Contents

Preface

This third edition of *Clinical Pediatric Nephrology* continues to have as its main goal providing a primer of pediatric nephrology. Its intended audience includes committed medical students and general trainees, as well as pediatric nephrology fellows and pediatric nephrologists. Our focus remains on the clinical diagnosis and management of pediatric renal disorders.

The book has been thoroughly updated, and each chapter has been rewritten. The number of chapters has expanded from 37 to 53. In part, this represents a degree of specialization, with several chapters divided to focus on specific disorders as their pathogenesis has been clarified. The organization of the book has also been changed with an additional emphasis on the physiology of kidney diseases. Sections now cover kidney anatomy and development, diagnostic evaluation, disorders of homeostasis, glomerular and tubular diseases, systemic diseases and the kidney, acute and chronic kidney disease, renal replacement therapies, hypertension, inherited disorders, urologic disorders, and research tools. We believe that this reorganization and the expansion in the number of chapters better reflects the status of pediatric nephrology today. Each chapter includes "Key Points" boxes to emphasize issues that the authors and editors believe are important take-aways in the section, a set of review questions for the reader, and where appropriate a clinical vignette describing how the information in the chapter could be clinically applied in real life.

An important change has been an evolution in the editorship. Dr. Larry Greenbaum has joined the editorial team. He brings immense experience as an academic nephrologist, clinician and a researcher to the editorial team. His role in shaping the content of the third edition is evident in all sections of the book. We also wish to express our sincerest gratitude and thanks to Dr. Sudesh Makker, who guided the editorial work in the first two editions of this book.

We wish to thank all the contributors who worked diligently with us, under tight time-lines, through several revisions of their texts, and who willingly provided elements for the chapters that are unique to this publication. The outstanding editorial, production, and marketing teams at Taylor and Francis have provided support that has been essential to our reaching fruition. We are especially grateful to Our sincerest thanks to Henry Spilberg, who has managed the publication of the second edition and guided us in the concept design of the third edition of this book at Taylor and Francis. Miranda Bromage, who has taken over the reigns, has been an inspiration to work with. She provided her extraordinary skills in guiding the production of the book. Henry and Miranda were instrumental in advocating for an "all-color" book, which has enhanced its content and visual appeal. We thank both of them from the bottom of our hearts. Amy Blalock and Linda Van Pelt provided their superb expertise in copy editing and composing the galleys. Kyle Meyer, at the Boca Raton office of CRC Press-Taylor and Francis worked patiently with us in the editing of galleys of all chapters. Without his help, publication of this book would not have materialized. Figures in this edition were drawn by a very talented pool of artists. They are the unsung heroes of this work. We wish to thank each one of them for their contributions.

We owe a major debt of gratitude to two groups. Our students, residents, nephrology fellows and colleagues have provided inspiration and frequently challenged us on communication of scientific and educational content, as well as the format of this work. Most importantly, our families, who tolerate our busy and often distracting schedules have provided consistent support and a sense of perspective as we undertook this task. They provide an essential foundation for our lives. It is only with their individual commitments that we have succeeded in completing this task. We owe our heartfelt gratitude and appreciation to each one of them.

PART A

Kidney anatomy and development

Anatomy and embryology of the urinary tract

KURT E. JOHNSON

Kidneys serve as an important metabolic organ that eliminates nitrogenous waste products, maintains fluid and electrolyte balance, and performs important hormonal functions, such as synthesis of 1-25-dihydroxy vitamin D and erythropoietin. Being paired organs, kidneys have also been used in living organ donation for renal replacement therapy in patients with end-stage renal disease (ESRD). Developmental aspects of kidney have received considerable attention recently and much has now been deciphered about the control of renal and ureteric development. It is also becoming increasingly clear that nephron endowment at birth is an important fetal factor that may determine the development of hypertension and chronic kidney disease (CKD) in adults. This chapter discusses the clinically relevant anatomy and embryogenesis of the kidneys and the urinary tract.

GROSS STRUCTURE AND RELATIONS

In adults, each kidney is reddish-brown, approximately 11 cm long, 5 cm wide, and 3 cm thick, and weighs approximately 130 g. By renal ultrasound measurement, renal length in healthy newborns has been reported to be 4.21 ± 0.45 cm for the right kidney and 4.32 ± 0.46 cm for the left kidney.[1] Kidneys grow with age and achieve adult length by approximately 18 years of age.[2,3] Interestingly, renal length is greater in obese children, possibly reflecting hypertrophy resulting from hyperfiltration.[4] Both kidneys are more or less similar in shape, with a convex lateral surface and a deep recess at the hilum of the kidney on the medial surface that is called the renal sinus. The renal artery and vein

and some adipose tissue occupy the renal sinus, along with a funnel-shaped expansion of the ureter known as the renal pelvis. Within the kidney, the renal pelvis is divided into two elongated major calyces and several shorter branches called the minor calyces.

> ### KEY POINT
>
> Newborn kidneys are approximately 4.5 cm long as measured by ultrasound.

The two kidneys lie on the posterior abdominal wall along either side of the vertebral column in the retroperitoneal space, but at slightly different levels. The left kidney has its superior pole at approximately the level of the middle of T11 vertebral body and its inferior pole at approximately the level of the bottom of L2. In contrast, the right kidney lies slightly lower, with its superior pole at the top of T12 and its inferior pole at the top of L3. The superior poles of each kidney are in contact with the diaphragm, and their posterior surfaces are covered by skeletal muscles (from medial to lateral): psoas major, quadratus lumborum, and transversus abdominis.

In a longitudinally cut section, the kidney has a darker cortex, whereas the inner medulla is lighter in color. Each kidney has a collection of triangular renal pyramids, or lobes, with a base bordering the cortex and an apex projecting as renal papillae into the minor calyces (Figure 1.1). Each renal pyramid consists of medullary tissue associated with the corresponding cap of cortical tissue. The distinction
Figure 1.1 Cut surface of normal kidney of a child with anatomic landmarks shown. (Photograph provided by Ronald Przygodzki, MD.)

between cortex and medulla in the kidneys is made difficult by the projection of medullary tissue into the cortex as medullary rays and by the cortical tissue bundled between the renal pyramids, known as the renal columns of Bertin.

The ureters are 25 cm long in an adult but are of variable length in children. The ureter has a thick, fibromuscular wall and a small lumen. Along its descent from the abdominal cavity (upper half) into the lesser pelvis (lower half), the ureter is located retroperitoneally and is closely adherent to the overlying peritoneal lining. Ureters enter the urinary bladder posteriorly. The urinary bladder is a hollow muscular organ located posterior to the symphysis pubis, and its superior surface is covered by a reflection of the peritoneal lining. It is innervated by nerves from the vesical plexus, which has fibers from two distinct sources: (1) sympathetic lumbar nerves through the hypogastric plexus and (2) parasympathetic pelvic splanchnic nerves.

MICROSCOPIC ANATOMY

The renal parenchyma consists of functional units called uriniferous tubules, each with two distinct components: (1) the nephron and (2) the collecting tubules. The nephron consists of the Bowman capsule, proximal convoluted tubules (PCTs), loop of Henle, and distal convoluted tubules (DCTs). Nephrons have highly variable lengths. In general, the superficial (cortical) nephrons are shorter and the deep (juxtamedullary) nephrons are longer, mostly because of the longer loop of Henle. These long nephrons are important

in the urinary concentrating mechanism (Figure 1.2). Uriniferous units converge to form the apex of the renal pyramids as they enter the minor calyces. Starting at the bases of the renal pyramids, adjacent to the corticomedullary junction, bundles of tubules and associated blood vessels may project toward the surface of the kidney as radially arranged medullary rays.

The most proximal structure of the nephron is the Bowman capsule, a thin-walled, spherical dilation, which is deeply invaginated into a two layered, cup-like structure, with a visceral layer and a parietal layer. The space between these two layers, which is continuous with the lumen of the PCTs, is called the urinary (or Bowman) space. The concave depression in the Bowman capsule is occupied by a network of capillaries known as the glomerulus. The glomerulus and Bowman capsule together constitute a renal corpuscle and comprise the functional filtering units in the kidney.

The PCT receives the glomerular filtrate from the urinary space of Bowman capsule. It is lined by a simple columnar epithelium. Its cells have an abundance of mitochondria that make the cytoplasm intensely acidophilic. Epithelial cells of the PCT have an elaborate apical microvillous brush border, which fills much of the lumen of the PCT, and deep invaginations of the basilar surface membrane. The lateral borders of individual cells are extensively interdigitated, thus giving the individual cells the appearance of a tree stump with elaborate buttressing. These microscopic features play an important role in the reabsorption of tubular water, electrolytes, bicarbonate, phosphate, and amino acids. Proximal tubules also reabsorb and metabolize filtered albumin in proteinuric states and return the amino acids and dipeptides to body's nutrition pool. The PCT leads into a proximal straight tubule, and from there the glomerular filtrate passes into the descending thin limb, the ascending thin limb, and the ascending thick limb of the loop of Henle.

Once the glomerular filtrate has ascended the loop of Henle, it passes into the DCT. A portion of the DCT contacts the vascular pole of the renal corpuscle, where it forms the macula densa of the juxtaglomerular apparatus (JGA). The DCT is lined by simple cuboidal epithelium, although it has a wider lumen than the PCT. There are only scattered apical microvilli in the DCT. The cells in the thin limbs of the loop of Henle are generally flattened and are often frankly
Figure 1.2 Diagrammatic representation of nephrons arranged in the kidney. Juxtaglomerular nephrons have long loops of Henle that dip deep into medulla and are important in the countercurrent urine concentrating mechanism. Cortical nephrons have relatively short loops of Henle. (Figure in the public domain; artwork by Holly Fischer. Reproduced under Creative Commons Attribution 3.0.)

squamous. The collecting tubules, the last component of the nephron, have squamous epithelium, whereas the collecting ducts have taller epithelial cells, starting as cuboidal cells in the cortex but growing taller along the route of descent to the renal papilla, eventually to form tall columnar cells in the walls of the papillary ducts (of Bellini), just before they penetrate the area cribrosa to enter the minor calyx.

RENAL BLOOD SUPPLY

Blood flow through the kidneys is surprisingly extensive (approximately 25% of cardiac output), with approximately 90% flowing through the cortex and the rest flowing through the medulla. This immense blood supply ensures rapid removal of nitrogenous wastes from the blood by the kidneys. The renal artery enters the renal sinus and divides

into anterior and posterior branches, which then form segmental arteries. Segmental arteries branch into lobar arteries for each renal pyramid (lobe), which then branch again, passing in the renal columns, between the renal pyramids as interlobar arteries. Once the interlobar arteries have penetrated to the corticomedullary junction, they branch into arcuate arteries, which run parallel to the surface of the kidney. At regular intervals along the arcuate arteries, interlobular arteries project radially toward the most superficial parts of the cortex. As the interlobular arteries pass from the deep cortex to the superficial cortex, they send out branches called afferent arterioles that supply blood to the glomeruli. After leaving the glomerulus, blood enters the efferent arteriole. From here, the blood follows different pathways for cortical nephrons and juxtamedullary nephrons. In cortical nephrons, with short loops of Henle, blood passes through a complex network of capillaries, some surrounding the PCTs and DCTs (as a cortical peritubular capillary network). In contrast, in juxtamedullary nephrons, with long loops of Henle, the efferent arterioles (vasa recta), follow the loop of Henle to its tip. These blood vessels then drain into interlobular veins, arcuate veins, interlobar veins, and eventually the renal vein.

KEY POINTS

- Efferent arterioles of juxtamedullary nephrons develop anatomically distinct, long vascular channels that dip deep into the medulla along the side of their own nephrons and are called vasa recta.
- Vasa recta are low-flow arteries and are prone to desaturation-induced sickling of red blood cells in patients with sickle cell anemia or sickle cell trait.

The spaces between the renal tubules are filled with connective tissue, known as the renal interstitium. It is relatively sparse in the cortex but more abundant in the medulla. The renal interstitium also connects to a distinct connective tissue capsule around the entire kidney, with an inner layer of potentially contractile myofibroblasts and an outer layer of fibroblasts.

THE RENAL CORPUSCLE

The renal corpuscle is a prominent feature of the renal cortex. It consists of three main structures: (1) the glomerulus, a network of capillaries supplied by the afferent arteriole and drained by the efferent arteriole; (2) the Bowman capsule, an invaginated, balloon-like expansion of the PCT; and, (3) mesangial cells (Figure 1.3). Glomerular capillary endothelial cells have numerous 70- to 100-nm fenestrae
Figure 1.3 Light microscopy showing a glomerulus with the juxtaglomerular apparatus. DT, distal tubule; EMC, extraglomerular mesangial cells MC, mesangial cell with mesangial matrix; MD, macula densa; PC, parietal epithelial cell; and VC, visceral epithelial cells.

(transcellular pores) without diaphragms, and they rest on a basement membrane (Figure 1.4A). The glomerular basement membrane (GBM) is a multilayered structure with a lamina rara interna (adjacent to capillary endothelium), a lamina densa, and a lamina rara externa (adjacent to the podocytes). The laminae rarae are rich in polyanions such as heparan sulfate. These negatively charged macromolecules presumably repel anions that would otherwise cross from the capillary lumen into the urinary space (and vice versa). In addition, the laminae rarae have an abundance of fibronectin, a cell adhesion glycoprotein. Mesangial cells form a

supportive complex between the capillary endothelial cells. They can proliferate and produce a basement membrane–like material and appear to have contractile, secretory, and phagocytic activity.

GBM is one of the thickest and most functionally important basement membranes in the body. The GBM is a complex extracellular matrix that is formed by both capillary endothelial cells and podocytes. It contains type IV collagen, laminin, fibronectin, entactin, and proteoglycan complex with polyanionic glycosaminoglycans such as heparan sulfate. The thickness of the GBM varies with age; it is a mean of 373 nm in men and 326 nm in women.[5] In children, however, GBM is thinner at birth, rapidly increases in size by the second year of life, and reaches adult proportions by 9 to 11 years of age.[6,7] Before 1 year, the thickness of GBM has been reported to be 132 to 208 nm, and it reached 244 to 307 nm by 11 years in one study.[6] Thinned GBM is usually seen in Alport syndrome, thin basement membrane nephropathy (TBMN), and occasionally in immunoglobulin A (IgA) nephropathy.

By electron microscopy, the GBM has a thick, central, electron-dense lamina densa (see Figure 1.4A), with less electron-dense layers adjacent to the capillary endothelial cells (lamina rara interna), and podocytes (lamina rara externa). The collagen is thought to function as a scaffold for the attachment of other glycoproteins and proteoglycans that constitute the rest of the GBM. Type IV collagen consists of three intertwined α-chain monomers, each with three distinct domains: the 7S N-terminus, a middle helical collagenous domain, and a C-terminus noncollagenous (NC1) domain.[8] The GBM also allows attachment of epithelial cells (through cell surface integrin receptors for extracellular matrix molecules such as collagen, laminin, and fibronectin) to itself and one another, and it serves as a part
Figure 1.4 **(a)** Electron micrograph of the basement glomerular capillary. Capillary cross section showing an endothelial cell (EndC), the lamina rara interna (LRT), the lamina rara externa (LRE), the lamina densa (LD), the podocyte foot processes (PC), the epithelial cell cytoplasm (EpC), and the slit diaphragm (SD). **(b)** Electron micrograph showing extensive interdigitation of the podocyte foot processes around the basement membrane on the external or urinary side.

of the selective filtration barrier between the lumen of the glomerular capillary (the vascular space) and the lumen of the Bowman capsule (the urinary space).

PODOCYTES

The visceral layer of the Bowman capsule is formed by a sheet of stellate epithelial cells called podocytes, which have a large central cell body containing a nucleus and numerous primary, secondary, and tertiary branches projecting from the cell body. Podocytes have foot processes, which interdigitate extensively and attach the podocytes to the lamina rara externa of the GBM (Figure 1.4B).

The gaps between the adjacent foot processes, known as filtration slits, are covered by a zipper-like slit diaphragm (SD), which forms the second barrier to macromolecular transport after glomerular endothelial and GBM barriers.[8] The structure and function of SDs have been the subject of intense study. Discoveries in this area have provided important insights into the role played by the podocytes in glomerular function. The zipper-like structure of SD is made up of protein molecules from the two adjacent foot-processes that overlie each other in the midline to form the filtration barrier.[9] Of these molecules, nephrin was the first to be identified. Nephrin, which forms the bulk of SD filtration barrier, is a transmembrane protein that is anchored to the cytoplasmic membrane by podocin.[10,11] Neph 1, Neph 2, and Neph3 are other important podocyte-SD proteins that are structurally similar to nephrin and are believed to react with both nephrin and podocin to maintain the cytoskeletal structure and scaffoldings within podocytes.[12–15] The podocyte foot processes are anchored to the GBM by $\alpha_3\beta_1$ integrin.

KEY POINTS

- Epithelial cells and their foot processes are now recognized as among the most functionally relevant cell types in the glomeruli.
- Alterations in podocytes resulting from gene mutations have been linked to the pathogenesis of several types of nephrotic syndrome in children.
- With aging, podocytes are normally shed in urine.
- Injured podocytes do not regenerate.

Mutations in podocytes foot process–associated proteins cause proteinuria and nephrotic syndrome. Nephrin (*NPHS1* gene) mutation in humans result in the Finnish type of congenital nephrotic syndrome, whereas podocin (*NPHS2* gene) mutation also gives rise to steroid-resistant nephrotic syndrome.[15–17] In experimental animals, Neph1-lacking mice develop severe proteinuria that resembles the nephrin mutation in humans.

THE JUXTAGLOMERULAR APPARATUS

The DCT returns to its parent glomerulus and rests close to the vascular pole, in proximity to the afferent arteriole (see Figure 1.3). This specialized structure is the JGA. The JGA consists of three identifiable microscopic structures: (1) specialized cells of the DCT known as the macula densa, (2) juxtaglomerular (JG) cells in the afferent arteriole, and (3) extraglomerular mesangial (EGM) cells. The JGA is a sensor for sodium delivery to the distal nephron and alters the afferent and efferent arterial tone and blood flow through the locally generated renin-angiotensin system (RAS).

KEY POINTS

- The JGA is a specialized structure that is essential for renin-angiotensin hormone generation.
- The JGA controls intraglomerular pressure by regulating the relative diameter of the afferent and efferent arterioles.

Macula densa

The macula densa is the collection of columnar epithelial cells in the wall of the DCT in intimate contact with the vascular pole of the Bowman capsule and the JG cells. Here, the nuclei of the tubular epithelial cells are more crowded together than in the rest of the DCT. The apical surfaces of cells in the macula densa have numerous microvilli and a single cilium.

Juxtaglomerular cells

JG cells are modified smooth muscle like cells in the wall of the afferent arteriole. They are also sometimes found in smaller numbers in the wall of the efferent arteriole. They contain electron-dense granules of renin. As systemic blood pressure falls, the JG cells release their renin granules into the systemic circulation. Renin then cleaves angiotensinogen into the decapeptide angiotensin I. Angiotensin I is converted in pulmonary circulation into angiotensin II by the angiotensin-converting enzyme (ACE) in endothelial cells of alveolar capillaries. Angiotensin II, a potent vasoconstrictor, helps restore blood pressure to the normal range.

Extraglomerular mesangial cells

EGM cells look like fibroblasts. They provide a communicating connection between the macula densa and the JG cells. Ultrastructural studies reveal that EGM cells have long, thin processes that contact both other elements of the JGA. In addition, there are gap junctions at the tips of these processes where the EGM cells contact other cells, probably thus allowing communication among the three cell types of the JGA.

RENAL EMBRYOLOGY

Kidney and ureters develop from the intermediate mesoderm, a bulbous ridge of tissue that lies in the intraembryonic mesoderm between the somites and the lateral plate mesoderm. In contrast, bladder and the urethra develop from the urogenital sinus. Renal development occurs in three phases in a cranial to caudal sequence, starting in the fourth week. The first two stages, pronephros and mesonephros, are transitional renal structures, whereas the third stage, the metanephros, forms the definitive kidney (Figure 1.5).

The pronephros is the first renal structure, which arises as few solid or vesicular tissue segments in the cervical region at the beginning of the fourth week. It degenerates by the end of the fourth week and leaves no adult remnants. The mesonephric kidney and its associated mesonephric duct form in the urogenital ridge of the intermediate mesoderm from the upper thoracic to the upper lumbar segments. The mesonephric kidney forms rudimentary nephrons and probably functions in humans to produce some dilute urine. Most of the mesonephros degenerates by the end of the eighth week. The mesonephric duct persists in boys and men as the epididymis, the vas deferens, and the seminal vesicle, structures that drain the testis. In girls and women, the mesonephric duct forms vestigial structures such as the epoöphoron and Gartner cysts.

The metanephric kidney is the definitive kidney and the last to develop. It begins to form in the fifth week and is

Figure 1.6 Developmental stages of the kidney in the fetus. After the ureteric bud branching, the mesenchymal cells aggregate around the tip of the ureteric bud to form cap-mesenchyme. Next, these cells evolve through the stages of renal vesicle, comma-shaped body, and then S-shaped body. The end of S-shaped body that is closest to the ureteric bud fuses with it and becomes part of the distal nephron, whereas the opposite end invaginates to give rise to the glomerular structure. Endothelial cells invade the glomerulus to form glomerular capillaries.

Figure 1.5 A diagrammatic view showing various phases of renal development in the embryo. The pronephros and mesonephros degenerate, whereas the metanephros formed at 5 weeks of gestation gives rise to the definitive kidney.

located in the caudal portion of the urogenital ridge. An evagination of the mesonephric duct, called the ureteric bud, grows into the surrounding mesenchyme of the urogenital ridge, called the metanephric blastema. By a reciprocal inductive interaction, the metanephric blastema triggers branching of the ureteric bud, thus ultimately forming the renal pelvis, major calyces, minor calyces, and collecting tubules. Meanwhile, the ureteric bud stimulates formation of blood vessels and nephrons in the metanephric blastema. Transformation of the metanephric blastema into a nephron undergoes the developmental stages of renal vesicle, comma-shaped body, and S-shaped body (Figure 1.6). The proximal portion of the S-shaped body invaginates to form the Bowman capsule with a cup-like recess for the development of glomerular capillaries. The distal potion connects to the branching ureteric bud to form the collecting duct.

ASCENT OF THE METANEPHROS

The metanephric kidneys originate in the pelvis (S1 to S2 level), but following decurvature of the body axis and lumbar and sacral body growth, the definitive kidneys ascend to the lumbar area (T12 to L3). The metanephric kidney ascends between 6 and 9 weeks of gestation. When the caudal poles

of the metanephroi fuse, the ascent of a horseshoe kidney is halted by the inferior mesenteric artery, a branch from the aorta that supplies hindgut derivatives. Initially, the metanephroi are supplied by sacral branches of the aorta, but as they ascend cranially, they take new branches from the dorsal aorta that eventually develop into the renal arteries. The caudal branches usually degenerate, but supernumerary renal arteries sometimes persist, often caudal to the main renal artery. During ascent, the fetal kidneys also rotate medially by 90 degrees, so that the renal hilum, with the ureter and renal vessels, faces medially. In arrested ascent, metanephric kidneys may be formed in the pelvis, either unilaterally or bilaterally, resulting in ectopic or pelvic kidneys.

CLOACA AND FORMATION OF THE UROGENITAL SINUS

The most caudal portion of the early hindgut is the cloaca. The hindgut precursor and cloaca have a diverticulum, called the allantois, which projects far into the umbilical cord. By the fifth week, the proximal part of the cloaca becomes slightly expanded into a precursor of the urinary bladder. During the fifth week and onward, the urorectal septum divides the cloaca into a posterior anal canal and an anterior urogenital sinus. The urogenital sinus eventually gives rise to major portion of urinary bladder, and the pelvic part that becomes the membranous and prostatic urethra, and phallus. Each ureter enters the urinary bladder more lateral to the midline of the bladder, to form a roughly triangular structure called the trigone of the bladder, which is defined by the two ureteric inlets superiorly and the urethral outlet inferiorly. The proximal ends of the ureters become incorporated into the wall of the urinary bladder, so that it is lined transiently by mesodermally derived epithelium in the trigone. Later, the trigone is overgrown by endodermally derived epithelium from the rest of the bladder.

The distal portion of the allantois eventually degenerates, but the proximal portion persists as a urachal diverticulum that still projects into the umbilical cord. Eventually, the proximal urachal diverticulum forms the median umbilical ligament. Rarely, however, persistent urachus can lead to urachal fistula, wherein urine leaks from the bladder into the umbilicus or urachal cysts in the median umbilical ligament.

INTRAUTERINE RENAL FUNCTION

In humans, the pronephros is a rudimentary structure. It does not form functional nephrons and involutes in a short time. The human mesonephric kidney forms rudimentary renal corpuscles with a Bowman capsule and glomerulus and associated tubules, but there is little substantiation of its function. Mesonephric nephrons have short loops of Henle, a structure suggesting that the small volume of urine produced in the mesonephros is likely to be dilute. By the 16th week of gestation, the mesonephric kidney loses

its functional capacity, and the metanephric kidney develops into a urine-producing structure, with renal corpuscles and well-differentiated PCTs with microvillous brush borders at the lumen. However, because the loops of Henle are not fully developed, fetal urine is hypotonic with respect to plasma and is slightly acidic. At term, the human fetus voids approximately 450 mL/day into the amniotic fluid. The urethra is patent in the fetus at approximately 8 weeks.

> ### KEY POINT
>
> The urethra is patent by the eighth week of gestation, and urine begins to form a part of amniotic fluid at around that time.

NEPHRON ENDOWMENT AND FUTURE HEALTH RISKS

Each normal adult kidney has approximately 1 million nephrons, but this estimate is quite variable. Using mature adult kidneys obtained at autopsy, Nyengaard and Bendtsen[18] noted the mean nephron number to be 617,000. A more recent US-Australian, multiethnic autopsy study[19] in adults revealed a significant variation in nephron number, ranging from 210,332 to 1,825,380 in each kidney, with a mean of 870,582 ± 31,062.

Nephron number in human fetuses increases throughout gestation, from a mean of 15,000 at 15 weeks to 740,000 in each kidney by 40 weeks.[20] This number appears to plateau at approximately 36 weeks.[20] Nephrogenesis in full-term fetuses concludes by approximately 34 to 36 weeks of gestation, and new nephrons are not formed after birth.[20,21] Premature infants, conversely, have fewer nephrons, and nephronogenesis may continue after birth for as long as 3 months.[22,23] The clinical impact of low endowed nephron number in premature infants is likely to last a lifetime and is referred to as fetal programming. Indeed, renal length and volume by ultrasonography are known to be significantly lower in young adults who were born prematurely (at less than 32 weeks), a finding suggesting long term adverse renal consequences and risks in these persons.[24] An increased risk for hypertension and CKD associated with prematurity, low birth weight, and intrauterine growth retardation was suggested by Brenner et al.,[25–27] starting in the 1980s. In an Australian study,[28] 18-year-old survivors of extreme prematurity (gestational age less than 28 weeks) had higher

> ### KEY POINT
>
> Poor nephron endowment at birth (fetal programming) affects blood pressure, development of microalbuminuria, and can lead to ESRD in adults.

ambulatory blood pressure readings, thus lending weight to the hypotheses proposed by Brenner and others. A meta-analysis of studies relating prematurity and blood pressure also demonstrated a higher blood pressure in persons who were born prematurely (range, 28.8 to 34.1 weeks).[29]

The link between poor nephron endowment and CKD is plausible, but less well established. Microalbuminuria noted in otherwise healthy nondiabetic adults (46 to 54 years old) has been correlated with low birth weight as a risk factor.[30] Increased prevalence of ESRD in adults born with a birth weight of less than 2.5 kg was noted in one study in the United States, and the odds ratio for ESRD was 1.4 (95% confidence interval [CI], 1.1 to 1.8), as compared with a birth weight of 3 to 3.5 kg.[31] Carmody and Charlton[32] suggested that apart from low nephron endowment in premature infants, other factors that may enhance the risk for CKD include neonatal acute kidney injury, use of nephrotoxic antibiotics, poor nutrition, and hypoxia in early life.

KEY POINTS

Renal risks in premature infants are compounded by:

- Acute kidney injury
- Hypoxia
- Use of nephrotoxic drugs
- Poor nutrition

CONGENITAL ABNORMALITIES OF THE KIDNEY AND URINARY TRACT

The term *congenital abnormalities of the kidney and urinary tract* (CAKUT) denotes developmental urologic and renal abnormalities encountered in children.[32,33] CAKUT, as a term, also emphasizes the shared developmental destiny of the kidney and the urinary tract (Figure 1.7). The CAKUT spectrum encompasses diverse clinical disorders, such as unilateral or bilateral renal agenesis, renal hypodysplasia, multicystic dysplastic kidney (MCDK), ureteropelvic junction obstruction, posterior urethral valves, vesicoureteral reflux (VUR), duplex renal collecting system, ectopic ureters, and megaureter.

KEY POINT

CAKUT, as a concept, reflects a common origin of renal and urologic anomalies in utero.

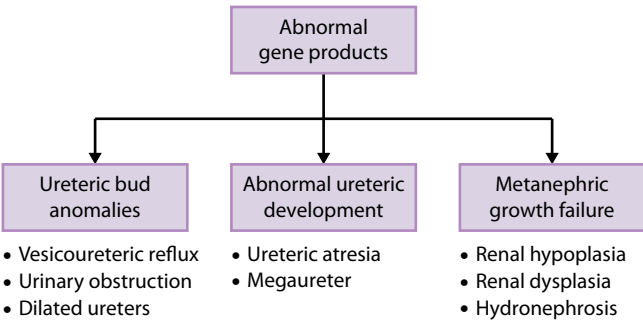
CAKUT occurs in approximately 1 in 500 live births, but severe abnormalities resulting in neonatal death occur less frequently, in approximately 1 in 2000 births.[33,34] By using prenatal ultrasound as the screening method in 709,030 live births, stillbirths, and induced abortions, 1130 infants


Figure 1.7 Pathogenesis of congenital abnormalities of the kidney and urinary tract. This unifying hypothesis breaks from previously believed concepts that developmental renal defects arise from urinary obstruction. It is now believed that genetic defects disrupt critical signaling processes between the ureteric bud and nephrogenic mesenchyme, eventually leading to uronephrologic developmental disorders. (Based on Ichikawa I, Kuwayama F, Pope JC, 4th, et al. Paradigm shift from classic anatomic theories to contemporary cell biological views of CAKUT. Kidney Int. 2002 61:889–98.)

and fetuses were diagnosed with at least one renal or urologic abnormality, amounting to an incidence of 1.6 in 1000 pregnancies.[35] CAKUT is often encountered as an isolated or sporadic anomaly, but it can also be a clinical feature of numerous syndromes. Additionally, an increased risk of urinary tract anomalies has been reported in the close family members of these patients.[36,37] Some of the common CAKUT malformations are discussed here, as well as in Chapter 2. VUR is discussed in Chapter 48.

Renal agenesis

Bilateral renal agenesis is an uncommon disorder. Potter described 20 cases of bilateral renal agenesis in 5000 autopsies performed in children and estimated the incidence to be 1 in 3000 to 1 in 4000 births.[38,39] Approximately 25% to 40% of fetuses with bilateral renal agenesis are stillborn. Bilateral renal agenesis can result in the clinical features of Potter sequence as a result of prolonged lack of intrauterine urine and oligohydramnios.[40–42] Potter sequence (or Potter syndrome) is characterized by: bilateral renal agenesis (or severe fetal renal disease), oligohydramnios, pulmonary

KEY POINTS

Potter sequence includes:

- Renal agenesis or severe dysplasia
- Oligohydramnios
- Pulmonary hypoplasia
- Low-set ears
- Clubfeet
- Pointed nose

hypoplasia, clubfeet, micrognathia, a pointed nose, and low-set malformed ears.[40] Potter facies refers to the typical facial features seen in Potter sequence. Potter sequence can result from any fetal disorder that leads to prolonged oligohydramnios. There has been an ongoing speculation that bilateral renal agenesis may be an inherited disorder, primarily because of a significantly higher incidence of occult renal defects in close relatives of index cases.[43] Recessive mutations in the integrin α_8-encoding gene *ITGA8* have been described in families with fetal loss secondary to bilateral renal agenesis.[44] Such findings are likely to stimulate investigative pathways to genetic pathogenesis of bilateral renal agenesis.

Accurate information of the incidence of unilateral renal agenesis is difficult to obtain because many of these cases go undetected as a result of compensatory hypertrophy of the contralateral kidney, as well as normal intrauterine and postnatal renal function. Using renal ultrasound screening in healthy school-age children (6 to 15 years), Sheih et al.[45] reported the occurrence of unilateral renal agenesis to be 1 in 290 in the general population of children. European data also suggest the incidence of unilateral renal agenesis to be 1 in 2000 births.[46]

Unilateral renal agenesis is often associated with ipsilateral defects in other genital duct derivatives such as the ductus deferens in boys and the uterine tubes and uterus in girls. VUR is common (approximately 25%) in these patients, and extrarenal malformations affecting the gastrointestinal, cardiac, and musculoskeletal systems are seen in approximately 30% of patients.[46] An increased incidence of renal anomalies in the children and siblings of patients with unilateral renal agenesis has been noted in some studies.[36]

Pelvic and horseshoe kidneys

Pelvic kidney and horseshoe kidney are related renal malformations that result from failed ascent of the kidneys. In horseshoe kidney, the caudal poles of the metanephric kidney are fused. Horseshoe kidney is one of the most common congenital anomalies of the kidney. On the basis of abdominal CT scan data in 15,320 patients, the incidence of horseshoe kidney was noted to be 1 in 666.[47] Approximately half of the patients diagnosed with horseshoe kidney are asymptomatic; the remainder present for renal stones and ascending urinary tract infections.[48] The Rovsing sign, consisting of nausea, vomiting, and abdominal pain that is accentuated on hyperextension, is seen in a minority of patients with horseshoe kidney.[48] Horseshoe kidney can occur as an isolated congenital birth defect but is more frequent in patients with Turner syndrome and trisomy 18 (Edwards syndrome).[48,49]

Multicystic dysplastic kidneys

MCDKs are developmental, nonfunctional cystic masses caused by abnormalities in metanephric differentiation. These kidneys are characterized by abnormal and
Figure 1.8 **(a)** Cut section of a kidney from a neonate shows cystic dysplasia. Renal architecture is poorly defined, numerous cysts are present, and the corticomedullary differentiation is absent. **(b)** Microscopic section of a kidney with renal dysplasia. Arrows shows the presence of cartilage. Tubulointerstitial tissue is poorly organized, and a large dilated renal tubule (T) is shown. (Photomicrograph courtesy of Arthur Cohen, MD.)

noncommunicating dilated cysts of variable size, with little identifiable renal structure or stroma (Figures 1.8 and 1.9). Renal arterial flow and excretory functions, as demonstrable by mercaptoacetyltriglycine (MAG3) renal scan, are absent.

MCDK is commonly identified by the presence of a unilateral cystic kidney in the fetus during prenatal ultrasound evaluation. Cystic kidneys may involute during gestation in some cases, and the infant is born with a solitary kidney. Other modes of presentation include an abdominal mass noted by the parents or during a clinical examination within few months of birth. In a study of 97 infants with the diagnosis of MCDK, 85% of the cases were detected by prenatal ultrasound evaluation, 4% by the presence of a mass postnatally, and 11% by a postnatal ultrasound examination

Figure 1.9 Renal ultrasound scan showing multiple large cysts in an infant with multicystic dysplastic kidney disease. Nuclear scan demonstrated no blood flow or excretory function in this kidney.

performed for an unrelated diagnosis.[50] MCDK is slightly more common on the left side in some studies, whereas other investigators have noted a right-sided predominance; these findings suggest that both sides can be equally involved.[38,39] Contralateral kidneys show abnormalities in approximately 40% of cases that include renal agenesis, renal dysplasia or hypoplasia, VUR, hydroureter or pyelectasis, duplex collecting system, and ectopic ureters.[39] In a meta-analysis of the abnormalities in the contralateral system, Schreuder et al.[51] reported VUR in approximately 20% cases: 15% in the contralateral system, ipsilateral VUR in 3.3%, and bilateral VUR in 2.4% cases. Ureteropelvic junction obstruction was the next most common anomaly in the contralateral renal system, accounting for 4.8% cases in this meta-analysis.

Involution of the cystic mass occurs usually occurs over several years, but the rate of involution is variable. Some patients have complete involution of the MCDK in utero and are thus born with a solitary kidney and unilateral agenesis. Complete involution of the MCDK was noted in 34% at 2 years (165 patients), 47% at 5 years (117 patients), and 59% at 10 years (43 patients) in a study from the United Kingdom.[52] The contralateral normal kidney usually undergoes compensatory hypertrophy.

Hypertension has been well documented in patients with MCDK and is believed to be mediated by the RAS.[53] More recent studies, however, point out that the risk of hypertension in MCDK is low. In a review of 29 studies, Narchi et al.[54] reported hypertension to be present in only 6 of the 1115 cases, a finding suggesting the mean probability of developing hypertension in MCDK to be 5.4 in 1000 cases (estimated 95% CI, 1.9 to 11.7 per 1000).

A high risk for Wilms tumor and renal cell carcinoma in the MCDK was suggested in older studies. However, the risk of tumors was very low in several more recent, comprehensive, well-conducted studies.[55,56] Surgical resection of the MCDK, which was often practiced until the late 1980s for the prevention of hypertension and to protect against development of malignant disease, appears to be difficult to justify with the evidence-based results.[54–57]

WAGR syndrome

Wilms tumor, aniridia, genitourinary abnormalities, and mental retardation (WAGR) was first reported as a distinct clinical disorder by Miller et al.[58] in 1964 (Online Mendelian Inheritance in Man [OMIM] number 194072). It is now well established that the disorder results from deletion in distal band of 11p13 in such a way that *WT1* and *PAX6* genes, which are adjacent to each other, are affected by the deletion.[59] The *WT1* gene deletion results in renal malformations and risk for Wilms tumor; whereas the *PAX6* gene deletion results in aniridia and brain malformations.

The *WT1* gene encodes for Wilms tumor suppressor protein (WT1), a transcription factor containing a DNA binding domain, with four zinc fingers. WT1 transcription factor is essential for the development of the nephron, as well as the gonads, and is thought to be involved in

mesenchymal-epithelial transition in the renal and germ cell lines.[60] With mutations in the *WT1* gene, the development of glomeruli and of the proximal and distal tubules is adversely affected, leading to renal malformations. A propensity for Wilms tumor in WAGR and other syndromes with the *WT1* gene mutation, such as Denys-Drash syndrome, results from the presence of undifferentiated or poorly differentiated mesenchymal cells in the kidneys.[60,61]

The genital malformations seen in WAGR syndrome include cryptorchidism, ambiguous genitalia, hypospadias, streaked ovaries, and hypoplastic uterus. Renal and urinary tract anomalies encountered in WGAR syndrome include hypoplastic kidneys, unilateral renal agenesis, duplicated ureters,, development of focal segmental glomerulosclerosis, nephrogenic rests, nephroblastomatosis, and renal cysts.[62] Aniridia can be partial or complete and results in severe visual impairment. Apart from risk of CKD and ESRD imposed by the development of Wilms tumor, patients with WAGR syndrome are inherently at an increased risk for development of ESRD. The National Wilms Tumor Study Group reports the incidence of ESRD to be 53% in patients with WAGR syndrome.[63,64] Monitoring of kidneys by ultrasound every 3 months until 6 years of age has been recommended in some studies for Wilms tumor surveillance in patients with WAGR syndrome.[62]

Bladder exstrophy

Bladder exstrophy is an uncommon developmental anomaly seen in newborn infants. It is caused by a ventral body wall, an anterior bladder wall defect, and eversion of the bladder wall mucosa. The term exstrophy, which is derived from the Greek word *ekstriphein*, means "turned inside out." In the newborn infant, the exposed bladder mucosa is bright red and has a raw appearance. The exposed mucosa sometimes undergoes metaplasia, forming colonic epithelium rather than transitional epithelium. Bladder exstrophy is also associated with other congenital abnormalities of the external genitalia such as bifid penis, epispadias, and abnormal scrotal development

Using the Healthcare Cost and Utilization Project Nationwide Inpatient Sample database, Nelson et al.[65] estimated the incidence of bladder exstrophy to be 2.15 in 100,000 live births (or approximately 1 in 40,000 births). The male-to-female ratio was equal in this study, and the congenital malformation appeared to be more common in whites than in nonwhites. Some genetic analyses have demonstrated a higher prevalence of duplication of 22q11.21 in patients with bladder exstrophy.[66]

Surgical repair of bladder exstrophy has evolved since the 1990s. Both early closure and delayed closure of the defect are acceptable surgical options and are generally dictated by technical preference of the surgical team.[67] Postrepair attention to incontinence, recurrent urinary tract infections secondary to associated VUR, and correction of epispadias are common concerns to be addressed during childhood. Many patients require continent urinary diversion procedures,

as well as bladder augmentation by cystoplasty. However, lower urinary tract symptoms persist in 80% of patients with exstrophy as they grow into adulthood.[68] Sexual dysfunction is also a concern in adulthood.[69] In addition, adenocarcinomas occur with higher frequency in the exposed bladder mucosa. Surgical intervention and repair can extend the patient's life and ensure normal renal function.

Angiotensin-converting enzyme fetopathy

Experimental observations indicate that RAS exerts its influence on renal development by promoting the ureteric bud branching process and therefore plays a key role in nephrogenesis.[70,71] The RAS may affect ureteric bud branching and nephrogenesis through its influence on GDNF, the *WT1* gene, and the *PAX2* gene. Disruption of the RAS during nephrogenesis by ACE inhibitors (ACEIs) is well known to cause fetopathy.[70,72] ACEI fetopathy risk is low if the drug is consumed in the first trimester.[72–74] Clinical characteristics of ACEI fetopathy are: oligohydramnios, renal tubular dysgenesis, neonatal anuria, skull defects, intrauterine growth retardation, and patent ductus arteriosus.

KEY POINTS

- The RAS plays a crucial role in nephrogenesis.
- Maternal ACEI use after the first trimester is associated with fetopathy that includes renal dysgenesis.

SUMMARY

A significant advance in our understanding of the signal pathways involved during development of the kidneys and the urinary tract in fetal life has occurred since the 1990s. What has also become obvious is that the renal development is supported by the development of the rest of the urinary tract, especially the ureteric bud. A disruption in any of these developmental processes can lead to abnormalities of renal development and CAKUT. Nephron endowment at birth is beginning to be recognized as an important predictor of CKD and hypertension in adults. Attention to prenatal health and prevention of poor nephron endowment may be ways that kidney disease and hypertension can be prevented in adults.

REVIEW QUESTIONS

1. The juxtamedullary nephrons have long loops of Henle that participate in:
   a. Sodium reabsorption
   b. Chloride transport
   c. Urine concentrating mechanism
   d. None of the above
2. Nephrin constitutes a structural component of:
   a. Endothelial cytoskeleton
   b. Podocyte cytoskeleton
   c. Slit diaphragm
   d. Bowman capsule
3. Which of the following combinations are transitional embryonic kidneys?
   a. Metanephros and mesonephros
   b. Mesonephros and pronephros
   c. Pronephros and metanephros
   d. None of the above

4. In a premature infant, nephrogenesis can continue up to 3 months after birth:
   a. True
   b. False
5. Characteristic finding on MAG3 renal scan in a patient with multicystic dysplastic kidney (MCDK) is:
   a. Photopenic areas in the affected kidney suggesting cysts
   b. Arterial flow from the surrounding tissue
   c. Adequate blood flow but no excretory function
   d. No demonstrable renal blood flow and no excretory function
6. Vesicoureteral reflux on the same side or contralateral side of MCDK occurs in:
   a. Fewer than 5% cases
   b. 20% cases
   c. 50% cases
   d. Almost always in all patients
7. Wilms tumor, aniridia, genitourinary anomalies, and mental retardation (WAGR) is caused by:
   a. Mutation in WT1 gene
   b. Mutation in PAX6 gene
   c. Mutation in PAX6 and WT1
   d. Mutation in *WT1* and GDNF
8. ACEI-induced fetapathy is more common if the drug exposure occurs in:
   a. First 2 weeks of pregnancy
   b. Six to 12 weeks of pregnancy
   c. Last week of pregnancy
   d. After first trimester of pregnancy
9. Horseshoe kidneys are common in:
   a. Down syndrome
   b. Turner syndrome
   c. WAGR syndrome
   d. Renal coloboma syndrome
10. Low nephron number at birth is associated with:
    a. Future risk of diabetes mellitus
    b. Future risk of cardiac disease
    c. Future risk of hypertension
    d. No associated risk of disease

Molecular basis of developmental renal disease

NORMAN D. ROSENBLUM

Developmental abnormalities of the urinary tract are common and account for 30% to 50% cases of end-stage renal disease in children.[1] Formation of the kidney consists of a complex series of morphogenetic events during intrauterine development that are complete by approximately 34 weeks of gestation. However, growth of kidney cells continues after birth, as does functional development of the kidneys. Renal development is incomplete at birth, even in full-term infants and to a greater extent in preterm infants. Mature levels of renal function are not achieved until approximately 2 years of age. The objectives of this chapter are to supplement the broad concepts of renal embryologic development discussed in Chapter 1 and to explore the molecular events involved in nephrogenesis.

EARLY FETAL KIDNEY DEVELOPMENT

In mammals, the kidneys develop in three stages, from rostral (head end) to caudal (rump end): the pronephros, the mesonephros, and the metanephros (permanent kidney). The pronephros is rudimentary and nonfunctional. The mesonephros functions briefly and then involutes toward the end of the first trimester. The metanephros does not involute and becomes the permanent kidneys. Metanephric development begins during the fifth week of gestation, and urine excretion is initiated at approximately the 10th week of gestation.

During fetal life, the kidneys are lobulated, but a lobular appearance is present even at birth. Thereafter, the external kidney surface becomes smooth as the kidney grows. It is becoming increasingly apparent that the number of nephrons endowed at birth has an important bearing on the susceptibility to hypertension and chronic kidney disease as adults.[2] Minimizing disruptions in fetal renal development may, indeed, be central to preventing kidney disease in adults.

Initially, the kidneys lie adjacent to each other in the pelvis, and the hilum of each faces ventrally (toward the anterior abdominal wall). As the trunk grows, the kidneys come to lie higher in the abdomen and farther apart. In addition, the hilum rotates almost 90 degrees. By 9 weeks of gestation, the kidneys attain their adult positions. Malrotation and ectopic kidney location are caused by abnormal rotation and ascent, respectively. Failure of the kidneys to migrate upward from the pelvis results in the formation of pelvic kidneys. These kidneys are positioned close to each other and may fuse in some cases to give rise to a *pancake kidney*. In approximately 1 in 500 persons, the inferior poles fuse before ascent, thus generating a *horseshoe kidney*.

> ### KEY POINTS
>
> - The met anephros develops at approximately 5 weeks.
> - Urine excretion starts at approximately 10 weeks.

> ### KEY POINTS
>
> - Failure to migrate up (cephalad) from the pelvic location in ectopic kidneys.
> - Pancake kidney and horseshoe kidney result from fusion of the fetal kidneys.
Figure 2.1 Stages of renal morphogenesis. Ureteric bud outgrowth from the wolffian duct is modulated by factors secreted by the metanephric blastema and the mesoderm surrounding the duct (1). Morphologic intermediates formed during nephrogenesis consist of condensation of the metanephric cap around the ureteric bud branch (2) renal vesicle comma shape (3), S shape (4), elongation of the tubule (5), invasion of blood vessels into the glomeruli, and formation of the glomerular corpuscle (6). (Modified from Chau YY, Hastie ND. The role of Wt1 in regulating mesenchyme in cancer, development, and tissue homeostasis. Trends Genet. 2012;28:515–24.)

At the earliest stage of kidney formation, the renal arteries are derived as branches of the common iliac arteries. As the metanephroi ascend, they receive branches from the distal aorta, then from the abdominal aorta. Normally, the distal branches disappear, and the abdominal branches become the permanent renal arteries. Variations in the arterial supply are common and reflect the changing nature of the arterial supply during fetal life. Although most persons have a single renal artery, approximately 25% have two to four.[3]

METANEPHRIC DEVELOPMENT

Metanephric induction occurs at 5 weeks of gestation, at a time when the ureteric bud is induced to grow out from the wolffian (mesonephric) duct and invade the metanephric blastema. The blastema is composed of a heterogeneous population of cells, including mesenchymal cells that eventually transform into epithelial, glomerular, tubular progenitors, and stromal cells that support the formation of glomerular and tubular elements.

Under the direction of growth factor–mediated signals elaborated by the metanephric mesenchyme, the ureteric bud undergoes repetitive growth and branching events, a process termed branching morphogenesis. In general, each branch divides to form two daughter branches that create generations of ureteric bud branches. In reciprocal fashion, the ureteric bud induces the mesenchyme adjacent to each bud tip to develop through a stereotypic sequence of structures consisting of mesenchymal aggregates (known as cap mesenchyme), renal vesicles, and comma-shaped and S-shaped bodies (Figure 2.1). At the distal end of the S-shaped body, a layer of epithelial cells gives rise to future podocytes. The basal aspect of these cells rests on the future glomerular basement membrane. A cleft between the podocytes becomes the glomerulus and the proximal tubule.

KEY POINTS

- Under the influence of growth factors from metanephric mesenchyme, the ureteric bud undergoes programmed and repetitive divisions or branching morphogenesis.
- Ureteric branching provides the biologic architecture for nephrogenesis.
Figure 2.2 Patterning of the kidney into a cortex and medulla. The cortex consists of nephrons with short and long tubular (Henle) loops and collecting ducts that connect to the distal tubules. The medulla consists of the tubules from long loops of Henle and collecting ducts that terminate in the papillae.

Endothelial and mesangial cells migrate into this cleft. Each branch of the ureteric bud and its daughter collecting ducts induce formation of one nephron.

The formation of 15 generations of ureteric buds and collecting ducts induces an identical number of nephrons. The remaining nephrons are formed by induction of approximately 10 nephrons around the stem of an elongating ureteric bud and collecting duct branch that are initially formed. The connecting tubules of each of these nephrons then attach to the stem of the collecting duct branch in series to form an arcade (Figure 2.2). After formation of arcades, the terminal branch of the 15th generation begins to elongate and to develop a succession of ampullae that also induce nephrons on each side of the terminal branch. During the latter stages of kidney development, tubular segments formed from the first five generations of ureteric bud branching undergo remodeling to form the pelvis and calyces.

SEQUENCING MOLECULAR EVENTS

During embryogenesis, formation of tissues is controlled by one or more morphogenetic pathways that consist of a hierarchy of control elements integrated within a circuit. An ever-expanding body of knowledge of embryonic renal development has been generated by the study of experimental models, most notably in the mouse, which has kidney development closely resembling that in humans.

Nephron development is initiated by the activity of one or more genes that control the behavior of target cells. These target cells are either those in which the genes are themselves expressed or the neighboring cells. After receiving appropriate signals, the target cells are instructed to engage in a repertoire of activities that include proliferation, programmed cell death (apoptosis), movement, shape change, or alteration in their interactions with extracellular matrices. One or more of these changes in cell behavior will influence the manner in which a particular three-dimensional structure (e.g., a collecting duct) is constructed. In turn, changes in cell behavior and structural architecture affect inducing gene expression, thereby creating a feedback mechanism.

URETERIC BUD OUTGROWTH

Outgrowth of the ureteric bud from the wolffian duct performs a critical role in nephrogenesis. Development of the ureteric bud from the wolffian duct is controlled by genes expressed in both in the wolffian duct and the metanephric blastema.[4] These genes function within a morphogenetic pathway and tightly regulate the pathways that promote or inhibit ureteric bud development and eventual nephrogenesis.

> ### KEY POINTS
>
> Key genes regulating ureteric bud growth are:
> - *Pax2*: transcription factor
> - *Eya1*: transcription factor
> - *GDNF*: growth factor
> - *RET*: the GDNF receptor

Genes expressed in the metanephric blastema that are required for ureteric bud outgrowth include the transcription factors *Pax2* and *Eya1*, the secreted growth factor glia-derived neurotrophic factor (GDNF), and RET, which is the GNDF cell surface receptor. Genes that function upstream of *Gdnf* either limit or promote its expression, thereby precisely controlling ureteric bud outgrowth. *Pax2* and *Eya1* are positive regulators of *Gdnf* and promote its expression.[5,6] Homozygous deficiency of *Pax2, Eya1, Gdnf,* or *Ret* in mice causes failure of ureteric bud outgrowth and results in bilateral renal agenesis or severe renal dysgenesis, depending on the gene involved. Identical phenotypes have also been observed in mice deficient in heparan sulfate 2-sulfotransferase, a finding demonstrating a critical role for heparan sulfate in mediating interactions between the ureteric bud and the metanephric blastema.[7]

Foxc1 (also known as *Mf1*), a forkhead/winged helix transcription factor, is expressed during embryonic development in a metanephric domain similar to that of *Gdnf*. Homozygous *Foxc1*-null mutant mice exhibit renal abnormalities consisting of ureteric duplication, hydroureter, and ectopic ureteric buds, findings suggesting that *Foxc1* negatively controls the domain of *Gdnf* expression.[8] BMP4 (bone

KEY POINTS

- BMP4, expressed in the mesenchymal cells surrounding the wolffian duct, exerts an inhibitory control by regulating the site from which the ureteric bud would emerge.
- BMP4 prevents development of ectopic ureteric bud sites from emerging.

morphogenetic protein 4) is another inhibitory gene that is expressed in the mesenchymal cells surrounding the wolffian duct. By inhibiting ectopic ureteric budding, *BMP4* regulates the site in the wolffian duct from where the ureteric bud emerges.[9] *Bmp4* heterozygous null mutant mice develop renal and ureteric abnormalities, such as hypodysplastic or dysplastic kidneys, hydroureter, ectopic ureterovesical junction, and double collecting system.[9]

During kidney development, the site of ureteric bud outgrowth is invariant, precisely positioned, and the number of outgrowths is limited to one. It is believed that outgrowth of a single ureteric bud at the appropriate position is controlled by mesenchymal factors that restrict the location of ureteric bud outgrowth (Figure 2.3). Furthermore, the site of ureteric bud outgrowth from the wolffian duct determines the final site of the ureter orifice in the bladder. A more caudal or cranial budding from the wolffian duct can lead to a defective ureterovesical valve, urinary outflow obstruction, and aberrant insertion of the ureteric bud into the metanephric mesenchyme that can result in renal dysplasia.

COLLECTING DUCT BRANCHING AND ELONGATION

The relatively fixed number and spatial pattern of collecting ducts in the mature kidney suggest that ureteric bud branching morphogenesis is tightly regulated. In mice,
Figure 2.3 Gene products that control cellular events and induction of the ureteric bud in the wolffian duct. Mesenchymal cells at the caudal end of the nephrogenic cord (light blue cell) express various factors that activate expression of glial-derived neurotrophic factor (GDNF). In addition, mesenchymal cells release gremlin-1 (GREM1), an inhibitor of bone morphogenetic protein (BMP) signaling, and other still unidentified factors. Released GDNF binds to RET and GDNF-family receptor α_1 (GFRA1) receptors that are on the epithelial cells of the mesonephric duct (wolffian duct). The combination of these signals induces ureteric budding. Mesenchymal cells at a more rostral level (dark blue cell) express forkhead box protein C1 (FOXC1), slit homologue 2 (SLIT2), and its receptor roundabout homologue 2 (ROBO2), leading to a repression of GDNF. In epithelial cells of the mesonephric duct, the tyrosine kinase inhibitor sprouty 1 *(Spry1)* suppresses RET activation. Finally, BMP4 also inhibits ureter outgrowth. EYA1, eyes-absent homologue 1; GDF11, growth differentiation factor-11; HOX11, homeobox protein 11; NPNT, nephronectin; WT1, Wilms tumor transcription factor. (From Schedl A. Renal abnormalities and their developmental origin. Nat Rev Genet. 2007;8:791–802.)

fewer ureteric bud branches are formed in the posterior than in the anterior portion of the kidney. This asymmetry is probably controlled, in part, by *Hox* genes, originally described as regulators of body segmentation in fruit flies.[10] In addition to their critical roles during ureteric bud outgrowth, GDNF and its cognate receptors stimulate ureteric bud branching. In mice, genetic deficiency of *Gdnf* and *Ret* causes decreased ureteric bud branching. RET expression is controlled by members of the retinoic acid receptor (RAR) family of transcription factors. These members, including RAR α and RAR β_2, are expressed in stromal cells surrounding *Ret*-expressing ureteric bud branch tips.[11,12] Mice deficient in these receptors exhibit a decreased number of ureteric bud branches and diminished expression of *Ret*.

KEY POINTS

- GDNF plays a critical role in ureteric bud formation, as well as branching of the bud.
- Inhibitory signals and positive gene signals are crucial for programmed ureteric bud branching and renal morphogenesis.

Two members of the fibroblast growth factor (FGF) family of signaling peptides stimulate collecting duct morphogenesis in mice. Homozygous null mutations in the *Fgf7* gene result in a reduced number of ureteric bud branches and underdevelopment of the renal papilla.[13] Mice with a homozygous null mutation in *Fgf10* also have kidneys that are smaller than those in wild-type mice and exhibit a decreased number of medullary collecting ducts, medullary dysplasia, and dilatation of the renal pelvis.[14] Thus, a repertoire of signaling pathways promotes renal branching morphogenesis.

Renal branching morphogenesis is also regulated by inhibitory signaling pathways. In mice, BMP signaling through their activin-like kinase (ALK) receptors inhibits branching morphogenesis. Targeted overexpression of ALK3 in the ureteric bud lineage decreases branching morphogenesis and is associated with decreased nephron formation.[15] Deficiency of BMPs and their signaling intermediates is associated with increased branching.[16] Thus, integration of signals from these diverse and opposing pathways by ureteric bud and collecting duct cells controls branching behavior.

Elongation of collecting ducts is noted during later stages of renal development. This is accomplished by cell divisions that are aligned with the long axis of the duct, a process termed oriented cell division. Members of the WNT family of secreted proteins, specifically WNT9b and WNT7b, are required for collecting duct elongation and formation of the medulla and papillae.[17,18] Collecting ducts deficient in WNT9b dilate during embryonic development because of loss of alignment of the mitotic spindle with the long axis

of the tubule, and they develop into large cysts postnatally. Similar abnormalities in the medulla are observed in mice lacking WNT7b.

FORMATION OF THE CALYCES AND PELVIS

Patterning of the collecting system to form the calyces and pelvis is controlled by sonic hedgehog (SHH), by members of the BMP family, and by angiotensin and its cell surface receptors. SHH is a secreted growth factor that controls cell determination and proliferation in many developmental contexts. In mice, *Shh* deficiency interferes with formation of the smooth muscle layer surrounding the upper ureter and causes dilatation of the pelvis.[19] Loss of *Bmp4* expression appears to be a pathogenetic mechanism in the genesis of hydronephrosis in these mice. Consistent with these observations, a subset of mice with spontaneous and engineered mutations in *Bmp4* and *Bmp5* demonstrates dilatation of the ureters and collecting system (ureterohydronephrosis), and ureteral bifurcation.[20,21] Mutations in the genes encoding components of the renin-angiotensin axis, best known for their role in controlling renal hemodynamics, also cause abnormalities in the development of the renal calyces and pelvis.

KEY POINT

Sonic hedgehog (SHH) and members of the BMP gene family control the patterning of the renal collecting system: the calyces and the pelvis.

Mice that are homozygous null for angiotensin receptor-1 (*Agtr1*) demonstrate atrophy of the papillae and underlying medulla.[9] The underlying defect appears to be a decrease in proliferation of the smooth muscle cell layer lining the pelvis that results in decreased thickness of this layer in the proximal ureter. Mutational inactivation of *Agtr2* results in a range of anomalies including vesicoureteral reflux (VUR), a duplex kidney, renal ectopia, ureteropelvic junction stenosis, ureterovesical junction stenosis, renal dysplasia, renal hypoplasia, multicystic dysplastic kidney (MCDK), or renal agenesis.[22] Null mice demonstrate a decreased rate of apoptosis of the cells around the ureter, a finding suggesting that *Agtr2* plays a role in modeling of the ureter. Together, these studies highlight the role of smooth muscle patterning in the formation of the pelvic-ureteric junction.

FORMATION OF GLOMERULAR AND TUBULAR PRECURSORS

The development of metanephric derivatives begins when the blastema is rescued from apoptosis and is induced to

proliferate coincident with the invasion of the ureteric bud. Expression of the Wilms Tumor 1 *(Wt1)* gene product, a transcription factor, is critical in maintaining viability of the metanephric blastema at this early stage of development.[23] With the invasion of the ureteric bud, the blastemal cells differentiate along distinct pathways. Cells adjacent to the ureteric bud tips aggregate and begin to display morphologic and molecular features characteristic of nephron epithelial cells, a process termed mesenchymal to epithelial transformation (MET). Other metanephric mesenchyme cells, which are stromal cells, give rise to endothelial and mesangial cells and interstitial fibroblasts.

KEY POINT

Morphologic and molecular transformation of mesenchymal cells adjacent to the ureteric bud into various epithelial components of the glomeruli is termed mesenchymal-to-epithelial transformation (MET).

MAINTAINING PROGENITOR CELL POOL

A pool of self-renewing progenitor cells gives rise to nephrons and controls transformation of metanephric mesenchyme cells into cells with specific differentiated characteristics. The molecular mechanisms that control maintenance of this pool are being defined at an ever-increasing level of detail. Before and after invasion of the metanephric mesenchyme by the ureteric bud cells, expression of genes including *Wt1, Fgf8* and its cognate receptors, and *Bmp7* is required to maintain cell viability.[23–25] In the absence of these gene products, metanephric mesenchyme cells undergo apoptosis, and very few, if any, nephrons form.

The cells that can take part in the formation of any nephron progenitor structure—glomerulus, proximal tubule, and distal tubule—are marked by expression of *Six2,* a transcription factor. SIX2-positive cells are then further specified to become differentiated cells in proximal or distal nephron segments. Analysis of gene expression in these segments has identified a large number of genes, the expression of which is restricted to either segment.[26,27] Some of these genes are functionally required to define the identity of these segments. For example, distal segments require the expression of *Brn1,* a transcription factor.[28] In contrast, expression of *Lhx1* and NOTCH family members is required for establishment of the proximal tubule.[29,30]

PODOCYTE AND ENDOTHELIAL DIFFERENTIATION

Several classes of genes are required for formatting podocytes and for directing the migration of endothelial cells into the glomerulus. As nephrogenesis proceeds, *Wt1* expression becomes restricted to the podocyte lineage. Transcription of *Wt1* results in the formation of multiple isoforms generated by alternative splicing. Mutations in *Wt1* that prevent the generation of certain splice forms result in formation of abnormal glomeruli, thereby implicating *Wt1* in glomerulogenesis.[31] *Lmx1b* is a transcription factor mutated in patients with nail-patella syndrome and is expressed in podocytes.[32] Mutational inactivation in mice decreases formation of foot processes and decreases expression of the α_3 and α_4 chains of type IV collagen. *Pod1* is a basic helix-loop-helix class transcription factor that is expressed in podocytes in S-shaped bodies. *Pod1* deficiency in mice results in arrest at the single capillary loop stage of glomerular development.[33]

KEY POINTS

- Podocyte and vascular endothelium formation in the glomeruli is controlled by multiple genes.
- The *Wt1* gene plays an important role in glomerulogenesis.

Kreisler (MafB), a leucine zipper class transcription factor, is expressed in podocytes. *Kreisler* deficiency in mice results in failure of foot process attachment to the basement membrane.[34] The α_3 chain of $\alpha_3\beta_1$ integrin is required for formation of foot processes in mice.[35] Podocalyxin is a sulfated cell surface sialomucin that is expressed on the surface of podocytes. In a podocalyxin-deficient state, foot process and slit diaphragm assembly is abrogated.[36] Podocyte-derived vascular endothelial growth factor A (VEGF-A) and Notch 2 play central roles in directing endothelial cell migration into glomeruli. Inactivation of VEGF-A in podocytes by genetic means in mice disrupts glomerular capillary formation.[37] Similarly, inactivation of *Notch2,* a member of a family of cell determination genes, results in a similar phenotype.[38]

GENE FUNCTIONS AND DEVELOPMENTAL RENAL DISORDERS

The human and mouse genome projects have been complementary in generating a rapid expansion of our knowledge of human developmental biology. Although the diversity of human phenotypes projects existence of more than 80 loci associated with renal dysplasia, to date mutations in a much smaller number of genes have been implicated in pathogenesis.[39] The functions of a subset of these genes have been elucidated in genetic mouse models that provide critical insights into the molecular control of normal and abnormal renal development (Table 2.1). Some of the disorders described here are also discussed in Chapters 1 and 46.

Table 2.1 Human gene mutations exhibiting defects in renal morphogenesis

Primary disease	Gene	Kidney phenotype	References
Alagille syndrome	JAGGED1	Cystic dysplasia	49
Apert syndrome	FGFR2	Hydronephrosis	50
Beckwith-Wiedemann syndrome	p57KIP2	Medullary dysplasia	51
Branchio-oto-renal (BOR) syndrome	EYA1	Unilateral or bilateral agenesis or dysplasia, hypoplasia, collecting system abnormalities	52
Campomelic dysplasia	SOX9	Dysplasia, hydronephrosis	53
Fraser syndrome	FRAS1	Agenesis, dysplasia	54
Hyoparathyroidism, sensorineural deafness, and renal anomalies (HDR) syndrome	GATA3	Dysplasia	55
Kallmann syndrome	KAL1	Agenesis	56
Mammary-ulnar syndrome	TBX3	Dysplasia	57
Meckel Gruber syndrome	MKS1 MKS3 NPHP6 NPHP8	Cystic dysplasia	58
Nephronophthisis	CEP290, GLIS2, RPGRIP1L,NEK8, SDCCAG8,TMEM67, TTC21B	Cystic dysplasia	59
Okihiro syndrome	SALL4	Unilateral agenesis, VUR, malrotation, cross fused ectopia	60
Pallister Hall syndrome	GLI3	Agenesis, dysplasia, hydronephrosis	61
Renal coloboma syndrome	PAX2	Hypoplasia, VUR	62
Renal hypodysplasia, isolated	TCF2, PAX2, EYA1, SIX1, SIX2, SALL1, RET, BMP4, DSTYK	Hypoplasia, VUR	63–67
Renal tubular dysgenesis	Renin, angiotensinogen, ACE, AT1 receptor	Tubular dysgenesis	68
Rubinstein-Taybi syndrome	CREBBP	Agenesis, hypoplasia	69
Simpson-Golabi-Behmel syndrome	GPC3	Medullary dysplasia	70
Smith-Lemli-Opitz syndrome	DHCR7	Hypoplasia, cysts, aplasia	71
Townes-Brock syndrome	SALL1	Hypodysplasia, VUR	72
Zellweger syndrome	PEX1	Cystic dysplasia	73

ACE, angiotensin-converting enzyme; AT1 receptor, angiotensin I receptor; VUR, vesicoureteral reflux.

PAX2

Heterozygous mutations in *PAX2* are found in patients with the renal coloboma syndrome (Online Mendelian Inheritance in Man [OMIM] 120330) that is characterized by renal hypoplasia and VUR. Heterozygous *Pax2* mutations in mice result in a similar phenotype.[40] Investigation of *Pax2* suggests that it functions in the ureteric bud to promote cell proliferation and inhibit apoptosis.[41] These results support a model that proposes that *Pax2* controls the number of ureteric bud branches, thereby determining the number of nephrons formed.

EYA1

EYA1, a transcription factor, is mutated in patients with branchio-oto-renal (BOR) syndrome (OMIM 113650) and

with unilateral or bilateral renal agenesis, or dysplasia.[42] In mice, the spatial pattern of *Eya1* expression overlaps that of *Gdnf* at the time of ureteric bud outgrowth. Because biallelic inactivation of *Eya1* causes renal agenesis and abrogates *Gdnf* expression, *Eya1* is thought to function upstream of *Gdnf* to control ureteric bud outgrowth.

