day divided q 6 h, if organism is susceptible.	Ampicillin 200 mg/kg/day divided q 6 h, *or* Vancomycin 40 mg/kg/day divided q 6–8 h
Group B streptococci	Penicillin G 150,000–200,000 units/kg/day divided q 6 h, or Ampicillin 200 mg/kg/day divided q 6 h	Ampicillin 200 mg/kg/day divided q 6 h Oxacillin 100 mg/kg/day divided q 6 h, or Vancomycin 40 mg/kg/day divided q 6–8 h
Staphylococcus aureus	Use susceptibility to guide therapy. Use susceptibility results to guide therapy.	Use susceptibility results to guide therapy
Staphylococcus saprophyticus		

Oral cefixime also can be used to treat older children and adolescents with febrile UTI. Alternatively, a short course of intravenous antibiotic therapy (2 to 4 days), followed by oral antibiotic therapy may be used. In children treated with intravenous antibiotics, single daily dosing of aminoglycosides is reported to be as safe and effective as every 8 hour dosing.[164,165] The AAP guidelines state that evidence distinguishing among treatment durations of 7, 10, or 14 days is lacking, and a treatment range of 7 to 14 days is appropriate for the management of UTIs.[4] Children with additional risk factors, such as underlying urinary abnormalities, may require a prolonged course of parenteral therapy.

KEY POINTS

- Neonates with UTI should be hospitalized for intravenous therapy.
- Infants under 1 month of age should have a complete sepsis evaluation to evaluate for concomitant bacteremia or meningitis.
- Oral therapy may be considered in uncomplicated patients.
- The treatment of pyelonephritis is generally 14 days.
- Infection with ESBL organisms may require prolonged parenteral therapy in an otherwise healthy child.

CYSTITIS

Oral antibiotic treatment is generally adequate for treatment of uncomplicated cystitis. A short course of antibiotics (3 days) has been shown to be effective for treatment of adults with uncomplicated cystitis and normal urinary tract anatomy. Short-course oral antibiotics also have been shown to be safe and effective in treating cystitis in children with normal urinary tracts.[166,167] In these studies, there were no significant differences in the recurrence rate of UTI, or development of resistant organisms at the end of treatment with short antibiotic therapy. Three days of oral TMP-SMX has been found as effective as conventional therapy (longer than 5 days) in treatment of cystitis.[164,167] A meta-analysis of studies of comparing short-course therapy (less than 3

days) to long-course therapy (longer than 10 days), however, found insufficient evidence to safely endorse short-course therapy.[168]

Single-dose amoxicillin has been found to be an ineffective treatment of cystitis and is not recommended.[166,167] Madrigal et al. noted an unacceptably high recurrence rate of UTI (20.5%) in children treated with a single dose of TMP-SMX, compared to a recurrence rate of 5.6% and 8%, for children treated with a 3-day and 7-day course of treatment with TMP-SMX, respectively.[169]

TREATMENT OF EXTENDED-SPECTRUM β-LACTAMASE URINARY TRACT INFECTION

The increasing prevalence of multidrug-resistant uropathogens has posed clinicians with new therapeutic dilemmas. Selection of appropriate antimicrobial therapy should, eventually, be guided by the susceptibility results of the urine culture. ESBL isolates are resistant to all β-lactam antibiotics, including penicillins, monobactams, and cephalosporins. ESBL organisms remain susceptible to carbapenems and cephamycins.[170] Ciprofloxacin may be a possible therapeutic option; however, plasmid-mediated gene transfer also may result in resistance to fluoroquinolones, aminoglycosides, and TMP-SMX. If the index of suspicion for an ESBL organism is particularly high, such as in patients with prolonged or complex hospital course, previous antibiotic use, indwelling medical devices, invasive procedures, or history of ESBL infections, empiric coverage of ESBLs with a carbapenem antibiotic may be indicated.

COMPLICATIONS OF URINARY TRACT INFECTION

RENAL SCARS

Acute pyelonephritis has the potential to cause tubulointerstitial damage and renal scar formation. Host response, tubular injury, and ischemia during acute pyelonephritis result in the formation of renal parenchymal scars. Using DMSA renal scan, renal parenchymal abnormalities suggestive of acute pyelonephritis are detected in the acute phase (less than 15 days) in 50% to 85% of children with the first episode of acute pyelonephritis.[171-173] A meta-analysis of 33 published studies meeting inclusion criteria found that overall prevalence of renal scarring after 5 months was only 15% (confidence interval [CI], 11% to 18%) in patients who had a febrile UTI.[174] Such scars are sometimes denoted as "primary scars," are common in boys.[173] Girls, on the other hand, are more prone to developing recurrent UTI and secondary renal scars. Because renal scarring following febrile

UTI occurs in some patients, whereas others are spared, the roles played by mediators of inflammation and genetic predisposition have been proposed.[175,176] However, a meta-analysis of the literature was unable to definitively link specific genetic polymorphisms with an increased risk for renal scarring.[177] Urinary tract abnormalities, especially severity of VUR, influence renal scarring, being more common in grade III or higher.[174,178,179] The number of acute pyelonephritis events also has a bearing on the incidence of renal scarring. Jodal reported that renal scars were seen in only 9% of children with one episode of acute pyelonephritis, whereas 58% of children with four or more episodes of pyelonephritis developed chronic scars.[180]

Pyelonephritic renal scars are usually present in the upper and lower poles of the kidney, possibly because of the type of papillae present in these regions. Patients with severe bilateral renal scarring can develop decreased creatinine clearance compared to those with unilateral or mild scarring.[181,182] It is possible that compensatory hypertrophy in the contralateral kidney leads to a normal glomerular filtration rate (GFR) in patients with unilateral damage. Reports that early and effective treatment of acute pyelonephritis prevents acute renal parenchymal damage but the impact on development of renal scars is conflicting.[183,184]

HYPERTENSION

The prevalence of hypertension in patients with history of UTI has been reported to be 1.2% to 35%.[184-189] In some studies, a higher prevalence of hypertension has been reported in patients with renal scars, and the relative risk for hypertension has been estimated to be 2.9 times higher in those with renal scars compared to those without renal scarring.[186] Hypertension in these patients is believed to be mediated by renin released by the ischemic renal scar tissue.

CHRONIC KIDNEY DISEASE

Chronic pyelonephritis is an uncommon cause of ESRD in children.[185,190] Smellie et al. followed 226 children with VUR and UTI into adulthood over 10 to 41 years and noted that CKD developed in 10% of patients in whom renal functions were assessed, and ESRD evolved in 1.9% percent.[191] The 2013 report of the US Renal Data System (USRDS) lists chronic pyelonephritis and reflux nephropathy as the primary diagnosis of ESRD in 3.5% in the 2000 to 2006 cohort and 2.5% in the 2007 to 2011 cohort.[192] According to rhe 2011 annual report of the North American Pediatric Transplant Cooperative (NAPRTCS) database, chronic pyelonephritis and interstitial nephritis account for 1.4% all patients on dialysis.[193] A review of the published literature on the relationship of UTI and CKD led Salo et al.[194] to conclude that UTI without associated structural abnormalities does not lead to CKD and ESRD. It is possible that a decreasing trend in CKD resulting from febrile UTI (chronic pyelonephritis)

reflects early diagnosis and improved management of these patients.

FUNGAL URINARY TRACT INFECTION

Fungal UTI in children is primarily caused by *Candida* species and is most frequently seen in neonates or older children in the intensive care unit (ICU), in immunocompromised patients, and in those with prolonged indwelling urinary drainage catheters. Bryant et al.[195] reported a prevalence of 0.5% candiduria among 8790 infants admitted to the neonatal ICU (NICU).[196] *Candida* species was the pathogen recovered in 42% of neonates with hospital-acquired UTI in the NICU.[196] Candida UTI is more commonly seen in preterm and low-birth-weight babies and may present with nonspecific symptoms of fever, feeding intolerance, respiratory distress, lethargy, apnea, and abdominal distention.[197,198] Oliguria or anuria can be seen as a result of obstruction of the urinary tract by a fungus ball (Figure 49.3). Renal involvement also can manifest as rising serum creatinine and nonoliguric renal failure.

DIAGNOSIS

Growth of greater than 10^4 CFU/mL *Candida* organism in a single urine culture obtained in a catheterized urine sample is generally considered as diagnostic of candidal UTI.[196-198] Abnormalities in renal ultrasound and CT scan are common in patients with funguria. Renal fungus balls or a fungal abscess are reported in 35% to 40% of patients on renal imaging studies.[195,196] Because of its portability, ultrasonography can be used as the initial investigative tool for detecting renal lesions, but CT scan and or magnetic resonance imaging also may be necessary in some cases.
Figure 49.3 Renal ultrasound showing dilated calyces, pelvis, and proximal ureter. An echogenic fungus ball (arrow) is seen. The patient's blood and urine grew *Candida parapsilosis*.

TREATMENT

Positive blood culture for fungus or candidemia has been reported in 30% to 50% in neonates with candiduria.[195,196] Therefore, systemic antifungal therapy is recommended in the treatment of patients with fungal UTI. Amphotericin B monotherapy is the preferred therapy for candiduria in neonates in the United States.[199] Intravenous amphotericin B is administered at a dose of 1 mg/kg/day. Amphotericin B is preferred to the lipid formulations of amphotericin B in neonates with renal candidiasis, because lipid formulations penetrate renal tubules poorly.[197,199] Renal function and serum electrolytes should be monitored closely in these patients, and the amphotericin B dose should be decreased if serum creatinine rises. Hypokalemia resulting from renal tubular acidosis may require potassium supplementation.

The Infectious Disease Society of America (IDSA) guidelines for the treatment of candidiasis, recommends no treatment for patients with asymptomatic cystitis.[200] Because of the risk for dissemination, treatment may be considered irrespective of symptoms in high risk patients such as neonates, patients undergoing urologic procedures, or neutropenic patients. For symptomatic cystitis and pyelonephritis, IDSA recommends fluconazole therapy for 2 weeks, with amphotericin as an alternative therapeutic option.[200] The site of infection within the urinary tract and the clinical response determine the length of treatment of funguria. Treatment for at least 3 weeks after negative blood and urine cultures is generally recommended. Surgical intervention is reserved for patients with fungus balls causing severe obstruction of the urinary tract, or those with renal abscess requiring drainage.

KEY POINTS

- Fungal UTIs are primarily caused by *Candida* species.
- Admission to an ICU, prolonged indwelling catheters and an immunocompromised condition predispose to fungal UTIs.
- Growth of greater than 10,000 CFU/mL from a catheterized urine sample is diagnostic of candidal UTI.
- Fluconazole or amphotericin may be used to treat candidal UTIs. Infants generally should be treated with amphotericin.

Irrigation of the urinary bladder by an aqueous solution of amphotericin B has been used for the treatment of uncomplicated fungal infection of the lower urinary tract. Amphotericin is used in a concentration of 50 mcg/mL in

sterile water. Such therapy has, however, come into question recently. Lack of controlled studies to evaluate the dose and duration of therapy, as well as availability of oral fluconazole as a treatment option, has decreased the attractiveness of amphotericin B bladder irrigation for the treatment of funguria.[201] Bladder irrigation has a high relapse rate and generally should be reserved for refractory infections with resistant organisms. The IDSA guideline does not recommend bladder irrigation for uncomplicated cystitis; its potential role in the treatment of fluconazole-resistant *Candida* infections has been suggested.[200]

VIRAL HEMORRHAGIC CYSTITIS

Viral hemorrhagic cystitis is commonly seen in immunocompromised patients and is especially common in patients with bone marrow transplantation (BMT). Viral hemorrhagic cystitis in BMT occurs either 1 to 2 weeks after transplantation (early onset) or 4 to 6 months later (late onset). Viruses associated with late-onset hemorrhagic cystitis are adenovirus, polyoma BK virus, cytomegalovirus, human herpesvirus-6, and simian virus 40 (SV40).[202–206] A prospective study of 102 children who underwent allogenic stem cell transplantation found that 25.5% of patients developed hemorrhagic cystitis, of which 80.8% were due to BK virus, 15.4% to adenovirus, and 3.8% to JC virus.[207]

Gross hematuria, severe suprapubic pain, and dysuria are common symptoms of viral hemorrhagic cystitis. Diagnosis of viral cystitis in an immunocompromised host is made by quantitative polymerase chain reaction (PCR) obtained in the urine. Serologic methods are less reliable in immunocompromised hosts, who may not be able to mount a good antibody response.[208] Ultrasound examination of the urinary bladder in hemorrhagic cystitis shows a thickened bladder wall. This finding may resemble the ultrasound features seen in rhabdomyosarcoma of the bladder.

KEY POINTS

- Hemorrhagic cystitis can be the result of chemotherapy, viral infection or radiation.
- Late-onset hemorrhagic cystitis may occur in BMT patients with adenovirus, BK virus, cytomegalovirus, or JC virus.
- Diagnosis of viral cystitis may be made by quantitative PCR from the urine.
- Viral cystitis is generally self-limited, but may be treated with cidofovir in immunocompromised patients.

Viral cystitis is self-limiting and resolves in approximately 2 to 3 weeks. Persistence of ultrasound findings or symptoms is an indication for cystoscopy and biopsy of the bladder wall. Symptomatic therapy is usually sufficient in hemorrhagic cystitis. Cidofovir, a newer antiviral agent, has been used in the treatment of polyoma BK, as well as adenoviral hemorrhagic cystitis, but well-controlled studies are lacking.[209-211] The propensity of cidofovir to cause nephrotoxicity limits its use to the most severe cases at this time.

Asymptomatic bacteriuria

Bacteriuria present in children without any clinical manifestations of UTI has been well known. Such asymptomatic bacteriuria (ABU) can occur in all age groups and is more common in girls than boys.[212] Wettergren et al.[10] described ABU in 2.5% of unselected boys and 0.9% of girls in infancy. In their landmark epidemiologic study, Kunin et al.[1] screened 9878 school children in Virginia. They reported the prevalence of ABU to be 1.1% in girls and only 0.04% in boys. Similarly, in screening of 13,464 schoolgirls aged 4 to 18 years in Newcastle, the prevalence of asymptomatic bacteriuria was noted to be 1.9%.[212,213] In contrast, the prevalence of asymptomatic bacteriuria in boys was only 0.2%.

The spectrum of organisms isolated in patients with ABU is similar to that associated with symptomatic UTIs. *E. coli* was noted to be the most common organism (91.7%) in the Newcastle study, followed by *Klebsiella* species (5.2%), *Proteus mirabilis* (1.2%), *Streptococcus faecalis*, *group B streptococci*, and coagulase-positive *Staphylococcus* (0.4% in each group).[213] Although it was initially thought that *E. coli* causing ABU are less virulent, further research has revealed highly variable virulence properties of ABU *E. coli*. Some strains of *E. coli* associated with ABU do seem to be less adherent to epithelial cells compared to disease-causing strains. Among ABU *E. coli* that do adhere to epithelial cells, there may be a reduced host proinflammatory cytokine response compared to uropathogenic *E. coli* strains.[214]

Although patients are asymptomatic at the time of initial detection, close evaluation of these children may reveal a history of nonspecific symptoms, such as urgency, abdominal pain, nocturia, frequency of urination, or generally poor health. Complete absence of recent symptoms has been reported in 24% to 56% of cases and a history of UTI can be demonstrated in 13% to 21% cases.[1,213] Minor structural abnormalities of the urinary tract, such as caliectasis, hydronephrosis, and abnormalities in renal size have been noted in 10% of 20% cases.[1,213]

Management of ABU had been controversial. Kunin recommended treatment to reduce morbidity associated with UTI.[2] Savage et al. demonstrated that antibiotic therapy did not alter long-term recurrence or eradication of bacteriuria.[215] Lindberg et al.[216] also noted that despite clearance of bacteriuria by antibiotics, there was no difference in recurrence rate in the treated and untreated groups over 3 years

of observation.[216] The Newcastle Covert Bacteriuria Study Group also showed similar results on treatment with antibiotics.[212] Based on these observations, patients with ABU need not be treated with antibiotics, unless symptomatic infections are demonstrated.

The long-term outlook of patients with ABU is generally optimistic. Of children, 40% to 50% become culture negative in 2 to 5 years without any antibiotic therapy.[217] Although up to 15% of patients with ABU may have renal scars when investigated, new scar formation is unusual.[212,215]

SUMMARY

Infections of the urinary tract are a common childhood disorder that can lead to significant morbidity and hospitalizations. Our understanding of the structural and molecular predispositions to UTI makes it possible to develop a unified diagnostic and therapeutic approach that can be practiced in tertiary care centers and in the community. Such a unified management approach may result in a lowered long-term risk for renal damage. Recent data suggest that the renal scarring resulting from UTI may be determined by host inflammatory response, presence of urinary tract abnormalities, and the bacterial virulence. UTI and chronic pyelonephritis is, by itself, an uncommon cause of CKD and ESRD.

Clinical Vignette 49.1

A previously healthy 3-month-old male infant presented to his pediatrician with a 3-day history of fever. Besides a mild cough, he was otherwise asymptomatic. His pediatrician obtained a urinalysis, which showed 20 WBCs, positive nitrites, and positive leukocyte esterase. A urine culture was obtained via catheterization, and the patient started on oral amoxicillin. Three days later the urine culture demonstrated greater than 100,000 CFU/mL of *E. coli* resistant to all β-lactam antimicrobial agents, but sensitive to ciprofloxacin, carbapenems, and nitrofurantoin. The child was admitted to a local hospital and given 2 days of intravenous ciprofloxacin before being transitioned to oral ciprofloxacin.

After approximately 5 days of oral ciprofloxacin at home, the patient developed a red rash along his torso and extremities. He returned to his pediatrician and was diagnosed to have an allergy to fluoroquinolones. The pediatrician transitioned the boy to nitrofurantoin and discharged him home. Shortly after finishing his course of nitrofurantoin, the patient became febrile again and returned to his pediatrician. He was otherwise doing well, although his oral intake is slightly decreased from his baseline. The pediatrician obtained a repeat urine culture, which again demonstrated greater than 100,000 CFU/mL

of ESBL *E. coli*. The patient was admitted for further therapy. He was treated with intravenous meropenem, and his fever quickly defervesced in the next 36 hours.

TEACHING POINTS

- This case describes an otherwise healthy young boy who presents with a UTI resulting from an ESBL organism. The initial choice of ciprofloxacin is appropriate, despite the patient's young age, because he has an infection with a multidrug resistant organism.
- His subsequent development of a presumed fluoroquinolone allergy is unfortunate, because it limits his therapeutic options to parenteral agents. Although the initial organism was susceptible to nitrofurantoin, this agent is not indicated for the treatment of pyelonephritis in children and it is not surprising that the child relapsed.
- In view of the development of allergy to ciprofloxacin, the only appropriate therapeutic option is an intravenous carbapenem, preferably meropenem.
- Despite his excellent and rapid clinical recovery, this patient must receive 14 days of therapy with intravenous meropenem, but may be eligible for intravenous therapy at home. A patient's eligibility for home therapy should be made on an individual basis.
- This child should undergo a renal ultrasound while hospitalized, and a VCUG also may be indicated. Generally, it seems that VCUG is not indicated until the second episode of UTI, although abnormalities on renal ultrasound could trigger a more through radiologic evaluation.
- Given that the patient did not receive appropriate therapy after developing a fluoroquinolone allergy, it may not be necessary to obtain additional imaging to explain his subsequent relapse. The timing of further imaging studies is controversial, and it may be appropriate to obtain the VCUG once he has recovered from his current infection.

REVIEW QUESTIONS

1. Which bacteria are responsible for most UTIs in children?
   a. *E. coli*
   b. *S. aureus*
   c. *Klebsiella* species
   d. Group B streptococci
   e. *Staphylococcus saprophyticus*

2. The 2012 AAP Task Force on Circumcision states that all male infants should undergo circumcision.
   a. True
   b. False

3. Which symptoms or laboratory test results differentiate cystitis from acute pyelonephritis?
   a. Abdominal pain
   b. Excessive crying
   c. Hematuria
   d. Fever
   e. Dysuria

4. According to the 2011 AAP UTI Practice Guideline, what is the minimum colony count diagnostic of urinary tract infection?
   a. 100,000 CFU/mL
   b. 50,000 CFU/mL
   c. 20,000 CFU/mL
   d. 10,000 CFU/mL

5. All children under 2 years of age should have a renal ultrasound after diagnosis of UTI.
   a. True
   b. False

6. A 6-year-old girl with a history of spina bifida requiring routine urinary catheterization has a history of multiple episodes of UTI. She has been on multiple courses of antibiotics and was recently admitted after failing outpatient therapy on cefixime. You are suspicious she may have developed an ESBL infection. What is the *best* choice of empiric therapy for this child?
   a. Ceftriaxone
   b. Ceftazidime
   c. Meropenem
   d. Ampicillin-sulbactam

7. A male infant is born at 25 weeks' gestation and develops candiduria at two weeks of age while in the neonatal intensive care unit. Which antimicrobial agent should be empirically started?
   a. Fluconazole
   b. Micafungin
   c. Itraconazole
   d. Amphotericin

8. Which of the following viruses may cause cystitis in an immunocompromised patient?
   a. Adenovirus
   b. BK virus
   c. HHV-6
   d. CMV
   e. All of the above

9. Which of the following therapies is indicated in a 16-year-old girl with *Proteus mirabilis* bacteriuria found during a routine health screen?
   a. Cefixime
   b. Trimethoprim-sulfamethoxazole
   c. Ciprofloxacin
   d. Amoxicillin
   e. No therapy.

10. *E. coli* associated with asymptomatic bacteriuria have fewer virulence factors than pathogenic *E. coli.*
    a. True
    b. False

Pediatric renal tumors

EUGENE MINEVICH, ARMANDO J. LORENZO, W. ROBERT DEFOOR, AND MARTIN A. KOYLE

Tumors of the kidney account for fewer than 8% of childhood neoplasms. Although the great majority of these are embryonal (mostly Wilms) tumors, other malignancies also may be seen. Both the primary lesion and the effects of therapy have implications for the treating pediatric nephrologists. A clinicopathologic classification of renal tumors in children shown in Table 50.1 provides a framework for discussion in this chapter. It is likely that emerging genetic and molecular data may be instrumental in therapeutic and prognostic classification of these malignancies in the future.

WILMS TUMOR (NEPHROBLASTOMA)

Wilms tumor (WT), or nephroblastoma, is the most common primary malignant renal neoplasm of childhood. The multidisciplinary approach to this tumor by the National Wilms Tumor Study Group (NWTSG, now under the Children's Oncology Group [COG]) and the International Society of Pediatric Oncology (SIOP), has become an example for successful cancer treatment. Owing to refinements in surgery, chemotherapy, and radiation therapy, the overall cure rate for WT exceeds 85%. Studies of tumor genetics have laid the foundation for our understanding of tumor suppressor genes and genomic imprinting.

EPIDEMIOLOGY

The annual incidence of WT is 8 cases per million children younger than 15 years, representing 6.3% of cases of childhood cancer.[1] In the United States, approximately 450 new cases are diagnosed each year, making WT the fourth most common pediatric cancer by specific histologic type.[1] Girls have a slightly increased risk for the tumor with a male-to-female ratio of 0.92 to 1.00. The mean age at diagnosis is 44 months for unilateral disease and 31 months for bilateral disease. WT in the adult population is rare, although numerous cases have been reported.[2]

The majority of WT cases are sporadic and unilateral. Familial WT is uncommon, occurring in only 1.5% of the affected patients.[3] Most cases of familial WT occur in distant relatives rather than parents or siblings. Sixteen percent of cases of familial WT are bilateral, compared with 7% of sporadic cases. Children with bilateral disease present at a younger age, and their mothers tend to be older. Genitourinary anomalies (hypospadias, cryptorchidism, renal fusion anomalies) are present in 4.5% of patients with WT.[4]

GENETICS AND EMBRYOLOGY

WT is thought to result from an abnormal proliferation of metanephric blastema, without normal differentiation into tubules or glomeruli. Although WT was one of the original paradigms of the Knudson and Strong two-hit model of cancer formation, it has become apparent that several genetic events participate in Wilms tumorigenesis.[5] The first suppressor gene *WT1* (the only WT gene isolated to date) was identified as a direct result of the study of children with WT who also had aniridia, genitourinary anomalies, and mental retardation (WAGR syndrome).[6] Cytogenetic analysis of children with WAGR syndrome revealed deletions at chromosome 11p13, which was later found to encompass a

Table 50.1 Clinicopathologic classification of renal tumors in children

Nephroblastic Tumors
- Nephroblastoma (Wilms tumor)
- Nephroblastomatosis and nephrogenic rests

Mesenchymal Tumors
- Clear cell sarcoma
- Rhabdoid tumor
- Congenital mesoblastic nephroma

Metanephric Tumors
- Metanephric adenoma
- Metanephric adenofibroma
- Metanephric stromal tumor

Renal Epithelial Tumors
- Papillary renal cell carcinoma
- Renal medullary carcinoma
- Renal tumor associated with Xp11.2 translocation

Mixed Tumors
- Angiolipoma

Table 50.2 Clinical and genetic conditions associated with increased risk for Wilms tumor

High risk (>20%)
- WAGR syndrome (Wilms-aniridia-genitourinary-mental retardation) (*WT1* deletions)
- Denys-Drash syndrome (truncating and pathogenic missense *WT1* mutations)
- Familial Wilms tumor
- Perlman syndrome
- Mosaic variegated aneuploidy
- Fanconi anemia (D1/biallelic *BRCA2* mutations)

Moderate risk (5% to 20%)
- Fraser syndrome (*WT1* intron 9 splice mutations)
- Beckwith-Wiedemann syndrome (11p15 uniparental disomy, isolated H19 hypermethylation)
- Simpson-Golabi-Behmel syndrome (*GPC3* mutations/deletions)

Low risk (<5%)
- Isolated hemihypertrophy
- Bloom syndrome
- Li-Fraumeni syndrome, Li-Fraumeni-like association
- Hereditary hyperparathyroidism–jaw tumor syndrome
- Mulibrey nanism
- Trisomy 18 or Edwards syndrome
- Trisomy 13 or Patau syndrome
- 2q37 deletions

contiguous set of genes, including *PAX6* (the gene responsible for aniridia) and *WT1*.[7,8] *WT1* encodes a transcription factor critical to normal kidney and gonadal development; its deletion in experimental models has been shown to result in major genitourinary maldevelopment.[9] Although germinal deletions or mutations in *WT1* have been documented in almost all patients with WAGR syndrome and the related Denys-Drash syndrome (nephropathy, WT, and pseudohermaphroditism), only a small number of patients with sporadic WT carry *WT1* mutations.[10,11]

KEY POINTS

Overgrowth syndromes are associated with increased risk for WT, which include:
- Beckwith-Wiedemann syndrome
- Isolated hemihypertrophy
- Perlman syndrome (facial gigantism, renal dysplasia, islet hypertrophy, mental retardation, and WT)
- Sotos syndrome (cerebral gigantism)

A second WT predisposing gene *(WT2)* has been identified on chromosome 11p15.[12] This locus has been proposed based on studies of patients with both WT and Beckwith-Wiedemann syndrome (BWS). BWS is an overgrowth syndrome characterized by high birth weight, macroglossia, organomegaly, hemihypertrophy, neonatal hypoglycemia, abdominal wall defects, and ear pits and creases. Patients with BWS have a 5% to 10% risk for development of WT but are also predisposed to other malignant tumors, such as hepatoblastoma, neuroblastoma, and rhabdomyosarcoma.[13] Finally, mutations in the *p53* gene are observed in most cases of anaplastic histologic features of WT, implicating a role for this gene in progression from favorable to anaplastic histologic type.[14] Diverse genetic disorders that may be associated with an increased risk for WT are listed in Table 50.2.