SALL1

SALL1, a transcription factor, is expressed in the metanephric mesenchyme at the time of induction by the ureteric bud. Mutations in *SALL1* exist in patients with Townes-Brock syndrome (OMIM 107480). In *Sall1*-deficient mice, ureteric bud outgrowth occurs, but the bud fails to invade the metanephric blastema, with resulting renal agenesis. This failure

of invasion appears to be caused by a *Sall1*-dependent signal rather than the competence of the metanephric blastema to undergo induction.[43]

GLI3

The gene encoding GLI3 is mutated in patients with Pallister-Hall syndrome (OMIM 146510) and renal dysplasia. GLI3 is one member among a family of GLI proteins that control gene transcription. Their actions are controlled by SHH. All *GLI3* mutations identified to date result in the expression of a truncated protein that functions as a transcriptional repressor. Investigations in mice provide insight into the biologic significance of this repressor form of GLI3. During inductive stages of kidney development, GLI3 repressor represses the transcription of GLI1 and GLI2, renal patterning genes including *Pax2* and *Sall1,* and genes that modulate the cell cycle (cyclin D1 and N-Myc), resulting in renal aplasia or severe dysplasia.[44] During later stages of renal development, GLI3 repressor plays cell lineage-specific roles; it is required for ureteric branching but abrogates coordinated contraction of the ureter by deleterious effects on renal pacemaker cells.[45,46]

Glypican-3 and p57^{KIP2}

Investigation of the genes mutant in two human overgrowth syndromes, Simpson–Golabi–Behmel syndrome (OMIM 312870) and Beckwith-Wiedemann syndrome (OMIM 13650), provides novel insight into the pathogenesis of medullary renal dysplasia. Patients with Simpson–Golabi–Behmel syndrome have mutations in glypican-3, a glycosyl-phosphotidylinositol (GPI)–linked cell surface heparan sulfate proteoglycan. The pathogenesis of renal medullary dysplasia in *Gpc3*-deficient mice involves massive medullary collecting duct apoptosis preceded by increased ureteric bud proliferation.[47] Thus, *Gpc3* controls collecting duct cell number and survival. A role for control of the cell cycle in the pathogenesis of medullary renal dysplasia is further supported by the finding of medullary renal dysplasia in mice and humans (Beckwith-Wiedemann syndrome) with inactivating mutations in *p57*^{KIP2}, a cell cycle regulatory gene that encodes a cyclin-dependent kinase inhibitor.[48]

Table 2.1 lists clinical syndromes that feature renal anomalies and genes associated with these syndromes.[49–73] Identification of genes such as these has provided a basis for screening children with sporadic cases of renal hypodysplasia.[63,64,67,74,75] These investigations have identified mutations in genes including *TCF2, PAX2, EYA1, SIX1, SIX2, SALL1, RET, BMP4, and DSTYK.* Remarkably, mutations in genes previously identified in the context of a particular clinical syndrome have also been identified in patients with no evidence of that syndrome, other than the presence of a renal malformation.

Advances in genetics have generated a revolution in our understanding of congenital malformations of the kidney. Although it has been accepted that an association exists among poorly developed kidneys, renal dysfunction, and urologic abnormalities, a generation ago it was widely held that some sort of obstructive process led to maldevelopment. The discovery of these genetic relationships has led to an understanding that maldevelopment results from failure of programmed genetic control, with the likelihood that VUR and urinary tract obstruction stem from the same failure. As a result, we have come to understand that such disorders may demonstrate familial predisposition that can have clinical relevance.

The three categories of developmental abnormalities that can occur, separately or in concert, are renal hypoplasia, renal dysplasia, and abnormal development of the lower urinary tract.

HYPOPLASIA

Renal hypoplasia is characterized by a smaller than normal complement of nephrons in the kidney. The nephron structure and the overall renal architecture are well maintained. Hypoplasia can affect one or both kidneys. In hypoplasia, an abnormality in epithelial-mesenchymal interactions leads to decreased or abnormal branching of the ureter. Unless it is associated with other malformations, renal hypoplasia can be asymptomatic. Hypoplasia is often discovered as an incidental finding during an abdominal sonogram or other imaging studies, in which a smaller than normal kidney is detected. Decreased renal function and chronic kidney disease can be seen in patients with severe cases with bilateral disease. Renal hypoplasia has been reported to be a predisposing condition for hypertension later in life.[2]

MULTICYSTIC DYSPLASTIC KIDNEY

MCDK is reported to be the second most common renal anomaly diagnosed by prenatal ultrasound examination, with a reported prevalence of 1 in 3640 births.[76] MCDK can manifest as a flank mass in newborn infants. Renal ultrasound evaluation shows a large, cystic, nonreniform structure located in the renal fossa. The characteristic and diagnostic finding is absence of any function demonstrated by radionuclide scans. VUR in the contralateral normal kidney is the most common associated urinary tract abnormality and has been reported in approximately 25% of cases.[77] Hypertension can be seen some patients but appears to be less common than previously assumed.[77] Wilms tumor has been reported in patients with MCDK. It has been argued that these cases of apparent malignant degeneration in MCDK may actually result from nephrogenic rests.

Gradual reduction in renal size and eventual resolution of the mass of the MCDK are common. At 2 years, an involution in size by ultrasound examination has been noted in up to 60% of the affected kidneys.[78] Complete disappearance of the MCDK can occur in a minority of patients (3% to 4%) by the time of birth and in 20% to 25% by 2 years. Increase in the size of MCDK can be seen in some cases. The contralateral kidney shows compensatory hypertrophy by ultrasound evaluation.

Management of patients with MCDK has shifted from routine nephrectomy in the past to observation and medical therapy. Because of the risk of associated anomalies in the contralateral kidney, the possibility of VUR should be considered, and clinical follow-up for evolution of hypertension is advised. Renal ultrasound is generally recommended at an interval of 3 months for the first year of life and then every 6 months up to involution of the mass, or at least for up to 5 years. Compensatory hypertrophy of the contralateral kidney is expected and should be followed on ultrasound evaluations. Medical therapy is usually effective in treating hypertension in most patients, but nephrectomy may be curative in resistant cases.

RENAL DYSPLASIA

Renal dysplasia is characterized by the presence of malformed and disorganized tissue elements, a decreased number of nephrons, collecting ducts surrounded by muscular rings (Figure 2.4), and elements of aberrant development, such as cartilage, or even calcified tissue. Often, dysplasia is accompanied by hypoplasia of the kidney as well. Abnormalities of renal function and development of chronic kidney disease should be expected in patients with severe bilateral renal dysplasia or those with additional urinary tract malformations, such as obstruction. Potter syndrome, which is characterized by oligohydramnios, pulmonary hypoplasia, renal failure, low-set ears, and a beaked nose, may be observed in patients with severe cases of renal dysplasia.
Figure 2.4 Renal dysplasia. **(a)** A cut section of dysplastic kidney with malformed collecting system, lack of well-patterned renal parenchyma, and absence of corticomedullary differentiation. **(b)** Microscopic section of the kidney from the patient demonstrating malformed tubules. Some tubules are widely dilated (T). Arrows show cartilage within the renal parenchyma. (Figure courtesy of Arthur Cohen, MD.)

SUMMARY

This chapter summarizes the major morphologic features of the developing and mature kidney. The concept of morphogenetic pathways is presented as a means to understand how genes control cellular events that, in turn, build three-dimensional structures. Genetic pathways that control normal renal branching morphogenesis are assuming an important role in understanding nephrogenesis and are likely to be explored in detail. An understanding of genetic mutations associated with renal hypoplasia and dysplasia has begun to appear, and it provides a link to the congenital abnormalities of the kidney and urinary tract (CAKUT) malformations complex. An understanding of the genetics of renal development also highlights the close developmental path that the urinary tract and the kidneys take in their mutual organogenesis. All these discoveries provide a window into our understanding of the pathogenic role played by genetic mutations in clinical disorders of the kidney and the urinary tract encountered by pediatric nephrologists.

REVIEW QUESTIONS

1. Metanephric induction begins at:
   a. Week 7 of gestation
   b. Week 10 of gestation
   c. Week 5 of gestation
   d. Week 20 of gestation
2. Renal dysplasia is characterized by a decreased number of nephrons, the presence of collecting ducts surrounded by muscular rings, and elements of aberrant development, such as cartilage, or even calcified tissue.
   a. True
   b. False
3. Branchio-oto-renal (BOR) syndrome results from mutation of:
   a. *PAX2*
   b. *PEX1*
   c. *SOX9*
   d. *EYA1*
4. The most common urinary tract abnormality associated with multicystic dysplastic kidney (MCDK) is:
   a. Duplication of the collecting system
   b. Vesicoureteric reflux
   c. Posterior urethral valves
   d. Wilms tumor
5. During renal development, the *WTI* gene is important in:
   a. Glomerulogenesis
   b. Tubulogenesis
   c. Formation of the renal pelvis
   d. Renal ascent
6. BMP4, expressed in the mesenchymal cells surrounding the wolffian duct, exerts a positive control in directing the site from which ureteric bud would emerge.
   a. True
   b. False
7. Patterning of the renal collecting system (renal pelvis and calyces) is controlled by:
   a. Sonic hedgehog (SHH) and BMP gene family
   b. Renin, angiotensinogen genes
   c. *JAGGED1* gene
   d. *SIX1* and *SIX2* genes
8. The characteristic renal phenotype in Alagille syndrome consists of:
   a. Renal dysplasia
   b. Renal aplasia
   c. Multicystic dysplastic kidney
   d. Hypoplasia

Diagnostic evaluation of kidney diseases

3

Urinalysis

GEORGE J. SCHWARTZ

Urinalysis provides a window into the function and some inflammatory pathologic processes in the kidneys. A carefully conducted urinalysis can reveal underlying renal and systemic disorders. Evaluation of urine has been recorded since ancient times and was commonly practiced by Roman and Greek physicians.[1] Uroscopy (also known as urinoscopy), or visual examination of urine, eventually evolved as a formal science among English and Italian physicians during the Renaissance. The next major contribution to the technique of urinalysis was made by Thomas Addis, who developed the method for quantifying urinary excretion of red blood cells (RBCs) in the diagnosis and prognosis of Bright disease.[2] The science of urinalysis has further evolved in the last several decades, especially with the advent of the dipstick technology, wherein a fairly precise chemical analysis of urine can be ascertained within a few minutes by the bedside or in the clinic facility. This chapter will discuss the urinalysis procedure and its diagnostic utility in nephrology.

URINE SAMPLE COLLECTION

In general, the most reproducible urine specimen for urinalysis is the one obtained on waking from sleep, because it is not influenced by exercise and can assess urinary concentration after withholding fluid overnight. It is often recommended that parents bring in the first morning urine from home when a child has difficulty urinating on command.

In absence of toilet training, younger children should have urine collected in a plastic bag device attached to the perineum. A patient identifier label should be affixed to the urine container before being handed over to the patient for collection. The container for urinalysis need not be sterile, but it should be clean. In adults, second morning urine is sometimes preferable to the first morning urine sample because of convenience and also because of concern that cellular elements in the urine may undergo autolysis in the bladder overnight.[3]

PRINCIPLES OF EVALUATION

Collected urine should be evaluated quickly, no later than 2 hours after collection. Routine urinalysis consists of the following three evaluation steps: (1) appearance of the collected urine, (2) chemical analysis, and (3) microscopy of the urine sediment.[4]

KEY POINTS

- Only a freshly collected urine sample should be used for urinalysis.
- Automated dipstick-based methodologies for chemical analysis have increased the range of tests that can be conducted with a few drops of urine.

In most clinical laboratories the chemical analysis of urine is done with the help of urine test strips, also known as dipsticks. Early versions of this technology were limited to detection of urine glucose and albumin, but current versions are able to test for urine pH, specific gravity, protein, blood, glucose, ketones, urobilinogen, nitrite, and leukocyte esterase. Change of color of the individual test strips after they have been moistened by the urine is used to determine the test results. To automate the urinalysis and standardize the results, several devices are available for clinical use, especially for point-of-care testing.

APPEARANCE AND CONSTITUENTS

Urine samples should be grossly examined and then routinely tested for pH, specific gravity, protein, blood, glucose, and nitrites using commercially available dipsticks.

APPEARANCE

Fresh urine generally ranges from pale yellow to deep amber. The color of urine may provide clues to some of the underlying renal and nonrenal disorders (Table 3.1). Red discoloration may be caused by the presence of blood (hematuria), hemoglobin (hemoglobinuria), or myoglobin (myoglobinuria). RBCs are seen only in the urinary sediment of patients with hematuria. Urinary bleeding from the bladder or other parts of the collecting system (urologic hematuria) tends to color the urine pink or red, whereas glomerular bleeding appears rusty brown or the color of cola or tea (Figure 3.1). Red urine also may be seen in patients with porphyrias, as well as after intake of beets, certain food additives, or some drugs.

The urine is usually clear but may be turbid because of the precipitation of phosphates in alkaline urine or uric acid in acid urine, especially on chilling. The presence of leukocytes in the urine also can render the urine cloudy.

ODOR

The normal odor of urine is mildly aromatic. Bacterial infection may lead to a fetid or ammonia odor. Some disorders of metabolism cause particular odors in the urine. In maple syrup urine, the urine smells like burnt sugar or maple syrup; in phenylketonuria the urine smells musty;

Table 3.1 Causes of abnormal urine color

Pathologic Causes	Physiologic, foods, drugs
Red-Burgundy-Pink	**Red-Burgundy-Pink**
• Menstrual contamination	• Beets
• Gross hematuria	• Blackberries
• Papillary necrosis (often with clots)	• Urates
• Hemoglobinuria, hemolysis	• Pyridium
• Myoglobinuria	• Phenolphthalein
• Porphyria	• Anthocyanin
• *Serratia marcescens* infection	• Rhodamine B
	• Aminopyrine
Dark Brown or Black	• Phenytoin sodium
• Homogentisic aciduria	• Azo dyes
• Alkaptonuria	
• Methemoglobinemia	**Dark Brown or Black**
• Melanin	• Senna
• Tyrosinosis	• Cascara
	• Aniline
Blue-Green	• Hydroxyquinone
• Obstructive jaundice	• Resorcinol
• Hepatitis	• Thymol
• Blue diaper syndrome (intestinal tryptophan transport defect)	**Blue-Green**
• *Pseudomonas* infections	• Carotene
• Phenol poisoning	• Chlorophyll
Cloudy-Milky	• Riboflavin
• Urinary tract infection	• Methylene blue
• Urates, uric acid (acid pH)	• Indigo-carmine
• Calculi, "gravel" (phosphates, oxalates)	• Resorcinol
• Chyluria	• Tetrahydronaphthalene
• Nephrotic syndrome	• Methocarbamol
• Radiographic dye (acid pH	
Figure 3.1 **(a)** Visible hematuria in a patient with post-streptococcal glomerulonephritis. The urine is dark coke-colored (glomerular hematuria). **(b)** Visible hematuria in a patient during passage of renal stone showing light pinkish urine color (urologic hematuria).

cystinuria and homocystinuria have sulfur-like odor; and tyrosinemia has an odor similar to that of fish or cabbage.

PH

Urine pH normally ranges from 4.5 to 8, depending on the acid-base balance, metabolic state, and dietary habits. In general, vegetarians may have a more alkaline urine pH and a high-protein meal may cause the urine pH to be more acidic. Freshly voided urine should be examined for determining pH, because loss of carbon dioxide to air will falsely alkalinize the pH. Bacterial contamination also may change the baseline pH, depending on the metabolism of the particular organism. This dipstick determination of pH is adequate for routine testing, but if a precise urine pH value is to be obtained, it can be done using a pH meter in the laboratory.

SPECIFIC GRAVITY AND OSMOLALITY

Urine osmolality is the key indicator of urinary concentration and is maximal after an overnight thirst (greater than 870 mOsm/kg in children younger than 2 years).[5] Urine osmolality is a function of the concentration of solutes present in the urine. Determination of the urine specific gravity and osmolality in a urine sample obtained after overnight thirsting can be a useful screening test for the diagnosis of diabetes insipidus. Apart from central and nephrogenic diabetes insipidus, urine specific gravity and osmolality may be decreased in renal insufficiency. Presence of protein, glucose, and osmotic contrast agents may increase urine specific gravity. In these cases, osmolality is the preferred measurement to assess urinary concentration ability.

Urine osmolality is not routinely measured in most clinical laboratories, but it can be approximated from the specific gravity according to the following formula[5]:

$$\text{Osmolality} = (\text{Specific gravity} - 1.000) \times 40{,}000$$

PROTEIN

Proteinuria is an important indicator of renal disease. Normally, the glomerulus restricts the filtration of proteins based on size and charge. Most proteins that are filtered are reabsorbed by endocytosis of the proximal tubule, and less than 10 mg/dL is found in normal urine. Most of these are low-molecular-weight proteins filtered at the glomerulus. Tamm-Horsfall protein (uromodulin) is a tubular glycoprotein normally secreted by the thick ascending limb of the loop of Henle and forms the matrix of urinary casts.[6]

Quantification of proteinuria

DIPSTICK TEST

The urinary dipstick examination for proteinuria is a convenient method for detection of proteinuria. This method is able to provide a semiquantitative estimate of the degree of proteinuria. The test is affected by the urinary concentration and pH level. Concentrated urine may give a positive reading even when the daily protein excretion is normal, whereas a dilute urine may result in a negative or only slightly positive reading, even in the presence of elevated daily protein excretion. False-positive results also may occur if the urine is highly alkaline; false-negative results can be seen in the presence of ingestion of large doses of ascorbic acid.

KEY POINTS

- First morning urine sample is preferred to quantify baseline proteinuria and establish the diagnosis of orthostatic proteinuria in children.
- Dipsticks are more specific for urinary albumin and are unable to detect globulin or Bence-Jones proteinuria.
- Very alkaline urine can give a false-positive dipstick test for protein.

SULFOSALICYLIC ACID TEST

Proteinuria also can be detected by using 10% sulfosalicylic acid, which precipitates urinary protein (Table 3.2). This semiquantitative assessment of the urine's turbidity correlates well with total urinary protein, including albumin. The sulfosalicylic acid test is not affected by urine pH or the presence of ascorbic acid.

KEY POINTS

Proteinuria can be quantified by:

- Dipstick (semiquantitative)
- 24-Hour urine collection
- Ratio of urine protein to urine creatinine

Table 3.2 Semiquantitative estimation of proteinuria using the sulfosalicylic acid precipitation test and the dipsticks

Sulfosalicylic acid			
Degree of turbidity		Protein (mg/dL)	Dipstick equivalent
No turbidity	Negative	No protein	Negative
Slight turbidity	Trace	1–20	Trace
Turbid (newsprint visible)	1+	30	1+
White cloud (heavy lines visible)	2+	100	2+
Fine precipitate (heavy lines invisible)	3+	300	3+
Flocculent precipitate (like yogurt)	4+	>500	4+ (2000 mg/dL)

Note: Sulfosalicylic acid test is conducted by adding 10 drops of 10% sulfosalicylic acid to 10 mL of urine. Sulfosalicylic acid detects all urinary proteins, including albumin. A dipstick test is more specific for albumin and does not detect globulins or tubular proteins.

Timed collection

The gold standard of urinary protein quantitation is the quantitative measurement of protein in a carefully timed urine collection, usually over 24 hours. Normal value for 24-hour urine protein excretion is less than 100 mg/m^2/day, and nephrotic range proteinuria exceeds 1000 mg/m^2/day, or 40 mg/m^2/h.[7] Calculation of the creatinine excretion index in the collected urine is often employed by nephrologists to judge completeness of the collected 24-hour urine sample. The creatinine excretion index, or creatinine excretion per kilogram of body weight (total urinary creatinine ÷ patient's weight), should be 15 to 20 mg/kg/24 h for the urine collection to be considered adequate.

Protein-to-creatinine ratio

Because of the difficulty in collecting timed urine samples in children, spot urine protein and creatinine estimation is preferred in children and also has been endorsed by the Kidney Disease Outcomes Quality Initiative (KDOQI) clinical practice guidelines.[8] The urine protein-to-creatinine (mg/mg) ratio correlates well with the 24-hour urine protein excretion.[9-13] Normal value for urinary protein-to-creatinine ratio is less than 0.2, but is slightly higher in younger children (Table 3.3). Proteinuria is considered to be of nephrotic range if the protein-to-creatinine ratio exceeds 2.0.[9,10] An approximate value of 24-hour urine protein excretion can

Table 3.3 Urinary protein-to-creatinine ratios showing age-related 95th percentiles

Age (years)	Protein (mg/mg creatinine)
<2	0.492
2–13	0.178
>13	0.178

Source: Data from Houser MJ. Assessment of proteinuria using random urine samples. J Pediatr. 1984;104:845.

be calculated from urine protein and creatinine obtained in a spot sample and using the following formula[11]:

$$\text{24-Hour urinary protein excretion} = \text{Urine protein/urine creatinine} \times 0.63 \; (mg/m^2/day)$$

MICROALBUMINURIA

Microalbuminuria (also known as albuminuria), is used to screen children with diabetes of 5 years or longer of duration and is usually expressed as an albumin-to-creatinine ratio (ACR). Normal ACR is less than 30 mg/g creatinine.[14,15] Urine collections of 24 hours are not necessary in most children, and a spot urine sample estimation is sufficient for screening purposes. Orthostatic proteinuria in children can affect the quantification of ACR; therefore, estimation using the first morning urine sample is recommended.

KEY POINTS

- In patients with diabetes, urine ACR estimation is used to detect early manifestations of diabetic nephropathy.
- First morning urine should be used for measuring the ACR ratio in children with diabetes.
- Normal ACR is less than 30 mg/g of creatinine.

BLOOD

Dipsticks detect the presence of hemoglobin in the urine. The reaction relies on the peroxidase-like activity of hemoglobin to catalyze the reaction of a hydroperoxide with tetramethylbenzidine to give a green-blue color. Myoglobin also will give a positive reaction with the dipsticks. Therefore, a positive dipstick test for blood may be the result of hematuria, hemoglobinuria (intravascular hemolysis), or myoglobinuria (muscle injury or disease). Identification of RBCs on urine microscopy establishes the diagnosis of hematuria, and lack of RBCs suggests hemoglobinuria or myoglobinuria. Differentiation between hemoglobinuria and myoglobinuria can be accomplished

using immunochemical methods. A negative dipstick test rules out hematuria.

KEY POINTS

A positive test for blood may result from:

- Hematuria
- Myoglobinuria
- Hemoglobinuria

GLUCOSE

Dipstick detection of glucose is based on the oxidation of glucose by glucose oxidase. False-negative results occur if there are large quantities of reducing agents, such as vitamin C, tetracyclines, or homogentisic acid in the urine. False-positive results have not been reported. Glycosuria is seen in patients with diabetes mellitus and those with proximal tubular disorders, such as Fanconi syndrome. Renal glycosuria is an isolated proximal tubular defect of glucose reabsorption and is distinguished from diabetes mellitus by a normal simultaneously obtained serum glucose level and a normal hemoglobin A1C level. Abnormalities in SGLT2, a critical tubular glucose transporter located in the S1 segment of the proximal tubule, has been demonstrated to be associated with familial renal glycosuria.[16]

KEY POINTS

Glucosuria with a normal simultaneously drawn serum glucose level can be the result of:

- Renal glycosuria
- Fanconi syndrome

NITRITE

More than 90% of common urinary pathogens are nitrite-forming bacteria that convert urinary nitrate to nitrite with the help of the enzyme nitrate reductase. Nitrite can be detected in urine using a dipstick containing *p*-arsanilic acid, which reacts with nitrite to generate a diazonium compound that is then converted to 3-hydroxy-1,2,3,4-tetrahydrobenzo-quinolin-3-ol to produce a pink azo dye. Bacteria must be in contact with urine for 2 to 4 hours to allow nitrate conversion to nitrite and result in a positive test. Patients who have urinary frequency associated with the urinary tract infection (UTI) may not allow sufficient bacterial contact time, resulting in a false-negative urine test for nitrite. It is also important to point out that the nitrite test is not able to detect UTIs secondary to *Staphylococcus saprophyticus, Pseudomonas*

species or enterococci, all of which lack the enzyme nitrate reductase and are unable to convert nitrate to nitrite.[17] A false-positive reading will occur if bacterial overgrowth is allowed to occur during inappropriate transport of the urine to the laboratory. False-negative results occur in the presence of ascorbic acid. The nitrite test for UTI is highly specific, but its sensitivity is low. Meta-analysis of pediatric studies demonstrated that the specificity of nitrite test was 98% (96% to 99%) and sensitivity was 49% (41% to 57%).[18]

KEY POINTS

- The nitrite test cannot detect infections caused by organisms that do not produce the nitrate reductase.
- Bacterial contact with urine needs to be at least 2 to 4 hours (in the bladder) for the nitrite test to be positive.
- The nitrite test has high specificity (98%) but low sensitivity (50%).

LEUKOCYTE ESTERASE

Leukocyte esterase (LE) has been incorporated into the routine dipstick evaluation of urine for almost a decade. The LE test is a colorimetric test that detects the presence of esterase produced by the polymorphonuclear leukocytes in the urine and is therefore used for the diagnosis of UTI. False-positive results may be seen in contamination of urine with vaginal secretions, tubulointerstitial nephritis, and severe glomerulonephritis. False-negative LE test results can be caused by high urinary protein concentration (nephrotic syndrome) and high urinary ascorbic acid level. Combining the LE and nitrite tests offers a better sensitivity and specificity profile than either of them separately. In a meta-analysis of pediatric studies, the LE test or nitrite-positive dipstick had a specificity of 88% (82% to 91%) and sensitivity of 79% (69% to 87%).[18]

MICROSCOPIC ANALYSIS

Microscopic examination of the urine is used semiquantitatively to confirm the presence of RBCs, cellular casts, crystals, and bacteria. Urine for microscopy should be freshly obtained, because stored samples are prone to developing autolysis of the cells and casts, rendering the evaluation inaccurate.

KEY POINTS

- Freshly obtained urine samples should be used for microscopy.
- Stored or frozen samples result in disruption of cellular elements.

Technique

The Clinical and Laboratory Standards Institute recommends that each laboratory should standardize the urine microscopy procedure. A standard urine volume (10, 12, or 15 mL) should be spun for a standard time of 5 minutes.[19] The centrifuge speed should be such as to achieve a relative centrifugal force (RCF) of approximately 400. To calculate RCF from rotations per minute (RPM) for a specific centrifuge, following formula should be used:

$$RCF (g) = 1.18 \times 10^{-5} \times Radius (cm) \times RPM^2$$

After centrifugation, the supernatant is decanted, and the pellet resuspended in the remaining 0.25 to 0.5 mL of urine (Figure 3.2). The sediment is gently resuspended in urine by tapping the pellet in the centrifuge tube, and is then examined under low-power ($10 \times 10 = 100 \times$) and high-power ($10 \times 40 = 400 \times$) microscopy. An examination of five random fields at $40 \times$ throughout the slide permits assessment of the number of

KEY POINTS

- Urine should be centrifuged at standardized speeds for 5 minutes.
- Unstained specimens provide adequate information for most clinical purposes.
- Staining the urine sediment may be indicated to identify some cellular elements.

Supernatant
Pellet

Figure 3.2 Centrifuged urine in a conical tube in a patient with visible hematuria showing the pellet of red blood cells at the bottom and the clear supernatant.

cells per high-power field (hpf). Urinary microscopy is generally performed in unstained urinary sediment slides. If a detailed analysis and identification of white blood cells (WBCs) is necessary (e.g., identification of eosinophils in interstitial nephritis), the sediment may be stained by Sternheimer-Malbin stain (Sedi-Stain, Becton, Dickinson, Franklin Lakes, NJ).

Red blood cells

In healthy children the normal upper limit for the number of RBCs in fresh midstream urine is 2 to 4 per hpf. The morphology of the RBCs should be reviewed in high power to distinguish between glomerular and nonglomerular hematuria. Dysmorphic RBCs with a large variation in size and shape, cell wall blebs, and distribution of hemoglobin content are more likely to be seen with glomerulonephritis (Figure 3.3).[20] The dysmorphic RBCs with a doughnut shape or with one or more blebs are also known as G1 cells. Eumorphic or normal RBCs are observed in nonglomerular urinary bleeding secondary to stones, hypercalciuria, and trauma.[21,22] At times, glomerular hematuria also can have a mixture of eumorphic and dysmorphic RBCs. The value of erythrocyte morphology in the diagnosis of glomerular disease in patients with persistent isolated hematuria was evaluated by Fogazzi et al.[23] In 16 such patients (10 children and 6 adults) classified as having glomerular hematuria, a renal biopsy showed glomerular disease in 14 of the 16 patients (87.5%).

White blood cells

In healthy children, the upper limit of normal for the number of WBCs in fresh midstream urine is 0 to 4 per hpf, with most of these being neutrophils. Neutrophils are recognizable by the presence of a multilobed nucleus and granular cytoplasm. In UTIs, neutrophils are the dominant type of WBCs noted in the urinary sediment and lymphocytes may be present in large numbers in urine during acute renal transplant rejection. Although eosinophils in the urinary sediment (eosinophiluria) can be seen in allergic interstitial nephritis, they are not pathognomonic of this disorder and can be seen in other inflammatory lesions of the kidneys and the urinary tract.[24]

Renal epithelial cells

Epithelial cells found in urine can come from the renal tubules, collecting system, or bladder, each with distinctive morphologic characteristics. Renal tubular epithelial (RTE) cells are only slightly larger than white cells and have a large central nucleus (Figure 3.4). These are normally present in small numbers in the urinary sediment, but an excessive number may be seen in acute kidney injury (AKI) and acute
Figure 3.3 **(a)** Crenated red blood cells (RBCs) seen in concentrated (hypertonic) urine. These cells are isomorphic RBCs that are deformed in a hypertonic urine (intracellular dehydration). They do not represent glomerular hematuria. **(b)** Dysmorphic RBCs showing margination of hemoglobin and formation of "doughnut-shaped RBCs." **(c and d)** Acanthocytes or G1 cells (RBCs) in glomerular hematuria with cytoplasmic blebs (Mickey Mouse RBCs). Arrows point to the various types of dysmorphic cells in the urinary sediment. ([a] and [c] reproduced with permission from: Fogazzi GB, Verdesca S, Garigali G. Urinalysis: core curriculum 2008. Am J Kidney Dis. 2008;51:1052.)

renal transplant rejection. In nephrotic syndromes, RTEs may appear granular because of the accumulation of proteins or lipids in cytoplasmic vesicles. "Oval fat bodies" is the term reserved for fat-laden RTE cells seen in patients with nephrotic syndrome (Figure 3.5A). When viewed with a polarized light source, birefringence of lipid droplets in the RTE cells results in the Maltese-cross appearance of these cells (Figure 3.5B).

Bladder epithelial cells are three to four times the size of leukocytes, are thin, may appear folded upon themselves along edges, and have a relatively small nucleus. Although normally present in the urinary sediment, an excessive number may be seen in cystitis and urethritis. Transitional cells originate in the renal pelvis and ureters and are midway between RTE cells and bladder epithelial cells in their cellular characteristics.

Casts

Casts are cylindrical structures formed in the renal tubules by the precipitation of Tamm-Horsfall protein (uromodulin) and are sometimes overlaid with cellular elements. Hyaline casts are derived entirely from Tamm-Horsfall protein and appear as translucent cylindrical
Figure 3.4 Renal tubular cell showing large central nuclei and granular cytoplasm. (Reproduced with permission from: Fogazzi GB, Verdesca S, Garigali G. Urinalysis: core curriculum 2008. Am J Kidney Dis. 51:1052, 2008.)

structures. These may be seen in concentrated urine of normal children, as well as in fever, exercise, dehydration, diuretic use, congestive heart failure, and nephrotic syndrome. Cells may be trapped within the matrix, giving rise to cellular casts. Degeneration of the cellular elements eventually leads to formation of granular casts

(Figure 3.6A). Cellular casts are classified according to the dominant cell type included therein (red, white, or epithelial cell). WBC casts can be observed in acute pyelonephritis, glomerular diseases, and transplant rejection. RBC casts appear as round discoid cells embedded in the Tamm-Horsfall matrix and may be further identified by the hemoglobin pigment within the matrix of the cast (Figure 3.6B). RBC casts are pathognomonic of glomerular bleeding, or glomerulonephritis.

Waxy casts are similar to hyaline casts, but are more broad (Figure 3.6C). They are commonly seen in chronic renal diseases. Large waxy casts (broad casts) are often seen in chronic kidney disease (CKD). Broad casts are believed to originate in damaged nephron segments or from the collecting system. Fatty casts result from the incorporation of fat within the Tamm-Horsfall matrix and are common in nephrotic syndrome. Casts made of renal tubular cells can be seen in AKI (Figure 3.6D). A muddy brown cast is a specific type of granular cast seen in AKI that is an intensely brownish color and may be derived from degeneration of tubular epithelial cells. Light brown pigment casts also can be seen in hemoglobinuria and myoglobinuria.

Bacteriuria

Significant bacteriuria usually can be detected using a 40 × objective. From a standardization perspective, centrifuged urine (10 mL) sediment stained with Gram stain provides the most reproducible results. This method has been reported to have 95% sensitivity with 1 bacterium per oil immersion field and 95% specificity for bacteriuria if more than 5 bacteria are visualized.[25] Being cumbersome and time-consuming, the

test is rarely performed in the office or emergency departments, for which it was primarily intended.

Crystals

Solutes are normal constituents of urine and can precipitate as crystals if their solubility changes with the decrease in temperature outside the body, especially in a supersaturated state. Although most urinary crystals have no diagnostic significance, excessive amounts of crystals and presence of some distinct types of crystals may be diagnostically relevant.

AMORPHOUS CRYSTALS

Amorphous crystals are made of either urate or phosphate.[25,26] Amorphous phosphate crystals are found in alkaline urine, and urate crystals are seen in acidic urine. Amorphous phosphate crystals precipitate in the urine tube as a white button on spinning, whereas the urate crystals are brick red (Figure 3.7). Amorphous phosphate precipitate
Figure 3.7 Centrifuged urine showing brick-brown sediment that is characteristic of uric acid (urate) crystals in acidic urine.

can be dissolved by addition of acetic acid, and amorphous urate crystals are dissolved by adding a few drops of alkali or by warming the urine tube.

CALCIUM OXALATE CRYSTALS

Calcium oxalate crystals are envelope-shaped crystals (Figure 3.8A) found in normal urine.[4,26,27] They also can be shaped like dumbbells. Excessive amounts of calcium oxalate crystals can be seen as a result of dietary intake of foods with a high oxalate content, such as spinach, tomatoes, rhubarb, and asparagus. Calcium oxalate crystals may be prominent in hyperoxaluria and some forms of hypercalciuria, particularly in acid urine and in stone formers.

STRUVITE CRYSTALS

Struvite (magnesium ammonium phosphate) crystals are also known as triple phosphate crystals.[4,26,27] They are often seen are seen in patients with UTIs caused by bacteria, such as *Proteus, Pseudomonas, Klebsiella, Staphylococcus,* and *Mycoplasma* species, that produce the urea-splitting enzyme urease. Struvite crystals are transparent and rectangular, giving the appearance of a coffin lid. These are more common in alkaline urine.

URIC ACID CRYSTALS

Uric acid crystals can have multiple shapes, such as amorphous plates, diamonds, and trapezoids, and often appear yellow or orange under the microscope (Figure 3.8B).[4,26,27] Uric acid crystals are more commonly seen if the urine has been left standing for an extended period at room temperature, especially if the urine is acidic. Although they are normally seen, the presence of uric acid crystals in a fresh urine sample may indicate the presence of a stone. Other conditions in which uric acid crystals can be found are tumor lysis syndrome, leukemic children undergoing chemotherapy, and the rare genetic disorder Lesch-Nyhan syndrome.

AMMONIUM URATE CRYSTALS

Ammonium urate crystals are commonly seen when urine is left standing for a prolonged period and the action of urea-splitting bacteria produces free ammonia. These crystals appear in various shapes, ranging from needle-like to the characteristic "thorn apple" shape.[4,26,27]
Figure 3.8 Urinary crystals in unstained urinary sediment. **(a)** Envelope-shaped square crystals of calcium oxalate. **(b)** Uric acid discoid-shaped crystals. **(c)** Hexagonal clear crystals of cystinuria. (Figure courtesy of Uri Alon, MD.)

CYSTINE CRYSTALS

The hexagonal crystals of cystinuria (Figure 3.8C) in acid urine are characteristic of cystinuria, a genetic disorder of renal cysteine transport that results in recurrent cystine stones. Cystine crystals are not seen in normal urine.

DRUG CRYSTALS

Many drugs have been associated with crystalluria, which can sometimes cause AKI by precipitation within the tubules. Compiling the list of such drugs continues; the well-known ones are amoxicillin, sulfonamides, ciprofloxacin, acyclovir, ganciclovir, indinavir, atazanavir, and triamterene.[28-34] Crystals of each of these drugs have a characteristic microscopic appearance. Some drugs, such as furosemide, can cause hypercalciuria and may cause crystalluria, nephrocalcinosis, or even renal stones.[34] Drug-induced crystalluria can cause renal tubular obstruction and AKI.

SUMMARY

Urinalysis provides an important insight into renal physiology and also can provide diagnostic clues into many pathologic states. It is often the first investigation in the evaluation of patients with renal disease. The technology of urinalysis has been evolving over the years, especially with the development of chemical analysis using dipsticks. Screening for proteinuria, hematuria, and UTI in the emergency department and physician offices has been particularly facilitated by these developments. Microscopic analysis of the urine sediment requires knowledge and the experience of having viewed the sediment in physiologic as well as disease states. Use of stock images for determining the formed urinary sediment components is evolving but is an imperfect technique at this stage.

REVIEW QUESTIONS

1. Urine was collected on your 3-year-old febrile patient at home and was stored at room temperature for 18 hours. Urinalysis showed specific gravity 1.015, pH 6.5, protein negative, blood negative, nitrite positive, and leukocyte esterase negative. Your recommendation is:

   a. Patient has a UTI, obtain a urine culture and start on antibiotics.
   b. Patient does not have a UTI, but a culture should be obtained.
   c. Patient does not have a UTI, and nothing more needs to be done.
   d. Patient does not have a UTI, and a urine culture does need to be obtained. Obtain a urinalysis in freshly obtained urine in the clinic.

2. You need to evaluate urinary sediment in a patient with suspected glomerulonephritis who has had visible hematuria for 1 week but is improving, with only faintly pink urine. You are unable to evaluate the urinary sediment for the next 4 hours. Your laboratory technician labeled the urine sample and froze it at –20° C, with the hope of preserving the casts and cellular elements for you to evaluate later. When you evaluated the urine sediment later in the day after thawing it, you found unclear cell types and no clearly identifiable casts were present. Choose the *best* interpretation of these findings.

   a. Patient does not have glomerulonephritis.
   b. Patient's cellular elements and casts were likely disrupted by freezing.
   c. Patient has glomerulonephritis, but there is no evidence of it in the urinary sediment.
   d. Patient's urine sample may have been labeled incorrectly.

3. A 3+ positive test for heme on dipstick is diagnostic for the presence of:
   a. Blood in urine
   b. Myoglobin in urine
   c. Hemoglobinuria secondary to intravascular hemolysis
   d. All of the above

4. A meta-analysis of pediatric studies has indicated that urine nitrite test for UTI:
   a. Correlates best with a randomly obtained urine.
   b. Has low specificity and high sensitivity.
   c. Has high specificity and low sensitivity.
   d. Correlates poorly with UTI.

5. Drug-induced crystalluria can result in:
   a. Acute kidney injury
   b. Renal stone formation
   c. Nephrocalcinosis
   d. All of above

6. Which of the following correlates highly with significant bacteria in the urine of a patient with UTI?
   a. 1 bacterium/HPF seen in uncentrifuged urine under 40× magnification
   b. 1 bacterium/oil immersion field seen in centrifuged urine stained with Gram stain

    c. 1 bacterium/HPF seen in centrifuged urine stained with Gram stain

    d. 1 bacterium/oil immersion field seen in centrifuged urine stained with Sedi-Stain

7. Urine obtained for urinalysis needs to be collected in a clean container that does not have to be sterile.

    a. True

    b. False

8. A 10-year-old male patient in septic shock is noted to have a serum creatinine level of 2.0 mg/dL. Although the patient has good urine output, the intensive fellow wants a nephrology consult. Urinalysis shows specific gravity 1.010, pH 6.5, blood 3+, protein 2+. Microscopic analysis shows TNTC RBCs, a few granular casts, an occasional muddy brown cast, and many renal tubular epithelial cells. Your interpretation of the patient's urinalysis, given the clinical picture is:

    a. Patient has prerenal azotemia.

    b. Patient has acute kidney injury.

    c. Patient has glomerulonephritis.

    d. Patient has acute interstitial nephritis.

9. Dipstick detection for detection of proteinuria is:

    a. Specific for tubular proteinuria

    b. Nonspecific and detects all types of urinary proteins

    c. Able to detect microalbuminuria

    d. Specific for albuminuria

10. UTI caused by *Proteus, Pseudomonas, Klebsiella, Staphylococcus,* and *Mycoplasma* that produce the urea-splitting enzyme urease can result in crystalluria and renal stones.

    a. True

    b. False

Clinical assessment of renal function

GEORGE J. SCHWARTZ

The kidney plays a central role in the maintaining fluid and electrolyte balance, acid-base homeostasis, systemic blood pressure, and erythrocyte production through erythropoietin, as well as maintaining bone and mineral metabolism. Clinical evaluation and interpretation of these complex functions can be categorized into tests for glomerular functions, tubular functions, and hormonal functions (Table 4.1). Clinicians use broad sets of evaluation tools to judge renal function in adults and children. Such evaluation requires testing blood and urine, and it may include injection of exogenous substances to measure glomerular filtration rate (GFR). Dynamic radiologic tests, such as radionuclide renal scans, to evaluate renal perfusion and excretion functions are equally important in evaluation of renal functions. Estimated GFR (eGFR) determination with mathematical formulas using either creatinine (Cr) or cystatin C (Cys-C) has been an important step in early discovery and clinical follow-up of renal dysfunction in children and adults. This chapter discusses the pathophysiology, test methodology, and interpretation of clinically useful renal function tests.

GLOMERULAR FILTRATION RATE

GFR provides the most common and best estimate of overall functioning renal mass. Knowledge of GFR enables the clinician to determine progression of the renal disease, predict the development of end-stage disease, adjust medications excreted by the kidney, and rationally prescribe fluids and solutes. Because of the importance and clinical utility of GFR, several different approaches have been used to estimate or determine it.

PHYSIOLOGY OF GLOMERULAR FILTRATION

Approximately 20% of the cardiac output flows through the approximately 2 million glomerular capillary units.[1] The glomerulus consists of a tuft of capillaries interposed between the afferent and efferent arterioles. The glomerular capillary wall, through which the filtrate must pass, is made up of three layers: the fenestrated endothelial cell, the glomerular basement membrane (GBM), and the epithelial cell (podocyte) (Figure 4.1). The epithelial cells are attached to the GBM by discrete foot processes. The pores between the foot processes are slit pores, which are covered by a thin membrane called a slit diaphragm.[1–3] The GBM is derived from material produced by endothelial and epithelial cells, including type IV collagen, laminin, nidogen, and heparan sulfate proteoglycans. Laminin and nidogen form a tight complex to promote cell adhesion. The anionic heparan sulfate proteoglycans serve to form the charge barrier to the filtration of anionic macromolecules.[1,2]

One of the major functions of the glomerulus is to allow the filtration of small solutes such as sodium and urea and water while restricting the passage of larger molecules. This action permits the kidney to maintain homeostasis by excreting the daily solute load derived from dietary intake, but preserving the larger proteins. Solutes up to the size of inulin (molecular weight [MW] 5200) are freely filtered, whereas myoglobin (MW 17,000) is filtered less completely than inulin, and albumin (MW 69,000) is filtered only to a minor degree. Filtration is also limited for ions or drugs that are bound to albumin.

Table 4.1 Laboratory investigations used in clinical investigations of kidney functions

Test category	Test name
Glomerular function	Glomerular filtration rate
	Urinary protein excretion and microalbuminuria
Tubular function	Urinary concentrating ability
	Urinary acidification
	Enzymuria and abnormal tubular proteinuria
Hormonal function	Erythropoietin production and anemia
	Vitamin D and bone health regulation
	Renin-aldosterone control of salt and blood pressure

Starling forces

GFR is determined by two factors: the filtration rate in each nephron (single nephron GFR or SNGFR); and the number of filtering nephrons (nephron mass), which are approximately 1 million units per kidney in humans at birth. Blood entering through the afferent arteriole passes through the glomerular capillary tuft and exits through the efferent arteriole. Along the glomerular capillary tuft, a portion of the glomerular filtrate is ultrafiltered into the Bowman space (urinary space). This ultrafiltrate is processed by the renal tubules and collecting duct and eventually leaves the kidney as urine. Fluid movement across the glomerulus is governed by Starling forces, which are proportional to the permeability of the glomerular capillary wall and to the balance between hydraulic and oncotic pressure gradients:

$$\text{SNGFR} = L_p S \,(\Delta \text{ hydraulic pressure} - \Delta \text{ oncotic pressure})$$
$$= L_p S \,[(P_{gc} - P_{bx}) - s(\pi_p - \pi_{bs})]$$

where L_p is the unit permeability (or porosity) of the capillary wall, S is the surface area available for filtration, P_{gc} and P_{bs} are the hydraulic pressures in the glomerular capillary and the Bowman space, π_p and π_{bs} are the oncotic pressures in the plasma entering the glomerulus and in the Bowman space, and s is the reflection coefficient of proteins across the capillary wall (ranging from 0 [completely permeable] to 1 [completely impermeable]).

With the filtrate being essentially protein free, π_{bs} is 0, and s is 1, so that:

$$\text{SNGFR} = L_p S \,(P_{gc} - P_{bs} - \pi_p).$$

The $L_p S$ in the glomerular capillary is 50 to 100 times that of a muscle capillary, and the capillary hydraulic pressure (and mean gradient favoring filtration $[P_{gc} - P_{bs} - \pi_p]$) is much greater in the glomerulus than in a muscle capillary.[3,4] These factors contribute to the high rate of glomerular filtration in the kidney.

The plasma oncotic pressure (π_p) rises in response to the ultrafiltration of protein-free fluid. After the filtration of 20% of the nephron plasma flow, filtration equilibrium is normally achieved. Further filtration at the same plasma flow does not occur because the plasma oncotic pressure equals the hydraulic pressure, and there is no net ultrafiltration pressure. Thus, the presence of filtration equilibrium indicates that renal plasma flow is a major determinant of GFR.[2-4]

Size selectivity

The glomerular barrier filters molecules based on size and charge. Both the GBM and the slit diaphragms contribute to size selectivity.[1,2,5] The size limitation in the GBM represents functional pores in the spaces between the tightly packed cords of type IV collagen.[2] There is also an important role for cellular elements and slit diaphragms in limiting the passage of macromolecules.[1,2,6] Most pores of the glomerular capillary wall are relatively small (mean radius, ~4.2 nm). They partially restrict the filtration of albumin
(mean radius, 3.6 nm) but allow the passage of smaller solutes and water. The endothelial cells do not contribute to size selectivity because the endothelial fenestrae are relatively wide open and do not begin to restrict the passage of macromolecules with a radius of less than approximately 40 nm.[7] However, endothelial cells do contribute to charge selectivity (see later). Modeling of the glomerular filtration barrier suggests that the major portion of the capillary wall functions as an isoporous membrane, but a very small fraction of the filtrate passes through larger pores.[5]

KEY POINTS

- Permeability of the glomerular capillaries is 50 to 100 times greater than that of capillaries in muscles, thus allowing for filtration to occur.
- Starling forces in the glomerular capillary favor ultrafiltration up to the limit of 20% of nephron plasma flow.
- Both size selectivity and charge selectivity appear to be important in preventing macromolecular transport (e.g., plasma proteins) across the GBM.

Charge selectivity

Molecular charge is the second major determinant of filtration across the GBM.[1,2,6] The inhibitory effect of charge results from the electrostatic repulsion by anionic heparan sulfate proteoglycans, in both the endothelial fenestrae and the GBM.[1,2,8] Filtration of albumin amounts to only approximately 5% of filtration rate of neutral dextran of a similar molecular radius. Thus, charge is considered important in limiting the filtration of albumin.

CLINICAL ASSESSMENT OF GLOMERULAR FILTRATION RATE

Concept of clearance

Given that the total kidney GFR is equal to the sum of the SNGFRs in each of the functioning nephrons, the total GFR can be used as an index of functioning renal mass. A decline

---

KEY POINTS

- Determination of GFR provides the best estimate of overall kidney function.
- GFR can be measured by classical renal clearance or plasma disappearance techniques.
- GFR can also be estimated from endogenous biomarkers such as Cr and Cys-C

---

in the GFR may be the only clinical recognizable sign of renal disease, even when urinalysis results and serum electrolyte composition are relatively normal. Serial monitoring of GFR can be used to estimate severity and to monitor the course of kidney disease. Measurement of GFR is also useful in determining the appropriate dose of drugs that are excreted through the kidney.

The most common measurement of GFR is based on the concept of clearance, which is defined as the equivalent volume of plasma from which a substance would have to be totally removed to account for its rate of excretion in urine per unit of time. The renal clearance of a substance x (C_x) is calculated as follows:

$$C_x = \frac{U_x \cdot V}{P_X}$$

where V is urine flow rate (mL/min) and U_x and P_x are the urine and plasma concentrations of substance x, respectively. C_x is expressed as mL/min and is usually normalized to a standard 1.73 m², idealized adult body surface area (BSA) (C_x in mL/min/1.73 m²) by the factor 1.73 / BSA, where BSA is the BSA (in m²) of the examined subject.

For the plasma clearance to reflect GFR accurately, the marker used must be freely permeant across the glomerular capillary, uncharged, biologically inert, and neither secreted nor reabsorbed by the renal tubule. In the case of an ideal marker (Table 4.2), the renal excretory rate of substance x equals the rate of marker x filtered across the glomerulus:

$$P_x \, GFR = U_x \, V$$

Or

$$GFR = \frac{U_x V}{P_{x,}}$$

Properties of biologic or pharmaceutical markers commonly employed for determination of GFR in children and adults are listed in Table 4.3.

Table 4.2 Characteristics of an ideal marker for estimation of glomerular filtration rate

1. Nontoxic
2. Biologically inert
3. Not protein bound in plasma
4. Exclusively and freely filtered by the glomeruli
5. Not reabsorbed by the renal tubules
6. Not secreted by the renal tubules
7. No extrarenal excretion
8. Assay highly sensitive and reliable
9. Clearance not affected by concentration in plasma over a wide range

Table 4.3 Commonly used markers for determining glomerular filtration rate

Endogenous Markers
- Creatinine
- Cystatin C
- Blood urea nitrogen

Exogenous Markers
- Inulin
- Iothalamate
- Iohexol
- Radionuclide agents
  - DTPA
  - EDTA
  - Iothalamate

Abbreviations: DTPA, diethylene triamine penta-acetic acid; EDTA, ethylene diamine tetra-acetic acid.

> **KEY POINTS**
>
> - Clearance of a substance is the volume of plasma from which it would be completely removed in a unit of time.
> - Inulin clearance, considered the "gold standard," is seldom performed in clinical circumstances.

Inulin clearance

GFR is measured indirectly through the concept of clearance discussed earlier. The gold standard for measuring GFR is clearance of inulin, a fructose polysaccharide, which has a mean molecular radius of 1.5 nm and an MW of approximately 5200 daltons. Inulin is freely filtered and not protein bound, and is not reabsorbed, secreted or metabolized by the kidney. Therefore, in the case of inulin as a marker, the $C_x = C_{In} = GFR$.[9]

The classical (standard) inulin clearance requires an intravenous priming dose followed by a constant infusion to establish a steady-state inulin plasma concentration.[10] After equilibration for approximately 45 min, serial urine samples are collected every 10 to 20 min through an indwelling bladder catheter. Under current practice, the insertion of a bladder catheter for renal functional measurement alone is not justifiable, and therefore urine collections are obtained every 20 to 30 min, as dictated by the urge of the patient to urinate. In this case, urine flow is maintained high by providing an initial oral fluid load of 500 to 800 mL water/m² and replacing urine output with intake of water (mL for mL).[11] Inulin is assayed in the timed urine collection, as well as in the serum. GFR is calculated using the clearance formula given earlier. GFR by inulin clearance methodology in newborns, infants, and children is given in Table 4.4.

The use of inulin clearances in children is limited by several concerns. First, some children may not be toilet trained and are unable to provide accurate collections of timed urine. Second, urologic problems are common causes of chronic kidney disease (CKD) in infants and young children, some of whom may have significant vesicoureteral reflux, neurogenic bladders, and bladder dysynergias.[12] Collecting timed urine samples in such patients is problematic and fraught with error. Technical difficulties encountered in performing inulin infusions, reaching a steady state of inulin distribution, and accurately measuring inulin concentrations in plasma are added concerns. In addition, the inulin assay is not very specific, and it can be potentially hazardous (boiling acid reagents). These problems have rendered the standard inulin clearance impractical for use in children.

Constant infusion technique without urine collection

Despite previously stated concerns, understanding the principles behind inulin clearance is helpful in comprehending the rationale of using clearance of various molecules for determining GFR. The clearance of a substance denotes its removal from the blood. Therefore, it is possible to determine the plasma clearance by infusing the substance at a constant rate until a steady state is achieved.

Table 4.4 Properties of markers commonly used to determine glomerular filtration rate

	Inulin	Creatinine	Iothalamate	DTPA	EDTA	Iohexol
MW (Da)	5,200	113	636	393	292	821
Elimination half-life (min)	70	200	120	110	120	90
Protein binding (%)	0	0	<5	5	0	<2
Space distribution	ECW	TBW	ECW	ECW	ECW	ECW

Source: Adapted from Rahn KH, Heidenreich S, Bruckner D. How to assess glomerular function and damage in humans. J Hypertens. 1999;17:309–17.
Abbreviations: Da, daltons; DTPA, diethylene thiamine penta-acetic acid; ECW, extracellular water; EDTA, ethylene diamine tetra-acetic acid; MW, molecular weight; TBW, total body water.

This constant infusion technique has used inulin, although other markers, especially radionuclide tagged tracers, also can be used (discussed later). After equilibration of the marker in its distribution space, the excretion rate equals the infusion rate. The renal clearance of the molecule can then be calculated from the rate of infusion and the concentration in plasma.[13]

$$C_x = \frac{I_x R}{S_x}$$

where I_x is infusion concentration of substance x, R is infusion rate (mL/min), S_x is the serum concentration of x, and C_x is the clearance in mL/min/1.73 m².

The constant infusion method will overestimate GFR if steady concentration of the marker is not achieved.

Endogenous creatinine clearance and the use of cimetidine

Because of the difficulties with administering and measuring inulin, endogenous Cr clearances have been used to estimate GFR. Clearance of Cr provides a useful clinical tool, albeit less precise than inulin clearance, for estimation of GFR. Cr clearance is determined by the following formula:

$$C_{cr} = \frac{U_{cr}\ V}{S_{cr}}$$

where C_{cr} is Cr clearance, U_{cr} is urine Cr concentration, V is flow rate of urine in mL/min, and S_{cr} is serum Cr, and the calculation is normalized to BSA by multiplying by the factor 1.73 / BSA in m².

Adequacy of urine collection is essential for this test. The relative constancy of Cr production and its urinary excretion in the steady state helps one analyze for completeness of the collection. Historically, Cr clearance is derived from a 24-h urine collection. On the day of the test, the child is asked to void and empty the bladder in the morning (7 a.m.), the urine is discarded, and the time is noted as the start of the collection. All urine voided in the next 24 h is collected in the container as part of this collection. At the end of 24 h (7 a.m. on the next day), the bladder is emptied, and the last void is deposited in the container as the final part of the collection. The volume of urine is noted accurately, and the urine is analyzed for Cr concentration. Blood (for serum Cr) is drawn during the urine collections. Urinary Cr excretion (Cr index) should generally exceed 15 to 20 mg/kg/day in children older than 3 years of age and is 20% higher than that for pubertal adolescent boys.[14–16] Lower Cr index values generally indicate urine collection of less than 24 h or loss of some urine. Nevertheless, daily

variation in urinary Cr excretion results in a standard deviation of 10% to 15%.[17]

Averaging several short clearance periods (~30 min) after water loading tends to minimize errors in urine collection and improve supervision of the study.[18–20] Large variations in urine Cr excretion often indicate significant vesicoureteral reflux or inadequate bladder emptying, and they may warrant bladder catheterization to improve accuracy of the test. In addition, Cr concentration is affected, to a small extent, by dietary intake of meat, exercise, and pyrexia. More importantly, it is well known that Cr is secreted by the renal tubules; this secretory component accounts for approximately 10% of the urinary Cr excretion in normal individuals.[20] Therefore, Cr clearance exceeds inulin clearance, by at least 10%, particularly at low levels of GFR.[10]

Whereas in the steady state, Cr production equals its urinary excretion, Cr production is not constant during growth, by more than doubling from term infancy to adolescence.[14,21] The consequence of the increasing Cr production with growth is the steady increase in plasma Cr as a function of age, with an additional increase resulting from the increment in muscle mass in male adolescents (Figure 4.2).[22]

The administration of cimetidine to patients with renal disease causes a decrease in renal tubular Cr secretion that results in a reduction in Cr clearance to the level of actual GFR.[23] A protocol for cimetidine treatment developed for use in children has similarly equated Cr clearance to the level of GFR.[19] This requires that cimetidine be given for 3 days at a dose of 20 mg/kg/day, divided into two doses, to a maximum of 1600 mg per day (with a sliding scale reduction for decreases in GFR).[19] After an oral load of 7 to 8 mL/kg of fluids, four urinary collection periods of approximately 30 min each

Figure 4.2 Serum creatinine as a function of age in boys (red circles) and girls (blue circles) with 1 standard error estimate, taken from 772 boys and girls females. Creatinine was measured using a modification of the Technicon Autoanalyzer Jaffe assay. (From Schwartz GJ, Haycock GB, Spitzer A. Plasma creatinine and urea concentration in children: normal values for age and sex. J Pediatr. 1976;88:828–30.)

follow, with urine replaced milliliter for milliliter during this time. Although the cimetidine protocol is a convenient and an inexpensive procedure for estimating GFR, there are likely to be inaccuracies in children with severe reflux, neurogenic bladders, and bladder dyssynergias.

Serum creatinine

Cr is produced by enzymatic degradation of creatine that is primarily synthesized in the skeletal muscles. The urinary excretion of Cr is determined by muscle catabolism and is hence an index of muscle mass.[16] In the steady state, serum Cr correlates well with the muscle mass, but several physiologic, pharmacologic, and pathologic states can affect its serum concentration (Table 4.5).[20,24] Cr has an MW of 113 daltons. It is eliminated from the body exclusively by the kidneys, primarily by glomerular filtration, but also to a small extent by tubular secretion. Whereas urinary Cr contributed by tubular secretion does not normally exceed 10%, this fraction rises greatly in chronic renal insufficiency, so Cr clearance may greatly exceed GFR.[20] Diffusion of Cr into the gut with subsequent catabolism may also interfere with the accuracy of its clearance in uremic patients.[25] GFR

KEY POINTS

- Growth and development lead to increased muscle mass and therefore elevated serum Cr concentration.
- Height factored by serum Cr (ht/S_{cr}) provides an accurate estimate of GFR in most children.

Table 4.5 Factors that influence serum creatinine level

Increase serum creatinine	Decrease serum creatinine
Hyperglycemia (Jaffe)	Malnutrition
Ketotic states (Jaffe)	Dietary protein restriction
Cephalosporins (Jaffe)	Bilirubin (Jaffe)
Flucytosine (enzymatic method)	Advanced liver disease
Cimetidine (block tubular secretion)	Female sex
Trimethoprim (block tubular secretion)	Advanced age (adults)
Vigorous exercise	
Cooked meat	
Creatine nutritional supplement

based on Cr clearance in infants, children, and adolescents is listed Table 4.6.

Creatinine-based estimated glomerular filtration rate

The close relationship between Cr clearance and GFR on the one hand and Cr production and muscle mass on the other has led to the concept of estimating GFR (eGFR)

from serum Cr and some parameter of body habitus. This has been detailed by Schwartz et al.,[26] using the following formula:

$$eGFR \ (ml/min/1.73 \ m^2) = \frac{kL}{S_{cr}}$$

where eGFR is estimated GFR in mL/min/1.73 m², k is a constant determined empirically by Schwartz et al.,[21] L is height in cm, and S_{cr} is serum Cr in mg/dL.

This formula is also based on the relationship that Cr clearance is reciprocally proportional to serum Cr. A dimensional analysis of k (mg Cr/100 min × cm × 1.73 m²) indicates that k is equal to $U_{Cr}V / L$, which is directly related to urinary Cr excretion that, in turn, is proportional to lean body mass.[14,21].

Using Cr, the value of k was determined Schwartz et al. to be 0.45 for term infants during the first year of life,[14] 0.55 for children and adolescent girls,[26] and 0.7 in adolescent boys.[15] eGFR, using Schwartz's formula, generally provides a good estimate of GFR (r ~ 0.9) when compared with Cr and inulin clearance data.[19,26]. Interestingly, at high values of GFR, the variation between inulin clearance and GFR estimated by the Schwartz formula was approximately 20%, but it was much smaller at lower levels of GFR.[19,26]. There was no explanation for this finding. The eGFR Schwartz formula can be rewritten as follows:

$$GFR(ml/min/1.73m^2) = \frac{Height \ in \ centimeters}{Serum \ creatinine(mg/dL)} \times k$$

Where k = constant based on age:
    0.70 in adolescent boys
    0.55 in adolescent girls and children
    0.45 in full-term newborns
    0.33 in preterm infants

The foregoing given constants were generated using Cr measured using a modification of the Technicon Autoanalyzer (Seal Analytical, Mequon, WI), which relied on a modification of the Jaffe chromogen reaction to determine Cr. The newer generation of autoanalyzers determine serum Cr enzymatically, using the creatinase methods. Although the enzymatic Cr method appears to agree with "true" Cr obtained from the Jaffe reaction after Fuller earth absorption, some manufacturers use calibration factors (bias) to produce Jaffe-comparable results. This bias is not linear and therefore is unlikely to improve the accuracy of serum Cr determination in children. Without the bias, the enzymatic Cr generally runs 10% to 20% lower than those measured by the Jaffe method.[27] Therefore, one would anticipate that k values should be comparably smaller than those listed earlier.

The Schwartz formula for eGFR was revised to overcome the approximately 20% bias of overestimation of GFR.[28] The modified Schwartz formula used a single value of k for children with mild to moderate CKD who were 1.5 to 18 years of age:

$$eGFR(mL/min/1.73m^2) = \frac{Height \ in \ centimeters}{Serum \ creatinine \ (mg/dL)} \times 0.413$$

If using SI units:

$$GFR(mL/min/1.73 \ m^2) = \frac{Height \ in \ centimeters}{Serum \ creatinine \ (\mu mol/L)} \times 36.2$$

The modified Schwartz formula has been validated only in patients with CKD; it may not be applicable to patients with acute kidney injury (AKI). Additionally, this formula mandates using enzymatic serum Cr measurement that is calibrated to reference standards of isotope dilution mass spectroscopy (IDMS), but not to "Jaffe" (alkaline picrate) methods.[29] Staples et al.[30] successfully extended the updated Schwartz formula to adolescents with higher levels of GFR. Whereas some clinical laboratories can mathematically convert the results from the Jaffe method to IDMS-traceable results by instrument-specific factors provided by the manufacturers of equipment for assaying serum Cr; this black box approach may be flawed by the magnitude of correction required for children with low levels of serum Cr.

Counahan et al.[31] generated a similar formula for estimating GFR using "near-true" Cr determinations, and the resulting k in their study was 0.43. This value of k is lower than the original Schwartz formula's value and may reflect the lower value of Cr after removal of non-Cr chromogen with an ion exchange resin. However, this k represents a value that is very close to the updated value of 0.413 obtained in the Chronic Kidney Disease in Children (CKiD) study of children with CKD.[28] Indeed, this k is approximately 20% lower than the original k obtained from the modified Technicon Autoanalyzer and is in keeping with the expected reduction in apparent serum Cr concentration with the "true" method.

These eGFR formulas must be used with caution and may not be accurate in cases of severe obesity, malnourishment, or limb amputation because in these patients body height may not accurately reflect muscle mass.[21] Additionally, these estimate formulas are not accurate when GFR is rapidly changing, such as in patients with AKI or those in the intensive care unit.[32]

The Cockcroft-Gault equation, used to estimate GFR in adults, may also be useful in children older than 12 years of age.[33]

$$eGFR = (140 - age) \ (body \ weight \ in \ kg)/(72 \times S_{cr})$$

where eGFR is the estimated GFR using the Cockcroft-Gault equation in boys; in girls, a correction factor of 0.85 is used.

This formula has limited utility in pediatrics because of the inaccuracies in children 8 years old or younger. Whereas there is good overall agreement with standard inulin clearances in children, the correlation with GFR is less consistent than with the Schwartz estimate, and the scatter appears larger.[34] In general, the Modification of Diet in Renal Disease (MDRD) eGFR equation is not useful in children.[34]

Cystatin C

Cys-C is a low-MW protein (13 kDa) that is produced by all nucleated cells.[35] Cys-C is filtered by the glomeruli and is reabsorbed in the proximal tubules by megalin-facilitated endocytosis.[36] Cys-C is catabolized in the proximal tubule, and an insignificant amount may be recovered in urine.[37] Because megalin is also involved in the endocytosis of albumin present in the glomerular filtrate, saturation of megalin in proteinuric states may result in increased urinary Cys-C excretion without affecting the serum concentration.[38,39]

Cys-C has been proposed as an endogenous marker for GFR that could be more accurate in detecting more subtle decrements of GFR.[40] The advantage of Cys-C over serum Cr as an marker for GFR lies in the finding that serum Cys-C levels fluctuate very little beyond the first year of life and are not largely influenced by age, gender, and body weight.[41,42] However, several clinical conditions can alter serum Cys-C level and need to be considered in estimation of Cys-C–based GFR (Table 4.7).[43–54] In addition, because Cys-C is almost entirely reabsorbed and metabolized in the proximal renal tubules, it cannot be used to measure GFR by traditional clearance techniques (e.g., Cr clearance). Therefore, Cys-C GFR can be estimated only by mathematically derived formulas or eGFR calculations. In AKI,

Table 4.7 Clinical conditions and pharmacologic therapies that affect serum cystatin C level

Serum cystatin c level	Clinical conditions
Increase	Obesity
	High-dose methylprednisone
	Kidney transplant
	Hyperthyroidism
	Amyotrophic lateral sclerosis

however, the presence of Cys-C in urine may be used as an early indicator of proximal tubular injury.

Serum Cys-C levels are high in full-term neonates and gradually decline in the first 4 months of life. Serum Cys-C levels are even higher in preterm infants and appear to be inversely influenced by gestational age (Table 4.8).[55–57] One criticism of the normative Cys-C data in preterm infants is that many children in this cohort have other medical conditions that may directly influence their serum Cys-C levels. Near-adult serum levels of Cys-C are reached by 1 year of age (Table 4.9). Beyond the first year, the constancy of Cys-C is relatively stable and is largely independent of muscle mass, gender, body composition, and age.[48] In an analysis of National Health and Nutrition Examination Survey III (NHANES III) data, Groesbeck et al.,[58] however, noted that serum Cys-C levels in girls and women 12 to 19 years of age are lower than in boys and men. Similarly, obesity has also been noted to influence serum Cys-C level.[45]

KEY POINTS

- Because Cys-C is reabsorbed and metabolized by the proximal renal tubule, its urinary excretion is nearly zero. Therefore, traditional clearance methods of determining GFR with Cys-C are not applicable, and only eGFR calculations are valid.
- Combining plasma Cys-C with serum Cr in estimation of GFR formulas greatly enhances the accuracy of eGFR.