PATHOLOGY

Wilms tumors can be variable in size, and margins are usually well circumscribed that separate it from normal kidney. Cut surface usually appears tan and may be lobulated (Figure 50.1).
Figure 50.1 Cut section of the kidney showing Wilms tumor affecting the lower pole of the kidney. Tumor is well demarcated and shows tan-brown cut surface with a few hemorrhages.

Hemorrhages may be present in the tumor mass. The classic histologic pattern (Figure 50.2) is composed of epithelial, blastemal, and stromal elements (triphasic). Approximately 90% of all renal tumors have favorable histologic findings. Up to 7% of WTs have unfavorable histologic features, which are characterized by diffuse anaplastic changes, a feature that predicts poor outcome. Anaplasia is defined as cells with nuclei having a diameter greater than normal, with increased nuclear
Figure 50.2 Light microscopy of Wilms tumor showing the classic or triphasic microscopic findings. Three elements of the tumor pathologic tissue (triphasic) consist of densely packed tumor cells with scant cytoplasm and large nuclei (asterisk), mesenchymal stroma consisting of fibroblast-like structures, and epithelial elements forming primitive renal tubules within islands of tumor cells (arrows). Primitive glomeruli may be in seen in some cases. Several primitive blood vessels are seen within the tumor in this patient (arrow head).

content or polyploid mitosis. Finally, clear cell sarcoma of the kidney and rhabdoid tumor of the kidney previously included in the WT category of unfavorable histologic findings are in fact clearly separate malignant entities.

Nephrogenic rests (NRs) are foci of embryonal kidney cells that persist abnormally into postnatal life. Histologically, these structures are similar to those of WT. They are present in approximately 1% of newborn kidneys and usually regress or differentiate by early childhood.[15] Because NRs are present in the kidneys of approximately 40% of patients with WT, it is presumed that the rests represent WT precursors.[16] *Nephroblastomatosis* is the diffuse or multifocal presence of nephrogenic rests.[17] NRs are subdivided as *intralobar* (ILNR) and *perilobar* (PLNR) according to their position in the renal lobe.[15] ILNRs are less common and are associated with WT syndromes discovered earlier in life (e.g., WAGR, Drash syndrome). PLNRs are associated with bilateral tumors and syndromes that present later (e.g., BWS and hemihypertrophy).

CLINICAL PRESENTATION

The vast majority of patients with WT present with an asymptomatic palpable abdominal mass. They also may present with abdominal pain, gross hematuria, hepatomegaly, varicocele, or lower extremity edema. Hypertension may result from either renal tissue compression by the tumor leading to renal ischemia (known as Page kidney) or by renin production by the tumor itself.[18] A small number of patients who have bleeding into their tumor may present with signs of hypotension, anemia, and fever. Rarely, patients with advanced-stage disease may present with respiratory symptoms related to the presence of lung metastases. More recently, WT has been diagnosed in utero with fetal ultrasonography.[19]

Every child should have a complete physical examination. Because of the concerns of rupture of the tumor capsule and local spread, care should be exercised not to palpate the tumor repeatedly or deeply. High-risk patients, such as those with syndromes or isolated physical findings having a high association with WT (aniridia, hemihypertrophy, BWS, WAGR syndrome), require regular, periodic screening by renal ultrasound to ensure that any asymptomatic tumor is identified before it becomes clinically manifested, and to provide the opportunity for nephron-sparing surgery.[20] Laboratory evaluation should include complete blood cell count, chemistry profile including renal function tests, routine electrolytes with calcium, urinalysis, and coagulation studies. Radiologic studies form an essential part of initial diagnostic evaluation, and are discussed below.

EVALUATION

Radiographic imaging is performed to evaluate the dimensions and location of the abdominal mass, to characterize

Figure 50.3 Computerized axial tomography showing a large Wilms tumor in the left kidney.

Table 50.3 Surveillance recommendations for patients at high risk for developing Wilms tumor

- Surveillance should be offered to children at greater than 5% risk for Wilms tumor.
- Surveillance should be offered only after review by a clinical geneticist.
- Surveillance should be carried out by renal ultrasonography every 3 to 4 months.
- Surveillance should continue until 5 years in all conditions except Beckwith-Wiedemann syndrome, Simpson-Golabi-Behmel syndrome, and some familial Wilms tumor pedigrees, in which it should continue until age 7 years.
- Surveillance can be undertaken at a local medical center with experience in pediatric ultrasonography.
- Screen-detected lesions should be managed at a tertiary care specialized center.

Source: Modified from RH, Walker L, Olsen/E, et al. Surveillance for Wilms tumour in at-risk children: pragmatic recommendations for best practice. Arch Dis Child. 2006;91:995–9. Reproduced with permission.

tumor origin, determine local extension, evaluate the contralateral kidney, and determine venous involvement of the malignancy. Renal ultrasonography (US) with Doppler technique is usually employed initially, because it can confirm the location as well as the nature of the tumor (cystic vs. solid). US also can provide good dynamic imaging of the renal vein and inferior vena cava. Abdominal computerized tomography (CT) and occasionally magnetic resonance imaging (MRI) can provide additional delineation data on the tumor's origin and extension, lymph node involvement, bilateral kidney involvement, invasion into major vessels, or liver metastases (Figure 50.3). Newly improved and efficient three-dimensional volume-rendering software is now available for visual reconstruction of tumor anatomy.[21] Chest radiographs, chest CT scan, or both should be obtained to evaluate the chest and identify any pulmonary metastases, which, if present, upstages the patient and hence the treatment.[22] Patients with conditions that have increased risk for WT should undergo periodic surveillance by renal US. Suggested guidelines for surveillance are given in Table 50.3.

STAGING

The staging of WT is critical to determining therapy and prognosis. The most widely accepted system in North America is the one developed by the National Wilms' Tumor Study Group (NWTSG) and extended by the Children's Oncology Group (COG). The NWTSG/COG approach allows pathologic and surgical staging to predict tumor behavior and tailor subsequent adjuvant therapy. Consequently, in North America, most patients with suspected WT undergo nephrectomy with lymphadenectomy immediately. Exceptions include patients with bilateral renal tumors, neoplasms in a solitary kidney, and the presence of tumor thrombus extending above the level of

the hepatic veins, situations that are managed with initial chemotherapy. The NWTS-V staging of WT is shown in Table 50.4. The NWTSG has further classified WT patients into low-risk and high-risk patients according to the presence of favorable versus unfavorable histologic findings based on the postnephrectomy histology.

TREATMENT APPROACHES

The approach to a patient with WT varies in Europe, compared to the North American approach.[23] Although most Societe Internationale D'oncologie Pediatrique (SIOP) centers make a presumptive diagnosis of WT based on imaging studies alone, in the United Kingdom, a needle biopsy may be performed to avoid misdiagnosis and to ascertain histology. The SIOP centers administer prenephrectomy chemotherapy, realizing that there may be as much as a 5% misdiagnosis rate and hence incorrect treatment. Over the past 30 years, these centers have shown that preoperative therapy decreases the incidence of tumor rupture during surgery.[24,25] Chemotherapy also downstages the tumor and in cases of metastases decreases the need for postoperative radiotherapy. Chemotherapy may shrink the tumor and eliminate overt signs of tumor spread. Chemotherapy clearly affects the final staging process and thus can sometimes confuse interpretation of results with the North American data. Despite the differences in approaches on either side of the Atlantic, both produce equally high rates of overall treatment success. Hence, there is no obvious better approach and both philosophies gain knowledge from one another synergistically. Nephrectomy, via a transperitoneal approach, is the initial

Table 50.4 National Wilms Tumor Study clinicopathologic staging of Wilms tumor

Stage	Clinicopathologic staging
1	Tumor limited to kidney and completely excised. No penetration of the renal capsule or involvement of renal sinus vessels.
2	Tumor extends beyond the kidney but is completely excised with negative margins and lymph nodes. At least one of the following has occurred: penetration of the renal capsule, invasion of the renal sinus vessels, biopsy of the tumor before removal (except for fine needle aspirate, which may qualify as stage 1), or spillage of tumor locally during removal.
3	Gross or microscopic residual tumor remains postoperatively (including inoperable tumor, positive surgical margins, diffuse tumor spillage involving peritoneal surfaces, regional lymph not metastasis, or transected tumor thrombus.
4	Hematogenous metastasis or lymph node metastasis outside the abdominal or pelvic cavities.
5	Bilateral renal tumors at diagnosis.

Source: Neville HL, Ritchey ML: Wilms' tumor: overview of National Wilms' Tumor Study Group results. Urol Clin North Am. 2000;27:435–42. Reproduced with permission.

treatment for unilateral disease if the mass can be completely resected. This is usually done via a chevron incision.

Current recommendations are to administer preoperative chemotherapy only to children with bilateral disease and those with inoperable tumor at presentation, intravascular tumor extension above the hepatic veins, and a tumor involving a solitary kidney. Pretreatment dramatically reduces tumor thrombus for patients with caval extension and tumor burden, which will substantially reduce the surgical morbidity.[26–28] Patients with bilateral disease, solitary kidney, or renal insufficiency or abnormalities of the non-involved kidney should be considered for a renal-sparing protocol, if at all possible.[29]

Partial nephrectomy of unilateral WT has been explored by some investigators to avoid late occurrence of renal dysfunction and the risk for metachronous WT.[30,31] They argue that nephrectomy for unilateral WT increases the risk for hypertension, proteinuria, glomerulosclerosis, and renal insufficiency owing to injuries from hyperfiltration and adjunctive chemotherapy or radiotherapy.[32–34] Most WTs are too large for a partial nephrectomy at initial presentation; therefore, preoperative chemotherapy is usually necessary if renal-sparing surgery is to be considered.

Current protocols do allow for flank approaches to the tumor, but the role of laparoscopy is being debated.[35] Whereas in the past, contralateral exploration was mandatory, modern imaging, which is able to uncover the smallest of contralateral tumors, and with the knowledge that the majority of these patients will receive adjuvant therapy that will likely have an impact on nonvisible lesions, this practice is no longer necessary.[36] In North America, however, lymph node sampling is mandatory, and, if it is not done, patients are automatically upstaged to stage 3, with the inherent need for more aggressive chemotherapy. In those with presumed bilateral disease, the current practice is to administer up-front chemotherapy without initial surgical exploration or biopsy. Of note is that in North America, just as when lymph nodes are not submitted for pathologic examination, any biopsy mandates upstaging to a stage 3.[37]

The major complications of surgical therapy have continued to decrease. A recent review of the records of patients in NWTS-IV found an 11% incidence of surgical complications after nephrectomy.[38] The most common complications were hemorrhage and small bowel obstruction. Risk factors associated with increased surgical complications are higher local tumor stage, intravascular extension, *en bloc* resection of other visceral organs, and incorrect preoperative diagnosis.[39]

KEY POINTS

- European data suggest that presurgical chemotherapy may shrink the tumor and decrease the likelihood of tumor rupture during surgery.
- With modern imaging techniques, exploration or biopsy of the contralateral kidney is not necessary.
- Lymph node sampling during surgery provides important information for staging. Omission of this surgical step can adversely affect treatment decisions.

TREATMENT OF NEPHROGENIC REST TUMOR

Surgical management becomes more controversial in the case of unilateral or bilateral multiple NRs, as seen in patients with nephroblastomatosis. The histologic appearance may be indistinguishable from that of WT. Thus, the growth pattern of the lesion as seen on serial imaging may be the best indication of the need for a nephrectomy. Accordingly, serial imaging is important in planning the appropriate intervention and avoiding unnecessary surgery. However, in children presenting with diffuse hyperplastic PLNR, seen as a ring surrounding the entire kidney, surgery

should be considered because of the high risk for WT. Most of these cases will manifest with bilateral disease, and partial nephrectomy after chemotherapy is a consideration.

POSTSURGICAL MANAGEMENT

Consecutive trials of the NWTSG, beginning in the late 1960s, provided critical insights into the role of adjuvant therapy for WT. The intergroup studies sought to refine adjuvant therapy regimens, with each study intensifying the therapy provided to high-risk patients and decreasing or modifying the therapy to lower risk patients.[40] NWTSG-I and NWTSG-II revealed that postoperative radiation was unnecessary in stage 1 disease and that the combined use of vincristine and dactinomycin was more efficacious than either drug alone. NWTSG-III showed that patients with stage 2 tumors with favorable histologic findings can be treated without abdominal irradiation if vincristine and dactinomycin are administered. This study also revealed that the addition of doxorubicin to the two-drug regimen improves outcome in stage 3 and 4 disease with favorable histologic findings. The remainder of the study focused on postoperative radiation treatment.

The last of the NWTSGs showed that pulse-intensive therapy is equally efficacious, less toxic, and more cost-effective than the conventional regimen, with overall 4-year survival rates of patients with favorable histologic findings approaching 90%.[41] The ongoing NWTSG-V was designed to find possible roles of gene expression in identifying patients at greater risk for relapse.[40] The role of adjuvant chemotherapy in providing benefit to children younger than 24 months who have small stage 1 tumors with favorable histologic features is being explored in this protocol. The current treatment algorithm of WT based on its stage and histology is shown in Table 50.5.

KEY POINTS

- WT is sensitive to chemotherapy and radiotherapy.
- Postoperative radiotherapy is not routinely recommended in stage 1 and 2 disease.
- Combined chemotherapy with vincristine and dactinomycin is more efficacious than either drug alone.

BILATERAL WILMS TUMOR

Bilateral WT occurs in approximately 5% to 10% of patients with WT. These children pose a therapeutic challenge because of difficulty in obtaining local control while sparing renal parenchyma. Compared to patients with unilateral WT, patients with bilateral tumors have an increased rate of renal failure, estimated to be 3.8% among patients treated in the NWTSG-IV.[42] The most common cause of renal failure in this patient group is need for nephrectomy because of tumor progression or recurrence, and not therapy-related effects.

In a child with bilateral WT, as noted previously, performing biopsies on both kidneys is no longer mandated. If tumor is identified in both kidneys, patients should be given preoperative chemotherapy that is appropriate for the tumor stage and histology. After 6 weeks of chemotherapy, the patient should be reassessed with abdominal CT to determine the feasibility of resection. If the tumor size has decreased, partial nephrectomy may be performed. If persistent tumor is discovered, additional chemotherapy, in addition to radiation is appropriate. Definitive surgery should not be delayed beyond 12 weeks after initiation of chemotherapy. Patients undergoing initial biopsy followed by postoperative chemotherapy had survival equivalent (83% at 2 years) to that of patients undergoing initial surgical resection.[43] Rarely, bilateral nephrectomies are necessary, and a mandatory waiting period of 2 years should be considered before kidney transplantation in such cases.

RECURRENT WILMS TUMOR

With refinement of treatment modalities the cure rate for WT is in excess of 85%.[44] However, 10% to 15% of patients with favorable histologic findings, as well as 50% of patients with anaplastic tumors, experience primary progression or tumor recurrence. Most relapses are diagnosed within the first 2 years after the original diagnosis. The most common sites of recurrence are the lung, tumor bed, liver, bone, and lymph nodes. Approximately 1% of children presenting initially with unilateral WT develop metachronous bilateral disease.[31] Patients with NRs (particularly PLNRs) and especially those children who were younger than 12 months at diagnosis have a statistically significant increased risk for developing a contralateral tumor. As a result, some authors recommended more frequent surveillance for this group of patients.[31]

With aggressive therapy, up to 80% of patients with favorable prognostic features can be cured. Factors associated with favorable prognosis after recurrence include favorable histologic features, initial treatment with only vincristine and dactinomycin, relapse to the lungs only, relapse in the abdomen of a patient who did not receive abdominal irradiation, and relapse more than 12 months after the original diagnosis.[45,46]

KEY POINTS

- Recurrence rate of WT in the contralateral kidney is low (1%).
- Most recurrences occur within 2 years of the initial diagnosis.
- Common sites of recurrences are lungs, tumor bed, and liver.

Table 50.5 Treatment protocol for Wilms Tumor: National Wilms Tumor Study—V

Stage, histology	Surgery	Chemotherapy	Radiotherapy*
Stage 1 or 2 with FH Stage 1 with anaplasia	Nephrectomy	Dactinomycin Vincristine (18 wk)	No
Stage 3 or 4 with FH Stage 2–4 with focal anaplasia	Nephrectomy	Dactinomycin Doxorubicin Vincristine (24 wk)	Yes
Stage 2–4 with diffuse anaplasia Stage 1–4 CCSK	Nephrectomy	Vincristine Doxorubicin Cyclophosphamide Etoposide (24 wk)	Yes
Stage I–4 RTK	Nephrectomy	Cyclophosphamide Carboplatin Etoposide (24 wk)	Yes

Abbreviations: FH, favorable history; CCSK, clear cell sarcoma of kidney; RTK, rhabdoid tumor of kidney.

* Current radiotherapy dosage is approximately 1080 cGy for the abdomen and 1200 cGy for the lung. Only patients with stage 4 with lung metastases receive whole lung radiotherapy

To improve the outcomes, many different chemotherapy regimens have been attempted. These include salvage chemotherapy with ifosfamide, platinum, and etoposide, with a response rate up to 72%.[46,47] In addition, some patients have been treated with high-dose chemotherapy followed by autologous hematopoietic stem-cell rescue.[48]

LATE EFFECTS OF TREATMENT

Numerous organ systems can be affected by the late sequelae of anticancer therapy. The late effects of WT treatment have received considerable attention because WT usually is curable, with an increasing number of long-term survivors. Renal function can be affected by several modalities of treatment, including nephrectomy, chemotherapy (especially the one used to treat recurrent disease), and radiation. Although most WT survivors have only one kidney, only 0.25% of patients were found to have end-stage renal disease (ESRD).[42] The median interval from diagnosis to onset of ESRD was 21 months. Renal failure is most prevalent in patients with bilateral WT.

Another recognized long-term effect of WT therapy is congestive heart failure (CHF), which was found to have a cumulative frequency of 4.4% 20 years after diagnosis of WT in patients initially treated with doxorubicin.[49] Risk factors for CHF included increasing cumulative doxorubicin dose and radiation to the lung and left hemiabdomen. An analysis of pregnancy outcome among WT survivors revealed that women who received flank radiation therapy were at increased risk for fetal malposition, premature labor, low birth weight, and occurrence of congenital malformations.[50] Gonadal irradiation can produce hypogonadism and temporary azoospermia in boys.[51] In females, the main therapeutic modality shown to cause ovarian dysfunction is radiation.[52] Finally, the cumulative incidence of second malignancy in WT survivors was 1.6% 15 years after diagnosis of primary tumor.[53]

CLEAR CELL SARCOMA

Clear cell sarcoma of the kidney (CCSK) is now considered a separate tumor, distinct from WT. The peak incidence is between 3 and 5 years of age. Unlike WT, CCSK is associated with bone and brain metastases in 40% to 60% cases. Bilateral involvement thus far has not been reported, nor has the presence of congenital anomalies associated with WT been noted. The classic histologic pattern consists of a cellular lesion of polygonal cells with round or oval nuclei having a delicate chromatin pattern and indistinct nucleoli.[54] NWTSG-V recommends treating CCSK at all stages with the same regimen used for WT with diffuse anaplasia (excluding stage 1). Expected 4-year survival is 75%.[55] Important predictors of improved survival are lower stage, younger age at diagnosis, and absence of tumor necrosis.[56]

RHABDOID TUMOR OF KIDNEY

Rhabdoid tumor of the kidney (RTK) is another tumor that was formerly categorized as an unfavorable histologic pattern of WT. It accounts for 2% of the renal tumors in the NWTSG database.[57] RKT is characterized by large cells with abundant acidophilic cytoplasm, frequently with a discrete zone of pale eosinophilia, which is made of fibrillary inclusion bodies. Nuclei are large with very prominent nucleoli.

The tumor is typically large, often replacing the entire kidney. It manifests early in life (median age 11 months), with more than 50% of patients younger than 1 year of age. Metastases may be found not only in the lungs and liver, but also in the brain (unlike WT).[58] In addition, RTK can be associated with second primary tumors in the brain (10% to 15%), the most common being medulloblastoma.[59] RTK is the most aggressive and lethal childhood renal tumor, with an overall mortality of 80%.[58] The current treatment protocol consists of nephrectomy, followed by chemotherapy
Figure 50.4. Computerized axial tomography showing a renal cell carcinoma in the left kidney.

with carboplatinum, etoposide, and cyclophosphamide for 24 weeks, along with radiotherapy.

RENAL CELL CARCINOMA

Renal cell carcinoma (RCC) is an uncommon renal epithelial malignant tumor in children. It represents 2% to 5% of primary renal malignant tumors of childhood (Figures 50.4 to 50.6).[60] Childhood RCC may resemble the adult clear cell and papillary subtypes.[61] RCC has been reported in infancy, but most patients are older, with a mean age of 9 to 15 years. Most children present with abdominal mass (24% to 55%), hematuria (42%), and pain (32%). Children also may have hypertension, fever, weight loss, and polycythemia.[62] Approximately 25% of children with RCC have distant metastatic disease at presentation, most commonly to the lung, liver, and bone. Imaging studies cannot differentiate
Figure 50.5 Cut section of the kidney showing well-circumscribed renal cell carcinoma with fatty yellow coloration of the tumor.
Figure 50.6 Light microscopy of renal cell carcinoma showing tumor cells arranged in nests, with small nuclei and clear cytoplasm.

RCC from other renal tumors. (Figure 50.4). Renal cell carcinomas are usually smaller than Wilms tumor in size, but may be large in some (Figure 50.5). Histologic examination shows tumor cells with small nuclei and clear cytoplasm arranged in nests (Figure 50.6).

The most significant prognostic variable for survival of pediatric patients with RCC is accomplishing a complete resection and histologically low-stage disease.[63] Survival for patients presenting with stage 1 disease is greater than 90%, approximately 50% for patients with stage 2 and 3 disease and almost 0% for patients with stage 4 disease.[64] The tumor is not responsive to radiotherapy, and there is no effective chemotherapy for nonlocalized or relapsed disease.

CONGENITAL MESOBLASTIC NEPHROMA

Congenital mesoblastic nephroma (CMN) is the most common renal tumor in infants, with a mean age at diagnosis of 3.5 months.[65] CMN occurs in two forms: the typical, or fibromatous, type is seen almost exclusively in infants under 3 months of age and is benign. The second one, or atypical (cellular) variety, is usually seen in older children but also occurs in infants. The latter type is potentially malignant and capable of recurrence and metastasis.[66,67] Hypertension may occur from renin hypersecretion.[68] Hypercalcemia also has been reported, owing to tumor secretion of prostaglandin.[66] Nephrectomy alone is an adequate treatment option for infants younger than 3 months of age and perhaps even in older patients with typical fibrous histologic findings and complete tumor resection. Chemotherapy with a WT regimen should be considered for patients with incomplete resection, cellular features, or a high mitotic index and certainly for any patient with evidence of metastasis or recurrence. Partial nephrectomy should not be performed because the risk for local recurrence is high owing to the tumor's tendency to infiltrate surrounding renal parenchyma.

ANGIOMYOLIPOMA

Angiomyolipoma is a benign hamartoma-like mass composed of smooth muscle, blood vessels, and fat. This lesion is seen almost exclusively in children with tuberous sclerosis, which is characterized by mental retardation, seizures, glial nodules in the brain, adenoma sebaceum, phakoma of the retina, and hamartomas of the liver, heart, bone, or kidney. It is estimated that 80% of patients with tuberous sclerosis complex have angiomyolipomas and that the frequency increases with age.[69] Tumors are frequently bilateral and multifocal. Females appear to be more susceptible to multiple and larger tumors than males.[70] Hormonal influences (progesterone receptors in the smooth muscle cells of angiomyolipomas) may offer an explanation to the gender differences in tumor growth at puberty.

Most angiomyolipomas less than 4 cm do not pose a clinical concern. Larger tumors are at risk for hemorrhage.[71] Management should be nonoperative, with periodic reimaging for small asymptomatic lesions. Nephron-sparing approaches are recommended for children with large or symptomatic tumors. Angioinfarction of amenable lesions or partial nephrectomy should be considered.

SUMMARY

Renal tumors in children are rare. Advances in management have been the result of cooperative studies enrolling patients from different centers. This strategy is bound to be the basis for future improvements in diagnosis and therapy. The introduction of nephron-sparing procedures and minimally invasive surgery is expected to change current surgical management. Long-term complications from surgery, chemotherapy, and radiation need to be addressed as survivors grow into adulthood.

REVIEW QUESTIONS

CASE 1

A 2-day-old boy is found to have a hard, palpable abdominal mass on routine newborn examination. The pregnancy and delivery were unremarkable. There is no relevant family history. Both parents and an older 7-year-old sibling are healthy. No other abnormalities are encountered on physical examination. The baby appears well. He underwent an abdominal ultrasound and, subsequently, a CT scan of the abdomen, shown.
1. Based on the presentation and findings on imaging studies, the findings on the left kidney are *most* likely to represent:
   a. Wilms tumor
   b. Congenital mesoblastic nephroma
   c. Clear cell sarcoma
   d. Renal cell carcinoma
   e. Multilocular cystic nephroma

2. The *best* next step in management is:
   a. Percutaneous biopsy
   b. Open biopsy
   c. Chemotherapy (Wilms tumor protocol) and repeat imaging in 6 weeks
   d. Partial nephrectomy
   e. Radical nephrectomy

CASE 2

A 3-year-old boy presents with rapid increase in abdominal girth. He has been healthy and has no significant medical or surgical history. His family history is unremarkable. Physical examination demonstrated a normal blood pressure for age, no dismorphic features, and a palpable abdominal mass. CT evaluation is shown below.

3. Based on these findings, all of the following are indicated *except:*
   a. Chest CT scan
   b. Doppler ultrasound of the renal vein and vena cava
   c. Port placement for chemotherapy
   d. Bilateral nephrectomies
   e. Screen for predisposition syndromes
4. Which of the following are associated with a predisposition to Wilms tumor?
   a. Macroglossia
   b. Aniridia
   c. Hemihypertrophy
   d. Cryptorchidism
   e. All of the above
5. Which of the following surgical principles regarding the management of renal masses consistent with Wilms tumor is *true:*

   a. Ipsilateral adrenalectomy is always indicated.
   b. Removal almost always includes radical resection of adjacent structures, such as spleen, tail of pancreas, bowel segment, and liver segment.
   c. Early intraoperative tumor rupture demands aborting the procedure and proceeding with chemotherapy and radiation.
   d. Ipsilateral lymph node sampling always should be done.
   e. Nephron-sparing surgical procedures should not be offered.

CASE 3

A 14-year-old patient with tuberous sclerosis has the following findings on a routine CAT scan imaging study.
6. Which one of the following is an *accepted* step in management for the lesion highlighted with an arrow?
   a. Serial imaging with ultrasound
   b. Reimage every 3 months with CT scan
   c. Open biopsy
   d. Radical nephrectomy
   e. Partial nephrectomy and lymph node dissection

Urolithiasis in children

URI S. ALON AND TARAK SRIVASTAVA

Urolithiasis has become more common in children over the past few decades, probably as a result of rapid changes in the society's dietary habits and socioeconomic status. Epidemiologic studies indicate an increasing trend of calcium oxalate and/or calcium phosphate stones in the upper urinary tract in children in industrialized countries, rather than the infection-related ammonium urate stones in the bladder of the past century and now seen mostly in less affluent countries.

Urolithiasis is a disorder "shared" by the urologist and the nephrologist. The role of the urologist is to extract the stone from the urinary tract and correct anatomic abnormalities of the genitourinary tract as indicated, whereas the role of the nephrologist is to identify the cause for the stone and plan a management strategy to prevent stone recurrence.

EPIDEMIOLOGY

Changes in global socioeconomic conditions and the subsequent changes in dietary habits have affected not only the incidence but also the site and chemical composition of calculi.[1,2] At the beginning of the last century, bladder calculus from ammonium urate was relatively frequent in Europe, but over time it has changed to the more common renal-ureteral calculus made up of calcium oxalate, phosphate, or both, probably related to a diet rich in proteins, refined carbohydrates, and sodium and low in potassium and citrate.[1–4] Bladder stones are still common in the developing world,

whereas in industrialized countries upper tract stones predominate. The majority of bladder stones seen in developed, affluent countries are a result of bladder dysfunction or bladder reconstruction. In the United States the incidence of urolithiasis is highest among whites, especially in the "stone belt" in the Southeast, peaking in July, August, and September. This has been linked to higher exposure to sunlight and consequently increased production of vitamin D and calcium absorption from the intestine on one hand and higher incidence of dehydration on the other.[2] Kidney stone formation was described among lifeguards in Israel for the same reason.[5] In recent years an increase in pediatric urolithiasis has been observed. Lattimer et al.[6] in 1951 reported no cases of urolithiasis in 21,835 patients at the Babies Hospital in New York. In later studies, the incidence of urolithiasis in children was reported as 1 in 6000 and 1 in 7600 hospitalized children.[7,8] Malek et al.[9] in 1975 described 78 cases of urolithiasis in 145,000 hospitalized children (1 in 1850); 32% of the calculi were from infection, with a greater incidence in boys (2:1 ratio) and an even distribution of patients in all age groups. Stapleton et al.[10] described 112 children with urolithiasis. Of these, 94% were white, 59% were boys, and calcium oxalate stones predominated. Milliner and Murphy[11] observed that only 19 of 221 children in the Mayo Clinic had bladder or urethral calculi whereas the rest of the urolithiasis cases were present in the upper urinary tract and ureters, unlike the distribution in developing countries, in which bladder stones are more frequent.[11] Osorio and Alon[12] found the incidence of hypercalciuria to be significantly lower in African-American children compared with white

children. Penido et al.[13] showed a threefold increase in urolithiasis incidence in a pediatric nephrology clinic between 1999 and 2011. Our observation also has been validated by Routh et al.[14] and Sas et al.[15] who showed the incidence of kidney stones in children has increased over the past decade. Thus, epidemiologic studies have shown an increasing trend ("stone wave") associated with a change in social conditions and in eating habits; however, the importance of genetic predisposition as recognized by racial distribution and family history of urolithiasis cannot be disregarded.

PATHOGENESIS

Stone formation is a complex process. In a simple solution, such as water, a solute will precipitate out of a solution once its saturation point, or the solubility product of ions, is reached. In contrast to water, in a complex solution such as urine a situation of supersaturation of stone promoters such as calcium, oxalate, and uric acid occurs as a result of the presence of many other ions and molecules in the urine that allow these promoter ions to remain in solution even at higher concentrations. Some of the better known substances that inhibit stone formation, include citrate, pyrophosphate, magnesium, and glycosaminoglycans. Other inhibitors in this category described in the literature are Tamm-Horsfall protein, uropontin, nephrocalcin, FK506 binding protein 12 (FKBP-12), bikunin, lithostathine, and others. The point at which urine will no longer hold a substance in solution is called the *formation product,* and it also may be influenced by urine pH. At the formation product, spontaneous nucleation takes place to form new crystals. The nucleation can be homogeneous or heterogeneous. The former refers to the joining of similar ions into crystals. Heterogeneous nucleation results when one crystal grows around another type of crystal, for example, calcium oxalate crystallizing around a uric acid or cystine crystal. Sloughed epithelial cells and other materials also can provide the nidus around which heterogeneous nucleation can occur. Thus, for stone formation or crystallization to materialize, either intermittent or continuous urinary

supersaturation must occur. Supersaturation is affected by water intake and urine flow rate. High urine flow rate induced by increased fluid intake reduces urine supersaturation. This holds true for all stone types and thus is one of the mainstays of therapy for urolithiasis. Insufficient urine flow is one of the more common causes of pediatric urolithiasis, and unfortunately even after diagnosis only a minority of patients adheres to high fluid intake.[13,16,17] To form a stone, multiple crystals need to combine together, a process called *aggregation,* which is thought to take place in the tubules or the collecting system. It seems that to allow this process to take place, crystals have to anchor to the urinary epithelium for a limited time and not be washed away by urine, by a process that is yet not fully understood.[2,18] The presence of anatomic abnormalities that impede urine flow and of urinary tract infections (UTIs), which change the milieu in the urinary tract system, are also known contributors to stone formation.

Nanobacteria, which have the ability to produce carbonate apatite on their cell wall, also have been implicated in stone formation. These bacteria may act as a nidus for kidney stones and in one study were isolated from 97% of the kidney stones.[19] The urinary proteome contains over 1500 proteins, but only a small subset of these proteins have been associated with stone formation.[20] These stone matrix proteins are under intense study for their role in stone formation at the present time.[21–23] Thus, many factors play a role in stone formation: presence of promoters, lack of inhibitors, urine flow rates, anatomic abnormalities, nanobacteria, stone matrix proteins, UTIs, and homogeneous or heterogeneous nucleation, all of which have to be considered when planning a therapeutic strategy to prevent formation of recurrent stones.

CLINICAL MANIFESTATIONS

The two most characteristic manifesting symptoms of urolithiasis are pain and hematuria. Less common manifestations are UTI and acute renal failure. In other cases, stones can be detected as an incidental finding by imaging studies of the abdomen or urinary tract done for another purpose. These asymptomatic stones may at times cause obstructive uropathy.

Acute renal colic presents abruptly as a severe paroxysmal pain in waves on the affected side, associated, at times, with nausea and vomiting. The child with renal colic will usually writhe in pain or move constantly to try to find a position of comfort. The pain can occur anywhere from the flank down to the ipsilateral groin. This visceral type of pain is caused by distention of the proximal urinary collecting system from distal obstruction or from passage of the stone (or associated blood clot and debris). The location of the pain may give information about the possible location of the stone. Stones within the kidney or in the proximal ureter produce flank pain. As the stone moves down,

---

KEY POINTS

Pathogenesis of stone formation requires:

- Supersaturation of promoters (affected by water intake).
- Decreased urinary concentration of inhibitors.
- Appropriate pH needs for the ions to precipitate.
- Nidus for crystals to deposit around.
- Stasis, urinary tract abnormalities, and infection may further promote stone formation.

the pain radiates around the front of the abdomen into the lower quadrant. Referred pain often occurs in the ipsilateral groin, testicle, and labia as the stone reaches the ureterovesicle junction. Urolithiasis and UTI are closely related. Calculi may develop as a consequence of UTI and form struvite or carbonate apatite stones *(vide infra).* Urolithiasis places the child at risk for UTI, and the infection may be the initial presentation for stones. Presentation with UTI is more common in younger children, whereas acute renal colic is more common in older children. Lower ureter and bladder stones may manifest with hematuria, dysuria, or urgency, thus mimicking a UTI. Stones may also move within the ureter without any associated resistance or obstruction, causing painless hematuria, which can be either macroscopic or microscopic. The finding of hematuria with urolithiasis is relatively consistent throughout childhood. Macroscopic or microscopic hematuria has been observed in as many as 90% of children with urolithiasis.

CLINICAL EVALUATION

At the initial visit, the medical history should focus on risk factors for stone formation and complications such as UTI, voiding dysfunction, and surgical procedures on the urinary tract. A positive family history for stone disease can be obtained in 22% (Turkey) to 75% (United States) of children with urolithiasis.[24,25] Clinical features suggestive of a hereditary cause for stone disease in childhood are shown in Table 51.1.

Table 51.1 Clinical features indicating possible hereditary cause of pediatric urolithiasis

- Infantile or early childhood presentation
- Parental consanguinity
- Family history of urolithiasis
- Multiple, bilateral, and/or recurrent stones
- Coexistence of tubular dysfunction manifested by polyuria, acidosis, growth retardation, and/or renal failure
- Presence of nephrocalcinosis
- Dysmorphic and extrarenal manifestations suggestive of a syndrome

A wide variety of medical conditions can be associated with urolithiasis in children, including gastrointestinal disorders associated with malabsorption, cystic fibrosis, myelodysplasia, and immobilization. Recurrent skeletal fractures may indicate the presence of hyperparathyroidism or other bone diseases. A history of prematurity (especially with use of furosemide), use of supplemental vitamin D, and enteral or parenteral nutrition formulas high in calcium and/or phosphorus should be obtained. The dietary history must search for any dietary excesses or deficiencies and intake of medications, vitamins, and supplements. Medications such as steroids, chemotherapy drugs, anticonvulsants, loop diuretics, acetazolamide, other carbonic anhydrase inhibitors, uricosuric drugs, and antacids have been associated with urolithiasis (Table 51.2). Ketogenic diets used to treat

Table 51.2 Medications associated with urolithiasis (listed alphabetically)

Calcium stone formation
- Acetazolamide
- Amphotericin B
- Antacids (calcium and noncalcium antacids)
- Glucocorticoids
- Loop diuretics
- Theophylline
- Topiramate
- Vitamin D
- Zonisamide

Uric acid stone formation
- Acetohexamide
- Allopurinol (xanthine stones)
- Ascorbic acid
- Benzbromarone
- Calcium ipodate
- Chlorprothixene
- Cinchophen
- Dicumarol
- Estrogen
- Glycerol guaiacholate
- Halofenate
- Iodopyracet
- Iopanoic acid
- Ketogenic diet
- Meglumine iodipamide
- Outdated tetracyclines
- Phenylbutazone
- Phenolsulfonphthalein
- Probenecid
- Salicylates
- Sodium diatrizoate
- Zoxazolamine

Medications that may precipitate into stones
- Acyclovir
- Ceftriaxone
- Felbamate
- Indinavir
- Sulfadiazine
- Triamterene

Figure 51.1 Urine microscopy showing **(a)** clear hexagonal cysteine crystals, **(b)** calcium oxalate crystals (envelope shaped), and **(c)** uric acid crystals.

intractable seizures in children are associated with uric acid stones.[26] Excess salt and insufficient potassium intake may contribute to stone formation.[12]

Urogenital tract abnormalities predispose to the formation of infected stones. Therefore, a careful urologic evaluation of patients with infected stones is mandatory. Children on clean intermittent catheterization via a Mitrofanoff conduit, exstrophy-epispadias complex, and bladder augmentation frequently develop urolithiasis.[27–29]

The examination should search for chronic diseases, including failure to thrive (distal renal tubular acidosis [RTA]), hypertension (renal disease), skeletal findings of rickets, soft tissue calcification (hypercalcemia), and abnormal external genitalia.

Urinalysis should always be part of the evaluation process in the physician's office, and any abnormality might present a clue to the source of stone formation. As mentioned in later discussion, urine specific gravity provides a good idea about the patient's hydration. Attention should be paid to urine pH and the presence of crystals, which can provide a clue to diagnosis, but only cystine crystals are pathognomonic (Figure 51.1). On rare occasions, the presence of proteinuria may indicate a need to search for a tubular disorder.[30] At times, when infection-related stones are suspected or indicated by urinalysis, urine culture might be needed as well.

LABORATORY AND RADIOLOGIC EVALUATION

The laboratory evaluation is based on three components: stone analysis, biochemical profile of the urine (stone risk analysis), and blood tests. All efforts must be made to obtain the stone, either by straining the urine or by the medical team extracting it. However, in many cases the stone is not captured, and in others, even if its composition is known, further analysis is needed to define the metabolic abnormality leading to its formation. For instance, calcium oxalate stones can be caused by excess calcium or oxalate in the urine, or diminished citrate or urine flow, or any combination of these.

A timed 24-hour urine collection should be performed for volume, creatinine, calcium, sodium, potassium, uric acid, oxalate, citrate, phosphorus, and magnesium (Table 51.3). In certain circumstances, measurements may need to be done for cystine, glycerate, glycolate, 2,8-dihydroxy adenine, orotic acid, xanthine, hypoxanthine, ornithine, lysine, and arginine. Urinary calcium excretion is increased during acute pyelonephritis and with immobilization. The 24-hour urine sample should be evaluated ideally after the patient is free of stones, free of infection, and on his or her usual diet with normal fluid intake. The accuracy of the collection is validated by calculating creatinine excretion (creatinine index) expressed as mg/kg/24 h.[13] An important component of the diagnostic urine evaluation is the assessment of urinary volume *(vide infra)*. In geographic regions where calcium oxalate and phosphate stones constitute the vast majority of stones, we recommend a step-wise approach to analyzing urine chemistry. First, only urine calcium excretion is assessed, with the rest of the urine sample kept refrigerated. Only when hypercalciuria is ruled out are other chemistries analyzed.[17]

In situations in which it may be difficult to collect a 24-hour urine sample, random urine samples may be used (Table 51.4). It should be emphasized that normative data for random urine specimens using creatinine as denominator were established in children with normal muscle mass and should not be used in patients with significantly increased or decreased muscle mass because of the effect on urine creatinine. In such cases, another denominator such as urine osmolality can be used. The normal value for the calcium-to-osmolality ratio [urine calcium (mg/dL)/osmolality (mOsmol/kg H_2O) × 10] is established at less than 0.25.[31]

KEY POINTS

- 24-Hour urine collection must include creatinine expressed as mg/kg/24 h to validate accurate collection.
- When analyzing a random urine sample, urine creatinine can serve as denominator only in those with normal muscle mass.

Table 51.3 Normal 24-hour urinary excretion rates in children studied for urolithiasis

Normal values for 24 hour urine collection samples	
Volume	20–25 mL/kg/24 h
Creatinine excretion	15–20 mg/kg/24 h in adolescent male
	12–15 mg/kg/24 h in adolescent female
Creatinine clearance	>90 mL/min/1.73 m^2
Uric acid excretion	<815 mg/1.73 m^2/24 h
	<35 mg/kg/24 h
Calcium excretion	<4 mg/kg/24 h
Sodium excretion	<3 mEq/kg/24 h
Potassium excretion	>3 mEq/kg/24 h
Magnesium excretion	>88 mg/1.73 m^2/24 h
Oxalate excretion	<52 mg/1.73 m2/24 h
	<2 mg/kg/24 h
Citrate excretion	>180 mg/g creatinine in children
	>128 mg/g creatinine in adult males
	>300 mg/g creatinine in adult females
Protein excretion	<4 mg/m^2/h
Cystine excretion	<60 mg/1.73 m^2/24 h
Urine glycolate	0.19 ± 0.07 mmol/24 h
Xanthine*	20–60 µmol/24 hr
Hypoxanthine*	20–100 µmol/24 h

*Mayo Clinic laboratories.

Table 51.4 Normal urine excretion rates in random urine samples corrected for urinary creatinine excretion*

Normal values for random urine samples	
Calcium/creatinine (mg/mg)	<0.2
Oxalate/creatinine (mg/mg)	<0.05
Uric acid/creatinine (mg/mg)	<0.65 (10–14 yr)
	<0.60 (14–17 yr)
Uric acid/GFR	<0.56
Tubular phosphate reabsorption/ GFR (mg/dL)	4.1 ± 0.6 (12–16 yr)
	3.3 ± 0.3 (>16 yr)
Magnesium/creatinine (mg/mg)	>0.05
Sodium/potassium (mEq/mEq)	<2.5
Citrate/creatinine (mg/mg)	>0.18 in children
	>0.14 in adult males
	>0.30 in adult females
Cystine/creatinine (mg/mg)	<0.075
Glycolate/creatinine (mmol/mmol)	<0.013 (>12 yr)
L-Glycerate/creatinine (µmol/mmol)	<28

* Note that these values can be utilized only in children with normal muscle mass.

Table 51.5 Urinary stone composition and structure

Calcium oxalate
- Calcium oxalate monohydrate (whewellite)
- Calcium oxalate dihydrate (weddellite)

Calcium phosphates
- Calcium phosphate, carbonate form (carbonate apatite)
- Calcium phosphate, hydroxyl form (hydroxyl apatite)
- Calcium hydrogen phosphate dihydrate (brushite)
- Tricalcium phosphate (whitlockite)

Purines
- Uric acid
- Xanthine
- Sodium acid urate
- Ammonium acid urate
- 2,8-Dihydroxyadenine
- Orotic acid

Cystine
- Cystinuria

Drugs
- Acyclovir
- Indinavir
- Triamterene
- Ceftriaxone
- Felbamate
- Sulfadiazine
- Silicate

Miscellaneous
- Magnesium ammonium phosphate hexahydrate (struvite)
- Magnesium phosphate (newberyite)

The four most common types of stones are calcium oxalate, calcium phosphate, uric acid, and struvite (Box 51.5). The initial blood work for all patients undergoing examination for stones includes tests for renal function, electrolytes, calcium, phosphorus, magnesium, uric acid, and parathyroid hormone. Subsequent blood work may be needed for vitamin D levels, enzyme assays, and genetic studies.

Plain abdominal radiographs detect only radiopaque stones and have a low sensitivity (62%) and specificity (67%) for making the diagnosis of urolithiasis.[32] Radiolucent stones that are not detectable by plain x-ray of the abdomen include uric acid stones, cysteine stones, and those caused by antiretroviral drug indinavir. Ultrasound can be used to detect such stones. Plain x-ray of the abdomen as well as the traditional intravenous pyelography have been replaced in recent years by ultrasonography and computed tomography
Figure 51.2 Renal ultrasound evaluation of left kidney demonstrating a stone (upper arrow) and the associated posterior shadowing (lower arrow).

Figure 51.3 A computed axial tomography scan of abdomen showing bilateral nonobstructing renal stones.

(CT).[2,33,34] Ultrasound evaluation presents the advantage of not exposing the child to ionizing radiation. Apart from the stone itself, a renal sonogram also usually reveals a posterior shadowing, a conical (dark) area that represents the segment where ultrasound waves are unable to penetrate through the density of the renal stone (Figure 51.2). The disadvantages of the renal ultrasound are that it is operator dependent and that stones in ureters may be difficult to locate, especially in patients with significant intestinal gaseous dilatation. A noncontrast spiral CT, readily available in most emergency rooms 24 hours per day, is now replacing other imaging techniques during acute episodes of urolithiasis (Figure 51.3). In patients requiring repeat studies we recommend maximal use of ultrasonography to minimize exposure to CT-related radiation.

Nephrocalcinosis (Figure 51.4) may be seen in many patients with high risk for stone disease or recurrent stones. Medullary nephrocalcinosis is often associated with renal tubular acidosis (RTA-1 or distal RTA), hypercalciuria,

primary hyperparathyroidism, sickle cell disease, medullary sponge kidney, hypervitaminosis D, and, less commonly, renal tuberculosis. Cortical nephrocalcinosis is less common and is usually seen in oxalosis and dystrophic calcifications associated with acute cortical necrosis of hemodynamic origin (following shock).

SPECIFIC TYPES OF RENAL STONES

HYPERCALCIURIA CALCULI

Hypercalciuria is the most common metabolic abnormality detected in children with stones, causing mainly the formation of calcium oxalate stones and to a lesser extent calcium phosphate stones or a mixture of the two.[17] Before development of kidney stones, hypercalciuria can manifest as frequency-dysuria syndrome with or without microscopic or gross hematuria.[35] In a prospective study

KEY POINTS

- Radiolucent stones that cannot be detected by plain x-ray are:
  - Uric acid stones
  - Cystine stones
  - Indinavir stones
- Ultrasound can detect radiolucent stones

KEY POINTS

- When investigating children with urolithiasis, the use of CT should be minimized because of exposure to radiation.
- Urinary tract ultrasound is a preferred option for evaluation of most patients, because it does not involve harmful ionizing radiation.
Figure 51.4 Nephrocalcinosis in a patient with renal tubular acidosis-1 (RTA-1; distal RTA) seen in **(a)** plain radiograph and **(b)** computed axial tomography scan of the abdomen. Nephrocalcinosis is predominantly affecting medullary regions.

KEY POINTS

- Medullary calcification is common in:
  - Renal tubular acidosis (RTA-1 or distal RTA)
  - Hypercalciuria
  - Hyperparathyroidism
  - Hypervitaminosis D
  - Hyperuricemia
  - Sickle cell–associated pyramidal calcification
  - Medullary sponge kidney
  - Milk-alkali syndrome
  - Renal tuberculosis-dystrophic calcification
  - Other causes of papillary necrosis
- Cortical calcifications are common in:
  - Cortical necrosis (hemodynamic) dystrophic calcification
  - Oxalosis

---

of 83 children referred for unexplained hematuria without proteinuria or previous kidney stones, 26% of children had hypercalciuria.[36] In this subset of children with hematuria and hypercalciuria, Garcia et al.[37] found persistent hematuria in 29% and persistent hypercalciuria in 70% at 1 year follow-up. At 2 and 3 years of follow-up, they found persistent hematuria in 38% and 61% had persistent hypercalciuria, with 17% developing kidney stones.[37] Similarly, in a prospective study by the Southwest Pediatric Nephrology Study Group, 13% of children with hypercalciuria and hematuria developed kidney stones within 1 to 4 years of follow-up.[24]

Hypercalciuria can result from genetic or acquired causes (Table 51.6).[30] The gastrointestinal tract, bone, and kidneys play major roles in calcium metabolism under the influence of diet, fluid and electrolyte homeostasis, parathyroid hormone, calcitonin, and vitamin D metabolites. Calcium reabsorption in the renal tubules is increased by parathyroid hormone, volume contraction, alkalosis, and thiazide diuretics and decreased by volume expansion, hypercalcemia, acidosis, phosphate depletion, and loop diuretics. Thus, increased calcium excretion in the urine can occur from (1)

Table 51.6 Causes of hypercalciuria in children

Alimentary Hypercalciuria (Absorptive Hypercalciuria)
- Idiopathic
- Increased vitamin D intake
- Increased (supplemental) calcium intake

Renal Hypercalciuria (Reabsorptive Hypercalciuria)
- Impaired renal calcium reabsorption
  - Idiopathic
  - Distal renal tubular acidosis
  - Dent disease
  - Bartter syndrome
  - Familial hypomagnesemia with hypercalciuria
  - Familial hypercalciuria
  - Use of loop diuretics (furosemide)
  - Abnormalities in parathyroid calcium sensing receptor
  - High dietary salt intake
  - Low dietary potassium intake
- Bone resorption (may be associated with hypercalcemia)
  - Immobilization
  - Hyperparathyroidism
  - Corticosteroid use
  - Neoplasms
- Renal tubular phosphate leak
- Increased vitamin D synthesis (may be associated with hypercalcemia)
  - Sarcoidosis
  - Neoplasms
- Idiopathic

increased intestinal calcium absorption (idiopathic, vitamin D excess, increased enteral intake), (2) impaired renal tubular calcium reabsorption (idiopathic, distal RTA, Dent disease, Bartter syndrome, familial hypomagnesemia and hypercalciuria, abnormalities in calcium sensing receptor, loop diuretics), (3) bone resorption (immobilization, hyperparathyroidism, steroid use, neoplasms), (4) renal tubular phosphate leak, (5) increased 1,25 dihydroxy vitamin D synthesis (sarcoidosis, neoplasms, idiopathic), (6) decreased 1,25-$(OH)_2$-D-24 hydroxylase (CYP24A1) deficiency, and (7) overly high dietary salt intake and potassium intake that is too low.[30,38–40]

Although idiopathic hypercalciuria remains the most common form of hypercalciuria, a systematic search for secondary causes of hypercalciuria should be made when clinically or biochemically suspected *(vide infra)*. Idiopathic hypercalciuria has been attributed to either a defect in renal tubular reabsorption of calcium (renal hypercalciuria) or enhanced absorption by the gastrointestinal tract (absorptive hypercalciuria). An oral calcium loading test was popular in the past to differentiate between these two forms of idiopathic hypercalciuria.[41] However, the current belief is that absorptive and renal forms of hypercalciuria may represent a continuum spectrum of a single disease, and the oral loading test to differentiate between the two entities is no longer used clinically. Aladjem et al.[42] reevaluated calcium loading tests after an interval of 3 to 7 years in children who were initially diagnosed as having absorptive or renal hypercalciuria and found a different result in more than half of the children studied. On the other hand, they found a strong relationship between urinary sodium and calcium excretion and suggested a detrimental role for dietary sodium in idiopathic hypercalciuria. This clinical observation has been reported by other investigators, who also have observed an inverse effect of dietary potassium on urinary calcium excretion, that is, high dietary potassium intake decreases urinary calcium excretion by an unknown mechanism (Figure 51.5).[12]

> ## KEY POINTS
>
> - Idiopathic hypercalciuria remains the most common form of hypercalciuria in children.
> - Urine sodium and potassium, reflecting their dietary intake, affect urine calcium in opposing directions. Sodium increases and potassium decreases urinary calcium excretion.

Whenever hypercalciuria is detected as a risk factor for urolithiasis in a child, a secondary cause should be considered because successful correction of hypercalciuria in such cases depends on eradication of the primary cause.[43] An elevated serum calcium level should lead to evaluation for parathyroid hormone and 1,25$(OH)_2$ vitamin D. In the presence of normal serum calcium concentration, estimates of dietary
Figure 51.5 Effect of potassium therapy in 11 children with idiopathic hypercalciuria on their urine sodium-to-potassium and urine calcium-to-creatinine ratios. (Reproduced with permission from Osorio AV, Alon US. The relationship between urinary calcium, sodium, and potassium excretion and the role of potassium in treating idiopathic hypercalciuria. Pediatrics. 1997;100:675–81.)

sodium and potassium intake should be made based on urinary excretion and measurement of serum phosphorus and tubular phosphate reabsorption per glomerular filtration rate (TP/GFR) should be obtained. An increased phosphate loss in urine stimulates synthesis of 1,25$(OH)_2$ vitamin D and causes secondary hypercalciuria from increased gastrointestinal absorption of calcium. Children who are immobilized or on long-term steroid therapy can have hypercalciuria associated with or without hypercalcemia.