Several eGFR calculations using serum Cys-C level have been validated in adults and children, and these calculations correlate well with traditional GFR measurements by inulin clearance, Cr clearance, or radionuclide GFR.[59–62] However, these calculations are generally more complex for bedside clinical use than the Schwartz eGFR calculations. Because

Table 4.9 Serum cystatin C reference ranges in infants, children, and adolescents

Age group	Mean and range
0–3 mo	1.37 (range, 1.81–2.32)

serum Cys-C levels are known to be elevated in patients with renal transplants and to underestimate the true GFR in these patients, a correction factor of 1.2 has been suggested by Zappitelli et al.[61] to be applied to Cys-C–based GFR in transplant recipients.

Additional accuracy in estimating GFR can be derived from formulas that incorporate both serum Cr and Cys-C. Such formulas, by Bouvet et al., Zappitelli, and Schwartz, are capable of estimating 80% of determinations within 30% of measured GFR and nearly 40% within 10% of measured GFR.[29,61–63] Modification of the Schwartz equation using immunonephelometric measurements of Cys-C was derived from the CKiD population of children with mild to moderate CKD and proved very accurate, with 91% of estimates falling within 30% of measured GFR and 45% within 10% of measured GFR.[62] Table 4.10 lists the eGFR calculations using serum Cr, Cys-C and the combination of Cys-C and Cr.

Single injection clearance techniques

The renal clearance of a substance that is not metabolically produced or degraded and that is excreted from the body totally or almost totally in the urine can be calculated from compartmental analysis by monitoring its rate of disappearance from the plasma following a single intravenous injection.[64] The mathematical model for the disappearance curve is an open two-compartment system. The GFR marker is injected in the first compartment, equilibrates with the second compartment, and is excreted from the first compartment by glomerular filtration. Initially, the concentration falls rapidly but at a progressively diminishing rate because of diffusion of the marker in its distribution volume as well as its renal excretion. Thereafter, the slope of the decline of plasma concentration reflects predominately its renal excretion rate. This latter decrease occurs at the same exponential rate in the compartments wherein it is distributed.

Indeed, the plasma disappearance curve can be resolved into two exponential decay curves by plotting the log of the plasma concentration as a function of time and applying the technique of curve stripping (Figure 4.3). The terminal slow (renal) portion of the curve (line A) is extrapolated back to zero time, and its Y intercept (A) and slope (α) are determined. When the values along line A are subtracted from the original curve, a second linear function (line B) is obtained. Its Y intercept (B) and slope (β) are also noted. The clearance of the substance, taken as GFR, can be calculated as follows[64]:

$$GFR = Dose \times 0.693 / [(\exp (A)/\alpha + (\exp (B) / \beta)],$$

where Dose is the administered amount of GFR marker, and GFR is normalized to 1.73 m^2 by multiplying by 1.73 / BSA.

Thus, to obtain an accurate plasma disappearance curve, several blood samples are required. Extension of sampling to 5 h is essential to ensure accuracy at low levels of GFR.

Figure 4.3 Disappearance of iohexol as a function of time after injection into the blood. The natural log of the iohexol concentration is plotted against the time in minutes. The curve can be stripped into two components: the slow or renal curve with slope α and intercept A. When those points are subtracted from the initial curve, a straight line with a steeper slope β defines the fast or distribution curve with intercept B.

Excellent and comparable results may also be obtained using the one-compartment (renal curve) model, by which samples are obtained 2 to 5 h after injection, as described by Brochner-Mortensen[65]:

$$GFR = C1 \times GFR (A) + C2 \times [GFR (A)]^2$$

where GFR (A) = Dose / [exp (A)/α], and C1 = 0.9908 and C2 = 0.001218, as generated by Brochner-Mortensen in adults by comparing to plasma disappearance curves for chromium-51–ethylene diamine tetra-acetic acid (EDTA).

Recently, Ng et al.[66] have developed a universal equation to calculate GFR from the slow renal disappearance curve in children and adults.

$$GFR = slowGFR / [1 = 0.12 * (slowGFR / 100)]$$

where slowGFR is the GFR calculated from the iohexol dose divided by the area under the renal (slow) curve.

Such an equation has allowed the CKiD cohort to use a two-point plasma disappearance GFR by sampling at 120 and 300 min after iohexol infusion. Such an equation can be applied universally and is not dependent on the dose of infused iohexol. The results obtained were superior to those generated from the pediatric and adult forms of the Brochner-Mortensen one-compartment models noted earlier.

Diethylene triamine penta-acetic acid, ethylene diamine tetra-acetic acid, and iothalamate

Historically, the plasma disappearance curve was most often used when assessing GFR with radionuclides. Even with single injection techniques, radioactive markers are best avoided in small children. Moreover, families are reluctant to approve of repeated use of radioactivity to monitor the course of CKD. Diethylene triamine penta-acetic acid (DTPA) has an MW of 393 daltons and is excreted primarily by glomerular filtration. GFR can be measured in each kidney by using a scintillation camera and the technetium-99m (99mTc)–DTPA complex; however, the correlation with 24-h Cr clearances is only fair.[67] The plasma clearance of 99mTc-DTPA significantly exceeds the urinary clearance.[68,69] Conversely, the plasma clearance of 99mTc-DTPA correlates well with the renal clearance of inulin.[68] Failure to measure GFR accurately may reflect the findings that 99mTc can dissociate from DTPA during the study and there can be variations in protein binding depending on the ligand attached to DTPA.[70] Some preparations with calcium-sodium-DTPA gave results comparable to those with chromium-51–EDTA, whereas others underestimated GFR by 7% to 22%.[70] Thus, the accuracy of 99mTc-DTPA may depend on the commercial source.

EDTA is another marker for determining GFR. It has an MW of 292 daltons and is used as a chelate of chromium- 51–,

primarily in Europe. Its plasma clearance exceeds its urinary clearance by approximately 6 mL/min, particularly in patients with reduced renal function.[68] However, plasma clearance of chromium-51–EDTA (^{51}Cr-EDTA) agrees well with that of renal inulin clearance, a finding indicating that it is a good marker for GFR. Values of ^{51}Cr-EDTA plasma clearances increase from birth to age 18 months and plateau thereafter.[68] The absolute numbers agree well with measurements performed using inulin clearances given in Table 4.5.

Iothalamate sodium has an MW of 637 daltons. It has been used as iodine-125 (^{125}I) radiolabeled or without a radioactive label, and its plasma concentration is measured by x-ray fluorescence, high-performance liquid chromatography (HPLC), or capillary electrophoresis. In a comparison of agents, the plasma clearance of ^{125}I-iothalamate was 13% higher than that of ^{51}Cr-EDTA.[71] The difference was reduced by pretreatment of the patients with probenecid, an organic anion secretory inhibitor. Extensive laboratory studies have shown unambiguously that iothalamate is actively secreted by renal proximal tubular cells, and it may also undergo some tubular reabsorption.[71] The renal clearance of iothalamate significantly exceeds that of inulin in patients with normal renal function,[72] and any reported agreement with inulin clearance may reflect a fortuitous cancellation of errors between tubular excretion and protein binding.[73,74] Thus, iothalamate cannot be recommended as an ideal marker for measuring GFR.

Iohexol

A reliable alternative to inulin clearance avoids both the use of radioactivity and the problems related to timed urination and continuous infusion of the marker. Iohexol is a non-ionic, low-osmolar, x-ray contrast medium (Omnipaque) that is safe and nontoxic. Iohexol is used for angiographic and urographic procedures and is eliminated from plasma exclusively by glomerular filtration.[74] Iohexol has an MW of 821 daltons and a plasma elimination half-time of approximately 90 min; it is distributed into the extracellular space and has less than 2% plasma protein binding.[74–76] Iohexol is excreted completely unmetabolized in the urine with 100% recovery within 24 h after injection.[76] Because iohexol can be quantified in small samples, capillary and venous sampling can be employed.[77] Extrarenal elimination of iohexol in a setting of reduced GFR is negligible.[78] Iohexol is measured in deproteinized plasma or serum by HPLC or x-ray fluorescence. The commercially available preparations contain two isomers of iohexol, both of which are handled similarly by the body.[77,79] In practice, the major peak, eluting at approximately 5 min, is used for determining serum and plasma concentrations.[79] Most studies indicate close agreement between GFR (measured by inulin clearance) and clearance of iohexol, measured as standard renal clearance or plasma disappearance.[76,79–82] There is not only a very good correlation between plasma iohexol clearance and that of chromium-51–EDTA, but also no difference between the methods by Bland-Altman analysis.[83] Direct comparison

with iothalamate indicates that the iothalamate clearance exceeds that of iohexol by 19%.[84]

Modeling of plasma disappearance of iohexol indicates that its excretion conforms to a two-compartment open

system.[76,79] In a pilot study for the National Institutes of Health-supported CKiD study, we found that even with low GFR, serum iohexol concentrations decrease exponentially along the slow (renal) curve within 60 to 120 min of injection.[84] GFR measured after 5 h was comparable to that after 6 h, but shortening to 4 h in children resulted in a significant 3% overestimation of GFR.[85] Such studies have demonstrated the accuracy of GFR measurement obtained from two- and three-point blood sampling during the renal disappearance curve. The clearance of iohexol (GFR) may also be calculated from the slow (renal) plasma disappearance curve (one-compartment system approximation beginning 120 min after injection) according to the method of Brochner-Mortenson (see earlier), or by applying the Chantler correction, which assumes a correction factor of 0.87.[65,86,87] However, the Ng calculation is more accurate, is better correlated, and provides smaller bias and root mean square error.[66]

The collection of urine without urinary catheters (using various methods to establish that the bladder is empty after voiding) does not add significant accuracy to the clearance estimate.[85,86] The 24-h urine determinations may vary by as much as 10% to 15% from one day to another, and a similar phenomenon is noted when averaging multiple short urine collections.[17] Therefore, a fair correlation with standard inulin clearance is perhaps the best that can be expected, especially because bladder catheterization is considered more than minimal risk. The plasma disappearance of a marker that is excreted only by glomerular filtration may in fact be the gold standard that replaces the standard inulin clearance.

Determination of glomerular filtration rate by radionuclide scan

Estimation of GFR by use of radioisotopes is a commonly used technique in children, particularly with the limited availability of inulin and difficulties in collecting accurate timed urines in children. Commonly used radioisotopes are ^{99m}Tc-DTPA, ^{131}I or ^{125}I-Hippuran (a solution containing iodohippurate sodium), and ^{99m}Tc-MAG-3 (mercaptoacetyl-triglycine). Only the first is useful for GFR measurement. One method calculates GFR from the uptake of labeled

tracer in each kidney and allows determination of separate assessment of each kidney separately (split functions).[67] A second method uses the disappearance of the labeled marker from the plasma, and, as noted earlier, DTPA is variably accurate as a marker of GFR.[87]

Hippuran is secreted and thus does not give a measure of GFR, but rather of renal blood flow. Because of protein binding, Hippuran is not as accurate as p-aminohippurate for this purpose. Yet, it has been used as a dynamic radionuclide renographic determinant of renal function that complements the predominantly anatomic information provided by most other imaging techniques. MAG-3 has now supplanted hippuran for this purpose because of its higher extraction ratio, which results in improved renal images.[88]

> **KEY POINT**
>
> When corrected for body surface area, GFR reaches adult levels by the second year of life.

GLOMERULAR FILTRATION RATE TREND DURING CHILDHOOD

As seen in Table 4.4, full-term newborn infants have a very low GFR of 20.8 ± 5 mL/min/1.73 m² at birth, and by 19 days the GFR increases to 46.9 ± 12.5 mL/min/1.73 m².[89-97] Preterm babies, conversely, have even lower GFR, with a mean of 14.0 ± 5 mL/min/1.73 m² at 1 to 3 days. An increasing trend in GFR is, however, noticeable in the first 8 weeks in both full-term and preterm infants. Vieux et al.[98] reported GFR determined by 12-h Cr clearance methodology in very preterm infants, ranging from 27 to 31 weeks of gestation. An inverse relationship of GFR to the gestational age was noted in this series, with most preterm infants having the lowest median GFR. Mathematical derivation of median expected GFR in the very preterm infants can be calculated by the formulas proposed by these authors (Table 4.11).[98] Improvement in GFR is noted throughout infancy. When corrected for body surface area, GFR reaches adult levels by 2 years of age.

> **KEY POINTS**
>
> - Kidney tubular functions are responsible for reabsorbing filtered solutes and regulating serum concentrations of electrolytes, divalent ions, and neutral solutes; various transporters are expressed by the kidney to perform these functions.
> - Clearance studies and urine collection under specific conditions enable physicians to assess such tubular functions globally.

Table 4.11 Calculation of expected median glomerular filtration rate in very preterm infants at day 7 to 28 of postnatal life

Postnatal day	Median GFR (mL/min/1.73 m²)
Day 7	$-63.57 + (2.85 \times GA)$
Day 14	$-60.73 + (2.85 \times GA)$
Day 21	$-58.97 + (2.85 \times GA)$
Day 28	$-55.93 + (2.85 \times GA)$

Source: Data from Vieux R, Hascoet JM, Merdariu D, et al. Glomerular filtration rate reference values in very preterm infants. Pediatrics. 2010; 125:e1186–92.
Example: In a 27 week gestation baby at 7 days of age the median expected GFR is: $-63.57 + (2.85 \times 27)$, or 13.38 mL/min/1.73m2.
Abbreviations: GA, gestational age in weeks; GFR, glomerular filtration rate.

The presence of low GFR in newborns, especially in very preterm babies, indicates that the doses of all drugs, especially those excreted by the kidneys, must be appropriately adjusted to avoid drug toxicities.

TESTS FOR TUBULAR FUNCTIONS

The renal tubules transport solutes, hydrogen ions, organic ions, and water to maintain fluid, electrolyte, and acid-base homeostasis. Targeted evaluation of renal tubular functions may be necessary if there is suspicion of specific transport defects such as renal bicarbonate wasting, persistent metabolic acidosis, a concentrating defect, or a specific electrolyte transport disorder. Tests exploring specific aspects of the renal tubular functions under conditions in which the renal tubules must develop an adaptive response may uncover disorders that are not readily apparent under basal conditions.

Renal regulation of acid-base balance requires the reclamation of bicarbonate that is filtered at the glomerulus, primarily in proximal tubular function. Failure to reabsorb the filtered bicarbonate results in proximal renal tubular acidosis (PRTAs, or Type 2 RTA), a well-known cause of failure to thrive. Children with PRTA exhibit significant urinary bicarbonate loss. A second major renal function in maintaining acid-base homeostasis comprises the excretion of protons (H^+) and the generation of new bicarbonate to replenish the bicarbonate pool in the body. This function is primarily attributable to the distal nephron, predominately the cortical and medullary collecting ducts. The tests described in the

> **KEY POINT**
>
> Bicarbonate is reabsorbed quantitatively up to a threshold level, primarily by proximal tubular function.

next sections help characterize functions of the renal tubular segments. These tests have been functionally categorized as dealing with bicarbonate reabsorption, hydrogen ion excretion, water reabsorption, and solute reabsorption.

TESTS FOR RENAL BICARBONATE HANDLING

Renal bicarbonate threshold

Edelmann et al.[99] defined the renal threshold for bicarbonate as the point at which urinary excretion of bicarbonate exceeded 0.01 to 0.02 mmol/dL GFR, and this corresponded to a urine pH between 6.5 and 7.0. Oetliker and Rossi[100] considered urinary pH higher than 6.8 as a criterion for renal threshold. The bicarbonate titration is usually conducted after determining that the urine pH is less than 5.8 and therefore contains very little bicarbonate. At that point, the serum bicarbonate concentration is considered to be below the renal threshold.

> **KEY POINTS**
>
> - Synthesis and secretion of ammonia provide a major buffer for the excretion of acids and maintenance of acid-base homeostasis during acidosis.
> - There is a maturational rise in the ability to concentrate and dilute the urine, and specific tests for these functions are given in this chapter.
> - Urinary handling of a variety of solutes demonstrates maturational decreases in the excretion of sodium, potassium, calcium, phosphate, magnesium, and oxalate.

A baseline arterialized capillary blood sample or arterial blood is sampled for measurement of total carbon dioxide (tCO_2), pH, and partial pressure of CO_2 (pCO_2). Then, an intravenous solution of 0.2 to 0.5 M sodium bicarbonate ($NaHCO_3$) is infused at a rate anticipated to raise serum bicarbonate by approximately 2 mEq/L/h. Renal bicarbonate threshold is the serum bicarbonate level at which urine pH reaches between 6.5 and 7. Bicarbonate thresholds are 20 to 22 mM in infants, 22 to 24 mM in children, and higher than 24 mM in adolescents, but they are substantially reduced in children with PRTA.[73,100] In early investigative works, GFR with inulin was simultaneously obtained to evaluate bicarbonate filtered load and the serum threshold. However, endogenous Cr to calculate GFR and fractional excretion of bicarbonate (FE_{HCO3}) at the normal bicarbonate threshold is considered adequate.[101] The bicarbonate infusion is often doubled after the bicarbonate threshold is determined. This is to provide an additional alkali load for the purpose of calculating urine-blood pCO_2 (U-B pCO_2) to assess distal nephron function (discussed later). Clearly, this test must be done without significant volume expansion,

which is known to lower serum bicarbonate threshold and raise FE_{HCO3}, thus necessitating a slow infusion rate.

Because of its complex procedure, the bicarbonate threshold test is not generally performed in most clinical cases. Other easily performed clinical tests that provide similar diagnostic evidence are preferred over this test.

Fractional excretion of bicarbonate

The fraction of filtered bicarbonate excreted in urine is negligible in normal individuals. However, large amounts of filtered bicarbonate are lost in the urine of patients with PRTA. The fractional excretion of bicarbonate (FE_{HCO3}) test determines the fraction of filtered bicarbonate excreted in urine and can be used to differentiate PRTA from other types of RTA. The FE_{HCO3} is calculated from the following formula:

$$FE_{HCO3} = \frac{U_{HCO3} \times S_{crea}}{S_{HCO3} \times U_{creat}} \times 100$$

where U_{HCO3} is urine bicarbonate, S_{crea} is serum Cr, S_{HCO3} is serum bicarbonate, and U_{creat} is urine Cr.

Whereas serum bicarbonate, serum Cr,, and urine Cr can be easily assayed in most clinical laboratories, urine bicarbonate assay requires the use of blood gas machine. The conventional blood gas machines measure pH and pCO_2 and then mathematically calculate the bicarbonate value, using the Henderson-Hasselbalch equation. The output results from the blood gas machine are mathematically final data points, and no further calculations are necessary. Many clinical laboratories, however, do not feel comfortable in allowing the use of urine samples in the same blood gas machines as used for testing blood. The lack of harm to the machines or to the validity of the urine bicarbonate test results was convincingly demonstrated by Gonzalez et al.[102] Mathematically, urine HCO_3^- can be calculated from the Henderson–Hasselbalch equation:

$$HCO_3^- = \alpha CO_2 \times pCO_2 \times 10^{pH-pK}$$

where α is the solubility coefficient of urinary pCO_2 (0.0309).

$$pH = pK + \log (HCO_3^- / 0.03 \times pCO_2)$$

where pK is corrected for cation concentrations using the formula:

$$6.33 - 0.5 \times \sqrt{\text{urine sodium (mmol/L)} + \text{urine potassium (mmol/L)}}$$

The expected FE_{HCO3} at a normal level of serum bicarbonate is less than 5% in distal RTA (DRTA), greater than 15% in PRTA, and between 5% and 15% in type IV hyperkalemic RTA.[103] Apart from the diagnostic information, calculation

of FE_{HCO3} at the normal level of serum bicarbonate threshold also provides guidance in determining the appropriate initial dosage of bicarbonate therapy in children with RTA.

TESTS FOR URINARY ACIDIFICATION

The proton secretory capability of the distal nephron is tested to diagnose RTA in the presence of observed metabolic acidosis. Distal tubular secreted protons are present in solution, as determined by urine pH, or bound to two major urinary buffers, the phosphate and to a greater extent with ammonia. Titratable acid refers to the amount of alkali needed to raise the urine pH to 7.4. Urinary net acid excretion equals the sum of titratable acid and ammonium, minus bicarbonate.

Urine pH

Urine pH is a screening tool for distal tubular proton secretion. By examining the pH of the second fasting urine of the morning, one can exclude the possibility of incomplete or minor forms of DRTA if the pH is less than 6.0. The range of urine pH in early morning urine of normal children is 5.16 to 7.07, with a median pH of 6.0.[104] This clearly demonstrates the low specificity of urine pH as a screening test. Children who cannot concentrate the urine may also be unable to decrease urine pH adequately. Similarly, in patients with decreased extracellular volume, the urinary acidification defect may be a result of lack of sodium at the luminal side of the distal nephron. Other conditions causing high urine pH during metabolic acidosis include the following:

- Urinary infections with urea-splitting organisms
- Severe potassium depletion stimulating ammoniagenesis and generating excessive ammonia to buffer all free luminal protons
- Gastrointestinal losses producing avid salt retention with decreased distal sodium delivery, leading to an abnormal distal luminal electrochemical gradient and subsequent increased urinary pH[105,106]

Therefore, it is important also to measure urinary sodium and osmolality in addition to pH and ammonium, because a low pH associated with reduced ammoniuria does not exclude defective distal acidification, and contrarily, high ammoniuria may cause urine pH not to decrease to less than 5.5.

Urine-blood partial carbon dioxide pressure

Urine minus blood pCO_2 (U-B pCO_2) is an extension of bicarbonate threshold test discussed earlier, or it can be performed as a stand-alone test. In the setting of alkaline urine (and a higher driving force) resulting from bicarbonate

loading, increased secretion of protons (H^+) is also favored distally. The secreted protons combine with filtered bicarbonate to generate carbonic acid. Because of the limited carbonic anhydrase activity in the luminal side of the medullary collecting duct, the carbonic acid dehydrates very slowly into CO_2 and water.[107] This medullary trapping of CO_2 and the unfavorable surface-to-volume ratio of the lower urinary tract limit the diffusion of CO_2 out of the tubular lumen. Thus, the partial pressure of urinary CO_2 (U pCO_2) remains elevated with ongoing proton secretion, and this can be used as a reliable index of distal nephron proton secretion in conjunction with bicarbonate titration test.[108]

The U-B pCO_2 in the setting of alkaline urine (pH >7.5) is capable of detecting subtle defects of distal nephron acidification.[109,110] The normal value for U-B pCO_2 is greater than 20 mm Hg.[110,111] In DRTA, this value is less than 20 mm Hg.

Ammonium chloride loading test

Renal proton excretion (distal tubular function) is tested by measuring urinary ammonium excretion in response to an acid load. The acid load is usually given as ammonium chloride at a dose of 75 to 150 mEq/m², usually by oral route dissolved in lemon juice and sugar, or as enteric-coated capsules given over an hour. This regimen generally results in a state of moderate metabolic acidosis with blood pH lower than 7.33 and serum bicarbonate approximately 16 to 18 mEq/L. Normal subjects lower urine pH to less than pH 5.5 and increase net acid excretion to more than 70 μEq/min/1.73 m² (Table 4.12).[110,112] Patients with DRTA cannot

Table 4.12 Maturational changes of the renal response to an acute acid load seen in infants and children*

Term (1–3 wk)[†]	5.0 ± 0.2	32 ± 8[‡]	56 ± 9[‡]	88 ± 8[‡]
Infants (1–16 mo)	4.9 ± 0.1	62 ± 16	57 ± 14[‡]	119 ± 30
Children (7–12 yr)	4.9 ± 0.2	50 ± 10	80 ± 12	130 ± 14

Solution: Data from Edelmann CM, Jr., Rodriguez-Soriano J, Boichis H, et al. Renal bicarbonate reabsorption and hydrogen ion excretion in infants. J Clin Invest. 1967;46:1309–17.

* Mean ± SD; minimum urine pH (UpH); maximal titratable acid, ammonium, and net acid excretion in timed urine collections given as ± Eq/min per 1.73 m². Acute acid load was NH₄Cl given orally at 3.9 to 5 mEq/kg (75 to 100 mEq per m²) for infants and 5.4 mEq/kg (150 mEq per m²) for children.

[†] Data from [1]Svenningsen NW. Renal acid-base titration studies in infants with and without metabolic acidosis in the postneonatal period· Pediatr Res. 1974;8:659–72.

[‡] Significantly different ($P < 0.05$) from values in children by Tukey's test.

[§] Data from Schwartz GJ, Haycock GB, Edelmann CM, Jr., et al. Late metabolic acidosis: a reassessment of the definition. J Pediatr. 1979; 95:102–7.

decrease urine pH to less than 5.5 or increase net acid excretion to more than 70 µEq/min/1.73 m². In PRTA, these levels are achieved once serum bicarbonate falls to less than the reduced renal threshold. Patients with type IV RTA have a normal ability to decrease urine pH but defective excretion of ammonium and net acid. Like the bicarbonate titration test, the ammonium chloride loading test is seldom performed in clinical practice, and it has been replaced by other indirect measures of urinary ammonium excretion.

Urinary net charge

Urinary ammonium assay is not routinely performed in most clinical laboratories, and the ammonium chloride loading test is difficult to perform in clinical circumstances. Urinary net charge (UNC) or urinary anion gap is used as one of the surrogate tests for urinary ammonium excretion.[110,113–115] UNC is calculated from the urinary electrolytes obtained in a spot urine sample using the following formula:

$$UNC = UNa^+ + UK^+ - UCl^-$$

where UNa^+ is urinary sodium, UK^+ is urinary potassium, and UCl^- is urinary chloride.

A negative UNC is the appropriate response to chronic metabolic acidosis, indicating that urinary ammonium is present; a positive value suggests an absence of urinary ammonium and a defect in distal urinary acidification. The UNC cannot be used in high serum anion gap acidosis (because of excessive urinary organic anions) or in severe volume depletion with avid sodium retention (because of

decreased distal delivery). Caution should be used when interpreting the UNC in neonates.[116]

If excessive unmeasured urinary anions are suspected, urinary ammonium concentration can also be estimated from the difference between measured and calculated urine osmolalities.[115,117]

Urine $NH_4^+ = 0.5 \times$ Osmolality − [2(Na⁺ + K⁺) + urea / 2.8 + glucose / 18]

where ammonium (NH_4^+), Na⁺, and K⁺ are in mM; urea and glucose are in mg/dL.

A value lower than 20 mM is anticipated in a patient with DRTA.

Furosemide test

Furosemide increases distal sodium delivery, which generates an electronegative lumen potential, thus favoring proton secretion. This observation has been used to test distal tubular acidification. Within 2 h of furosemide administration (dose, 1 mg/kg) intravenously or orally, normal subjects excrete urine with pH lower than 5.2 and with kaliuresis. In a study of 20 children given 1 mg/kg furosemide, the mean urine pH recorded was 4.96, and fractional excretion of potassium (FE_K) was 35.4%.[118]

Patients with DRTA who have an intrinsic defect in the proton pump cannot maximally decrease urine pH in response to furosemide. Conversely, patients with type IV RTA and those with subnormal distal proton secretion secondary to low distal delivery of sodium (i.e., nephrotic syndrome) or reversible impairment of sodium distal reabsorption (i.e., sickle cell anemia or lithium administration) respond normally.

Acetazolamide test

The acetazolamide test is an extension of the U-B pCO_2 test and bicarbonate loading test to evaluate distal proton secretion capacity.[119] Acetazolamide inhibits carbonic anhydrase and reduces proximal tubular reabsorption of bicarbonate with resultant bicarbonaturia and alkaline urine. Acetazolamide simulates a bicarbonate load presented to the distal nephron. After oral acetazolamide administration at a dose of 15 to 20 mg/kg, pCO_2 is measured in blood and urine. A normal response shows an increase in urine pCO_2, suggesting increased proton secretion in the distal nephron, and U-B pCO_2 reaches to more than 20 mm Hg. Children with primary defects of the distal proton pump do not increase urine pCO_2.

TESTS FOR GLUCOSE HANDLING

The glucose loading test evaluates the glucose transport capacity of the proximal tubule. This test can be helpful in patients with a suspected diagnosis of Fanconi syndrome or PRTA. Filtered glucose is reabsorbed in the proximal tubule, and below a threshold level, all filtered glucose is reabsorbed and none is present in the urine. Once the filtered glucose saturates the proximal tubular transport systems, the maximal rate of reabsorption is attained. From that point onward, the urinary glucose excretion equals the filtered load of glucose. This test determines the serum glucose level at which the proximal tubular glucose transport is fully saturated.

To test the proximal tubular reabsorption of glucose, the patient should be in a fasting state so that the urine is free of glucose. The patient is hydrated by providing a water load (5 mL/kg). A 30% glucose solution is infused at a starting rate of 1.6 mL/m² per min, and the infusion rate is progressively increased to provide an increasing glucose load.[120] After a 20-min equilibration period, two or three 15-min collections of urine are obtained. Accurate urine collections may require bladder catheterization in young children. Serum samples are obtained at the midpoint of each urine collection period. The titration curve can be generated from the obtained data.

The normal serum glucose threshold is 180 mg/dL; the maximal tubular reabsorption of glucose normalized to 1.73 m² body surface area averages 213 ± 73 mg/min for infants 2.5 to 24 weeks old and 362 ± 96 mg/min for children 1.5 to 13 years old.[111] When it is normalized to GFR, there is no difference in maximum tubular glucose reabsorption (294 ± 74 mg/dL GFR for infants and 283 ± 47 mg/dL GFR for children).[121] Patients with Fanconi syndrome and PRTA have reduced thresholds for glucose reabsorption and have persistent glycosuria as a part of their symptom complex. The presence of glucose in the urinalysis should prompt the physician to the possibility of proximal tubular dysfunction.

TESTS FOR URINARY CONCENTRATING ABILITY

The ability to concentrate urine is an important evolutionary function of the kidneys. Difficulty in concentrating urine can be seen in many clinical conditions and may lead to repeated episodes of dehydration in infants if the condition is not recognized early. The simplest way to test urinary concentrating ability is to measure urinary osmolality after withholding fluids overnight. If frank diabetes insipidus is suspected, there is a significant risk of dehydration with this maneuver. In such cases, the water deprivation test should be performed during daytime under careful observation and over shorter a period of 6 to 8 h. A loss of 3% of body weight should be set as a trigger to terminate the test.

The overnight fluid withholding water derivation test involves giving a normal noon meal on the test, followed by a dry evening meal for dinner. The child does not ingest any water or food until the test is completed by the next morning. The bladder is emptied at bedtime, and all urine passed from bedtime to 7 a.m. is pooled as an overnight collection. Two subsequent urine collections are made in the morning for osmolality. Urine osmolality increases after 12 h of water deprivation. In healthy children older than 2 years of age, the mean value of urinary osmolality in the first and second urine samples voided after the overnight collection is greater than 1000 mOsm/kg (Table 4.13).[122,123] Infants during the first month of life concentrate the urine to approximately 60% of levels in older children. Maximal urinary concentration in these newborns can actually be enhanced to almost mature levels by ingesting a very high-protein diet (8 g/day/kg) while restricting in fluids to 120 mL/kg.[124]

In the absence of heavy proteinuria or radiocontrast material in the urine, osmolality can be approximated from urine specific gravity by multiplying the last two digits of the refractometric measurement by 40.[122] For example, a specific gravity of 1.027 corresponds to an osmolality of 1080 mOsm/kg, which denotes a normal concentrating capacity.

A longer period of fluid restriction may be required in patients with primary polydipsia because of hypotonic

Table 4.13 Urinary concentrating capacity in infants and children*

medullary interstitium in these patients. In such cases, a progressive reduction in fluid intake over days to weeks may be required before exposing the child to a concentrating test.

Vasopressin stimulation test

If a concentrating defect is demonstrated or suspected, the sensitivity of the kidney to exogenous antidiuretic hormone (ADH) is necessary to determine responsiveness to the hormone and to differentiate nephrogenic diabetes insipidus from a deficiency of ADH (central diabetes insipidus). Although vasopressin can be used, the agent used most commonly is 1-desamino-8-D-arginine vasopressin (desmopressin, DDAVP), which can be given intranasally or orally at doses of 10 μg in infants and 20 μg in children.[123] In infants, the usual fluid intake is restricted by 50% in the 12 h following DDAVP administration to prevent water retention and development of hyponatremia. Osmolality is measured in the individual urine samples over the 6 to 8 h after DDAVP administration. Assessing urinary concentration capacity by giving DDAVP at bedtime and collecting first morning urine sample the following morning also yields reliable results in children.[125]

TESTS FOR URINARY DILUTION ABILITY

When challenged with excess water, kidneys are able to excrete additional urine volume and rebalance the fluid status. This is an important homeostatic function that may be impaired in some patients and thus lead to fluid overload. Excretion of dilute urine requires the following important prerequisites: (1) ADH secretion must be completely, or nearly completely, suppressed; and (2) the nephron segments responsible for water free solute reabsorption (the ascending limb of the loop of Henle and the proximal portion of the distal convoluted tubule) must be morphologically and functionally intact. Inadequate free water clearance by the kidneys can result in inappropriate water retention and hyponatremia. Evaluation of renal water excretion, therefore, is important in the assessment of patients with true hyponatremia.

Osmolar and free water clearance

To understand the concept of water clearance more thoroughly, it is important to conceptualize that water excretion in urine consists of two separate compartments: (1) a vehicle for removal of daily solute load removal in an iso-osmotic state, the osmolal clearance (C_{osm}); and (2) water excretion that is not associated with any solute excretion, or free water clearance (C_{H_2O}). Of the two theoretical subparts, the volume of water excreted as C_{osm} (in mL) is determined by the solute content in diet. Water excretion as C_{H_2O} (in mL), conversely, represents the fraction that needs to be excreted to maintain a neutral fluid balance.

Total urinary water excretion (V) in mL = C_{osm} (mL) + C_{H_2O} (in mL)

Rewriting the formula:

$$C_{H_2O} \text{ (in mL)} = V \text{ (mL)} - C_{osm} \text{ (mL)}$$

Osmolar clearance is calculated by the following formula:

C_{osm}(in mL/min)

$$= \frac{\text{Urine Osmolality (}U_{osm}\text{)} \times \text{Urine Volume in mL(V)}}{\text{Plasma Osmolality } P_{osm}}$$

Therefore,

$$C_{H_2O}(\text{in mL}) = V(\text{mL}) - \frac{U_{osm}(\text{mL}) \times V(\text{mL})}{P_{osm}}$$

Or

$$C_{H_2O}(\text{in mL}) = V(\text{mL}) \times \left[1 - \frac{U_{osm}(\text{mL})}{P_{osm}} \right]$$

EXAMPLE

Urine volume = 4 mL/min

Urine osmolality = 150 mOsm/kg

Plasma osmolality = 285 mOsm/kg

Free water clearance or C_{H2O} (in mL/min) = $4 \times \left[1 - \frac{150}{285} \right]$

Or 4 × [1 − 0.52]

Or 4 × 0.48 = 1.92 mL/min

INTERPRETATION

Calculating free water clearance (C_{H_2O}) is used a tool to judge fluid status and responsiveness to ADH in patients with hyponatremia and other hypo-osmolar states. A C_{H2O} of zero means that the kidneys are excreting sufficient water to maintain a balanced volume status. A positive C_{H_2O} value reflects that more free water is being removed than ingested and that the body is in a net negative state of water balance. A negative C_{H_2O} value, which is also known as tubular reabsorption of water ($T^c_{H_2O}$), suggests that kidneys are retaining water in an amount greater than ingested, as would be the case in the syndrome of inappropriate antidiuretic hormone (SIADH), or volume depletion.

Water loading test

The water loading test is rarely performed in clinical circumstances, but it may be necessary in a patient with

hyponatremia. This test provides information on whether kidneys are excreting appropriate amount of free water to maintain homeostasis. The intent of the test is to suppress vasopressin and aldosterone maximally and to determine the following:

1. Measure the percentage of intake fluid volume excreted in a defined time.
2. Calculate indices of free water clearance and osmotic clearance.
3. Because renal free water is generated by reabsorption of solute without accompanying water in the diluting segment of the tubule (ascending limb of loop of Henle and proximal part of distal convoluted tubule), water load can also provide an indirect estimate of solute reabsorption in these segments of the nephron.[126]

PROCEDURE

The water loading test (also referred to as the Chaimovitz test) consists of providing an initial oral load of water at 20 mL/kg, followed by a constant intravenous infusion of 2000 mL/1.73 m^2 of 0.45% saline, administered over 2 h.[126] Urine and serum samples collected every 20 min and midpoint serum samples are also obtained for the next 4 h. Total volume of intake of fluids and urine excreted in 4 h is documented.[126,127] Calculations for osmolar clearance

(C_{osm}) and free water clearance (C_{H2O}) are performed at the peak of sustained diuresis, by using the formulas given earlier. Both infants (1 to 15 months old) and children (2 to 12 years old) are able to lower the urinary osmolality to 51.8 ± 12.8 mOsm/kg and 54.1 ± 13.3 mOsm/kg, respectively.[127,128] Clearances of solute (x), such as sodium, potassium, and chloride, are performed using the previously discussed clearance formula:

$$C_x = \frac{U_x \times V}{S_x}$$

INTERPRETATION

Normal individuals, including children, are able to excrete the entire volume or more of the fluid intake in 4 h of the test. Excretion of less than 80% of fluid intake as urine indicates an abnormally elevated amount of ADH, such as in SIADH.

Tubular sodium transport has been studied using the water loading test. To produce maximally dilute urine, sodium transport in the diluting tubular segments is enhanced. In patients with impaired sodium transport in these segments, decreased sodium absorption can be calculated from the obtained test data. Indeed, the water loading test was important in characterizing the site of sodium and chloride transport defects in Bartter syndrome.[126] Although the computed indices given in Table 4.14 can provide

Table 4.14 Urinary indices in normal infants and children undergoing maximal free water clearance*

Parameter	Infants	Children

Potassium clearance (mL/dL GF)	19.9 ± 12.0	12.9 ± 5.2[†]
Distal delivery (water + sodium, mL/dL GF)	20.4 ± 2.9	15.3 ± 2.6[†]
Percentage of sodium reabsorbed distally (%)	90.8 ± 4.5	90.9 ± 3.3
Creatinine clearance (mL/min/1.73 m^2)	88.5 ± 27.1	124.8 ± 25.2[†]

Source: Data from Rodriguez-Soriano J, Vallo A, Castillo G, et al. Renal handling of water and sodium in infancy and childhood: a study using clearance methods during hypotonic saline diuresis. Kidney Int. 1981;20:700–4.

* Data are mean ± SD. Data obtained at peak values of sustained water diuresis, resulting from an oral water load of 20 mL/kg over 30 min plus 0.45% saline at 1000 mL/h/1.73 m^2 over 2 h. N = 22 for infants (0.25 to 15 mo), 17 for children (2 to 12 years old). GF, glomerular filtrate; glomerular filtration rate is approximated by endogenous creatinine clearance.

† Significantly different from infants ($P < 0.05$).

Notes: Standard clearance formula: $Cx = Ux \times V/Px$ and is corrected to glomerular filtrate or 1.73 m^2 body surface area. Free water clearance, C_{H2O} = Volume – Osmolar clearance, and it provides an estimate of sodium reabsorption by the diluting segments. Distal delivery = free water clearance + sodium clearance; in the absence of bicarbonaturia or hyperkaluria, distal delivery is nearly identical when using sodium or chloride clearance. Percentage of sodium reabsorbed distally = free water clearance / (free water + sodium clearances).

useful information about tubular transport, several theoretic assumptions used in the test model require interpretation with caution.[127]

TESTS FOR URINARY SOLUTE EXCRETION

The kidneys refine the homeostasis of electrolytes by varying their urinary excretion. Most of these solutes are freely filtered and are either secreted or reabsorbed by the tubules. The urinary excretion of such solutes thus reflects tubular transport functions of the kidney. The following section briefly summarizes the normal handling of a variety of such electrolytes and their clinical interpretation.

Sodium, chloride, and potassium

On a normal Western diet, children excrete approximately 3 to 4 mmol/kg/ day of sodium. Water and salt homeostasis requires independent regulation of sodium and water because the intake of each may vary independently. Thus, the concentration of sodium in the urine depends on the degree of concentration or dilution, in addition to intake. For this reason, the excretion of urinary solutes is frequently normalized to that of Cr. Under conditions of severe volume contraction, sodium can be undetectable in the urine. Normal sodium/Cr ratios are depicted in Table 4.15.

The handling of sodium is often expressed as a fractional excretion rate. The fractional excretion of sodium (FE_{Na}) is calculated as follows:

$$FE_{Na} = \frac{U_{Na}/S_{Na}}{U_{Cr}/S_{Cr}} \times 100$$

FE_{Na} ranges from 0.3% to 1.6% depending on salt intake.[129] In patients with prerenal acute renal failure, FE_{Na} is less than 1%, whereas it is greater than 3% in acute tubular necrosis.

Chloride is handled similarly to sodium. The measurement of urinary chloride is useful in the diagnosis of metabolic alkalosis. A urinary chloride concentration greater than 10 mM indicates metabolic alkalosis of renal origin, whereas lower concentrations of urinary chloride suggest volume contraction as the cause of metabolic alkalosis.

Urinary potassium excretion is approximately 1 to 2 mmol/kg/day, and regulation of this process occurs in the distal nephron under the influence of aldosterone and the amount of salt and water delivered to the distal nephron. The renal ability to conserve potassium is not as effective as for sodium, such that urinary potassium excretion does not decrease to less than 15 mM. Normal potassium/Cr ratios are depicted in Table 4.15. Normal fractional potassium excretion in children ranges from 10% to 30%.[101]

Transtubular potassium gradient

The transtubular potassium concentration gradient (TTKG) is a semiquantitative estimation of potassium secretory process in the distal nephron, primarily cortical collecting duct.[130] The test is useful in evaluating the appropriateness of the potassium secretory process in the presence of hypokalemia and hyperkalemia.[131] Two important assumptions for the test are as follows: (1) urine is not dilute, and urine osmolality should exceed that of plasma (>300 mOsm/kg); and (2) urinary sodium is greater than 25 mmol/L, so distal potassium exchange is not limited by low distal sodium delivery.

TTKG is calculated in a spot urine sample by the following formula:

$$TTKG = \left[\frac{U_K}{S_K} \div \frac{U_{osm}}{S_{osm}} \right]$$

Where U_K is urine potassium, S_K is serum potassium, U_{osm} is urine osmolality, and S_{osm} is serum osmolality.

Table 4.15. Age-dependent fifth and ninety-fifth percentiles for urinary solute/creatinine ratios*

Solute/Cr (mol/mol)	Age (yr)

Source: Data from references 73, 134, and 140.
Abbreviations: Ca, calcium; Cr, creatinine; K, potassium; Mg, magnesium; Ox, oxalate; P, phosphate; Ur, urate.
* For conversion to mg units, 1 mmol = 113 mg Cr; 23 mg Na; 39 mg K; 40 mg Ca; 32 mg P; 24 mg Mg; 90 mg Ox; and 168 mg Ur.

INTERPRETATION

Indirectly, TTKG tests the action of aldosterone in the distal nephron. TTKG in normal infants (1 to 12 months old) has been shown to be higher (median, 7.8 months) than in children 1 to 15 years old (median, 6.0 years).[132] This may reflect a higher level of serum aldosterone level in infants, as compared with children and adults. In hyperkalemia, TTKG is expected to be high, usually greater than 10. A low TTKG in presence of hyperkalemia in such cases suggests hypoaldosteronism or pseudohypoaldosteronism.[118,132] Rodriguez-Soriano et al.[132] noted that in children with hyporeninemic hypoaldosteronism and pseudohypoaldosteronism, TTKG ranged between 1.9 and 4.1. Normal response in patients with hypokalemia, conversely, is expected to be a low TTKG. Elevated TTKG in such circumstances indicates a mineralocorticoid excess state, either endogenously or when mineralocorticoids (fludrocortisone) are administered exogenously.[133]

Calcium, phosphate, and magnesium

Urinary calcium excretion is often examined as a cause of hematuria and kidney stones. The excretion of calcium depends not only on diet but also on age, with higher rates of calcium excretion in infants.[134,135] In a southern Italian study, the urinary excretion of calcium ranged from 3 to 4 mg/kg per day in children 3 to 5 years old and decreased to 1.5 to 2.5 mg/kg per day in children 15 to 16 years old.[136] In children older than 5 years of age, hypercalciuria is usually defined as the excretion of more than 4 mg/kg/day or a urine calcium/Cr ratio greater than 0.2, and it constitutes a risk factor for the development of kidney stones or nephrocalcinosis.[137,138]

Urinary phosphate excretion decreases with maturation.[139] Older children normally excrete 15 to 20 mg/kg per day, compared with 35 to 40 mg/kg per day in young children.[136] After age 4 years, the fractional excretion of phosphate is approximately 7% ± 3%.[96]

Urinary magnesium excretion also shows a maturational decrease, as shown by the magnesium/Cr ratios (see Table 4.15). Older children excrete 1.5 to 2.0 mg/kg per day, compared with 2.3 to 2.6 mg/kg per day in younger children.[136] The fractional excretion of magnesium is normally approximately 5%, but it decreases to less than 1% in the setting of magnesium deprivation.[139]

Uric acid, oxalate, and citrate

Elevated concentrations of uric acid and oxalate and low levels of urinary citrate are also risk factors for the development of kidney stones. Both oxalate and uric acid show maturational decreases in urinary excretion.[140–146] Uric acid excretion decreases from 10 to 20 mg/kg/day in 3- to

5-year old Italian children to 5 to 10 mg/kg/day in older children.[136] Brazilian children show a decrease from 5 to 15 mg/kg/day (mean, 10.5 ± 5.0 mg/kg/day) in preschoolers to 4 to 10 mg/kg per day (mean, 7.0 ± 3.0 mg/kg/day) in adolescents.[143] Hyperuricosuria is also diagnosed by examining urine uric acid concentration factored by Cr clearance ($U_{urate} \times S_{creat} / U_{creat}$, each in mg/dL); hyperuricosuria is defined by a value greater than 0.54 to 0.56 mg/dL of glomerular filtrate.[138,144] Alternatively, hyperuricemia is defined as excretion of uric acid greater than 815 mg/24 h/1.73 m[2].[145]

Urinary oxalate excretion ranges from 1 to 2 mg/kg per day in Italian children 3 to 5 years of age and decreasing to 0.3 to 0.7 mg/kg/day in older children.[136] Table 4.15 shows the decrease in urine oxalate/Cr ratios with age.[140] Hyperoxaluria is also defined as urinary oxalate exceeding 0.5 mmol (45 mg)/24 h/1.73 m[2], or 0.048 mg oxalate/mg Cr (0.06 mol/mol) in children older than 5 years of age.[140]

Urinary citrate excretion normally averages 0.03 mmol (6.3 mg)/kg/24 h.[146] The range of urinary excretion of citrate does not show maturational changes, but it is clear that girls excrete more urinary citrate than do boys.[147] Hypocitraturia predisposes to kidney stone formation. Hypocitraturia is defined as a urinary citrate/Cr ratio less than 300 mg/g (0.176 mol/mol) in girls and 128 mg/g (0.074 mol/mol) in boys.[147]

NOVEL BIOMARKERS OF RENAL FUNCTION

Assessment of renal function in patients with AKI is challenging in the context of a very sick child in the intensive care unit undergoing multiple confounding pharmacologic interventions. A rise in serum Cr, which is the most readily available clinical marker of renal function, is a late event marker that rises after more than 50% of the renal function has been lost, making it unsuitable for early detection of renal disease.[148] Serum, Cys-C level, conversely, has been shown to rise before detectable changes in serum Cr are seen.[149] In addition, Cr- or Cys-C–based GFR equations have not been validated in patients with AKI, but these equations may provide a "guesstimate" of the GFR at given point in time for therapeutic considerations in patients.

The last decade has seen a sizable effort toward development of biologic markers that may help in early detection and follow-up of renal function in acutely sick individuals.[150] The role of the novel proteomic biomarkers includes early diagnosis of AKI, concordance with GFR, and allowance of an assessment of therapeutic interventions by monitoring progression. Although several biomarkers have been proposed (Figure 4.4), none is able to predict GFR under the mandated clinical conditions.
Figure 4.4 Anatomic localization of novel biomarkers along the nephron. ADMA, asymmetric dimethyl arginine; CTGF, connective tissue growth factor; GGT, γ-glutamyl transpeptidase; GST, glutathione-S-transferase; IL-18, interleukin-18; KIM-1, kidney injury molecule-1; LDH, lactate dehydrogenase; NAG, *N*-acetyl glucosaminidase; NGAL, neutrophil gelatinase-associated lipocalin. (From McMahon GM, Waikar SS. Biomarkers in nephrology: core curriculum 2013. Am J Kidney Dis. 2013;62:165–78.)

Many of the novel proteomic markers for evaluation of renal function can be assayed in urine and blood. Although urinary markers have many advantages, such as being close to the site of injury and potential early detection of abnormalities, potential disadvantages, such as variability resulting from urinary concentration and hydration status, also exist. Broadly, the proposed novel markers of renal injury can be classified into two subgroups[148]:

1. Preformed and upregulated in renal injury
2. Induced by renal injury

Preformed biomarkers are normally present in renal tissue and are released into circulation or urine by renal injury. Examples include: N-acetyl-γ-glucosaminidase (NAG), γ-glutamyl transpeptidase (GGT), kidney injury molecule-1 (KIM-1), and lactate dehydrogenase (LDH). In other cases, the preformed biomarkers may be freely filtered at the glomerulus and are normally reabsorbed by the tubules. In case of renal cell injury, these markers fail to become reabsorbed by their respective tubular segments and are excreted in urine. Examples of this category of preformed biomarkers include: β2-macroglobulin, microalbuminuria, urinary Cys-C, and retinol binding protein-4 (RBP-4). The second class of biomarkers comprises those induced by renal injury or inflammation. Examples of this class of biomarkers include neutrophil gelatinase–associated lipocalin (NGAL), interleukin-18 (IL-18), and osteopontin (OPN).

The utility of biomarkers in the diagnosis and follow up of renal injury is evolving. At this time, no clear gold standard biomarkers have been established. It is likely that a panel of biomarkers will provide a better measure of renal injury in AKI, by evaluating multiple sites of tubular injury in the nephron. The utility of biomarkers in the diagnosis of AKI is also discussed in Chapter 30.

SUMMARY

Clinical care of children with acute and chronic kidney diseases requires an assessment of renal function from both diagnostic and follow-up perspectives. GFR is long established as the best indicator of overall human renal function. Estimation of GFR by clearance methodology, using exogenously administered and endogenous markers, has been the mainstay of evaluations over the past several decades. An estimation of GFR from endogenous biomarkers by various mathematical equations has been attempted since the 1980s, and many of these methods are available for clinical use. Because of a lack of steady state for Cr as well as Cys-C in AKI, application of the GFR equations cannot be advocated. Indeed, to predict early renal injury in AKI, especially when surgical interventions are necessary or nephrotoxic treatments are planned, several novel markers of renal function are being evaluated. So far, no gold standard markers have been established, and it is likely that a panel of such markers may be clinically relevant. For the near future, to obtain an accurate appraisal of renal function, GFR may require direct measurement by plasma or renal clearance techniques.

REVIEW QUESTIONS

1. A 5-year-old boy was admitted with the diagnosis of acute lymphoblastic leukemia. After induction chemotherapy he was noted to be hyponatremic, with a serum sodium concentration of 131 mmol. Normal saline was given as maintenance solution. Five days later he developed generalized tonic-clonic seizures. His serum electrolytes were as follows: glucose, 107 mg/dL; sodium, 122 mmol/L; chloride, 82 mmol/L; potassium, 3.5 mmol/L; and bicarbonate, 22 mmol/L. BUN was 16 mg/dL, and creatinine was 0.6 mg/dL. A

diagnosis of SIADH was entertained. The calculated serum osmolality of this patient is:

  a. 244
  b. 122
  c. 256
  d. 287

2. In a 10-year-old girl who had her right leg amputated at the hip 6 months ago for osteosarcoma, the Schwartz formula and modified Schwartz formula do not predict GFR accurately, and loss of limb needs to be accounted for.

  a. True
  b. False

3. Accuracy of predicting GFR by formulas based on serum cystatin C and serum creatinine is:

  a. No better than each one alone
  b. Less accurate than each one alone
  c. Better than each one alone
  d. Cystatin C alone is always better.

4. Cystatin C is an ideal marker for determining GFR. However, classic clearance methodology for clearance, by using a timed collection of urine and serum concentration, cannot be used with cystatin C because:

  a. It is not produced at a constant rate.
  b. It is freely filtered by glomeruli but is entirely reabsorbed in the loop of Henle.
  c. It is freely filtered by glomeruli but is entirely metabolized in the proximal renal tubule.
  d. It is not freely filtered by the glomeruli.
  e. It cannot be assayed in urine.

5. The modified Schwartz eGFR formula mandates using enzymatic serum creatinine measurement that is calibrated to reference standards by isotope dilution mass spectroscopy (IDMS), but not to "Jaffe" (alkaline picrate) methods.

  a. True
  b. False

6. Urea splitting organisms, such as *Proteus, Pseudomonas, Klebsiella, Staphylococcus,* and *Mycoplasma* hydrolyze urea to ammonium and lead to the following changes:

  a. Decreased urine pH
  b. No change in urine pH
  c. Raised urine and blood pH
  d. Raised urine pH only

7. Evaluate this statement: "When C_{H2O} is a positive number, it indicates increased free water clearance and a diuretic state."

  a. True
  b. False

8. Novel biomarkers of renal function are useful for:

  a. Early detection of AKI
  b. Indicating the onset of AKI after cardiovascular surgery or contrast use
  c. Providing information on the potential site of tubular injury in AKI
  d. All of the above

9. A 2½ year old white boy presented with a large right abdominal mass of 2 weeks' duration. He also had decreased appetite. Laboratory studies on presentation were as follows (in mmol/L): serum sodium, 130; potassium, 3.9; chloride, 92; and bicarbonate, 21. BUN and creatinine were 10 mg/dL and 0.4 mg/dL, respectively. The patient weighed 13.7 kg and was 92.5 cm tall. He underwent an open biopsy of the abdominal mass that documented the diagnosis of rhabdoid tumor of the right kidney. Regional lymph nodes and lungs had metastases. Right nephrectomy was followed by chemotherapy. He also underwent right flank and whole lung radiation. DTPA nuclear GFR was 48 mL/min/1.73 m^2 at 6 months. Serum creatinine was 0.6 mg/dL at 6 months, and the serum cystatin C level was 1.03 mg/L. His height and weight at 6 months postoperatively (2.5 years of age) were 13.6 kg and 95.7 cm, respectively. Calculated GFR by various formulas at 6 months was as follows: 104.5 mL/min/1.73 m^2 (original Schwartz), 65 mL/min/1.73 m^2 (IDMS-traceable Schwartz GFR formula), and 65.8 mL/min/1.73 m^2 (CKiD). The patient's estimated GFR is best reflected by all, *except:*

  a. CKiD formula
  b. Schwartz original eGFR
  c. DTPA nuclear GFR
  d. IDMS-traceable creatinine based Schwartz GFR

10. In the case given in question 9, a poor correlation of DTPA nuclear GFR and serum creatinine–based eGFR is *best* explained by:

  a. Patient's receiving radiation therapy
  b. Fluid volume retention
  c. Chemotherapy causing renal toxicities
  d. Loss of muscle mass resulting from poor nutrition

11. A 30-kg male patient has a 2-day history of gross hematuria and left flank pain. He is treated with intravenous fluids, analgesics, and a blocker agents in the emergency department. He passes a stone in the urine. A 24-h urine study shows the following: volume, 1200 mL; citrate, 400 mg/g creatinine; oxalate, 0.05 mg/mg creatinine; and Ca/Cr ratio, 0.45. The stone passed is *most likely* to be:

  a. Uric acid
  b. Calcium phosphate
  c. Calcium oxalate
  d. Struvite

Normal and abnormal kidney function in neonates

DAVE T. SELEWSKI AND DAVID J. ASKENAZI

The neonatal period represents a period of rapid changes in renal blood, glomerulogenesis, and physiology that impacts kidney function. This chapter reviews the timing of glomerular development and the physiologic changes that occur following birth, with a particular focus on the pathophysiology associated with perturbation in these processes. This includes a discussion of the impact of prematurity on processes such as tubular function, glomerulogenesis, and glomerular filtration. Finally, this chapter focuses on acute kidney injury (AKI), including definition, high risk populations, and the implication for both short-term and long-term outcomes.

RENAL PHYSIOLOGY FOLLOWING BIRTH

RENAL BLOOD FLOW

Changes in renal blood flow shortly after birth drive changes in the neonatal glomerular filtration rate (GFR). There are marked changes in the proportion of cardiac output distributed to the kidneys throughout development and immediately following birth. The blood flow to the fully mature adult kidneys typically accounts for 20% to 30% of the cardiac output. This is in stark contrast to the developing fetal kidney, which receives 2.5% to 4% of cardiac output.[1] In the first 24 hours after birth, this increases to 6% of the cardiac output and continues to increase to 10% of the cardiac output at 1 week of life[2,3] and to 15% to 18% of the cardiac output at 6 weeks.[4] The dynamic changes in renal blood flow that occur following birth are driven by increased renal perfusion pressure and decreased renal vascular resistance.

KEY POINT

There are dynamic changes in renal blood flow following birth, with increase in the percentage of cardiac output delivered to the kidney from 2.5% to 4% in the fetal kidney to 6% of the cardiac output at 24 hours of life, 10% of the cardiac output at 1 week of life, and to 15% to 18% of the cardiac output at 6 weeks.

The increased renal perfusion pressure in the neonatal period results from an increased systemic blood pressure secondary to increased cardiac output and changes in systemic vascular resistance. Following birth there is an increase in the cardiac index, resulting in increased cardiac output in neonates. At the time of birth, the placenta typically receives approximately 40% of the cardiac output. The act of clamping the placenta leads to a significant increase in systemic vascular resistance following birth. Consequently, there is a steady increase in systemic blood pressure during the neonatal period. Although these factors contribute to increases in renal blood flow, the largest contribution results from changes in the renal vascular resistance.[5]

Renal vascular resistance and peripheral vascular resistance both remain high following birth, but renal vascular resistance begins to decrease at 24 hours of life. The decrease in renal vascular resistance occurs at a time when systemic vascular resistance is increasing. As shown in animal models, the decrease in renal vascular resistance is the major contributor to increased renal blood flow in neonates.[5] The decreased renal vascular resistance is driven by a number of factors, including a redistribution of renal blood flow within the kidney, changes in the number of vascular channels, and factors affecting glomerular arteriolar resistance.[6]

The distribution of renal blood flow in the fetal and newborn kidney is different from that in an adult kidney. In the newborn kidney, renal blood flow is preferentially directed toward the renal medulla and the inner cortex. This is reflective of the fetal development of the kidney. Following birth, there is increased renal blood flow to the outer cortex. The change of distribution of renal blood flow matures over the first 3 months of life. The increased distribution of blood to the outer cortex contributes to the decreased renal vascular resistance and subsequent increases in renal blood flow following birth.

KEY POINT

Renal blood flow in the fetal and newborn kidney is distributed differentially throughout the kidney relative to an adult kidney, with blood flow preferentially directed toward the renal medulla and inner cortex.

A potential determinate of renal blood flow is the cumulative diameter of vessels. This can be increased by changes in individual diameter and by an increase in the number of vessels. The increased number of vessels is driven by nephrogenesis. In the developing fetus, nephrogenesis is complete by 34 to 36 weeks. The extent to which premature infants complete their potential nephrogenesis after birth has yet to be determined. The degree to which nephrogenesis continues will determine overall renal vascular resistance.[5] Conversely, in a term infant, an increase in vessel number does not make a significant contribution to changes in renal blood flow.

The primary factor determining renal blood flow after birth is changes in the arteriolar resistance driven by the response of small arteries to neurohormonal stimuli. The afferent and efferent arterioles remain the primary determinants of individual glomerular blood flow and contribute to overall renal vascular resistance. The primary drop in renal vascular resistance following birth occurs at the afferent arteriole pole, which allows for increased flow as cardiac output increases.

CONTROL OF RENAL BLOOD FLOW IN THE NEWBORN

Autoregulation

The mature kidney has an intricate ability to maintain renal blood flow and GFR despite hemodynamic changes. Two components of this regulation are the myogenic reflex and tubuloglomerular feedback (TGF). The myogenic reflex is an element that is intrinsic to the vascular smooth muscle. In response to increased stretch representing increased flow, the afferent arterioles contract, maintaining a constant renal blood flow and GFR. This phenomenon has been demonstrated in isolated renal vessels. The role of the myogenic reflex in the fetal and neonatal kidney remains unclear.

The second regulatory mechanism is TGF, which describes the phenomenon by which the cells of the macula densa sense the distal tubular fluid flow. This system seeks to maintain a constant flow distally. A number of vasoactive substances are involved in TGF, including angiotensin II (ATII), adenosine, endothelin, and nitric oxide (NO).

Renin-angiotensin system

The renin-angiotensin system (RAS) is active throughout fetal development and contributes significantly to renal vascular resistance during the fetal and neonatal period through its vasoconstrictive activity. In the fetal and early neonatal period, the circulating levels of renin, angiotensin-converting enzyme (ACE), and angiotensin are frequently higher than adult levels.[7,8] During fetal development, renin production occurs in areas outside of the juxtaglomerular apparatus.[2,9,10] Renin levels are elevated throughout fetal development and remain high in neonates relative to adult values.[11] Following birth, renin production decreases throughout the kidney until it is found only in the juxtaglomerular apparatus.[12] ACE levels remain low throughout fetal life, with slight increases noted approaching term. Levels sharply increase following birth and peak at levels greater than adult values.[8] ATII levels are elevated during the fetal period and remain elevated in the neonatal period.

As part of the maturation of the RAS, there are changes in the types of angiotensin receptors. There are two forms of the angiotensin receptor, AT-1 and AT-2, which are expressed differentially in the fetus and neonate. The AT-1 receptors are coupled to G-proteins, and activation results in increased intracellular calcium and diacylglycerol. The AT-2 receptors are not associated with a G-protein, but instead activate an intracellular phosphatase, decreasing levels of cyclic adenosine monophosphate (cAMP). The AT-2 receptor is expressed in the fetal kidney and plays an

important role in kidney development. The expression of AT-2 receptors decreases significantly following birth, but remains present at low levels in adult tissues.[13] The AT-1 receptor is initially at low levels in the developing fetus, but increases rapidly during hemodynamic development of the kidney and after birth.[14] The AT-1 receptor primarily mediates vasoconstriction. In animal models, disruption of either AT-1 or AT-2 receptors is capable of causing congenital malformations of the kidneys and genitourinary tract.

ATII is the effector of the RAS and is highly active in the newborn. ATII acts as a vasoconstrictor on both the afferent and efferent arterioles, leading to increased renal vascular resistance via the AT-1 receptor. ATII is capable of increasing the GFR because the relative diameter of the efferent arteriole is smaller than that of the afferent arteriole, resulting in a greater increase in resistance and increased GFR. ATII also acts in the proximal tubule to increase sodium reabsorption by increasing expression of a number of sodium cotransporters.

Prostaglandins

Prostaglandins (PGs) are potent vasodilators and increase renal blood flow by causing vasodilatation of the afferent arteriole.[15] PGE_2 and PGI_2 are the major PGs involved in the regulation of renal blood flow. Under basal conditions there are low levels of PGs present in the neonatal kidneys. PGs become important to maintain renal perfusion during times of stress, including the neonatal period. During critical illness, PGs counterbalance the effects of ATII, catecholamines, and other vasoconstrictive substances elicited by a stress response.

PGs are increased when vasoconstrictive hormones activate phosphatidylinositol turnover, resulting in the production of diacylglycerol, which, following cleavage, leads to the production of PGs.[16] This damps the vasoconstriction of the afferent arteriole, preserving renal blood flow and maintaining GFR. This likely explains the decrease in urine output that can occur with neonatal exposure to inhibitors of PG formation (e.g., indomethacin or ibuprofen).

Nitric oxide

NO is produced by NO synthetase in vascular endothelial cells. NO is a potent vasodilator of the microcirculation, leading to vasodilatation by activation of cyclic guanosine monophosphate (cGMP). NO is released in response to a number of physiologic stimuli that result from increased vasoconstriction. NO plays a critical role maintaining renal blood flow in the developing kidney and following birth by dampening the effects of potent vasoconstrictors such as AT-2.[17] In animal models, blockade of NO late in fetal

development resulted in significantly increased renal vascular resistance and decreased renal blood flow.[18]

Bradykinin

Bradykinin is a product of the kallikrein-kinin system and is the major vasodilator produced by this system. Bradykinin elicits vasodilatation by inducing NO and PG production, leading to increased renal blood flow and natriuresis.[19] Blockade of the bradykinin receptors during fetal development can have an impact on nephrogenesis in animal models and predispose to salt-sensitive hypertension.[20,21]

Endothelin

Endothelin is known to be a potent vasoconstrictor produced by endothelial cells of the renal vasculature, distal tubular cells, and mesangial cells. Endothelin production is regulated by bradykinin, AT-2, catecholamines, and shear stress. Endothelin causes both afferent and efferent arteriolar vasoconstriction, but there is a greater effect on the afferent arteriole, leading to decreased renal blood flow and GFR.[22]

Adenosine

Adenosine is a breakdown product of adenosine triphosphate and plays an important role in TGF. The effects of adenosine depend on which receptors are activated. Through its action on AT-1 receptors, adenosine causes constriction of the afferent arteriole; binding to AT-2 receptors causes dilation of the afferent and efferent arterioles. Adenosine therefore plays a role in renal blood flow and the distribution of blood flow throughout the kidney. During stress, adenosine predominately causes dilation of the arterioles. Theophylline is nonspecific antagonist of adenosine and has been shown to ameliorate hypoxia-induced renal damage in rabbit models.[23,24] In high-risk neonates with oliguric kidney injury, theophylline has been shown to improve urine output and GFR.[25] Subsequent randomized clinical trials have shown improved renal function and urine output in high-risk neonates treated with theophylline.[26–28]

Renal nerves

The renal nerves act to control renal vascular resistance primarily by the release of catecholamines and their subsequent action on the afferent arteriole mediated through the α_1 adrenoceptor.[29,30] Catecholamines also increase renin release. Around the time of birth, there is an initial rise in catecholamine levels that contributes to increased renal vascular resistance. Over the first couple days of life these levels fall significantly,[31] likely contributing to decreased renal vascular resistance.

GLOMERULOGENESIS

Renal development commences during the fifth week of gestation with partially functional temporary organs (the pronephros and metanephros), and the first nephrons are formed by approximately the eighth week of gestation. Urine output commences at approximately 12 weeks of gestation. The number of glomerular generations increases during gestation, with 4 generations at 14 weeks and 12 or 13 generations at 36 weeks. The juxtamedullary nephrons develop initially, with superficial ones following. Nephrogenesis continues until 34 to 36 weeks of gestation, at which time the number of nephrons, 1.6 to 2.4 million, approximates that of an adult.[32] Autopsy studies suggest that the extrauterine environment is not amenable to neoglomerulogenesis, leading to low nephron number in premature infants.[33]

Lower nephron number can result in single-nephron hyperfiltration. This enhances GFR such that individuals with a low nephron number can have a GFR that is comparable to that in individuals with normal nephron numbers. The impact of low nephron endowment may become problematic over time as single nephron hyperfiltration may cause dynamic changes leading to glomerulosclerosis and progressive loss of kidney function.