One of the greatest risk factors for pediatric stone formation is a low urinary flow rate.[13,16] Therefore, management of all patients with urolithiasis starts with the recommendation to maintain a high oral fluid intake. A good way to monitor compliance is to assess urine specific gravity during clinic visits. Most pediatric urologists and pediatric nephrologists recommend maintaining the specific gravity at or below 1.010.[17] Unfortunately, adherence with generalized recommendations such as "have a high fluid

> ## KEY POINTS
>
> - A good way to advise on the recommended additional fluid intake is by calculating the difference between the desired urine output of 24 mL/kg/24 h and the actual 24-hour urine volume.
> - In hypercalciuric patients, the urine sodium-to-potassium ratio should be less than 2.5.
> - The addition of amiloride to thiazide diuretics protects against hypokalemia and, by itself, further decreases urine calcium.
Figure 51.6 Mean (± standard deviation) urine specific gravity recommended by physicians versus readings in children with urolithiasis and control children. (Reproduced with permission from: Alon US, Zimmerman H, Alon M. Evaluation and treatment of pediatric idiopathic urolithiasis: revisited. Pediatr Nephrol. 2004;19:516–20.)

intake" or "make sure the urine looks like water" is quite poor (Figure 51.6). A more precise way of recommending high fluid intake is based on the goal of having urine flow of at least 1 mL/kg/h. Knowledge of a child's weight and urine volume during 24-hour urine collection can indicate what additional fluid intake is required to achieve the goal. For instance, in a 40-kg child with a goal of 960 mL/24 h, if 24-hour urine collection had a volume of 660 mL, the family can be advised on the need of additional daily fluid intake of 300 mL. It is important that the child also stays hydrated during the night.

When idiopathic hypercalciuria is confirmed, the next step is to assess whether dietary manipulation can normalize calcium excretion. We recommend a diet of recommended dietary allowance (RDA) for protein and calcium that is not excessive in salt (2.0 to 2.4 g sodium per day) and supplemented with at least the RDA of five servings of fruits and vegetables (3.0 to 3.5 g potassium per day). Indeed, only a minority of children in the United States adhere to the RDA of fruit and vegetable intake.[44] Compliance with these dietary recommendations can be assessed by measuring the urine sodium-to-potassium ratio, which should be less than 2.5. If, in 4 to 6 weeks, hypercalciuria persists, treatment with potassium citrate at 0.5 to 1.5 mEq of potassium/kg/day is recommended. If the child does not tolerate potassium citrate or fails to correct hypercalciuria, a thiazide diuretic can be added.[17] Another potential reason, although not yet fully substantiated, to convert from potassium citrate to thiazides is in patients developing highly alkaline urine, which by itself may promote calcium phosphate stones.[45] Chlorothiazide 15 to 25 mg/kg/day or hydrochlorothiazide 1.5 to 2.5 mg/kg/day can be used. In contrast to the latter two that need to be given on a twice-daily schedule to achieve maximum anticalciuric effect, chlorthalidone, a

longer acting agent, can be given as a single daily dose of 0.5 to 1 mg/kg/day.[46] Children on long-term thiazide diuretics will need to be monitored for dyselectrolytemia, hyperlipidemia, and hyperglycemia. The addition of amiloride might further enhance the anticalciuric effect and protect from hypokalemia.[47] Dietary restriction of calcium is not recommended, because it puts the growing child at risk for negative calcium balance and poor bone mineralization. It also may increase urinary excretion of oxalate from increased gastrointestinal absorption of oxalate resulting from decreased luminal availability of calcium to bind with it. For the same reasons, drugs such as sodium cellulose phosphate, acting by complexing intestinal calcium, are not used in children. Neutral phosphate can be used in children with hypercalciuria secondary to tubular phosphate leak. In children with hypercalciuria secondary to RTA, potassium citrate is the drug of choice for treatment of hypercalciuria. At times, this may need to be supplemented by sodium bicarbonate and calcium-sparing diuretics.

In recent years, more attention has been given to the combination of hypercalciuria, stone formation, osteoporosis, and fractures described in both adults and children.[48–50] In some cases this "syndrome" can be due to an identifiable genetic mutation.[51] A decrease in bone mineral density has been reported in 30% to 42.6% of children with idiopathic hypercalciuria.[52–54] Schwaderer et al.[55] showed that the dietary recommendations alone do not alter the natural history of lumbar bone mineral density, and therapy with potassium citrate is beneficial in children with hypercalciuria. Recently bisphosphonates have been demonstrated to improve bone density and lower urine calcium levels in hypercalciuric children with decreased bone density who were resistant to traditional therapy.[50]

KEY POINTS

- Some hypercalciuric patients also may have osteopenia.
- Treatment of the hypercalciuria in these patients may improve their bone mineral status.

HYPOCITRATURIA CALCULI

A decrease in urinary citrate excretion is an important factor in the genesis of urolithiasis, particularly in the form of calcium oxalate stones. Hypocitraturia can be either idiopathic, secondary to systemic acidosis or hypokalemia, or associated with various bowel diseases. Systemic acidosis and hypokalemia are believed to impair citrate synthesis and increase renal resorption, resulting in hypocitraturia. Thus, a finding of decreased urinary citrate excretion should alert the clinician to the possibility of distal or incomplete RTA, and evaluation of (urine-blood) pCO_2 following oral

acetazolamide should be done.[56] In addition, a subtle renal acidification defect can occur secondary to renal tubular injury from chronic hypercalciuria and urolithiasis.[57] Naturally, in patients with acidosis or hypokalemia the electrolyte abnormalities should be corrected. Potassium citrate is the rational drug of choice in children with reduced urinary citrate excretion, as well as in those with hypercalciuria and hyperuricosuria, with close monitoring of urine pH. A diet rich in fruits and vegetables is recommended to enhance urine potassium and consequently citrate excretion (Figure 51.7).[39]

Because of some conflicting data about the normative values of urine citrate we evaluated a healthy school-aged population and found the 5th percentile at 180 mg citrate per gram of creatinine for both genders.[58] Furthermore, to find out why some hypercalciuric children develop stones and others do not, we compared their urine calcium-to-citrate ratio and found it to be higher in the stone-forming group (Figure 51.8). Further analysis has shown that the calcium-to-citrate ratio less than 0.33 decreases the risk for stone formation. This parameter has the advantage of being independent of the accuracy of urine collection, and its utility as both risk indicator and treatment goal was recently confirmed in studies in adults and children.[59,60] Interestingly, fruits rich in either potassium, such as melon, or citrate, such as lemon and orange, improve urine citrate excretion.[61,62]

KEY POINTS

The calcium-to-citrate ratio is a good indicator of the patient's risk for stone formation and a ratio of less than 0.33 mg/mg can serve as a therapeutic goal.
Figure 51.7 Effect of change in urine potassium excretion on urine citrate excretion. (Reproduced with permission from: Meschi T, Maggiore U, Fiaccadori E, et al. The effect of fruits and vegetables on urinary stone risk factors. Kidney Int. 2004;66:2402–10.)

HYPEROXALURIA CALCULI

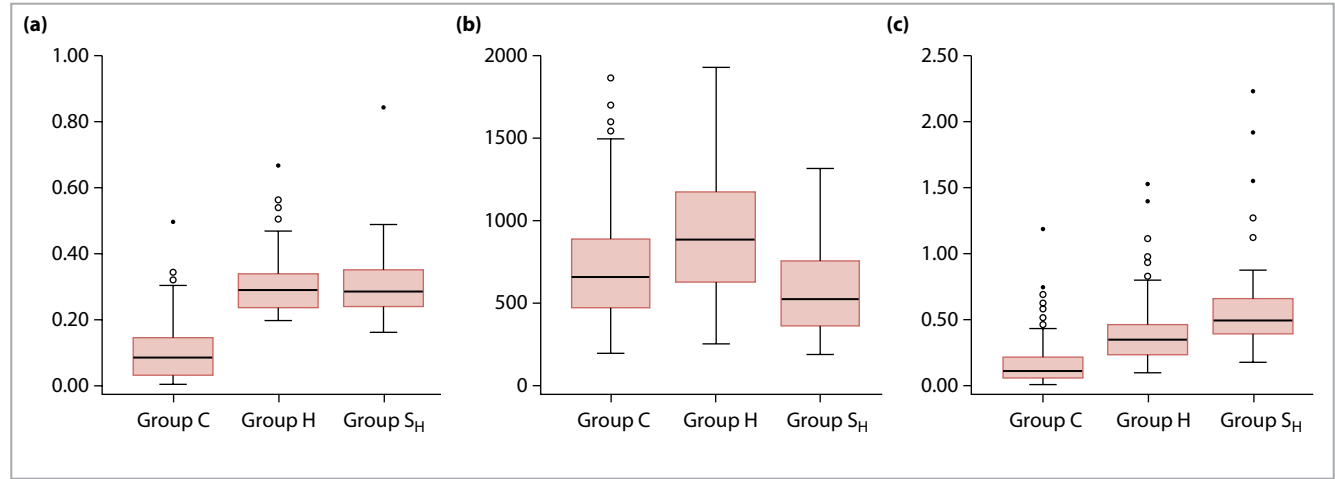
Under normal circumstances the majority of oxalate that appears in the urine is derived from endogenous production with almost equal contribution from ascorbic acid metabolism and glyoxylate metabolism. Only 10% to 15% of urinary oxalate is believed to originate from the diet. Mild hyperoxaluria can be either idiopathic or secondary to enteric hyperoxaluria from fat malabsorption. Mild hyperoxaluria can be observed in adolescents who develop food fads rich in vegetables (with high oxalate content), high in vitamin C, or poor in pyridoxine (which leads to build-up of glyoxylate). In enteric hyperoxaluria, excess fat in the gastrointestinal


Figure 51.8 Box plot distribution of (a) urine calcium-to-creatinine, (b) citrate-to-creatinine, and (C) calcium-to-citrate in groups C (controls), H (hypercalciuric children with no stones), and S_H (hypercalciuric stone formers). lumen binds to luminal calcium, which makes the latter unavailable to bind dietary oxalate, leading to increased gastrointestinal absorption of oxalate. Absence of the anaerobic intestinal oxalate-degrading bacterium *Oxalobacter formigenes* also may play a role in some cases of secondary hyperoxaluria, as has been shown in cystic fibrosis patients, in whom the development of renal stones is quite common.[63]

Moderate-to-severe hyperoxaluria is observed in primary hyperoxaluria type I and type II. In type I, the more prevalent form, the genetic mutation is in alanine:glyoxylate aminotransferase, resulting in increased urinary excretion of oxalate, glyoxlic acid, and glycolic acid. Once renal failure has developed, this leads to recurrent urolithiasis, nephrocalcinosis, renal failure, and systemic oxalate deposition (oxalosis). In type II, a rare entity, the defect is in the D-glycerate dehydrogenase enzyme, resulting in increased urinary excretion of oxalate and L-glycerate.

In children with hyperoxaluria-associated urolithiasis, a low-oxalate diet is recommended (Table 51.7). In cases of secondary hyperoxaluria resulting from fat malabsorption, a fat-restricted diet supplemented by increased calcium intake is also recommended. Most individuals with inflammatory bowel disease also have low urine citrate levels, so potassium citrate can be added as well. In primary hyperoxaluria, a trial of treatment with pyridoxine is warranted. Reduction of oxalate production by pyridoxine is effective in some children with primary hyperoxaluria in reducing the urinary excretion of oxalate. Recent studies show that only those with certain mutations will benefit from pyridoxine therapy.[64,65] The starting dose is 10 mg/day and may be increased gradually to 100 mg/day. Magnesium, citrate, pyrophosphate, and thiazide diuretics in combination also can be used in children with primary hyperoxaluria. In severe cases with systemic oxalosis, dialysis and liver-kidney transplantation may be required.

KEY POINTS

- Inflammatory bowel disease, ileostomy, and fat malabsorption predispose to uric acid and oxalate stone resulting from:
  - Chronic volume contraction
  - Bicarbonate loss and need to produce very acidic urine (low pH)
  - Low urinary citrate and magnesium
- In steatorrhea, excess fat in stool binds calcium (saponification), leaving an abundance of oxalate in the gut to be absorbed.

URIC ACID CALCULI

Uric acid stones account for 2% to 4% of urolithiasis in children. Contrary to calcium stones, uric acid stones are radiolucent. The excretion of uric acid is found to be increased in some children with hypercalciuria, and thus may serve as nidus for development of calcium oxalate and phosphate stones. In children older than 2 years of age, the normal uric acid excreted per glomerular filtration rate (GFR) value is less than 0.56 mg/dL (Uric acid/GFR = $U_{uric\ acid} \times S_{creatinine}/U_{creatinine}$).[66] In addition, Matos et al.[67] published age-related nomograms of ratios of random urine uric acid to creatinine, which are higher in infancy and decrease as the child grows older (Figure 51.9).[67]

An increased urinary uric acid excretion may result from increased glomerular load of uric acid (from excessive dietary purine intake, hematologic or myeloproliferative disorders, or metabolic errors such as Lesch-Nyhan syndrome, glycogen storage disease type 1, etc.) or from isolated or generalized tubular defects. In a child with uric acid stones and hyperuricemia, an evaluation for purine salvage enzymes, hypoxanthine guanine phosphoribosyl transferase (HPRT), and phosphoribosyl pyrophosphate synthetase (PRPS) should be made.[68] Complete HPRT deficiency results in Lesch-Nyhan syndrome, in which the afflicted males have severe neurologic abnormalities in addition to recurrent uric acid calculi.

Urolithiasis associated with increased urine uric acid in the face of low or normal serum uric acid can occur from a primary tubular defect in uric acid handling by the kidney (such as in hereditary renal hypouricemia, hereditary hypouricemia with hypercalciuria and osteoporosis), secondary generalized tubular disorders, or iatrogenic administration of various uricosuric drugs (see Table 51.1).

In a significant number of patients with uric acid urolithiasis, urinary uric acid excretion may be normal. The culprit in these cases is persistent low urinary pH. Urine pH plays an important role in uric acid urolithiasis because uric acid crystals are poorly soluble in acidic urine and precipitate easily. Whereas at urine pH of 6.5, uric acid solubility is 1200 mg/L, it decreases to 200 mg/L at pH of 5.3. This is clinically best exemplified by development of uric acid urolithiasis in children on ketogenic diets for intractable seizures. Despite normal urinary uric acid excretion, the systemic acidosis leads to a constantly low urine pH and hypocitraturia. This is further worsened by poor fluid intake and prolonged immobilization, which lead to stone formation.[26] Interestingly, recent studies found an association between uric acid stones and overweight and insulin resistance causing low urine pH as a result of decreased ammonia production.[69] The therapy for uric acid calculi in most patients includes efforts to alkalinize the urine to a pH of 6.5 to 7.0 with potassium citrate and to maintain a high urine flow rate. A diet low in purine is recommended. This includes restriction of red meat, fish, fowl, coffee, cocoa, chocolate, cakes with a high yeast content ("Danish" for instance), and sardines (Table 51.7). In cases of increased uric acid production treatment with allopurinol may be necessary.

2,8-DIHYDROXYADENINE CALCULI

Deficiency in adenine phosphoribosyl transferase (APRT) is an autosomal recessive disorder leading to formation of

Table 51.7 Dietary considerations in children with urolithiasis

HIGH POTASSIUM	HIGH OXALATE	HIGH PURINES
Fruits and fruit juices	Beets	Alcohol
Apricots	Berries: blackberries, blueberries,	Asparagus
Avocado	strawberries, raspberries, currants,	Cauliflower
Banana	gooseberries	Chickoo
Cantaloupe	Celery	Custard apple
Grapefruit juice	Chocolate	Dry beans (lentils, lima and kidney
Honeydew	Cocoa	beans)
Kiwi	Cranberry juice	Fish: Anchovies, sardines (canned),
Nectarine	Dried figs	herring, mackerel, cod, halibut, tuna,
Orange	Gelatin	carp
Orange juice	Grape juice	Gravies
Pear	Green beans	Meat extracts: Bouillon, broth,
Prune juice	Green onions	consommé, stock
Raisins	Grits	Meat: Beef, pork, lamb, poultry
Tangerine juice	Leafy greens: Collard greens, dandelion	Mushrooms
Tomato juice	greens, Swiss chard, spinach, escarole,	Organ meats: Kidney, liver, pancreas,
V-8 juice	mustard greens, sorrel, kale, rhubarb	brain, heart
Vegetables	Leeks	Peas

excessive 2,8-dihydroxy adenine. These calculi are hard to distinguish from uric acid stones, and specialized chemical analysis is required to distinguish between the two. These children generally have normal levels of uric acid in the serum and urine. At times a clue to diagnosis is brownish crystals on the baby's diaper. The suspicion is that 2,8-dihydroxyadenine urolithiasis is underreported because most of these patients are incorrectly suspected of having uric acid lithiasis and respond to allopurinol (which eliminates the lithogenic 2,8-dihydroxyadenine from the urine). Thus, the correct diagnosis is often missed. The importance of correct diagnosis relies on the fact that alkalization of urine indicated for uric acid stones decreases the solubility of 2,8-dihydroxyadenine and thus increases the risk for urolithiasis. A low-purine diet is also recommended. Thus, presentation with a uric acid–like stone without increases in serum or urine uric acid excretion, or presence of other

factors predisposing to uric acid calculi formation, may require evaluation for a 2,8-dihydroxyadenine stone.

KEY POINTS

- Uric acid stones can be formed as a result of either excessive amounts of uric acid in the urine, low urine pH, or both.
- Preventive intervention includes urine alkalinization.

XANTHINE CALCULI

Xanthine stones occur primarily from a deficiency in the enzyme xanthine dehydrogenase and secondarily from
Figure 51.9 The 5th and 95th percentiles of urinary **(a)** oxalate-to-creatinine and **(b)** uric acid–to-creatinine ratios in normal children. (Reproduced with permission from: Matos V, Van Melle G, Werner D, et al. Urinary oxalate and urate to creatinine ratios in a healthy pediatric population. Am J Kidney Dis. 1999;34:e.1-e6.6.)

allopurinol therapy, which inhibits the enzyme. In hereditary xanthinuria, the enzyme deficiency results in an inability to degrade hypoxanthine and xanthine to uric acid. Uric acid is virtually undetectable in plasma and urine on a purine-free diet and is replaced in the urine by xanthine and to a lesser extent hypoxanthine in the ratio of 3:1 to 4:1. Xanthine calculi should be suspected when orange-brown sediment is noted in the urine. Xanthine stones are radiolucent.

There is no specific therapy for xanthine stones other than increased fluid intake. Special attention should be given to maintain dilute urine during the night. In cases of secondary xanthine stones due to allopurinol therapy, as in children with Lesch-Nyhan syndrome, consideration should be given to lowering the dose of allopurinol to allow the highest tolerated concentration of uric acid that can be controlled by concomitant urinary alkalinization and lessening the xanthine load (as xanthine solubility is almost unaffected by urine alkalinity).

CYSTINE CALCULI

Cystinuria is an autosomal recessive disorder characterized by increased urinary excretion of cystine and other dibasic amino acids: ornithine, lysine, and arginine. Children with cystinuria are classified as type A, B, or AB based on the genetic mutation and the severity of urinary cystine excretion.[70,71] Children with type A have a mutation in gene *SLC3A1,* with homozygous children having a urine cystine excretion in the range of 2000 to 5000 μmol/gCr (molecular weight of cystine, 240) and heterozygous children having a cystine excretion in the range of 25 to 125 μmol/gCr. In type

B the mutation is in gene *SLC7A*, with homozygous children having a urine cystine excretion similar to that of type A, but heterozygous children have a cystine excretion in the range of 100 to 1000 μmol/gCr; the excretion is lower in the mixed form type AB, in which the child has one disease-causing mutation in each gene *SLC3A1* and *SLC7A9*.

Cystinuria accounts for 2% to 4% of children with kidney stones in developed countries. A higher incidence may be encountered in areas endemic for consanguinity. Cystine stones are usually, but not always, radiopaque because of presence of sulfur ions and occasionally may have a component of or serve as a nidus for a calcium oxalate stone. One study showed that cystinuria can be associated with hypercalciuria (18%), hyperuricosuria (22%), and hypocitraturia (44%) probably caused by renal tubular acidification defect.[72] Cystine crystals appear as flat, hexagonal, and colorless (see Figure 51.1) and should be searched for in concentrated acidic urine. Normal individuals excrete less than 60 mg of cystine per 1.73 m² of body surface area per day, whereas patients who are homozygous for cystinuria often have excretion rates greater than 400 mg/1.73 m²/day. Patients with nonspecific proximal renal tubular aminoaciduria may excrete as much as 200 mg of cystine/1.73 m²/day. The solubility of cystine in urine is approximately 250 mg/L up to pH 7.0 and rises sharply with higher pH, up to 500 mg/L or more above pH 7.5.[73]

The medical therapy includes high fluid intake, diet, urinary alkalization, and medications.[74,75] The treatment goal in this condition is to maintain a high fluid intake of 1.5 to 2.0 L/m²/24 h to maintain a urinary cystine concentration of less than 300 mg/L. The fluid intake should be distributed throughout the day and night. More than in any other stone

disease, nocturnal diuresis is of crucial importance. Patients should ideally drink a large amount of water before going to sleep and get up at least once at night to void and have additional water intake. Furthermore, the urine needs to be alkalinized to a pH of 7.5. To attain a urinary pH of 7.5, the daily alkali dose of sodium bicarbonate or potassium citrate can reach 3 to 4 mEq/kg/day. Patients should be instructed to monitor their urinary pH and to maintain pH between 7.0 and 8.0. Because cystine excretion correlates with dietary sodium intake, a low-salt diet is indicated combined with high fruit juice (mostly citrus) intake. The latter contain citric acid and potassium, thus increasing both diuresis and alkali load. The diet should be normal RDA for protein, and patients should avoid excessive protein intake because the precursor for cystine is the methionine amino acid in dietary proteins.

In children in whom hydration, decreased salt intake, and urinary alkalinization have failed, D-penicillamine, or α-mercaptopropionylglycine (tiopronin, Thiola) may be used. Both these compounds are sulfhydryls that cleave cystine into two cysteine moieties to form mixed disulfides, which are 50 times more soluble than cystine. Tiopronin, (Thiola) forms a mixed disulfide of Thiola-cysteine, which is then excreted. D-penicillamine is administered at a dose of 20 to 50 mg/kg/day in divided doses, with half of the daily dose taken at bedtime because urinary cystine concentration is maximal during the night. The dose for α-mercaptopropinyl glycine (Thiola) is 15 mg/kg/day. The therapy should be supplemented with pyridoxine hydrochloride (vitamin B_6) 25 to 50 mg/day because of the antipyridoxine effect of the drug. The adverse effects of D-penicillamine include skin rash, fever, lymphadenopathy, and loss of taste. Proteinuria may develop after several months of treatment and may progress to nephrotic syndrome, which improves on discontinuation of therapy. Because of the potential for serious toxic effects associated with its long-term use, it is recommended to either discontinue therapy or maintain only the bedtime dose as prophylaxis when calculi are no longer present. Captopril, which is a sulfhydryl agent, has been used with mixed results in cystinuria. The surgical therapy includes lithotomy with or without chemolysis with N-acetylcysteine, D-penicillamine, Thiola or tromethamine under the direction of the urologist.

INFECTION CALCULI

Infection-related stones constitute approximately 2% to 3% of the stones in children and are more common in young children. "Infection stone," "infection-induced stones," and "triple-phosphates stones" are all synonymous terms that refer to magnesium ammonium phosphate or struvite ($MgNH_4 PO_4$-$6H_2O$) and carbonate apatite ($Ca_{10}[PO_4]_6CO_3$) stones. The formation of struvite stones requires an alkaline urinary pH, which is provided by breakdown of urea by uropathogens, such as *Proteus* and *Staphylococcus aureus,* and less commonly *Klebsiella, Serratia, Pseudomonas,* and *Staphylococcus epidermis,* which produce urease.

Abnormalities of the genitourinary tract, especially the presence of obstruction, predispose to the formation of infected stones. Infection with the previously mentioned organisms sometimes produces a soft radiolucent mucoid substance called a *matrix concretion* that may calcify rapidly into a radiopaque stone and account for some of the rapid formation of struvite stones seen in clinical practice. These stones can completely fill and form a cast of the pelvicalyceal system and are known as *staghorn calculi.* These staghorn calculi have the potential of causing severe urinary obstruction, pyelonephritis, and urosepsis. One of the essential management strategies in infection-related stones is to sterilize the urinary tract. As with any other infected foreign body, surgical removal of the offending agent may become necessary to sterilize the biologic system. Staghorn calculi in children invariably must be removed and, rarely, nephrectomy may be required. In some selected cases, irrigation with hemiacridin or buffered citrate to dissolve struvite stones has been used. Acetohydroxaminic acid is a urease inhibitor that has been used to reduce production of urinary ammonia and carbon dioxide to decrease struvite stone formation, but does not dissolve the struvite stones once they are formed. This has been used effectively in adults but has been limited by its psychoneurologic and musculointegumentary side effects, and, therefore not yet been approved for use in children.[76] With improved management of both pediatric obstructive uropathy and UTIs, infection-related stones are rarely seen today in industrialized countries.

IDIOPATHIC CALCULI

In a number of children in whom a stone is not retrieved, routine urine chemistry analysis may be normal. In such cases an investigation for less common causes such as hypomagnesemia should be done. If still normal, we recommend as first step only nonpharmacologic interventions, including high fluid intake and an appropriate diet (see later). On rare occasions, the addition of potassium citrate is needed. We believe

---

KEY POINTS

Therapy of cysteine stones is complex and can be frustrating because of stone recurrence. Principles include:

- Adequate hydration and urine volume
- Alkalinizing urine with oral bicarbonate (maintain pH 7 to 8)
- Citrate fruit supplement
- Low dietary salt
- Avoid excessive dietary protein
- D-penicillamine
- Tiopronin, Thiola
- Captopril
- Cystine stones are resistant to ESWL
- Surgical removal, such as endourologic basketing or lithotomy may be necessary

that this is due to the fact that although each of the individual biochemical variables, such as calcium, uric acid, oxalate, and citrate, still may be within the normal range, under certain condition their product(s) may exceed supersaturation.

MEDICAL MANAGEMENT OF UROLITHIASIS

Renal colic requires symptomatic treatment with quick pain control (narcotic analgesics), hydration (oral or parenteral flow rate equaling 1.5 to 2.0 times maintenance), and prophylactic antibiotics (after appropriate cultures have been obtained). Children need to be admitted to the hospital if they have intractable vomiting, intractable pain, UTI with obstruction, single kidney, or transplanted kidney. After resolution of renal colic, a course of expectant observation may be recommended for small (<4 mm) distal ureter or nonobstructed renal stones while urine is strained for stone retrieval. Stones 4 mm or greater in diameter rarely pass spontaneously and most of the time require surgical intervention.[77] In adults, combination treatment with nifedipine and corticosteroids, and more recently nonsteroidal anti-inflammatories combined with α_1 blockers, may enhance stone expulsion.[49,78] In cases of stones causing intractable pain, large obstructing stones, or anuria (solitarily functioning kidney or bilateral stones), urgent surgical treatment is necessary.

One of the greatest risk factors for pediatric urinary stone formation is a low urinary flow rate. A high fluid intake is critical in preventing supersaturation of the urine regardless of the cause of urolithiasis. Children with urolithiasis have a lower diagnostic 24-hour urine volume than do normal children.[16] Furthermore, global warming and other conditions of hot ambience may result in insufficient urine output in spite of adequate fluid intake.[79] We recommend that children drink enough fluids to have urine that has no color to it. We advise the family to prepare daily, in advance, the fluids the child needs to consume with an optional reward system. As discussed earlier, minimal recommended fluid intake can be "tailored" for each patient based on weight and 24-hour urine volume. This amount should be further increased during outdoor activities in hot days.

> ### KEY POINT
>
> Higher fluid intake is required during outdoor activities in hot days. The rule of thumb is that "the urine should look like water."

Based on epidemiologic observations there is no doubt that diet plays a role in urolithiasis.[1] Robertson et al.[4] showed the increased consumption of animal protein in Leeds, UK correlated with increased incidence of calcium oxalate stone in the population. Borghi et al.[80] showed that in men with recurrent calcium oxalate stones and hypercalciuria, restricted intake of animal protein (54 g/day) and salt

(50 mmol/day), combined with a normal calcium intake (30 mmol/day), provides greater protection than the traditional low-calcium diet (10 mmol/day). Curhan et al.[81] showed that high intake of phytate, present in fruits, vegetables, and whole grains, lowered the risk for kidney stones in younger women. Shuster et al.[82] showed that patients who consumed more than 160 mL of phosphoric acid containing soft drinks at the time of diagnosis of a stone had a significantly higher recurrence-free interval if the soda was discontinued. The association between consumption of sugar-sweetened soda and higher risk for stone formation was recently confirmed by Ferraro et al.[83] Thus, it appears that the more we deviate from a traditional balanced diet with normal intake of protein, salt, fruits, and vegetables and supplement them with rich fast foods and artificial drinks, the more we increase our risk for urolithiasis. Therefore, a diet with RDA protein and calcium intake, low in sodium and oxalate, and rich in potassium is recommended for children with hypercalciuria and idiopathic stones. In those with absorptive oxaluria, a low-oxalate, low-fat, and high-calcium diet is recommended and in those with hyperuricosuria, a diet low in purines.[49] In adults, higher dietary magnesium intake was found to have a beneficial effect in preventing stone formation.[38]

SURGERY IN MANAGEMENT OF URINARY CALCULI

A surgical approach may be necessary in children with obstructive or infected urolithiasis. The factors that must be taken into account when selecting the choice of surgical therapy for urolithiasis depends on the size of the calculus, its location and composition, and the associated urinary tract anatomy. The surgical approach to urolithiasis may consist of extracorporeal shock wave lithotripsy (ESWL), percutaneous nephrolithotomy (PCNL), endoscopic basket extraction (Figure 51.10), open surgical approach or a combination of these different techniques.[84]
Figure 51.10 Uroendoscopic basket used to extract ureteric stones by ureteroscopy.

ESWL is frequently used in children with urolithiasis. Urolithiasis from uric acid and calcium oxalate dihydrate calculi is most responsive to ESWL; calcium oxalate monohydrate, struvite, and brushite are more difficult to fragment, whereas cystine calculi are resistant to ESWL. ESWL has a good success rate and is applicable in almost 80% of the pediatric stones. Its role may be still limited in children with large calculi, lower pole stones, and stones in anatomically abnormal urinary tract.[85] ESWL is safe and effective, with very little difference in success rates among different lithotriptors. Although renal blood flow is reduced transiently following ESWL, no significant decreases in mean ipsilateral and total glomerular filtration rate, or long-term lesions on dimercaptsuccinic acid (DMSA) renal scans have been identified in children undergoing ESWL.[86,87] The common side effects observed with ESWL are renal or perinephric hematoma, post-treatment flank pain, gross hematuria, and trauma to extrarenal tissues lying in the blast path, such as skin bruising at the entry site of the shock wave, and pulmonary impacts (infiltrates, contusion, and hemoptysis).

Percutaneous nephrolithotomy can be used alone or in combination with other surgical techniques in management of urolithiasis. It is especially useful in children with a large stone burden, orthopedic rods for spine stabilization, or a history of renal surgery. A percutaneous access to the renal pelvis is established, and a rigid or flexible nephroscope is used to manipulate the calculi. Currently available nephroscopes can accommodate laser, electrohydraulic, or ultrasonic probes; grasping forceps; basket extractors; or a combination. The calculi can then be broken down and extracted. The procedure carries the risk for significant blood loss requiring transfusion and possible urosepsis. Similarly, endoscopic procedures using ureteroscopes and cystoscopes can be used to remove a calculus using basket retrieval, grasping forceps, electrohydraulic, or ultrasonic or laser lithotripsy. Open surgery is required for calculi that are not amenable to ESWL, PCNL, or endoscopic techniques. In recent years with improved imaging techniques and pediatric-dedicated instrumentation, there has been a rise in use of endoscopic extraction and percutaneous approach and decrease in ESWL, with open surgery being extremely rarely used.[88] In children with severe stone burden, complex urinary anatomy, or previous surgical procedures, a combination of these techniques may be used together or in succession.

OUTCOME

The literature suggests that 50% of adults will have a recurrence within 10 years, depending on the type of urolithiasis.[49] Recent reports indicate higher risk for ESRD in adults with urolithiasis.[89,90] Noe,[91] on follow-up of 27 of 44 children with hypercalciuric stones, found that 9 (33%) developed a recurrence 3 to 15 years after the initial episode (mean 7.2).[91] There was a significant association with a positive family history of stones in first-degree relatives. Hypercalciuria was the main risk factor for recurrence of stones with or without structural abnormality. In a randomized controlled study, Soygur et al.[92] have shown that 60 mEq/day of potassium citrate given to adults with calcium oxalate stones after ESWL significantly reduced the recurrence rate. Thus, the benefits of potassium citrate and thiazide therapy have to be weighed against the risk of long-term use of these medications, especially in children presenting with a first-time idiopathic stone. Thus, we emphasize the need to develop healthy eating and drinking habits in all children with a stone and consider drug therapy only in children in whom we can identify an underlying metabolic disorder or children who develop recurrent stones.

SUMMARY

There is a general agreement on the worldwide increase in incidence of pediatric urolithiasis. Whereas part of this increase may be due to improved diagnostic techniques, other reasons are environmental, mostly changes in dietary habits and climate conditions. The most common causes of pediatric urolithiasis include insufficient fluid intake and hypercalciuria, followed by hypocitraturia. The best diagnostic tool is noncontrast CT, but because of the involved radiation its use should be limited and instead urinary tract ultrasound used. The 24-hour urine collection biochemistry analysis continues to be the gold standard for diagnosis and the intervention based on it (at times assisted by blood chemistry findings). High fluid intake is the universal treatment for all types of kidney stones and should be part of public health policy. Similarly, public education about the opposing roles of dietary sodium and potassium in calcium stone formation should be promoted. If nonpharmacologic intervention does not correct the urine biochemical abnormalities, pharmacologic intervention is indicated. The latter is often the case in patients with noncalcium stones.

REVIEW QUESTIONS

1. The greatest risk factor for pediatric stone formation is:
   a. Hypercalciuria
   b. Low urine flow
   c. Hypocitraturia
   d. Hyperoxaluria

2. A child with body weight of 50 kg has a 24-hour urine volume of 700 mL. The additional daily fluid intake recommended for this child will be:
   a. 300 mL
   b. 400 mL
   c. 500 mL
   d. 600 mL

3. In a teenager with idiopathic hypercalciuria, dietary intervention will include:
   a. Sodium intake of 2000 to 2300 and potassium intake of 3000 to 3500 mg/day
   b. Sodium intake of 1500 to 1800 and potassium intake of 3000 to 3500 mg/day
   c. Sodium intake of 1500 to 1800 and potassium intake of 2000 to 2500 mg/day
   d. Sodium intake of 2000 to 2300 and potassium intake of 2000 to 2500 mg/day

4. The risk in administrating potassium citrate is:
   a. Upset stomach
   b. Development of hypercholesterolemia

c. Severe diarrhea
d. Rendering the urine too alkaline

5. When employing thiazide diuretics:
   a. Sodium intake should be liberalized
   b. K-citrate should not be used concomitantly
   c. The addition of amiloride is beneficial
   d. Osteopenia may worsen

6. Numerical goals in managing children with hypercalciuria-to-hypocitraturia include:
   a. Urine calcium/citrate ratio < 0.20 and Na/K ratio < 2.5
   b. Urine calcium/citrate ratio < 0.33 and Na/K ratio < 2.5
   c. Urine calcium/citrate ratio < 0.20 and Na/K ratio < 3.5
   d. Urine calcium/citrate ratio < 0.33 and Na/K ratio < 3.5

7. Gastrointestinal issues causing hypocitraturia are usually associated with:
   a. Severe constipation
   b. Fat malabsorption
   c. Gastroesophageal reflux
   d. Chronic diarrhea

8. Mild absorptive hyperoxaluria is best treated by:
   a. Dietary oxalate restriction
   b. Administration of *Oxalobacter formigenes*
   c. Dietary calcium supplementation
   d. Avoidance of food high in fat

9. High incidence of uric acid stones in obese population is due to:
   a. Diet rich in purines
   b. Diet rich in salt
   c. Decreased ammonia production
   d. Insufficient fluid intake

10. To protect against stone formation in children on ketogenic diets, it is advisable to give:
    a. Potassium citrate
    b. Thiazide diuretics
    c. Allopurinol
    d. Magnesium oxide

ANSWER KEY

Voiding disorders

HANS G. POHL

Derangements in the normal pattern of micturition result in a variety of urinary tract symptoms and morbidity. Such voiding disorders range from mild manifestations that represent no more than a social nuisance to severe dysfunctional elimination associated with recurrent cystitis, acute pyelonephritis, or both; hydronephrosis; and vesicoureteral reflux (VUR). Voiding disorders in children result from immature bladder function, abnormal voiding habits, and urinary sphincter dysfunction. Recurrent urinary tract infections (UTIs) and upper urinary tract changes resulting from voiding dysfunction, are generally seen in severe sphincter dysfunction associated with high bladder pressure generated during voiding, incomplete bladder emptying, functional bladder outlet obstruction, or a combination of these. Rarely, anatomic causes of incontinence are encountered from conditions such as spina bifida, posterior urethral valve, and prune belly syndrome that can affect the bladder, the urinary sphincter, or both. Diet and social factors also influence toileting behavior and need to be addressed early in the management of these patients.

NORMAL VOIDING

A normal voiding cycle is a two-phase process, consisting of low-pressure and adequate volume bladder filling, followed by complete evacuation of the bladder.[1] Both of these phases of the voiding cycle are coordinated and active processes.

Bladder filling requires inhibition of bladder contraction and increased tone of the urinary sphincter complex. As the bladder approaches fullness, tension receptors in the bladder wall trigger afferent nerves that send signals of the need to void. Voluntary voiding involves inhibition of sphincter contractions and coordinated contraction of the bladder smooth muscle.

In the neonate, bladder filling is followed by reflexive emptying (voiding reflex). This reflexive micturition cycle is controlled by the sacral spinal cord and occurs approximately hourly. After 6 months of age, the urinary volumes increase and the frequency of voiding decreases as the control of voiding shifts from the sacral cord to the pontine voiding center, thus establishing the spino-bulbo-spinal reflex pathway.[2,3]

Around the age of 2 years, the child develops conscious sensation of bladder fullness and has urge incontinence. Between 2 and 4 years of age, the child acquires voluntary control of bowel and bladder function in the following sequence: (1) nocturnal bowel control, (2) daytime bowel control, (3) daytime bladder control, and (4) nocturnal bladder control.

A majority of children demonstrate an adult voiding pattern by 4 years of age. The timing of this sequence is influenced by ethnic, cultural, economic, and individual family differences. In the United States, the mean age at which daytime urinary control is achieved is 2 to 3 years but may vary from 1 to 5 years.[4] Of children 4 to 9 years of age, 5% to 10% may experience at least some daytime wetting.[4] In general, most school-aged children void between four and six times daily.[4]

Many functional and anatomic disturbances of voiding manifest as wetting. Thus, we have organized the discussion of these entities by the likelihood of renal damage associated with each (Table 52.1). In this classification, conditions such as daytime frequency syndrome, giggle incontinence, and overactive bladder (OAB) that are not associated with upper urinary tract injury, do not require extensive imaging or intensive follow-up. Alternatively, voiding disorders such as dysfunctional elimination, Hinman syndrome, posterior urethral valve (PUV), and neurospinal dysraphisms may cause deterioration of renal functions by virtue of high-pressure voiding and UTI. Three miscellaneous conditions—cerebral palsy (CP), attention deficit/hyperactivity disorder, and hypercalciuria—are addressed as well.

EPIDEMIOLOGY

Urinary incontinence is frustrating for parents, socially ostracizing to patients and, and often regarded as a clinical nuisance by many physicians. It is estimated that

Table 52.1 Clinical classification of voiding disorders in children

Low Risk for Upper Urinary Tract Deterioration
Daytime frequency syndrome
Postvoid dribbling
Giggle incontinence
Stress urinary incontinence
Primary nocturnal enuresis
Paradoxical incontinence or ectopic ureter in girls
Sensory deficient bladder
Overactive bladder

High Risk for Upper Urinary Tract Deterioration
Dysfunctional elimination
Non-neurogenic neuropathic bladder or Hinman syndrome
Posterior urethral valve
Neurospinal dysraphism

Miscellaneous Causes
Cerebral palsy
Attention deficit/hyperactivity disorder
Hypercalciuria

approximately 417,000 visits to pediatrician's offices are made annually for incontinence, with primary nocturnal enuresis (PNE) representing 38% of these cases. Of such children, 75% are evaluated between 3 and 10 years of age, and 15% to 20% are between 11 and 17 years of age.[5]

The rate of outpatient visits for PNE in both the commercially insured and Medicaid populations has more than doubled from approximately 100 per 100,000 children to 283 per 100,000 children in the 6-year period from 1994 to 2000.[5] Whether there is a true increase in the prevalence of childhood incontinence or merely an increased awareness of the need to treat has led to increased referrals is unclear. Urinary incontinence in children must be evaluated in the context of the child's age, because attainment of daytime and nighttime urinary control follows a predictable maturational process. For instance, urinary incontinence is quite a normal phenomenon in children under the age of 3 years.

DISORDERS WITH LOW RISK FOR UPPER URINARY TRACT DETERIORATION

DAYTIME FREQUENCY SYNDROME

Daytime frequency syndrome (DFS) consists of acute-onset urinary urgency and frequency, with or without rare episodes of incontinence and without any definable clinical cause. DFS primarily affects boys 4 to 8 years old (mean, 4.5 years) and is more prevalent in the spring and fall. No certain cause for the syndrome has been established, although some authors postulate that DFS is caused by psychosocial stress with seasonal variation.[6–10] DFS is characterized by urinary frequency without dysuria that occurs every 10 to 20 minutes during the daytime but abates completely during sleep. Nocturnal enuresis (NE) is not a feature of DFS. Evaluation of the patient is by history and physical examination, with a normal urinalysis and a negative urine culture. DFS is a self-limiting disorder and

requires support and reassurance. Resolution of symptoms is common without any specific therapy and can occur in 2 days to 16 months, with an average of 2.5 months.[6,11]

POSTVOID DRIBBLING

Postvoid dribbling or vaginal voiding occurs in prepubertal girls who are very thin or obese. In both cases an abnormal position precludes the girl from adequately opening her legs, thus causing vaginal trapping of urine. Once voiding concludes, the pooled urine drains shortly after assuming an upright posture. The diagnosis may be based on history alone, with dribbling occurring shortly after voiding. Occasionally, perineal itching suggests yeast infections. The itching is usually caused by chemical irritation and does not need be treated with antifungals.

The physical examination is usually normal, or may reveal labial adherence or labiovulvar erythema. Radiographic evaluation is not warranted. Treatment consists of having the girl sit on the toilet facing the wall (backward), with the legs spread apart. If the patient is unable or unwilling to do this, a stool or seat adaptor can be used, although these are usually cumbersome. If labial adherence is present, precisely applied topical estrogen (conjugated estrogen [Premarin] ointment, 0.625 mg) applied twice daily for no longer than 6 weeks is usually curative. Concerns regarding the potential long-term risk for cancer has significantly curtailed its use by many. Instead, application of betamethasone 0.05% ointment can be offered to lyse the labial adherence. Rarely does labial adherence require surgical lysis.

In males, urethral pooling, usually in a congenital or acquired urethral diverticulum, may cause postvoid dribbling. The physical examination is normal or may show ventral penile swelling, especially following voiding. In most circumstances, the child has previously undergone a hypospadias repair. The treatment is surgical.

GIGGLE INCONTINENCE

Giggle incontinence, or enuresis risoria, is a disorder characterized by complete bladder emptying with giggling, laughter, or exertion. This condition may be related to cataplexy, a part of narcoleptic syndrome complex. Genetically, giggle incontinence has been linked to human leukocyte antigen (HLA) DR2 and has a strong familial predisposition.[12,13] The condition occurs primarily in peripubertal girls, is rarely seen in boys, and can persist into adulthood.[13,14] The patient is dry during day and night but experiences daytime bladder emptying associated with giggling or laughing.

Characteristic history alone is sufficient for making the diagnosis of giggle incontinence. Physical examination and urinalysis are normal in most cases. Urodynamic

and radiographic evaluation are not warranted. Frequent voiding, especially before social engagements, can be adequate treatment. Anticholinergics or Kegel exercises for strengthening pelvic floor are usually not helpful. However, methylphenidate has been shown to decrease frequency of the episodes with as-needed or continuous usage.[13] Conditioning therapy with low-voltage electric shocks to the back of the hand also has been shown to be effective.[15]

STRESS URINARY INCONTINENCE

Stress urinary incontinence is the loss of urine with physical activity, coughing, or sneezing. This occurs most commonly in adolescent and young adult female athletes. Nygaard et al.[16] studied 156 nulliparous college varsity athletes with a mean age of 19.9 years. The prevalence of incontinence while participating in their sports was 28%. Of these females, 40% had noted incontinence in high school and 17% in junior high school.[16,17]

The diagnosis of stress incontinence is made by history. Physical examination and urinalysis are usually normal. Radiographic examination is not warranted, unless evidence of spina bifida occulta exists on physical examination (e.g., hair tuft, lipoma, asymmetric gluteal crease). In these cases an MRI of the spine should be obtained to exclude spinal cord tethering.

> ### KEY POINT
>
> Abnormal sacral or gluteal examination should always prompt radiographic examination for spinal dysraphism abnormality.

PRIMARY NOCTURNAL ENURESIS

Primary nocturnal enuresis (PNE) is defined as bedwetting in an individual who has never been dry at night. When the child begins wetting the bed after a period of nighttime continence has been achieved, enuresis is termed as being secondary.[18] PNE is usually monosymptomatic and is not associated with daytime symptoms. Although NE is considered normal in infants, society expects night dryness by 5 years of age. NE affects approximately 15% of 5-year-old children, but prevalence diminishes gradually to only 3% of adolescents.[19,20] A familial form of the disease, characterized by an increased incidence of PNE in children of enuretic parents is well known.[21]

Pathogenesis

Pathogenesis of PNE is unclear, but dysfunction of the bladder, kidneys, and central nervous system has been implicated. Urodynamic evaluation of enuretic

children during waking and sleep has shown that many children with PNE have reduced bladder capacity and demonstrate overactivity, like the infantile bladder.[18] One criticism of many of these studies has been the possible inclusion of children with daytime symptoms. One study demonstrated that the incidence of bladder overactivity might be only 16% in pure monosymptomatic enuretics.[18] Nevertheless, it appears that children with enuresis may be a heterogeneous group, with some displaying reduced functional bladder capacity only during sleep. Other children with monosymptomatic enuresis have bladder overactivity during the day and at night. These patients manage to compensate during wakeful states and do not have daytime wetting. At least one study has challenged the dictum that enuresis is characterized by complete evacuation of the bladder by demonstrating elevated postvoid residual urine measurements (>10% of bladder volume) and abnormal bursts of electromyography activity suggesting sphincter dyssynergia.[22]

Urine production usually decreases at night under control of the circadian rhythm of secretion of antidiuretic hormone (ADH).[23] Loss of the normal nighttime production of ADH results in polyuria that can exceed the functional capacity of the bladder and result in enuresis. Rittig and colleagues have done much of the work on ADH mediation of enuresis, demonstrating that nocturnal urine production was significantly greater than daytime urine production in some enuretic children.[24] This finding was explained when significantly lower nocturnal levels of ADH were demonstrated in concert with large volumes of dilute urine in enuretic children.[25] Recently, aquaporin channels, ADH-responsive transmembrane proteins responsible for urinary concentration, have been implicated in the pathophysiology of enuresis.[26]

A maturational delay in the ability to sense bladder filling and inhibit bladder contraction until wakefulness has also been implicated as a causative factor in enuresis.[27,28] There are mixed reports about a sleep arousal and developmental delay in enuretics. Some authors claim that enuretics are more difficult to arouse. However, the asymptomatic siblings of such patients have been noted to be equally as hard to awaken.[29–32]

KEY POINTS

- Some patients with NE have reduced bladder capacity or infantile (overactive) pattern on urodynamic studies.
- Loss of nocturnal ADH circadian rhythm can be seen in some as a cause of NE.
- Maturational delay and sleep arousal disorders have been implicated in some.

Treatment

Treatment of NE is divided into three categories: observation, behavioral, and pharmacologic. Observation is sufficient if the wetting does not cause a major social or family disruption, especially since PNE has an annual spontaneous resolution rate of 15%. Behavioral modification or conditioning therapy in the form of an enuresis alarm requires significant motivation of the parents and child and continued use for up to 6 months. This is, however, the most effective form of treatment available, with permanent cures occurring in over 90% in well motivated families. Relapse rate can be 25% to 30% after short-term use of the alarm for 6 to 8 weeks.[33,34] Pharmacotherapy for PNE is discussed in detail later in this chapter.

PARADOXICAL INCONTINENCE

Paradoxical incontinence is continuous dribbling despite a normal voiding pattern. This phenomenon is exclusively seen in girls and is caused by an ectopic ureteral insertion distal to the external urinary sphincter complex, with the most common ectopic ureteral site being the urethra (35%), vaginal vestibule (34%), and vagina (25%).[35] Although boys also may have distally inserting ectopic ureters, the insertion site (e.g., seminal vesicles, vas deferens) is always proximal to the external urinary sphincter and thus incontinence is prevented.[36,37]

The physical examination should include inspecting the girl's perineum with her in the frog-legged position with the labia spread. With patience, urine often can be seen pooling in the vaginal vestibule. Radiologic investigation typically relies on identifying the ectopic ureter or the renal unit it subtends. Renal bladder ultrasound, voiding cystourethrogram, intravenous pyelogram, and computed axial tomography have been used to identify the real unit responsible for the incontinence. However, the renal unit attached to such an ectopic ureter is invariably dysplastic and often poorly visualized by traditional imaging, particularly because hydronephrosis is seldom, if ever, seen. Pattaras et al.[38] reported on a small cohort of girls with paradoxical incontinence from ectopic ureters. Nuclear renal scintigraphy with technetium-99m dimercaptosuccinic acid (DMSA)

KEY POINTS

- Ectopic ureter insertion causes paradoxical incontinence in females because the ureter inserts distal to the external urinary sphincter.
- Most renal units associated with an ectopically inserted ureter are very dysplastic, contributing little to total renal function.
- DMSA renal scans are the best means of identifying the dysplastic renal unit associated with an ectopic ureter.

reliably detected and localized the hypoplastic ectopic kidneys and poorly functioning upper pole moieties in each case. Thus, once the clinical presentation suggests paradoxical incontinence from an ectopic ureter, nuclear renal scintigraphy should be considered during the initial radiologic evaluation.[38–40]

SENSORY DEFICIENT BLADDER

Young girls and occasionally boys will avoid urinating for an extended period. Typically, the patient will awaken, eat, and go to school without voiding. The first void often occurs mid-day or even after school, with the patient often rushing to the toilet. They may wet themselves on the way to the toilet or be damp already. The clinician makes the diagnosis by asking the following three questions: (1) Does the child urinate on awakening in the morning? (2) Does the child use the toilet at school? (3) How many times does the child void during a typical day?

The patient's symptoms consist of dysuria, urgency with a full bladder, bedwetting, urinary dribbling, or a combination of these. These children may present with a UTI or for workup of a fever and abdominal pain. Physical examination may be normal or demonstrate a palpable bladder. Urinalysis is likely to show bacteriuria, and urine culture may be positive. A prevoid and postvoid renal bladder ultrasound should be done to evaluate postvoid residual. The infection should be treated and antibiotic prophylaxis continued if there have been multiple UTIs and until effective frequent bladder emptying is achieved.

KEY POINTS

- Patients with sensory deficit bladders usually hold urine for long periods and have urinary urgency and dribbling as common symptoms
- These patients are prone to getting UTIs.

OVERACTIVE BLADDER

Overactive bladder (OAB) with its many synonyms (bladder instability, urge syndrome, hyperactive bladder, persistent infantile bladder, detrusor hypertonia), is the most common voiding dysfunction of childhood. Its occurrence peaks between 5 and 7 years of life, and it has an incidence of 57.4%, with a female preponderance (60.1% in females and 38.9% in males).[41] The cause of this disorder is thought to be delayed functional development of cortical inhibitory control over the voiding reflex mediated through the reticulospinal pathways or in the inhibition center of the cerebral cortex.[42–45] In response to the urge to urinate, the child learns to

contract the external urinary sphincter to suppress the bladder contraction and delay voiding. In some circumstances, the child can be seen running to the toilet in response to the urgency, and incontinence occurs when the toilet is not reached in time. Other children are able to remain dry if they concentrate on their bladders but are often wet at play or when absorbed in activity of interest. Holding maneuvers (leg crossing, squatting, Vincent curtsey) are a common observation by parents and are the child's attempt to suppress the bladder contraction by exerting pressure on the external urinary sphincter.[46]

Sphincter tightening and holding maneuvers result in increased bladder muscle stretch because contraction occurs against a fixed resistance. The OAB is associated with vesicoureteral reflux in 20% to 50% of children. In such circumstances, management of VUR should include addressing the OAB as a clinical issue. Otherwise, spontaneous resolution of the VUR may be impeded and recurrent UTIs may occur.[6,47–49]

Although imaging is not warranted in the majority of children with OAB, those who are resistant to conservative management may benefit from prevoid and postvoid renal-bladder ultrasound and an assessment of postvoid residual urine volume. The sonogram can provide information regarding upper urinary tract dilatation, bladder wall thickening, and the child's ability to empty the bladder. Voiding cystourethrography and urodynamics are recommended only if febrile UTIs have been present, or evidence of urinary tract decompensation has been documented sonographically.[50,51] Frequently, urodynamic findings include reduced functional bladder capacity with uninhibited bladder contractions.[45]

KEY POINTS

- OAB is the most common voiding dysfunction in children.
- VUR is seen in in 20% to 50% of children with OAB. If untreated, OAB impedes spontaneous resolution of VUR.
- Imaging is not necessary initially, but should be considered when conservative measures fail.
- Initial management includes timed voiding, treatment of constipation, anticholinergic medication, and antibiotic prophylaxis for those with a history of frequent UTIs.

Conservative management of the OAB consists of timed voiding, anticholinergic therapy, prophylactic antibiotics, and treatment of any underlying constipation.[49,50,52–56] The success of timed voiding depends on the child's motivation to urinate before a spontaneous bladder contraction. If this schedule would require the child to void at a socially

unacceptable frequency, anticholinergic medication should be considered. When used appropriately, anticholinergic medications offer a reasonable degree of success. These measures, in combination with elimination of caffeine, result in elimination of symptoms in 87% of children treated conservatively.[50] The child's parents must understand that treatment is a long-term process, taking an average of 2.7 years, with a range from 0.2 to 6.6 years. Because UTI may promote bladder instability, any active UTI should be treated with appropriate antibiotics. The patient should then be placed on prophylaxis with trimethoprim-sulfamethoxazole (TMP-SMX) or nitrofurantoin until a normal voiding pattern has been established.