RENAL TUBULAR FUNCTION

The proximal tubule is responsible for the bulk of solute reabsorption that occurs in the kidney, including bicarbonate, glucose, phosphate, and amino acids. The driving force for much of the absorptive processes in the proximal tubules and throughout the nephron is the gradient created by the Na^+-K^+-ATPase.[34] The Na^+-K^+-ATPase is on the basolateral membrane of tubular cells. The Na^+-K^+-ATPase maintains the low intracellular sodium concentration and negative electrochemical potential that drive a number of reabsorptive processes.[35] Na^+-K^+-ATPase activity is lower in neonates and increases significantly in the proximal tubule and each segment of the nephron after birth.[36,37]

SODIUM BALANCE

In the immediate neonatal period, there is a significant natriuresis, which can be profound in preterm infants.[38] This natriuresis is mediated by atrial natriuretic peptide.[39] Following birth, urine sodium excretion is high and is inversely proportional to the maturity of the neonate.[40] In premature infants, fluid losses over the first week of life may be desirable because high fluid intake can be associated with patent ductus arteriosus, bronchopulmonary dysplasia, cardiac failure, necrotizing enterocolitis, and intraventricular hemorrhage.[41]

The inhibition of sodium transport peaks at 4 days following birth and is followed by a shift to conserve sodium, which is needed for growth. This shift toward sodium conservation is driven by maturational changes of sodium transport across multiple nephron segments. In the proximal tubule, there is an increase in activity of the Na^+-H^+ exchanger, the renal sodium/phosphate type 2 (NaPi-2) transporter, and sodium cotransporters (with glucose, amino acids, and phosphate) driven by maturation of the basolateral the Na^+-K^+-ATPase. The thick ascending limb of the loop of Henle undergoes significant maturational changes, which at birth has 20% of the adult capacity to transport sodium.[42] This is due to low activity of the Na^+2Cl^- K^+ cotransporter and Na^+-K^+-ATPase. Following birth, there is significantly increased activity of both transporters. Furthermore, maturational changes occur in the sodium chloride cotransporter in the distal tubule and the epithelial sodium channel in the collecting duct.

POTASSIUM BALANCE

In older children and adults, there is a neutral potassium balance. During the period following birth, the neonate requires a positive potassium balance to sustain rapid growth.[43] However, even with potassium loading, term infants are able to excrete high amounts of potassium. The capacity to excrete potassium is lower in premature infants, which increases the risk for hyperkalemia. Some have suggested that 25% of infants with extremely low birth weight (less than 1000 g) develop at least one episode of hyperkalemia.[44] Consequently, term and preterm infants frequently have higher potassium levels than older children.[45]

The proximal tubule reabsorbs 50% to 65% of filtered potassium.[43,46,47] As mentioned previously, the mechanisms for the reabsorption of potassium in the loop of Henle are immature following birth; this increases the amount of potassium delivered to the distal nephron.[43,46] The distal nephron is responsible for the final modulation of potassium excretion. There

are two channels that are the rate-limiting steps in potassium secretion in the distal nephron. The renal outer medullary potassium channel, found on the principal cells, is responsible for the basal secretion of potassium. The maxi-K$^+$ channel, located on the principal and intercalated cells, is responsible for flow-dependent potassium secretion.[48] In contrast, reabsorption of potassium occurs in the distal tubule by an H-K$^+$-ATPase, which is abundant during the neonatal period. The potassium-retaining characteristics of the neonatal kidney result from a paucity of apical secretory potassium channels and a predominance of the apical H-K$^+$-ATPase.[43]

ACID-BASE BALANCE

The proximal tubule is responsible for reabsorption of approximately 80% of the filtered bicarbonate. The tubular acidification that drives this process is accomplished by two transporters responsible for H$^+$ excretion: the Na$^+$-H$^+$ exchanger and H$^+$-ATPase. In the adult kidney, the Na$^+$-H$^+$ exchanger is responsible for the majority (approximately two-thirds) of H$^+$ excretion.[49,50] Newborns have a lower bicarbonate level than adults. In term neonates the average bicarbonate level is 22 mEq/L, and in premature infants it may be as low as 15 mEq/L.[51,52] This results from decreased H$^+$ secretion into the proximal tubule. There is decreased activity of the Na$^+$-H$^+$ exchanger (approximately one-third of adult) in neonates, which increases by several-fold following birth. H$^+$-ATPase is virtually undetectable in the proximal tubule at birth, and then increases substantially.[53,50]

GLUCOSE REABSORPTION

Glucose reabsorption occurs exclusively in the proximal tubule. In healthy adults, the proximal tubule is responsible for reabsorption of 100% of the filtered glucose, but glycosuria occurs if the blood glucose exceeds the normal threshold. Glucose is reabsorbed in a sodium-dependent manner by two transporters in the proximal tubule. In the S1 segment, there is a high activity–low affinity transporter (SGLT-2) that removes the majority of filtered glucose. Abnormalities in this transporter are responsible for benign familial glycosuria. In the S3 segment of the proximal tubule, there is a low activity–high affinity transporter (SGLT-1). Abnormalities in this transporter are responsible for hereditary glucose-galactose malabsorption. Early studies demonstrated that neonatal rabbits transported glucose at approximately one-third the rate of adult rabbits.[54] Consequently, premature infants are more susceptible to renal glycosuria.[55]

PHOSPHATE BALANCE

In the growing neonate, phosphate is necessary for bone growth, along with many enzymatic activities. As a result, reabsorption of phosphate during the neonatal period is very high. The serum phosphate in neonates is higher than in adults.[56,57] Human and animal studies have shown that the fractional reabsorption of phosphate is much higher in

neonates than in adults.[58–60] In fact, neonates reabsorb up to 99% of the filtered phosphate on the first day of life and 90% by the end of the first week of life.[57,61] Multiple factors in the neonatal period contribute to the increased reabsorption of phosphate, including a decreased responsiveness to parathyroid hormone,[62,63] maturational changes in NaPi II transporters,[64] and contributions from growth hormone and thyroid hormone.[65] Additives to breast milk and special formulas have been designed for premature infants to assist them in maintaining positive calcium and phosphorus balance.

AMINO ACIDS TRANSPORT

Amino acids are actively resorbed by sodium-dependent active transport on the luminal side and transported across the basolateral membrane by facilitated diffusion in the proximal tubule. Transporters exist for amino acids with similar properties, including neutral, acidic, and basic amino acids. Neonates are known to have a generalized aminoaciduria that is worsened with prematurity.[66,67]

KEY POINTS

- The proximal tubule is responsible for the bulk of solute reabsorption that occurs in the kidney, including bicarbonate, glucose, phosphate, and amino acids. Immature function can lead to lowered serum bicarbonate, glycosuria, and aminoaciduria during the neonatal period.
- During the neonatal period there is a drive to maintain a positive potassium and phosphate balance to ensure growth. As a result, term and preterm infants are known to have higher potassium and phosphate levels.

GLOMERULAR FUNCTION RATE

GFR is the most useful measurement of kidney function. GFR is measured indirectly through the concept of clearance (the equivalent volume of plasma from which a substance would have to be totally removed to account for its rate of excretion in urine per unit of time). Clearance is calculated by dividing the excretion rate of a substance by its plasma concentration ($C_x = U_x \times V/P_x$); where U_x and P_x are urine and plasma concentrations of substance x, and V is urine flow rate. C_x is expressed as milliliters per minute and is usually normalized to a standard body surface area of 1.73 m^2.[68] GFR is the best clinical test to estimate a functional renal mass, which can assist the clinician in prescribing fluids and electrolytes, determine disease progression, and appropriately prescribe medications excreted by the kidney.

The gold standard method for GFR measurement is inulin clearance. Table 5.1 shows the GFR measured by inulin

Table 5.1 Inulin clearance glomerular filtration rate in healthy premature infants

Age	mL/min/1.73 m²
1–3 days	14.0 ± 5[70]
1–7 days	18.7 ± 5.5[112]
4–8 days	44.3 ± 9.3[113]
3–13 days	47.8 ± 10.7[113]
1.5–4 mo	67.4 ± 16.6[113]
8 years	103 ± 12[114]

clearance in preterm infants. Depending on degree of prematurity, GFR steadily improves from 10 to 20 mL/min/1.73 m² during the first week of life to 30 to 40 mL/min/1.73 m² by 2 weeks following birth, concomitant with alterations in renal blood flow. Thereafter, GFR improves steadily over the first few months of life.[69,70]

Although inulin clearance is the gold standard, it is not commonly used in clinical or research studies as a continuous inulin infusion and frequent laboratory measurements are needed. Other methods that approximate this gold standard include single-injection clearance techniques in which evaluation of the rate of disappearance from the plasma is used to approximate overall clearance. For example, a single injection of iohexol is an accurate alternative to inulin clearance and does not require a radioactive tracer.[69]

Serum creatinine (SCr) is the most common method to monitor renal function, but has significant shortcomings:

- SCr concentrations may not change until 25% to 50% of the kidney function has already been lost.

- At lower GFR, SCr overestimates renal function because of the tubular secretion of creatinine.
- SCr varies by muscle mass, hydration status, sex, age, and gender.
- Different methods (Jaffe reaction vs. enzymatic) produce different values, and medications and bilirubin can affect SCr measurements by the Jaffe method.[71,72]
- Once a patient receives dialysis, SCr can no longer be used to assess kidney function, because SCr is easily dialyzed.

Additional problems with using SCr in neonates include:

- SCr in the first few days of life reflects maternal kidney function and not the infant's renal function.
- Overall GFR in term and preterm infants is very low, and there is a very wide distribution of normal SCr values, which vary greatly depending on level of prematurity and age[73] (Figure 5.1).
- Bilirubin levels in premature infants are normal at birth, rise in the first several days, and return to normal after a few weeks. If the Jaffe method of measuring SCr is used, this may have tremendous impact on the interpretation of SCr.[71] Similarly, cephalosporins, histamine-2–receptor blockers, trimethoprim/sulfa, and other medications can affect SCr measurements. SCr-based estimations of GFR in neonates have suggested the following formula for children younger than 1 year of age.[74]

$$k * SCr/ht;$$

where k = 0.33 for infants with low birth weight and 0.45 for infants with normal birth weight

However, caution should be used in extrapolating this into clinical practice for several reasons. This formula represents an estimate, and the true GFR may be off in either

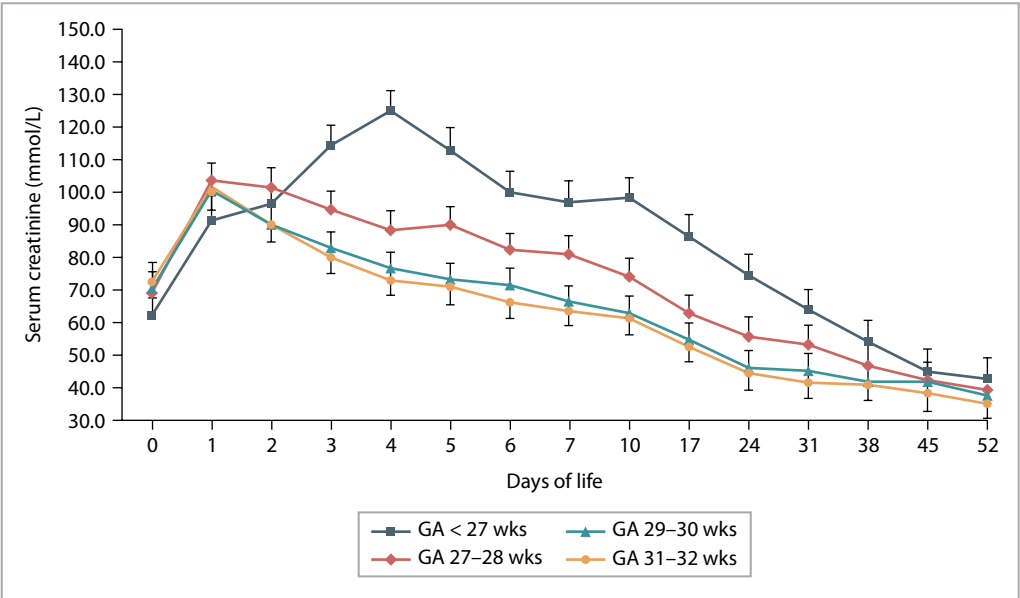

Figure 5.1 Change in serum creatinine during the first 52 days of gestation based on gestational age. (Reproduced with permission from: Gallini F, Maggio L, Romagnoli C, et al. Progression of renal function in preterm neonates with gestational age < or = 32 weeks. Pediatr Nephrol. 2000;15:119–24.)

direction by 20% or more. In addition, these formulas were derived using the Jaffe calorimetric method to measure SCr. The enzymatic method has replaced the Jaffe method at most hospitals; thus, these formulas may no longer be applicable.

Cystatin C, an endogenous proteinase inhibitor has been extensively studied as a measure to estimate GFR and as a marker of AKI. Because cystatin C is not influenced by the maternal level and is highest at birth, it may be superior to SCr for estimating GFR in neonates. Cystatin C concentrations significantly decrease from day 1 to day 3 of life and are independent of gestational age, birth weight, and maternal renal function in infants with very low birth weight.[75] Cystatin C does not differ between males and females. Thus, cystatin C seems to have many of the theoretical advantages needed to be an ideal marker of renal function.[76] However, there are limited data on cystatin c in neonates, including a lack of studies linking levels of Cystatin C levels with short-term and long-term outcomes.

> **KEY POINT**
>
> Depending on the degree of prematurity, GFR steadily improves from 10 to 20 mL/min/1.73 m^2 during the first week of life to 30 to 40 mL/min/1.73 m^2 by 2 weeks.

NEONATAL ACUTE KIDNEY INJURY

Historically, neonatal AKI has been classically defined by oliguria, anuria, a persistent SCr of 1.5 mg/dL or greater, or all of these. We[77–81] and others[82–85] have used contemporary categorical definitions that require a rise in SCr to make the diagnosis of AKI, similar to definitions published by the Acute Kidney Injury Network (AKIN) groups in 2007[86] and more recently in 2012 by KDIGO. A neonatal AKI definition (Table 5.2) has been adapted for neonates from the 2012 KDIGO definition. The following modifications have been made to account for specific issues.

- Because SCr normally declines over the first week of life,[73] each SCr is compared to the lowest previous value.
- As SCr of 2.5 mg/dL represents GFR less than 10 mL/min/1.73 m^2 in neonates, this cutoff is used to define stage 3 AKI (as opposed to 4.0 mg/dL in adults).

> **KEY POINT**
>
> Neonatal acute kidney injury can be defined by adapting the 2012 KDIGO definition based on absolute rise in creatinine from a previous trough.

NEONATAL ACUTE KIDNEY INJURY OUTCOME

AKI is associated with mortality in critically ill children[87,88] and adults,[89-93] even after controlling for medical comorbidities, severity of illness scores, and patient demographics. Over the past few years, epidemiologic studies in several high-risk groups of neonates have been performed. These studies add to the sparse literature on the incidence and outcomes of AKI by focusing on specific neonatal groups. In addition, researchers are no longer relying on arbitrary, binary definitions of neonatal AKI (e.g., SCr of 1.5 mg/dL or greater) and instead are using contemporary, categorical AKI frameworks such as modifications of the AKIN[94] staging system and the risk, injury, failure, loss, and end-stage renal disease (RIFLE) classification[87,89] that allow for improved diagnosis and staging of AKI by severity.

Recent epidemiology studies in infants with very low birth weight, sick near-term and term infants admitted to level 2 or 3 neonatal intensive care units (ICUs), term infants with severe perinatal asphyxia who undergo therapeutic hypothermia, infants who receive extracorporeal membrane oxygenation (ECMO), and infants who undergo cardiopulmonary bypass (CPB) surgery confirms that AKI is common in high-risk newborns and that those with AKI have significantly worse outcome. Although larger studies will be needed to determine the contribution of AKI to neonatal morbidity and mortality, these single-center studies

Table 5.2 Definition of acute kidney injury in the neonate

Stage	SCr criteria	Urine output (UOP criteria)
0	No change or rise < 0.3 mg/dL	UOP > 1 cc/kg/h (over previous 24 h)
1	↑ SCr of ≥ 0.3 mg/dL or ↑ SCr to 150-199% of baseline	UOP > 0.5 cc/kg/h and ≤ 1 cc/kg/h (over previous 24 h)
2	↑ SCr to 200%–299% of baseline	UOP > 0.1 cc/kg/h and ≤ 0.5 cc/kg/h (over previous 24 h)
3	↑ SCr to ≥ 300% of baseline or SCr ≥ 2.5 mg/dL or Receipt of dialysis	UOP ≤ 0.1 cc/kg/h (over previous 24 h)

Note: Baseline SCr is defined as the lowest previous SCr value.

suggest that AKI is independently associated with mortality, when controlling for potentially confounding demographics, comorbidities, and interventions.

INFANTS WITH VERY LOW BIRTH WEIGHT

In 2011, Koralkar et al.[95] published a prospective study on 229 infants with very low birth weight (birth weight between 500 and 1500 g) infants. They categorized each infant according to a modified AKIN definition (see Table 5.2). Using this framework, 41 of 229 (18%) of the cohort developed AKI (stage 1, 10; stage 2, 10; stage 3, 21). Infants with AKI were more likely to have lower birth weight, younger gestational age, and lower Apgar scores, as well as higher rates of assisted ventilation and inotropic support. In the AKI group, 42% (17 of 41) died, compared with 5% (9 of 188) in the non-AKI group (hazard ratio [HR], 9.3; 95% confidence interval [CI], 4.1 to 21.0; $P < 0.01$). Those with AKI had higher mortality independent of multiple adjusted confounders (adjusted HR, 2.3; 95% CI, 0.9 to 5.8; $P = 0.06$).

In 2012, Viswanathan et al.[96] published a retrospective analysis on 472 infants with extremely low birth weight (<1000 g). Using a cutoff of SCr of 1.5 mg/dL or greater to define AKI, the incidence of AKI was 59 of 472 (12.5%). They then performed a matched case-control study (matching for time period, birth weight (±10%), and gestational age (±1 week). Mortality in those with AKI was 33 of 46 (70%) compared to 10 of 46 (22%) in those without AKI ($P < 0.001$).

SICK NEAR-TERM AND TERM INFANTS

In 2013, Askenazi et al.[97] published on 58 neonates with birth weight greater than 2000 g and 5-minute Apgar score of 7 or less admitted to a level 2/3 neonatal intensive care unit (NICU). AKI occurred in 9 of 58 (16%) infants. All infants without AKI survived, whereas 2 of 9 (22%) of those with AKI died ($P < 0.001$).

INFANTS WITH PERINATAL ASPHYXIA TREATED WITH HYPOTHERMIA

In 2012, Selewski et al.[98] published a retrospective study on 96 infants who received hypothermia. Using the AKIN definition for AKI, they found that 36 of 96 (38%) infants developed AKI. Only 1 of 58 (2%) infants without AKI died compared to 5 of 36 (14%) with AKI ($P = 0.1$). Those with AKI had longer NICU stays ($P < 0.02$), longer hospitalizations ($P < 0.01$), and longer duration on mechanical ventilation ($P < 0.001$).

INFANTS ON EXTRACORPOREAL MEMBRANE OXYGENATION

In a large retrospective cohort study using data from the Extracorporeal Life Support Organization registry,

Askenazi et al.[99] evaluated the impact of AKI and renal support therapy (RST) in infants who receive ECMO for noncardiac reasons. AKI was defined as SCr of 1.5 mg/dL or greater at any point in the hospitalization. Of the 7941 neonates in their cohort, 27.4% died. Nonsurvivors had higher rates of AKI than survivors (19% vs. 3.9%; $P < 0.0001$), and more nonsurvivors received RST than survivors (39.7% vs. 16%; $P < 0.0001$). After adjusting for numerous confounding variables, neonates with AKI had 3.2 higher odds of death than those without AKI ($P < 0.0001$); neonates who received RST had 1.9 higher odds of death ($P < 0.0001$) than those who did not receive RST.

Two smaller studies had similar findings. In a retrospective chart review of infants with congenital diaphragmatic hernia requiring ECMO, Gadepalli et al.[100] found 48 of 68 patients (71%) had AKI by the RIFLE classification. Patients with AKI "failure" (300% rise in SCr) had increased time on ECMO, decreased ventilator-free days, and decreased survival (27.3% with "failure" vs. 80% without AKI; $P = 0.001$). Shuhaiber et al.[101] also found higher rates of AKI in nonsurvivors versus survivors (80% vs. 40%; $P = 0.03$) in a small sample of patients (n = 20; 75% neonates) requiring more than one ECMO run after congenital heart surgery.

INFANTS UNDERGOING CARDIOPULMONARY BYPASS SURGERY

Outcomes after AKI in infants undergoing CPB surgery have been reported. Blinder et al.[102] conducted a retrospective chart review of 430 infants (<90 days, median age 7 days) who had CPB. Using a modified AKIN definition (which included urine output criteria), they documented AKI in 225 of 430 (52%) infants (stage 1, 133, stage 2, 60, stage 3, 30). Postoperative AKI of all stages was associated with longer ICU stay; AKI stages 2 and 3 were associated with increased risk for prolonged mechanical ventilation and need for postoperative inotropic therapy. The mortality rate in those with AKI was higher than in those without (27 of 225 [12%] vs. 6 of 205 [3%]; $P < 0.001$). Moreover, risk for death increased with AKI severity (stage 2 OR, 5.1; 95% CI, 1.7 to 15.2; $P = 0.004$; and stage 3 OR, 9.5; 95% CI, 2.9 to 30.7; $P = 0.0002$).

Krawczeski et al.[103] evaluated 374 patients (including 35 neonates) undergoing CPB surgery. They defined AKI as an absolute increase in SCr of 0.3 mg/dL or greater from baseline within 48 hours of surgery and found that 8 of 35 (23%) had AKI by median 1 day after CPB. No differences in mortality were seen between the neonates with AKI and those without in this small neonatal subset.

In 2013, Alabbas et al.[104] published a retrospective study on 122 infants who received CBS. Using the AKIN definition, the incidence of AKI incidence was 76 of 122 (62%) (AKI stage 1, 22; stage 2, 19; stage 3, 33). Severe stage 3 AKI was associated with increased mortality (OR, 6.7; 95% CI, 1.08 to 41.5) and longer ICU stay (HR, 9.1; 95% CI, 1.3 to 61.0).

KEY POINT

AKI in the neonatal population has been shown to be associated with clinically significant outcomes in multiple neonatal populations, including infants with low birth weight, near-term and term infants, newborns with perinatal asphyxia treated with therapeutic hypothermia, newborns undergoing ECMO, and newborns following CPB.

RISK FOR CHRONIC KIDNEY DISEASE IN NEONATES

Premature infants are at high risk for death and other morbidities, including AKI during their initial hospitalization. With the increasing survival of premature infants over the last few decades, focus is now turning toward reducing long-term morbidities. Growing evidence suggests that premature infants are at risk for chronic kidney disease (CKD). A recent meta-analysis showed that premature infants are more likely to have albuminuria, end-stage renal disease, and lower estimated GFR compared to their term peers.[105] Among the 489 children in the Chronic Kidney Disease in Children (CKiD) study sponsored by the National Institutes of Health, there was a high rate of abnormal birth history (low birth weight, less than 2500 g) (17%), prematurity (<13%), small for gestational age (15%), and admission to an ICU (41%), and these factors were associated with decreased stature.[106] Thus, as more extremely premature infants survive and live into adulthood, the impact of CKD on premature infants is a significant long-term concern.

The reasons why premature infants are at risk for developing CKD remain unclear. One explanation is that because nephrogenesis continues until 34 weeks after conception and premature infants are born with a paucity of nephrons.[32] The extrauterine environment may not be amenable to neoglomerulogenesis and proper glomerular development.[33] Another explanation is that premature infants are at risk for acute hypoxic, hyperoxic, ischemic, septic, and nephrotoxic events between birth and termination of glomerulogenesis. The concept that AKI leads to CKD has been clearly elucidated in animal,[107] pediatric,[108,109] and adult[110] cohorts, such that we now know that AKI is a strong risk factor for CKD. Although the pathogenesis from AKI to CKD continues to be explored, most experts believe that endothelial damage leads to nephron dropout and interstitial fibrosis.[111] AKI during ongoing nephrogenesis may play an important role in limiting renal endowment and contribute to reduced renal function.

KEY POINT

The long-term renal function of neonates, particularly premature neonates and neonates with AKI, is unknown and warrants further study.

CONCLUSION

The care of the neonate with kidney dysfunction requires consideration of the dramatic changes in kidney function during the neonatal period. There is significant concern about the long-term consequences of AKI in the neonate, even when kidney function appears to normalize. AKI in the premature infant appears to increase the risk for CKD.

SUMMARY

Neonates are exposed to a variety of stressors that may lead to AKI. Moreover, AKI in neonates may lead to CKD, or even ESRD, as illustrated in Clinical Vignette 5.1. Decreasing kidney size has an ominous prognosis and is usually associated with development of ESRD, albeit not always immediately.

Clinical Vignette 5.1

A male infant was born via emergent cesarean section after the mother fell and had placental abruption. Apgar scores at 1, 5, and 10 minutes were 1, 4, and 8, respectively. The infant's blood urea nitrogen (BUN)/creatinine steadily rose to 50 mg/dL and 4.0 mg/dL during the first week of life. A peritoneal dialysis catheter was placed in anticipation for the need of dialysis. Because he maintained adequate urine output to keep up with intake, renal replacement therapy was not initiated at that time. By week 2 of life, BUN increased to 110 mg/dL and SCr rose to 6.3 mg/dL and the infant was less alert. His renal ultrasound showed bilateral hyperechoic kidneys with poor corticomedullary differentiation, measuring 4.5 and 4.6 cm on the left and right, respectively. Dialysis was initiated with hourly cycles of the peritoneal dialysis solution Dianeal (Baxter, Newbury, UK). Dwell volumes were advanced slowly, and the number of cycles was diminished. Two months after the initiation of peritoneal dialysis, a renal ultrasound showed that the kidneys were shrinking (now at 4.1 and 3.6 cm). Peritoneal dialysis was held for a 48-hour period to determine if the infant's native kidney function had improved. The BUN and creatinine rose sharply, and thus the child was restarted on peritoneal dialysis. At

age 3 months, a similar trial off dialysis showed that he continued to have a sharp increase in BUN and creatinine, and thus his diagnosis changed from AKI to end-stage renal disease (ESRD). At 12 months, he continues on peritoneal dialysis. He weighs 10.2 kg (50th percentile for age) and his length is 72 cm (10th percentile for age). He is achieving neurodevelopmental milestones appropriate for his age. He has been placed on the kidney transplant waiting list and is on six medications to manage his CKD.

REVIEW QUESTIONS

1. Which of the following factors is the *most* important contributor to the increase in renal blood flow following birth?
   a. Increased cardiac output
   b. Increased renal vascular resistance
   c. Decreased renal vascular resistance
   d. Increased circulating plasma volume
   e. Changes in systemic resistance

2. Which of the following statements about the renin-angiotensin system is *not true*?
   a. Fetal renin levels are higher than adult levels.
   b. Neonatal angiotensin-converting enzyme levels are higher than adult levels.
   c. There is a shift from a predominance of angiotensin receptor type 2 to angiotensin receptor type 1 following birth.
   d. Disruptions of the angiotensin type 1 or type 2 receptors are capable of causing congenital malformations of the kidney.
   e. AT-2 receptors are coupled to G-proteins.

3. Fetal urine output begins at what week during gestation?
   a. 5th week
   b. 8th week
   c. 12th week
   d. 20th week
   e. 36th week

4. Nephrogenesis is completed at:
   a. 28 week s of gestation
   b. 36 weeks of gestation
   c. 40 weeks of gestation
   d. 2 weeks following birth
   e. 2 years of age

5. Which of the following statements about neonatal sodium homeostasis is *not true*?
   a. There is an increase in activity of the Na^+-H^+ exchanger in the proximal tubules after birth.
   b. There is an initial natriuresis that affects term and preterm neonates equally.
   c. There is a shift toward sodium conservation at day 4 of life.
   d. The loop of Henle has 20% of the adult capacity to transport sodium.
   e. There are maturational changes in the distal tubule handling of sodium after birth.

6. When compared to older infants, neonates can be expected to have a lower level of which of the following?
   a. Serum potassium
   b. Serum phosphorus
   c. Serum bicarbonate
   d. Urine glucose
   e. Urine amino acids

7. Which is *true* of the definition of neonatal acute kidney injury?
   a. Oliguria should be the only criterion because all neonates with AKI are oliguric.
   b. An absolute serum creatinine greater than 1.5 mg/dL is the best approach.
   c. There are currently no large prospective studies that have tested different definitions against hard clinical outcomes.
   d. Because SCr is stable over the first week of life,

looking at an absolute rise in SCr from baseline provides the best definition of neonatal AKI.

   e. The need for dialysis should serve as the definition of AKI.

8. Acute kidney injury has been shown to be associated with adverse outcomes in which neonatal populations?

   a. Infants with very low birth weight

   b. Near term/term infants

   c. Newborns with perinatal asphyxia treated with therapeutic hypothermia

   d. Newborns undergoing extracorporeal membrane oxygenation

   e. Newborns following cardiopulmonary bypass

   f. All of the above

9. Compared to the adult kidney, fetal renal blood flow is typified by which of the following?

   a. Low renal vascular resistance

   b. Greater flow to the renal cortex

   c. Greater flow to the renal medulla

   d. A larger percentage of the cardiac output

Diagnostic imaging of the urinary tract

EGLAL SHALABY-RANA, BRUCE MARKLE, AND DOROTHY BULAS

Radiologic imaging plays a vital role in the evaluation of the urinary tract in children. Multiple imaging modalities are available for the diagnostic workup of renal disorders in children, including voiding cystourethrography (VCUG), ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI). Ultrasonography is particularly useful in the evaluation of the structure of the kidneys and bladder without the use of ionizing radiation. Fetal ultrasound examination has been instrumental in the identification of urologic abnormalities long before they become clinically evident. CT and MRI, with their excellent spatial resolution, are useful in the evaluation of the kidneys and vascular structures. These imaging modalities are often complementary, each with its clinical indications and applications, as well as limitations.

VOIDING CYSTOURETHROGRAPHY

INDICATIONS

Voiding cystourethrography (VCUG) is performed for the detection of vesicoureteral reflux (VUR), and for delineating the anatomy of the urinary bladder and urethra. Common indications for a VCUG are urinary tract infection (UTI), and the presence of hydronephrosis, hydroureter, or both. Assessing for VUR before renal transplantation is another use of the VCUG.

TECHNIQUE

The VCUG needs no specific patient preparation except for explanation of the procedure to the child if age-appropriate.

The presence of parents, a child-life specialist, or both can facilitate the procedure in an apprehensive child. However, if the patient is extremely anxious and not allowing the study to be performed, oral sedation with midazolam, in anxiolytic doses, can be used with the added benefit of amnestic effect of this medication.[1] This may be the case in an older child, typically 3 years of age and older. If sedation is to be used, the study needs to be scheduled in advance, with the child maintained fasting for the appropriate length of time.

An initial scout abdomen radiograph (kidney-ureter-bladder [KUB]) is taken to assess for the presence of calculi along the urinary tract, as well as examine the spine for dysraphism (spina bifida). The stool burden also can be assessed. Subsequently, using sterile technique, the bladder is catheterized with a feeding tube. A urine specimen is usually obtained and sent to the laboratory for culture.

Radioiodinated contrast (Cystoconray, Mallinckrodt Pharmaceuticals, St. Louis, MO) is then instilled into the bladder under gravity drip. An early filling image is taken to evaluate for bladder filling defects, such as ureterocele, which may be obscured by a contrast-filled bladder. Expected bladder filling volume can be approximated by the formula:

$$\text{Bladder volume (mL)} = (\text{Age in years} + 2) \times 30$$

One can also observe for signs of a full bladder, including slowing of the contrast drip, patient discomfort and crying, and upturning of the toes. Images are taken of the full bladder, each ureterovesical junction, the kidney fossae, and the urethra.

Complications of VCUG include UTI, chemical cystitis, vasovagal attack from an extremely full bladder, and retrograde spread of infection leading to acute pyelonephritis

INTERPRETATION

The normal urinary bladder is a smooth-walled globular structure centrally placed in the bony pelvis. Urethral walls are smooth, and the posterior urethra is visualized as a nondistended, smooth-walled passage. The urethral passage is subdivided into the anatomic areas of anterior urethra and posterior urethra. In males, the anterior urethra consists of the penile urethra and the bulbous urethra. The posterior urethra begins at the bladder neck and encompasses prostatic urethra and the membranous urethra (Figure 6.1). The female urethra, on the other hand, is a short tube and does not have the complex anatomy of the male urethra. Ureterocele is an abnormal congenital dilatation of the distal portion of the ureter, which herniates into the bladder. Ureteroceles are commonly seen in the duplex collecting system, usually in association with the upper moiety. Because of the narrowing of its ureteral orifice into the bladder, the
Figure 6.2 Contrast VCUG showing a ureterocele (arrows).

ureterocele often causes obstruction of its ureter resulting in hydronephrosis and hydroureter. Ureterocele is recognized as a filling defect low in the bladder during the early bladder-filling image (Figure 6.2). Bladder wall trabeculation (Figure 6.3) occurs as a result of functional
Figure 6.1 Contrast voiding cystourethrography showing normal radiologic anatomy of the male urethra.
Figure 6.3 Contrast voiding cystourethrography in a patient with spina bifida with a trabeculated elongated bladder (Christmas tree bladder), consistent with a neuropathic bladder.
Figure 6.4 Contrast voiding cystourethrography demonstrating a bladder diverticulum (arrow).

(neuropathic bladder) or mechanical bladder outlet obstruction (posterior urethral valve). Diverticula of the bladder (Figure 6.4) also can be seen in the previously mentioned clinical circumstances or may be associated with VUR. Posterior urethral valves (PUVs), which are seen exclusively in boys, result in a dilated posterior urethra with obstructed flow of contrast below the level of the valve (Figure 6.5).
Figure 6.5 Contrast voiding cystourethrography showing posterior urethral valve. Characteristic dilatation of the prostatic urethra by the posterior urethral valve is seen (arrows).

Table 6.1 International Reflux Study in Children grading of vesicoureteric reflux[2]

Grade I:	Reflux into the ureter only.
Grade II:	Reflux into the collecting system without blunting of calyces.
Grade III:t	Reflux into the collecting system with mild blunting of calyces with preservation of papillary impressions; ureter may be mildly dilated.
Grade IV:	Reflux into the collecting system with moderate blunting of calyces with some loss of papillary impressions with occasional complete loss of papillary impressions (clubbing); ureter dilated and tortuous.
Grade V:	Clubbing of most of calyces. Ureter is dilated and tortuous.

CLASSIFICATION OF VESICOURETERAL REFLUX

VUR, if present, can be classified into five grades according to the International Reflux Study in Children grading (Table 6.1).[2] Figure 6.6 shows the VCUG features of these five grades of reflux. Intrarenal reflux may be sometimes seen in association with the high grade VUR (IV and V). In the duplicated collected system, wherein the upper moiety is obstructed, the lower moiety is filled with the contrast and shows an inferior and a lateral displacement of the opacified lower pole moiety. This configuration is referred to as the "drooping lily" sign (Figure 6.7) and should suggest a duplicated collecting system with VUR on the affected side.

RENAL ULTRASOUND

Ultrasound is an ideal modality for the evaluation of the genitourinary system of fetuses, children, and adults. It is typically inexpensive, does not involve the use of ionizing radiation, does not require sedation, can assess organs in multiple planes, and can evaluate arterial and venous flow with the use of Doppler ultrasound. Ultrasonography can evaluate renal size, position, anatomy, urinary bladder masses, anomalies, and prevoid and postvoid bladder volume. Ultrasound also provides useful information about structures around the urinary tract that may obstruct the kidney and bladder.

Limitations of ultrasound investigative procedures include the inability to penetrate gas or bone. Resolution also may be restricted in crying infants and obese patients. Ultrasound is operator dependent and requires expertise for appropriate technical performance and interpretation.
Figure 6.6 Contrast voiding cystourethrography five grades of vesicoureteric reflux. **(a)** Grade 1 vesicoureteral reflux (arrow). Contrast flows into the lower part of the ureter. **(b)** Grade II vesicoureteral reflux. Calyces are sharp, with deep papillary impressions. **(c)** Grade III vesicoureteral reflux. Calyces are blunted, but papillary impressions are preserved. **(d)** Grade IV vesicoureteral reflux. Calyces are significantly blunted, with very shallow papillary impressions. Ureter is also dilated. **(e)** Grade V vesicoureteral reflux. Ureters are dilated and tortuous ureter and clubbing of most calyces are seen.

Despite these limitations, ultrasound is a cornerstone in the evaluation of renal and bladder anatomy.

RENAL SIZE

Ultrasonographic evaluation of the kidney begins with an assessment of size. Normal data for renal size in children are available for birth through adolescence (Figure 6.8).[3,4] Abnormalities in renal size can be observed in numerous disorders, listed in Table 6.2. Regression equation for determining renal size based on the observations of Rosenbaum et al.[3] is as follows.

For children older than 1 year:

$$\text{Renal length (cm)} = 6.79 + 0.22 \times \text{age (years)}$$

For younger than 1 year:

$$\text{Renal length (cm)} = 4.98 + 0.155 \times \text{age (months)}$$

Figure 6.7 Contrast voiding cystourethrography showing vesicoureteral reflux into the lower pole moiety of a duplex system. Downward displacement and lateral position of the collecting system result in the so-called "drooping lily" appearance.

Table 6.2 Causes of abnormal renal size

Small Kidney(s)
- Renal hypoplasia and dysplasia
- Renal arterial stenosis
- Reflux nephropathy
- Chronic kidney disease

Unilateral Nephromegaly
- Acute pyelonephritis
- Renal vein thrombosis
- Renal tumor
- Hematoma (renal or perirenal)
- Renal abscess
- Urinary tract obstruction, hydronephrosis
- Beckwith-Weidemann syndrome

Bilateral Nephromegaly
- Polycystic kidney disease
- Acute glomerulonephritis
- Bladder outlet obstruction, hydronephrosis
- Bilateral Wilms tumor
- Glycogen storage diseases
- Acute lymphatic leukemia (leukemic infiltrates)
- Lymphoma
Figure 6.8 Renal size in children as determined by sonography. Age is represented in years unless specified otherwise. (Reproduced from Han BK, Babcock DS. Sonographic measurements and appearance of normal kidneys in children. Am J Roentgenol. 1985;145: 611–6.)

EVALUATION OF RENAL ARCHITECTURE

Location and configuration of the kidneys are important in the identification of pelvic, horseshoe, and duplex kidneys. Renal parenchyma is assessed for masses, cysts, calcifications, and echogenicity. Loss of corticomedullary differentiation, sometime referred to as "medical renal diseases" (MRDs), is a nonspecific radiologic sign that can be seen in a variety of disorders, such as acute tubular necrosis, infections, glomerulonephritis, glomerulosclerosis, and autosomal recessive polycystic kidney disease (ARPKD).

KEY POINT

Renal ultrasound provides a radiation-free imaging modality that allows evaluation of renal size, architecture, blood flow, and hydronephrosis.

EVALUATION OF RENAL VESSELS

Using duplex, color, and power Doppler imaging, renal ultrasound can characterize renal vascular flow. The renal arteries and veins, as well as smaller arcuate vessels, can be assessed for renal artery stenosis, renal vein thrombosis, or renal transplant rejection.

Fetal Urogenital Ultrasonography

Congenital anomalies of the urogenital tract are found in 3% to 4% of the population.[5] Lethal urinary tract anomalies account for 10% of spontaneous pregnancy losses.[6] A systematic prenatal sonographic approach includes evaluation of the amniotic fluid volume, characterization of genitourinary anomalies, and search for associated abnormalities such as the VACTERL association (vertebral anomalies, anal atresia, cardiac defects, tracheoesophageal fistula, and renal and radial limb anomalies).

In their early development, fetal kidneys are located close to the sacral area in the pelvic region and eventually ascend to their lumbar location at approximately the 6th to 9th week. Fetal kidneys are visualized by ultrasound at approximately the 12th to 13th week, and their characteristic fetal architecture can be discerned by the 20th week.[7] The normal fetal kidney has a lobulated appearance with distinct hypoechoic pyramidal structures and variable corticomedullary differentiation (Figure 6.9).

Amniotic fluid

Although urine production begins at approximately 5 to 8 weeks of gestation, contribution of urine to

Figure 6.9 Renal ultrasound in a normal term infant. Fetal lobulations (arrows) are seen on the surface of the kidney. The renal cortex is more echogenic than the liver, and the prominent renal pyramids are hypoechoic.

amniotic fluid is minor before the 16th week of gestation. Lack of fetal urine output after 16 gestational weeks, however, results in a rapid decline in amniotic fluid volume. Under these circumstances, the fetus develops the classic Potter sequence, which includes low-set ears, flat nose, clubfeet and hands, and growth restriction. Pulmonary hypoplasia is common in these patients and is often the cause of significant neonatal morbidity and mortality. Lethal genitourinary anomalies are associated with minimal or no urine production. These include renal agenesis, bilateral multicystic dysplastic kidneys, autosomal recessive infantile polycystic kidney disease, and severe posterior urethral valves.

Antenatal hydronephrosis

Antenatal dilatation of the renal collecting system is a common finding in the fetus. Most cases of pelviectasis noted

---

KEY POINTS

- Fetal ultrasound allows prenatal diagnosis of urogenital tract abnormalities.
- The SFU has provided guidelines for grading antenatal hydronephrosis in the fetus.
- Guidelines for postnatal evaluation of antenatal hydronephrosis will require consensus development.
- More than 50% of infants with antenatal hydronephrosis demonstrate resolution over 12 to 18 months of postnatal follow-up with ultrasound.

| SFU grade 1 | SFU grade 2 | SFU grade 3 | SFU grade 4 |

| Urine barely split sinus | Full pelvis, major calyces dilated | Uniformly dilated minor calyces, parenchyma spared | Parenchymal compromise |

Figure 6.10 Society of Fetal Urology classification of antenatal hydronephrosis. (Reproduced with permission from: Timberlake MD, Herndon CDA. Mild to moderate postnatal hydronephrosis: grading systems and management. Nat Rev Urol. 2013;10: 649–5.)

on routine ultrasound evaluation in early gestation resolve during pregnancy, and only approximately 20% persist into the postnatal period.[7] Measurement of the anteroposterior pelvic diameter (APD) is commonly used to assess fetal hydronephrosis and is a surrogate for potential urinary tract pathology. The fetal APD normally measures less than 3 mm, but its measurement can be affected by gestational age, maternal hydration, and fullness of the fetal bladder.[7,8] There is little consensus on the minimal threshold for APD at various gestational ages that is predictive of urinary tract pathology.[7] Calyceal or ureteral dilatation should always be regarded as an abnormal sonographic finding in a fetus, regardless of the renal pelvic size.

The Society of Fetal Urology (SFU) has developed a grading system for antenatal hydronephrosis. According to this classification, antenatal hydronephrosis is classified into four grades (Figure 6.10), which provide a uniform set of diagnostic criteria for clinical care.[7] It is important to recognize that sonography is unable to differentiate between a dilated urinary collecting system resulting from urinary obstruction and a nonobstructed dilated system secondary to abnormal ureteric muscle development or VUR. Apart from the severity of antenatal hydronephrosis, it is also important to determine if the renal parenchyma is thinned and the calyces and ureters are dilated. If both kidneys are affected and the parenchyma is thinned, echogenic, or has cortical cysts (SFU grade III or IV), close prenatal follow-up is necessary because of the risk for oligohydramnios.

Postnatal imaging protocols for patients with antenatal hydronephrosis continue to evolve.[9] Sonography should be avoided on the first day of life, because the neonate may be in a state of dehydration, which can underestimate the degree of hydronephrosis and result in a false-negative ultrasound study.[10] Need for a VCUG in such patients is less clear. Following these patients by ultrasound evaluation reduces the need for VCUG to less than 50%.[9] In the presence of a strong suspicion of urinary obstruction, MAG-3 renal scan with furosemide (diuretic renal scan) may provide the needed diagnostic information.

KEY POINT

Ultrasound evaluation of antenatal hydronephrosis on day 1 of life may give a false-negative result because of low urine flow.

OBSTRUCTIVE UROPATHY

Obstruction at the ureteropelvic junction (UPJ) is the most common form of urinary tract obstruction noted in children. Sonographically, the central pelvis and calyces are dilated with varying degrees of cortical thinning (Figure 6.11). The ureter is normal in size and usually not visualized. Obstruction at the ureterovesical junction (UVJ) can be due to a stricture, ureteroceles (Figure 6.12),

KEY POINTS

- UPJ obstruction is the most common type of urinary obstruction noted in children.
- Bilateral hydronephrosis in a male infant should raise the suspicion of PUV.
- Febrile UTI may be the initial manifestation of patients with ureteral obstruction.

Figure 6.11 Ureteropelvic junction obstruction. Renal ultrasound showing significant pelvic and calyceal dilatation, and cortical thinning resulting from ureteropelvic junction obstruction.

Figure 6.13 Fetal ultrasound demonstrating "key-hole sign." Ureters are dilated bilaterally, bladder wall is thickened, and inferiorly dilated posterior urethra gives the impression of a key hole.

or an ectopic ureteric insertion. Bilateral hydronephrosis may result from lower urinary tract obstruction, such as PUV, urethral stenosis, or atresia. Renal ultrasound in patients with PUV may demonstrate a thick-walled bladder and a dilated prostatic urethra below it, resulting in the so-called "keyhole sign" (Figure 6.13). A thick trabeculated bladder wall noted on ultrasonography (Figure 6.14) is usually suggestive of neurogenic bladder.

CYSTIC DISEASES

Multicystic dysplastic kidney (MCDK) is a distinct disorder characterized by a nonfunctional cystic kidney. Sonographically, MCDK is diagnosed by the presence of

multiple noncommunicating cysts of varying sizes with minimal surrounding echogenic tissue (Figure 6.15). MCDK is associated with contralateral renal anomalies in up to 25% of cases.[11] VUR in the contralateral (normal kidney) is seen in 20% to 25% of patients with MCDK and may need to be ruled out if the patient develops a UTI.[11] To differentiate MCDK from severe UPJ obstruction in the affected kidney, additional imaging to determine renal blood flow and function, such as with MAG-3 renal scan, is necessary. The diagnostic feature of MCDK is absence of any renal blood flow and lack of excretory activity on the affected side. Regression of the cysts in MCDK is common over several years.[12]

Figure 6.12 Prenatal ultrasound at 24 weeks of gestation demonstrates a transverse image of bladder containing a cyst consistent with a ureterocele.

> ### KEY POINTS
>
> - MCDK presents as a multicystic mass without any functional renal tissue.
> - Cysts are noncommunicating.
> - MAG-3 renal scan shows no perfusion or excretion in the affected kidney.
> - Contralateral kidney may have VUR or other abnormalities in approximately 25% of cases.
> - Involution of the cystic mass is common.

Autosomal recessive polycystic kidney disease (ARPKD) has a wide spectrum of clinical presentations, ranging from perinatal severe renal disease to the juvenile form with minimal renal disease and dominant hepatic fibrosis. Kidneys are enlarged and are echogenic as a result of microcysts, and corticomedullary differentiation is poor (Figure 6.16). Prenatal ultrasound diagnosis of ARPKD may be delayed
Figure 6.14 Ultrasound image of the urinary bladder showing thickened bladder wall and trabeculations of the mucosa (arrows) in a patient with neurogenic bladder.

Figure 6.15 Transverse image of the right kidney in a patient with multicystic dysplastic kidney demonstrating multiple cysts of varying size that do not connect with each other. No normal renal parenchyma is present.

Figure 6.16 Renal ultrasound in an infant with autosomal recessive polycystic kidney disease. Longitudinal view of the kidney demonstrates an echogenic kidney with poor corticomedullary differentiation. No clear evidence of cysts is present.
Figure 6.17 Renal ultrasound showing multiple cysts scattered throughout the renal parenchyma in a patient with autosomal dominant polycystic kidney disease.

until the third trimester because kidneys may appear normal earlier in gestation.

Autosomal dominant polycystic kidney disease (ADPKD) is characterized by presence of cysts in the kidney, liver, and some other organs, such as the pancreas and spleen. Prenatally, the kidneys may appear normal or large and echogenic with the variable presence of cysts. Multiple cysts scattered throughout the parenchyma are the hallmark of ADPKD (Figure 6.17). Hemorrhage and calcifications can develop within larger cysts that appear heterogeneous sonographically. A variety of inherited syndromes and genetic and chromosomal disorders that are associated with renal cystic disease are discussed further in Chapter 43.

RENAL NEOPLASMS

Mesoblastic nephroma, also known as fetal renal hamartoma, may manifest prenatally or neonatally as a solid unilateral vascular mass. This benign tumor cannot be differentiated from a Wilms tumor radiographically, and nephrectomy is generally recommended.[13]

Wilms tumor, also known as nephroblastoma, usually manifests as a large mass distorting the collecting system and the renal capsule. By ultrasound, the mass is typically solid, hyperechoic, and homogeneous. The mass may obstruct the collecting system, and the renal tissue may be severely compressed into a thin rim. Hemorrhage and necrosis may make the tumor heterogeneous in appearance, and cystic components have been reported. Doppler ultrasound study is particularly useful in assessing spread of the tumor into the renal vein and the inferior vena cava.

Cystic nephroma is a rare lesion seen in children that is considered to be benign. It is composed of multiple cysts of varying size. This mass is difficult to distinguish from a cystic Wilms tumor, because both may appear well circumscribed, with multiloculated cysts and septations.

COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING

CT and MRI are well-established cross-sectional imaging techniques used for diagnosis of renal and retroperitoneal disease in children. Both methods yield relatively high spatial resolution images of the kidneys and the surrounding retroperitoneal structures. Thin-section data sets are now routinely obtained by rapidly scanning multidetector CT systems. CT systems should be optimized for age-appropriate exposure parameters.

Radiation exposures from CT and all radiation-based methods should be included in the clinician's and radiologist's considerations regarding appropriateness of imaging studies. Non–radiation-based imaging as alternative methods should be considered before CT. Wherever possible, imagers should use techniques such as automatic exposure control and lower dose acquisitions combined with noise-reducing "iterative reconstruction" methodologies.[14] CT radiation exposure data should be included in the image data set, and CT reports should document exposure parameters. Data obtained with CT can be used to reconstruct coronal, sagittal, and oblique imaging planes. Three-dimensional surface renderings also can be obtained when large density differences allow separation of various tissues—for example, contrast-enhanced renal vessels, or contrast-enhanced collecting systems.

CT is most commonly used in detection of urinary calculi (without contrast material) and for rapid evaluation of renal neoplasms, particularly at the time of presentation. CT is also capable of demonstrating intra-abdominal spread of the neoplasms and vascular invasion. CT provides a superior technique for demonstration of metastatic disease in lungs, an important staging parameter in the renal neoplasms.

KEY POINTS

- Both CT and MRI are high-resolution imaging modalities.
- Radiation dose in CT needs to be minimized in children.
- MRI takes longer for image acquisition than CT.

MRI has the advantage of acquiring sectional images directly in virtually any anatomic plane without any ionizing radiation exposure, but the examination time is considerably longer for MRI. Whereas CT scan acquisition time can be a few seconds, MRI acquisition sets take several minutes per acquisition, and a complete MRI examination entailing multiple sequences can take 30 to 45 minutes or more. Sedation is frequently necessary for MRI in children younger than 8 years of age. Preparatory desensitization to the MRI gantry environment can reduce the need for sedation in some patients, particularly when combined with preparatory counseling by child-life specialists in advance of the actual scan date.

A single CT acquisition gives a single phase of vascular and renal contrast enhancement. Multiple phases require additional acquisitions, incurring an additional radiation exposure, ideally avoided to minimize overall radiation exposure.[15,16]

CONTRAST NEPHROTOXICITY IN COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING

The intravenous contrast agents used in CT can cause nephrotoxicity. This risk is enhanced in patients with acute kidney injury (AKI), chronic kidney disease (CKD), dehydration, diabetes, compromised systemic perfusion, and concurrent use of other nephrotoxic drugs.[17,18]

Ionic, high-osmolality contrast agents have osmolality in the range of 1400 to 2070 mOsm/kg, and "low" osmolality, nonionic agents range from 700 to 800 mOsm/kg. Iso-osmolar agents are also now available. Current recommendations for contrast administration include the use of low-osmolality and iso-osmolar agents, adequate hydration, urine alkalinization, and administration of the lowest possible contrast dose necessary for an adequate examination. N-acetyl cysteine, an antioxidant, may be used to ameliorate the nephrotoxic effects of the contrast drugs, but its efficacy is controversial.[19]

KEY POINTS

- Contrast agents used for CT and MRI can be nephrotoxic.
- Nephrotoxicity is enhanced in states of dehydration, diabetes mellitus, concurrent use of other nephrotoxins, and use of high osmolality contrast agents.

GADOLINIUM CONTRAST AGENTS AND NEPHROGENIC SYSTEMIC FIBROSIS

Nephrogenic systemic fibrosis (NSF) is a rare but painful, debilitating, and sometimes fatal disorder seen in the setting of renal insufficiency and administration of gadolinium-based contrast agents (GBCAs).[20-23] NSF has been generally reported in patients with advanced CKD (GFR less than 30 mL/min/1.73 m^2), with many patients being on dialysis. Patients with CKD III (GFR 30 to 60 mL/min/1.73 m^2) and AKI also should be considered at risk for developing NSF. The need for GBCA administration should be examined carefully in such patients. Presence of metabolic acidosis at

the time of receiving GBCA is also considered a potential risk factor in developing NSF.[21]

Clinical manifestations of NSF consists of swelling, induration, and tightening of the skin, often with a peau d'orange appearance in the lower and upper extremities.[21,22] In some patients the clinical picture can simulate scleroderma. Involvement of deep soft tissues also occurs in NSF; this can include the skeletal muscle and myocardium.[23] NSF has been reported in several pediatric patients.[24] Progressive worsening of symptoms is usual, and there is no known therapy. Risk for NSF has been reported to be 2.4% with each exposure of GCCA in presence of advanced CKD or end-stage renal disease.[25]

The pathogenesis of NSF is not fully understood. The GBCA metabolites are primarily excreted in urine, and retention of GBCA metabolites in renal failure is thought to result in eventual dissociation of gadolinium ion from the carrier ligand. Free gadolinium (a toxic metal species) has poor solubility and is precipitated in various tissues in conjunction with other ions, such as phosphate or carbonate.[21,26] The gadolinium precipitates are thought to incite an inflammatory response in the deposition sites.[26,27] Macrophage and fibroblast proliferation is common at these sites.[21]

LIMITATIONS OF MAGNETIC RESONANCE IMAGING

The dominant limitation of MRI imaging arises from the longer overall imaging time required for a complete study. In addition, longer imaging times introduce a significant element of artifact, engendered by physiologic motion from respiration, from gastrointestinal peristalsis, and even from

cardiovascular pulsations. Recently updated MRI pulse sequences have improved but not eliminated respiratory motion-based artifacts. Bowel motion is generally uncompensated, but imaging plane selection can ameliorate its effects.

ASSESSING RENAL FUNCTION WITH COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING

Although nuclear medicine studies have forged the early path to clinical application of imaging for determination of renal function, the dynamic studies of renal perfusion and function also have been performed using MRI and CT.[28–30] CT use is limited because of the high radiation exposure required for serial sampling of the kidneys during passage of contrast through the kidneys. In MRI imaging, serial sampling of signal intensity of kidneys can yield time-signal intensity curves of the transit of the contrast from which the glomerular filtration rate (GFR) can be calculated.[31]

COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING ANGIOGRAPHY

Rapid thin-section imaging, improved data reconstruction techniques, and rapid contrast injections have made it possible to create angiographic images from cross-sectional data sets. This allows relatively low-risk performance of CT and MR angiograms. The spatial resolution and temporal resolution of these methods do not, however, approach that of traditional catheter-based angiography. Demonstration of the aorta and central, first- and second-order branch vessels can be achieved reasonably well with CT and MR angiography. However, because many cases of renovascular hypertension in children are due to small segmental artery lesions or small accessory renal artery lesions, the role of screening CT angiography and MR angiography in such patients remains controversial.

CT angiography involves a rapid intravenous injection of radiographic contrast material, combined with rapid spiral volume acquisition. This is typically done in sedated, free-breathing infants and young children. Older children and adolescents can be coached to breath-hold, producing more accurate data with less bulk motion artifact. Three-dimensional images of the vessels are created from the acquired data. Limitations to the anatomic accuracy include uncompensated bulk motion, intrinsic pulsatile vascular motion, and some intrinsic CT artifacts.

MR angiography is a highly developed technique in imaging adult patients and is used for evaluation of intrinsic aortic disease and evaluation of patients with possible renovascular hypertension.[32] With a rapid intravenous injection of GBCA, three-dimensional images of the central arterial and venous structures can be obtained (Figure 6.18). The small size of the vessels of small children is more difficult
Figure 6.18 Magnetic resonance angiogram. **(a)** An arterial-phase image in a 4-year-old child showing the major central vascular structures of the abdominal arterial tree. **(b)** Filling of the venous structures and a general opacification of the parenchymal organs.

to image compared to imaging in adults. Nonetheless, parenchymal perfusion defects can be well demonstrated in smaller lobar and segmental vascular territories. More recently, noncontrast MRI sequences have been developed for evaluation of central renal arteries.

COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE UROGRAPHY

The urine-filled collecting system also can be imaged for combined anatomic and physiologic information in dilated and obstructed systems and in dilated and non-obstructed systems by performing MRI urography.[33,34] Noncontrast anatomic images can be generated, taking advantage of long T2 dephasing characteristics of urine (in a fashion similar to that used for MR cholangiopan-creatography). This allows demonstration of the fluid-filled renal collecting systems, showing anatomic sites of urinary obstruction and fluid-filled structures such as genitourinary tract cysts, ureteral stricture, ureteroceles, and ureteral ectopia. Anatomic demonstration of the overall anatomy of the abdomen and pelvis is displayed as well.

Physiologic urinary dynamics can be examined using contrast-enhanced MR urography. Following injection of gadolinium and its excretion into the urinary tract, T1-weighted images show a strong signal from the collecting systems while most other tissues show moderate or low signal intensity (Figure 6.19). Thus, the collecting systems can be imaged from the calyces to the level of urinary bladder. Differential uptake in the two kidneys, excretion, and clearance of the contrast can be demonstrated with rapid serial image sequences.
Figure 6.19 Magnetic resonance imaging, nephrogram, and urographic phases. **(a)** The early nephrogram is visible in this patient with small scarred right kidney secondary to reflux nephropathy and left renal compensatory hypertrophy. **(b)** The calyces, pelvis, and proximal ureters in the normal left kidney are well seen on the urographic phase as the gadolinium contrast agent is concentrated in the collecting system, and as the nephrogram fades.

COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING IN RENAL INFECTIONS

CT and MRI are infrequently used modalities for diagnosis of UTIs, but may be useful in selected cases as a sensitive method for detecting acute pyelonephritis and renal scarring. Ischemic focal defects in the renal parenchyma associated with acute pyelonephritis can be demonstrated with contrast-enhanced CT (Figure 6.20), as well as with contrast-enhanced MRI (Figure 6.21). A wedge-shaped parenchymal defect in renal cortex representing ischemic parenchyma can be seen in acute pyelonephritis. MRI has been shown to have diagnostic accuracy in detecting changes in acute pyelonephritis similar to that of cortical scintigraphy (dimercaptosuccinic acid [DMSA] renal scan) in experimental and clinical studies.[35,36] Renal scarring of the kidney associated with chronic pyelonephritis also can be delineated by MRI

Figure 6.20 Contrast-enhanced computed tomography in a patient with acute pyelonephritis showing the characteristic wedge-shaped defects in the right kidney. Subtle defects are present in the left kidney, in addition.

Figure 6.21 Gadolinium-enhanced inversion recovery magnetic resonance imaging showing numerous wedge-shaped zones of abnormal high signal intensity throughout the right kidney. The abnormal perirenal, peripelvic, and periureteric high signal indicates perirenal inflammation.

Figure 6.22 Magnetic resonance imaging coronal T2-weighted images showing irregularly dilated and clubbed calyces adjacent to adjacent focal zones of thinned renal parenchyma in a patient with renal scarring.

(Figure 6.22). Severe acute pyelonephritis may occasionally give rise to swelling and a sizeable mass lesion in the kidney, sometimes referred to as lobar nephronia, which may mimic a neoplasm. The mass can be seen as arising from the renal cortex with variable contrast-enhancement patterns.

Renal abscess is recognized by CT as a poorly enhancing mass with a necrotic center. Diffuse bacterial or fungal microabscesses or miliary renal infection may be difficult to diagnose with CT or MRI. The kidneys may be enlarged but show a poor degree of enhancement. Small, discrete parenchymal lesions (microabscesses) may not be evident on CT or MRI in the early stage of development.

DIAGNOSIS OF MASS LESIONS BY COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING

Most patients with a known, palpable, or suspected abdominal mass lesion undergo CT or MRI cross-sectional imaging following preliminary anatomic triage provided by ultrasonography. This serves to separate hydronephrosis and recognizable cystic lesions from solid lesions, mixed cystic and solid lesions, and lesions arising from perirenal tissues.

Tumors

Both CT and MRI provide a global anatomic view of the entire abdomen, as well as delineation of bowel, vascular

structures, and normal renal parenchyma as distinct from pathologic renal tissue. Demonstration of bilateral renal masses or the presence of one dominant lesion with additional foci of parenchymal nodules suggests the presence of rests of metanephric blastema or nephroblastomatosis (Figure 6.23). These are important diagnostic clues for early detection and risk assessment for Wilms tumor, because

Figure 6.23 Wilms tumor and nephroblastomatosis. CT shows multiple renal masses. One exophytic lesion present in each kidney represents nephroblastomatosis (arrow).
Figure 6.24 Contrast-enhanced computed tomography scan in a patient with Wilms tumor showing a necrotic but well-circumscribed mass arising from in the left abdomen. The mass expands the normal renal tissue creating a "claw" appearance at the boundary between mass and the normal renal tissue.

nephrogenic rests are considered to be precursors of Wilms tumor.[37-39] CT and MRI in Wilms tumor usually demonstrate a renal mass that often compresses the surrounding tissue. Bilateral lesions may be present, and areas of hemorrhage or cyst formation may be seen within the tumor (Figure 6.24). Both CT and MRI provide important information about Wilms tumor and its extension into the surrounding tissues. CT also provides a "one-stop" investigation of the thoracic and abdominal cavities for detection of metastases.

KEY POINTS

- CT and MRI in renal mass lesions provide a comprehensive imaging modality.
- Vascular extension of tumors can be assessed by CT or MRI.
- CT of the lungs done at the same time as CT of the primary renal tumor provides information for tumor staging.

Renal cysts

CT and MRI play an important role in the evaluation of cystic masses of the kidney.[40,41] The dominant imaging feature of a benign or simple cyst is that it is smooth and has a thin wall with a discrete outline. There are usually no internal debris, septations, or mural nodularity within the cyst. On CT or MRI studies there is a homogeneous internal fluid character. Simple cyst fluid has a CT attenuation of less than 20 Hounsfield units on noncontrast images. Mural enhancement following intravenous injection of contrast agents is either minimal or completely absent. Very slight enhancement may represent

compressed normal renal parenchyma around the wall of the cyst or may result from imaging artifacts, such as partial volume effect within adjacent tissue. Following any acute hemorrhage, simple cysts may develop internal debris and subsequently a single thin internal septation.

Some cystic masses may communicate with the renal collecting system. These are diagnosed when contrast agents opacify the cyst on delayed images, indicating a calyceal diverticulum or a pyelogenic cyst (which communicates directly via the renal pelvis). A nonenhancing cystic mass at the renal pelvis indicates a parapelvic cyst, which is an encysted lymphatic collection that often follows trauma or surgery. Developmental effect of an embryonic rest is also an etiologic possibility.

In autosomal recessive forms of polycystic kidney disease (ARPKD), CT and MRI also play a largely supportive imaging role following ultrasonography. The characteristic pattern of ARPKD consists of diffusely enlarged kidneys with uniformly high signal intensity on T2-weighted images. In ARPKD, CT and MRI provide a more global anatomic view of the kidney and associated hepatic disease (hepatic fibrosis).

Multiple renal cysts may be the primary renal manifestation of important heritable multiorgan disorders, such as ADPKD, tuberous sclerosis, Von-Hippel–Lindau disease, Jeune syndrome, Zellweger syndrome, and congenital fibropolycystic disease of the liver. Whereas ultrasound may demonstrate only a few lesions in early ADPKD, CT and MRI may provide information on the full extent of the renal lesions. For example, a patient with a single small, "simple" cyst shown on ultrasonography may demonstrate multiple lesions on CT or MRI, because the sonographic window can be obscured by ribs and bowel gas at times. In addition, CT and MRI also allow global visualization of pancreatic, splenic, or hepatic abnormalities associated with ADPKD. Although the liver demonstrates diffuse and moderate-to-large cystic lesions in ADPKD, fusiform dilatation of the intrahepatic ducts is usually noted in Caroli disease.[42] A "central dot sign," corresponding to the portal vein branch protruding into the lumen of a dilated bile duct also may be seen in Caroli disease.

SUMMARY

A host of radiologic modalities, including ultrasound, VCUG, CT, and MRI, are available for the imaging workup of urinary tract disorders in children. Imaging can assist in the diagnosis of abnormalities, beginning in intrauterine life through childhood. The spectrum of disease ranges from congenital anomalies to infections and tumors. At times, multiple imaging modalities are used in a complementary fashion to make the diagnosis as well as to guide the management.

REVIEW QUESTIONS

1. All of the following are indications for a VCUG *except*:
   a. Urinary tract infection
   b. Hydronephrosis/hydroureter
   c. To determine kidney function
   d. Preoperative renal transplantation

2. Regarding vesicoureteral reflux, which of the following is *false*?
   a. There are five grades of reflux.
   b. Grade I reflux indicates contrast material in the calyces.
   c. Intrarenal reflux may be seen with higher grades of reflux.
   d. The ureter is often dilated in grades IV and V reflux.

3. Regarding the procedure of the VCUG, all statements are true, *except*:
   a. The bladder needs to be catheterized.
   b. Oral sedation with midazolam is available in cases of extreme anxiety.
   c. Infection is not a complication of performing VCUG.
   d. Parents and child-life specialist may help facilitate the study.

4. Regarding interpretation of the contrast VCUG, the International Reflux Study classifies VUR into:
   a. 4 grades of reflux
   b. 5 grades of reflux
   c. Mild, moderate, and severe grades of VUR
   d. Grade I, Grade II, Grade III

5. Ultrasound is *the best* modality to evaluate for severity of renal obstruction.
   a. True
   b. False

6. Echogenic kidneys with loss of corticomedullary differentiation are specific findings for glomerulonephritis.
   a. True
   b. False

7. At 20 weeks of gestation, routine ultrasound demonstrates mild pelviectasis (4 to 7 mm) in the fetus. What is the likelihood of pyelectasis persisting after birth in the baby?
   a. 20%
   b. 40%
   c. 60%
   d. 80%

8. A good-quality CT scan of the kidneys should include which of the following?
   a. Intravenous contrast material administration
   b. A three-phase study including delayed excretion images
   c. Multiplanar reconstructions of source images
   d. Catheter drainage of the bladder
   e. Hydration and diuretic administration

9. All the following may contribute to potential radiographic contrast material nephrotoxicity *except*:
   a. Acidosis
   b. Dehydration
   c. *N*-acetyl cysteine therapy
   d. Diabetes mellitus
   e. Prior contrast material administration

10. Which of the following is true regarding nephrogenic systemic fibrosis (NSF)?
    a. It is not a risk for pediatric-age patients who are not dehydrated.
    b. The serum creatinine is a satisfactory screen for administration of gadolinium-based MRI contrast agents (GBCAs).

c. A history of dialysis is the only determining factor.

d. There are a few GBCA agents that are considered safe for patients with renal failure (GFR less than 30).

e. Dissociation of free gadolinium ion from the contrast agent ligand plays a role.

11. Which imaging modality is best for screening for recessive polycystic kidney disease?

a. x-ray of the abdomen

b. Radionuclide renal cortical scan

c. CT scan of abdomen

d. Ultrasonography

e. Noncontrast MRI

Radionuclide renal imaging

EGLAL SHALABY-RANA, MARY ANDRICH, AND MASSOUD MAJD

The chief advantage of radionuclide imaging in pediatric nephrology over other imaging modalities is its ability to provide quantitative functional data. These imaging techniques include renal scintigraphy and radionuclide cystography. Pharmacologic interventions, such as the administration of furosemide or captopril in association with renal imaging, can further improve diagnostic accuracy. Additionally, overlying gas, stool, or plastic tubing does not hamper acquisition of imaging data. In some radionuclide imaging procedures, the ionizing radiation exposure is significantly less compared to other radiographic procedures.

RADIOPHARMACEUTICALS

Several different ^{99m}Tc-labeled radiopharmaceuticals are currently available for imaging of the kidneys, ureters, and bladder. The clinical indication determines which of the following radiopharmaceuticals is used.

1. ^{99m}*Tc-DMSA (dimercaptosuccinic acid):* Approximately 60% of ^{99m}Tc-DMSA is taken up by the proximal tubular cells from the peritubular capillaries by active anion transport, and 40% percent is filtered by the glomerulus and excreted in urine. Selective tubular uptake and absence of interference from pelvicalyceal activity makes ^{99m}Tc-DMSA an ideal imaging agent for demonstration of focal parenchymal abnormalities in acute pyelonephritis, renal scarring, and infarcts.
2. ^{99m}*Tc-MAG3 (mercaptoacetyltriglycine):* ^{99m}Tc-MAG3 is primarily cleared by tubular secretion, allowing excellent visualization of the collecting systems, ureters and bladder, and renal parenchyma. This is used in diuresis renography in the evaluation of hydronephrosis and hydroureter. It is also the agent of choice to evaluate renovascular hypertension using captopril renography. In addition, renal transplants can be well evaluated with this agent.
3. ^{99m}*Tc-DTPA (diethylenediamine pentaacetic acid):* ^{99m}Tc-DTPA is filtered by the glomeruli, allowing visualization of the collecting systems, ureters, and bladder. ^{99m}Tc-DTPA is used in the determination of glomerular filtration rate (GFR).
4. ^{99m}*Tc-pertechnetate:* This radionuclide is used in bladder filling for radionuclide cystography to evaluate for vesicoureteral reflux (VUR) in children with urinary tract infection (UTI). Pertechnetate is the radionuclide of choice; however, in patients with an augmented bladder, Tc-sulfur colloid should be used to avoid absorption of radionuclide causing additional radiation dose to the patient.

RENAL CORTICAL IMAGING

Renal cortical scans are primarily used for the diagnosis of acute pyelonephritis and renal cortical scars in patients with febrile UTI. A less common indication of dimercaptosuccinic acid (DMSA) scintigraphy may be to search for a small ectopic kidney that may be difficult to detect by sonography and for follow-up evaluation after renal trauma.

After intravenous administration of ^{99m}Tc-DMSA in a dose of 0.05 mCi/kg (minimum dose 0.5 mCi and maximum

3 mCi), renal cortical images are obtained at 1.5 to 2 hours.[1] A high-resolution collimator is used to acquire posterior and posterior oblique images of each kidney. Use of pinhole magnification improves the resolution of the images, improving diagnostic accuracy (Figure 7.1). An alternative imaging technique is the use of single-photon emission computed tomography (SPECT). Because of the length of the study and image acquisition time, sedation may be necessary for children under the age of 4 years.

ACUTE PYELONEPHRITIS

The diagnosis of acute pyelonephritis may not always be reliably made on the basis of clinical criteria alone.[2] Under such clinical circumstances, cortical scintigraphy or DMSA scan has been shown to be a useful adjunct in the diagnosis of acute pyelonephritis.[3,4] The accuracy of DMSA scan in the diagnosis of acute pyelonephritis has been noted to be comparable to that of both computed tomography (CT) and magnetic resonance imaging (MRI).[5] DMSA scans are able to provide information on the renal parenchymal location of acute pyelonephritis, as well as the extent of renal tissue involvement.

The scintigraphic features of acute pyelonephritis consist of the decreased uptake of tracer (photopenic defects) without associated volume loss of the renal tissue (Figure 7.2). Three different patterns of photopenia can be seen: focal, multifocal, and the infrequently seen diffuse type. Focal defects are not specific for acute pyelonephritis and may be seen with renal masses, infarcts, or traumatic lesions. These defects must be interpreted within the clinical context.

RENAL SCARRING

Renal scars may develop in patients who have had acute pyelonephritis and may have an impact on management of children with UTI.[6,7] Renal scars are identified on the DMSA scan by the presence of photopenic defects associated with renal parenchymal volume loss (Figure 7.3). When a DMSA scan shows evidence of acute pyelonephritis, consideration should be given to a repeat study in 6 to 12 months to assess for scarring. Approximately 60% of all foci

---

KEY POINTS

- DMSA scanning is a useful adjunct in the diagnosis of acute pyelonephritis and detection of renal scars following acute pyelonephritis.
- Acute pyelonephritis is characterized by photopenia in the area of infection.
- Pyelonephritic scars, on the other hand, are characterized by renal parenchymal volume loss, in addition to photopenia.

of acute pyelonephritis, in the absence of high-grade VUR, resolve without scar formation.[7]

ECTOPIC KIDNEY

Cortical scintigraphy is helpful in the detection of a small ectopic kidney in girls who present with urinary incontinence.[8,9] DMSA can be instrumental in localizing an ectopic kidney associated with an ectopic ureteral insertion. Such an ectopic kidney is typically small, is situated in the anterior pelvis, and may be difficult to locate by sonography because of overlying bowel loops. Although the function is usually poor, the ectopic kidney can be easily detected by anterior planar or SPECT imaging.

RENAL FUNCTIONAL IMAGING

DIURESIS RENOGRAPHY

Diuresis renography uses furosemide in conjunction with ^{99m}Tc-MAG3 scan to evaluate patients with hydronephrosis and hydroureter who may be suspected to have urinary tract obstruction. Apart from assessment of renal function and the diagnosis of the site, diuresis renography can also determine the degree of obstruction and may play an important role in the management of hydronephrosis and hydroureter in infants and children.

KEY POINTS

- Diuretic renography is helpful in the diagnosis of urinary obstruction. It effectively replaces intravenous pyelography in children.
- Neonates presenting with hydronephrosis may require serial diuretic renography.

Technique

The most commonly used technique of diuresis renography, recommended by the Society for Fetal Urology and the Pediatric Nuclear Medicine Council, involves administration of furosemide 20 to 30 minutes after injection of ^{99m}Tc-MAG3.[10] Alternative techniques are to administer furosemide either at the time of ("F-0") or 15 minutes before ("F-15") injection of ^{99m}Tc-MAG3.[11]

The parents are instructed to maintain the child's normal hydration status, and feedings are not withheld before the study. An intravenous catheter is placed, and hydration with 5% dextrose in one-third normal saline is administered over the course of the entire examination. Infused fluid volume is usually 15 to 20 mL/kg. Placement of an indwelling bladder catheter is recommended to eliminate the effect of increased intravesical pressure on postdiuresis drainage. In addition, the catheter serves to alleviate patient discomfort, decrease the likelihood of VUR, and reduce gonadal radiation exposure from radioactive urine. ^{99m}Tc-MAG3 in a dose of 0.05 mCi/kg (minimum 1 mCi) is then injected, and a conventional renal scan is obtained for the first 30 minutes. When the dilated system is completely filled with the tracer, furosemide (1 mg/kg; maximum dose 40 mg) is injected intravenously and sequential dynamic images are obtained for an additional 30 minutes. Urine output is recorded during the 30 minutes after diuretic administration to assess adequacy of response by the kidneys.

After completion of the imaging, time-activity curves are generated from the diuresis renogram and washout half-time ($t_{1/2}$) is calculated for each kidney. The half-time ($t_{1/2}$) represents the time needed for half of the activity to clear from the collecting system after administration of the diuretic. If significant residual tracer is noted in the dilated collecting system after the diuresis renogram, static posterior images of the kidneys are obtained, before and after the patient is held upright for 15 minutes, to assess the effect of gravity on drainage. The percentage of clearance is then calculated.[12]

Interpretation

Interpretation is made by examining the images in conjunction with the quantitative data, including washout half-times, residual tracer activity, the shape of the curve and post upright clearance. Factors affecting the shape of the renogram curve and the rate of washout of tracer from the kidney include the degree of obstruction, renal function, capacity and compliance of the dilated system, state of hydration, bladder fullness, dose and timing of diuretic injection, and patient position.

A flat or rising scintigraph curve, with no significant improvement in drainage on postupright positioning, cortical retention, or both (Figure 7.4) is highly suggestive of urinary obstruction. In neonates, hydronephrosis may be dynamic, changing over time, therefore the diagnosis of urinary obstruction may be difficult to establish based on a single study. However, the initial study provides a baseline for follow-up evaluation of postdiuresis drainage.[13]

CAPTOPRIL-ENHANCED RENOGRAPHY

Captopril-enhanced renography is a provocative test for the diagnosis of renovascular hypertension in children and adults. The original work on captopril renal scan in children

KEY POINTS

- Captopril-enhanced renography may be helpful in the screening evaluation of suspected renovascular hypertension.
- If the scan is positive, patients will require an angiographic confirmation.

Right kidney

Figure 7.4 Diuresis renal scan in ureteropelvic junction obstruction. Image demonstrates tracer accumulation in a dilated right collecting system and normal clearance on the left. A flat washout curve after furosemide scan is consistent with high-grade obstruction.

was done using ^{99m}Tc-DTPA,[14,15] but ^{99m}Tc-MAG3 is currently the preferred radiopharmaceutical agent because of its more efficient extraction, especially in patients with azotemia.[16] The uptake of ^{99m}Tc-MAG3, which is handled by tubular secretion, is independent of GFR. However, its clearance from the cortex depends on adequate GFR. Therefore, in the presence of renal artery stenosis, GFR is maintained by constriction of the efferent arterioles, mediated by angiotensin II, which can be verified in a precaptopril MAG-3 scan. Following administration of an angiotensin-converting enzyme inhibitor (ACEI), such as captopril, both the afferent and efferent arterioles dilate, resulting in a decrease in glomerular capillary hydrostatic pressure, decrease in GFR, and decrease in clearance of tracer from the renal cortex, seen visually as renal cortical retention.

Technique

A baseline precaptopril renal scan is obtained with ^{99m}Tc-MAG3. For blockade of the renin-angiotensin system, either captopril (1 mg/kg; maximum dose 50 mg, given orally), or enalaprilat (0.03 to 0.04 mg/kg, given intravenously) may be used. A repeat renal scan is then obtained 1 hour after oral administration of captopril or 10 minutes after intravenous administration of enalaprilat. Renogram curves are generated for both the pre-ACEI and post-ACEI scans. A commonly used adaptation in adults is to do a post-ACEI scan first, and, if normal, the examination is finished. If any abnormality is seen, the patient returns at a later time for repeat scan after the patient has been off of the ACEI for at least 2 days. Use of calcium channel–blocking agents at the time of the study may cause false-positive or false-negative results. Therefore, this class of antihypertensive medications should be discontinued before the study.[17]

Interpretation

The scintigraphic manifestation of decreased renal function is prolonged cortical retention of tracer. A positive study is strongly suggestive of renovascular hypertension and requires further investigation by arteriography (Figure 7.5). A negative study result after a single dose of ACEI does not necessarily exclude the diagnosis of renovascular hypertension. In patients in whom there is a strong clinical suspicion, the scan may be repeated after the patient has been on ACEI for several days. Occasionally, the follow-up scan may become positive after 3 to 4 days of ACEI therapy.

RENAL TRANSPLANT EVALUATION

Ultrasonography is the study of choice for imaging renal transplant kidneys. It is able to assess the perfusion and the architecture of the transplanted kidney, as well as assess for hydronephrosis.[18] However, if renal function information is needed, radionuclide imaging using ^{99m}Tc-MAG3 provides an accurate, noninvasive, and non-nephrotoxic technique for evaluation of function of the transplanted kidney. Perfusion is also well evaluated with this technique[19] (Figure 7.6).

Acute kidney injury

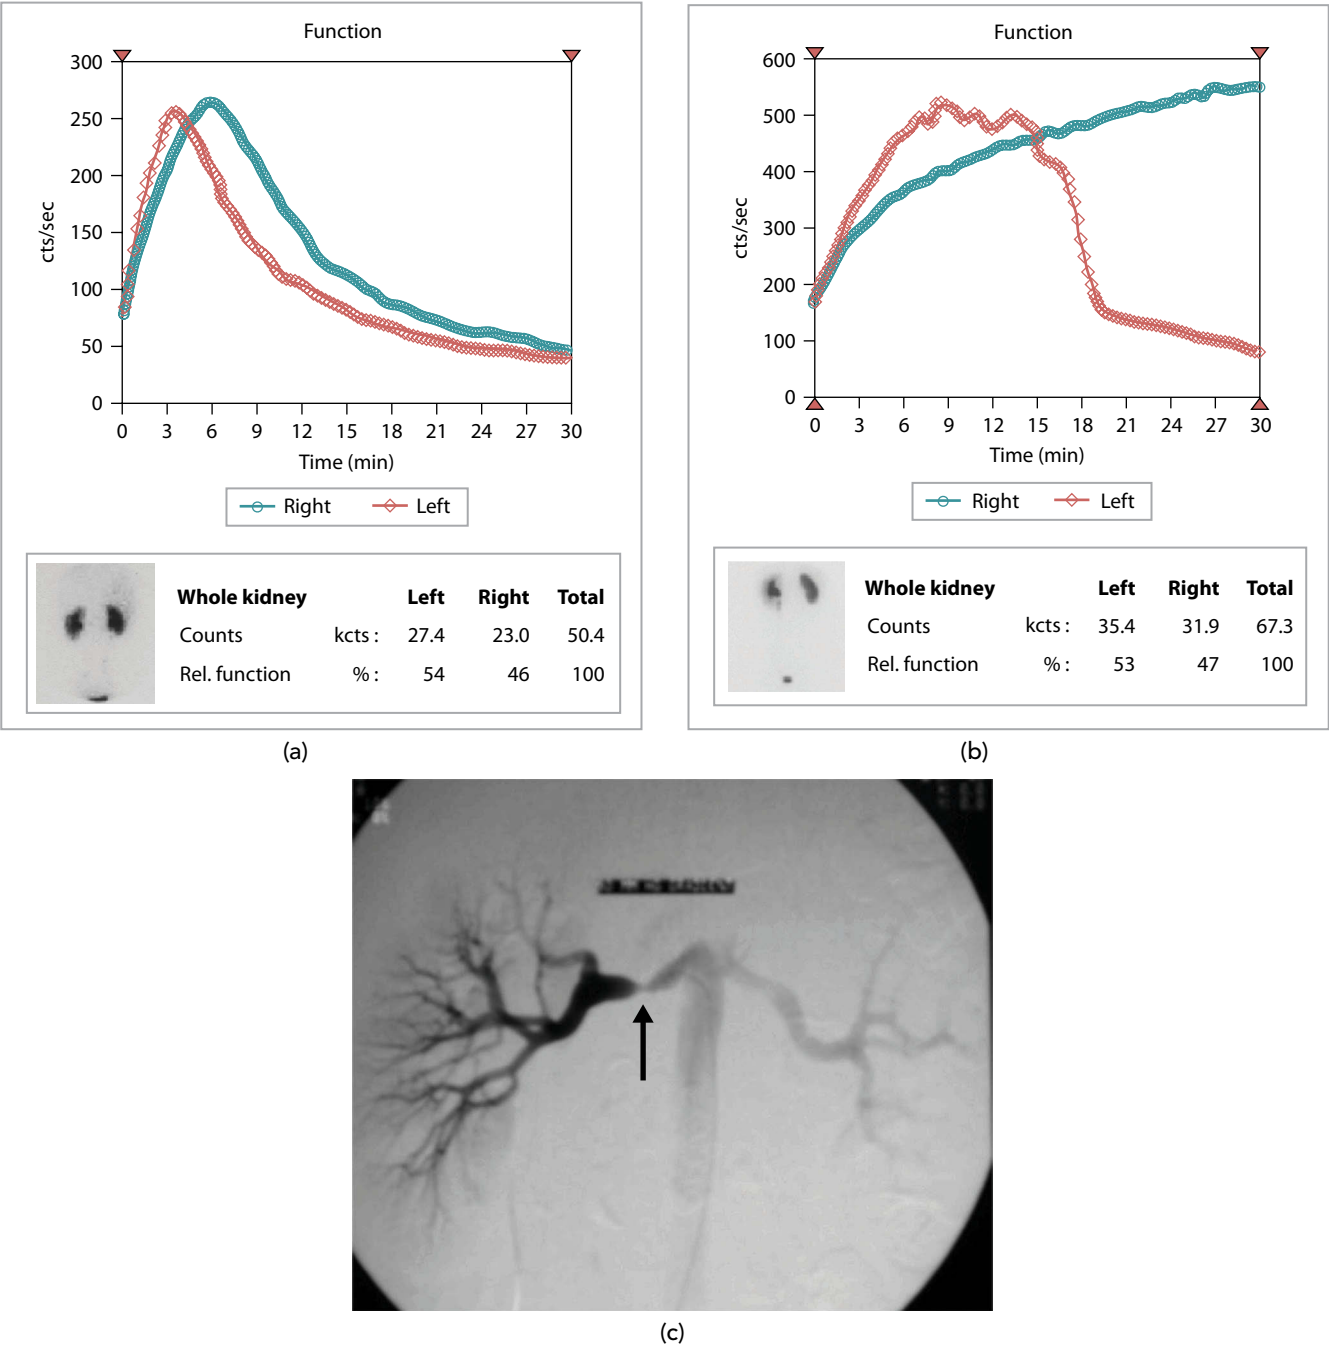
Scintigraphically, acute kidney injury (AKI) is characterized by adequate blood flow to the renal allograft; excretory function is diminished or absent. This is manifested by progressive parenchymal tracer accumulation and delay in excretion, and in severe cases by lack of any urine excretion


Figure 7.5 Captopril renal scan in right renal artery stenosis. **(a)** Precaptopril image showing normal renal scan with time-activity curve demonstrating normal and symmetric clearance from both kidneys. **(b)** Postcaptopril image shows significant cortical retention on the right side and normal clearance on the left side. Time-activity curve shows rising curve on the right side, also indicative of cortical tracer retention. **(c)** Renal arteriogram demonstrates stenosis of the main right renal artery (arrow).

over the 30-minute imaging sequence (Figure 7.7) Toxicity from immunosuppressant drugs may cause similar scintigraphic changes. The distinguishing feature is the time of onset, being much later (2 to 3 weeks postoperative) with drug-induced toxicity, and the immediate post-transplant period in the case of acute tubular necrosis.

Vascular compromise

Absence of flow in the initial post-transplant scan indicates either vascular obstruction (arterial or venous) or hyperacute rejection. These entities cannot be distinguished on renal scan, although hyperacute rejection is almost nonexistent
Figure 7.6 Normal renal transplant MAG-3 renal scan. (a) Flow images (1-second images) show prompt flow to the kidney, within two frames of the aorta. (b) Dynamic functional images demonstrate good parenchymal extraction, excretion, and drainage. Note good cortical clearance of tracer.
Figure 7.7 Acute kidney injury of renal transplant MAG-3 renal scan. (a) Normal flow images (1-second images).
(b) Dynamic functional images show good cortical uptake with almost no excretion of tracer by 30 minutes and significant cortical retention. Minimal tracer is seen in the ureter and bladder in the last three frames.

now because of the extensive preoperative testing of the recipient.

Allograft rejection

The scintigraphic findings of acute allograph rejection are decreased perfusion and decreased function. This contrasts with the findings in AKI, in which renal perfusion is well preserved. AKI and acute allograft rejection may coexist, and differentiation may be difficult. Chronic rejection is characterized by gradual evolution of chronic kidney disease and unique allograft biopsy findings. Serial renal scans demonstrate a gradual decrease in perfusion and function.

Perinephric fluid collection

Perinephric fluid collections leading to partial obstruction of the urinary tract or compression of the vascular pedicle can occur in renal transplants and are frequently identified on ultrasonography. On the early ^{99m}Tc-MAG3 scintigraphic images (first 30 minutes), perinephric fluid collections appear as a photopenic defect surrounding the kidney or in its vicinity. Delayed imaging is useful in distinguishing photopenia in the case of a hematoma or lymphocele from accumulation of tracer in a urinoma, which also can present as a fluid-filled mass around the renal allograft on ultrasonography.

GLOMERULAR FILTRATION RATE

Assessment of the GFR in patients receiving nephrotoxic chemotherapy is the primary indication for radionuclide determination of the GFR. The use of radionuclide techniques eliminates the need for urine collection and is the method of choice for determining an accurate GFR in infants and children. The radioactive tracers used for the determination of GFR are: carbon-14 (^{14}C) inulin, iodine-125 (^{125}I) iothalamate, chromium-51 (^{51}Cr) ethylenediaminetetraacetic acid (EDTA), and ^{99m}Tc-DTPA. ^{51}Cr EDTA is commonly used in Europe, but ^{99m}Tc-DTPA is the most widely used tracer in the United States. DTPA meets the criteria for an ideal GFR agent, except for the fact that 5% to 10% of the injected dose is protein-bound.

Several radionuclide-imaging techniques are available for calculating GFR.[20-22] The most commonly used method in children involves injection of a radiotracer, followed by posterior imaging of the kidneys for 20 minutes. Two or three blood samples are drawn 2 to 3 hours after injection of the radiotracer. These blood samples are centrifuged to yield plasma, and radioactivity is counted in the samples, using a well counter. Calculation of GFR is based on plasma clearance of the tracer. Another method uses volume distribution to calculate GFR in children. This technique uses a single plasma sample taken 2 hours after the injection of a dose of ^{51}Cr-EDTA.[23]

RADIONUCLIDE CYSTOGRAPHY

Radionuclide cystography (RNC) is used to diagnose VUR. Although VUR is often evaluated by the fluoroscopic voiding cystourethrogram (VCUG), RNC is an alternative method, especially in girls. Similar to the VCUG, the bladder is catheterized except that radioisotope and saline are infused, instead of radio-opaque contrast media. Imaging is begun immediately at the start of filling and continues through the end of voiding. Therefore, reflux that occurs at any time during the examination (filling or voiding) is identified (Figure 7.8). As with the VCUG, if a patient is extremely anxious and unable to cooperate for the radionuclide cystogram, oral midazolam in anxiolytic doses may be used. This medication has the added benefit of providing an amnestic effect for the procedure.[24]

RNC offers several advantages over the VCUG. By far the greatest of these is the significantly lower gonadal radiation dose, less than 5 mrads in girls and less than 2 mrads in boys.[25] Because of the continuous monitoring, the RNC may be more sensitive than the VCUG in the detection of reflux.[26]

Figure 7.8 Radionuclide cystogram demonstrates vesicoureteral reflux into the collecting systems, bilaterally.

The major disadvantage of RNC, because of its limited spatial resolution, is the inability to evaluate the urethra and grade reflux accurately. Bladder wall abnormalities, such as diverticula and ureteroceles, may remain undetected but are easily seen on ultrasound studies.

The RNC is best suited for the initial diagnostic workup of VUR in girls, in whom urethral anomaly is rare. However, it is not recommended for the initial evaluation in boys because of the inability to evaluate the urethra with this technique. Because of its relatively low radiation burden,[27] RNC is the imaging method of choice for follow-up in patients undergoing serial evaluations, such as children with known VUR. This is applicable for both female and male patients after an initial VCUG in a boy excludes a posterior urethral valve.

KEY POINTS

- Radionuclide cystography, because of its high sensitivity for VUR and its low radiation burden, is recommended when serial follow-up studies are required.
- Radionuclide cystography is not adequate for providing information on urinary tract anatomy, such as posterior urethral valve.

SUMMARY

Nuclear imaging techniques are a useful adjunct to other diagnostic imaging modalities in the management of pediatric nephrology patients. Diuresis renography provides critical information about conditions such as obstructive uropathy. Renal cortical scanning demonstrates the extent of parenchymal involvement in pyelonephritis and scarring. Radionuclide studies offer an opportunity to view the results from a functional perspective. Together with anatomic imaging, they assist the pediatric nephrologist in the care of patients

REVIEW QUESTIONS

1. A six-month-old female infant is hospitalized with a febrile urinary tract infection. The radiopharmaceutical to be used for assessment for acute pyelonephritis imaging is:
   a. 99mTc-MAG3
   b. 99mTc-pertechnetate
   c. 99mTc-DMSA
   d. 99mTc-DTPA

2. For the patient in question 1, renal cortical imaging demonstrates multiple areas of photopenia, without loss of volume, involving both the upper and lower poles of the right kidney. The diagnosis is:
   a. Renal scarring
   b. Multifocal acute pyelonephritis
   c. Normal study

3. Clinical indications for DMSA renal cortical scintigraphy include:
   a. Urinary tract infection
   b. Search for a small ectopic kidney
   c. Follow-up in renal trauma
   d. All of the above.

4. A 2-month-old male infant was diagnosed to have prenatal hydronephrosis in one kidney. Left-side hydronephrosis was confirmed by a postnatal ultrasound recently. There was no evidence of VUR on the VCUG. You should schedule this baby for a:
   a. DMSA renal scan
   b. Captopril renal scan
   c. Radionuclide cystogram
   d. Diuretic renogram

5. The initial imaging on the patient in question 4 demonstrates prompt and symmetric renal function with pooling of activity in the dilated left renal collecting system and prolonged washout half-time. Drainage on the right side is normal. Renal function is normal bilaterally. Which of the following would be the *best* investigative recommendation?
   a. MRI of the abdomen
   b. Repeat diuretic renography in 6 months
   c. Radionuclide cystogram in 6 months
   d. DMSA renal scan

6. All of the statements regarding captopril-enhanced MAG-3 renal scan are true *except:*
   a. The primary use is in the diagnosis of obstructive uropathy.
   b. The primary use is in the diagnosis of renal artery stenosis.
   c. Calcium channel–blocking medication should be discontinued for at least 2 days before the study.
   d. Either captopril or enalaprilat may be used for ACE blockade.

7. To assess the function of the transplanted kidney, the *best* choice of radionuclide investigation is:
   a. 99mTc-DTPA
   b. 99mTc-pertechnetate
   c. 99mTc-DMSA
   d. 99mTc-MAG3

8. The *main* indication for obtaining a 99mTc-DTPA renal scan is:
   a. Evaluate for obstructive uropathy
   b. Evaluate for vesicoureteral reflux
   c. Determine the glomerular filtration rate
   d. There are no current indications for obtaining a 99mTc-DTPA renal scan

9. The following are correct regarding radionuclide cystography *except:*
   a. Oral midazolam may be used for anxiolysis as necessary.
   b. The radiotracer used is 99mTc-pertechnetate.
   c. It is indicated in the evaluation of vesicoureteral reflux.
   d. The bladder does not need to be catheterized.

10. Which one of the following statements *best* compares and contrasts the VCUG and the radionuclide cystogram (RNC)?
    a. The VCUG has higher resolution allowing delineation of anatomy and more accurate grading of reflux

compared to the RNC, which has higher sensitivity for detecting reflux and offers less radiation burden.

b. The RNC has higher resolution allowing delineation of anatomy and more accurate grading of reflux compared to the VCUG which has higher sensitivity for detecting reflux and offers less radiation burden.

c. The RNC and VCUG are very similar to each other, one simply a radionuclide study and the other a fluoroscopic study.

d. None of the above.

Renal biopsy

NATALIE S. UY, MIHAIL M. SUBTIRELU, AND FREDERICK J. KASKEL

Renal biopsy is an important tool for establishing the morphologic diagnosis and prognosis, as well as guiding therapy of renal disease in children and adults. Although a renal biopsy can be performed by an open surgical procedure, the percutaneous method is the preferred manner of obtaining the renal biopsy sample in most children. Although percutaneous renal biopsy of palpable tumors was first performed in 1934 by Ball, the use of percutaneous renal biopsy for the diagnosis of medical disease was introduced by Iversen and Brun in 1951.[1,2] Since then, the technique has been continuously enhanced by better guidance and instruments. The advent of real-time ultrasound and automated biopsy needles during the last two decades has simplified the procedure and further improved its success and safety.[3]

INDICATIONS FOR RENAL BIOPSY

Broadly, indications of renal biopsy include establishing the morphologic nature of the renal disease, assist in predicting prognosis and disease evolution, and in developing an appropriate therapy plan. Renal biopsy may also be used to monitor the response to therapy and disease progression. The value of renal biopsy in influencing management of patients with renal disease is well known.[4]

A common indication for renal biopsy in children is poorly responsive nephrotic syndrome. Corticosteroid-responsive nephrotic syndrome in children is considered to be due to minimal change disease (MCD), and a renal biopsy is not necessary in such patients.[5] On the other hand, a diagnostic renal biopsy is generally recommended in patients with corticosteroid-nonresponsive or corticosteroid-resistant nephrotic syndrome, or where an underlying glomerulonephritis is suspected to be the cause of nephrotic syndome.[5,6] Focal segmental glomerulosclerosis (FSGS) is a common form of glomerulonephritis encountered in such patients.[7] Renal biopsy is also commonly performed for histologic diagnosis of persistent non-orthstatic proteinuria, which may be indicative of an underlying primary glomerulonephritis, such as FSGS, membranous glomerulonephritis (MGN), or membranoproliferative glomerulonephritis (MPGN).

Another common indication for renal biopsy is persistent isolated hematuria when the diagnosis of Berger disease or immunoglobulin A nephropathy (IgAN), Alport syndrome, or thin basement membrane disease is being considered.[6] Renal biopsy is also recommended in children with acute glomerulonephritis who exhibit a rapidly progressive clinical course. Renal biopsy in such cases should be considered an urgent diagnostic procedure and used to guide therapy. Renal biopsy is generally not considered in patients with non-complicated acute postinfectious glomerulonephritis.

Renal biopsy can be of immense diagnostic value in patients with acute kidney injury (AKI), where intrinsic renal diseases, such as rapidly progressive glomerulonephritis, interstitial nephritis, and vasculitis are suspected to be the etiology. On the other hand, in AKI of hemodynamic or nephrotoxic origin, a renal biopsy is generally unnecessary. In children with chronic renal insufficiency of

Table 8.1 Indications for renal biopsy in children

Absolute Indications
- Rapidly progressive glomerulonephritis
- Acute renal failure with nephrotic or nephritic syndrome
- Steroid-resistant nephrotic syndrome
- Persistent, nonorthostatic proteinuria
- Persistent glomerular hematuria, suggestive of active glomerulonephritis
- Atypical or nonresolving acute glomerulonephritis
- Systemic diseases with renal involvement (systemic lupus erythematosus, vasculitis, metabolic diseases such as Fabrey disease)
- Chronic kidney disease of unclear etiology, if kidneys are normal in size
- Renal transplant dysfunction

Relative Indications
- Monitoring response to therapy
- Monitoring drug nephrotoxicity
- Protocol biopsies of renal allograft

Table 8.2 Contraindications to percutaneous renal biopsy

Absolute Contraindications
- Uncontrolled coagulation abnormalities
- Uncontrolled severe hypertension
- Uncooperative patient (under conscious sedation)
- Acute pyelonephritis

Relative Contraindications
- Severe azotemia or end-stage renal failure
- Anatomic abnormalities of the kidney
- Solitary kidney (not transplant)
- Coagulopathy
- Concurrent use of drugs affecting coagulation (e.g., aspirin, dipyridamole)
- Chronic pyelonephritis
- Concurrent urinary tract infection
- Tumors
- Pregnancy
- Extreme obesity

unknown etiology, a renal biopsy may be able to establish the underlying diagnosis. This information is especially relevant in assessing the risk for recurrence of the original disease after renal transplantation. In advanced renal disease, the kidneys may be small and densely echogenic on ultrasound evaluation, and a renal biopsy may only demonstrate atrophic renal tissue and glomerulosclerosis, often referred to as "end-stage kidney."

Renal biopsy is routinely used for the evaluation of renal transplant allograft dysfunction, which may be due to acute and chronic allograft rejection, drug toxicity, recurrence of original disease, or de novo renal disease. Protocol renal allograft biopsies are useful for the diagnosis and post-treatment monitoring of acute rejection and for the surveillance of chronic allograft nephropathy.[8] Table 8.1 presents a list of common indications for renal biopsy.

CONTRAINDICATIONS TO PERCUTANEOUS RENAL BIOPSY

Percutaneous renal biopsy is an invasive, elective procedure, with well-defined risks. Absolute contraindications to percutaneous renal biopsy (Table 8.2) include clinical conditions associated with high risk of complications. Relative contraindications to renal biopsy (Table 8.2), on the other hand, are clinical circumstances that adversely impact the safety or technical performance of the procedure, and increase the potential for complications. An open surgical diagnostic renal biopsy may be considered if the patient has well-established contraindications to the percutaneous procedure.

PREPARING THE PATIENT

Adequate preparation for the renal biopsy is the key for a successful and safe procedure. It should start with a thorough prebiopsy evaluation consisting of four elements: history taking, physical examination, laboratory evaluation, and ultrasonographic evaluation of the kidneys. Important elements of the history are bleeding diathesis (personal or family history); allergies to agents used during the renal biopsy; use of aspirin, nonsteroidal anti-inflammatory drugs, or other anticoagulation therapy; and history of severe hypertension. Key elements of the physical examination are blood pressure evaluation, biopsy site assessment, and assessment of anatomic abnormalities that may interfere with imaging or positioning the patient during the biopsy. Laboratory evaluation should include a complete blood count and platelet count, biochemical profile, coagulation profile, type and screen, and urinalysis. A complete ultrasonographic evaluation of the kidneys should be done in advance to evaluate for anatomic abnormalities that might constitute absolute or relative contraindication for a percutaneous renal biopsy.[3]

The procedure needs to be scheduled in advance to ensure a collaboration of the teams involved (nephrology, ultrasonography, pathology). Depending on the institutional practices and prevailing patient needs, the patient

Table 8.3 Prebiopsy order set

- Nothing by mouth for 6 hours before biopsy
- Obtain consent for the procedure
- Send and follow results for:
  - Complete blood count with platelet count
  - Basic metabolic panel for renal function
  - Coagulation profile (prothrombin time, partial thromboplastin time)
  - Bleeding time, if clinically indicated
  - Urinalysis
- Type and hold one unit of packed red blood cells
- Place an intravenous line
- Start intravenous maintenance fluids

may be admitted overnight before the procedure or come on the morning of the procedure. Medications that may affect coagulation must be interrupted for an appropriate duration to ensure a safe procedure. The patient must be instructed to take nothing by mouth (NPO) for 6 hours before the biopsy.

The renal biopsy procedure is generally done in a radiology procedure room that is appropriate for anesthesia and conscious sedation support. Current clinical practice is to guide the renal biopsy with a real-time ultrasound probe. This requires the help of a renal ultrasound technician in the procedure. The pathology department must be notified in advance so the biopsy specimen can be processed in a timely fashion. An intravenous access is placed before the procedure, and maintenance intravenous fluid appropriate for age is provided. An informed consent, appropriate for the patient's age, needs to be obtained before the procedure. The type of sedation and the premedication vary according to institutional protocol. A young or uncooperative patient may require general anesthesia. This is prearranged with the anesthesiologist. Continuous cardiorespiratory monitoring should be started before the procedure and continued until the recovery phase. In absence of any complications, patients are returned to their rooms for postbiopsy care. Table 8.3 provides prebiopsy orders.

BIOPSY IMAGING

Since the introduction of the percutaneous renal biopsy more than 50 years ago, the safety and use of the procedure have been enhanced by the technologic advancements in imaging and guidance instruments. Intravenous pyelogram with fluoroscopy, the initial modality to image the kidney for the biopsy, was largely replaced by ultrasound in the mid-1980s.[3,9] The 1990s witnessed the introduction of automated ultrasound-guided biopsy devices.[10,11] Real-time ultrasound is the favored method in most centers, but other imaging modalities, such as computed tomography (CT),

also can be used for guidance when localization by ultrasound is unsatisfactory (i.e., obese patient or focal lesions).

BIOPSY INSTRUMENTS

VIM-SILVERMAN NEEDLE

In the mid-1950s, Kark et al. and Muehrcke et al. revolutionized the field by using a new technique for percutaneous renal biopsy.[12–14] Besides changing the patient's position from sitting to prone, they replaced the aspiration needle used by Iversen and Brun[2] with a Franklin modified Vim-Silverman needle (Figure 8.1). Their technique increased the success rate of the biopsy from less than 40% to above 90% and significantly decreased the associated morbidity.[3]

The Franklin modified Vim-Silverman needle consists of a trocar, a fitting obturator, and a cutting needle with prongs. The trocar and the fitting obturator are introduced together into the renal cortex after which the obturator is removed, and the cutting needle with prongs is introduced through the trocar. The cutting needle is advanced into the renal parenchyma followed quickly by the trocar. While the relative position of its components is maintained, the biopsy needle is quickly removed. The biopsy core is collected between the prongs of the cutting needle. The Vim-Silverman needle is not disposable and has now been abandoned because of the development of automatic biopsy needles.

TRUE-CUT NEEDLE

The True-Cut needle (Baxter Healthcare Corporation, Valencia, CA) (Figure 8.2) became popular in the late 1970s and 1980s. This was the first semiautomatic disposable needle introduced for renal biopsy procedures. The True-Cut needle consists of a cutting needle encased into a trocar. The cutting needle slides into the trocar to a preset depth. The trocar and the cutting needle are introduced together into the renal cortex. Once in the renal tissue, the cutting needle is advanced rapidly into the renal parenchyma,

Figure 8.1 Franklin modified Vim-Silverman biopsy needle. The obturator (C) fits into the trocar (T). The cuttings prongs (CP) are shown separately.

Figure 8.2 Disposable True-Cut biopsy needle (Baxter Healthcare, Valencia, CA).

followed by the trocar. The needle and trocar are removed together, and the biopsy core is collected from the cutting needle.

SPRING-LOADED AUTOMATED BIOPSY DEVICES

Automatic biopsy devices were introduced in late the 1980s.[15] Several variations of the automated devices are available for clinical use today (Figures 8.3 to 8.6). These devices, when used with real-time ultrasound guidance, have diminished the operator error and improved the success of the procedure.[3,16,17] The automated systems were initially partially reusable (disposable needle and reusable spring-loaded

Figure 8.3 Bard Monopty Biopsy Instrument (C. R. Bard, Covington, GA).

Figure 8.4 Meditech ASAP (Meditech, Boston Scientific, Watertown, MA).

Figure 8.5 Bio-Pince biopsy needle (Ascendia AB, Sollentuna, Sweden).

Figure 8.6 Easy-Core biopsy needle (Boston Scientific, Natick, MA).

device), but the currently available devices are fully automatic, for single use, and disposable. The instrument consists of a trocar encasing a cutting needle. Both are mounted on a spring-loaded handle. The needle is armed into the trocar, introduced till the renal cortex is reached, and advanced by releasing the loaded spring with the push of a button or a release switch. One of the disadvantages of the automatic biopsy needles is that the length of the cutting core cannot be adjusted, making it hazardous to use these devices in very small infants, especially those with a thin cortical core. Bio-Pince (Argon Medical Devices, Plano, TX) (see Figure 8.6) is the only commercially available biopsy needle that allows adjustment of the stroke length (also known as "throw") of the cutting core from 13 to 33 mm.

BIOPSY PROCEDURE

The patient is brought to the procedure room accompanied by a nurse and with continuous cardiorespiratory monitoring. The patient is placed in the prone position on the biopsy table, with a roll of sheets placed under the abdomen to stabilize and push the kidney toward the operator.[12,13] The lower pole of the left kidney, the optimal biopsy area, is localized by ultrasound, and the corresponding point is marked on the skin on the back of the patient (Figure 8.7). The distance from the skin to the renal capsule is recorded from the ultrasound data. The anesthesiology support personnel administer conscious sedation to the patient.

The biopsy area is prepped with povidone-iodine and draped. Local skin anesthesia is done with 1% lidocaine. A spinal tap needle is used to anesthetize the biopsy tract and confirm orientation of the biopsy needle by ultrasound. A small incision of the skin, sufficient to allow the passage of
Figure 8.7 Diagram showing landmarks for localization of renal biopsy site in the left kidney.

KEY POINTS

- Technical advances in imaging and instruments have made the percutaneous renal biopsy a safe diagnostic procedure.
- Percutaneous renal biopsy is usually performed with real-time ultrasound guidance and advanced instruments, which have diminished operator error and improved the success of the procedure.
Figure 8.8 Renal ultrasound of the kidney capturing the moment as the biopsy cutting edge (arrow) enters the kidney for retrieving the renal tissue core.

the biopsy needle, is made using a scalpel. Under real-time ultrasound guidance the biopsy needle is introduced and advanced, using the recorded angle and length of passage, until it reaches the outer kidney cortex (Figure 8.8). If possible, the patient is instructed to hold the breath, and the maneuver to obtain the core of tissue is performed (depending on the biopsy instrument used). The biopsy needle containing the tissue core is quickly removed.

The biopsy tissue obtained is immersed in normal saline and observed under a dissecting microscope for quality and glomerular content. Usually two cores are sufficient to obtain an appropriate biopsy sample. A successful renal biopsy brings at least 20 glomeruli. The biopsy core is then divided and prepared for light microscopy, immunofluorescence, and electron microscopy.

BIOPSY IN A RENAL TRANSPLANT

The presence of a single kidney allograft in the renal transplant is not a contraindication for percutaneous renal biopsy. The kidney allograft is usually located in an anterior position, in the right or left lower quadrant, and is easily palpable. In preparation for the procedure, the patient is placed in the supine position. Depending on the position,

usually the upper pole is located by ultrasound and marked on the skin and the depth from skin to the renal capsule is recorded. The rest of the procedure is essentially the same. Caution is necessary because the fibrous tissue (capsule) of the kidney allograft may be firm and difficult to penetrate. If the kidney allograft is located in an unusual or inaccessible position, percutaneous biopsy by an interventional radiologist or open biopsy is generally indicated. In highly experienced centers, percutaneous renal biopsies of allografts placed extraperitoneally or intraperitoneally have been reported to have similar complication rates.[17]

POSTRENAL BIOPSY CARE

Once the percutaneous renal biopsy is completed, the kidney is examined by ultrasound in search for hematomas. This examination may be postponed or repeated later in appropriate cases to increase the chance of detecting a hematoma.[3] Once the ultrasound is completed, the skin is cleaned with povidone-iodine and a pressure dressing is applied. The patient is positioned on the back and transported to an observation area, accompanied by a nurse and with continuous cardiorespiratory monitoring.

The postbiopsy procedure observation orders should be instituted immediately, especially for monitoring the vital signs for any evidence of hypovolemia (Table 8.4). The observation period is needed for the immediate detection of any complications, particularly hemorrhage and anesthesia-related events. The length of postbiopsy hospital

Table 8.4 Postbiopsy order set

- Place patient flat on the back for 6 hours without bathroom privileges
- Continuous cardiorespiratory monitoring until awake from sedation
- Monitor vital signs:
  - Every 15 minutes for 1 hour
  - Every 30 minutes for 2 hours
  - Every 1 hour for 4 hours
- Check biopsy site with each set of vital signs
- Inform physician if:
  - Changes in vital signs outside set parameters
  - Back pain
  - Abdominal pain
  - Active bleeding at the biopsy site
  - Visible urinary bleeding or passage of clots
- Obtain hemoglobin and hematocrit at 4 hours postbiopsy
- Strict intake and output monitoring
- Inform physician if no urine output for 6 hours
- Normal diet once the patient is awake; encourage oral fluid intake
- Discharge patient after 6 to 8 hours, if stable

stay is debatable. There is evidence to point that a shorter observation period (8 hours) with same-day discharge from the hospital is sufficient in selected patients and is more economical.[19-22]

COMPLICATIONS FOLLOWING RENAL BIOPSY

Complications following a renal biopsy can be separated into minor, major, and severe categories. Technical advancements in both imaging techniques and biopsy needles have kept the complication rate low. Although the incidence of minor complications are common and may reach 100%, major complications have been reported in 5% to 10% of cases.[6] Severe complications are rare. Depending on the era of studies, the reported complication rate is variable. Most complications are the result of bleeding into the collecting system with subsequent hematuria or at the biopsy entry point into renal cortex resulting in perinephric hematoma. Significant postbiopsy bleeding may occasionally result in a drop in hematocrit, with the need for transfusion, surgical intervention, or both. Severe bleeding with the need for nephrectomy is an extremely rare occurrence. In a literature review of 19,459 percutaneous renal biopsies, need for nephrectomy was reported in 13 cases (0.06%).[23] Death directly attributable to renal biopsy is exceptionally rare, with a reported frequency of up to 0.08% in older reviews and 0.02% in the more recent sreviews.[3,23] Table 8.5 and Table 8.6 list complications associated with kidney biopsy.[24-63]

KEY POINTS

- Minor complications such as microscopic or gross hematuria and perinephric hematoma are common, but severe complications are rare.
- The success and safety of the renal biopsy in children requires a knowledgeable and experienced nephrologist familiar with the technique.

The main factor associated with higher complication rate is a lower estimated glomerular filtration rate (chronic kidney disease stages 3 to 5), which may be related to platelet dysfunction in the uremic state.[60] Other various conditions that increase the risk for complications include obesity, pregnancy, solitary or small kidney, multiple needle passes, and thrombocytopenia. Most complications occur within 8 hours of the biopsy, but even in those with later complications, readmission rates are not high, suggesting that hospital admission may not be required routinely in all patients who had percutaneous renal biopsy.

Table 8.5 Complications following kidney biopsy

1. Minor
   - Microscopic hematuria
   - Macroscopic hematuria (transient)
   - Perirenal hematoma (not clinically significant)
2. Major
   - Macroscopic hematuria (requiring observation or intervention)
   - Perirenal hematoma (clinically significant)
   - Arteriovenous fistula
   - Renal artery pseudoaneurysm
3. Severe
   - Need for a major surgical intervention
   - Death

Strategies to reduce the complications include efforts to minimize bleeding, including obtaining a complete blood cell count and coagulation profile before the procedure, and identifying patients at higher risk (i.e., thrombocytopenia) for bleeding. Cessation of medications that increase the risk for bleeding (i.e., aspirin) before the procedure is warranted in at-risk patients. Adequate control of hypertension before the procedure is essential because elevated blood pressure is a risk factor for bleeding after the procedure.

Microscopic hematuria

Microscopic hematuria is the most common complication of renal biopsy and occurs in almost all patients.[3] It usually resolves without intervention and has no clinical significance.

Macroscopic hematuria

The incidence of macroscopic hematuria after native or allograft biopsies in children is ranging from 2.7% to 26.6%.[22] Macroscopic hematuria usually is not clinically significant and resolves spontaneously within 24 to 48 hours. Rarely, macroscopic hematuria may produce a significant drop in hematocrit, with need for transfusion. The need for an intervention (radiographic or surgical) to stop the bleeding is extremely rare. Infrequently, significant gross hematuria may result in formation of clots with subsequent urinary tract obstruction (Figure 8.9). In most patients, observation and good intravenous hydration may be sufficient, as well as beneficial, in preventing the formation of large clots.

Perinephric hematoma

The reported incidence of perinephric hematoma following renal biopsy depends on the modality of evaluation. Before the advent of ultrasound and computed tomography, the reported incidence of clinically detectable perinephric hematoma was 1.4%.[46] A recent pediatric study

Table 8.6 Incidence of complications following kidney biopsy

Complication		Incidence (%)	References
Microscopic hematuria		100	3
Macroscopic hematuria		2.7-26.6	22, 24-36, 59, 60, 61, 63
Urinary tract obstruction secondary to blood clots		0.5-5	37-45
Perirenal hematoma	Clinical examination	1.4	46
	Ultrasound	6-70	3
	CT scan	57-91	3
Renal arteriovenous fistula		5-18	47-53, 60, 63
Clinically significant drop in hematocrit requiring blood transfusion		0.9-4.1	31, 34, 36, 54
Nephrectomy for complications of renal biopsy		0.06	23
Death directly attributable to renal biopsy		0.02-0.08	3, 23

reported the incidence of postbiopsy hematomas to be 8.1%.[60] It is well known that the incidence of perinephric hematoma, assessed by CT, can be up to 91%.[3] Most perinephric hematomas are clinically insignificant and self-limiting (Figure 8.10). Flank pain or abdominal pain may be encountered in some patients with a perinephric hematoma.

KEY POINTS

- Microscopic hematuria occurs in almost all patients after a renal biopsy.
- Visible hematuria has been reported in 2.7% to 26.6% patients.
- Need for nephrectomy is uncommon for renal biopsy complications (0.06%).
- Death attributable to renal biopsy procedure has been reported in 0.02% to 0.08% of cases.
Figure 8.10 Renal ultrasound of a patient showing perirenal hematoma following native kidney biopsy. Hematoma is marked by the arrows. The hematoma measured 5.6 × 1.7 cm.
Figure 8.9 Bladder ultrasound examination showing a large hematoma in the bladder following a renal biopsy procedure. The patient had nephrotic syndrome with poor urinary flow, allowing the urinary bleeding to remain in the bladder for a sufficient period and develop into a clot.

Arteriovenous fistula

Renal arteriovenous fistula (AVF) is a well-recognized complication of percutaneous renal biopsy (Figure 8.11). The reported incidence of AVF following renal biopsy is 6% to 18%, as diagnosed by angiography and 5% to 12%, as diagnosed by color Doppler ultrasound.[47–53] Development of hypertension, hematuria, and abdominal bruit after renal biopsy are clinical clues to the presence of an AVF. Most AVFs are found within 1 month of renal biopsy, but diagnosis can be delayed for years depending on imaging follow-up and clinical symptoms. Renal transplant and multiple needle passes are associated with a higher incidence of AVF.[63] AVFs can cause steal syndrome with relative ischemia of the renal parenchyma outside the lesion, which may induce secondary arterial hypertension, GFR deterioration, or heart failure secondary.[63] Most of these fistulas resolve spontaneously within 1 year, but it is recommended that even small asymptomatic AVFs should be followed by color Doppler ultrasound because of potential for complications.[3] Gradual
Figure 8.11 Color Doppler evaluation of the kidney demonstrating an arteriovenous fistula following a renal biopsy procedure. The fistula is marked by the area showing the admixture of blue and red blood flow pattern (arrow).

enlargement of an AVF can lead to late bleeding, resulting in renal rupture. Large, symptomatic AVFs may need to be managed by radiologic or surgical intervention, such as coil embolization or stent graft.[3, 63]

Miscellaneous complications

Infectious complications, such as bacteremia, sepsis, perirenal abscesses, fistulas, and gastrointestinal tract injury, as well as severe hemorrhage and death resulting from injury to the lumbar artery have also been described.[40,54,57,58]

SUMMARY

The technical advances in imaging and instruments have made the percutaneous renal biopsy a safe diagnostic procedure. Use of real-time ultrasound guidance and advanced instruments are the standard of care in our days. In spite of all the advancements, there are still a group of well-defined contraindications for a percutaneous renal biopsy that the clinician must consider carefully. Finally, the success and safety of the percutaneous renal biopsy in children require a knowledgeable and experienced pediatric nephrologist familiar with the technique.

REVIEW QUESTIONS

1. Which of the following is *not* considered an *absolute* contraindication for a percutaneous renal biopsy?
   a. Uncooperative patient
   b. Chronic glomerulonephritis
   c. Uncontrolled severe hypertension
   d. Acute pyelonephritis
2. Which of the following statements regarding complications of a renal biopsy is *false*?
   a. Microscopic hematuria is the most common complication.
   b. The incidence of perinephric hematoma following renal biopsy depends on the modality of evaluation.
   c. Most arteriovenous fistulas require surgical intervention.
   d. Macroscopic hematuria usually resolves spontaneously within 24 to 48 hours.
   e. Intravenous hydration is sufficient in most patients to prevent the formation of large clots.
3. The optimal biopsy site for a native kidney is the:
   a. Upper pole of the right kidney
   b. Lower pole of the right kidney
   c. Upper pole of the left kidney
   d. Lower pole of the left kidney
4. Which of the following is *not* an indication for renal biopsy in children?
   a. Rapidly progressive glomerulonephritis
   b. Steroid-resistant nephrotic syndrome
   c. Renal allograft dysfunction
   d. Persistent glomerular hematuria
   e. Steroid responsive nephrotic syndrome
5. Prebiopsy evaluation should include:
   a. Complete blood count
   b. Basic metabolic panel
   c. Ultrasonographic evaluation of the kidneys
   d. Coagulation profile
   e. All of the above
6. A 10-year-old girl underwent a percutaneous renal biopsy and was discharged from the outpatient surgical unit after 6 hours of observation. Next morning the patient complained of left side abdominal pain, which was noted to be 8 on a 10-point scale, and was persistent. Her parent gave her acetaminophen 325 mg orally, but there was no resolution of pain. She is now seen in the emergency room. Patient has been urinating well and the urine color is clear yellow. She was afebrile, and abdominal examination showed tenderness in the left upper quadrant and along the left flank. The biopsy site was very tender to touch. No guarding or rebound tenderness was noted. Your *most likely* initial diagnostic consideration is:
   a. Urinary tract infection
   b. Perforation of the abdominal viscera
   c. Perinephric hematoma
   d. Muscular pain at the biopsy site
   e. Previously undiagnosed renal stone
7. Initial management of the patient should include all *except:*
   a. Renal ultrasound
   b. Obtain a complete blood count
   c. Prescribe intravenous morphine
   d. Prescribe oral codeine and discharge her home
8. You decided to admit the patient and noted that her hematocrit had decreased from prebiopsy value of 39% to 24% in the emergency room (hemoglobin 13 g/dL to 8 g/dL). Patient received morphine intravenously and

was relieved of pain. She had mild tachycardia, pulse 99/min, and BP 105/59 mm Hg. Renal ultrasound demonstrated a large perinephric hematoma. Management of the patient will include all *except:*

a. Observe the patient and continue on IV morphine.
b. Ask for invasive radiology team to evacuate peri-nephric hematoma.
c. May give 5% albumin intravenously.
d. Arrange for a blood transfusion.
e. Repeat CBC in 2 to 4 hours.

9. Hypertension is a presenting manifestation of the post–renal biopsy arteriovenous fistulas.

a. True
b. False

ANSWER KEY

1. b
2. c
3. d

Hematuria and proteinuria

KANWAL KHER AND MARVA MOXEY-MIMS

Hematuria and proteinuria are the two most common abnormalities in the urinalysis that lead to referral of children to pediatric nephrologists or urologists. Use of automated test strips (dipsticks) in performing screening urinalyses in office practice has further enhanced the rate of detection of these urinary abnormalities. Visible or gross hematuria (GH) can be unnerving for children and their parents, especially if associated symptoms of dysuria or abdominal pain are present. Despite its asymptomatic nature, microscopic hematuria (MH) and low-grade proteinuria may also indicate a serious underlying renal disease. This chapter discusses the epidemiology and clinical evaluation of hematuria in children.

HEMATURIA

Although hematuria is a common manifestation of many disorders of the kidney and the urinary tract, its mere presence does not necessarily signal a progressive illness. The finding of isolated MH in children may be of minor clinical significance. Concern is warranted when the hematuria is accompanied by proteinuria, hypertension, or renal insufficiency. The presence of associated clinical symptoms, such as dysuria, abdominal pain, or an abdominal mass, also requires prompt attention.

DEFINITIONS

Hematuria can be an isolated and an asymptomatic event, or it may be associated with symptoms such as dysuria, abdominal pain, or systemic disease. In general, hematuria resulting from urologic causes, such as a lower urinary tract infection, passage of stone, or bladder or renal tumors, may be associated with the foregoing manifestations. Glomerular hematuria, conversely, may not cause any urinary symptoms but may have systemic disease manifestations, such as edema, hypertension, rash, or joint pains.

Gross hematuria

Visible blood in urine , or GH, depending on the site and type of renal and urinary tract disease, can be rust colored, tea (or cola) colored, bright red, or pink. Rusty urine (cola-colored urine, smoky urine) is usually the result of bleeding from the upper urinary tract, such as in glomerulonephritis. Red or pink urine, in contrast, is usually associated with bleeding in the lower urinary tract, which comprises the bladder and urethra. Apart from the color, timing of visible blood within the micturition cycle is also relevant, and may indicate the site of the bleeding within the urinary tract.

KEY POINTS

- Brownish (rusty, smoky, cola-colored) hematuria is usually of glomerular origin.
- The presence of proteinuria and RBC casts supports a diagnosis of GH.
- "Urologic" hematuria is usually pinkish or red.
- Terminal hematuria, in which a drop of blood is present at the end of micturition, usually suggests lesions in the bulbar or prostatic urethra.

INITIAL HEMATURIA

The presence of blood at the start of micturition is known as initial hematuria and indicates a lesion in the urethra distal to the external urinary sphincter.

TOTAL HEMATURIA

The presence of visible blood in urine throughout micturition is considered total hematuria and can be caused by lesions in the kidneys or bladder.

TERMINAL HEMATURIA

When blood is visible at the end of urination, it is referred to as terminal hematuria, and it usually denotes an injury or disease proximally, in the bulbar or prostatic region of the urethra. Terminal hematuria is often reported as a stain in the patient's underwear or a drop of blood at the end of urination. An example of this type of bleeding is urethrorrhagia seen adolescents who strain and create a high-pressure–associated injury to the posterior urethral mucosa. Although some patients have associated symptoms of dysuria, most patients are asymptomatic. Urethrorrhagia is generally a benign condition that improves with minimal therapeutic intervention.

Microscopic hematuria

MH is defined as five or more red blood cells (RBC)/high-power field (hpf) of a centrifuged urine specimen. MH is considered persistent if it is present in two to three urinalyses over a 2- to 3-week period.

DETECTION OF HEMATURIA

RBCs are normal components of urine. Thomas Addis[1] observed that the urinary RBC excretion rate in normal volunteers ranged between 48,900 and 65,600 cells in 12 hours. The urine test strips (or dipstick) used for detection of MH employ paper impregnated with orthotoluidine buffered with organic peroxide. Hemoglobin in the urine or in the RBCs catalyzes the oxidation of orthotoluidine with peroxide to a blue color. The intensity of the color is evaluated against a color chart supplied by the manufacturer of the test strips to quantify the degree of hematuria. In recent years, the process of reading the dipsticks has been automated and is less prone to observer interpretation errors.

The dipstick test detects heme molecules, and a positive test result may indicate hematuria or hemoglobinuria. Demonstrating RBCs in microscopic analysis is essential to differentiate hematuria from the two types of pigmenturia (myoglobinuria and hemoglobinuria). Dipsticks are quite sensitive and may detect as few as two to three RBCs/hpf. A false-positive dipstick result can occur if the urine sample is highly concentrated, contains high concentrations of ascorbic acid, is contaminated with

Table 9.1 Causes of "red" or dark-colored urine

Hematuria

- Sulfa drugs

cleaning agents such as povidone-iodine, hypochlorite, or has microbial peroxidase. Red discoloration of urine can also result from certain medications, food or vegetable dyes, bilirubin, porphyrins, or inborn errors of metabolism (Table 9.1). Details of testing for hematuria are also discussed in Chapter 3.

EPIDEMIOLOGY OF HEMATURIA

As compared with MH, visible hematuria or GH is less common during childhood. Over a period of 2 years, Ingelfinger et al.[2] reported that in a walk-in clinic setting, 185 of the 12,395 patients' visits (or 1.3 per 1000 visits) were attributable to a GH event. In a 10-year study of children with hematuria, Greenfield et al.[3] found that GH was predominantly seen in boys older than 3 years of age. In

KEY POINTS

- MH is common is school children.
- It is transient in many cases.

this study, 272 of the 342 patients (80%) were boys. Only 6% of patients were younger than 3 years of age, 199 were 3 to 12 years old (58%), and 36% were 13 to 20 years old.[3]

Dodge et al.,[4] in their landmark study from Texas, reported a new case incidence of MH in 6- to 12-year-old school girls to be 22 per 1000 (2.2%), and 9 per 1000 (0.9%) in boys. More importantly, the study noted that the prevalence of MH decreased by 50% when urinalyses were repeated a second or third time over 2 to 6 weeks.[4] Vehaskari et al.[5] reported that MH was present in 4.1% of 8954 Finnish children 8 to 15 years old. In a national screening of school children extending over 13 years (1974 to 1986), the prevalence rate of MH in Japanese children was found to be to be 0.54% in elementary school children and 0.94% in the junior high school children.[6]

ETIOLOGY OF HEMATURIA

Bleeding from the urinary tract can be arbitrarily considered in two groupings. The first is glomerular or nephrologic hematuria resulting from diseases that affect the nephron (Table 9.2). The second category is urologic hematuria or bleeding originating from the urinary collecting system, urinary bladder, or urethra (Table 9.3). This classification

Table 9.2 Causes of glomerular hematuria in children

1. Acute post-infectious glomerulonephritis
2. Chronic glomerulonephritis
   - Immunoglobulin A nephropathy
   - Mesangioproliferative glomerulonephritis
   - Membranoproliferative glomerulonephritis
   - Focal segmental glomerulosclerosis
   - Membranous nephropathy
3. Inherited nephropathies
   - Alport syndrome
   - Thin basement membrane nephropathy or benign familial hematuria
   - Nail-patella syndrome
   - Fabry disease
   - Polycystic kidney diseases (usually trauma associated)
   - Medullary cystic disease
4. Systemic disorders
   - Systemic lupus erythematosus
   - Hemolytic uremic syndrome
   - Henoch-Schönlein purpura
   - "Shunt" nephritis
   - Goodpasture syndrome
5. Tubulointerstitial diseases
   - Acute pyelonephritis
   - Nephrocalcinosis
   - Interstitial nephritis
   - Tuberous sclerosis
   - Acute tubular necrosis

Table 9.3 Causes of urologic or nonglomerular hematuria

1. Infections
   - Bacterial cystitis
   - Viral cystitis (immunocompromised patient)
     - BK virus
     - Adenovirus (types 11, 21)
     - Cytomegalovirus
   - Parasitic cystitis
     - Schistosomiasis
   - Pinworm infestation
2. Chemical cystitis
   - Cyclophosphamide
   - Crystal violet
   - Radiation cystitis
3. Stone diseases
   - Urinary calculi
   - Hypercalciuria
4. Urethrorrhagia
5. Urinary tract trauma
   - Accidental
   - Associated with instrumentation (catheterization)
6. Urethral or bladder foreign body
7. Urinary bladder tumors
   - Papilloma
   - Hemangioma
   - Rhabdomyosarcoma
8. Hematologic disorders
   - Sickle cell trait or disease
   - Coagulopathies
9. Vascular disorders
   - Renal vein or artery thrombosis
   - Nutcracker syndrome
   - Loin pain hematuria syndrome
10. Miscellaneous
    - Exercise-induced hematuria

allows clinical distinction and focused investigations in the patient affected by hematuria.

EVALUATION OF HEMATURIA

The aims of evaluation of hematuria in a pediatric patient are to (1) localize the site of urinary bleeding and (2) determine the cause of hematuria. Historical data and physical examination provide vital insight into the site and potential cause of hematuria.

HISTORY AND PHYSICAL EXAMINATION

A thorough medical and family history, physical examination, and urinalysis with microscopic evaluation of the sediment are key to determining

the origin of hematuria. A directed history, physical examination, and investigation pathway should guide the treating nephrologist in the management of these patients (Table 9.4). Information on the type of hematuria (initial, total, or terminal) and any associated symptoms may be helpful in determining the site and cause of hematuria. As noted previously, terminal hematuria manifests with a drop of blood at the end of micturition, or stained underwear, and is associated with lesions of the bulbar or posterior urethra. Urethrorrhagia is a term used to describe terminal hematuria seen in preadolescent and adolescent boys who are otherwise asymptomatic. Total hematuria can be the result lesions affecting the bladder or kidneys.

KEY POINTS

- Synpharyngitic hematuria occurring 24 to 48 hours after an upper respiratory infection is typical of IgA nephropathy.
- Synpharyngitic GH can also be seen in thin basement membrane nephropathy (TBMN) and Alport syndrome.

Abdominal or flank pain associated with hematuria may indicate renal stone passage. Distension of renal pelvis in ureteropelvic junction obstruction can also result in flank pain (Dietl's crisis) but hematuria is uncommon, unless associated with trauma. Development of hematuria within 24 to 48 h of an upper respiratory tract infection (synpharyngitic hematuria) may point to immunoglobulin A (IgA) nephropathy. In contrast, poststreptococcal (postinfectious) glomerulonephritis is characterized by streptococcal pharyngitis (or impetigo) approximately 2 weeks before the onset of GH. The presence of GH in patients with compromised renal function and nephritic urinary sediment should alert the nephrologist to the possibility of glomerulonephritides, such as membranoproliferative glomerulonephritis (MPGN), rapidly progressive glomerulonephritis (RPGN), or Henoch-Schönlein purpura (HSP) nephritis.

A family history of renal disease and deafness are features of Alport syndrome, and a family history of hematuria (usually microscopic) without any history of deafness or renal failure may suggest benign familial hematuria.

Physical examination should include evaluation of blood pressure and documentation of any evidence of edema or rash. The presence of these findings would

Table 9.4 Important aspects of history and physical examination in evaluation of hematuria

Patient History
- Timing of hematuria in micturition cycle (throughout/onset/terminal)
- Color of urine, brown or rusty versus red or pink
- Associated urinary symptoms
  - Dysuria
  - Urinary frequency
  - Urinary urgency
  - Suprapubic area pain
  - Abdominal pain, colic
  - Costovertebral angle pain
- Recent upper respiratory infection and relation to onset of hematuria
- Exercise
- Trauma
- Medication
- Muscle or joint pain
- Skin rash
- Stone passage

Family History
- Chronic kidney disease
- Hematuria
- Deafness (Alport syndrome)
- Nephrolithiasis
- Sickle trait and sickle disease
- Coagulopathy

Physical Examination
- Weight: recent weight gain (edema)
- Blood pressure: hypertension
- Fever
- Evidence of edema
- Rash, purpura
- Swelling of joints, evidence of arthritis
- Suprapubic tenderness
- Costovertebral angle tenderness
- Abdominal mass

support the diagnosis of glomerulonephritis or systemic vasculitis. An abdominal mass in the suprapubic region may indicate a bladder lesion, such as a mass or urinary obstruction, whereas a flank mass could be caused by a renal lesion, such as hydronephrosis, large polycystic kidneys, or a tumor.

Urine Color

GH of glomerular origin is associated with brownish, tea-colored, or cola-colored urine, as opposed to the pink or

bright red color seen with nonglomerular hematuria, or urologic hematuria). The dark color of glomerular hematuria reflects conversion of hemoglobin in the acidic urine to acid hematin (brownish) during transit from the kidneys through the rest of the urinary tract. In patients with visibly red or dark urine without evidence of blood on dipstick testing, other causes of urinary discoloration need to be ruled out (see Table 9.1). Urine that is dipstick positive for blood but without erythrocytes documented on urine microscopy may be due to hemoglobinuria or myoglobinuria (Table 9.5). Pallor and icterus are other clinical findings in hemoglobinuria, whereas a history of severe exercise, myalgia, and demonstration of muscle tenderness suggest myoglobinuria. For diagnostic confirmation of myoglobinuria or hemoglobinuria, urine spectrophotometry is necessary.

Table 9.5 Causes of hemoglobinuria and myoglobinuria

Hemoglobinuria
- Hemolytic anemias
- Mismatched blood transfusions
- Mechanical erythrocyte damage (artificial cardiac valves, extracorporeal circulation)
- Sepsis or disseminated intravascular coagulation
- Freshwater near drowning
  - Toxins
  - Carbon monoxide
  - Lead
  - Turpentine
  - Phenol
- Naphthalene

Myoglobinuria
- Muscle injury
- Severe exercise
- Prolonged seizures
- Prolonged coma
- Hypokalemia
- Electrical injury
- Thermal injury
- Myositis
  - Viral infections (influenza A and B, Coxsackie B, Epstein-Barr)
  - Collagen-vascular diseases (dermatomyositis, polymyositis)
- Poisons
  - Snake venom
  - Scorpion bite
- Drugs and toxins
  - Statins
  - Colchicine
- Cocaine

KEY POINTS
- Red urine can have causes other than hematuria, such dietary ingredients, coloring dyes, or drugs.
- A positive dipstick test result for blood may also signify hemoglobinuria or myoglobinuria.
- Brick red diaper staining in neonates is often caused by uric acid crystals. Test results for blood are negative in these cases.