DISORDERS WITH HIGH RISK FOR UPPER URINARY TRACT DETERIORATION

Dysfunctional elimination syndrome

Dysfunctional elimination syndrome (DES) encompasses constipation, urge incontinence, voiding postponement, infrequent voiding, and urinary retention that develop from a learned response to bladder overactivity.[57–59] In an effort to avoid incontinence, the patient contracts the sphincter complex, adopts postures, or both, which effectively suppresses the urinary or fecal urgency temporarily.

In its mildest form, DES is characterized by infrequent bowel movements, hard stools requiring straining, voiding postponement, and a strong or "staccato" stream that results in daytime urinary incontinence, fecal incontinence, or both. More severe forms of DES may manifest with incontinence, UTIs, bladder wall changes (distention, thickening, trabeculations, or reduced bladder contractility), VUR, and hydronephrosis.[44,49,60–62]

There is a close relationship between VUR and dysfunctional elimination. VUR can be identified in 30% to 50% of patients with DES.[49,52,63] However, this association may be biased because the majority of patients included in the studies presented with recurrent UTIs, a group known to have a high prevalence of VUR (30% to 35%). Koff et al.[49] found that among 143 patients felt to have primary VUR, 43% were identified as having significant bowel and bladder disturbances. In the children with VUR and dysfunctional elimination, breakthrough UTIs occurred in 82%; in 18% of children with VUR, no evidence of dysfunctional elimination had breakthrough UTIs.[57] These data demonstrate the influence that dysfunctional elimination has in the pathogenesis of UTI and underscores the notion that VUR itself is not a risk factor for UTI. Several studies have reported improved resolution rate of VUR in children who also were provided therapy for coexisting dysfunctional

elimination, in addition to standard antimicrobial prophylaxis. Conversely, failure to address dysfunctional elimination results in a higher failure rate following antireflux procedures.[49,53,56,57] Although many children with VUR do not have abnormal voiding patterns on urodynamic investigation, and most children with DES do not have VUR, it is recommended that children with recurrent UTIs and VUR be screened for dysfunctional elimination as part of the initial evaluation.

DES is clinically suspected from the presenting history of the patient. Frequently, obesity (in as many as 30%) and psychosocial stressors (in as many as 40%) coexist with DES and should be addressed concurrently.[64] The physical examination is usually normal, but it also may reveal a palpable bladder and possibly palpable stool in the colon. An abdominal radiograph may demonstrate fecal retention. Renal and bladder ultrasound should be used to screen for increased postvoid residual urine volumes. A voiding cystourethrogram is not warranted unless documented febrile UTIs have occurred and VUR is suspected.[51] The use of noninvasive urodynamic studies combining uroflowmetry and patch electrodemyography has gained popularity among some who rely on flow patterns to select individualized treatment approaches. Staccato voiding is the most frequently seen pattern (58%), followed by interrupted and mixed patterns (19% and 10%, respectively).[65]

Treatment should first address the bowel dysfunction using cleansing with oral laxatives and enemas, if needed. A maintenance program should involve increasing the daily dietary fiber intake as well as by supplementation with a goal of a daily bowel movement. Behavioral modification should also focus on retraining urinary elimination to ensure regular and complete evacuation of the bladder. Children with bladder instability can be treated with anticholinergics, such as oxybutynin, hyoscyamine, or tolterodine, with the caveat that treatment of constipation must be addressed concurrently. If urodynamic evidence demonstrates staccato voiding, biofeedback treatments aimed at relaxation of the pelvic floor during voiding have demonstrated normalization of flow patterns in 96%.[66]

NON-NEUROGENIC NEUROGENIC BLADDER (HINMAN SYNDROME)

Non-neurogenic neurogenic bladder represents extreme voiding dysfunction involving the lower urinary tract and affecting the upper tracts in the absence of any neurologic dysfunction.[60] Hinman syndrome constitutes functional bladder outlet obstruction resulting from a learned discoordination between bladder contraction and sphincter relaxation. The majority of patients are young males who have day and night wetting associated with chronic urinary retention, fecal retention and soiling, recurrent UTIs, and impaired renal function.[60] In addition to the clinical presentation, one also may elicit a social history significant for

divorced, domineering parents; parental alcoholism; and drug, sex, or generalized abuse. Physical examination, as in DES, may demonstrate only fecal or urinary retention, and the neurologic examination is entirely normal. The diagnosis is often suggested when evidence of hydronephrosis is seen on a sonogram obtained during the evaluation for suspected DES. Some patients may present with manifestations of advanced renal dysfunction and complications from it. Voiding cystourethrography often shows a dilated, trabeculated bladder with VUR. An MRI should be obtained to exclude spina bifida occulta. These boys should be referred for urodynamic studies. Because many boys ultimately require intensive bladder retraining with biofeedback, it is practical to place a suprapubic cystostomy tube under anesthesia through which urodynamic studies and multiple biofeedback sessions can be performed without the need for repeated catheterizations. Botulinum toxin injection of the external sphincter has been performed successfully when biofeedback has failed.[67,68]

POSTERIOR URETHRAL VALVE

Young[69] described three variations of congenital urethral membranes in 1915, a nomenclature that persists to date. Of these, only two are truly associated with urinary obstruction and are of clinical relevance. A type I valve, which represents anomalous insertion of the mesonephric duct into the fetal cloaca, is found cystoscopically between the prostatic urethra and external urinary sphincter and accounts for 95% of clinical cases.[70] The less common (5%) type III valve represents incomplete dissolution of the urogenital membrane and is encountered within the membranous urethra beyond the external sphincter.[71] Currently, most cases of PUV are diagnosed antenatally by ultrasonography. The characteristic imaging findings in such fetuses consist of bilateral severe hydronephrosis, bladder distention, bladder wall thickening, perinephric urinoma or ascites, and amniotic fluid abnormalities are seen in a male fetus.[72]

Despite endoscopic ablation of the valve in the newborn period, up to 50% of these boys will have incontinence well past toilet training, possibly because of associated primary bladder dysfunction.[73] Urodynamic assessment has shown changing patterns of bladder dysfunction with overactivity predominating in childhood leading to myogenic failure in adolescence.[74] Unfortunately, bladder dysfunction appears to correlate with deterioration in renal function through as yet unclear mechanisms.[73] Ultimately, most boys can achieve continence through institution of clean intermittent catheterization, anticholinergic medication, or both or surgical reconstruction of the urinary tract. Urodynamic studies should be performed to guide therapy, with the goal of ensuring low-pressure bladder filling and complete and regular evacuation of urine.

KEY POINTS

- Hinman syndrome, which is a discoordination between the detrusor contraction and sphincter relaxation, is initially managed through biofeedback.
- Bladder dysfunction from PUV is not static. Whereas detrusor overactivity predominates in childhood, myogenic failure is seen in adolescence.

NEUROSPINAL DYSRAPHISMS

Myelomeningocele accounts for 90% of all spinal dysraphic states, and it affects the lumbar, sacral, thoracic, and cervical spine, in decreasing prevalence.[75] An effective physical examination in patients with myelodysplasia would include palpation of the abdomen for bladder distention and fecal retention. In addition, urinary sphincter tone can be estimated based on inspection of the anal sphincter for laxity and reflexive contraction. Because the level of the lesion does not predict the type or degree of lower urinary tract dysfunction, neurologic and urodynamic examination of these patients is crucial.

Urodynamic studies immediately following newborn closure of the spinal defect and later have shown three main categories of prevalent bladder function: (1) a coordinated bladder and sphincter (19%), (2) discoordination with or without bladder overactivity (45%), and (3) complete paralysis (36%).[76-78] These patterns are not fixed and can change over time, resulting in varying patterns of bladder dysfunction.

Renal bladder sonography may show a dilated bladder with bladder wall thickening and dilated upper urinary tracts. Voiding cystourethrography reveals a trabeculated bladder, and VUR may be present. Magnetic resonance imaging (MRI) is the test of choice for anatomic detail of the spinal cord.[79] MRI is used to evaluate tethering of the spinal cord, syrinx or hydromyelia, increased intracranial pressure secondary to ventriculoperitoneal shunt malfunction, and partial herniation of the brainstem and cerebellum. Radiologic evaluation is repeated any time there is a change in neurologic, orthopedic, or urodynamic assessment.

Treatments are aimed at preserving nephron function and facilitating low-pressure voiding. Clean intermittent catheterization (CIC) alone or in combination with anticholinergics is used to keep the intravesical pressure less than 40 cm H_2O.[80-82] Rarely, a vesicostomy must be performed when the above therapies are not sufficient in adequately decompressing the bladder.[83,84]

MISCELLANEOUS CAUSES

CEREBRAL PALSY

Cerebral palsy (CP) a nonprogressive perinatal brain injury, is characterized by neuromuscular disability, specific symptoms complex, or cerebral dysfunction. Its incidence—currently 1.5 per 1000 live births—is increasing as smaller, younger premature infants are surviving.[85] Incontinence in children with CP is related to the degree to which the physical disability impairs reaching the toilet in time. Continence often develops at an age later than expected. If dryness is not achieved by late childhood or early puberty in a child who is physically capable and who appears trainable, further evaluation by urodynamic testing is recommended.[86] The most common clinically relevant urologic findings are exaggerated sacral reflexes, detrusor overactivity, and detrusor-sphincter dyssynergia.[87] Radiographic evaluation is not generally necessary.[88] Anticholinergics are able to provide relief of uninhibited bladder contractions in most patients with these problems. If the child has a large volume of postvoid residual urine, CIC should be advocated.

ATTENTION DEFICIT/HYPERACTIVITY DISORDER

Children with attention deficit/hyperactivity disorder (ADHD) have a greater risk for daytime (ninefold) and nighttime (threefold) enuresis than age-matched controls.[89] The risk for daytime enuresis appears to increase with age, whereas the risk for nighttime enuresis lessens as children get older.[89] Some improvement in wetting has been demonstrated following the use of methylphenidate.[90]

KEY POINTS

- Most infants with neurogenic bladder have detrusor overactivity; the next most common pattern is detrusor hyporeflexia.
- Children with CP might be incontinent as a result of their physical limitation because they cannot reach the toilet in time. It might also result from bladder overactivity and detrusor-sphincter discoordination.

HYPERCALCIURIA

Idiopathic hypercalciuria has been identified in 20% to 30% of children with hematuria, dysuria, frequency-urgency syndrome, or voiding dysfunction.[91–93] It is postulated that the high concentrations of calcium in the urine irritates the bladder, causing involuntary incontinence. Although most nephrologists accept the definition of hypercalciuria as urinary calcium excretion greater than 4 mg/kg/day in children with urolithiasis, some have recommended that urinary calcium excretion greater than 2 mg/kg/day be the considered the threshold for defining hypercalciuria in children with enuresis or dysuria.[92,94] Successful treatment of the hypercalciuria can result in reduction of urinary symptoms and wetting in these patients.[94,95] Treatment is based on dietary measures aimed at decreased salt and oxalate intake and increased dietary fluid intake. Dietary calcium intake is generally not curtailed, because it is important in maintaining proper bone health in a developing child. Thiazide diuretics are helpful in reducing hypercalciuria when dietary measures fail.

EVALUATION

HISTORY

The diagnosis of childhood voiding disorders is made primarily by history and physical examination. Radiologic, laboratory, and complex urodynamic evaluation are rarely required but may be considered in circumstances when the clinical manifestations include UTI (febrile and afebrile), when physical examination suggests neurologic dysfunction, or when simple behavioral change or pharmacotherapy has been unsuccessful.

Elimination diary

Obtaining an accurate history of incontinence is of paramount importance and may be sufficient to arrive at a diagnosis. An assessment of the onset, pattern, severity, and circumstances surrounding the incontinence episodes should be noted. The interview should include the child also, depending on the child's age and maturity level.

We have found it useful to provide families with a questionnaire in advance of the initial evaluation, such that observations can be made before arriving at the clinic (Figure 52.1). These surveys document the degree to which wetting occurs during the day and night, the pattern of urinary and fecal elimination, specific behavioral patterns that can be observed in conjunction with wetting, drinking habits, and whether a UTI has coexisted with the wetting disturbance. Additionally, parents are requested to record the number of times the child voids or exhibits wetting during a 2-day interval (Table 52.2) Armed with this preliminary information, one can then obtain a more detailed history that focuses on pertinent positive observations.

Primary versus secondary disorder

Whether the voiding disorder is of new onset (secondary) or whether the child has never been completely continent since toilet-training was completed (primary) should be

Figure 52.1 Voiding questionnaire.

determined. This distinction is critical because secondary wetting disturbances are more likely associated with an identifiable abnormality in contrast to children who present with primary incontinence. For example, diabetes insipidus or diabetes mellitus, PUV, and tethered spinal cord all may manifest with a history of secondary daytime or nighttime incontinence.[96–98] Exceptions to this rule do occur, however. For instance, continuous dribbling of urine in some girls as a consequence of an ectopic ureter ending periurethrally may result in what appears as a primary incontinence, because these patients are never reported to be completely dry.

Bladder capacity estimation

Expected bladder capacity can be estimated based on the interval between voids and the maximal voided volumes that have been recorded on the elimination diary. Expected bladder capacity should be compared with calculated estimates of bladder capacity based on age, using the following formulas[99]:

Bladder capacity (ounces) less than 2 years = [2 × age (years)] + 2

Bladder capacity (ounces) 2 to 13 years = (age [years]/2) + 6

Table 52.2 Voiding diary

Patient: Please fill out this diary for your child. Keep the diary for at least 3 days (*2 weekend days and at least 1 school day*). Record every time your child uses the bathroom, has wetting accidents, and has bowel movements. Also, please record activity and fluid intake.

DATE/TIME	Urinated/ Peed	Wetting accidents	Describe accident (Soaked/ Damp)	Activity at time of accident (School/Sleep)	Fluid intake (Type/Amount)	Bowel movement (Hard/Soft/ Loose)

Urinary stream

The characteristics of the urinary stream and events immediately before and following should be noted. Children with sensory deficient bladders do not recognize bladder filling and will typically wet themselves without recognition, often described as "sitting in their own urine." By comparison, the child with urgency frequency is seen to cross the legs, squirm, grab the genitalia, or sit on one heel to inhibit the detrusor contraction. A weak urinary stream in a boy may reflect a PUV, and staccato voiding in either gender may occur because of poor relaxation of the external urinary sphincter. Upward deflection of the urinary stream, a phenomenon seen almost exclusively in circumcised boys, occurs because of meatal stenosis. However, meatal stenosis is not the cause of voiding dysfunction or enuresis. Finally, postvoid dribbling may represent release of urine pooled in the vagina on standing in girls or from a urethral diverticulum in boys, particularly those with a history of urethral trauma or surgery.

Bowel function

Constipation, usually from idiopathic causes, is known to occur in as many as 10% of school-aged children.[58,99] Constipation has been associated with UTIs, urgency-frequency syndrome, urinary retention, incontinence, and upper urinary tract deterioration in children.[58,100,101] Significant improvement in voiding symptoms and diminished frequency of recurrent UTIs in children following specific treatment of constipation only is well documented. For this reason, it is important to inquire regarding the consistency and frequency of bowel movements, fecal incontinence, and whether prior therapy for encopresis or constipation has been attempted. However, because parents may not accurately know the bowel habits of their older children, it is often helpful to include children in the interview by specifically asking them whether any bowel movements passed are hard, painful, or associated with blood. Dietary factors may influence fecal consistency, and thus elimination, so a detailed dietary history should be obtained. This history should explore concomitant medication use that may predispose to constipation, such as anticholinergics, anticonvulsants, antacids, oral iron, and psychotherapeutics.

PHYSICAL EXAMINATION

A comprehensive physical examination is warranted in every child with voiding dysfunction, which is most often normal. The examination should include a review of the abdomen, genitalia, perineum, anus, lower back, and lower extremity neurologic status. Palpation of the abdomen should be performed with attention to identifying constipation, which would be suggested by fullness in the lower quadrant or rectum. A palpably distended urinary bladder, particularly shortly after the child has voided, may indicate more severe voiding disturbance such as those caused by neurologic conditions, PUV, or pelvic malignancies.

In boys, when meatal stenosis is suspected, the urethral meatus should be inspected by carefully trying to spread the meatus open. If urethral mucosa is seen to evert from the meatus, the diagnosis of stenosis can be excluded. To confirm meatal stenosis, the child may be observed voiding. Typically the urinary stream is deflected upward in meatal stenosis, and to direct the stream into the toilet, the boy must aim the penis downward at an acute angle. In girls, a bifid clitoris or a urethral meatus that is patulous anteriorly is diagnostic for epispadias. An ectopic ureter to the periurethral area is suggested by continuous pooling of urine in the vaginal vault.

Rectal examination is typically not warranted in most patients with wetting. However, boys with new onset or secondary voiding dysfunction who complain of the need to strain to void, weak stream, hesitancy, or both, should be examined rectally because these symptoms are associated with prostatic rhabdomyosarcoma. In girls, rhabdomyosarcoma manifests more commonly as a vaginal introitus mass rather than with voiding complaints. Inspection of the lower back may disclose evidence of spinal dysraphism (see later). Finally, a neurologic examination of the lower extremities also may suggest spinal cord abnormalities if loss of or asymmetric strength, coordination, or both are seen.

INVESTIGATIONS

In the vast majority of cases, urinalysis with a dipstick and microscopic examination provides important information regarding UTI and some metabolic disorders. When a negative dipstick analysis is combined with negative urine microscopy, infection can be excluded reliably and a formal urine culture is not warranted.[102,103] Dipstick analysis for urinary protein, glucose, and specific gravity is helpful to screen for causes of polyuria, such as diabetes mellitus or insipidus (nephrogenic or central). Generally, a urine specific gravity measurement of 1.022 or greater, in the absence of proteinuria or glucosuria, indicates adequate concentrating ability. Lower urine specific gravity measurements that are associated with polydipsia and polyuria should be further evaluated to exclude diabetes insipidus.

Imaging studies

Most voiding disorders can be accurately diagnosed by clinical history only, and imaging studies are rarely necessary. Prevoid and postvoid renal-bladder ultrasonography (RBUS) is warranted to assess bladder emptying and evaluate for hydronephrosis in patients with voiding abnormalities, especially if these are present in association with febrile UTI. Hydronephrosis may suggest the presence of other anatomic abnormalities, such as VUR or PUV, which can contribute to the risk for upper urinary tract deterioration in presence of infection. In the absence of a history of febrile UTI, children do not need to have VCUG, unless other risk factors for VUR, such as a family history of reflux, are present. The advent of office-based RBUS has led some

to perform this test in all children presenting with urinary incontinence. However, few children demonstrate such inefficient emptying to justify this practice.

A plain radiograph of the abdomen is helpful in demonstrating increased fecal load in children who are suspected of having constipation but do not yield reliable information on questioning. Additionally, the radiograph also screens for occult spinal dysraphism, a rare but well-recognized cause of secondary wetting and bowel disturbances.

Screening for occult dysraphism

Rarely, unrecognized spina bifida associated with spinal cord tethering or spinal cord tumors may cause elimination disorders. Patients known to be at risk for spinal cord tethering include those with imperforate anus or VATER syndrome (vertebral defects, imperforate anus, tracheoesophageal fistula, and radial and renal dysplasia) (up to 45%), and cloacal exstrophy (up to 100%).[105–108] These patients are easily identified, but many more subtle cases of spinal cord tethering occur in the context of spina bifida occulta.

The radiographic appearance of occult spinal dysraphisms may not be visible until after 5 to 7 years of age when ossification is complete.[109] This finding can be observed in as many as 30% of normal men and 17% of normal women. When spina bifida occulta occurs as a bony abnormality and without cutaneous manifestations, it is considered a normal variant without clinical consequence. MRI examination of the spine is not warranted in such individuals. When cutaneous manifestations, such as a dimple or hair patch, are seen in a child with voiding dysfunction, an MRI should be performed.

Any child with secondary day and night wetting, new-onset constipation or encopresis, or a significant delay in toilet training should be evaluated for occult spinal disorders. Neurologic evaluation and examination of the back for skin dimpling, hair tufts, accessory skin tags or tails, and pigmentation should be undertaken in an effort to identify spinal dysraphism. In children with gait disturbances, the relative symmetry of the gluteal muscles also should be evaluated. Finally, sensation and tone of the anal sphincter can be used as a proxy for urethral sphincter function.

Urodynamic studies

Urodynamic studies are usually recommended only for children with significant urinary, fecal, or both elimination problems, a diagnosed PUV, or Hinman syndrome. These patients are at risk for upper tract deterioration and may be found to have hydronephrosis, renal cortical scarring, or both on presentation. The data collected from urodynamic studies should be compared with values from normal children.[110] Noninvasive urodynamic studies, which comprise uroflowmetry with patch electromyography, have been advocated by some to select children for more rigorous treatment by biofeedback or those more likely to benefit from α-adrenergic therapy.[65]
Figure 52.2 Nonlinear curve showing relationship between age (years) and bladder capacity (milliliters). (Adapted from: Kaefer M, Zurakowski D, Bauer SB, et al. Estimating normal bladder capacity in children. J Urol. 1997;158:2261–4.)

THERAPEUTIC APPROACHES

In most cases, simple behavioral modification is sufficient to improve the incontinence. Surgery is rarely necessary and is performed only for severe cases of dysfunctional elimination that are recalcitrant to conventional behavioral modification or when signs of upper urinary tract changes are present. In some children, pharmacotherapy is used as an adjunct to behavioral modification.

Timed and double voiding

The establishment of regular elimination habits is of paramount importance, particularly among children who are infrequent voiders and in those whose incontinence is not associated with frequency. The child should be encouraged to void as frequently as necessary to prevent wetting, based on the patterns recorded in a voiding diary. Because many of these children do not sense the need to void at lower volumes, voiding on a schedule can be associated with well-defined events throughout the day, such as waking, before meals, and before bedtime. Multialarm wristwatches are also helpful as auditory cues for timing of urination.

Older children may have large-capacity bladders, high postvoid residual urine volumes, and double or repeat voiding may be necessary. For instance, this "yo-yo" pattern may be observed especially in children with prune belly syndrome, bilateral high-grade VUR, and Hinman syndrome, in whom the upper urinary tract is highly compliant.

Initiation of double voiding can obviate the need for clean intermittent catheterization (CIC). These children should be reevaluated by RBUS after institution of double voiding to ensure that hydronephrosis is improving. Persistent or progressive hydronephrosis and UTI reflect poor compliance with these measures and demonstrate the need for more intense therapy with CIC.

Enuresis (wetting) alarms

Enuresis alarms worn during the day by children with daytime wetting have been reported to result in appropriate behavior modification, achieving a success rate of over 60%. Unfortunately, use of enuresis alarms during the day is more cumbersome than multialarm watches that can provide similar benefit.

Bowel program

In children with associated constipation, a bowel program should be instituted to ensure that the rectum remains empty of stool.[59] Various treatment modalities can be tailored to the severity of constipation. Increasing fiber and liquid intake, bulking agents, stool softeners, and laxatives can be tried first (Table 52.3) Suppositories, enemas, disimpaction, or a combination of these may be necessary. The recommended daily amount of fiber can be calculated using the formula:

Grams of fiber needed per day (20 g maximum) = Age (Years) + 5

For milder cases, dietary modification, fiber supplementation, or both may follow an initial bowel clean-out using laxatives. Severe constipation may require initial manual

Table 52.3 Fecal elimination programs

	Minimal dose	Maximal dose
Bulking Agents		
Fiber*	Age (yr) + 5 (g) per day	20 g/day
FiberCon	1 cap (6–12 yr) or 2 caps (≥12 yr) daily	1 cap tid (6–12 yr), 2 caps tid (≥12 yr)
Metamucil wafers	1 wafer bid (6–12 yr)	2 wafers tid (>12 yr)
Senokot	1 tablet or teaspoon daily	3 tablets or teaspoons daily
Citrucel	7.5 mL in 8 oz water daily (6–12 yr)	7.5 mL in 8 oz water tid (6–12 yr)
	15 mL in 8 oz water daily (>12 yr)	15 mL in 8 oz water tid (>12 yr)
Stool Softeners		
Mineral oil	1 mL/kg daily	2.5 mL/kg bid
Lactulose	1 mL/kg daily	1 mL/kg tid
Colace	20 mg/day (3–6 yr), 40 mg/day (7–12), or 50 mg/day (>12 yr) divided bid or tid	60 mg/day (3–6 yr), 120 mg/day (7–12), or 200 mg/day (>12 yr) divided bid or tid
Laxatives		
Milk of Magnesia[†]	1 mL/kg daily	1 mL/kg tid
Magnesium citrate[†]	1 oz/yr of age (<6 yr)	1 bottle (>6 yr)
Castor oil	2.5 mL daily	50 mL daily (for adults)
GoLYTELY	8-oz glass q20min until rectal effluent is clear	100 mL/kg or 4 L in adult-size teenagers
MiraLAX[‡]	5 mL in 40 oz water daily	17 g (1 heaping tablespoon in 8 oz water daily (adult dose, may be reduced in children)
Suppositories		
Glycerin	1 per rectum daily to qod	1 per rectum bid
Dulcolax	½ to 1 per rectum daily (not for chronic use)	1 per rectum bid
Enemas		
Fleet phosphate[§]	1 pediatric dose daily	1 pediatric dose bid
Tap water[¶]	100–250 mL enema daily	100–250 mL enema bid
Milk of Magnesia	1:1 milk to magnesia (30–150 mL) daily	1:1 milk to magnesia (30–150 mL) tid
Fleet mineral oil	½ dose daily	1 enema daily

bid, twice per day; qid, every other day; tid, three times per day.
* Dietary texts provide tables with the amount of fiber (in grams) in various foods.
† May result in hypermagnesemia.
‡ Advantage is no taste; safety undetermined in children; preliminary reports suggest safe in children older than 2 years of age for 6-month period.
§ May result in hyperphosphatemia.
¶ May result in hyponatremia.

disimpaction and rectal clean-out using enemas, followed by administration of laxatives, such as MiraLAX, magnesium citrate, or polyethylene glycol-electrolyte solution (GoLYTELY). In these circumstances, abdominal films obtained before and during therapy are helpful in demonstrating the fecal load. Once the clean-out phase has been completed, a maintenance phase lasting as long as 1 year should be continued with daily oral laxatives. Failure to continue these measures often results in recurrent constipation.[59]

Biofeedback techniques

Biofeedback techniques rely on combining Kegel exercises to strengthen pelvic floor, along with urodynamic studies and positive reinforcement. Biofeedback has been used successfully to treat children with urinary and bowel elimination problems, recurrent UTI, and VUR, particularly when the underlying abnormality during voiding is a nonrelaxing pelvic floor.[111–123]

In general, after a complete urodynamic evaluation is performed, the child's perineal muscular activity is monitored during filling and voiding by an electromyographic electrode. The urodynamic equipment displays pelvic floor contraction as visual or auditory cues that the child can control. The goal is to teach the child to relax the sphincter complex completely during voiding.

McKenna et al.[121] recognized the difficulty to maintain a child's focus during these arduous biofeedback sessions. They devised a computer game that the child controls with perineal muscular activity. Using this method, they reported effective treatment of voiding dysfunction in 41 children with various forms of dysfunctional elimination habits. Overall, 90% to 100% of patients improved in all categories. Of the group, 52% of cases of nocturnal enuresis, 61% of diurnal enuresis, 33% of constipation and 73% of encopresis were completely cured.