RED DIAPER IN NEONATES

Neonates are sometimes noted to have brick red diaper staining in the first weeks of life as a result of the presence of uric acid crystals in the urine. Test results for hemoglobin in these urine samples are negative. This is a benign and self-limited finding, and no therapy is usually required. Subtle dehydration has been suggested to be the cause of uric acid precipitation in the diapers of these neonates, but the finding may be the consequence of elevated urinary uric acid excretion in these neonates.[7]

Lesch-Nyhan syndrome, in contrast, is a rare X-linked recessive disorder that is characterized by persistent gritty orange-red discoloration of the diapers, with eventual uric acid stones. These patients have self-mutilating behavior, severe developmental delay, and poor muscle tone. Hyperuricemia and hyperuricosuria are present on laboratory evaluation. Lesch-Nyhan syndrome is caused by the deficiency of the enzyme hypoxanthine-guanine phosphoribosyltransferase.

URINE MICROSCOPY

Establishing the nature of hematuria, whether it is glomerular or nonglomerular, is an important first step in the evaluation of patients with hematuria, and it facilitates a focused evaluation of patients. Urine microscopy of the spun urine sediment can be used to determine whether hematuria is glomerular in origin.[8,9] Glomerular hematuria results from disruption of the glomerular filtration barrier that leads to the formation of dysmorphic erythrocytes, characterized by variability of cell size, irregular outlines, and ringed or doughnut shapes (Figure 9.1). Additional findings of glomerular hematuria in urinalysis include proteinuria and RBC and granular casts. Nonglomerular hematuria, conversely, is characterized by eumorphic erythrocytes (uniform size and shape), absence of casts, and often an absence of accompanying proteinuria. Severe urinary bleeding may, however, be associated with proteinuria because of admixture of plasma with urine. Unusual causes of hematuria include parasitic infections, such as schistosomiasis. A history of travel, microscopic examination of urine
Figure 9.1 Red blood cell (RBC) morphology in hematuria. **(a)** Eumorphic RBCs; the cell outlines are smooth, and hemoglobin is uniformly distributed in the cells. **(b)** Dysmorphic RBCs with a doughnut shape; the hemoglobin is marginated toward the periphery of the RBC. **(c)** Dysmorphic RBC with target shape, hemoglobin is marginated into the center and along the periphery of the RBC. **(d)** Dysmorphic RBC with an irregular cell wall and margination of hemoglobin in these areas that give rise to a "Mickey Mouse" RBC shape.

Figure 9.2 Unstained urine sediment of an 8-year-old boy who visited Africa for 2 months and developed gross hematuria on arrival to the United States. The picture shows an egg of *Schistosoma*.

(Figure 9.2), and immunologic tests may be necessary for diagnosis in such cases.

FOCUSED INVESTIGATIONS OF NONGLOMERULAR HEMATURIA

After establishing whether hematuria is glomerular or nonglomerular, the investigational pathways diverge. Patients with nonglomerular hematuria are investigated for urologic and anatomic causes of the condition, whereas patients with the glomerular type of urinary sediment need to be investigated for glomerulonephritis or tubulointerstitial diseases.

The investigative pathway of nonglomerular or urologic hematuria should include urine culture to rule out the possibility of urinary tract infection. A negative urine culture result and persistent symptoms of dysuria and suprapubic tenderness may be seen in patients with viral cystitis. Detection of viral DNA by polymerase chain reaction (PCR) for adenoviruses, BK virus, and JC virus is available in most clinical laboratories and should be sought in patients with a suggestive history, especially those with a kidney or bone

marrow transplant, or those with an immunocompromised clinical state. It is important to note that viral culture of urine requires long incubation periods for the test. Renal and bladder ultrasound scans should be obtained to rule out structural urinary tract anomalies, calculus disease, or tumors. Sickle cell status should be determined in African-American patients, if not done previously. Hypercalciuria is a common cause of nonglomerular MH in children, and it should be ruled out by measuring the calcium/creatinine ratio in a spot urine sample or by a 24-h urine collection. A non-contrast computed tomography (CT) scan and urinary "stone risk analysis" are indicated in patients who are suspected to have urolithiasis. The high radiation dose of CT scans must be carefully considered while determining the benefit of this diagnostic test in any given patient.

Cystoscopy is not generally necessary in most children with hematuria, but it may be warranted if bladder disease such as bladder hemangioma or tumors of the bladder (papilloma, rhabdomyosarcoma) or urethra are suspected as the cause of hematuria. Cystoscopy may also be helpful in localizing the site of GH to one of the ureteral orifices. Further investigations in such cases can then be focused on the anatomic site with documented unilateral hematuria.

FOCUSED INVESTIGATIONS OF GLOMERULAR HEMATURIA

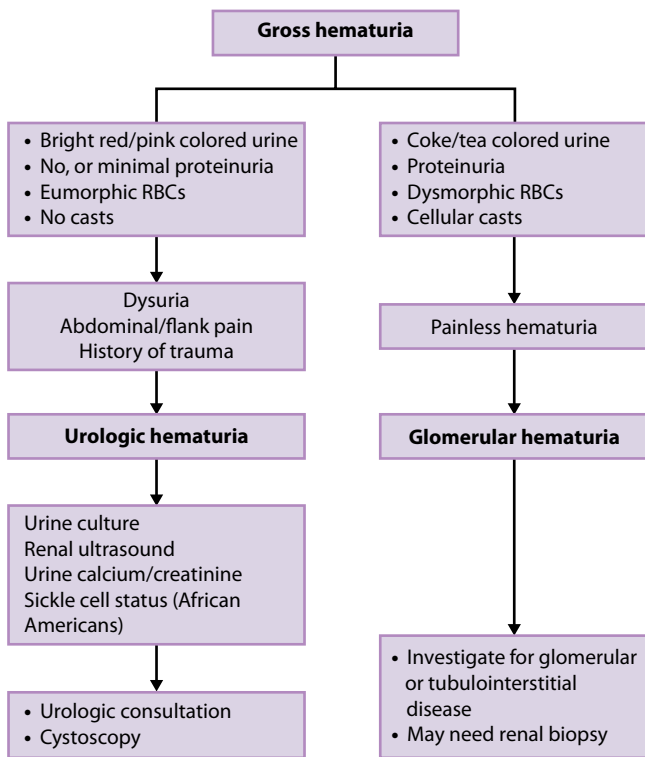
Hematuria can be the dominant clinical manifestation of several types of glomerulonephritis. In general, because of concerns for long-term renal damage, chronic kidney disease (CKD), and hypertension, investigations and treatment of these patients must be expedited. A history of hematuria in parents suggests a familial type of hematuria, such as benign familial hematuria, also known as thin basement membrane nephropathy (TBMN), or Alport syndrome.


Figure 9.3 Outline of evaluation of gross hematuria. RBCs, red blood cells.

Because postinfectious glomerulonephritis occurs frequently in children, patients with glomerular hematuria should undergo a panel of tests to rule out this diagnosis complement 3 and 4 (C3 and C4), anti–streptolysin O (ASO) titer, and anti-DNAse B titer. Proteinuria should be quantified in all patients considered to have glomerular hematuria. This can be done by determination of the protein/creatinine ratio in a spot sample of urine or by collection of a 24-h urine. Evaluation for systemic lupus erythematosus (SLE) should include screening tests, such as antinuclear activity (ANA) and, anti-dsDNA antibody). Patients suspected to have vasculitis should be tested for the presence of anti–neutrophil cytoplasmic antibodies (ANCAs). A diagnostic renal biopsy may be considered in patients when glomerular hematuria is associated with renal dysfunction, hypertension, and nephrotic syndrome. Flow diagrams of investigation in patients with GH and with MH are shown in Figures 9.3 and 9.4.

Diagnostic yield

Clinically significant diagnostic yield of investigations in GH is higher compared with MH. For example, of the 228 patients with GH investigated by Bergstein et al.,[10] 53 patients warranted a renal biopsy, and 36 of these patients had IgA nephropathy. Other important diagnoses uncovered in this assessment of GH were 51 cases of hypercalciuria, 3 cases

of Alport syndrome, and 1 case of Wilms tumor. Even after extensive investigations, 37.7% (86) patients in this study had no definable cause of GH. Despite discovery of a few patients with malignant disease, most studies suggest that concern for renal or bladder malignant diseases in children with GH is low.[4,10]

It is reassuring that the published literature on the subject of investigating isolated MH (without proteinuria) suggests a benign outcome in most children. Because of the low yield of clinically significant disorders, Dodge et al.[4] argued against screening for hematuria. This is especially important because hematuria was transient in approximately 50% of patients. Similarly, of the 342 children with MH investigated by Bergstein et al.,[10] no cause was found in 274 (80%). Hypercalciuria comprised the largest single cause of MH in these patients. Feld et al.[11] also demonstrated a lack of serious renal disease in children presenting with isolated MH. The Japanese experience of screening school children has also shed some important light on the absence of serious chronic disease in children with isolated MH. Murakami et al.[6] reported that only 0.009% of screened children were found to have chronic kidney disease (CKD). Commenting on these findings, Stapleton[12] recommended a more restrained approach in investigating children with asymptomatic MH. Although it is true that parents expect clinicians to embark on extensive investigations to map the precise source of the bleeding, discussion and explanation using an evidence-based approach may allow tailoring of investigations.

KEY POINTS

- Because of the low yield of isolated MH, a restrained approach with limited investigations is recommended.
- Glomerular hematuria, however, should be investigated fully.

PROTEINURIA

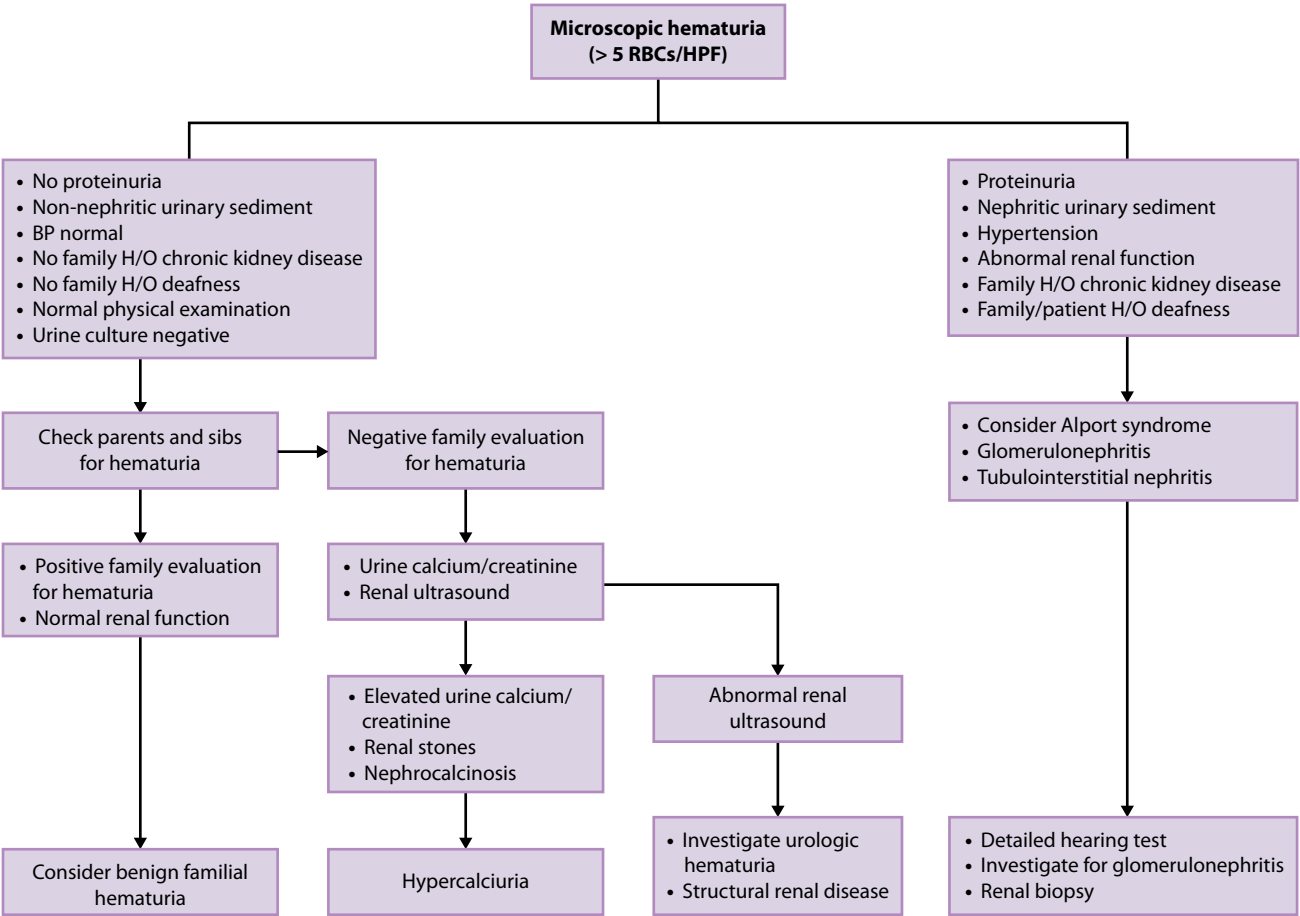
Proteinuria is regarded as an important marker of renal disease. Glomerulonephritis, nephrotic syndrome, tubulointerstitial nephritis, and numerous forms of inherited disorders are characterized by presence of proteinuria. Moreover, proteinuria, by itself, is now considered injurious to the proximal renal tubules (PRTs) and may lead to ongoing tubulointerstitial nephritis. The presence of minute quantities of albumin in urine or microalbuminuria (MA) is well recognized as the forerunner of diabetic nephropathy and has been prognostically linked to cardiac disease and hypertensive renal disease.[13,14]


Figure 9.4 Outline of evaluation of microscopic hematuria. BP, blood pressure; H/O, history of; HPF, high-power field; RBC, red blood cell.

EPIDEMIOLOGY OF PROTEINURIA

Several studies have noted a high prevalence rate of transient proteinuria in children. Vehaskari and Rapola[15] screened 8954 children in Finland and reported that 959 (10.7%) children had proteinuria in a single urinalysis. When two urinalyses were considered, the prevalence declined to 2.5%, and only 0.1% had persistent proteinuria in all four urinalyses performed. The increasing prevalence rate of proteinuria with increasing age in children was well described in this study, as well as that of Dodge et al.[4]

ETIOLOGY OF PROTEINURIA

A false-positive test result for proteinuria can be caused by urinary tract infection, vulvovaginitis, urethritis, prostatitis, and contamination by menstrual blood. Transient proteinuria can also be seen after exercise, dehydration, or fever.[16,17] Orthostatic or postural proteinuria is a common condition encountered in older children and adolescents. Persistent or "fixed" proteinuria can be a manifestation of nephrotic syndrome, glomerulonephritis, interstitial nephritis, some inherited nephropathies, and CKD). Causes

of proteinuria in children are listed in Table 9.6, and urinary protein excretion in various age groups during childhood is given in Table 9.7.

> ### KEY POINTS
>
> - Postural or orthostatic proteinuria should be ruled out in children by performing a first morning urine protein/creatinine ratio (≤ 0.2).
> - Fixed or nonorthostatic proteinuria requires complete evaluation, sometimes including a renal biopsy.

PATHOPHYSIOLOGY OF PROTEINURIA

The glomerular capillary wall (GCW) is a complex and selective filtration barrier composed of three distinct layers: (1) endothelium with fenestrations and glycocalyx, (2) glomerular basement membrane (GBM), and (3) epithelial cells and the complex network of podocytes (Figure 9.5).

Table 9.6 Causes of proteinuria

Nonpathologic and Transient Proteinuria
- Orthostatic proteinuria
- Fever
- Exercise

Glomerular Disorders (also see Table 9.2)
- Nephrotic syndrome
- Acute and chronic glomerulonephritis
- Hypertension
- Diabetes mellitus
- HIV nephropathy
- Inherited nephropathies (Alport syndrome, podocytopathies, Fabry disease; also see Table 9.1)

Tubular Disorders: Inherited
- Cystinosis
- Wilson disease
- Lowe syndrome
- Dent disease
- Fanconi syndrome

Tubular Disorders: Acquired
- Interstitial nephritis
- Reflux nephropathy
- Antibiotics and drug induced
- Antiretroviral therapy induced
- Acute tubular necrosis
- Heavy metal poisoning

Artifactual Conditions
- Vulvovaginitis
- Urinary tract infection
- Urethritis
- Prostatitis
- Periurethral infections
- Perineal contact irritation
- Menstrual blood contamination

HIV, human immunodeficiency virus

Table 9.7 Normal 24-h urinary protein excretion in children by age groups

Age group	Protein excretion (mg/24 h)	Protein excretion (mg/24 h/m² bsa)
Premature (5–30 days)	29 (14–60)	182 (88–377)
Full-term (7–30 days)	32 (15–68)	145 (68–309)
2–12 mo	38 (17–85)	109 (48–244)
2–4 yr	49 (20–121)	91 (37–223)
4–10 yr	71 (26–194)	85 (31–234)
10–16 yr	83 (29–238)	63 (22–181)

Endothelial Layer

Endothelium comprises the innermost layer of the glomerular capillary and remains in direct contact with circulating plasma and the cellular constituents of blood. The body of the glomerular endothelial cell rests within the hilum of the capillary loop, in close proximity to mesangial cells. A thin layer of endothelial cytoplasm extends from the endothelial cell and envelops the inner aspect of the capillary lumen. The endothelial cytoplasm has 70- to 100-nm pores known as endothelial fenestrations (EFs). The EFs constitute 30% to 50% of the inner capillary surface.[18]

> **KEY POINTS**
>
> - The role of the endothelial barrier in restricting protein outflow from the glomerular capillary lumen remains unclear.
> - The endothelial surface layer, composed of glycocalyx and plasma components, may indeed be important as a barrier.

Glomerular capillaries possess hydraulic conductivity (permeability) that permits passage of large volumes of ultrafiltrate and small solutes. Simultaneously, these capillaries also exhibit selective permeability that actively restricts passage of albumin (3800 kDa) and other larger molecules. Low-molecular-weight (LMW) proteins (MW less than 2800 kDa), such as β2-microglobulin and amino acids are relatively easily filtered but are reabsorbed in the PRTs. The role played by the three constituent layers of the GCW in macromolecular transport and proteinuria has been a subject of intense investigations, controversy, and debate. From a functional perspective, and given our current state of knowledge, the three layers seem to be equally important in the macromolecular transport.

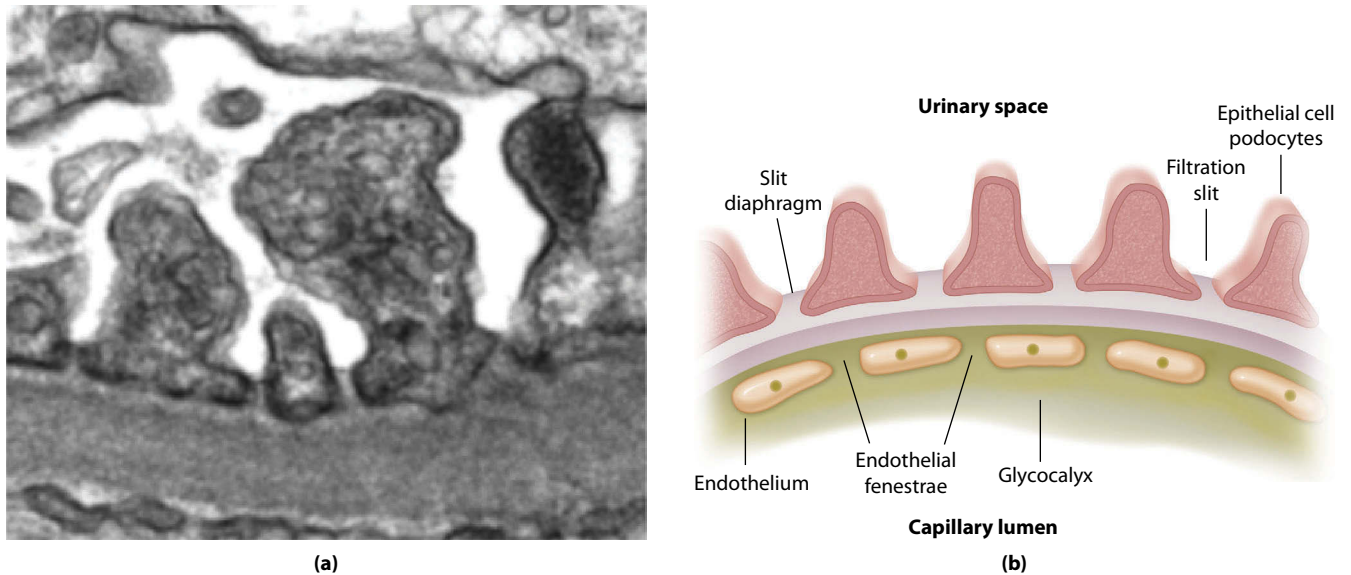
Conventional thinking postulates that because of the large pore size of EFs, endothelium does not pose a significant barrier to macromolecular transport. Several other observations suggested that the endothelial cell layer is more complex and provides selective transport characteristic to the GCW.[18,19] Advanced electron microscopy of endothelium demonstrates an additional layer of glycocalyx (Figure 9.6) and plasma components, known as the endothelial surface layer (ESL), that loosely covers the endothelial cell's cytoplasm and EFs. The ESL extends up to 200 nm above the cell surface.[19] The role played by the ESL in protein and other macromolecular transport across the glomerular capillaries is not fully


Figure 9.5 **(a)** Electron micrograph showing filtration slit with adjacent podocytes (P), slit diaphragm (arrowheads) bridging between the two podocytes and the glomerular basement membrane (GBM). **(b)** Conceptual representation of the glomerular filtration barrier that shows the podocytes resting on the glomerular basement membrane, slit diaphragms between the podocytes, and the endothelial cells lined by the glycocalyx.

understood. Available evidence suggests that apart from regulating many vascular functions, the ESL may be important in bestowing anionic charge to the endothelial barrier and help in preventing protein leak across the GCW.[20-23] Using multiphoton microscopy measurements, Salmon et al.[23] demonstrated that loss of the ESL in aging Munich-Wistar-Frömter rats was associated with proteinuria. These observations, although not proving the

role of the ESL in proteinuria and transglomerular capillary transport, do suggest a possible link between the development of proteinuria and endothelial dysfunction. Clearly, more needs to be learned about endothelial functions and their role in glomerular capillary macromolecular transport.

Glomerular basement membrane

The GBM is an acellular, gel-like structure composed of tightly woven type IV collagen, laminin, heparin sulfate proteoglycans, and nidogen.[24,25] Of these, type IV collagen is the dominant component of the GBM, which comprises more than 50% of the mass of the GBM. In adults, the GBM is 250 to 400 nm thick but it is considerably thinner in children. Ramage et al.[26] reported the thickness of the GBM at 1 year of age to be 194 ± 6.5 nm and at 11 years to be 297 ± 6.0 nm. During embryogenesis and glomerular development, both podocytes and endothelial cells contribute to the development of the GBM. Ultrastructurally, the GBM possesses three distinct layers: the thin lamina rara interna and the lamina rara externa, with the lamina densa sandwiched between them. Nanostructure localization suggests that the GBM consists of highly organized architecture and consists of laminated and possibly interacting proteins, potentially similar to what has now been well described to be the case with podocytes.[27]

The role of the GBM as a barrier to filtration of protein has been widely debated. Transgenic mice lacking laminin in their GBM have been shown to develop proteinuria and secondary podocyte foot process abnormalities.[28] These
Figure 9.6 Electron micrographic visualization of Alcian blue 8GX–stained rat left ventricular myocardial capillary demonstrating glycocalyx. (From van den Berg BM, Vink H, Spaan JA. The endothelial glycocalyx protects against myocardial edema. Circ Res. 2003;92:592–4.)

findings reinforce the view that integrity of GBM plays a critical role in the development of proteinuria in which both size selectivity and charge selectivity play a role.[29,30] An alternate school of thought suggests that the GBM is merely a prefilter with very limited size or charge barrier capability.[31] These investigators believe that slit diaphragms (SDs) of the podocytes are the primary determinants of macromolecular transport and proteinuria, a view referred to as the "two-barriers-in-series" concept.[32,33]

Podocyte layer

The outermost barrier for the passage of macromolecules and fluid across the GCW is the epithelial cell or the podocyte. Podocytes are large cells that line the urinary space side of the GBM. These specialized cells have branching cytoplasmic extensions known as foot processes that firmly anchor the podocytes to the GBM. The adjacent foot processes do not come in direct contact with each other and are separated by an approximately 40-nm-wide space known as the filtration slit. These filtration slits (see Figure 9.5) are bridged by the slit diaphragm (SD), a membrane-like structure. Important plasma membrane proteins, such as nephrin, NEPH1–3, podocin, Fat-1, P-cadherin, and P-cadherin, reside on the SD.[31,34–36]

KEY POINTS

- Podocytes are emerging as important cells in glomerular functions in disease and health.
- Many important membrane proteins reside in the podocytes and the SDs.
- The SD is important in glomerular filtration and preserving the permselectivity of the glomerular barrier.
- Podocytes do not reproduce, and their loss is permanent.
- Podocytes are thought to be involved in the pathogenesis of a range of diseases, such as minimal change disease, focal segmental glomerulosclerosis, other types of glomerulonephritic and diabetic nephropathy.

These proteins are believed to be intimately involved in cell-to-cell signaling and maintaining the normal cytoskeletal structure of podocytes and the associated foot processes. Before the discovery of these proteins in the SD and the podocytes, the importance of this cell and associated structures had been an enigma. It is now well known that the SD plays an important role in providing selective permeability characteristics to the glomerular capillaries.[31,33] The foot processes also contain the contractile protein actin in parallel bundles that constitute podocyte cytoskeleton and maintain its shape, and anchors podocytes to the GBM by transmembrane cell receptors that include integrins.[37]

Gene mutations resulting in abnormalities in the proteins present on SDs lead to specific clinical disorders that are associated with proteinuria or nephrotic syndrome (Table 9.8). Mutation of the nephrin gene *NPHS1* was the first such mutation described and is associated with the Finnish type of congenital nephrotic syndrome.[32]

An important biologic characteristic of podocytes is that these cells are unable to reproduce or replenish themselves in their mature state. Although some shedding of podocytes into the urinary space and excretion in urine is normal, this process can be accelerated by injury and disease states. Urinary loss of podocytes (or podocyturia) can result in a permanent and irreplaceable quantitative deficit of podocytes in the glomeruli (podocytopenia). Indeed, podocyturia and podocytopenia are known to be important findings in many glomerular diseases characterized by proteinuria, such as diabetic nephropathy, focal segmental glomerulosclerosis, membranous nephropathy, and human immunodeficiency virus (HIV) nephropathy.[37-39]

PERMSELECTIVITY OF THE GLOMERULAR FILTER

Glomerular capillaries possess a unique ability to filter plasma water, electrolytes, and other metabolites while retaining most proteins. The nature of glomerular capillary selective permeability (permselectivity) has been a matter of considerable debate. Based on experimental data and mathematical modeling, glomerular permselectivity has been attributed to (1) molecular size, (2) molecular charge, and (3) molecular configuration. Although it is true that some components of the GCW may be more important in providing size or charge selectivity, the current state of knowledge suggests that all elements of the filtration mechanism must be intact to prevent proteinuria from developing. Glomerular permeability is also discussed in Chapter 10.

KEY POINTS

Permeability of the GBM to macromolecules, such as plasma proteins, depends on:

- Molecular size
- Molecular charge
- Molecular configuration

Size selectivity

Using neutral dextran, passage of molecules has been demonstrated to be almost unrestricted until the molecular size reaches 20 Å. Beyond this molecular size, neutral dextran is progressively excluded from passage across the GCW into the filtrate. At a molecular size of 42 Å, there is negligible clearance of neutral dextran from the glomerular capillaries.[40] Albumin, which has a molecular size of 36 Å

Table 9.8 Genetic causes of proteinuria

	Chromosomal location	Gene name	Protein	Protein function
Syndromic disorders				
Congenital nephrotic syndrome	19q13.1	NPHS1	Nephrin	Essential component of podocyte SD protein complex
Denys-Drash syndrome	11p13	WT1	Wilms tumor 1	Podocyte-expressed transcription factor
Pierson syndrome	3p21	LAMB2	Laminin β2 chain	Subchain of GBM laminin-11
Schimke immunoosseous dysplasia	2q34-36	SMARCAL1	SWI/SNF2-related matrix-associated, actin-dependent regulator of chromatin, subfamily a-like 1	Gene regulation and replication and DNA repair
Nail-patella syndrome	17q11	LMX1B	LIM homeobox transcription factor-1β	Podocyte-expressed transcription factor
Alport syndrome, X-linked	Xq22.3	COL4A5	Type IV collagen, α 5 subchain	Subchain of GBM type IV collagen
Alport syndrome, AR	2q36-q37	COL4A3	Type IV collagen, α subchain 3	Subchain of GBM type IV collagen
Alport syndrome, AR	2q36-q37	COL4A4	Type IV collagen, α subchain 4	Subchain of GBM type IV collagen
Mitochondrial cytopathies	4q21.23	COQ2	Parahydroxy-benzoate-polyprenyl-transferase	Biosynthesis of coenzyme Q, involved in mitochondrial respiratory chain electron transport
Fechtner syndrome	22q12.3	MYH9	Nonmuscle myosin IIa heavy chain	Actin-binding protein involved in cell motility
Nonsyndromic disorders				
FSGS, AR	1q25-q31	NPHS2	Podocin	Essential SD-associated protein
FSGS, AR	19q13.1	NPHS1	Nephrin	Essential component of SD protein complex
FSGS, AD	19q13	ACTN4	Alpha-actinin-4	Actin-binding protein
FSGS, AD	11q21-q22	TRPC6	Transient receptor potential channel, subfamily 6	Podocyte-expressed calcium channel
FSGS, AD	14q32.33	INF2	Inverted formin 2	Actin-regulating protein
FSGS, not specified	6p12	CD2AP	CD2-associated protein	Actin-binding protein associated with SD protein complex
Diffuse mesangial sclerosis, not specified	10q23	PLCE1	Phospholipase C ε 1	Membrane phospholipid hydrolysis

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; FSGS, focal segmental glomerulosclerosis; GBM, glomerular basement membrane; SD, slit diaphragm.

(MW 66 kDa), is almost completely prevented from passing through the glomerular capillary barrier. High-MW proteins, such as IgG (MW 150 kDa), IgM (MW 900 kDa), and α_2-macroglobulin (MW 725 kDa), are unable to pass through the glomerular filtration barrier. In contrast, LMW proteins, such as β_2-microglobulin (molecular size 11.8 Å, MW 12 kDa), and immunoglobulin light chains are readily filtered.[41]

Using mathematical modeling, two distinct types of pore models have been hypothesized within the GCW: (1) the isoporous model and (2) the heteroporous model. The isoporous model suggests that cylindrical pores of the same size

(50 to 55 Å) are distributed throughout the GCW that hold back protein and other macromolecules above this size limit. The heteroporous model is based on the observation that in proteinuric states, such as glomerulonephritis, clearance of dextran greater than 45 Å increases significantly, whereas clearance of smaller molecules changes little, thereby suggesting the existence of a larger pores. The larger pores (>80 Å), which are also known as the "shunt pathway," are believed to be few in number and nonselective in their permeability characteristics.[41-43]

Charge selectivity

The presence of anionic charge in the components of the GCW has been well established.[44] The role played by this molecular charge in permselectivity and proteinuria has been extensively studied since the 1970s. The first clue about the role of anionic charges in proteinuria was the observation in normal rats that clearance of albumin was significantly lower than that of neutral tracer molecules of dextran of the equal molecular size.[44,45] Similar findings were also noted in nephrotic rats.[46] These observations raise the possibility that molecular size alone may not explain albuminuria and macromolecular transport across the GCW. Extending these observations, it was demonstrated that transport of cationic and neutral tracer molecules was preferentially facilitated across the GCW, as compared with anionic molecules.[47,48] Because plasma proteins possess an anionic surface charge, it has been suggested that the anionic charge of the GCW creates an electrostatic repulsive force that prevents passage of plasma proteins from the glomerular capillary lumen. The primary site for anionic charge in the GCW was initially considered to be the GBM, but the endothelial surface and the epithelial cell surface also have been shown to possess a negative charge.[30,31] Within the GBM, the lamina rara interna and the lamina rara externa demonstrate the most prominent anionic charge sites.[30] Anionic charge in the GBM results from the presence of heparin sulfate proteoglycan and hyaluronic acid.

Molecular configuration

In addition to size and charge, the shape of filtered molecules is also considered to be an important determinant of macromolecular transport across the GCW. This inference has been drawn from the fractional clearance of dextran and Ficoll (Sigma-Aldrich, St. Louis, MO), both of which have similar effective radius but a different structural configuration. Dextran is a complex branched polysaccharide, a polymer of glucopyranose, with an elongated or sausage-shaped molecular structure. Ficoll, in contrast, is a highly branched, polysaccharide-epichlorohydrin complexed molecule with a globular shape. Bohrer et al.[49] demonstrated that within 24 to 44 Å molecular size range, fractional clearance of dextran was higher than that of Ficoll. This led the investigators

to conclude that molecular configuration was important in macromolecular clearance from the GCW. More flexible molecular configuration of dextran was viewed as preferred over the rigidly structured Ficoll for passage through the GCW. Because most proteins are spherical, it is believed that such rigidly configured protein molecules behave like Ficoll and are prevented from passage across GCW. Findings that Ficoll may actually not be as tightly configured in solution as previously thought has put the role of molecular configuration into question.[50] In addition to configuration, molecular deformability may influence permselectivity of GCW to albumin and other macromolecules.

FATE OF FILTERED PROTEIN

It has been well known since the early 1950s that plasma proteins filtered from glomeruli are reabsorbed in the PRTs.[51] Micropuncture studies in rats revealed that the glomerular filtrate reaching the PRTs mostly contains LMW proteins and minor amounts of albumin (1 to 3 mg/dL).[52,53] Therefore, in an adult with a glomerular filtration rate (GFR) of 125 mL/min, or 180 L/24 h, the total amount of albumin filtered is 1800 to 5400 mg/day. However, normal urinary protein excretion under physiologic circumstances in an adult is less than 150 mg/24 h, a finding suggesting that renal tubules reabsorb most of the filtered albumin. The mechanism of reabsorption and metabolic pathways of degradation of the absorbed protein in the PRTs has been elucidated more recently.

> ### KEY POINTS
>
> - Most of albumin filtered at the glomerulus is reabsorbed in the PRTs.
> - PRTs take up filtered albumin through cubilin-megalin receptors and metabolize it to dipeptides and amino acids. These are returned to the body's pool along the basolateral surface.

Albumin present in the tubular lumen is reabsorbed in the PRT through active receptor-mediated endocytosis. The albumin molecules in the tubular lumen bind to the cubilin-megalin receptor complex.[54-56] Most of the albumin-receptor binding activity occurs in between the brush-border villi, rather than the tip of the PRT brush border. The albumin-receptor complex is internalized and forms cytoplasmic vesicles. The next step involves acidification of the vesicles, a step facilitated by the chloride channel-5 (ClC-5). This is an important step for albumin to be dissociated from the megalin-cubilin complex and for megalin to be recycled.[57] On dissociating from albumin, the megalin-cubilin complex is processed in the sorting endosomes and is eventually returned to the cell surface through recycling endosomes (Figure 9.7). Albumin, conversely, is passed on to the lysosomes for metabolic digestion to amino acids and dipeptides,
Figure 9.7 Diagrammatic representation of proximal tubular albumin reabsorption. ClC-5, chloride channel-5. See text for details.

which are returned to the body pool through the basolateral surface.[54,56]

Role of cubilin and megalin in protein reabsorption

Cubilin is an endocytosis receptor that is highly expressed in the PRT brush border, as well as in the intestines. Cubilin is a 460-kDa protein that does not have a transmembrane domain and remains anchored to the brush-border membrane by attaching itself to megalin.[54,55] For all practical purposes, the cubilin-megalin complex is considered to be the receptor for reabsorption of albumin and some LMW proteins from the tubular fluid. Cubilin binds to the albumin molecule, which along with megalin is internalized as an endocytosis vesicle. Cubilin is also present within the gastrointestinal tract, where it is known as the intestinal intrinsic factor-B_{12} receptor (IF-B_{12}).

The absence of IF-B12 (cubilin) leads to a rare form of megaloblastic anemia associated with proteinuria, also known as Imerslund-Gräsbeck syndrome.[58] Decreased megalin trafficking in the proximal tubular cells occurs in Dent disease, which is characterized by LMW proteinuria, hypercalciuria, and nephrocalcinosis.[59,60] Dent disease is caused by a mutation in renal ClC-5, which leads to an acidification defect of the endocytic vesicles, an essential step in processing albumin and LMW proteins in the PRT.[57]

NEPHROTOXICITY OF PROTEINURIA

Proteinuria, irrespective of its origin, in a patient with renal disease, is believed to contribute to ongoing and progressive deterioration of the kidney disease and function.[61] Several lines of clinical and experimental investigations support the proinflammatory sequence initiated by proteinuria and tubular absorption of protein. Proteinuria is also well known to be an independent risk factor for increased mortality and renal disease progression in both type 1 and type 2 diabetes mellitus.[62] Use of angiotensin-converting enzyme inhibitors (ACEIs) to reduce proteinuria has been shown to improve renal survival in these patients.[63] Self-sustaining interstitial inflammation and fibrosis induced by proteinuria have been shown to be important consequences of proteinuric states, and may serve as the terminal pathway for disease progression in patients with CKD.[62,63] Tubulointerstitial injury in association with proteinuria can arise from several independent and codependent mechanisms. These events are diagrammatically depicted in Figure 9.8 and are discussed here.

KEY POINT

Proteinuria, by itself, may cause renal damage and promote tubulointerstitial inflammation.

Proinflammatory chemokines

Proteinuric states are characterized by an excessive synthesis of a variety of proinflammatory cytokines and chemokines by the tubular cells. The trigger for these chemokines is the generation of nuclear factor κB (NF-kB) in the proximal
Figure 9.8 Diagrammatic representation of pathogenesis of tubulointerstitial fibrosis resulting from proteinuria. EETs, epoxyeicosatrienoic acids; IL-6, interleukin-6; IL-1, interleukin-1; Kim-1, kidney injury molecule-1; MCP-1, monocyte chemoattractant protein-1; mTOR, mammalian target of rapamycin; PAI-1, plasminogen activator inhibitor; NF-κB, nuclear factor κB; RANTES, Regulated on activation normal T cell expressed and secreted; TGFβ, transforming growth factor-β; TNF, tumor necrosis factor.

tubules in response to protein absorption.[64-66] NF-kB reacts with the mammalian target of rapamycin (mTOR) leading to downstream activation of proinflammatory chemokine genes. These include plasminogen activator inhibitor-1 (PAI-1), which is crucial in fibrogenesis, as well as chemoattractant proteins, such as monocyte chemoattractant protein-1 (MCP-1), RANTES (regulated on activation, normal T cell expressed and secreted), fractalkine, osteopontin, kidney injury molecule-1 (Kim-1), transforming growth factor-β (TGF-β), interleukin-1 (IL-1) and interleukin-6 (IL-6).[65-73] Generating of proinflammatory chemokines and cytokines in the peritubular interstitial space initiates mononuclear cells infiltration, proliferation of fibroblasts in the interstitium, and PRT cell apoptosis.[66,72] The end results of these cellular events are interstitial inflammation, fibrosis, and ongoing tubular cell damage.

Activation of complement

Complement, as a mediator of injury in proteinuria, has been investigated since the 1980s. Complement components range in size from 80 to 200 kDa, which can be filtered through the GCW in nonselective proteinuric state, but they can also be synthesized locally by the PRT cells and the leukocytes infiltrating the interstitial area.[74] The PRT cell brush border also possesses C3 convertase activity, which can initiate complement cascade events within the tubular lumen and the interstitium. Activation of the complement cascade leads to upregulation of genes for TGF-β and collagen type I, both of which create a profibrotic state in the interstitium.[65,75-77]

Epithelial-mesenchymal transition

Fibrogenesis is the final pathway in the development of tubulointerstitial fibrosis. The resident fibroblast population, along with its circulating population recruited by various proinflammatory cytokines and complement components, results in the formation of myofibroblasts.[74-77] In addition to these two sources, tubular epithelial cells and pericytes have also been shown to transform into myofibroblasts by a phenomenon known as epithelial-mesenchymal transition (EMT).[78-82] Myofibroblasts lay down collagen matrix and lead to fibrogenesis.

TYPES OF PROTEINURIA

Proteinuria can be classified into three categories: (1) glomerular proteinuria, (2) tubular proteinuria, and (3) overflow proteinuria.

Glomerular proteinuria

Proteinuria resulting from diseases of the glomerular ultrafiltration barrier (minimal change, other glomerulonephritides) is referred to as glomerular proteinuria. Urine protein electrophoresis (UPEP) analysis of glomerular proteinuria shows a pattern similar to serum protein analysis, with albumin constituting a dominant fraction (Figure 9.9 (a)). Glomerular proteinuria is detectable by urine dipsticks and can be quantified by usual techniques discussed below.

Tubular proteinuria

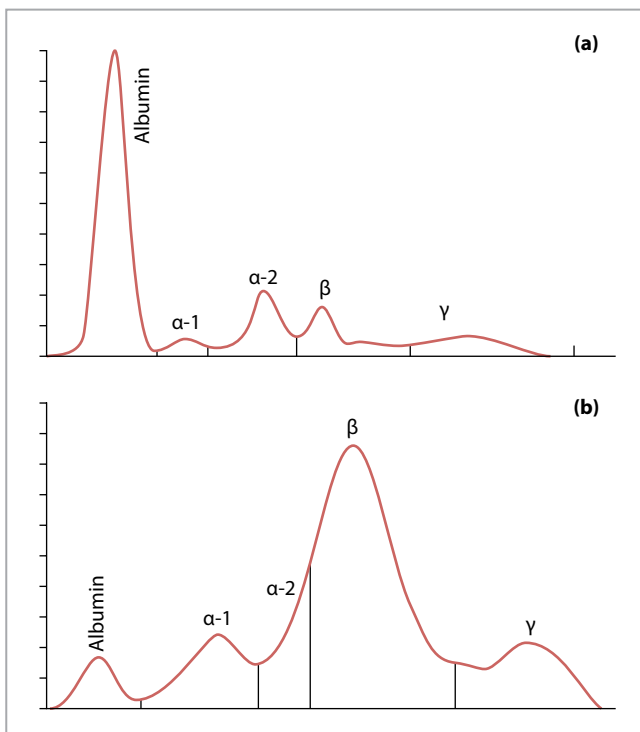
Many inherited tubulopathies (e.g., Fanconi syndrome), and acquired tubular disorders (e.g., nephrotoxins) are characterized by failure to reabsorb the LMW proteins by the PRT cells from the tubular lumen. Proteinuria seen in such clinical circumstances is referred to as tubular proteinuria. In contrast to glomerular proteinuria, urinary dipstick does not detect LMW proteins, and specific analytic methods are necessary to uncover tubular proteinuria. Three markers commonly used as indicators of tubular proteinuria in clinical practice are β_2-microglobulin, α_1-microglobulin, and retinol binding protein. UPEP in tubular proteinuria demonstrates significant α and β globulin peaks, in addition to albumin (Figure 9.9 (b)).


Figure 9.9 Urine protein electrophoresis (UPEP). **(a)** Patient with glomerular proteinuria. Of note is the large albumin peak. The UPEP pattern is similar to that of plasma. **(b)** Patient with tubular proteinuria. Globulin peaks dominate in this type of proteinuria.

> ### KEY POINT
>
> Proteinuria can result from glomerular leak (glomerular proteinuria), failure to reabsorb LMW protein in the PRT (tubular proteinuria), or a high plasma level of certain proteins (overflow proteinuria), and may cause renal damage and promote tubulointerstitial inflammation.

Overflow proteinuria

This is the least common type of proteinuria found in children. Monoclonal gammopathies characterized by high plasma concentrations of monoclonal immunoglobulin fractions in the serum lead these proteins to appear in the glomerular ultrafiltrate. Once proximal tubular reabsorption capacity of these filtered plasma proteins is exceeded, they begin appear in urine. Such proteinuria is known as overflow proteinuria. Bence-Jones protein, seen in multiple myeloma and other B-cell lymphomas, is an example of such overflow proteinuria. Bence-Jones protein was originally detected by heat precipitation methodology, but immunoelectrophoresis is now generally used to detect the monoclonal (M peaks) urinary protein excretion.

TAMM-HORSFALL PROTEIN

Another component of normal urine is the glycoprotein called Tamm-Horsfall protein (THP), or uromodulin. THP constitutes approximately 50% of the urinary protein excretion in normal subjects and is produced by the cells of the thick ascending loop of Henle and early distal convoluted tubule.[83] THP is not detected by the routine urinalysis techniques and is measured by immunoassay or high-performance liquid chromatography.

THP forms a gel-like core of the hyaline and other urinary casts. However, its role under physiologic conditions is not fully clear. THP may play a protective role against urinary tract infections by binding to *Escherichia coli,* and it may also protect against stone formation.[84,85] Transiently increased medullary echogenicity seen on ultrasound scans in neonates has been attributed to intratubular gelling of THP in presence of low urine pH.[86]

QUANTIFICATION OF PROTEINURIA

Urine dipstick provides a convenient method of detection of proteinuria and semiquantitative estimation. The test is affected by the urinary concentration and pH. Concentrated urine may give a positive reading even when the daily protein excretion is normal, whereas dilute urine may result in a negative, or only slightly positive reading even in the presence of elevated daily protein excretion. False-positive results may also occur if the urine is highly alkaline, and false-negative results can be seen after ingestion of large

doses of ascorbic acid. Twenty-four-hour collection of urine and the urine protein/creatinine ratio are other, more precise methods to quantify proteinuria. These techniques are further discussed in detail in Chapter 3.

KEY POINTS

- Dipstick (semiquantitative)
- 24 hour urine collection
- Urine protein/urine creatinine ratio

Microalbuminuria (MA) denotes urinary excretion of albumin in quantities less than detected by traditional dipstick and is defined as a persistent elevation of urinary albumin excretion of 30 to 300 mg/day.[87] Persistent MA is considered an early indicator of diabetic nephropathy and a harbinger of renal morbidity in patients with diabetes mellitus. Accumulating evidence suggests that MA also correlates with cardiac morbidity and mortality associated with hypertension, and it may reflect an underlying endothelial cell dysfunction in these patients.[88] MA is prevalent in young adult patients with obesity and metabolic syndrome.[89]

KEY POINTS

- MA is an important marker of early renal disease in diabetes mellitus.
- MA may also be an indicator of cardiovascular morbidity and mortality associated with hypertension.

EVALUATION OF PROTEINURIA

Proteinuria can be the only, and sometimes an early, indication of renal disease. Consequently, the purpose of investigations in evaluating a patient with proteinuria is to determine whether any renal disease exists. Orthostatic proteinuria (OP) should be ruled out, especially in adolescents, to avoid extensive and expensive investigations. The recommendation of the expert panel of Pediatric Nephrologists constituted by the National Kidney Foundation provides a framework for evaluation of proteinuria in children.[90]

History

A thorough history, physical examination, and urinalysis provide a clinical foundation for evaluation of patients with proteinuria. The historical aspects to be established are the duration of documented proteinuria, the presence of any symptoms indicative of nephrotic syndrome, a history

of any drug intake or exposure to toxins, and evidence of any primary collagen-vascular disorder characterized by rash, fever, joint pains, or any pulmonary symptoms. A family history of any renal disease must be ascertained to determine whether inherited disorders, such as Alport syndrome, need to be considered.

Physical examination

The purpose of physical examination is to establish blood pressure, evidence of edema, and any clinical manifestations of rash or joint involvement that may indicate vasculitis or collagen-vascular diseases. The respiratory system, including the sinuses, should be examined for any evidence of clinical disease, sinusitis, or polyps, as seen in Wegener granulomatosis (now reclassified as granulomatosis with polyangiitis).

Laboratory studies

Once proteinuria has been confirmed, and if it is isolated (i.e., no other urinary abnormalities), the first step should be to rule out the possibility of orthostatis proteinuria (OP). In the absence of OP, the patient can be characterized as having "fixed" proteinuria. Figure 9.10 provides an algorithm for laboratory investigations in these patients. The presence of hematuria, in addition to proteinuria, indicates the possibility of glomerulonephritis, and these patients need to be evaluated along the lines previously indicated in Figure 9.4.

ORTHOSTATIC PROTEINURIA

The term orthostatic proteinuria (OP) or postural proteinuria denotes documentation of proteinuria when the subject is ambulatory and the absence of any proteinuria in the supine posture. OP is more commonly seen in preteens, teenagers, and young adults. The characteristic feature of OP is mild, selective proteinuria that is seen only when the subject is upright.

The prevalence of OP in children is unclear. Some investigators have estimated it to be as high as 50% to 60% of children with proteinuria. In a published report, 91 children who were 6 to 19 years old were evaluated for diurnal variations in protein excretion, and 20% of them had proteinuria that could be characterized as OP.[91] Boys, those more than 10 years of age and with a body mass index greater than the 85th percentile, were more likely to have OP.

KEY POINTS

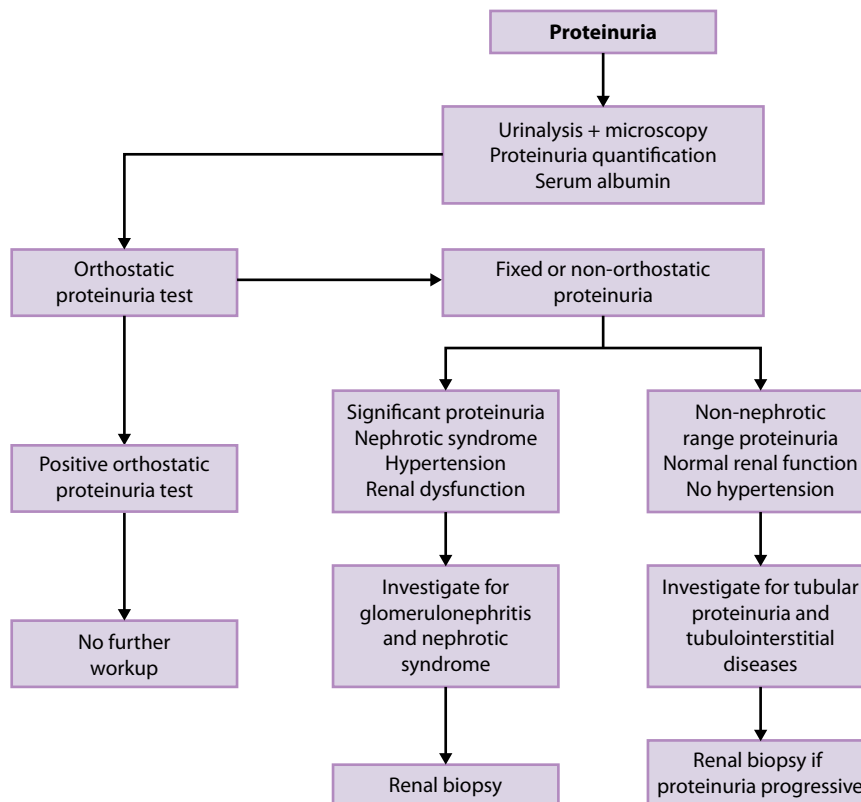
- OP is common in children.
- OP may affect 20% to 50% of children diagnosed to have proteinuria.
- OP may be associated with nutcracker phenomenon.


Figure 9.10 Schematic diagram for evaluation of proteinuria.

Pathogenesis

The cause of OP is unknown. Several case reports have implicated nutcracker phenomenon, or compression of the left renal vein by the aorta and another adjoining vessel, such as the superior mesenteric artery or vertebral artery.[92-94] In an interesting report, a renal transplant donor with OP was noted to have a kink in the renal vein at the time of donor nephrectomy.[94] After nephrectomy, the OP resolved in the transplant donor. The transplant recipient also did not develop proteinuria. The inference drawn by the authors of this report was that a kink in the left kidney was responsible for venous compression in the left renal vein and resultant OP. The role of nutcracker phenomenon as a possible cause of OP was reviewed by Marta et al.[95] The investigators evaluated published studies of OP with imaging data. Of the 229 subjects with OP between the ages of 5.2 to 17 years, these investigators found that 156 or 68% of the subjects had nutcracker phenomenon documented in imaging studies.

Renal pathologic features

The literature on renal biopsy findings in subjects with OP is scant. Renal biopsy performed in 6 young Air Force recruits with well-documented OP in the in the 1960s demonstrated only slightly thickened basement membranes.[96] A more recent study of 12 subjects with OP demonstrated only subtle and focal increase mesangial matrix, and deposition of

C3 complement and IgG was seen in 10 of the 12 patients.[97] Electron microscopic findings were normal in 11 of the 12 cases, and foot-process fusion was noted in 1 patient. It can be safely concluded that the renal biopsy findings in OP are not profound and may not even be specific.

Diagnosis

The diagnosis of OP employs a simple test to assess proteinuria during recumbent and upright postures. The principle of the test is to document proteinuria in the upright posture and its absence in recumbent posture. One can obtain differential timed urine collection of 12 h each: while the patient is recumbent and during upright posture. Protein is estimated in each of these urine collections. The diagnosis of OP is established by documenting normal (calculated 24-h) urine protein excretion in the recumbent sample, whereas the upright sample has significant proteinuria.

Alternately, a spot urine collection is obtained after 8 to 10 h of flat overnight rest (first morning void after waking up), and another sample is requested later in the day after 4 to 6 h of ambulation. It is important to remind patients to empty the bladder before sleeping. Both samples of urine are then evaluated for the protein/creatinine ratio. A normal urinary protein/creatinine ratio in the first morning sample (<0.2) and an abnormal protein/creatinine ratio in the afternoon sample suggest OP.

Prognosis

OP is considered a benign disorder. Rytand and Spreiter[98] provided 50-year follow-up in 6 patients with OP originally diagnosed by Thomas Addis. None of these patients had evidence of renal disease or worsening of their proteinuria. In a 10-year follow-up of 46 Air Force recruits, all were found to have normal renal function, and proteinuria was persistent in 49% cases.[99] Extending these studies to 20 years of follow-up in the same cohort, proteinuria had resolved in all except for 6 cases, and all had normal renal function.[100]

SCREENING FOR RENAL DISEASE

Although routine urinalysis had been an accepted part of screening for CKD in children previously, the American Academy of Pediatrics no longer recommends routine screening urinalyses.[101,102] Sekhar et al.[103] reported that the cost of each CKD diagnosis by routine urinalysis is $2779.50, thus rendering this screening test to be cost prohibitive. Mass screening for renal disease, with urinalysis as a tool, in school children in Japan and Singapore was also demonstrated to be ineffective.[104,105] Screening of adults in the United States for proteinuria as a marker of CKD was also not found to be cost effective.[106] The American College of Physicians has abandoned urinalysis as screening tool for detection of CKD.[107] Screening of high-risk and selected population groups may result in higher detection rates of renal disease.

SUMMARY

MH is a relatively common finding in pediatric practice. Evaluation of such patients is generally of low clinical yield and has not been considered cost effective. A higher clinical yield is expected in investigating patients with visible hematuria (GH). All investigations should be focused and conducted within a clinical pathway. Similarly, OP should be ruled out in all children with proteinuria before referral to a pediatric nephrologist. Fixed, or nonorthostatic, proteinuria needs to be investigated for the presence of renal disease and may require a diagnostic renal biopsy.

Clinical Vignette 9.1

A 15-year-old African-American boy was referred because of persistent proteinuria noted on three separate occasions by his primary care physician. The patient was otherwise asymptomatic. He had no history of swelling of the face of feet or gross hematuria. Physical examination revealed blood pressure of 122/76 mm Hg and was otherwise unremarkable. The primary care physician had obtained the following laboratory studies: 24-h urine protein collection, 520 mg; normal electrolytes; serum creatinine, 1.0 mg/dL; BUN, 22 mg/dL; serum albumin, 4.0 g/dL; total protein, 7.1 g/dL; total cholesterol, 179 mg/dL; complement C3, 94 mg/dL (normal); complement C4, 29 mg/dL (normal). Renal ultrasound findings were normal. Because of the asymptomatic nature of this patient's proteinuria, the diagnosis of orthostatic proteinuria was considered, and a first morning urine for protein and creatinine determination was obtained, which recorded 31/192 = 0.16. The diagnosis of orthostatic proteinuria was confirmed, and the patient was reassured.

TEACHING POINTS

This case represents a common clinical problem for which children are referred to pediatric nephrologists for consultation. The primary care physician had evaluated the patient extensively and had obtained normal data, except in the 24-h urine protein evaluation. The diagnosis of orthostatic protein was eventually established by the first morning urine protein/creatinine evaluation. If done as the initial evaluation in this asymptomatic patient, urine protein/creatinine could have established the diagnosis, and the expense incurred in the extensive evaluation of this patient could have been avoided. Once orthostatic proteinuria is established, no further evaluations are needed, and the patient can be followed by his or her primary care physician.

In contrast, if this patient did not have orthostatic proteinuria (in other words, if his proteinuria was "fixed"), he would need further evaluation, follow-up, and possibly a renal biopsy. Approximately 30% to 40% patients with focal segmental glomerulosclerosis present clinically with asymptomatic proteinuria, and a biopsy is necessary to confirm the diagnosis in such patients.

REVIEW QUESTIONS

1. Mass screening of children for proteinuria and hematuria is a useful strategy for detection of chronic kidney disease in children.
   a. True
   b. False

2. In a 2-week-old male newborn, parents report that the diaper is occasionally stained red-brown. They are concerned that he has blood in his urine. You reassure the parents with the suggestion that he probably has uric acid crystals in the urine and increasing fluid intake would be helpful. Six weeks later, the patients return, with the symptom that the infant was irritable and that the red-brown staining of the diapers has persisted. Urinalysis of a bagged urine specimen shows no protein or blood. Centrifugation 10 mL of urine shows a large amount of brownish red sediment. Microscopic analysis shows uric acid crystals in the sediment. You would obtain the following investigations:
   a. Urine for spot uric acid
   b. Urine for spot uric acid, spot creatinine
   c. Catheterization of the patient and determining an accurate 24-h urine uric acid
   d. Renal ultrasound, spot urine uric acid, and creatinine

3. Podocyturia and podocytopenia are known to occur in:
   a. Diabetic nephropathy
   b. Focal segmental glomerulosclerosis (FSGS)
   c. Membranous nephropathy
   d. HIV nephropathy
   e. All of the above

4. An 11-year-old white boy developed pink-brown urine following an upper respiratory tract infection. Results of cystoscopy performed in the community hospital were completely normal. His symptoms resolved in about 1 week. Six months later, he again developed fever, nasal stuffiness, and a sore throat, and visible hematuria ensued 2 days later. He was seen in the local emergency department. Urinalysis showed 3+ proteinuria, large (4+) blood, and numerous red blood cell casts in the microscopic examination of the sediment. Serum creatinine, 1.5 mg/dL; BUN, 39 mg/dL; normal electrolytes; ASO titer, normal; C3, 122 mg/dL; C4, 32 mg/dL; ANA, negative. The *least likely* diagnosis is:
   a. Poststreptococcal glomerulonephritis
   b. IgA nephropathy
   c. Thin basement membrane nephropathy
   d. Alport syndrome

5. Proteinuria, by itself, has been proposed to result in tubulointerstitial disease by which of the following mechanisms:
   a. Complement activation
   b. Induction of pro-inflammatory cytokines
   c. Epithelial-mesenchymal transformation
   d. All of the above

6. Mature podocytes can avidly reproduce in case of detachment or loss from the glomerular basement membrane.
   a. True.
   b. False.

7. Terminal hematuria is indicative of:
   a. Urinary tract infection
   b. Balanitis
   c. Posterior urethral or bulbar area lesions
   d. Bladder trauma

8. In the kidneys, cubilin and megalin are involved in:
   a. Proximal tubular phosphate reabsorption
   b. Urinary calcium reabsorption
   c. Reabsorption of urinary albumin and low-molecular-weight proteins
   d. Synthesis of Tamm-Horsfall protein

9. Tubular proteinuria is characterized by:
   a. Failure to reabsorb the low-molecular-weight proteins by the proximal tubular cells
   b. Absence of albumin in the urine protein electrophoresis
   c. Possible assay by determining the microalbumin/creatinine ratio
   d. Detection by a positive dipstick test for urine protein

10. Chloride channel-5 (ClC-5) is required in the reabsorption of tubular albumin at which of the following levels?
    a. Acidification of the endocytosis vesicles and dissociation albumin from the cubilin-megalin receptors complex
    b. Attaching tubular albumin to the cubilin-megalin complex
    c. Transporting of amino acids and dipeptides on the basolateral surface
    d. Transporting the cubilin-megalin complex to the tubular cell surface

Physiology of glomerular filtration

H. WILLIAM SCHNAPER

The functional unit of the kidney is the *nephron;* each kidney contains approximately 1,000,000 of these structures. Under normal circumstances, the adult human's kidneys filter approximately 150 L/day, more than three times the total body water. Although this system provides a highly efficient means of processing elements dissolved in our fluids, it presents a potential problem of dehydration unless the kidney reabsorbs most of this filtrate. Hence, the nephron has two critical functions: *filtration* and *reabsorption*. Reabsorption is accomplished through a series of highly specific mechanisms that are applied in the renal tubules. Indeed, most of the mass of the kidney is occupied by these structures. Approximately two-thirds of the filtrate is reabsorbed in the proximal tubule (Figure 10.1), with 20% reabsorbed in the loop of Henle and 12% in the distal tubule and cortical collecting duct. This yields 1% of the filtrate in the final urine, or on average approximately 1.5 L/day. How the different parts of the tubule selectively reabsorb elements of the filtrate is the subject of Chapters 11 to 15 of this textbook; this chapter focuses on the regulation of filtration.

GLOMERULUS

Filtration is accomplished in the *glomerulus,* a structure of capillary loops inside an epithelial capsule. The glomerulus was first described by Marcello Malpighi in the 17th century as a "gland" in the cortical part of the kidney, along with many tubules.[1] Given the kidney's obvious function in producing urine, great controversy raged subsequently regarding whether the glomeruli and tubules were connected. In 1842, William Bowman definitively described such a connection and suggested that the malpighian body was

"calculated to favor the escape of water from the blood."[2] Shortly thereafter, Carl Ludwig proposed that hydrostatic pressure is a critical determinant of the passage of water from the glomerular capillary into the urine.[2] Thus, the basic elements of glomerular filtration were drawn conceptually from the renal anatomy.

Like any effectively discriminating filter, the glomerulus has two essential functions: it must permit the passage of certain moieties, and it must restrict the passage of others. The *permissive* function allows the passage of the plasma water and certain, mostly relatively small, substances dissolved within it, from the glomerular capillaries into the urinary space. This property is critical for what we typically consider to be renal function, and its loss is the major determinant of whether renal replacement therapy is required. The *restrictive* function of the glomerulus serves to limit the passage of larger proteins and solid elements (erythrocytes and platelets) into the urine. Its failure does not cause a loss of kidney function as we usually apply the term, but failure of the restrictive component causes significant metabolic derangements such as are seen in the nephrotic syndrome. In addition, the restrictive property is so effective that its failure is a sensitive indicator of pathologic processes in the kidney, through our detection of hematuria or proteinuria. All these disease manifestations are covered in other chapters in this textbook; this chapter is intended to provide a

---

KEY POINT

The glomerular filter has two key functions: facilitating the passage of small molecules and restricting the passage of larger molecules and solid elements of the blood.
Figure 10.1 Conceptual structure of the nephron. The glomerulus, which comprises approximately 3% of the renal mass, accomplishes filtration. The remaining structure reabsorbs 99% of the glomerular filtrate, thus yielding 1% of the initial filtrate volume as urine. This ratio may change to accommodate variations in fluid intake and environmental conditions, largely accomplished by changes in net reabsorption at the distal tubule. Figures in boxes indicate the approximate fraction of the initial filtrate that is reabsorbed by different parts of the nephron. Note that the distal tubule apposes the entry and exit of the circulation from the glomerulus. (From National Institute of Diabetes and Digestive and Kidney Diseases Image Library, National Institutes of Health, Bethesda, MD.)

perspective on those chapters by focusing on the normal anatomy and physiology of the glomerulus.

FUNCTIONAL ANATOMY

Unlike the tubule with its myriad, specific transport mechanisms, the glomerulus uses an external force, the cardiac pump, to drive filtration. In the simplest conception, the glomerulus contains a specialized network of capillaries whose walls serve as a filter through which fluid is extruded from the vascular space. This fluid is then collected in the urinary space within the Bowman capsule (Figure 10.2), for subsequent processing by the complex epithelial transport apparatus in the tubule. The endothelial wall of the

glomerular capillaries is uniquely fenestrated (Figure 10.3), thereby permitting such passage. The capillaries in each glomerular tuft are supported by a "stalk" consisting of mesangial cells and a small amount of extracellular matrix (ECM) (Figure 10.4), and these vessels are surrounded by podocytes, unique epithelial cells that provide a support structure for the capillaries. Each of these cell types plays an important role in the regulation of glomerular function (Table 10.1).

During filtration, the first barrier encountered by the plasma (Figure 10.5) is the endothelium and its secreted glycocalyx coating composed of glycoproteins, likely derived from both endothelial secretion and plasma molecules.[3] This coating serves to slow the filtration of most molecules and to block the passage of larger ones.[4,5] The next significant component of the filter is the glomerular basement membrane (GBM). This structure, approximately 200 nm thick,[6] is derived from ECM secreted by both the

endothelium and the podocyte.[7] It provides a significant part of the restrictive component of the glomerular filter, as determined by perfusion studies of decellularized glomeruli, although the cellular layers may be more important for such restriction.[8] The GBM is composed largely of type IV collagen and laminin, with several other ECM components, the two most common being entactin and glycosaminoglycans (GAGs). The GAGs include both heparan sulfate[9] and chondroitin sulfate[10] proteoglycans.

KEY POINT

The three main components of the glomerular filter are the fenestrated endothelium and glycocalyx, the GBM, and the epithelial slit diaphragm.

Perhaps the most important restrictive component of the glomerular filter is provided by the podocyte, which, through both its attachment to the GBM and cell-cell adhesions, creates the most selective resistance to the passage of larger molecules. A set of intercellular adhesion molecules, many of which are relatively specific for the podocyte (Table 10.2), creates the *epithelial slit diaphragm* (SD), a porous structure that has been proposed to be the final barrier to molecular passage. The first major component of the SD to be discovered was *nephrin,* a protein with multiple

immunoglobulin-like domains that likely mediate homotypic protein-protein interactions between foot processes of adjacent cells.[11] The result is a latticelike network that provides both a sheetlike structure and openings that permit the transcapillary exit of some molecules.[12] Subsequently, several additional proteins were characterized as contributing to the SD structure, thus stabilizing that structure, fixing it to the cytoskeleton, or regulating cellular signals that promote or inhibit SD functions. These proteins include Neph1, FAT, podocin, CD_2AP, α-actinin-4, phospholipase Cϵ1, and TRPC6.[13]

Some controversy has arisen regarding whether the SD is the major restrictive component of the glomerular filter. It has been difficult to demonstrate actual trapping of large molecules solely at the level of the SD. Instead, studies using tracers to define the location of macromolecular restriction often have demonstrated localization to the GBM,[14] whereas others have indicated that trapping occurs at both the GBM and the SD.[15] Proponents of a major role for the SD have

suggested that other factors such as hemodynamics and electrostatic charge prevent significant macromolecular trapping at the SD (and potential clogging of the slit pore). This issue remains unresolved.

FACTORS GOVERNING GLOMERULAR FILTRATION

In the average adult, the glomerular filtration rate (GFR) is approximately 100 mL/min. Because we have approximately 10^6 nephrons, each glomerulus must filter fluid in the range of 10 to 100 nL/min. This estimate was confirmed by studies in Munich-Wistar rats, which have glomeruli on the kidney surface so that direct micropuncture measurements can be taken. These studies were used to determine single nephron GFR (SNGFR). Although there are some minor differences in studies among different rat strains, the data are sufficiently consistent to define principles of glomerular hemodynamics that contribute to determining SNGRF and whole kidney GFR.

VARIABLES AFFECTING NET FILTRATION

Unlike in the tubule, the "work" of glomerular filtration does not appear to require energy production by the glomerular cells. Instead, the forces governing GFR are supplied by physical properties of the vascular and urinary spaces and their contents. The process of egress across the glomerular filter can be considered as a mass transfer action, not unlike the events that occur with filtration by a dialysis membrane. These events are driven by the Fick laws for the diffusion of mass that, very broadly stated, are as follows: (1) transfer from one compartment to another is driven by gradients; and (2) as equilibration occurs between compartments, the impetus for this transfer decreases. Given that the function of the kidney is to filter the plasma, perfusion of the kidney by the blood stream is a critical force for glomerular filtration, manifested as hydrostatic pressure from within the capillary (Figure 10.6). This pressure is opposed by oncotic

Figure 10.6 Factors governing flux along the glomerular capillary wall. Net hydrostatic pressure (P) is opposed by net oncotic pressure (π). Fluid flux is also a function of the capillary surface available for filtration (S) and the permeability of the filter (k).

pressure resulting from substances that are dissolved in the plasma water. Other forces and factors are mentioned later. This brief discussion is meant to introduce the topic; readers interested in further details are referred to primary sources for more detail.

KEY POINT

The main forces affecting filtration by the glomerulus are blood hydrostatic pressure (outward) and plasma oncotic pressure (inward).

Based on the factors that govern glomerular filtration, we can derive a formula that characterizes these factors and can be applied to account for SNGFR. In a single dimension, fluid passage across a point on a capillary wall is proportional to the balance of pressures across the filter at that point. Therefore,

$$J_V \propto P - \pi$$

where J_V represents fluid flux (transfer across the filter), $\propto$ indicates a proportionate relationship, P represents net hydrostatic pressure (outward), and π represents net oncotic pressure (inward).

Hydrostatic pressure tends to force fluid out of the capillary, whereas oncotic pressure tends to oppose this movement, so oncotic pressure is subtracted from hydrostatic pressure in this equation. Because the net pressures represent the difference between opposing pressures in the glomerular capillary and in the Bowman space, we can substitute algebraic operations that define these net pressures:

$$J_V \propto (P_{(GC)} - P_{(US)}) - (\pi_{(GC)} - \pi_{(US)})$$

where GC is the glomerular capillary and US is the urinary space.

Because this is a one-dimensional formula, the amount of flux across the capillary in two dimensions must consider the surface area available for filtration, S, so that

$$J_V \propto S[(P_{(GC)} - P_{(US)}) - (\pi_{(GC)} - \pi_{(US)})]$$

Finally, because different filters and membranes have different permeability properties related to thickness, porosity, and other factors, each has a defined hydraulic permeability, k, based on the ability of that particular structure to permit the passage of a fluid. Therefore,

$$J_V = kS[(P_{(GC)} - P_{(US)}) - (\pi_{(GC)} - \pi_{(US)})]$$

Because it is difficult to measure surface area directly, the micropuncturists who defined these relationships inferred both k and S and combined them as K_f, so that

$$J_V = K_f[(P_{(GC)} - P_{(US)}) - (\pi_{(GC)} - \pi_{(US)})]$$
Thus, in applying Fick law to glomerular filtration, fluid diffusion across the glomerular filter is determined by the hydraulic permeability of the filter, the surface area available for filtration, and the balance of forces determined by the difference between the net hydrostatic pressure and the net oncotic pressure.

Although this derivation may seem complex, it is critical in considering the application of Fick's second law, which addresses potential changes in this equation resulting from the fact that glomerular filtration represents a dynamic system. Thus, in a child who is dehydrated, P_{GC} may be decreased, lowering SNGFR. This response defines what we call prerenal azotemia. Conversely, under conditions of volume expansion, P may increase, and quite possibly S may be increased by resultant stretching, thereby increasing fluid transfer across the membrane. In another example, a patient who has sepsis, numerous factors involving perfusion pressure (P), membrane permeability (k), and forces on both sides of the glomerular capillary wall will have significant effects on filtration.

As filtration of the plasma water occurs, and the intact capillary retains protein, the hydrostatic pressure will decrease and oncotic pressure will increase because protein concentration rises as plasma water is lost. Thus, along a hypothetic length of glomerular capillary, the net ultrafiltration pressure will decrease. Theoretically, a point could be reached at which the difference between P and π disappears, a point at which the force for ultrafiltration becomes zero and ultrafiltration should cease (Figure 10.7). This point of *filtration equilibrium*[16] would be difficult to demonstrate clinically, but it was critical to the investigators who established the characteristics of glomerular filtration because, by interfering with flow in the proximal tubule, they could cause the pressure in the urinary space to rise to the extent that glomerular filtration ceases. In this way, they could both directly and indirectly measure the forces governing filtration in the glomerulus.

PHYSIOLOGIC FEEDBACK REGULATING FILTRATION

Of more immediate clinical significance is the concept of *autoregulation*. Because of the importance of $P_{(GC)}$ in SNGFR, a condition in which SNGFR varies directly with systemic blood pressure would be untenable for maintaining steady-state renal function. Instead, autoregulation

KEY POINTS

- Autoregulation maintains constant pressure for filtration across a span of blood pressures.
- This process is accomplished by both myogenic forces in the vessel wall and active hormonal mechanisms regulating glomerular arteriolar resistance.
Figure 10.7 Filtration equilibrium. Because of extrusion of plasma water, the outward glomerular capillary hydrostatic pressure (solid line) decreases along the length of an idealized capillary, whereas the increased concentration of protein in the remaining intravascular volume increases the inward force of oncotic pressure (dashed line). Under conditions of high flow, the opposing forces of hydrostatic and oncotic pressure never equalize, so there is a net force for filtration (indicated by shaded area) along the entire length of the capillary. However, under low-flow conditions, the hydrostatic pressure decreases to the extent that, at some point, glomerular capillary hydrostatic pressure equals glomerular capillary oncotic pressure. At this point, there is no net force for filtration, and net flux effectively stops. Any further transfer of solute to the urinary space occurs by diffusion rather than by convection.

maintains $P_{(GC)}$ and SNGFR in a relatively constant manner (Figure 10.8) over a range of at least 40 mm Hg blood pressure.[17] This permits $P_{(GC)}$ to be maintained at a fairly stable value despite moment-to-moment variations in systemic pressure. Autoregulation is effected by a variety of factors, both passive (distensibility of the splanchnic bed, for instance) and active (variations in vascular tone), but the glomerulus benefits from a unique system involving the renin-angiotensin system.[18]

The glomerular circulation is regulated by certain factors that contribute to vasodilation, such as nitric oxide or cyclooxygenase,[19] or vasoconstrictors such as thromboxane

Figure 10.8 Autoregulation. Perfusion pressure and glomerular filtration rate are maintained at a constant value over a range of blood pressures rather than increasing in direct proportion to increases in pressure.

A and 20-hydroxyeicosatetraenoic acid (20-HETE).[20] An important consideration is the regulation of resistance in both the afferent and efferent arterioles of the glomerulus. Because the actual force for filtration is reflected by the drop in blood pressure along the glomerular capillary, the balance between the relative constriction of the two arterioles determines the amount of filtration (Figure 10.9). The net hydrostatic pressure for filtration of fluid is thus determined by the difference in resistance at these points.[21] If arteriolar resistance is very high or very low at both sites, there will be little net filtration pressure (see Figure 10.9). Conversely, constriction of the efferent arteriole but relative relaxation of the afferent arteriole increases filtration.

The distal tubule of the nephron loops back to and touches the vascular pole of the glomerulus, the site of entry and exit of the afferent and efferent arteriole, respectively (see Figure 10.1). Specialized cells in the tubule at this site, termed the *macula densa* (see Figure 10.2), sense distal tubular delivery of solute. Renin produced at this juxtaglomerular apparatus leads ultimately to the production of angiotensin II, a vasoconstrictor that modifies afferent

and efferent arteriolar resistance to regulate glomerular capillary blood flow. The rate of tubular fluid flow or the absolute concentration of salt at the macula densa[22,23] determines the level of renin production by the juxtaglomerular apparatus. Vasodilators such as nitric oxide appear to decrease afferent arteriolar resistance preferentially so that, at least at lower levels of renin-angiotensin activity, filtration is increased even in the presence of decreased renal blood flow. Higher levels of renin production constrict both the afferent and efferent vessels sufficiently that glomerular filtration is decreased.[18] In this manner, a feedback system maintains steady production of glomerular ultrafiltrate, somewhat independent of systemic blood pressure but consistent with the potential need to adjust glomerular filtration based on distal delivery of that filtrate. Thus, *tubuloglomerular feedback* regulates glomerular filtration to maintain a balance between glomerular filtration and tubular reabsorption. Other regulators of glomerular flow include vasoconstrictors such as norepinephrine; vasodilators such as histamine, certain prostaglandins, and bradykinin; and molecules that may directly affect K_f, such as antidiuretic hormone.

Renal nerve activity has a complex effect on whole organ kidney perfusion and may affect levels of angiotensin activity. However, it does not appear to affect glomerular filtration as strongly as the renin-angiotensin system,[24] and it may influence natriuresis more by altering peritubular blood flow and tubular sodium reabsorption.

Figure 10.9 Changes in afferent (Aff) and efferent (Eff) glomerular arteriolar resistance modulate the glomerular filtration rate. **(a)** Steady state. **(b)** Increased efferent resistance. **(c)** Increased afferent and efferent resistance. Red and green boxes represent sites of arteriolar smooth muscle where resistance is applied to afferent and efferent arterioles. Box size is proportional to vasoconstrictor tone Brackets show the drop in hydrostatic pressure across the capillary, a major determinant of filtration. The size of the arrow indicates the relative amount of filtrate.

REGULATION OF MACROMOLECULE CLEARANCE

Clearance studies using macromolecules of disperse sizes define a *permselectivity* curve (Figure 10.10), describing the clearance of macromolecules relative to the GFR.[25] Under normal physiologic conditions, such a curve has a sigmoid shape, where clearance of molecules with an effective molecular radius of up to 18 to 20 Å (1.8 to 2 nm) equals the GFR (i.e., such molecules are freely filtered). With increasing size, however, passage of molecules decreases until it is virtually absent at an effective molecular radius of 56 Å.[26] This upper limit defines the functional size of the SD pore and is consistent with studies that have been conducted analyzing the apparent size[27,28] and molecular constitution[12] of the SD. The explanation for the sigmoid curve, rather than an abrupt shutoff of filtration at 56 Å, is straightforward: Once molecules become large enough to interact with the slit pore, even if they are smaller than the pore, they may hit the side of the pore and bounce back into the vascular space, rather than passing through the pore (Figure 10.11).

All molecules, even those that are larger than the apparent molecular size limit of 56 Å, have some likelihood of crossing a semipermeable barrier, by the mechanisms of diffusion and convection. *Diffusion* occurs down a concentration gradient. In the case of protein, the concentration

Figure 10.10 Permselectivity curves derived in rats using macromolecules of disperse size. Clearance of molecules at each given size is shown with respect to the clearance of inulin as an indicator of glomerular filtration rate. Note that cations have facilitated clearance at any molecular size, whereas anions have decreased clearance. D, dextran; DEAE, diethylaminoethyl dextran; DS, dextran sulfate. (From Bohrer MP, Bayliss C, Humes HD, et al. Permselectivity of the glomerular capillary wall: facilitated filtration of circulating polycations. J Clin Invest. 1978;61:72–8.)

gradient is so different between the plasma and the urinary space that a small amount of protein always is present in the glomerular filtrate and may appear in the urine. Diffusion accounts for the clearance of large molecules, most commonly when plasma protein concentrations are elevated or filtration equilibrium is reached, as is the case in dehydration. Conversely, *convection* involves the movement of solute along with flow; it sometimes is referred to as "solvent drag." Convection is most likely to increase the amount of protein in the glomerular filtrate with maximal passage of plasma water across the filter, such as occurs in filtration disequilibrium consequent to volume expansion.

broadside). Albumin, which is filtered less than would be anticipated from its size, is a prolate ellipsoid (cigar shaped) and is unlikely to be distensible. Albumin also may be subject to *charge* restrictions. The glycocalyx and the coating of the cells comprising the glomerular filter are negatively charged. Further, the sulfation of GAGs in the GBM contributes to fixed negative charges in the GBM.[30] These electrostatic charges may facilitate the clearance of positively charged macromolecules and inhibit the passage of negatively charged ones[29] (see Figure 10.10). They could play a role in delaying or preventing the passage of some negatively charged proteins, such as albumin, through the glomerular filter, thus accounting for at least some of the restriction

KEY POINTS

- The principal determinant of macromolecular passage through the glomerular filter is steric hindrance (size and shape selectivity).
- Other determinants include electrostatic charge and hemodynamic factors.

Several additional factors may influence the passage of macromolecules through the glomerular filter. If the filter has properties of a porous structure, size considerations will be affected by shape and distensibility of the cleared molecule.[29] A long, thin, flexible macromolecule is more likely to pass through a pore than a spherical molecule of the same molecular weight (although this would depend whether the long molecule reached the pore end-on or

Figure 10.11 Steric hindrance causes a sigmoidal curve in permselectivity. As molecules approach the size where steric hindrance may affect filtration, the macromolecule may strike the edge of a pore in the filter. The larger the molecule, the more likely it is to strike the filter rather than going through the opening.

in clearance of albumin.[26] It has been suggested that this electrostatic hindrance depends not only on the fixed negative charges, but also on the subsequent establishment of a charge gradient across the glomerular filter through a process called "streaming potential,"[31] that acts on larger molecules trapped in the nonlinear flow of the subpodocyte urinary space.[32]

The mechanisms by which the SD is altered to permit the pathologic passage of larger molecules into the urine are discussed elsewhere in this textbook. Briefly, the main cause is likely to be the disruption of podocyte structural integrity. The stability of the SD requires interactions among the cytoskeleton, the cellular adhesion molecules, and accessory molecules that buttress the SD structure and make it relatively rigid. Any change in the interactions among these molecules is likely to cause a change in the size of the slit pore, or even a loss of the diaphragmatic structure, thereby decreasing the restrictive nature of the SD. Loss of charge selectivity may be a maintenance factor for increased clearance of negatively charged molecules in the presence of foot process effacement.[31]

CELL BIOLOGY OF THE GLOMERULUS

Despite this description of glomerular filtration as a relatively passive process, driven by hydrostatic and oncotic pressure, the three major cells of the glomerulus are active in several ways that contribute to glomerular physiology and function. The capillary endothelium, like all endothelial cells, produces proteins that regulate coagulation and inflammation.[33,34] The podocyte may have phagocytic properties, by absorbing proteins and other molecules such as immunoglobulins that enter the glomerular filter.[35] It serves an important support function in that it helps the capillary resist distending pressure within the vascular space. The loss of the podocyte permits such distention to bring the denuded basement membrane into contact with the Bowman capsule. This contact leads to synechia formation and the extrusion of vascular content directly into the interstitial space, an event implicated by many investigators in the pathogenesis of glomerulosclerosis.[36] Studies have suggested that the podocyte may have a highly mobile phenotype under certain conditions,[37,38] a capability that would futher modulate the podocyte's function in regulating transglomerular passage of macromolecules. Maintenance of the space between podocyte foot

processes is essential for optimal glomerular filtration, and foot process effacement may decrease GFR.[39]

The mesangial cell has numerous properties that are similar to those of contractile smooth muscle cells that regulate glomerular perfusion[40] or to those of phagocytic reticuloendothelial cells or inflammatory macrophages,[41-43] although it clearly cannot be characterized as being any one of those cells. The mesangial cell has been described as a pericyte,[44] similar to the Ito cells in the liver. Given its location in an area of the glomerulus where ECM accumulation frequently initiates, the mesangial cell has been considered a critical cell for the synthesis of ECM in glomerulosclerosis.

Communication among the primary cells of the glomerulus represents an important component of glomerular biology. Many investigators propose that vascular endothelial growth factor (VEGF) produced by the podocyte is the stimulus for fenestration of the glomerular endothelial cells.[45] Such a notion appears to contradict the general direction of flow through the glomerular filter, which runs centrifugally from the vascular space toward the urinary space, but more studies suggest that the flow of fluid through the filtration barrier is turbulent rather than streamlined, and paracrine VEGF signaling from the podocyte to the endothelial cell has been implicated in the pathogenesis of transgenic, podocyte-specific VEGF-deletion models.[46] Similarly, proteinuria is a major stimulus of glomerulosclerosis, which appears to initiate in the mesangium. The mechanism by which podocyte dysfunction or proteinuria activates mesangial ECM accumulation is not known, although it is possible that the delivery of large amounts of unanticipated molecules to the ultrafiltrate, inflammation, cell stretch or deformity, altered structure, and abnormal cell-cell communication all may contribute to altered mesangial cell physiology.

Finally, additional cells or cell types reside in the glomerulus. Macrophages are infrequent but present.[47] They appear to have little pathologic significance until normal physiology is perturbed. Additional fibroblasts are likely recruited to the glomerulus from the tubulointerstitium during disease.[48] Attention has focused on the parietal epithelial cells lining the Bowman capsule. It is now thought that these cells, when dedifferentiated, are capable of migrating onto the mesangial stalk to establish or reconstitute the podocyte population.[49]

KEY POINT

The three most important cells of the glomerulus are the podocyte, a specialized epithelial cell; the mesangial cell, a pericyte with contractile and phagocytic properties; and the endothelial cell.

SUMMARY

Together, these cells comprise a complex, synergistic biologic network that plays a critical role in (1) regulating glomerular function, (2) modulating the clearance of solvent and solute from the blood stream, and (3) controlling homeostatic function throughout the kidney. Even a minor disruption of the normal function of these cells can have significant consequences for kidney function and, by extension, total body physiology. The derangements that result are considered more extensively in other chapters of this book.

Sodium and volume homeostasis

MICHEL BAUM

This chapter will discuss how the kidney functions to maintain a relatively constant extracellular fluid volume and electrolyte composition despite the fact that our intake of salt and water can vary dramatically from day to day. The normal homeostatic mechanisms that preserve a constant *milieu interior* will be presented. The pathophysiology of disturbances in sodium (Na$^+$) composition will be discussed to provide a better understanding of common clinical problems encountered in pediatrics. Salient differences in Na$^+$ handling between the adult and neonatal kidney will also presented.

BODY FLUID COMPOSITION

Of the weight of an average child, 60% is composed of water, which is distributed between the intracellular and extracellular fluid compartments. As a neonate, 70% of our weight is water, and the fraction of our body weight that is water decreases as we age. Adipose tissue has only 10% water content compared to most organs, which contain 70% to 80% water, and thus excess fat reduces the percentage of body weight that is water. The concept of body composition and maintenance of fluid and electrolyte homeostasis is easily appreciated if we separate these compartments as is shown by the beaker filled with fluid in Figure 11.1. The intracellular compartment comprises 60% of our total body water, with the extracellular compartment making up approximately 40%. The extracellular fluid compartment is predominantly interstitial fluid that bathes cells. A small component of extravascular fluid is in the cerebrospinal fluid, peritoneal and pleural fluid, intraorbital fluid, lymph, and fluid in joint spaces. The intravascular compartment is only one fourth of the extracellular fluid volume. Thus, only approximately 7% to 10% of our total body water is intravascular. Maintenance of the volume and composition of the intravascular fluid space is critical for survival.

The composition of the intracellular and extracellular fluid volume is quite different. The extracellular fluid contains primarily the electrolytes that we are familiar with by measuring serum chemistries. The Na$^+$ concentration in extracellular fluid is 138 mEq/L, which is balanced by chloride anions and to a lesser extent bicarbonate. The electrolyte composition of the intravascular space is comparable to that of the interstitial fluid. In fact, there is a circulation of fluid across the capillary wall because of the hydrostatic pressure on the afferent end causing fluid egress. In the more distal end of capillaries, the hydrostatic pressure decreases as the protein oncotic pressure increases, which results in fluid movement from the interstitial space to the capillary. The forces depicting capillary fluid movement are shown in Figure 11.2.

KEY POINTS

- Of a child's body weight, 60% is composed of water.
- Intracellular compartment comprises 60% of total body water.
- Extracellular fluid is mostly in the interstitial space.
Figure 11.1 Beaker depicting the body fluid compartments. Sixty percent of our body is water. Sixty percent of total body water is in the intracellular compartment, and 40% is in the extracellular fluid compartment. Only 25% of the extracellular fluid compartment is intravascular, the rest being in the interstitial compartment.

The intracellular fluid composition is predominantly made up of potassium (140 mEq/L), whose charge is balanced predominantly by phosphate and negatively charged proteins. The sodium and chloride concentrations inside cells are negligible. The high intracellular potassium and low intracellular sodium concentration is maintained by the Na^+-K^+-ATPase on cell membranes. The separation of the electrolytes between cells and the extracellular fluid space is also maintained by the fact that cell membranes are virtually impermeable to electrolytes. Cells have a water channel designated aquaporin 1 that allows free movement of water between the intracellular and extracellular fluid volume. Thus, the osmolality, which is a measure of the number of particles per unit volume, is the same in the intracellular and extracellular fluid spaces.

CONCEPT OF MAINTENANCE FLUIDS

At this point we will turn back to our beaker of fluid in Figure 11.1 and discuss the concept of fluid and electrolyte balance and administration of maintenance fluids and electrolytes. Maintenance fluids replace the fluids and electrolytes that are normally lost when we are euvolemic under steady-state conditions. Maintenance fluids are often prescribed using the formula shown in Table 11.1.

We administer 1/2 normal saline with 20 mEq/L potassium chloride (KCl) to replace normal losses and maintain the composition of sodium and water unchanged under a basal state. Administration of maintenance fluids replaces the fluid losses from skin and respiration, which is known as *insensible water loss* because we do not realize we are losing this fluid, unlike losses that we know we are having from urine and stool. Insensible water losses are usually 25% of the fluid that is administered using the
Figure 11.2 Starling forces in the capillary bed. The capillary hydraulic pressure (Pc), on the arterial end of the capillary is higher than the interstitial hydraulic pressure (Pi) and favors movement of fluid from the capillary into the interstitial space. Capillary oncotic pressure (Πc), derived from serum albumin, is higher than interstitial oncotic pressure (Πi), which retards the movement of fluid out of the capillary and into the interstitium. Under normal conditions, the summation of the hydraulic and oncotic forces favors a small movement of fluid (and sodium) out of the capillary into the interstitium. At the venous end the hydraulic pressure is lower and the oncotic pressure has increased as a result of the egress of fluid. The net result is the absorption of interstitial fluid back into the capillary. Some of the remaining interstitial fluid is returned into the general circulation via the lymphatics.

"maintenance" formula. To simplify things, let us take our beaker and fill it to exactly 1 L with 140 mEq/L sodium chloride (NaCl). We come back the next day and find that the volume has decreased to 990 mL and the sodium concentration has increased by 1%. The maintenance for that beaker is 10 mL of water per day. Now let us poke a hole in the beaker and have it drip out 100 mL of 140 mEq/L a day. Maintenance for this new beaker is 10 mL of water for insensible evaporative losses and 100 mL of 140 mEq/L NaCl to replace the visible losses. We are like this beaker. If a patient has no kidneys, it would be necessary to just replace the insensible water losses from skin and respiration (stool losses are negligible). If the patient has kidneys, we go back to our formula—which is a good estimate of the losses of urine for a euvolemic child. If we are dealing with a patient who has impaired renal function, for example, we

Table 11.1 Daily maintenance fluid and solute requirement

Body weight	Fluid	Sodium	Potassium
1–10 kg	100 mL/kg	5 mEq Na/100 mL	2 mEq K/100 mL
11–20 kg	1000 mL+50 mL/ kg for each kg > 10 kg	5 mEq Na/100 mL	2 mEq K/100 mL
> 20 kg	1500 mL+20 mL/ kg for each kg > 20 kg	5 mEq Na/100 mL	2 mEq K/100 mL

can estimate the maintenance for that patient by measuring the urine output and the electrolytes in the urine and adding the insensible water loss to that volume. Note that we have not discussed volume depletion or ongoing losses; this will come later. So when does one use maintenance fluids? Maintenance intravenous fluids should be administered in a euvolemic patient who is not allowed to eat or drink because of an impending procedure—for example, to keep the patient euvolemic. This is a rare event. Under almost all circumstances when we administer intravenous fluids, the patient will be volume depleted and it is usually safer to administer isotonic normal saline.[1]

KEY POINT

Volume-depleted patients should initially receive isotonic fluid replacement.

RENAL REGULATION OF SODIUM

The glomerulus produces an ultrafiltrate of plasma that consists of an essentially protein-free solution with composition identical to that of blood. The adult kidney filters 150 L of fluid per day and delivers this fluid to the renal tubules, where, under normal circumstances, 99% of this fluid is reabsorbed.

The glomerular filtration rate (GFR) is regulated by changes in the relative resistance of the afferent and efferent arterioles. Under conditions of significant volume depletion it is desirable to decrease sodium excretion. In addition to an augmentation in sodium absorption, as described later, the increase in sympathetic nerve activity and angiotensin II secretion results in an increase in both efferent and afferent arteriolar vasoconstriction, as well as contraction of glomerular mesangial cells, which decreases the filtration surface area. These coordinated events result in a decrease in GFR and decrease in the delivery of salt to the kidney. The opposite can occur during volume expansion.

The renal tubules selectively reabsorb the filtered solutes that are needed by the organism while leaving waste products to be excreted in the urine. In addition to this filtration and absorption system, the kidney also secretes many organic anions and cations via specific transporters to increase the efficiency of removal of some protein-bound solutes that are not filtered. Diagrams of the nephron and the transporters involved in sodium and potassium reabsorption are shown in Figure 11.3.

The basic mechanism for sodium absorption by the kidney is the same in every nephron segment.[2] The sodium-transporting cells along the nephron have a basolateral Na^+-K^+-ATPase that generates an intracellular sodium concentration that is lower (~10 mEq/L) and an intracellular potassium concentration that is higher (~140 mEq/L) than that of the extracellular fluid. The Na^+-K^+-ATPase transports three sodium ions out of the cell for each two potassium ions it pumps into the cell. The fuel for this process is adenosine triphosphate (ATP). The ion composition gradient between the intracellular and extracellular compartments generated by the Na^+-K^+-ATPase and the basolateral potassium channel results in a negative potential difference of approximately −60 mV. The low intracellular sodium concentration and the large negative potential difference provide a driving force for apical sodium entry from the tubular lumen into the cell. Thus, most solute transport in the kidney is either directly or indirectly linked to the absorption of sodium. For example, glucose is reabsorbed from the luminal fluid by the proximal tubule via a sodium-dependent process. The energy for glucose absorption is the low intracellular sodium and the negative potential difference generated by the Na^+-K^+-ATPase. Glucose leaves the cell across the basolateral membrane by facilitated diffusion down its concentration gradient.

PROXIMAL TUBULAR SODIUM REABSORPTION

The proximal tubule is the work horse of the kidney, where the bulk of reabsorption occurs. The distal nephron is where the fine-tuning occurs. The proximal tubule receives the ultrafiltrate from the glomerulus and reabsorbs approximately 60% of the filtered salt and water filtered in an isosmotic fashion. The proximal tubule reabsorbs all of the filtered glucose and amino acids and the vast majority of the filtered phosphate. Although the proximal tubule is almost 10 mm long, most of the filtered glucose and amino acid absorption occurs in the first 2 mm.[3,4] The proximal tubule also reabsorbs 80% of the filtered bicarbonate and 60% of the filtered chloride.[3] Approximately two-thirds of bicarbonate is reabsorbed via a luminal Na^+-H^+ exchanger and one-third is via a proton pump.[5,6] The secretion of a proton by either of these two mechanisms results in the formation of carbonic acid (H_2CO_3), which dissociates into carbon dioxide (CO_2) and water (H_2O) with the aid of carbonic anhydrase that is present in the lumen. The CO_2 diffuses into the proximal tubule cell and reassociates with H_2O and with the help of carbonic anhydrase, which is also in the cytoplasm of the proximal tubule. The H_2CO_3 dissociates back into a proton, which is once again secreted across the apical membrane while the cellular bicarbonate is transported across the basolateral membrane via a $Na(HCO_3)_3$ cotransporter.[7]

The preferential reabsorption of organic solutes and bicarbonate leaves the latter parts of the proximal tubule devoid of organic solutes and with a higher luminal chloride and lower luminal bicarbonate than levels in the peritubular plasma.[2,4] Stated another way, the luminal fluid of the proximal tubule becomes almost isotonic normal saline. This
Figure 11.3 Diagram of the nephron showing the transporters present in each nephron segment responsible for NaCl transport.

change in luminal fluid composition provides a gradient for bicarbonate to move from the peritubular plasma into the tubular lumen and chloride to move from the lumen into the peritubular plasma. Because chloride is far more permeable than bicarbonate, the movement of this anion generates a lumen-positive potential that provides a driving force for sodium to move across the paracellular pathway into the peritubular plasma.[4] Thus, the change in solute composition, which occurs in the early proximal tubule, generates a driving force for NaCl absorption without the additional expenditure of energy. Approximately half of NaCl absorption is passive and paracellular.[8] The other half of NaCl transport is active and transcellular. It is mediated by the parallel operation of the Na^+-H^+ exchanger, which is responsible for bicarbonate reabsorption in the early proximal tubule, and a Cl^--base exchanger results in the net absorption of NaCl and secretion of proton and a base.[9] The nature of the base is unclear. There is evidence that it may be a hydroxyl ion, in which case one H_2O molecule would be secreted for each

NaCl absorbed or a bicarbonate ion, which would then be reabsorbed.[8,10] There is also evidence that the base is a formate molecule, in which case formic acid would be generated and reabsorbed (or recycled) back into the cell.[9]

The coordination between glomerular filtration and proximal tubule reabsorption, where the rate of proximal tubule reabsorption compensates for changes in glomerular filtration, is termed *glomerular-tubular balance*. Glomerular-tubular balance buffers the distal delivery of salt with changes in GFR, preventing a flood of salt with volume expansion with an increase in GFR and the opposite compensation with volume depletion.

Proximal tubule transport is modulated, in part, by peritubular capillary physical factors or Starling forces.[11] The peritubular capillary hydrostatic pressure opposes net proximal tubular sodium reabsorption, and the peritubular capillary oncotic pressure promotes reabsorption. The filtration fraction is the fraction of the renal blood flow filtered, which is regulated predominantly by the resistance of

the efferent artery. In the face of volume contraction there is an increase in filtration fraction by preferential contraction of the efferent arteriole to maintain a nearly normal GFR. The fluid entering the peritubular capillaries will have a lower hydrostatic pressure and higher oncotic pressure than under euvolemic conditions, which favors proximal tubule reabsorption. The opposite occurs in volume expansion, which decreases proximal tubule reabsorption.

SODIUM REABSORPTION IN THE LOOP OF HENLE

The thin limbs of the loop of Henle are able to reabsorb NaCl without expending energy.[2] The thin descending limb is impermeable to NaCl and highly permeable to water. Because the thin limb traverses the hypertonic medulla, water is abstracted and the luminal fluid becomes highly concentrated. At the bend of the loop the permeability properties of the tubule change drastically. The thin ascending limb is impermeable to water and highly permeable to both urea and NaCl. Thus, the concentrated fluid that is progressing upward into a less hypertonic environment has a gradient for NaCl and urea to diffuse out of the lumen into the medullary interstitium. This results in net NaCl absorption and helps generate a hypertonic medulla.

The thick ascending limb reabsorbs approximately 25% of the filtered NaCl. This segment is impermeable to water; thus, this thick ascending limb is in part responsible for creating a hypertonic medulla for urinary concentration. The thick ascending limb is also important for urinary dilution because the fluid that leaves this segment is hypotonic to serum. The apical membrane has a Na^+-K^+-$2Cl^-$ cotransporter that is inhibited by furosemide and bumetanide. This transporter results in the electroneutral absorption of sodium, potassium, and chloride; the two chloride ions balance the two positive charges from sodium and potassium, so the lumen of this segment is positive because there is an apical potassium channel. Some of the potassium reabsorbed by the Na^+-K^+-$2Cl^-$ transporter is secreted across the apical membrane into the lumen via this potassium channel. This lumen positive potential is quite important because it generates the driving force for the paracellular absorption of magnesium and calcium in this segment. The paracellular pathway in this segment is quite unique in that it is very permeable to cations. Thus, administration of loop diuretics not only results in a decrease in NaCl absorption but the enhanced excretion of magnesium and calcium, as well as other cations. Sodium, which enters the thick ascending limb leaves via the Na^+-K^+-ATPase, and the chloride exits the basolateral membrane by either a KCl cotransporter or a chloride channel. Mutations in the Na^+-K^+-$2Cl^-$ cotransporter, the apical potassium channel (renal outer medullary potassium [ROMK] channel), or the basolateral chloride channel give rise to Bartter syndrome, an inherited familial disease characterized by hypokalemic metabolic alkalosis and associated with elevated renin and aldosterone levels

secondary to chronic volume depletion.[12,13] Catecholamines, vasopressin, and renal nerves increase sodium transport in the thick ascending limb.[14,15]

DISTAL CONVOLUTED TUBULE

The distal convoluted tubule reabsorbs approximately 10% of the filtered sodium by a luminal electroneutral NaCl cotransporter. The NaCl cotransporter is inhibited by thiazide diuretics. All cases of Gitelman syndrome are due to an inactivating mutation of this transporter.[12,16,17] Both the thick ascending limb and the distal convoluted tubule reabsorb salt but are impermeable to water. The osmolality of the fluid that leaves the distal convoluted tubule is 50 mOsm/kg water. If vasopressin (antidiuretic hormone [ADH]) is not secreted to increase the permeability of the collecting tubule to water, the final urine will have an osmolality of 50 mOsm/kg water. In addition to the reabsorption of NaCl, the distal convoluted tubule also reabsorbs a substantial amount of calcium. Unlike in the thick ascending limb, however, the reabsorption of calcium is transcellular. Inhibition of the NaCl cotransporter with thiazide diuretics results in an increase in renal calcium absorption. Thus, whereas loop diuretics cause an increase in calcium excretion, thiazide diuretics decrease calcium excretion. This segment also is responsible for transcellular magnesium reabsorption. Thiazide diuretics result in a substantial amount of magnesium wasting. Sodium transport in the distal convoluted tubule is augmented by angiotensin II and catecholamines.[18,19]

FINE-TUNING THE URINE CONTENT: THE COLLECTING TUBULE

The collecting tubule is the final segment that adjusts the composition of the urine before urinary excretion. Although this segment reabsorbs only 1% to 3% of the filtered sodium, the collecting tubule nonetheless plays a critical role in regulating salt transport.[2] Sodium is reabsorbed by principal cells in this segment via an apical epithelial sodium channel (ENaC) (Figure 11.3). This leaves the lumen with a negative potential difference compared to the cell. This potential difference provides a driving force for potassium secretion, proton secretion, or the paracellular reabsorption of chloride. The sodium channel is regulated by aldosterone, which causes the sodium channel to insert into the apical membrane, and thus with aldosterone secretion there will be an increase in sodium absorption and potassium or proton secretion. Patients with Liddle syndrome have an overabundance of sodium channels on the apical membrane of the collecting duct, resulting in hypertension and hypokalemic metabolic alkalosis. The sodium channel is inhibited by the diuretics amiloride and triamterene. These diuretics cause an increase in serum potassium because they decrease the lumen negative potential that augments potassium secretion. Sodium absorption in this segment is primarily

regulated by aldosterone, which increases the number of ENaC transporters on the apical membrane. Activity of the basolateral Na^+-K^+-ATPase is also increased by aldosterone, which lowers intracellular sodium and provides a greater driving force for tubular sodium reabsorption. Vasopressin also increases the apical sodium transport, promoting insertion of ENaC in the apical membrane.

Whether the urine is concentrated or dilute compared to blood depends on the presence or absence of vasopressin (ADH). As noted, in the absence of vasopressin the hypotonic urine formed in the thick ascending limb and distal convoluted tubule will be excreted with an osmolality of 50 mOsm/kg water. However, in the presence of vasopressin, water channels (designated aquaporin 2) are shuttled from the cytoplasm into the apical membrane.[20] This increases the permeability of the apical membrane for water. There are also water channels on the basolateral membrane (designated aquaporin 3 and 4) for water to exit the cell. The interstitium is quite hypertonic because the accumulation of salt and urea via mechanisms discussed previously and osmotic equilibration occur. The urine of humans can be concentrated to an osmolality of 1200 mOsm/kg water. This pales by comparison to that of desert rodents, which have very long loops of Henle and can concentrate urine to over 3000 mOsm/kg water.

KEY POINT

During postnatal development there is an increase in the abundance of most renal transporters.

SOLUTE AND WATER TRANSPORT BY THE NEONATAL KIDNEY

The GFR of an adult is approximately 100 mL/min/1.73 m², whereas that of a term newborn is 2 mL/min. Even if the GFR for an adult's body surface area is factored, the neonate has a GFR of 30 mL/min/1.73 m². Premature neonates have an even lower GFR. The maturational increase in GFR occurs at the same rate if the baby is still in the womb or is born prematurely.[21,22] The GFR increases to adult values, corrected for surface area, by approximately 12 months of age. The increase in GFR is due to several factors. There is an increase in blood flow to the kidneys, an increase in glomerular filtration pressure, and, if the neonate is born before 34 weeks of gestation, an increase in glomerular number. The most important factor responsible for the postnatal increase in GFR by far is the increase in glomerular capillary surface area with maturation followed by the developmental increase in ultrafiltration pressure.

The principles discussed for solute transport in the adult tubule pertain to the neonate as well. This section will focus on the major differences between the adult and neonatal kidney. The driving force for most active solute transport remains the low intracellular sodium concentration and the negative cell potential difference. The Na^+-K^+-ATPase generates this low intracellular sodium and potential difference, but the activity of the pump is less in each nephron segment in neonates compared to in adults.[24–26] The lower activity of the pump parallels lower solute transport in each nephron segment in the neonate compared to in the adult.

NEONATAL PROXIMAL TUBULAR FUNCTION

The maturation of the neonatal proximal tubule keeps pace with the developmental increase in GFR, known as glomerular-tubular balance. Glomerular-tubular balance matches GFR to tubular reabsorption, as discussed previously. The neonatal proximal tubule reabsorbs all of the filtered glucose, the amino acids, and most of the filtered bicarbonate. There are some significant differences that should be noted. First, whereas glomerular-tubular balance is maintained in term neonates, this is not true of premature neonates born before 34 weeks of gestation, who often have proximal tubules that are not able to reabsorb the solutes delivered by glomerular filtration and thus have apparent Fanconi syndrome with glucosuria, amino aciduria, and renal tubular acidosis.[21] Although the rate of all transporters studied is less in the neonate than in the adult, there is one exception. The rate of phosphate transport is higher in the neonatal proximal tubule than in the adult.[27–30] There is an isoform of the apical sodium-phosphate cotransporter in the neonatal proximal tubule responsible for the high rates of phosphate transport, which has very low expression in the adult.[30]

Eighty percent of bicarbonate reabsorption occurs in the proximal tubule, mediated by the Na^+-H^+ exchanger, which is designated NHE3 in adults. In neonates there is virtually no NHE3 protein or messenger RNA (mRNA) present, but nonetheless there is Na^+-H^+ exchanger activity.[31] In neonates the predominant Na^+-H^+ exchanger is NHE8.[32,33] An isoform switch from NHE8 to NHE3 occurs at the time of weaning that is due to the increase in glucocorticoids and thyroid hormone that occurs at that time.[34,37] In the adult proximal tubule the H^+-ATPase accounts for one third of proton secretion in the adult segment; however, there is no H^+-ATPase activity in the neonatal proximal tubule.[5,6] Thus, not only are there quantitative differences in transport during postnatal maturation, but there are also differences in some of the transporters responsible for neonatal transport. Approximately 60% of the filtered NaCl is reabsorbed by the proximal tubule in the adult. In the adult, NaCl transport from the lumen to the blood is via both transcellular and paracellular mechanisms; however, the permeability of chloride, although high in the adult segment, is zero in the neonate and thus there is no passive chloride transport.[38,39] Finally, water transport deserves note. The abundance of aquaporin 1 is less in the neonate than in the adult segment; however, the permeability of water is actually higher in the

neonate.[40] This is due to the fact that the neonatal proximal tubule cytoplasm offers less resistance to water flow than that of the adult segment.

DISTAL NEPHRON

The distal nephron segments do not have an isoform switch for salt transporters, as has been described in the proximal tubule, but all segments studied have a lower rate of transport in neonates compared to that in adults. The thick ascending limb has been shown to have a lower rate of sodium reabsorption in the neonate than in the adult, which is one factor in the limited capacity of the neonate to produce concentrated urine.[41] The human neonate can concentrate urine to an osmolality of 600 mOsm/kg water. Finally, the neonatal cortical collecting duct has essentially no apical sodium channel and K^+ channel activity.[42,43] The maturational increase in apical sodium channel occurs well before that of the K^+ channel.[44,45] This paucity of K^+ channel occurs despite the fact that there are aldosterone and aldosterone receptors. The lack of K^+ channels limits the ability of neonates to excrete potassium and often is an important factor predisposing them to hyperkalemia.

Finally, salt handling and the response to a volume load in neonates and adults should be compared. If the effect of an isotonic volume challenge in a neonate and a comparable volume challenge in an adult are compared, the adult is found to be able to excrete the salt load far more briskly than is the neonate.[46] This is important clinically because neonates are able to be in positive salt balance despite drinking mother's milk, which has a very low salt content. It remains unclear how this occurs, but there is evidence of augmented sodium absorption by the distal convoluted tubule of the neonatal kidney in response to an isotonic fluid load compared to that of an adult.[47] The renin-angiotensin system likely plays a role mediating the increase in sodium absorption in the neonate, because losartan augments natriuresis and diuresis in response to a volume load in neonates.[48] Whereas the term neonate is adept at retaining NaCl, the premature neonate has problems with renal salt wasting because of the immaturity of the transporters in the kidney. This results clinically in hyponatremia and volume depletion unless premature infants have salt supplementation.

REGULATION OF EXTRACELLULAR FLUID VOLUME—AFFERENT LIMB

Under normal conditions our body is in balance so that the sodium intake is matched by the urinary sodium excretion. If we increase sodium intake by indulging in a very salty meal, we do not develop edema or heart failure if our kidneys and cardiovascular system are intact. We do not become hypernatremic, because we have osmosensors that will cause us to increase water intake. Over the course of a day or so we excrete the extra sodium and return to our old steady state level. The body has multiple afferent pathways to sense the effective fullness of the extracellular fluid volume to protect the organism from volume depletion or volume expansion. The end result of activation of these volume sensors is that signals are relayed to the kidney to regulate salt transport and urinary sodium excretion. There are sensors in both the arterial and venous systems that respond to the fullness of these spaces by responding to stretch to preserve volume homeostasis. Underfilling of the atria results in decreased afferent nerve activity to the hypothalamus and medulla causing an increase in sympathetic nerve activity.[49,50] Distention of the atria as occurs with volume expansion results in natriuresis secondary to an increase in afferent nerve traffic to the brain and a decrease in the afferent sympathetic nerve activity.[49,50] Distention of the atria also results in the release of atrial natriuretic peptide.[51] There is also a brain natriuretic peptide that is synthesized predominantly in the ventricles that produces natriuresis with ventricular distention, as occurs in congestive heart failure.[52]

Important to our survival are baroreceptors that sense volume depletion, located in the carotid sinus and aorta. Baroceptor activation results in an increase in sympathetic nerve activity, heart rate, activation of the renin-angiotensin system, and, if volume depletion is very severe, secretion of vasopressin. The kidney is able to autoregulate its perfusion pressure to maintain blood flow in response to hypoperfusion. This occurs by a myogenic reflex, as well as a tubuloglomerular feedback mechanism by which salt delivery to the macula densa of the thick ascending limb can affect afferent artery resistance to maintain glomerular filtration. Hypoperfusion of the kidney will result in renin secretion from the juxtaglomerular cells. There are also afferent volume sensors in the intestine and liver. Thus, the body has several systems in the arterial and venous side of the circulation to protect us from volume depletion.

REGULATION OF RENAL SODIUM TRANSPORT—EFFERENT LIMB

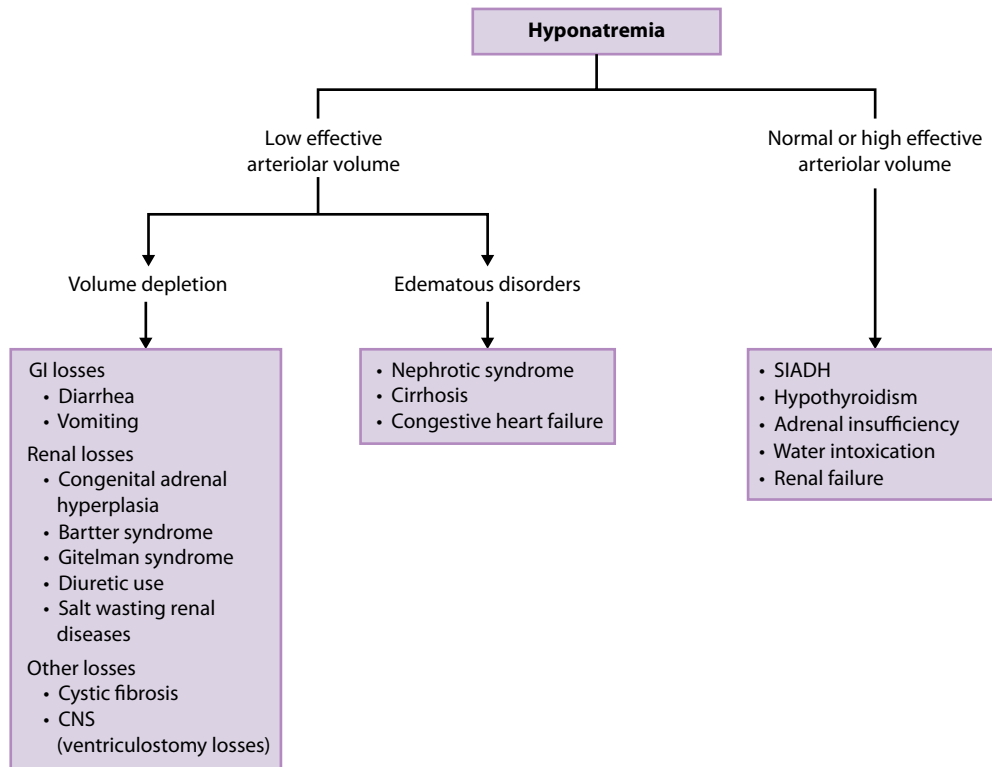
The kidney must regulate sodium reabsorption and excretion in the face of fluctuations in sodium intake or losses such as to maintain sodium homeostasis and defend against changes to the extracellular fluid volume. The afferent system described previously results in alterations in the renin-angiotensin-aldosterone system, sympathetic renal nerve activity, vasopressin secretion, and liberation of other factors that regulate tubular sodium reabsorption to balance sodium and water intake with urinary excretion. The kidney does this by regulating sodium absorption along the nephron. In addition to the kidney, sympathetic nerve activity and the renin-angiotensin system can affect cardiac output and vascular resistance. The changes in the major regulatory factors that occur in the face of a decrease in effective


Figure 11.4 Causes of hyponatremia.

arteriolar volume and volume expansion are shown in Figure 11.5A and 11.5B, respectively.

RENIN-ANGIOTENSIN SYSTEM

The systemic renin-angiotensin system plays an important role in regulation of proximal tubule sodium reabsorption. Renin is secreted by the kidney in response to a decrease in renal perfusion pressure to the juxtaglomerular cells of the afferent arteriole. In addition, the macula densa in the thick ascending limb responds to a decrease in luminal sodium as would be present in volume depletion, by stimulating renin secretion—a response known as tubular glomerular feedback. Third, an increase in renal nerve activity can increase renin secretion. Thus, a decrease in the effective arteriolar volume leads to an increase in plasma angiotensin II levels. angiotensin II preferentially vasoconstricts the efferent arteriole, resulting in an increase in filtration fraction modifying peritubular Starling forces, which will increase proximal

KEY POINT

With volume depletion there is an increase in angiotensin II, aldosterone, vasopressin, and sympathetic nerve activity to increase tubular transport of salt and water.

tubule reabsorption. The proximal tubule has angiotensin II receptors, and circulating angiotensin II can directly stimulate proximal tubule sodium reabsorption.[53] In addition to the systemic renin-angiotensin system, the proximal tubule contains all of the components of an autonomously functioning intrarenal renin-angiotensin system and secretes angiotensin II into the lumen at concentrations 100-fold higher than that found in the plasma. Both systemic and intraluminal angiotensin II stimulate proximal tubular sodium transport.[54]

RENAL NERVES

Sympathetic renal nerves innervate the glomerular capillaries and regulate filtration fraction. Sympathetic nerves also directly innervate the proximal tubule and regulate sodium homeostasis.[55,56] During volume contraction, there is an increase in renal nerve activity that stimulates proximal tubule transport. Conversely, renal nerve activity decreases during volume expansion, resulting in a decrease in transport by the proximal tubule. Renal nerves also increase renin secretion and thus contribute to raising systemic angiotensin II and aldosterone levels.

ALDOSTERONE

Aldosterone acts on the collecting tubule to increase sodium transport. The collecting tubule is responsible for only 1% to 3% of sodium absorption; however, because it is the last segment that transports sodium, it is critical for the final

modulation of salt transport. Aldosterone acts by increasing the trafficking of the epithelial sodium channel to the apical membrane of principal cells in the collecting tubule.[57] This will result in a lumen-negative potential difference, which will provide a driving force for potassium or proton secretion. Thus, hyperaldosteronism causes hypertension associated with a hypokalemic metabolic alkalosis. This is seen in Liddle syndrome, in which there is an increase in ENaC on the apical membrane secondary to an inherited defect in ENaC trafficking resulting in increase in apical membrane expression.[58]

VASOPRESSIN

Vasopressin levels are predominantly regulated by osmolality. However, under conditions of severely reduced effective arteriolar volume, vasopressin secretion is markedly enhanced. Vasopressin is a very potent vasoconstrictor that has direct effects on renal hemodynamics to increase the filtration fraction and secondarily proximal tubule reabsorption by affecting peritubular Starling forces. Vasopressin has a direct effect on the thick ascending limb and collecting duct to increase sodium reabsorption. Finally, vasopressin will increase the insertion of aquaporin 2, resulting in an increase in water absorption from the collecting duct.

COORDINATION OF REGULATORY PATHWAYS

Under conditions of severe volume contraction there is secretion of catecholamines, angiotensin II, vasopressin, and an increase in renal nerve activity. Left unabated, these factors would cause such intense vasoconstriction as to choke off renal perfusion and excessively reduce the GFR, potentially resulting in renal ischemia. The vasoconstriction would occur at a time when these hormones would be increasing transport and the need for ATP. This is a setup for acute kidney injury (AKI). However, angiotensin II, vasopressin, and catecholamine increase the renal production of prostaglandins. Prostaglandins have little role in regulating glomerular filtration or tubular transport under euvolemic or mild hypovolemia. Under severe volume contraction, prostaglandins are liberated, increasing renal blood flow and filtered sodium, causing vasodilatation of the efferent arteriole resulting in decrease in peritubular forces and decrease in proximal tubule transport . Prostaglandins have a direct effect inhibiting tubular NaCl transport by the thick limb and cortical collecting tubule. The importance of this buffering effect of prostaglandins under conditions of volume depletion is exemplified by the occurrence of AKI following administration of nonsteroidal anti-inflammatory agents (NSAIDs) to volume-contracted patients.[59]

In addition to the previously discussed factors that regulate transport, other hormones play a role. Endothelin inhibits renin release by juxtaglomerular cells.[60,61] Endothelin has a direct epithelial action to inhibit distal tubular salt transport,[62] Nitric oxide augments sodium excretion under conditions of volume expansion.[63] Atrial natriuretic peptide increases GFR and inhibits renin secretion.[64] Although atrial natriuretic factor does not directly inhibit proximal tubule transport, it blunts the effect of catecholamines and angiotensin II on proximal tubule transport.[65–68] Atrial natriuretic factor has a direct epithelial action to inhibit sodium and water transport by the collecting tubule.[69,70]

ASSESSMENT AND TREATMENT OF VOLUME AND SODIUM DISTURBANCES

VOLUME DEPLETION

The diagnosis and management of perturbations in the extracellular volume are an important part of medical care in pediatrics. Most pediatric patients who have volume depletion do so from vomiting and diarrhea. The severity of the problem can be ascertained by asking the frequency of fluid losses and the duration of time that this has been occurring. In children, extracellular volume depletion is quite common. Pertinent history and physical findings are outlined in Table 11.2, but it will be immediately apparent that assessment of volume status is quite crude. Most patients have a recent weight available that can be compared to the present weight that will give an idea of the degree of volume depletion. With mild volume depletion (3% to 5%), patients will be thirsty, have dry mucous membranes, and

Table 11.2 Historical and physical findings in extracellular volume depletion

Degree of dehydration	History	Physical findings
Mild (3%–5%)	• Thirst • Decreased urine output	• Dry mucous membranes
Moderate (6%–10%)	• Thirst • Decreased urine output • Change in mental status	• Dry mucous membranes • Sunken eyes • Sunken fontanelle • Postural hypotension • Tachycardia
Severe (>10%)	• Decreased urine output • Lethargy • Coma	• Dry mucous membranes • Sunken eyes • Sunken fontanelle • Poor perfusion— cool extremities • Hypotension • Tachycardia

have a decrease in urine output. More moderate degrees of volume depletion (6% to 10%) can result in poor skin turgor, with poor perfusion, sunken eyes or fontanelle, tachycardia and postural changes from decreased blood pressure, and irritability or listlessness. Severe volume depletion (>10%) is associated with lethargy or coma, hypotension, poor skin turgor, and sunken eyes or fontanelle.

Most, if not all, of the fluid losses that occur with acute volume depletion are due to losses from the extracellular fluid volume. The first goal in treating a patient with volume depletion is to stabilize the patient by administering a 10 mL/kg fluid bolus of normal saline. This may need to be repeated based on the severity of the volume depletion and the response to treatment. Once the patient's electrolytes, blood urea nitrogen (BUN), and creatinine have been stabilized, adjustments may be necessary in the subsequent fluids administered. However, most patients will have normal serum sodium levels or be hyponatremic. In patients with volume depletion, it is usually most appropriate to administer normal saline with the addition of potassium once ensuring that renal function is intact and the patient is not hyperkalemic.[1] Administration of hypotonic fluids can precipitate or worsen hyponatremia in the face of volume contraction where vasopressin levels may be elevated. Hypernatremic dehydration is rare, and the urine osmolality must be checked to rule out diabetes insipidus and correct the serum sodium slowly (see later discussion).

EDEMA FORMATION

Normally, the extracellular fluid volume correlates well with the effective arteriolar volume and an increase in one matches the other, resulting in natriuresis with volume overload. If excessive sodium intake is not matched by natriuresis, the patient is in positive sodium balance and eventually will become edematous. Edema formation can occur if there is primary sodium reabsorption by the kidney, as in acute glomerulonephritis, in which a factor is causing increased tubular sodium reabsorption. We do not know what this factor is, but hypertension, volume overload, and edema can occur even if the GFR is normal. Most edema formation occurs in the face of a decrease of an effective arteriolar volume. In nephrotic syndrome, cirrhosis, and congestive heart failure, sodium intake does not expand the effective arteriolar volume and Starling forces favor fluid distribution into the interstitial space. In nephrotic syndrome and cirrhosis the low oncotic pressure results in an imbalance of capillary fluid egress at the arterial end and fluid reabsorption at the venous end, resulting in expansion of the interstitial space. In congestive heart failure, there is increased venous pressure limiting fluid uptake at the venous end of the capillary. In these edematous disorders the effective arteriolar volume is reduced, resulting in the same response as seen with volume depletion that occurs in augmented renal tubular sodium transport.

> With volume depletion there is an increase in angiotensin II, aldosterone, vasopressin, and sympathetic nerve activity to increase tubular transport of salt and water.

HYPONATREMIA

Hyponatremia is defined as sodium concentration less than 135 mEq/L.[71] The serum sodium can be factitiously low if the blood is hyperlipidemic or hyperproteinemic and the specimen is measured by flame photometry. However, most modern laboratories measure sodium using ion-selective electrodes that eliminate this source of error. Hyperglycemia can cause a low serum sodium concentration because glucose is an osmotic agent that can cause a shift of water from the intracellular to the extracellular compartment and dilute the serum sodium concentration. For each 100 mg/dL of glucose in the serum above a normal level, the sodium will be lowered by 1.6 mEq/L. In contrast to the patient with true hyponatremia, these patients have a normal serum osmolality.

Three things are necessary to excrete free water and prevent or correct hyponatremia. To excrete free water (a hypotonic urine), there must be adequate delivery of fluid to the diluting segment, the diluting segment (thick ascending limb) must be functioning normally, and ADH) secretion must be suppressed. Problems in one or more of these three steps will result in the inability to excrete free water, which will either predispose the patient to develop hyponatremia or prevent the correction of hyponatremia. Some clinical conditions can interfere with the generation of hypotonic urine; these are outlined in Figure 11.4.

It is helpful to organize the differential diagnosis of hyponatremia based on the volume status of the patient. The most common cause for the inability to excrete free water in children is intravascular volume depletion. This is usually associated with total body volume depletion, but, as shown in Figure 11.4, hyponatremia also can be seen in patients with edema who have decreased effective arteriolar volume resulting from congestive heart failure, cirrhosis, and nephrotic syndrome. During effective arteriolar volume contraction the GFR decreases and the proximal tubule responds to volume contraction by reabsorbing a larger fraction of the filtered load of salt and water. This greatly diminishes the distal delivery of tubular fluid to the thick ascending limb, which is necessary for generating a concentrated medulla. In addition to the decreased distal delivery of fluid to the diluting segment, vasopressin will be secreted if there is significant decrease in effective arteriolar volume resulting in concentrated urine (Figure 11.5A). Finally, volume depletion causes thirst, which leads to the excessive ingestion of hypotonic fluid despite hyponatremia. Extracellular volume expansion,

on the other hand, induces adaptations that result in urinary excretion of sodium and water in an attempt to restore the euvolumic state (see Figure 11.5B). Administration of thiazide and loop diuretics such as furosemide is a frequent cause of hyponatremia. In addition to causing sodium loss and decreasing the effective arteriolar volume, they also inhibit transporters responsible for free water generation.

Newborn infants are predisposed to hyponatremia because of their low GFR and consequent low distal delivery of fluid to the diluting segment. If the parent inappropriately dilutes the formula, the infant never becomes satiated and will ultimately take in excessive amounts of hypotonic fluid. Thus, the intake of water will exceed the ability to excrete the free water even though the diluting system is intact and the urine osmolality in a neonate can be as low as in adults (50 mOsm/kg water).

Inappropriate secretion of antidiuretic hormone.

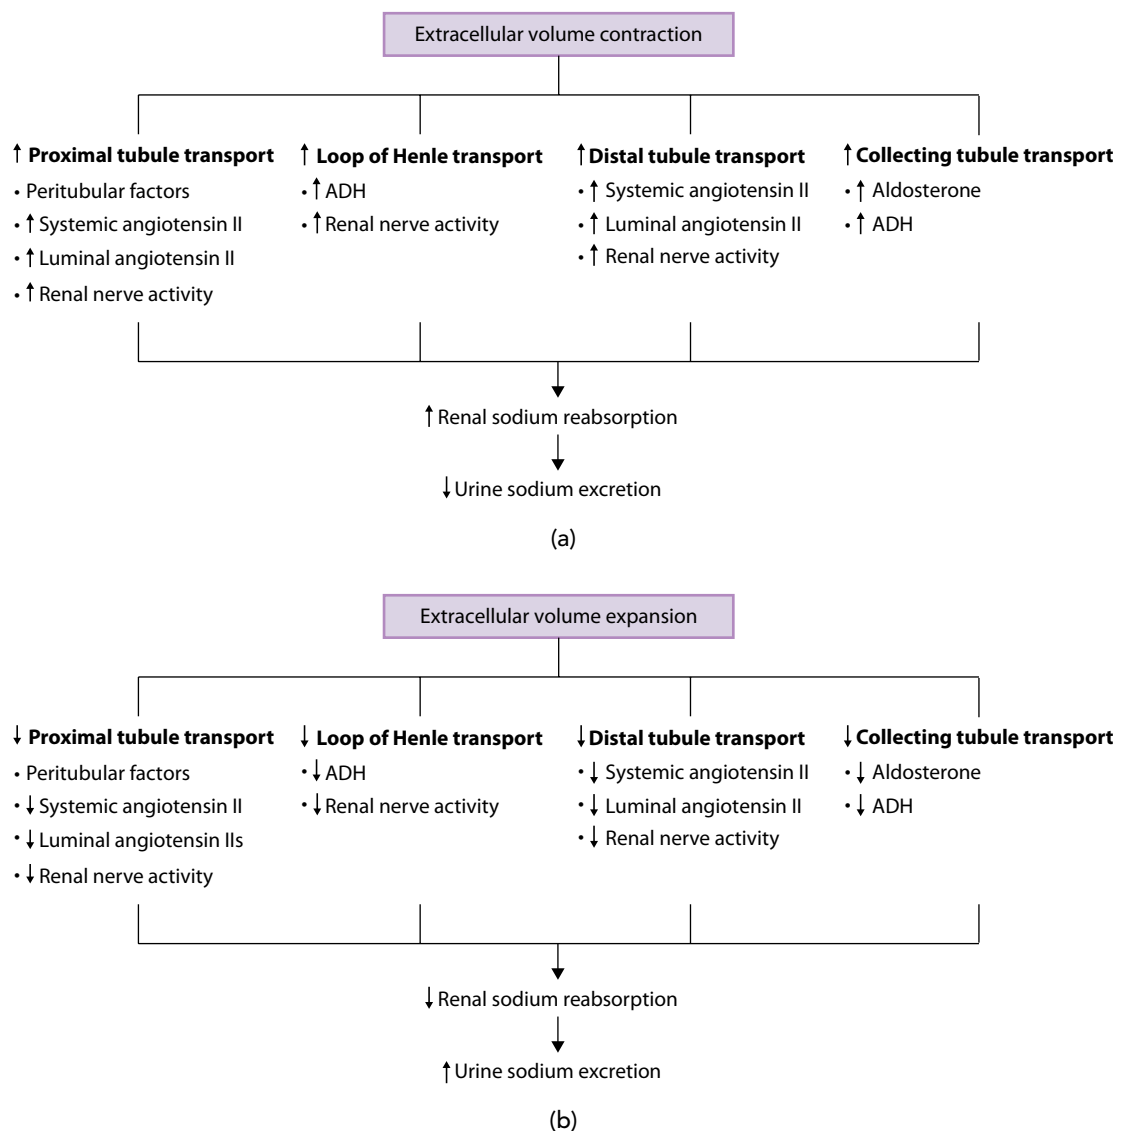
The syndrome of inappropriate antidiuretic hormone (SIADH) can be due to a number of causes, including carcinomas, pulmonary disorders, increased intracranial pressure, and drugs. Carbamazepine, cyclophosphamide, vincristine, chlorpropamide, narcotics, antipsychotics, antidepressants, and NSAIDs are the drugs most frequently associated with SIADH. The elevated levels of vasopressin lead to the excretion of concentrated urine despite the hypo-osmolality of the serum. The retention of free water leads to hyponatremia and inability to excrete free water to correct the hyponatremia. At the onset of SIADH, the urine osmolality may be quite high, but with time the osmolality can decrease to near isotonic levels.


Figure 11.5 Renal response to extracellular volume depletion **(a)** and extracellular volume expansion **(b)** are shown. The kidney acts to conserve sodium during states of volume contraction and excrete sodium when there is expansion of the effective arteriolar volume to maintain a constant extracellular fluid volume.

However, the urine is still inappropriately concentrated for the degree of hypo-osmolality. The volume status of these patients is usually normal or slightly elevated. As a result, their BUN and serum uric acid concentrations are usually low and the fractional excretion of sodium (a reflection of the increased effective arteriolar volume status) is usually high. However, occasional patients have SIADH and are volume contracted for other reasons, so a low fractional excretion of sodium does not rule out SIADH. The mainstay of treatment for SIADH is fluid restriction. Ultimately, the cause of SIADH needs to be determined and treated. In some cases, SIADH may become a chronic condition and tolvaptan should be considered (see later discussion).

KEY POINT

Patients with SIADH are usually euvolemic or slightly volume expanded and should be treated with fluid restriction.

Treatment of hyponatremia

The treatment of hyponatremia depends on the specific cause and whether the hyponatremia is of acute onset or chronic. Hyponatremia can cause altered mental status, headache, nausea, vomiting, muscle cramps, or seizure. If the patient is having a seizure, hypertonic saline is usually indicated. An increase in serum sodium of only 1 to 3 mEq/L is usually adequate to arrest the seizure activity. For purposes of correction, the amount of sodium to be administered is calculated by the following equation:

$$\text{Na Deficit} = [\text{Na}_{\text{Desired}} - \text{Na}_{\text{observed}}] \times [(\text{Weight in Kg}) \times (0.6)]$$

where $\text{Na}_{\text{Desired}}$ is the desired serum sodium value and $\text{Na}_{\text{Observed}}$ is the actual measured sodium. Administration of 1 to 2 mL/kg of 3% saline with a maximum of 100 mL in an adult will usually stop seizure activity secondary to hyponatremia.[1,72] The serum sodium should never be increased faster than 12 mEq/L in 24 hours or 18 mEq/L in 48 hours because of the risk for developing central pontine myelinolysis or osmotic demyelination syndrome.[72]

The recommendation to administer sodium versus fluid restriction will hinge primarily on the volume status of the patient. If the patient has volume depletion from gastrointestinal or other losses, the volume deficit must be replaced to replenish the patient's extracellular fluid volume, usually with normal saline. After appropriate volume expansion, the patient will be able to regulate free water excretion to correct the serum sodium concentration.

Treatment of patients with euvolemic or hypervolemic hyponatremia is more complex. Patients with SIADH as the cause of hyponatremia need to be fluid restricted. In general, administration of isotonic saline to patients with SIADH will not be beneficial, because most patients are euvolemic or hypervolemic and will retain water and excrete salt, which can worsen the problem. Fluid restriction remains the treatment of choice unless they are having acute neurologic symptoms. Patients with edematous states, such as in congestive heart failure, cirrhosis, or nephrotic syndrome, should be fluid restricted. Sodium administration to patients with edematous disorders will worsen their edema and may precipitate pulmonary edema in those with cardiovascular disorders. Diuretics will result in the excretion of hypotonic urine, which can be replaced with isotonic normal saline to increase the serum sodium concentration.

Vaptans, which are vasopressin receptor (V_2) antagonists, have been used in the treatment of chronic symptomatic hyponatremia. These agents are effective in increasing free water excretion and result in an increase in serum sodium levels.[73–75] Side effects from vaptans include polyuria and thirst. Very few data are available on the use of vaptans in children, and these agents have not been tested and thus cannot be recommended in the treatment of acute symptomatic hyponatremia. However, they may have a role in the treatment of chronic symptomatic hyponatremia secondary to chronic SIADH, congestive heart failure, or cirrhosis in children as in adults.

HYPERNATREMIA

Outside of the neonatal period, hypernatremia is a rare electrolyte disturbance. When we consume a salty meal, we feel thirsty and will consume enough water to normalize the serum osmolality. Although the kidney can concentrate urine to retain free water,[76] the body's primary defense against hypernatremia is thirst. Very small changes in the serum sodium concentration (and therefore in serum osmolality) result in signals from the thirst center in the hypothalamus to consume water to normalize the serum sodium. Thus, when evaluating a patient with hypernatremia, it is necessary to determine if the thirst center is intact or why the patient did not have access to water.