Pharmacologic therapy

Pharmacotherapy is reserved for voiding disorders associated with UTI or when significant social embarrassment is perceived. (Table 52.4). Any child with coexisting constipation should begin a bowel program before institution of any medication with anticholinergic effects, because these impair colonic motility as well. Anticholinergic and α-adrenergic medication may be contraindicated in

Table 52.4 Pharmacologic therapies available for treatment of daytime voiding disorders

Type (Brand Name)	Minimal dosage	Maximal dosage	Long-acting dosage
Anticholinergic			
Propantheline (Pro-Banthine)	0.5 mg/kg bid	0.5 mg/kg qid	
Oxybutynin (Ditropan)	0.2 mg/kg bid	0.2 ml/kg qid	Ditropan XL 5-20 mg daily
Hyoscyamine (Levsin)	0.03 mg/kg bid	0.1 mL/kg qid	Levsin timecap 1–2 bid
α-Adrenergic Agonist			
Phenylephrine (Entex)	0.5 mg/kg bid	1 mg/kg tid	Entex LA 1 tab bid
Pseudoephedrine (Sudafed)	30 mg qid (6–12 yr)	60 mg qid (>12 yr)	Sudafed 12-hr cap bid
Ephedrine	1 mg/kg/day qid	3 mg/kg/day qid	
α-Adrenergic Blockade			
Prazosin (Minipress)	0.05 mg/kg bid	0.1 mg/kg tid	
Doxazosin mesylate (Cardura)	0.5 mg/kg at bedtime	8 mg at bedtime	
Terazosin (Hytrin)	0.5 mg/kg at bedtime	10 mg at bedtime	
Smooth Muscle Relaxant			
Flavoxate (Urispas)	3 mg/kg bid	3 mg/kg tid	
Tricyclic Antidepressant			
Imipramine (Tofranil)	0.7 mg/kg bid	1.2 mg/kg tid	
Central Nervous System Stimulant			
Methyphenidate (Ritalin)	5 mg before social event	10 mg before social event	Ritalin SR 20 mg daily
Dextroamphetamine	NR		
Amphetamine (Adderall)			
Antibacterial Prophylaxis			
Nitrofurantoin (Macrodantin)	1–2 mg/kg at bedtime		
Trimethoprim-sulfamethoxazole (Septra, Bactrim, Sulfatrim)	0.5 mg/kg at bedtime		
Trimethoprim	0.5 mg/kg at bedtime		
Sulfisoxazole (Gantrisin)	50 mg/kg at bedtime		

bid, twice daily; NR, not recommended; qid, four times daily; tid, three times daily.
Figure 52.3 External manifestations of spinal dysraphism. (a) Hemangioma. (b) Sacral dimple. (c) Diastematomyelia. (d) Lipoma. (Photographs courtesy of John Myseros, MD, Division of Neurosurgery, Children's National Medical Center, Washington, D.C.)

children with closed-angle glaucoma or cardiac disease. Therefore, consultation with the appropriate specialist should precede their use.

ANTICHOLINERGIC AGENTS

Anticholinergic and musculotropic medications inhibit or reduce bladder overactivity. These medications increase the threshold potential for involuntary smooth muscle cell contraction, which translates into a greater volume of urine required before the bladder contracts. The side effects of anticholinergic medications include dry mouth, facial flushing, and constipation, and, in hot climates, hyperpyrexia may occur. If blurred vision or hallucinations occur, it is recommended that the dose be decreased.

α-ADRENERGIC STIMULANTS

α-Adrenergic agonists may be used to increase outlet resistance in patients with stress urinary incontinence. However, true stress urinary incontinence is unusual in a neurologically intact child and is customarily found in association with an anatomic abnormality of the bladder neck, such as epispadias or urogenital sinus abnormality. Teenage girls engaged in high-impact sports also have been found at risk for stress urinary incontinence.

TRICYCLIC ANTIDEPRESSANTS

Imipramine has been the most widely used tricyclic antidepressant in children, particularly in the treatment of NE. Some have reported efficacy of this class for treatment of daytime incontinence, as well. It has a dual mechanism of action, with anticholinergic effects causing detrusor muscle relaxation and α-adrenergic effects causing increased sphincter muscle activity. Tricyclics should be used only in older children and adolescents because of their relatively long half-life and risk for side effects. Anticholinergics remain the first-line therapy for daytime incontinence from detrusor overactivity, but tricyclics may be added in incrementally greater doses for refractory cases. Children who require high doses of tricyclics should be monitored for cardiac conduction defects and arrhythmias with electrocardiography.

α-ADRENERGIC BLOCKADE

The well-documented clinical efficacy of α-adrenergic blockade to improve urinary flow and decrease postvoid residual urine volumes in men with benign prostatic hypertrophy (BPH) has led some pediatric urologists to evaluate its utility in reducing functional outlet obstruction in children with enuresis.

The rationale for the use of α-adrenergic blockade in BPH relies on evidence of α-adrenergic receptors localized to the smooth muscle cells of the bladder outlet in both genders and especially to the prostatic tissue in males. However, in childhood enuresis associated with poor bladder emptying, it is generally believed that diminished flow results from incomplete relaxation of the external urinary sphincter and not as a result of increased tone of the bladder neck or prostatic tissues. Despite this apparent conflict, results of clinical studies using α-blocker therapy show promise.[124–126]

Three nonrandomized cohort studies of a total of 88 children have demonstrated statistically significant improvements in urinary flow rate and postvoid residual urine volumes that have resulted in cessation of or diminished enuretic episodes in approximately 80% of children treated with doxazosin (0.5 to 1 mg orally).[124–126] A major criticism of these studies has been the lack of standardized follow-up among the three studies and inclusion of varied causes of enuresis, although all children had evidence of poor bladder emptying. Side effects, related to postural hypotension, are diminished by administration just before bedtime.

CENTRAL NERVOUS SYSTEM STIMULANTS

Central nervous system stimulants, such as methylphenidate (Ritalin), have been used successfully to treat giggle incontinence. Children with ADHD and enuresis also have been found with diminished incontinence following institution of methylphenidate. The mechanism of action is unknown.

TREATMENT FOR PRIMARY NOCTURNAL ENURESIS

Pharmacologic therapy relies on improving functional bladder capacity through anticholinergic effects (oxybutynin, imipramine) or by diminishing nocturnal urine volume (vasopressin, desmopressin acetate [DDAVP]). Imipramine has been the first medication used to treat enuresis. It relies on antispasmodic effects on the bladder and stimulatory effects on the sphincter. Some data also suggest that imipramine may exert central effects that alter arousal, thus facilitating that the child awaken from sleep before enuresis occurs. Initial response rates to imipramine are approximately 50% but long-term cure rates, once the drug is discontinued, are poor (only 25%).[127]

Oxybutynin, a potent anticholinergic, may be helpful in the management of NE associated with bladder overactivity. Its efficacy as a single drug used to treat enuresis is approximately 10% to 50%.[128] One study evaluated combination therapy with imipramine and oxybutynin. Although the combination proved more efficacious in short-term results than either drug alone (90% achieved dryness), lasting results were seen in only 40% after the treatment was discontinued.[128]

A more direct approach to enuresis appears to be improving the kidney's concentrating ability during sleep through the use of vasopressin (DDAVP). The reported response rate to vasopressin is 40% to 70%.[129,130] The relapse rate on discontinuation is high, with only 30% of responders maintaining continence at 1 year.[131] Vasopressin can be administered intranasally as a spray as well as an orally administered tablet.

Functional bladder capacity remains an important feature in the pathogenesis of enuresis and, if unaddressed, is likely to be associated with treatment failure. In fact, several studies have shown that functional bladder capacity is a strong predictor of response to desmopressin.[132–134] One study correlated a bladder volume and wall thickness index to the response from desmopressin and found a statistically greater likelihood of resolution when DDAVP was prescribed to children with normal bladder volume and bladder wall thickness.[135] Enuretic children with reduced bladder volume and thick bladder wall and those with large bladder volumes and thin walls had a suboptimal response to oral desmopressin.[135]

ANTIBIOTICS

Symptomatic UTI should be treated with appropriate antibiotic therapy. Prophylactic antibiotics should be considered in children with voiding disorders who have recurrent infection, because chronic inflammation may perpetuate bladder instability. TMP-SMX, nitrofurantoin, and TMP alone have been used successfully as prophylaxis. On occasion, two antibiotics are required to adequately prevent recurrent UTI.[136]

CLEAN INTERMITTENT CATHETERIZATION

CIC is recommended in children who demonstrate persistently elevated postvoid residual urine volumes despite adherence to timed voiding and double voiding regimens and therapy for constipation. Although children are likely to develop bacteriuria with CIC, studies have demonstrated improved continence and diminished risk for pyelonephritis and upper urinary tract deterioration.[137] CIC should be performed at 3- to 4-hour intervals. So long as complete bladder emptying is achieved regularly, bacteriuria remains clinically insignificant in the majority of these children. The use of sterile catheters is unnecessary, and prophylactic antibiotics are not recommended unless the patient has been diagnosed with VUR. In such circumstances, every effort should be made to maintain sterile urine with daily antibiotic prophylaxis. Anticholinergic medication also may be used if evidence of bladder overactivity has been found.

ENDOSCOPY AND PROCEDURES TO REDUCE BLADDER OUTLET RESISTANCE

Historically, cystourethroscopy with urethral dilation has been used in some patients with dysfunctional voiding, based on the rationale that bladder outlet obstruction was the risk factor leading to recurrent UTIs in such girls.[138] In most treatment protocols, the urethra was dilated to 28 to 32 Fr, followed by prolonged antibiotic prophylaxis. Unfortunately, no objective clinical evidence exists that urethral dilation itself, in the absence of antibiotic prophylaxis, ever diminished the risk for UTIs.[138] This should be of no surprise, because the underlying problem in some girls with recurrent UTIs is nonrelaxation of the external

urinary sphincter during voiding that is untreated by dilatation. Therefore, the abnormal voiding pattern recurs after the procedure, as does the risk for UTI.

When behavioral modification and biofeedback techniques have failed to produce sphincter relaxation during voiding, a novel surgical option has been employed to temporarily paralyze the external urinary sphincter by endoscopic injection of botulinum-A toxin. Sphincter paralysis lasts between 2 and 9 months, during which the child learns to void without tightening his or her sphincter. As a result of improved bladder emptying, continence improves.[139]

SURGERY

Surgical interventions are rarely used anymore for incontinence related to dysfunctional elimination states. Perhaps the only indication would be very high postvoid residual urine volumes associated with upper tract deterioration, which cannot be managed by CIC, and in a patient in whom future fertility is not a concern. In those circumstances, one might consider a bladder neck incision or a Y-V plasty.

Neurologic and anatomic causes of incontinence require surgical intervention to promote continence when timed voiding and CIC have been unable to provide relief. Urodynamic studies are often helpful in determining the type of procedure to perform, such as augmentation cystoplasty, Young-Dees-Leadbetter bladder neck reconstruction, Mitrofanoff procedure, sling cystourethropexy or placement of artificial sphincter device. A pediatric urologist with experience in such matters should perform the evaluation of the child with severe voiding problems that have an anatomic cause.

SUMMARY

Incontinence, though acceptable in young children, becomes increasingly bothersome as children mature into school age. The symptom itself encompasses many disorders, both functional and anatomic. For most children who wet, a detailed history and physical examination will usually determine the type of wetting disorder and suggest an appropriate treatment course. For these children, simple behavioral modification, such as the use of a timed voiding schedule and dietary modification (which also may include the use of laxatives) can significantly diminish the number of wetting episodes and prevent UTI, when coexistent. When wetting presents with UTI and fever, radiologic evaluation should be performed and any underlying severe functional or anatomic abnormality rapidly addressed to prevent upper urinary tract deterioration.

REVIEW QUESTIONS

1. A 2-year-old girl is expected to begin toilet training in which of the following sequences:
   a. Daytime bowel, daytime bladder, nocturnal bladder, nocturnal bowel
   b. Nocturnal bowel, daytime bowel, daytime bladder, nocturnal bladder
   c. Daytime bladder, nocturnal bladder, nocturnal bowel, daytime bowel
   d. Nocturnal bladder, nocturnal bowel, daytime bowel, daytime bladder

2. A 6-year-old boy is referred shortly after the beginning of second grade with new-onset urinary frequency occurring every 15 minutes. He does not have nocturnal enuresis and has not had daytime wetting. He has never had a urinary tract infection and was completely asymptomatic before the school year began. His physical examination is normal. Your treatment recommendations include:
   a. Reassurance
   b. Renal bladder sonography with prevoid and postvoid views of the bladder to investigate whether he is retaining urine
   c. An MRI of the sacral spine
   d. Anticholinergic medication

3. A 7-year-old obese girl presents with daytime incontinence lasting over a year. She has been evaluated with multiple urine cultures and only mixed bacterial growth found. She denies urgency to void, voids approximately five times daily, and never wets the bed. Her mother states that her underpants are sporadically wet, with wetting occurring shortly after the girl voids. Her physical examination is normal. Your treatment recommendations include:
   a. Renal bladder sonography with prevoid and postvoid views of the bladder to investigate whether she is retaining urine
   b. An MRI of the sacral spine
   c. Anticholinergic medication
   d. Reassurance and encouragement to void with her legs widely spaced

4. An 8-year-old girl presents with incontinence occurring when she laughs hard. Her physical examination, urinalysis, and remainder of her history are normal. You diagnose giggle incontinence and offer a prescription for:
   a. Amitriptyline
   b. Oxybutynin
   c. Vasopressin
   d. Methylphenidate

5. A 9-year-old boy presents with nighttime wetting. He has never been completely dry at night and wets the bed approximately three nights of the week. His father had the same problem until the age of 13 years. A review of the boy's voiding patterns shows that he is dry during the day, denies urgency, and has normal bowel movements. He is interested in becoming dry soon because he is planning to join the Boy Scouts. Your treatment recommendations include:
   a. Nothing, because he will grow out of it around 13 years of age, just like his father
   b. Oxybutynin and a bowel program
   c. Vasopressin
   d. Amitriptyline

6. A 9-year-old boy presents with nighttime wetting. He has never been completely dry at night and wets the bed approximately three nights out of the week. His father suffered from the same problem until the age of 13 years. A review of the boy's voiding patterns shows that he occasionally has episodes of mild incontinence during the day preceded by the need to void and has bowel movements every several days. He is interested in becoming dry soon because he is planning to join the Boy Scouts. Your treatment recommendations include:
   a. Nothing as he will grow out of it around 13 years of age, just like his father.
   b. Oxybutynin and a bowel program
   c. Vasopressin
   d. Amitriptyline

7. A 6-year-old girl has never been completely dry. Despite that she has no symptoms other than persistently damp underpants, her pediatrician has evaluated her for suspected UTIs. Each urine culture has demonstrated either no growth or fewer than 10,000 CFU/mL of mixed growth. She was toilet trained at 23 months of age. She voids five times during the day, with normal sensation to void before and no evidence of urgency. Her panties are always wet, day and night. She does not wake up to urinate in the middle of the night. Your initial recommendation includes:
   a. Timed voiding to make certain that she is not in overflow incontinence
   b. A renal-bladder sonogram
   c. A KUB examination
   d. Renal scan
   e. A VCUG

8. A 6-year-old girl presents with a history of five culture-proved urinary tract infections. She has never had fever with them. Instead, the cultures are obtained because of her chronic urinary incontinence. She wets most every day, generally beginning around midday and into the afternoons. Her incontinence is never preceded by a sense of urgency. She will generally stay dry throughout the night, wakes around 7 am, but doesn't void until around lunchtime. She might void once more before bedtime. Which condition is she likely to have?
   a. Paradoxical incontinence
   b. Sensory deficient bladder
   c. Detrusor overactivity
   d. Primary nocturnal enuresis

9. A 4-year-old girl presents with a history of three culture-proved febrile urinary tract infections. Her only medications include MiraLAX for chronic constipation, though she takes it rarely and complains of abdominal pain. She is frequently wet during the day, and her incontinence is preceded by urgency. Your initial recommendations include:
   a. Timed voiding and better adherence to her bowel program
   b. Oxybutynin and a bowel program
   c. Trimethoprim-sulfamethoxazole nightly
   d. Renal bladder sonogram with prevoid and postvoid views and a contrast voiding cystourethrogram, and trimethoprim-sulfamethoxazole, nightly

10. A 5-year-old girl is diagnosed with dysfunctional voiding syndrome after an evaluation for wetting, constipation, and recurrent febrile UTIs. A VCUG was negative. Your treatment recommendation includes:
    a. Timed voiding
    b. Timed voiding, bladder program
    c. Timed voiding, bladder program, anticholinergics
    d. Timed voiding, bladder program, antibiotic prophylaxis

11. Identify the incorrect statement regarding voiding abnormalities.
    a. Hinman syndrome, which is a discoordination between the detrusor contraction and sphincter relaxation, is initially managed by injecting Botox (botulinum toxin) into the sphincter.
    b. Bladder dysfunction from posterior urethral valve is not static. Whereas detrusor overactivity predominates in childhood, myogenic failure is seen in adolescence.
    c. Most infants with neurogenic bladder have complete paralysis of detrusor function.
    d. Children with cerebral palsy are incontinent only as a result of their physical limitation, because they cannot reach the toilet in time.

Applied clinical biostatistics

SHAMIR TUCHMAN

The practicing pediatric nephrologist requires a basic and usable knowledge of how to assess and interpret the medical literature as it relates to the care of children with renal disease. The use of evidence-based approaches in making treatment decisions requires a fundamental understanding of epidemiologic principles and biostatistical methods. This chapter will provide an overview of the epidemiologic and biostatistical concepts that are meant to aid the practicing pediatric nephrologist in critically evaluating the medical literature.

STUDY DESIGN

Clinical research studies can be categorized into several different categories and subcategories, depending on the design and the prospective or retrospective nature of data collection. For convenience, the two broad categories for study designs that are most applicable to nephrology research are *observational* and *interventional* studies. A summary of these different study designs and their associated features is shown in Table 53.1.

INTERVENTIONAL STUDIES

In the context of clinical nephrology, interventional studies refer to clinical trials of investigational diagnostic or treatment interventions for renal disease. Interventional studies differ from observational studies in that treatment and treatment assignments to individual study subjects are preplanned, based on either random allocation or another assignment model. Randomized, double-blind, clinical trials in which treatment allocation is random and neither study subjects nor investigators know in advance who is receiving the study intervention are often referenced as the gold standard for study design. The advantages and disadvantages of such a study design are listed in Table 53.2.

In the context of interventional studies, one subgroup of this study design merits special mention. A *crossover interventional study* is one in which study subjects both act as the controls and receive the interventional treatment at different study points. The benefit of using this approach is that it improves the efficiency of the study design because the same power may be achieved to assess the effect of the intervention with a smaller sample size and hence less cost. Furthermore, using each of the study subjects as his or her own control minimizes the variation that occurs among study subjects. This helps achieve the same level of precision for estimating the effect of a treatment using fewer subjects. The limitations of using a crossover study design include their (1) increased complexity, (2) suitability only in disease conditions that are chronic and for which treatment provides a short-term effect but not a cure, (3) increased length of time that each study subject must remain in the study, and (4) the occurrence of carryover effects of the study intervention that may continue into the control study period, biasing the results toward the null hypothesis (e.g., no effect of intervention). In these situations, a wash-out period is used before crossing subjects over from intervention to control to ensure these effects have dissipated. In some instances, interventional studies with a crossover design are prone to bias when there exists a significant interaction based on the time a subject spends in the study. In these situations, data obtained after the crossover of patients may not be usable without introducing bias into the study results and analysis.

Table 53.1 Hierarchy of study design for making causal inferences

Study design	Description	Advantages	Disadvantages
Intervention	• Clinical trials; gold-standard to test interventions • Preplanned study subject allocation	• Best for making causal inferences • Best controls for confounding	• Expensive and time-consuming • Restricted generalizability
Cohort	• Often prospective • Study population followed over time for disease development	• Able to make causal inferences because exposure precedes disease development • Study several diseases concurrently	• Expensive and time-consuming • Impractical for studying disease with long time horizon • Poor for rare diseases • Exposures may change over time
Case-control	• Often retrospective • Diseased and control subjects identified *a priori* • Exposures determined retrospectively for cases and controls	• Less expensive • Exposures studied simultaneously • Ideal for rare diseases • Requires smaller sample sizes	• Cannot demonstrate causality • Only studies one disease • Can only approximate relative risk • Prone to bias in sampling and data collection
Ecologic	• Population based association study • Data not collected at individual level • Tracks trends in disease and exposure	• Quick and inexpensive • Makes use of preexisting databases	• Poor for proving causality • Hypothesis "generating" • No individual level exposure data collected
Case report	• Report of an "interesting" patient or series of patients with unique presentations or clinical course	• Often first clue to association between exposure and disease	• No statistical method for making associations • Speculative in nature

OBSERVATIONAL STUDIES

Observational studies rely on data collection in which treatment decisions are not tied to the study itself and no intervention is made to try to modify the course of the disease. Observational studies can be further sub-categorized into ecologic, cross-sectional, case-control, and cohort studies.

Ecologic studies

Ecologic studies are observational studies in which individual-level data are lacking and thus comparisons are made at the population level. Ecologic studies often make use of generally available data sets that do not identify individuals and make associations between potential exposures and the occurrence of disease in a population

Table 53.2 Advantages and disadvantages of a randomized controlled study design

Advantages	Disadvantages
1. Ability to make causal inferences or concrete conclusions about the effectiveness of clinical interventions (e.g., medications) because of the exposure preceding the effect. 2. Limit the effects of confounding factors that can be balanced between treatment groups if known and likely will be balanced as a result of randomization if unknown. 3. Improve efficiency of the study by increasing power by ensuring sufficient numbers of subjects in treatment and control groups.	1. Expensive and time-consuming. 2. Not well suited for studying effects that take a long time to develop. 3. Difficult to use in studying treatment for rare diseases when large recruitment populations may be needed. 4. May limit the study population to certain sexes, ages, or races, which may limit the generalizability of results. 5. Ethical considerations limit the use of certain exposures or medications with adverse effects deemed too serious to offset any potential benefit to study subjects.

or subpopulation. Therefore, they are relatively poor studies for making causal associations between exposure and disease and help generate hypotheses that can later be tested using cohort, case-control, or clinical trials. Cross-sectional studies are observational studies that collect data on entire groups of people (e.g., target population) at one point in time. Cross-sectional studies are well-equipped to define the prevalence of a disease state or exposure in a particular population. Therefore, cross-sectional studies are often able to quantify the absolute risk and odds ratio of developing a disease given a particular exposure of interest in a population.

Case-control studies

Case-control studies are usually retrospective and involve identifying groups of individuals with and without disease in a population and then retrospectively determining their exposure history of interest. Case-control studies are often less expensive and quicker to conduct than cohort studies because no prospective follow-up time is needed. They are good for studying diseases that develop over a long period and allow clinicians to look at multiple exposures that may lead to the disease. They are also superior at studying rare diseases and can usually answer the research question with smaller sample sizes and thus are less expensive. The disadvantages of case-control studies are that (1) they cannot determine causality because they do not relate the time sequence of exposure to disease, (2) they can investigate only one disease at a time, and (3) because there is no time lapse in the study, they often have difficulty in providing accurate estimates of relative risk.

Case-control studies are prone to bias in both sampling of the populations and ascertainment of exposure data. In addition, the method by which controls are selected for case-control studies may introduce a source of bias into the results. Ideally, controls (1) should be free of disease at the time of selection and ideally not have had the disease under study in the past, (2) should be drawn from the same population in which cases occur, and (3) should have the same baseline potential of developing disease as the cases. As an example, a case-control study of a disease that disproportionally occurs in women should draw its controls from a population that has the same gender distribution as that from which cases are sampled. Not to do so would introduce bias into the results.

On the other end of the spectrum, it is also possible to select controls that are too similar to cases in some unmeasured risk factor for disease occurrence. When this occurs, controls are said to be *over-matched*. As an example, in an effort to match for environmental exposures, using siblings of cases of disease as controls when the disease in question has a potential genetic predisposition may introduce bias into the results. A special type of case-control study is known as a *nested* case-control study. This is essentially a case-control study conducted in a population under investigation as a cohort study. A disease of interest is identified and exposure data already collected as part of the cohort study analyzed for its association with the disease.

Cohort studies

In cohort studies, subjects are followed over time for the occurrence of disease, with exposure data of interest often collected prospectively to determine its ultimate association with a disease. In the most basic example, two study populations are selected that differ in one or more particular exposure or risk factor from each other. Each study group is followed over time for the development of the disease of interest. In this way, the incidence of disease can be ascertained for each group and the associated risk of each exposure variable quantified. In large populations a representative but random sample of study subjects is used because of feasibility and cost considerations. All study subjects are free of the disease of interest on entering into a prospective cohort study.

One of the advantages of a cohort study is that there is a clear occurrence of relevant exposures before disease occurrence, which is essential in determining causality. Also, cohort studies, if of sufficient size and comprehensive in data collection, can determine relevant risk factors in the occurrence of multiple diseases. Cohort studies have limitations in that (1) they are not ideal for studying rare diseases or those that have a long time horizon for development, (2) they are prone to changes in exposures if the studies are long, (3) study subjects may diverge from their typical behavior or exposure pattern by simply knowing these are being monitored in the study, and (4) withdrawals from the study may bias the results if it is directly related to disease occurrence or exposures. Although many cohort studies are prospective, *retrospective* cohort studies may trace exposures predating study entry by participants and thereby ultimately save time and resources in coming to definitive conclusions. This can be done assuming the retrospective data are collected in their entirety.

Meta-analysis

The challenge for a diligent practitioner is to synthesize, compare, and contrast the totality of differing types of studies when examining the association between a risk factor and outcome and coming to a conclusion regarding the nature of an association or lack thereof. In doing so, the practitioner must take into account the size, quality, and design of each study. Traditionally, this has been done using a qualitative or *ad hoc* approach. However, there are quantitative methodologies used to combine the results of several similar but not necessarily identical studies examining the association between an exposure and disease. This type of study design is known as a meta-analysis.

Meta-analysis has two general goals. The first is to assess the consistency of the exposure-outcome association across different studies. The second is to attempt to generate a composite estimate of this association combining

the results of different studies. This improves the power to detect a significant association because it increases the sample size by combining studies. As a result, the confidence interval for an exposure-outcome association narrows, giving a more precise estimate of the association. This can be done by pooling study estimates or in certain cases pooling the raw data to generate a new estimate with a larger sample size. This process is fraught with potential pitfalls, not the least of which is forcing data together from studies that may have had different designs, definitions of the exposure and outcome, and divergent populations studied. This introduces bias into the meta-analysis and must be taken into account.

Before a meta-analysis can be properly conducted, a systematic review of the literature is required. This is a protocolized critical review of all the literature existing on a specified exposure and outcome association. This may include formal journal publications, conference proceedings, and published reviews on a designated topic often identified through journal database searches. The systematic review evaluates each study for its power, design, sources of bias, and generalizability of results in establishing the quality of the study. This is taken into account when deciding which studies to include in the meta-analysis and further taken into account (especially the size of the study population) in the actual meta-analysis when determining a summary estimate of the size and direction of an association.

Focusing on the quality of study to be included in a meta-analysis is inescapable and a central factor in deciding which studies are to be included. Assessing the quality of a study in terms of how it answers the hypothesis of the meta-analysis is also known as the *internal validity*. In this regard, studies are assessed based on (1) their design, with those with interventions (e.g., randomized clinical trials) being generally most desirable; (2) analytic approach ensuring that the authors appropriately controlled for confounding aspects and tested for interactions among risk factors; and (3) how the study was conducted in terms of issues such as selection of controls and incomplete data collection or follow-up (quality of data). Finally, studies also may be judged for their inclusion based on the generalizability of the results and application to different populations or settings. This concept is also often referred to as the *external validity*. In determining a summary estimate of an association between an exposure and disease, estimates of the association between exposure and outcome from separate studies in a meta-analysis must be pooled. If patient-level data are available, the raw data may be combined to give a single pooled estimate. Typically, this is not the case and study investigators must use methods in which a weight score is assigned to each study included. In combining these studies into one pooled estimate (e.g., relative risk), study investigators may use weights based on both the size of a study population and quality of the study design and conduct. Weighting based on study size is relatively straightforward. However, placing a quantitative estimate on study quality is much more complex. Furthermore, it is rare for any two individual studies to be exactly alike. Therefore, a meta-analytical approach also must account for the heterogeneity among the studies included. Finally, an important overarching limitation in the use of meta-analysis is publication bias. This may result from studies that were not submitted or were not accepted for publication because of an absence of a statistically significant association between an exposure and disease, as a result of small sample size, or because an association was revealed that was the opposite of what was expected. In general, publication bias will tend to bias the pooled estimate away from the null. The degree and importance of this bias on the overall results depend on several factors. The first is the size of pooled risk estimate from the meta-analysis. As an example, a relative risk that has a narrow confidence interval based on studies included with large sample sizes is unlikely to be affected significantly by unpublished studies that had relatively small sample sizes even if the risk estimates in these studies were opposite to those derived from the meta-analysis. Also, a meta-analysis that shows a strong association (e.g., high relative risk) between exposure and outcome is unlikely to be affected to the point of nonsignificance by unpublished studies documenting an opposite relationship or no relationship (e.g., negative studies). Finally, if only studies that did not show a statistically significant association are excluded from publication, but studies showing an opposite or protective effect of exposure are published and included in the meta-analysis, then the overall pooled estimate of effect is unlikely to change significantly by the inclusion of non–statistically significant results.

One tool by which study investigators can try to estimate the potential for publication bias is the *funnel plot*. A funnel plot is a graph of the log of the effect estimate (e.g., odds ratio or relative risk) on the *y*-axis against the inverse of the standard error (e.g., sample size estimate) on the *x*-axis. Funnel plots that are symmetric with points on either side of the zero association on the *y*-axis as well as points close to the zero line are usually interpreted as having minimal associated publication bias.

BIAS

Bias represents uncontrolled and unmeasured features of data that may result in changes in study results or its conclusions. Bias affects the internal validity of a study and may lead to incorrect conclusions about the nature, size, and degree of relationship between an exposure and disease. Bias may occur as a consequence of a systematic error in the study design, the way in which data were collected, or how the data were analyzed. There are several different categories of bias based on the specifics of the study design and conduct. A summary of these categories and associated types of bias is shown Table 53.3.

Selection bias occurs when subjects who volunteer or are selected to participate in a study are in some way different in

Table 53.3 Types of bias in study design and execution

Type of bias	Description
Selection	• Selected or volunteer subjects differ in characteristics that may be associated with disease from the general or control population • Most commonly affects case-control or retrospective cohort studies • Dealt with effectively when randomization is used, such as in randomized controlled trials
Information	
Recall bias	• Subjects recall exposure histories more clearly should they have the outcome or disease under study
Reporting bias	• Subjects may be hesitant to report events or exposures that are personally embarrassing or may affect their standing in the study
Observer bias	• Study staff charged with documenting observations or examination findings do so with preconceived notions of what those results should reveal
Follow-up bias	• Study subjects who drop out of a study may have inherent differences in comparison to the general populations under study
Hawthorne effect	• In prospective studies, patients under surveillance for the occurrence of disease or exposure of interest modify their behavior because of participation in the study
Surveillance (detection) bias	• Investigators following subjects prospectively for the occurrence of disease may follow those with a suspected risk factor more closely and/or for a longer period
Misclassification	
Random	• Inaccuracy in measurement is thought to have occurred to an equal degree in all study groups
Differential	• Errors in measurement or classification of disease occur preferentially in one or more study groups • Blinding of study subjects, investigators, or both when possible can mitigate misclassification bias

characteristics from the general population at risk for a the disease. This occurs particularly if these differences, which are often unmeasured, are associated with the occurrence of the disease under study. Selection bias is of particular concern in case-control and retrospective cohort studies. Selection bias does not typically occur in randomized controlled trials, in which randomization prevents systematic errors in selection, or in prospective cohort studies, in which the study population is chosen without regard to prior exposure history.

Information bias occurs when data gathering in a study is done incorrectly or inconsistently and affects the conclusions rendered. Examples of information bias include interviewer bias in which the person collecting the data from study subjects may influence the responses given or the structure of interview. Recall bias is a related phenomenon in which study subjects may recall exposure histories more clearly should they have the outcome or disease under study. Contrary to this, study subjects may be hesitant to report events or exposures that are personally embarrassing or that may affect their standing in the study. This is known as reporting bias. Observer bias may occur when study staff, charged with documenting observations or clinical findings, proceed with preconceived notions of what those results should look like.

Dealing with missing or incomplete observations also can be a significant challenge in collecting data. The way in which study subjects or patients may drop out of a study may be grounded in inherent differences among populations under study. Should this be the case, this would introduce follow-up bias to the study results. In prospective studies, patients under surveillance for the occurrence of disease or exposure of interest may modify their behavior, simply by the mere fact that they are being followed by study investigators. If this modification in their behavior introduces changes in the occurrence of disease or degree of exposure, this may bias study conclusions. This is known as the *Hawthorne effect*. Finally, study investigators following subjects prospectively for the occurrence of disease may follow those with a suspected risk factor more closely or for a longer time, potentially increasing the chances of detection. This is known as surveillance or detection bias.

Misclassification bias

In addition to sources of bias associated with gathering information in a study, bias may stem from the manner in which data are subsequently analyzed. One example of this concept is misclassification bias, wherein exposure or disease classification is flawed because of either inaccurate

measurement of exposure or diagnosis of disease. If the inaccuracy in measurement is thought to have occurred to an equal degree in all study groups, this is known as *random misclassification*. In this situation, the error in measurement may not necessarily adversely affect the study conclusions, because it has occurred to an equal degree among all participants. However, if errors in measurement or classification of disease occur preferentially in one or more study groups, this represents *differential misclassification* and may indeed distort study results toward a greater or lesser association between exposure and disease. Use of blinding of the study participants, investigators, or both can help mitigate differential misclassification.

BIOSTATISTICAL METHODS

In clinical research, in addition to the method in which a study was designed and conducted, the methodology and assumptions made in data analysis can have an impact on the ultimate conclusions of a study. The following section will present and discuss methods of data analysis commonly employed in epidemiologic studies, including regression analysis, assessment of risk, survival analysis, and receiver operating characteristic (ROC) curves. In addition, potential pitfalls associated with data analysis will be discussed.

REGRESSION ANALYSIS

Linear regression analysis

In its most basic form, a regression line represents a best fit line drawn through multiple data points that minimizes the sum of the squared distance (d_i) between all the sample points and the line (Figure 53.1). For a scatter plot of
Figure 53.1 Fitted regression line for scatter plot of *y* over *x*. α– *y*: intercept where fitted regression line contacts the *y*-axis. Value of *y* when *x* = 0. β: *slope of the fitted regression line; di: distance from each data point to fitted regression line.*

data associating a dependent (outcome) variable *y* with an independent variable *x*, the regression line is defined by the equation:

$$y = \alpha + \beta x \qquad (53.1)$$

In this example, α represents the value of *y* where the independent variable is 0 (e.g., the line contacts the *y*-axis). β represents the slope of this line and is positive when there is a positive relationship between *x* and *y,* and β takes on a negative value when there is an inverse relationship between *x* and *y.* β is 0 when there is no relationship between the independent and dependent variables.

Multivariate linear regression extends this methodology to include the relationship between one dependent variable and multiple independent variables. Multivariate linear regression serves to explain the variability in values of the *y* variable based on its relationship to multiple dependent variables *(x1, x2, …. xi).* In this way, we are able to determine the independent effect of a variable *xi* in relation to other variables that affect *y.* In essence, multivariate linear regression isolates the effect of each independent variable on *y,* holding the other independent variables constant. Multivariate linear regression is expressed by the equation:

$$y = \alpha + \beta_1(x_1) + \beta_2(x_2) + \beta_3(x_3) + \cdots + \beta_i(x_i). \quad (53.2)$$

In Equation 53.2, β represents the unique relationship of each independent variable with the dependent or outcome variable. As an example, in examining the factors (independent variables) that affect systolic blood pressure in children, one may hypothesize that body mass index (BMI), the daily sodium content in milligrams of their diet, a family history of hypertension, the amount of daily aerobic exercise, age, and gender may affect the ultimate systolic blood pressures. In this case, the regression equation would be written as:

Systolic blood pressure (mm Hg) = $\alpha + \beta_1$ (BMI) + β_2 (daily sodium intake in milligrams) + β_3 (family history of hypertension) + β_4 (amount of daily aerobic exercise in minutes) + β_5 (age in years) + β_6 (male or female)

$$(53.3)$$

In this hypothetical regression, one would expect the β-coefficients, $\beta_1, \beta_2, \beta_3, \beta_5,$ and β_6 to take on positive values as children with higher BMI, higher daily sodium intake, having a family history of hypertension, are older, and are male are likely to have a higher systolic blood pressure. Conversely, β_4 is likely to take on a negative value because children who get more exercise may have lower systolic blood pressure (e.g., inverse relationship). Each β-coefficient in a regression is associated with a *P* value, which tells the reader whether that particular independent variable is significantly associated with the outcome variable adjusted for all the other independent variables in the regression. A *P* value less than 0.05 gives some sense of the strength of the relationship between the dependent and independent variable. For example, a *P* value of 0.001

is more significant than a *P* value of 0.01, but both have a significant representation because of being less than 0.05.

Logistic regression analysis

Multivariate logistic regression follows the same principles as multivariate linear regression, the only difference is that the outcome variable is coded as a categorical (e.g., yes/no) variable. As in linear regression, independent variables can be either linear or categorical.

CONFOUNDING AND INTERACTION

A confounding variable is significantly associated with both the exposure and disease, but does not occur as a result of either. In this way, a confounding variable is able to partially or wholly explain the relationship between an exposure risk factor and disease occurrence. Therefore, the independent effect of the exposure as a risk factor for disease occurrence is lessened or sometimes negated, if the confounding variable is taken into consideration. Confounders are often intermediates in the pathway from a risk variable to the occurrence of disease. As an example, adolescent age is a risk factor for increased car accidents. However, adolescents are also more likely to text while driving, which increases the chances of a collision. Therefore, cell phone texting during driving confounds the relationship between the adolescent age group and traffic accidents.

Conversely, an interaction variable is one that modifies the relationship between exposure and disease, without explaining why the relationship exists. Unlike confounders, interaction variables are not on the pathophysiologic pathway between exposure and disease. As an example, smoking has a strong causal association with the development of lung cancer. In males, this association may be stronger than in females for the same number of cigarette pack-years smoked. Therefore, gender serves as an interaction variable for the relationship between smoking and lung cancer.

RISK ASSESSMENT

At its most basic level, relative risk compares the risk for developing disease between a group of people with and without a potential exposure. Risk is determined by the probability of developing disease, given the presence or absence of a risk factor. It is estimated by using the incidence of disease development in a group having the risk factor or exposure of interest. In Table 53.4, a 2×2 table in which disease and exposure status are known for a population, relative risk is calculated as the incidence of disease occurrence among those exposed: $a/(a + b)$ divided by the incidence of disease among those without the exposure: $c/(c + d)$.

$$\text{Relative risk (RR)} = [a/(a + b)]/[c/(c + d)] \quad (35.4)$$

A relative risk that equals 1 suggests that there is no effect of the risk factor of interest on disease. Risk factors with

Table 53.4 2×2 table of exposure and disease status in a case-control study

Exposure	Disease status		Total
	Disease	No disease	
Exposed	a	b	a + b
Unexposed	c	d	c + d
Total	a + c	b + d	n

relative risk values greater than 1 suggest increased risk for disease development, and those between 0 and 1 suggest protection against disease occurrence.

A separate but related measure to relative risk is the odds ratio. Unlike relative risk, which expresses the probability of developing disease given the presence or absence of a risk factor, the odds ratio estimates the number of those with disease divided by those without disease for each exposure group. Looking at Table 53.4, this calculates to a/b for those with exposure and c/d for those without the exposure. The odds ratio then becomes a/b divided by c/d.

$$\text{Odds ratio (OR)} = (a/b)/(c/d) = ad/bc \quad (53.5)$$

In case-control studies, relative risk is difficult to ascertain and the odds ratio is the only measure that can be calculated. The odds ratio often can be a good approximation of the relative risk, assuming that the disease under study is rare. In this situation, $(a + b)$ is approximately equal to b and $(c + d)$ is approximately equal to d so that the equation for relative risk looks identical to that for the odds ratio.

SURVIVAL ANALYSIS

In cohort studies or clinical trials, researchers want to get a sense of the occurrence of an outcome (e.g., death or disease) as a function of time in the study. To do this, an approach that estimates the probability of survival for two or more groups that differ in a particular exposure or intervention are compared. In its simplest form, this constitutes a life table that tracks the proportion of people still surviving (or disease free) at consecutive time points through the length of the study. In survival analysis, study subjects are censored when the event of interest occurs (e.g., death or disease). From that point onward, those subjects are not used in calculating the probability of survival at further time points in the cohort. The estimated cumulative survival probabilities at each time point in the study can be then plotted on the *y*-axis against time on the *x*-axis to give a survivor function or plot. As an example, Figure 53.2 shows a life-table survival plot of the cumulative survival probability of disease occurrence for a cohort followed for 10 years. Each study subject is screened for the occurrence of disease at yearly intervals. For the sake of simplicity, assume 100% retention in the study so that no study subjects get censored out of the study unless they develop the disease of interest and no
Figure 53.2 Survival plot of disease occurrence over time using life table and Kaplan-Meier methodologies. y-axis, probability of disease occurrence; x-axis, follow-up time in years; _____, life table methodology survival plot; ...., Kaplan-Meier methodology survival plot.

subjects die during the study period. At each time point, a progressively smaller proportion of the study population is free of disease. Because subjects are evaluated only on a yearly basis for disease, the probability of being free of disease at intermediate time points is assumed to be the same as the probability during the last year of evaluation. As can be seen in Figure 53.2, the theoretical disease in question will affect almost all individuals at the end of 10 years of follow-up. Actually, this is rarely the situation. In addition, many study subjects may be censored out of a cohort study for reasons other than the development of the end point of interest. Dealing with these individuals often means making the assumption that they left the study at the mid-point of each time interval. This method for dealing with those who left the study for reasons other than disease occurrence is valid only if censoring occurs uniformly through each study interval and the risk for disease (or death) at any time is uniform throughout the whole study period. Using this step-wise approach to survival analysis often leads to over-estimation of survival probabilities at a time point between study intervals. Progressively shortening the time intervals in which the population is assessed for the outcome may help mitigate some of these limitations. A method of doing just this is exemplified by the Kaplan-Meier approach to survival analysis. In the Kaplan-Meier approach, study time intervals are defined based on the time point at which a subject develops disease. This leads to a survival plot with the most possible time intervals of the shortest duration and helps minimize the problems with how to deal with the data from study withdrawals. The Kaplan-Meier approach maximizes the data that can be used to construct the survival plot. As shown in Figure 53.2, the time intervals between end points vary depending on disease occurrence and are shorter. As a result, the survival probability plot takes on a more linear appearance. This increases the power for

detecting differences in two survival plots in a population separated by an exposure of interest. Several methodologies are used to compare survival plots between two study populations. These include the Mantel-Haenszel methods, the log-rank test, and the weighted log-rank tests. Implicit in these methods is the assumption that the probability of a study outcome (e.g., events) remains constant within the time interval between events. This is known as the proportional hazards assumption.

RECEIVER OPERATING CHARACTERISTIC CURVES AND TEST STATISTICS

Assessing the value of clinical and laboratory variables is germane to arriving at a diagnoses in patients. Therefore, understanding the ability of a clinical or laboratory test to either confirm or rule out a diagnosis is very important for practitioners. Epidemiologic assessments help evaluate the reliability and usefulness of tests used to diagnose disease. In a population of patients known to have or not have a disease of interest, each is administered a diagnostic test to detect disease. In this situation, there are four potential outcomes. The test can correctly identify patients with the disease of interest, or true positives (TPs); the test can correctly rule out the presence of disease in those who are disease free, or true negatives (TNs). The test can be positive in those who really do not have disease, or false positive (FP), and the test can incorrectly clear patients of disease when they indeed have it, or false negative (FN). A simple 2×2 table, as shown in Table 53.5, is able to neatly express each of the scenarios. From these four outcomes, we are able to calculate the performance characteristics of each test. The first is the ability of a test to correctly identify persons with disease when they have it. This probability is known as sensitivity and is calculated as $a/(a + c)$.

$$\text{Sensitivity} = \text{TP}/(\text{TP} + \text{FN}) = a/(a + c) \quad (53.6)$$

Conversely, the probability of a test to be negative when a patient does not have disease is known as the specificity and is calculated as $b/(b + d)$.

$$\text{Specificity} = \text{TN}/(\text{TN} + \text{FP}) = d/(b + d) \quad (53.7)$$

At times, what practitioners really wish to know is the likelihood that a patient has a disease if the ordered test comes

Table 53.5 2×2 table of exposure and disease status in a case-control study

Test result	Disease status		Total
	Disease	No disease	
Positive	True positive (TP) a	False positive (FP) b	a + b
Negative	False negative (FN) c	True negative (TN) d	c + d
Total	a + c	b + d	n

back positive or, alternatively, can be reassured that he or she does not have the disease if a test comes back negative. These test statistics are known as the positive predictive value and negative predictive value, respectively. They are expressed by the equations $a/(a + b)$ and $d/(c + d)$ respectively.

$$\text{Positive predictive value (PPV)} = \text{TP}/(\text{TP} + \text{FP}) = a/(a + b) \tag{53.8}$$

$$\text{Negative predictive value (NPV)} = \text{TN}/(\text{TN} + \text{FN}) = d/(c + d) \tag{53.9}$$

In evaluating the usefulness of a new diagnostic test in a population, these test metrics are often compared to the performance of a known and well-used test already in clinical use. Both positive and negative predictive values are affected by the prevalence of a disease state in the population, even though the sensitivity and specificity of a test will not change. If we try to compare the performance of several tests at once, one metric that may be used is the likelihood ratio. The likelihood ratio is calculated as the sensitivity of a test divided by (1 – specificity). An increase in sensitivity or specificity may increase the likelihood ratio of a test. A useful plot that compares the performance of two or more diagnostic tests for disease is called the ROC plot.

An example of such a plot is shown in Figure 53.3. Consider three different diagnostic tests *a*, *b*, and *c* for a disease *y*. Test *c* has a sensitivity and specificity that when added together always equal 1. Therefore, when the sensitivity is 100%, the specificity is 0% and vice versa. Such a test has no discriminative value in diagnosing disease. Tests *a* and *b*, respectively, have proportionally higher sensitivities for a given specificity. Depending on the goals of the test (e.g., ruling in or ruling out disease), one may think test *a* or *b* may outperform the other. However, combining the two tests together as a composite may give the ideal diagnostic test for the disease *y*. A theoretically perfect diagnostic test

x would have 100% sensitivity or specificity at all times. A composite measure of how well a test performs can be estimated by the area under the ROC curve (AUC). Tests with a larger AUC that approaches the AUC of a perfect test tend to be better. Therefore, the AUC offers a convenient way of comparing two or more diagnostic tests.

SUMMARY

Modern research publications require an increasingly greater understanding of many principles of epidemiology and biostatistics. The practicing pediatric nephrologist should be well versed in many of these concepts to properly interpret both the relevance and quality of studies as applicable to their own patients. This chapter has introduced some of the basic concepts of study design, limitations, and analytical approaches used in epidemiology.

REVIEW QUESTIONS

1. You conducted a hypothetical observational study examining the clinical factors associated with the decline in estimated glomerular filtration rate (eGFR) in children with hypothetical inherited glomerulonephritis. The primary outcome of the study was the absolute change in eGFR after 1 year of observation. Hypothetically speaking, no patients were treated with any antiprogression medications during the study period. At the end of the study period, you analyze the data and produce a multilinear regression model of the outcome variable (absolute change in eGFR) and the potential significant covariates that you first tested using univariate models. The regression output is shown below. Please discuss the results of the regression in terms of the association and direction of effect of each covariate. For the sake of simplicity, assume that there were no significant interactions in this regression
Figure 53.3 Receiver operating characteristic plot comparing tests **(a)** and **(b)**. AUC, area under the curve; Test *x*, theoretically perfect discriminatory test; Test *c*, test without discriminatory ability.

model. All covariates were measured only once at the entry into the study. Gender was coded as 1 for male and 2 for female. U p/c is the urine protein-to-creatinine ratio on a first morning specimen.

Covariate	β-Coefficient	P Value	95% Confidence interval	
Age (yr)	6.625	0.024	0.762,	14.012
Gender	–6.761	0.003	–8.682,	–4.839
Systolic BP	2.322	0.041	0.157,	4.487
Diastolic BP	5.208	0.109	–1.638,	12.054
U p/c	8.312	0.0001	7.926,	8.698
Constant(α)	3.224	0.000	1.471,	4.977

Answer:
This regression analysis reveals that age, gender, systolic blood pressure, and a first morning urine protein-to-creatinine ratio are all significant determinants of the change (e.g., decline) in eGFR. Based on a nonsignificant *P* value, diastolic blood pressure was not found to be a determinant of change in eGFR in the multivariate models despite being significant in univariate analyses. There may be two potential reasons for this. The first is that diastolic blood pressure is intimately related to systolic blood pressure. Because they often run together (e.g., co-linear), placing both in the model may make one insignificant when adjusted for the other. The additional possibility is that there was not sufficient *power* in the study to detect a significant effect of diastolic blood pressure on eGFR. Although not provided, if there were insufficient numbers of patients in the study to perform a regression with five covariates, the diastolic blood pressure may have been affected by this. In looking at the remaining determinants, age, systolic blood pressure, and the first morning urine protein-to-creatinine ratio, all had positive and statistically significant β-coefficients in the regression. These data suggest that there is a direct relationship with these variables and eGFR in that older children with higher systolic blood pressures and higher urine protein-to-creatinine ratios had a higher absolute change in the eGFR over the year of the study. Conversely, gender had a negative association with eGFR, implying that females have a lesser change in eGFR (e.g., protective effect). Furthermore, looking at the *P* values and confidence intervals associated with the regression show that the strength of the association is strongest between the first morning urine protein-to-creatinine ratio and the eGFR. This can be inferred because of the narrow confidence interval and very low associated *P* values.

2. Given the results of the multivariate regression in Question 1, write the regression equation associated with this study.

Answer:
The variability in eGFR = 3.224 + 6.625*(age) + (–6.761)*(gender) + 2.322*(systolic BP) + 5.208*(diastolic BP) + 8.312*(U p/c)

3. You wish to evaluate two different diagnostic laboratory tests in terms of their ability to reliably identify disease in your population of patients. In attempting to do so, you administer the two diagnostic tests (a) and (b) to a study population of 100 subjects in which the presence or absence of disease has been confirmed using a gold-standard methodology. After performing both tests in your population, you are able to construct the following 2 × 2 tables.

Test (a):

Test (a) results	Disease status		
	Present	Absent	Total
Positive	22	7	29
Negative	3	68	71
	25	75	100

Test (b):

Test (b) Results	Disease Status		
	Present	Absent	Total
*Positive	18	2	20
Negative	7	73	80
	25	75	100

Calculate the sensitivity, specificity, positive predictive values, and negative predictive values for each test.

Test (a):
Sensitivity = TP/(TP + FN) = 22/22 + 3 = 0.88 × 100 = 88%

Specificity = TN/(TN + FP) = 68/68 + 7 = 0.91 × 100 = 91%

Positive predictive value (PPV) = TP/(TP + FP) = 22/22 + 7 = 0.76 × 100 = 76%

Negative predictive value (NPV) = TN/(TN + FN) = 68/68 + 3 = 0.96 × 100 = 96%

Test (b):

Sensitivity = TP/(TP + FN) = 18/18 + 7 = 0.72 × 100 = 72%
Specificity = TN/(TN + FP) = 73/73 + 2 = 0.97 × 100 = 97%

Positive predictive value (PPV) = TP/(TP + FP) = 18/18 + 2 = 0.90 × 100 = 90%

Negative predictive value (NPV) = TN/(TN + FN) = 73/73 + 7 = 0.91 × 100 = 91%

4. Compare the two diagnostic tests in question 3 in terms of their performance at both ruling in and ruling out disease in the population.

Answer:
One way to compare the performance of these two tests in this population is to calculate the likelihood ratios for each test.

For test (a): Likelihood ratio (a) = sensitivity/(1-specificity) = 0.88/(1 – 0.91) = 9.8
For test (b): Likelihood ratio (a) = sensitivity/(1-specificity) = 0.72/(1 – 0.97) = 24

In this scenario, test (b) has a higher likelihood ratio mostly because of its high specificity. However, the choice of which test is most favorable in this example hinges primarily on the characteristics of the disease under study. Should the disease in this example be serious and potentially fatal if undetected and/or curable on detection, test (a) may be preferable because of its higher sensitivity. This is due to the lower rate of false-negative results associated with test (a). A false-negative result in this scenario would have serious consequences for the health of this population because of disease severity. However, in a situation in which a disease is relatively mild and not associated with significant morbidity and mortality and/or further testing associated with a positive test result is both expensive and associated with its own risks, then test (b) may be preferable. This is because of its lower rate of false-positive test results (e.g., higher specificity).

5. You have conducted a case-control study examining whether maternal exposure to drug x during pregnancy is associated with the development of hypertension in children younger than 10 years of age. In performing this study, you retrospectively collect data on a group of children diagnosed with hypertension with age- and gender-matched controls sampled from the same general population. You retrospectively collect exposure data from the mothers of these children to drug x during pregnancy. From your data, you are able to construct the following 2 × 2 table:

Exposure history	Hypertension status		
	Hypertensive	Normotensive	Total
Exposed	20	25	45
Unexposed	5	50	55
	25	75	100

Calculate the odds of developing hypertension with exposure relative to not being exposed. How does this metric relate to the calculation of a relative risk?

Answer:
This question is asking for a calculation of the odds ratio from this case-control study. The odds ratio (OR) is calculated from the number of those with disease divided by those without disease for each exposure group. In this question this becomes:

$$OR = ad/bc = 20 \times 50/5 \times 25 = 1000/125 = 8.$$

In the situation in which a case-control study is examining a relatively rare disease, the odds ratio can be a good approximation of the relative risk. However, in this scenario in which hypertension is hypothetically present in 25% of the population, the relative risk for disease associated with exposure x is difficult to estimate.