The concentrating ability of the kidney depends on three major factors: (1) The ability of the hypothalamus and pituitary to synthesize and secrete ADH or vasopressin; (2) the ability of the kidney to generate an osmotic gradient across the collecting duct; and (3) the ability of the collecting duct to respond to ADH. Thus, the inability to maximally concentrate the urine may be due to a defect in one or more of these factors. However, patients who have a defect in the urinary concentrating mechanism will have a normal serum sodium concentration and osmolality as long as they are able to drink water to replace the urinary loss of free water.

Some disorders can impair the kidney's ability to concentrate urine. With *diabetes insipidus* there is either a defect in the production of vasopressin, termed *central diabetes insipidus,* or an inability of the kidney to respond to vasopressin, termed *nephrogenic diabetes insipidus.* A water deprivation test can determine whether a patient has diabetes insipidus

and whether it is central or nephrogenic. Water is withheld for a period until either the urine osmolality increases significantly or there is a rise in the serum sodium concentration with no change in the urine osmolality. If the urine osmolality increases significantly, the patient has primary polydipsia. If the patient's serum sodium increases and the urine osmolality remains hypotonic, the patient has diabetes insipidus. To determine if this is due to a central or renal defect, vasopressin is administered. An increase in the urine osmolality with vasopressin indicates that the patient has central diabetes insipidus. It should be pointed out that patients who present with hypernatremia have already been water deprived. At presentation, the urinary osmolality always should be measured to determine if the patient has a urinary concentrating defect. This will obviate the need to perform the water deprivation test in the future. The osmolality should be measured, not the specific gravity. The specific gravity is determined by the weight of solutes in solution, whereas osmolality is determined by the number of particles in solution. So if there is a small amount of protein or glucose, for example, the specific gravity will be very high even if the osmolality of the urine is low. With osmolality, a molecule of protein counts the same as that of glucose or sodium and it is thus a true measure of the number of particles in solution.

Central diabetes insipidus

Central diabetes insipidus usually results from trauma to the pituitary or a tumor in the hypothalamus or pituitary. Trauma can sometimes be due to neurosurgical procedures. Rarely, central diabetes insipidus is congenital. Some patients with holoprosencephaly have defects in the secretion of vasopressin. Central diabetes insipidus also can be seen with global dysfunction of the pituitary, the panhypopituitary syndrome. The treatment of central diabetes insipidus is to replace vasopressin, usually with DDAVP.

Nephrogenic diabetes insipidus

Nephrogenic diabetes insipidus results from defects in the collecting duct that prevent the normal response to vasopressin. It can be congenital or acquired. The most common inherited defect is due to a mutation in the vasopressin receptor (V2R) in the collecting duct. Most patients with congenital nephrogenic diabetes insipidus are male because the gene encoding the V2 receptor is on the X chromosome. Patients with nephrogenic diabetes insipidus usually present in the neonatal period with dehydration and fever from the urinary loss of free water. Females rarely can have nephrogenic diabetes insipidus secondary to a mutation in the vasopressin receptor as a result of unequal lyonization. Inherited defects in the AQP2 water channel also have been described. Most of these defects are inherited in the autosomal recessive fashion, but there have been mutations with autosomal dominant transmission.

Nephrogenic diabetes insipidus also can result from an acquired lesion. Obstructive uropathy can damage the cortical collecting duct to the extent that the collecting duct does not respond to vasopressin. Drugs such as lithium, amphotericin, and demeclocycline can impair the effect of vasopressin on the collecting duct. Other causes of acquired nephrogenic diabetes insipidus include hypokalemia and hypercalcemia.

Treatment of hypernatremia

The principal treatment of hypernatremia is to provide enough free water to correct the elevation in serum sodium concentration. The amount of water needed is known as the "free water deficit" and is calculated by the following equation:

$$Free\ water\ deficit(Liters) = \left[\frac{Na_{Observed} - Na_{Desired}}{Na_{Desired}}\right] \times \left[(Weight\ in\ kg) \times (0.6)\right]$$

where $Na_{Desired}$ is the serum sodium value to be achieved and $Na_{Observed}$ is the actual measured sodium. This calculation will give the free water deficit in liters. The serum sodium should be corrected by less than 15 mEq/L per day. Lowering the serum osmolality too quickly will result in cerebral edema with permanent neurologic sequela and potentially death.

One of the difficulties in treating hypernatremic dehydration is determining if the patient has an extracellular fluid volume deficit. Patients with hypernatremic dehydration may appear more volume replete than they actually are. If there was a history of vomiting or diarrhea, the patient may need to receive an isotonic fluid bolus before receiving the free water replacement. Once the extracellular fluid space is expanded, the kidney will be able to excrete the excess sodium. Again, this needs to be done carefully so that the patient's serum sodium does not decrease too rapidly and the patient does not become fluid overloaded.

SUMMARY

Regulation of fluid balance and electrolyte composition by the kidneys is essential for preserving the internal milieu of the body. Our understanding of the various aspects of ionic and water transport in the tubular cells of the kidney has been exponentially increasing in the last two decades. Discovery of aquaporins, or water channels in the cells, especially in the kidney, has further established mechanisms of movement of water across cellular barriers. A clear understanding of the vasopressin receptors (V_2) led to the development of vasopressin receptor (V_2) antagonists (vaptans), which are useful in the treatment of chronic symptomatic hyponatremia. Apart from this, a clear understanding of fluid and electrolyte requirement of sick infants and children is relevant from the clinical practice perspective of a pediatrician and pediatric nephrologist. This chapter has attempted to provide a basic outline of the scientific principles that guide clinical management of disorders of sodium and water homeostasis.

Clinical Vignette 11.1

A 6-month-old child was evaluated by his pediatrician and found to be in good health. The child is exclusively breast fed and has been growing at the 50th percentile for height and weight. Three days after his well-child care visit the child developed profuse diarrhea. The mother continues to breast feed the child; however, after 2 days of diarrhea the mother notes that the child is listless and has a decrease in urine output. She was instructed to go to a local emergency room, where the child looks somewhat lethargic and has sunken eyes although the extremities remain warm and well perfused with good capillary refill. Electrolytes reveal that the child has a serum sodium level of 128 mEq/L, potassium of 5.0 mEq/L, chloride of 111 mEql/L, bicarbonate of 10 mEq/L, BUN of 30 mg/dL, and creatinine of 1.0 mg/dL. Urine was obtained that shows a fractional excretion of sodium of 0.5%.

TEACHING POINTS

- The patient has hyponatremic dehydration and likely has prerenal azotemia. This is acute dehydration, so essentially all of the volume depletion is from the extracellular fluid volume.
- Multiple homeostatic mechanisms come into play to preserve the extracellular fluid volume. There is an increase in plasma angiotensin II, vasopressin, aldosterone, and renal sympathetic nerve activity, which augments renal tubular salt and water absorption. The high ratio of BUN to creatinine and the low fractional excretion of sodium are consistent with prerenal azotemia, and it is unlikely that severe tubular injury is present.
- The hyponatremia is due the mother feeding the child breast milk, which is hypotonic, and the fact that the volume depletion is severe enough to cause the liberation of vasopressin (ADH), which increases water absorption in the collecting tubule.
- Several findings on physical examination suggest that this patient is approximately 6% to 10% volume depleted. The patient has sunken eyes and is somewhat lethargic. However, all of the physical findings used to assess volume depletion are rather inaccurate. The most accurate way of determining the severity of this child's volume depletion is by comparing the weight at presentation with the weight of the child during the most recent examination by the pediatrician.
- The fluid that should be administered is normal saline. This will expand the extracellular fluid volume and help correct the hyponatremia. The child should be receive at least 10 to 20 mL/kg of normal saline, followed by enough saline to replete the child's volume depletion in addition to maintenance fluids.
- Electrolytes, BUN, and creatinine should be monitored frequently and potassium added to the intravenous fluids once it decreases to the normal range and the BUN and creatinine fall.

REVIEW QUESTIONS

1. Which nephron segment reabsorbs salt but not water?
   a. Thick ascending limb
   b. Proximal tubule
   c. Cortical collecting duct
   d. Thick descending limb
   e. None of the above

2. A patient with congestive heart failure has intractable hyponatremia. Which drug should be considered in the management?
   a. A nonsteroidal anti-inflammatory agent
   b. Morphine
   c. Tolvaptan
   d. Vasopressin
   e. Dexamethasone

3. In comparison to the adult kidney, the neonatal kidney is characterized by:
   a. Fewer glomeruli
   b. Fewer tubules
   c. Inability to dilute urine
   d. Inability to concentrate urine
   e. None of the above
4. A neonatal patient presents with a serum sodium of 154 mEq/L. You suspect diabetes insipidus. Your initial evaluation should include all of the following *except:*
   a. A family history
   b. Determination of how the child is fed
   c. A water deprivation test
   d. A urine osmolality
   e. An assessment of volume status of the child

5. Which statement about the collecting tubule is *incorrect*?
   a. It is responsive to aldosterone.
   b. It is responsive to vasopressin.
   c. It reabsorbs 1% to 3% of the filtered sodium.
   d. It has a lumen positive potential difference.
   e. It has an apical epithelial sodium channel.

Potassium homeostasis

CAROLINE GLUCK AND LISA M. SATLIN

Potassium (K^+) is the most abundant intracellular cation. Approximately 98% of the total body K^+ content in the adult is located within cells, primarily muscle, where its concentration ranges from 100 to 150 mEq/L. The remaining 2% of the total body K^+ content resides in the extracellular fluid (ECF). In the ECF, the K^+ concentration, generally ranging from 3.5 to 5.0 mEq/L in the adult, is tightly regulated by mechanisms that govern the *internal* distribution between the intracellular fluid (ICF) and EFC compartments and *external* balance between intake and output via the kidney and gastrointestinal (GI) tract.

The steep K^+ and sodium (Na^+) concentration gradients across cell membranes are maintained by the Na-K-adenosine triphosphatase (Na-K-ATPase), an enzyme present on the surface of essentially all eukaryotic cells that pumps three Na^+ ions out and two K^+ ions into the cell for each molecule of adenosine triphosphate (ATP) hydrolyzed. The unequal cation exchange ratio of the pump creates an electrical gradient across the cell membrane that determines, in large part, the resting membrane potential, which typically ranges from −30 mV to −70 mV (cell interior negative) in most mammalian cells. Pump activity is essential for normal cellular function and, in particular, is critical for the regulation of protein and glycogen synthesis, cell volume, intracellular pH, resting membrane potential, and thus muscle excitability and cardiac function.

POTASSIUM HOMEOSTASIS

The homeostatic goal of the adult is to remain in zero K^+ balance. To this end, approximately 90% to 95% of the typical daily K^+ intake of 1 mEq/kg body weight is ultimately eliminated from the body in the urine; the residual 5% to 10% of the daily K^+ load is lost through the stool. Normally, the amount of K^+ lost through sweat is negligible.

In contrast to the adult, infants older than approximately 30 weeks of gestation must maintain a state of positive K^+ balance.[1,2] Net retention of K^+ is necessary to ensure the availability of adequate substrate for the increase in cell number and K^+ concentration, at least in skeletal muscle, with advancing age.[3–5] The tendency to retain K^+ early in postnatal life is reflected in the observation that plasma K^+ concentrations in infants (>5 mEq/L), and particularly in premature newborns (>5.5 mEq/L), tend to be higher than in children.[1,2,6,7]

REGULATION OF POTASSIUM BALANCE BY DIETARY INTAKE AND REDISTRIBUTION

The daily dietary intake of K^+ in the adult generally approaches or exceeds the total K^+ normally present within the ECF space, which in an individual with an ECF volume of 12 to 14 L and serum K^+ concentration of 4 to 5 mEq/L, is approximately 50 to 70 mEq. Approximately 85% of ingested K^+ is reabsorbed by the gut in the adult.[8] The urinary excretion of an oral K^+ load is sluggish, with only 50% of the K^+ eliminated within the first 4 to 6 hours[9]; thus, it can be envisioned that the acute ingestion of 40 mEq of K^+ (as may be present in a quart of orange juice) could, if retained exclusively in the ECF compartment, nearly double the plasma K^+ concentration and lead to potentially serious consequences.[9] However, life-threatening hyperkalemia is not generally observed during this interval because of the

rapid (within minutes) hormonally mediated translocation of most of the ingested K+ into cells, particularly muscle and liver, a response mediated by the Na+-K+-ATPase.[9]

The hormonal, as well as other chemical and physical factors that acutely influence K+ redistribution, are listed in Table 12.1.

RENAL REGULATION OF POTASSIUM BALANCE

The three processes involved in renal K+ handling include filtration, reabsorption, and secretion. K+ filtered at the glomerulus is reabsorbed almost entirely in proximal segments of the nephron, whereas urinary K+ excretion, at least in the adult, is accomplished by K+ secretion in the distal segments of the aldosterone-sensitive distal nephron (ASDN) (Figure 12.1).

KEY POINT

Net urinary K+ excretion is accomplished by K+ secretion in the ASDN.

It is now well established that the neonatal kidney contributes to K+ retention early in life. In newborns, the renal K+ clearance is low, even when corrected for the prevailing low glomerular filtration rate (GFR).[1] The rate of K+ excretion expressed per unit body or kidney weight in infants and young animals subject to exogenous K+ loading is less than that observed in older subjects.[10] However, in response to exogenous K+ loading, infants like adults can excrete K+ at a

rate that exceeds its rate of filtration, indicating the capacity for net tubular secretion.[10] In a longitudinal prospective study of premature infants, the fractional excretion of K+ fell by half between 26 and 30 weeks of gestation, a postnatal change that was not accompanied by a significant change in absolute urinary K+ excretion.[1] Given that the filtered load of K+ increased almost three-fold during this same time interval, the constancy of renal K+ excretion was attributed to a developmental increase in the capacity of the kidney for K+ reabsorption.[1]

Sites of potassium transport along the nephron

K+ is freely filtered at the glomerulus. Studies in both suckling and adult rats indicate that approximately 65% of the filtered load of K+ is reabsorbed along the proximal tubule (Figure 12.2).[11–15] Reabsorption is passive in this segment, closely following reabsorption of filtered Na+ and water. Only approximately 10% of the filtered load of K+ reaches the early distal tubule of the adult, indicating that a significant amount of K+ is reabsorbed in the intervening segments, specifically across the thick ascending limb of the loop of Henle (TALH).[11] In contrast, up to 35% of the filtered load of K+ reaches the distal tubule of the newborn rat.[12] These observations suggest that postnatal maturation of the TALH is characterized by a developmental increase in its capacity for K+ reabsorption, a notion supported by the findings that both the diluting capacity and TALH Na-K-ATPase activity increase after birth.[14,15]

K+ reabsorption in the TALH is mediated by an Na-K-2Cl cotransporter (NKCC2), located on the apical (urinary) membrane, that translocates one K+ ion into the cell accompanied by one Na+ and two chloride (Cl−) ions. Transporter activity is ultimately driven by the basolateral Na+-K+-ATPase, which generates and maintains a low intracellular Na+ concentration and thus a chemical gradient favoring Na+ entry at the apical membrane. Diuretics such as furosemide and bumetanide that inhibit this Na-K-2Cl cotransporter block K+ (as well as Na+) reabsorption at this site and uncover K+ secretion, leading to profound urinary K+ losses (see later discussion of Bartter syndrome).

NKCC2 activity requires the presence of an apical K+ secretory channel, encoded by the *ROMK* (*r*at *o*uter *m*edullary *K* channel) gene, to recycle K+ across this membrane, thus ensuring an abundant supply of substrate for the cotransporter.[11,16,17] Loss-of-function mutations in *ROMK* lead to antenatal Bartter syndrome (type 2), also known as the hyperprostaglandin E syndrome, which is characterized by severe renal salt and fluid wasting, consistent with a pattern of impaired TALH function.[18]

Under baseline conditions in the adult, K+ secretion in the ASDN, which includes the distal and connecting tubules and cortical collecting duct (CCD), contributes prominently to urinary K+ excretion.[11] In contrast to the

Table 12.1 Factors involved in the regulation of potassium balance

Figure 12.1 Distribution of potassium (K⁺) in the body. Most of K⁺ is located in body cells. Note entry of K⁺ into the small intestine, where it is extensively reabsorbed. K⁺ may be secreted in the colon. The exit of K⁺ from the body is mediated by the kidney and, to a lesser extent, the colon. The distribution of K⁺ between extracellular fluid and intracellular fluid is dependent and regulated by a pump-leak mechanism involving both Na⁺-K⁺-ATPase and membrane K channels. Several factors modify cell K⁺ (see box with brown outline in the diagram). (Reproduced with permission from: Giebisch G, Krapf R, Wagner C. Renal and extrarenal regulation of potassium. Kidney Int. 2007;72:397–410.)

high rate of K⁺ secretion measured in CCDs of adult rabbits and perfused at physiologic flow rates in vitro, segments isolated from neonatal animals show no significant net K⁺ transport until after the third week of postnatal life.[19] By 6 weeks of age, after weaning, the rate of net K⁺ secretion in the CCD is comparable to that observed in the adult.[19] These results indicate that the low rates of K⁺ excretion characteristic of the newborn kidney are due, at least in part, to a low K⁺ secretory capacity of the CCD.

The CCD comprises two cell populations. Principal cells are considered to reabsorb Na⁺ and secrete K⁺, whereas intercalated cells primarily function in acid-base homeostasis but can reabsorb K⁺ in response to dietary K⁺ restriction or metabolic acidosis.[20] The direction and magnitude of net K⁺ transport in the ASDN represents the balance of K⁺ secretion and absorption, opposing processes proposed to be mediated by these two cell types.

TUBULAR POTASSIUM SECRETION

K⁺ secretion by principal cells in the CCD is accomplished by a two-step process. First, K⁺ is actively taken up into the cell at the basolateral membrane in exchange for Na⁺, a process mediated by the Na-K-ATPase. The high intracellular K⁺ concentration and lumen-negative voltage within this nephron segment, generated by apical Na⁺ entry across the epithelial Na⁺ channel (ENaC) and its electrogenic basolateral extrusion, create an electrochemical gradient that favors the passive diffusion of cell K⁺ into the luminal fluid through apical K⁺-selective channels. The small conductance secretory K⁺ (SK) channel, encoded by the *ROMK* gene, is considered to mediate baseline constitutive K⁺ secretion in this nephron segment.[11,21] A high conductance, stretch- and calcium (Ca²⁺)-activated BK (or maxi-K) channel, detected functionally in both principal and intercalated cells, mediates flow-stimulated K⁺ secretion.[21–24] In sum, K⁺ secretion in the CCD requires Na⁺ absorption (to establish a favorable electrochemical gradient) and the presence of K⁺ selective channels in the urinary membrane. Any factor that enhances the electrochemical driving force, such as an increase in tubular flow rate after administration of diuretics, or increases the apical membrane permeability to K⁺ will favor K⁺ secretion.

The limited capacity of the neonatal CCD for baseline net K⁺ secretion appears not to be due to an unfavorable electrochemical gradient.[15,25,26] Cumulative evidence now
Figure 12.2 A diagramatic representation of K+ transport along the nephron. Once filtered by the glomeruli, K+ undergoes extensive reabsorption and secretion in the renal tubules. K+ is actively secreted in the cortical collection tubules (large arrow). K+ reabsortion occurs in the proximal, as well as in the ascending, limb of the loop of Henle. Some of the reabsorbed K+ is returned to the descending limb of the loop of Henle via the medullary interstitial recycling. Also shown are the two cell types lining the distal tubule and cortical collecting duct. ATP, adenosine triphosphate; ASDN, aldosterone-sensitive distal nephron; ENaC, epithelial Na+ channel; H-K-ATPase, hydrogen, potassium, adenosine triphosphatase; MR, mineralocorticoid receptor; NCC, Na-Cl cotransporter; NKCC, Na-K-2Cl cotransporter; ROMK, rat outer medullary K+ channel; SK, = secretory K+ (channel).

suggests that the postnatal increase in CCD K+ secretory capacity is due to developmental increases in number of apical SK and BK channels, reflecting postnatal upregulation of transcription and translation of functional channel proteins.[27–30]

KEY POINTS

- K+ secretion in the distal nephron requires Na+ absorption (to establish a favorable electrochemical gradient) and the presence of K+-selective channels in the urinary membrane.
- Any factor that enhances the electrochemical driving force or increases the apical membrane permeability to K+ will favor K+ secretion.

Tubular potassium absorption

The distal nephron of K+-depleted adults may reabsorb K+ via a hydrogen (H+), potassium, adenosine triphosphatase

(H-K-ATPase), present at the apical membrane of acid-base transporting intercalated cells, that exchanges a single K+ (absorption) for a proton (secretion). Significant activity of the apical H-K-ATPase exists in neonatal intercalated cells, suggesting that the ASDN is poised to retain urinary K+ early in life.[31] As stated earlier, clearance studies in premature infants younger than 30 weeks gestational age suggest a developmental increase in the capacity of the kidney for K+ reabsorption.[1] Similar studies in saline-expanded dogs provide indirect evidence for a diminished secretory and enhanced reabsorptive capacity of the immature distal nephron to K+.[32]

LUMINAL AND PERITUBULAR FACTORS REGULATING RENAL POTASSIUM TRANSPORT

Sodium delivery and absorption

The magnitude of Na+ absorption in the ASDN determines the electrochemical driving force for K+ diffusion from the cell into the lumen (i.e., secretion). The dependence of K+

secretion on distal Na+ delivery becomes evident at tubular fluid Na+ concentrations of less than 30 mEq/L, a value below which K+ secretion falls sharply.[33,34] In vivo measurements of the Na+ concentration in distal tubular fluid generally exceed 35 mM both in adult and suckling rats and thus would not be expected to limit distal K+ secretion.[35]

<div style="border: 1px solid purple;">

KEY POINTS

- K+ secretion in the distal nephron can be enhanced by increasing distal delivery of Na+ or nonreabsorbable anions (e.g., in diabetic keto-acidosis [DKA]), increasing urinary flow rate (e.g., by loop diuretics), activation of the renin-angiotensin-aldosterone system, or a combination of these.
- The normal kidney can reduce urinary K+ excretion to a minimum of approximately 10 mEq/day (vs. urinary Na+, which can be reduced to zero).

</div>

Extracellular volume expansion or administration of many diuretics (osmotic diuretics, carbonic anhydrase inhibitors, loop and thiazide diuretics) is accompanied by an increase in urinary excretion of both Na+ and K+. The kaliuresis is mediated not only by the increased delivery of Na+ to the distal nephron, but also by the drug-induced increase in tubular fluid flow rate, which maximizes the chemical driving forces favoring K+ secretion, and activates the BK channel in the ASDN. K+-sparing diuretics, such as amiloride and triamterene, block distal Na+ reabsorption, which reduces the electrical potential gradient favoring K+ secretion.

Na+ delivered to the distal nephron is generally accompanied by Cl−. Cl− reabsorption, which occurs predominantly via the paracellular pathway, tends to reduce the lumen negative potential that would otherwise favor K+ secretion. When Na+ is accompanied by an anion less reabsorbable than Cl−, such as bicarbonate (HCO_3^-) (as in proximal renal tubular acidosis [RTA]; see later), β-hydroxybutyrate (in DKA) or carbenicillin (during antibiotic therapy), luminal electronegativity is maintained, thereby eliciting more K+ secretion than occurs with a comparable Na+ load delivered with Cl−.

Tubular fluid (urinary) flow rate

K+ secretion in the CCD of the adult is strongly stimulated by an increase in urinary flow rate, as follows volume expansion or administration of diuretics. The faster the urinary flow rate in the distal nephron, the slower is the rate of rise of tubular fluid K+ concentration as secreted K+ is rapidly diluted in urine of low K+ concentration. Maintenance of a relatively low tubular fluid K+ concentration maximizes the K+ concentration gradient and thus chemical driving force

favoring net K+ secretion. The electrical gradient favoring K+ secretion is further enhanced at fast tubular fluid flow rates by the flow-stimulated increase in ENaC-mediated Na+ absorption.[19,34,36] Finally, increases in luminal flow rate transduce mechanical signals, including circumferential stretch, into increases in cell Ca^{2+} concentration, which in turn, activate apical BK channels.[22]

Extracellular potassium and potassium intake

An increase in extracellular K+ concentration stimulates K+ secretion by its direct effect on stimulating (1) basolateral Na-K-ATPase–mediated uptake of K+ and (2) aldosterone and insulin secretion.[9,37] However, the changes in plasma K+ concentration and circulating levels of aldosterone following ingestion of a regular meal are relativity insignificant.[38,39] Recent studies provide evidence for a gut factor activated by dietary K+ that increases the renal excretion and extrarenal disposal of K+, independent of plasma K+ concentration.[40]

The adult kidney responds to an increase in K+ intake with an increase in urinary K+ excretion within approximately 1 to 2 days.[41] The adaptation to a high-K+ diet is associated with a rapid (within 6 hours) increase in density of conducting apical SK/ROMK channels in the CCD.[42] Apical ENaC and basolateral Na-K pump activity also increase under these same conditions, changes expected to enhance the electrochemical gradient favoring K+ secretion.[42] Chronic K+ loading also leads to an increase in BK channel protein expression and function in the distal nephron.[43]

Dietary K+ restriction leads to a fall in urinary K+ excretion, an adaptation associated with a reduction in number of active SK/ROMK and BK channels at the apical membrane[42,45] and stimulation of H-K-ATPase–mediated K+ reabsorption by intercalated cells in the ASDN.[42–46] Stimulation of H-K-ATPase activity in intercalated cells results not only in K+ retention, but also urinary acidification and metabolic alkalosis.

Acid-base status

Disorders of acid-base homeostasis can alter urinary K+ excretion. In acute metabolic acidosis, the net movement of H+ ions into cells from the ECF is associated with the movement of K+ out of the cells, resulting in hyperkalemia. Acidosis leads to a reduction in urine pH, which in turn inhibits apical SK/ROMK channel activity.[47,48] The net effect is a fall in urinary K+ excretion.[49] In chronic metabolic acidosis, K+ secretion is influenced by modifications of the glomerular filtrate (e.g., Cl− and HCO_3^- concentration), tubular fluid flow rate, and circulating aldosterone levels and thus has variable effects on urinary K+ excretion.

Both acute respiratory alkalosis and metabolic alkalosis result in increases in urine pH and K+ excretion. The alkalosis-induced stimulation of K+ secretion reflects two direct effects on principal cells: (1) stimulation of basolateral K+ uptake and (2) an increase in the permeability of the apical membrane to K+ as a result of an increase in activity of SK/ROMK channels.[11]

Mineralocorticoids

It is well established that aldosterone stimulates K+ secretion in the fully differentiated CCD. This effect of adrenal steroids is considered to be due primarily to an increase in the electrochemical driving force favoring K+ exit across the apical membrane, generated by stimulation of apical Na+ entry and reabsorption.[44]

Aldosterone action requires its initial binding to the mineralocorticoid receptor, followed by translocation of the hormone-receptor complex to the nucleus, where specific genes are stimulated to code for physiologically active proteins. Cellular effects within the fully differentiated CCD include increases in the density of active ENaC channels, as a result of recruitment of intracellular channels to the apical membrane, de novo synthesis of ENaC subunits, and activation of preexisting channels.[50–52] Aldosterone also stimulates Na-K-ATPase activity through both recruitment of intracellular pumps and increased total amounts of Na pump subunits.[53] The net effect of these actions is the stimulation of net Na+ absorption, leading to an increase in the electrochemical gradient facilitating net K+ secretion. The effects of aldosterone on ENaC and, to some extent, the Na-K pump appear to be indirect, mediated by aldosterone-induced proteins.[53]

Plasma aldosterone concentrations in the premature infant and newborn are high compared to those in the adult.[2,54] The density of aldosterone binding sites, receptor affinity, and degree of nuclear binding of hormone receptor appear to be similar in mature and immature rats.[55] Yet, clearance studies in fetal and newborn animals demonstrate a relative insensitivity of the immature kidney to the hormone, presumably because of a postreceptor phenomenon.[2,55,56] Measurements of the transtubular K+ gradient (TTKG; urine-to-plasma K+ concentration divided by the urine-to-plasma osmolality ratio), an index of the K+ secretory capacity of the distal nephron, have been reported to be lower in 27 than 30 weeks gestational age in preterm infants followed over the first 5 weeks of postnatal life.[57] The low TTKG has been attributed to a state of relative hypoaldosteronism but may also reflect the absence of K+ secretory transport pathways (i.e., channel proteins).

DEVELOPMENTAL ASPECTS OF RENAL POTASSIUM HANDLING

Infants older than approximately 30 weeks gestational age and young children must maintain a state of positive K+ balance for somatic growth. The kidney is the primary organ responsible for regulation of external K+ balance. Kidneys of full-term newborn humans and animals conserve K+. The ASDN is uniquely adapted to retain total body K+ early in life. In contrast to the robust net K+ secretion detected in single CCDs isolated from adult animals, CCDs isolated from newborns show no net K+ secretion during the few weeks of postnatal life. The magnitude and direction of net K+ transport in the CCD reflect the balance of opposing fluxes of K+ secretion and K+ absorption, proposed to be mediated by principal and intercalated cells, respectively. Evidence now indicates that the low capacity of the CCD for K+ secretion early in life is due to a limited capacity of principal cells for K+ secretion, reflecting, at least in part, a relative paucity of conducting K+ (SK/ROMK and BK) channels in the urinary membrane. A relative excess of K+ absorption by adjacent intercalated cells in this nephron segment may further reduce net urinary K+ secretion. Under conditions prevailing in vivo, the balance of fluxes mediated by these two cell types likely contributes to the relative K+ retention characteristic of the neonatal kidney.

DISORDERS OF POTASSIUM METABOLISM

The estimation of K+ balance depends on the measurement of extracellular (serum or plasma) K+ concentration. Although easily determined, the latter measurements may reflect changes in K+ redistribution between the extracellular and intracellular compartments without net gain or loss of this cation from the total body stores.

HYPOKALEMIA

Hypokalemia is defined as a serum K+ concentration less than 3.5 mEq/L. Although hypokalemia generally indicates a deficit in total body K+, it also may simply reflect a transcellular shift in K+ from the ECF into cells in the presence of normal body K+ stores. Table 12.2 summarizes the various causes of hypokalemia, which are discussed in the following section.

KEY POINT

The tendency of the neonatal kidney to retain K+ is necessary for growth. Positive potassium balance is due in part to a low K+ secretory capacity of the ASDN.

Table 12.2 Causes of hypokalemia

Factitious
- Elevated leukocyte count (e.g., as in leukemia)

Inadequate intake
- Dietary/parenteral

Transcellular shift
- Metabolic and respiratory alkalosis
- Insulin
- β-Adrenergic agonists (e.g., albuterol, terbutaline, epinephrine), dopamine, theophylline
- Hypokalemic periodic paralysis
- Barium toxicit

Renal loss
- Diuretics
  - Thiazides and loop diuretics
  - Osmotic diuretics (mannitol, glucose)
  - Carbonic anhydrase inhibitors
- Excess mineralocorticoid activity
  - Primary hyperaldosteronism (adrenal adenoma/hyperplasia)
  - Activation of renin-angiotensin-aldosterone pathway (renal vascular stenosis, renin producing tumors, or volume depletion)
  - Congenital adrenal hyperplasia (11-hydroxylase deficiency or 17-hydroxylase deficiency)
  - Increased corticosteroid level (Cushing's syndrome, high dose steroids)
  - Excessive licorice ingestion
- Renal tubular defects
  - Type 1 RTA
  - Type 2 RTA
  - Bartter syndrome
  - Gitelman syndrome
  - Liddle syndrome
- Endocrine derangements (thyrotoxicosis, vitamin D intoxication)
- Miscellaneous
  - Mg^{2+} deficiency
  - Drugs (e.g., penicillins, aminoglycosides, polymyxin B, and amphotericin)

Gastrointestinal loss
- Vomiting
- Biliary drainage
- Diarrhea
- Laxative or enema abuse
- Villous adenoma
- Ureterosigmoidostomies

Integumental loss
- Excessive sweating
- Severe burns

Clinical disorders of hypokalemia

FACTITIOUS HYPOKALEMIA

Factitious hypokalemia may be observed in patients with high white blood cells counts (e.g., in leukemia), whose blood samples are stored for prolonged periods at room temperature after collection.[58] The spurious hypokalemia, due to transcellular K^+ movement into white blood cells, can be avoided by immediate separation of cells from the plasma after phlebotomy or storage of the sample at 4° C.

INADEQUATE INTAKE

The response of the adult to a K^+-free diet is a reduction in K^+ excretion to approximately 10 mEq/day.[59] The inability of the adult kidney to produce a K^+-free urine, in light of the obligatory GI loss of K^+, can lead to hypokalemia after a prolonged period of inadequate intake. Because almost all foods contain some K^+, extreme dietary K^+ restriction is achieved in only a few clinical disorders, such as anorexia nervosa and intestinal malabsorption syndromes. Hypokalemia in the latter patient populations may be exacerbated by inappropriately high rates of urinary K^+ excretion secondary to magnesium (Mg^{2+}) deficiency; intracellular Mg^{2+} normally inhibits K^+ secretion through the SK/ROMK channel in the ASDN.[58] Hypokalemia also can be seen in patients who are receiving K^+-free parenteral fluids.

TRANSCELLULAR SHIFT OF POTASSIUM INTO CELLS

Alkalosis

Both acute metabolic and respiratory alkalosis are frequently accompanied by severe hypokalemia, resulting, in part, from the intracellular uptake of K^+ in exchange for H^+. Within hours of the onset of an acid-base disturbance, K^+ homeostasis is affected not only by the initial effect of pH on cell K^+ content, but also by changes in the renal handling of the cation. The profound hypokalemia characteristic of pyloric stenosis, for example, is, in part, due to the alkalemia-induced exchange of extracellular K^+ for intracellular H^+ and is exacerbated by two additional factors that stimulate renal K^+ excretion: volume contraction-induced hyperaldosteronism and delivery of nonreabsorbable anions (HCO_3^-) to K^+ secretory sites in the ASDN.

Insulin

Pharmacologic doses of insulin, as administered to patients with DKA, reduce plasma K^+ concentration by promoting K^+ uptake by muscle and liver cells. This insulin-induced redistribution of K^+ is exploited in the treatment of hyperkalemia with insulin with glucose.

Nonselective β-adrenergic agonists

Nonselective β-adrenergic agonists (e.g., epinephrine, isoproterenol), selective $β_2$-agonists (albuterol, terbutaline),

and dopamine directly promote K+ uptake by cells and stimulate insulin release. Theophylline and caffeine indirectly promote cellular K+ uptake by stimulation of sympathetic amine release. The reduction in plasma K+ observed in response to administration of these pharmacologic agents tends to be mild except when a K+ deficit already exists. Thus, for example, a surge in epinephrine secretion during an episode of acute myocardial ischemia can lead to severe hypokalemia in a hypertensive patient on chronic diuretic therapy, thereby increasing the risk for ventricular arrhythmia and sudden death. Treatment of asthmatics with albuterol or theophylline can lead to K+ redistribution and hypokalemia. The latter electrolyte imbalance, if severe, may impair the contractile ability of the respiratory muscles, thereby worsening respiratory status.

Familial hypokalemic periodic paralysis

In familial hypokalemic periodic paralysis, a rare autosomal dominant disorder, patients experience recurrent, transient episodes associated with a low serum K+ concentration (<2.8 mEq/L), lasting hours to days, that can vary in clinical intensity from mild muscle weakness to flaccid paralysis of the limbs and thorax. Attacks can be precipitated by maneuvers that decrease plasma K+ concentration, including carbohydrate-heavy meals (resulting from the stimulatory effect of insulin on the Na-K pump), rest after strenuous exercise (as K+ released during activity is taken back up into skeletal muscle), or stress. Familial hypokalemic periodic paralysis is associated with mutations in the skeletal muscle voltage-gated Ca^{2+} channel ($Ca_V1.1$) or voltage-gated Na^+ channel $Na_V1.4$.[60-62] Oral K+ supplements, spironolactone, and acetazolamide have been used with variable results to prevent recurrent paralytic episodes.[63,64]

Barium poisoning

Barium poisoning from ingestion or inhalation of large quantities of soluble barium salts, such as barium carbonate used in pesticides, and not the nonabsorbable barium sulfate preparation used in radiologic studies, produces a characteristic muscular paralysis that can lead to respiratory paralysis and death. Barium blocks the K+ conductance of muscle cells, thereby impairing the outward diffusion of K+ pumped into the cell via the Na-K-ATPase.[65] Thus, barium poisoning typically results in a severe fall in serum K+ secondary to the intracellular sequestration of this cation.[66] The clinical picture resembles hypokalemic periodic paralysis (muscle weakness and paralysis) with additional symptoms, including salivation, vomiting, diarrhea, hypertension, ventricular tachycardia, and fibrillation.[67]

Renal potassium loss

Renal causes of K+ wasting can be subdivided into those that are primarily (e.g., Conn syndrome or Cushing syndrome) or secondarily (e.g., diuretics, RTA) mediated by aldosterone.

EXCESS MINERALOCORTICOID ACTIVITY

Excess mineralocorticoid activity is well known to lead to renal K+ wasting. Autonomous adrenal aldosterone production (primary aldosteronism), as is observed in adrenal adenoma or bilateral adrenal hyperplasia, should be suspected in any adult who presents with the triad of hypokalemia, hypertension, and metabolic alkalosis.[68,69] Other pathophysiologic causes for activation of the renin-angiotensin-aldosterone pathway, which may lead to hypokalemia in children, include renal vascular disease and renin-producing tumors.

Certain forms of congenital adrenal hyperplasia (CAH) are associated with hypokalemia.[70] Specifically, 11-hydroxylase or 17α-hydroxylase deficiency, resulting from defects in the genes *CYP11B1* and *CYP17A1*, are associated with hypertension and hypokalemic alkalosis. In the former, impaired cortisol production leads to increased adrenocorticotropic hormone secretion, subsequent overproduction of the mineralocorticoid deoxycorticosterone (DOC), and adrenal androgen production; the excessive secretion of DOC leads to hypertension and hypokalemia. The latter form of CAH is also associated with impaired cortisol synthesis, with consequent features of mineralocorticoid excess but also defective production of adrenal androgens.

Some patients with Cushing syndrome (increased cortisol production) or those receiving pharmacologic doses of corticosteroids may present with hypokalemia, presumably a result of the mineralocorticoid effects of these hormones. Plasma levels of the naturally occurring glucocorticoid cortisol, which binds as avidly to the mineralocorticoid receptor, as does aldosterone, are approximately 100-fold greater than circulating levels of aldosterone. The enzyme 11-β-hydroxysteroid dehydrogenase type 2 (11β-HSD2), expressed in the ASDN, metabolizes cortisol to cortisone, which binds to the mineralocorticoid receptor poorly; this reaction is critical in preventing glucocorticoid-dependent activation of the mineralocorticoid receptor. Genetic loss of function or ingestion of inhibitors of 11β-HSD2 can thus lead to inappropriate activation of the mineralocorticoid receptor by cortisol and in turn severe hypertension and hypokalemia. Glycyrrhizic acid, an active ingredient in licorice, inhibits 11β-HSD2; ingestion of excess licorice can manifest with a picture similar to that of primary aldosteronism, but with low levels of aldosterone and plasma renin activity.[71]

DIURETIC USE (AND ABUSE)

A common cause of hypokalemia is diuretic use. Although the specific mechanism and site of action of each class of diuretic (thiazide, loop, and osmotic diuretics and carbonic anhydrase inhibitors) will determine its associated electrolyte and acid-base, all diuretics cause significant urinary K+ losses resulting from increased volume and Na+ delivery to the distal nephron. Fast tubular fluid flow rates stimulate K+ secretion into the urinary fluid by activation of the BK

channel and augmentation of Na^+ delivery and absorption in this segment, which enhances the electrochemical gradient favoring K^+ secretion. Hyperaldosteronism secondary to a diuretic-induced reduction in effective intravascular volume or concomitant edema (as the cause for administration of the diuretics) may further promote renal K^+ secretion; the metabolic alkalosis characteristic of high aldosterone states may enhance cell K^+ uptake, which in turn increases the concentration gradient favoring K^+ secretion. Finally, some diuretics may enhance distal delivery of nonreabsorbable anions, such as HCO_3^- (carbonic anhydrase inhibitors) to increase luminal electronegativity and K^+ secretion in the ASDN.

RENAL TUBULAR DEFECTS

Type 1 and 2 RTA

Renal tubular defects can result in renal K^+ wasting. Distal (type 1) and proximal (type 2) RTA both result in hypokalemia, albeit by different mechanisms. The mainstay of treatment for RTA is alkali therapy.

Distal RTA (dRTA) is characterized by a defect in H^+ secretion into the distal nephron; the failure to secrete positively charged protons into the urinary fluid results in increased luminal electronegativity, enhancing K^+ secretion but limiting Na^+ absorption. Consequent volume depletion results in secondary hyperaldosteronism, which additionally contributes to K^+ loss. Genetic causes of dRTA are due to mutations in acid-base transporting proteins in intercalated cells,[72,73] which secrete H^+ into the urinary fluid through apical H^+-ATPases functionally coupled to the basolateral Cl^-/HCO_3^- anion exchanger 1 (AE1). Loss-of-function mutations in *ATP6V1B1,* the gene encoding the B1 subtype unit of the apical H^+-ATPase, and *ATP6V0A4,* encoding the α subunit, lead to an autosomal recessive dRTA often associated with sensorineural deafness. Mutations in the gene encoding AE1 can manifest as a dominant or recessive dRTA and may be accompanied by erythroid changes. Mutations in the gene encoding AE1 encoding cytosolic carbonic anhydrase II are associated with a recessive mixed proximal-distal RTA, osteopetrosis, and cerebral calcification.

Proximal RTA (pRTA) is characterized by a reduced ability to reabsorb HCO_3^- in the proximal tubule, leading to excessive urinary HCO_3^- losses. The increased delivery of HCO_3^- to the distal nephron again increases the luminal electronegativity, enhancing K^+ secretion, whereas urinary wasting of Na^+ that escapes proximal reabsorption leads to volume depletion and hyperaldosteronism. The defect in proximal tubule HCO_3^- reabsorption may exist in isolation or as part of Fanconi syndrome, associated with proximal losses of not only HCO_3^- but also of phosphate, glucose, amino acids, uric acid, and low-molecular-weight proteins.[74] Genetic causes of pRTA most often follow an autosomal recessive pattern of inheritance. Loss-of-function mutations in the basolateral Na^+-HCO_3^- cotransporter (NBCe1, encoded by *SLC4A4*) lead to a recessive pRTA

with ocular and central nervous system abnormalities.[73] Administration of carbonic anhydrase inhibitors causes isolated proximal HCO_3^- wastage, but more severe Fanconi syndrome can be seen in patients given certain drugs, including ifosfamide, valproic acid, and various antiretrovirals, such as tenofovir.[74] dRTA may occur in association with other renal diseases accompanied by tubular dysfunction (renal transplantation, obstructive uropathy, pyelopnephritis).[75]

Inherited salt-losing tubulopathies, specifically Bartter syndrome and Gitelman syndrome, comprise another category of disorders associated with hypokalemia.[76,77] Patients with Bartter or Gitelman syndrome present with a biochemical profile including hypokalemic, hypochloremic metabolic alkalosis associated with high plasma renin activity and high aldosterone concentration.

BARTTER SYNDROME AND GITELMAN SYNDROME

In Bartter syndrome, patients typically present early in life with severe urinary salt wasting, polyuria, and hypokalemic alkalosis, a biochemical profile similar to that induced by furosemide. It is now known that Bartter syndrome may be due to mutations in genes encoding proteins critical for transepithelial transport in the TALH, which include the furosemide target NKCC2 (encoded by *SLC12A1,* type 1 Bartter syndrome), the apical SK/ROMK channel (*KCNJ1,* type 2), the basolateral Cl^- channel ClC-Kb (*CLCNKB,* type 3), or its associated subunit Barttin (*BSND,* type 4), and the calcium-sensing receptor (*CASR,* type 5).[76] As patients with antenatal Bartter (types 1 and 2) do not establish a transepithelial voltage gradient in the TALH robust enough to drive paracellular Ca^{2+} and Mg^{2+} absorption, these cations are lost in the urine, which predisposes patients to nephrocalcinosis. Typically, patients with Bartter syndrome are born prematurely, with complications that may include polyhydramnios and life-threatening dehydration in the neonatal period. Additional clinical manifestations to those identified previously include failure to thrive and growth failure. Barttin is also located in the cochlea, and patients with mutations in this protein often have deafness.

In Gitelman syndrome, inactivating mutations in the gene *(SLC12A3)* encoding the apical thiazide-sensitive Na-Cl cotransporter (NCC), in the distal convoluted tubule (DCT) lead to a milder salt-losing nephropathy than seen in Bartter syndrome, as would be observed in patients abusing thiazide diuretics.[76] Pediatric patients are often asymptomatic, but may be diagnosed coincidentally during a diagnostic workup for growth retardation, constipation, or enuresis. Because Gitelman syndrome is associated with hypocalciuria, measurement of urinary Ca^{2+} excretion may help distinguish between Gitelman syndrome and Bartter syndrome (which is associated with hypercalciuria).

LIDDLE SYNDROME

Liddle syndrome is a rare autosomal dominant disorder characterized by early-onset severe hypertension and

hypokalemic metabolic alkalosis, low plasma renin activity, and suppressed secretion of aldosterone.[78] The disorder is due to mutations in either the β or γ subunit of ENaC that lead to high constitutive levels of channel activity and Na^+ absorption in the distal nephron, enhancing the electrochemical gradient favoring K^+ secretion. Treatment of patients with inhibitors of ENaC, including amiloride or triamterene, normalizes blood pressure and hypokalemia.[79–81]

Drugs other than diuretics and miscellaneous disorders associated with hypokalemia secondary to urinary K^+ wasting are listed in Table 12.2.

Extracellular electrolyte Loss

Under normal circumstances, fecal excretion of K^+ is approximately 5 to 15 mEq/day. GI tract K^+ loss may increase significantly in the face of severe or prolonged diarrhea or laxative abuse. Vomiting and nasogastric suction can lead to volume depletion and metabolic alkalosis, which exacerbates renal K^+ loss via activation of the renin-angiotensin-aldosterone system and transcellular shift of K^+, respectively. The increased distal delivery of HCO_3^-, which serves as a nonreabsorbable anion, in metabolic alkalosis further promotes urinary K^+ secretion in the distal nephron.

Under normal circumstances, the concentration of K^+ in sweat is only 5 to 10 mEq/L. Integumental loss from either excessive sweating or severe burns may lead to volume contraction and secondary hyperaldosteronism. Of note, in severe burns, hyperkalemia may be seen initially as a result of cell breakdown, which is then followed by hypokalemia secondary to hyperaldosteronism that follows volume contraction.

Clinical manifestations of hypokalemia

The consequences of K^+ depletion affect many organ systems and depend on the magnitude and duration of the deficit. Most prominently affected are the neurologic and cardiovascular systems, muscles, and kidneys.

The ratio of intracellular K^+ concentration to that in the ECF is a major determinant of resting membrane potential (E_m) across the cell membrane. Alterations in the ICF to ECF K^+ concentration ratio will thus affect E_m and neuromuscular excitability. An acute reduction in the extracellular K^+ concentration (leading to a high ratio of intracellular to extracellular K^+) increases or hyperpolarizes E_m, thereby making the cell less excitable. This manifests as neuromuscular weakness and, in severe cases, paralysis. Death may follow from respiratory muscle failure. The effects of hypokalemia on cardiac conduction and rhythm are manifest on the electrocardiogram (ECG) and include ST segment depression, diminished T wave voltage, and appearance of the U wave. These abnormalities typically appear in patients with plasma K^+ levels less than 3 mEq/L. Hypokalemia-induced smooth muscle dysfunction is usually manifest as paralytic ileus and diminished ureteral peristalsis.

K^+ depletion also affects renal function. The most common abnormality detected is an inability to maximally concentrate urine. This is due to a reduction in the osmolar gradient in the medullary interstitium as well as impaired activation of renal adenylate cyclase in response to vasopressin.[82,83] In addition to this direct renal effect, K^+ depletion stimulates the central thirst center via increased production of angiotensin II (ATII).[84] The resultant polydipsia of severely hypokalemic patients further increases urinary output and exacerbates the concentrating defect.

Hypokalemia may affect carbohydrate and protein metabolism.[85,86] K^+ depletion suppresses insulin release, and thereby can result in glucose intolerance. The failure to thrive often seen childhood with severe hypokalemia and total K^+ depletion may be due to the disturbance in protein metabolism or insufficient substrate (body K^+, the predominant intracellular cation) for cellular growth.[87]

Diagnostic evaluation of hypokalemia

Diagnostic evaluation should be guided by a thorough history and physical examination. A detailed history should include the assessment of pattern of growth, presence of chronic illness, family history of similar disease, use of medications (e.g., diuretics, laxatives), and symptoms associated with the electrolyte disturbance. Physical examination must include measurement of growth indices, blood pressure, and assessment for edema and altered neuromuscular function.

The initial laboratory evaluation should include a complete blood count (CBC), serum electrolytes including HCO_3^- and Mg^{2+}, creatinine and glucose, and a urine analysis. If the laboratory data do not support the diagnoses of pseudohypokalemia or redistribution of K^+ from the ECF to ICF space (alkalosis or hypoglycemia), the hypokalemia likely represents total body K^+ depletion from GI tract, skin, or renal K^+ losses.

If the cause of hypokalemia is not immediately obvious, assessment of urinary K^+ excretion can be very helpful.

A low urinary K$^+$ concentration (<15 mEq/L) in the absence of recent diuretic use implies near maximal urinary K$^+$ conservation, suggesting that the hypokalemia is secondary to inadequate intake, a shift of K$^+$ into cells, or extrarenal losses (GI, skin). The presence of concomitant metabolic acidosis would suggest lower GI losses resulting from diarrhea or laxative abuse.

A high urinary K$^+$ concentration (>15 mEq/L or a urinary Na$^+$/K$^+$ ratio consistently less than 1 in the absence of renal failure) in a patient with hypokalemia is consistent with renal K$^+$ wasting. Inappropriate urinary K$^+$ wasting associated with hypertension and metabolic alkalosis is a classic finding in hyper-reninemic states, such as renal vascular stenosis and primary hyperaldosteronism. Metabolic acidosis with a high urinary K$^+$ concentration is also seen in DKA or type 1 or type 2 distal RTA. Bartter and Gitelman syndrome should be considered in patients with hypokalemic metabolic alkalosis, salt wasting with volume depletion, and hyper-reninemia and hyperaldosteronism.

Management of hypokalemia

Management of hypokalemia should be proportional to the severity of K$^+$ depletion. However, K$^+$ replacement should be done cautiously in the presence of complicating factors that affect the transcellular distribution of K$^+$ (e.g., acid-base status), especially in patients with renal or cardiac disease.

Mild hypokalemia will often respond to oral supplementation with foods containing a high K$^+$ content. Oral K$^+$ supplements will be necessary for moderate K$^+$ depletion. Among the oral preparations available in liquid, powder, and slow-release preparations are potassium chloride, potassium citrate, and potassium gluconate; the latter two formulations are ideal for patients with a concomitant acidosis in whom the organic anion provides potential alkali. The adverse effects associated with oral therapy, especially following administration of potassium chloride, include GI irritation, ranging from vomiting to ulceration, and K$^+$ intoxication.

Severe, symptomatic, or both hypokalemia types should be treated with intravenous (IV) potassium chloride. K$^+$ replacement fluid should be formulated in dextrose-free solution to prevent transcellular shifts of K$^+$ as the sugar stimulates insulin secretion. Conventionally, parenteral K$^+$ should be infused in a solution containing no more than 40 mEq/L and infused at a rate not to exceed 0.75 mEq/kg body weight in the first hour of therapy in children or 10 mEq/h in adults. When life-threatening paralysis or ventricular arrhythmias are present, more aggressive K$^+$ replacement may be appropriate in a monitored unit.

In patients with diuretic-induced hypokalemia who require continued use of their diuretic, addition of a K$^+$-sparing diuretic such as amiloride, triamterene, or spironolactone should be considered. Hypomagnesemia can lead to renal K$^+$ wasting and refractoriness to K$^+$ replacement. Mg^{2+} repletion facilitates correction of the coexisting K$^+$ deficit.

HYPERKALEMIA

Hyperkalemia is defined as a serum K$^+$ concentration greater than 6.0 mEq/L in the newborn and 5.5 mEq/L in the older child and adult. Hyperkalemia is generally due to a shift of K$^+$ from ICF to the ECF or inadequate urinary K$^+$ excretion and may not be accompanied by an increase in total body content of K$^+$. This is particularly evident in patients with DKA, who typically present with hyperkalemia yet are total body K$^+$-depleted. Table 12.3 summarizes the various disorders associated with hyperkalemia, which are discussed in the next section.

> ## KEY POINT
>
> Hyperkalemia is generally not detected in healthy adults subjected to a K+ load due to the efficiency of the initial rapid translocation of K+ that enters the ECF into the vast intracellular reservoirs and the subsequent excretion of the K+ load via the kidneys and GI tract.

Clinical disorders of hyperkalemia

PSEUDOHYPERKALEMIA

Pseudohyperkalemia represents an in vitro elevation in serum K$^+$ concentration in the absence of in vivo hyperkalemia, and is due to the transcellular movement of K$^+$ from the cytosol into the ECF during clotting or prolonged storage of a blood sample.[58] The concentration of K$^+$ in the serum is approximately 0.4 mEq/L higher than that in the plasma in samples with normal numbers of blood cells, reflecting release of the cation by leukocytes and platelets during in vitro clotting. Thus, an elevated serum, but not plasma K$^+$ concentration, may be measured in any hematologic disorder associated with marked elevation in number of white blood cells[88] or platelets.[88,89] Red blood cells can also release intracellular K$^+$ (and hemoglobin) via in vitro hemolysis.

Improper phlebotomy techniques may alter serum K$^+$ measurements. Contraction of the forearm muscles during fist clenching can lead to release of K$^+$ from muscle and elevation of the plasma K$^+$ concentration in blood sampled from that extremity.[90] Squeezing an infant's heel or transferring blood vigorously through a small-bore needle may result in hemolysis. Prolonged exposure of blood samples to the cold will inhibit Na-K-ATPase activity and lead to leakage of K$^+$ from the cells.

INCREASED POTASSIUM LOAD

Hyperkalemia is generally not detected in healthy individuals subject to an exogenous or endogenous K$^+$ load because of the efficiency of the initial rapid translocation of K$^+$ that enters the ECF into the vast intracellular reservoirs and the

Table 12.3 Causes of hyperkalemia

Pseudohyperkalemia
- Improper collection of blood
- Hemolysis
- Leukocytosis, thrombocytosis, polycythemia

Increased load
- Exogenous (oral vs. parenteral), blood transfusion
- Endogenous (cell breakdown)
  - Intravascular hemolysis
  - Rhabdomyolysis
  - Crush injuries
  - Severe exercise
  - Burns
  - Tumor lysis syndrome
  - Massive GI bleeds
  - Starvation

Transcellular shift
- Metabolic acidosis
- Hyperosmolarity
- Insulin deficiency
- Exercise during β adrenergic blockade
- Arginine infusion
- Succinylcholine
- Digoxin overdose
- Familial hyperkalemic periodic paralysis

Decreased renal excretory capacity
- Renal failure (acute/chronic)
- Mineralocorticoid deficiency
  - Addison disease
  - Hypoaldosteronism (hyporeninemic vs. defect in 21-hydroxylase or 18-hydroxydehydrogenase activity)
- Impaired tubular secretion without abnormalities in mineralocorticoid production
  - Pseudohypoaldosteronism
  - Obstructive and reflux uropathy
  - Sickle cell disease
  - Renal transplantation
  - Lead nephropathy
  - Systemic lupus erythematosus
  - Papillary necrosis
- Drugs
  - Prostaglandin synthesis inhibitors
  - K⁺-sparing diuretics
  - ACE inhibitors
  - Miscellaneous

Abbreviations: ACE, angiotensin-converting enzyme; GI, gastrointestinal.

subsequent excretion of the K⁺ load via the kidneys and GI tract. Common sources of exogenous K⁺ include K⁺-rich foods, oral or parenteral K⁺ supplements (including total parenteral nutrition), salt substitutes, high doses of potassium penicillin, and stored blood products.

Endogenous sources of K⁺ do not increase total body K⁺ content, but rather cause hyperkalemia through a decrease in the K⁺ content in the ICF compartment. Cell breakdown leads to release of K⁺ into the ECF to increase plasma K⁺ concentration. Significant endogenous K⁺ release can follow intravascular hemolysis, rhabdomyolysis, crush injuries, severe exercise, burns, tumor lysis syndrome, massive GI bleeds, and starvation.[91] Of note, patients with these conditions often experience concurrent acute kidney injury (AKI) (as follows hypotension or myoglobinuria), volume contraction, or both, conditions that will impair the ability to eliminate the K⁺ load.

TRANSCELLULAR SHIFT OF POTASSIUM INTO CELLS

Metabolic acidosis

In most states of mineral acid metabolic acidosis (uremic acidosis, NH_4Cl-induced acidosis), excess hydrogen ions (H⁺) in the ECF are apparently exchanged for intracellular K⁺ so that they may be neutralized by intracellular buffers.[92] However, clinical and experimental studies indicate that uncomplicated organic acidemias (including diabetic and alcoholic acidosis, lactic acidosis, acidemias secondary to methylmalonic and isovaleric acid, and ethylene glycol, paraldehyde and salicylate intoxications) do not produce hyperkalemia. Among the complicating factors that may cause hyperkalemia in patients with organic acidemias are volume depletion and renal hypoperfusion, preexisting renal disease, hypercatabolism, diabetes mellitus, and hyperosmolality, hypoaldosteronism, and subsequent therapy. The proposed mechanism(s) underlying the differing effect of mineral and organic acidemias on transcellular movement of K⁺ suggests that organic anions freely enter into cells without creating a gradient for the H⁺ ions and, thus, obviate the efflux of intracellular K⁺.

KEY POINT

Transcellular shifts in K⁺ can have large effects on extracellular K⁺ concentration.

Hormones

Cellular uptake of K⁺ is stimulated by multiple hormones, including insulin, catecholamines, and mineralocorticoids. Therefore, deficiency in any of these hormones (e.g., in diabetes, adrenal insufficiency) or impairment in their action (e.g., administration of β-blockers or angiotensin converting enzyme inhibitors) can contribute to hyperkalemia, especially if a K⁺ load is delivered concomitantly.

Drugs

Certain drugs enhance release of K⁺ from intracellular compartments, particularly muscle, into the ECF. Arginine hydrochloride, infused during growth hormone stimulation testing, may cause hyperkalemia as the cationic amino acid enters cells and displaces K⁺.[93] Succinylcholine is a

depolarizing muscle relaxant that causes release of K^+ from muscles and can be associated with an exaggerated hyperkalemic response in patients with neuromuscular disease, trauma, burns, tetanus, and renal failure.[94–96] In digoxin overdose, the Na-K-ATPase responsible for maintaining the transcellular Na^+ and K^+ gradients is inhibited, leading to K^+ leak from cells and in some cases, marked hyperkalemia.[97]

Familial hyperkalemic periodic paralysis

In familial hyperkalemic periodic paralysis, an autosomal dominant muscle Na^+ channelopathy resulting from a mutation in the *SCN4A* gene encoding the skeletal muscle voltage-gated channel $Na_v1.4$, disruption of the normal exchange of ions in skeletal muscle results in episodic attacks of flaccid weakness and intermittent myotonia that typically begin in the first decade of life.[98,99] During attacks, individuals may be hyperkalemic or normokalemic. Attacks may be precipitated by exercise, hypothermia, and fasting.

Nonoliguric hyperkalemia

Nonoliguric hyperkalemia (NOHK), defined as a serum K^+ concentration greater than 7.0 mEq/L during the first 72 hours of life in the presence of urinary output of greater than 1 mL/kg/h, is observed in 30% to 50% of infants with very low birth weight.[100,101] This disorder has been proposed to reflect Na^+-K^+ pump failure, leading to accumulation of K^+ in the ECF, as well as a limited renal K^+ secretory capacity.[7,102,103] Prenatal steroid treatment may prevent NOHK by stimulating Na-K-ATPase pump activity in the fetus, thereby stabilizing the cell membrane to prevent a shift of K^+ out of cells.[104]

DECREASED RENAL POTASSIUM EXCRETION

Acute kidney injury

Hyperkalemia is routinely observed in patients with the acute onset of oliguric AKI. The abrupt cessation of renal function leads to an increase in serum K^+ concentration of approximately 0.5 mEq/L/day.[105,106] This is due to both the reduction in GFR, which limits the amount of K^+ entering the glomerular filtrate, but also diminished urinary flow rates in the K^+ secretory sites of the ASDN. The rise in plasma K^+ concentration in many patients with renal failure may be exacerbated by endogenous tissue breakdown or administration of exogenous K^+ loads, as may accompany blood transfusions.

Chronic kidney disease

Serum K^+ concentration in patients with chronic kidney disease may be maintained within normal limits by a compensatory increase in K^+ excretion by surviving nephrons, usually until the GFR is less than 10% of normal. This adaptation may allow excreted K^+ to exceed filtered load in patients with major reductions in functional renal mass. However, these patients typically have an impaired ability to excrete an additional acute K^+ load. Uremia inhibits the ubiquitous Na-K-ATPase, resulting in impaired cellular uptake of K^+.

Mineralocorticoid deficiency

The renal excretory capacity for K^+ also may be limited by mineralocorticoid deficiency, as is observed in primary adrenal insufficiency (Addison disease), hyporeninemic hypoaldosteronism (type 4 RTA), and some forms of CAH that are not accompanied by synthesis of other compounds with mineralocorticoid activity such as DOC. More than 90% of cases of CAH are due to deficiency in 21-hydroxylase, secondary to mutations in *CYP21A2*, which leads to diminished or loss of mineralocorticoid and glucocorticoid production; these patients present with salt wasting, hyperkalemia, virilization of girls, and failure to thrive.[107] An isolated defect in aldosterone biosynthesis, secondary to aldosterone synthase (corticosterone methyloxidase, *CYP11B2*) deficiency, can manifest with hyponatremia and hypovolemia, as a result of salt wasting, and hyperkalemia.[108]

End-organ hyporesponsiveness

Patients may have impaired tubular secretion of K^+ as a result of end organ hyporesponsiveness without a deficiency of mineralocorticoid production. Pseudohypoaldosteronism type 1 (PHA1) is a rare inherited disease characterized by resistance to the actions of aldosterone. Infants with PHA1 typically present with failure to thrive, hyperkalemia and salt wasting that does not respond to exogenous mineralocorticoid administration; in fact, they are noted to have elevated levels of aldosterone.[109] Autosomal dominant PHA1 results from inactivating mutations in the gene encoding the mineralocorticoid receptor, whereas the autosomal recessive form of PHA1 is caused by mutations in genes encoding ENaC subunits.[110] Therapy with Na^+ supplementation generally corrects the clinical and biochemical abnormalities (except plasma aldosterone levels remain high).[111] Patients with Gordon syndrome, also known as PHAII, and familial hypertension with hyperkalemia, generally present with hyperkalemia, as expected in a state of apparent hypoaldosteronism, but also with hypertension. PHAII is due to mutations in the genes encoding the with-no-lysine (WNK) kinases, a family of kinases that regulate transport proteins in the distal nephron.[112] Type III PHA is typically transient and secondary to nephropathies, including obstructive uropathy, urinary tract infections, sickle cell disease, renal transplantation, and lead nephropathy.[113]

Drugs

Medications are a common cause of hyperkalemia. Nonsteroidal anti-inflammatory drugs (NSAIDs) have been proposed to induce hyperkalemia by reducing prostaglandin synthesis through cyclo-oxygenase inhibition; prostaglandins increase K^+ excretion by stimulating renin secretion (leading to aldosterone secretion), maintaining GFR through preglomerular arteriolar vasodilation, and direct effects on K^+ secretory channels sites in the distal nephron.[114,115] Spironolactone, as a competitive inhibitor of aldosterone, and the K^+-sparing diuretics triamterene and amiloride block luminal Na^+ entry, decreasing the

electrochemical gradient favoring K$^+$ secretion, in the distal tubule.

Trimethoprim and pentamidine, frequently prescribed to patients with immunodeficiency, inhibit distal nephron reabsorption of Na$^+$ by blocking apical ENaC in a manner similar to that of the K$^+$-sparing diuretics.[116,117] Angiotensin-converting enzyme (ACE) inhibitors, via suppression of ATII generation, lead to a reduction in aldosterone levels, which may lead to hyperkalemia; combination therapy with an ACE inhibitor and an angiotensin receptor blocker (ARB), compared with monotherapy, is associated with an increased risk for hyperkalemia and acute kidney injury.[118] Hyperkalemia, hypercalciuria, and acidosis often complicate the use of calcineurin inhibitors, immunosuppressive drugs used to prevent organ rejection.[119]

Clinical manifestations of hyperkalemia

The clinical consequences of hyperkalemia result from the adverse electrophysiologic effects of an altered transmembrane K$^+$ gradient on excitable tissues. Specifically, an increased extracellular K$^+$ concentration shifts the resting membrane potential to a less negative value (e.g., from −90 mV to −80 mV), initially enhancing tissue excitability. Thus, hyperkalemia may manifest as skeletal muscle weakness, paresthesias, and ascending flaccid paralysis.

Although cardiac toxicity generally occurs when the serum K$^+$ concentration rises above 7 mEq/L, treatment should be initiated in any patient with suspected hyperkalemia if ECG abnormalities characteristic of hyperkalemia are noted. The first and most specific ECG abnormality seen with hyperkalemia (usually apparent at serum K$^+$ levels above 7 mEq/L) are tall, peaked T waves. The P-R interval lengthens and the QRS complex then widens. As K$^+$ concentrations rise above 8 mEq/L, the *P* wave amplitude decreases and may disappear with atrial standstill. As ventricular conduction time continues to lengthen, the QRS complex merges with the peaked T wave, producing a "sine wave" pattern. Finally, ventricular fibrillation or asystole may occur at K$^+$ concentrations above 10 mEq/L.

Diagnostic evaluation of hyperkalemia

A detailed history should be sought first, with careful documentation of the child's growth pattern, history of chronic illness, and medication review (ACE inhibitors, K$^+$-sparing diuretics, trimethoprim, corticosteroids, β-blockers, and NSAIDs). A physical examination should include measurement of growth indices and blood pressure, and signs of any chronic illness. An ECG must be obtained promptly in any patient with hyperkalemia.

Pseudohyperkalemia should first be excluded by evaluation of plasma (not serum) K$^+$ concentration from a free-flowing venipuncture or vascular access. Additional laboratory tests, including CBC, repeat set of plasma electrolytes with HCO$_3^-$, creatinine, and glucose and urine analysis, are generally appropriate. Urine electrolytes can provide information about renal K$^+$ conservation. The TTKG provides an indirect estimate of aldosterone bioactivity in the distal nephron and is calculated as described earlier.[57] In adults with normal adrenal and renal function given an oral K$^+$ load, the TTKG increases above 10 within 2 hours, reflecting the stimulated mineralocorticoid activity.[120] Low TTKG values (<6 in adults, <5 in infants and children) are inappropriate in patients with hyperkalemia and may reflect hypoaldosteronism or pseudohypoaldosteronism.[57,121]

Management of hyperkalemia

Management of hyperkalemia is multipronged and includes measures to (1) reverse the membrane effects of hyperkalemia, (2) enhance the transfer of K$^+$ from the ECF into cells, and (3) remove K$^+$ from the body. The first two measures are only temporizing, so multiple treatments should be initiated concurrently.

> ### KEY POINT
>
> The goal of hyperkalemia management is to stabilize cardiac muscle membrane potential and shift extracellular K$^+$ into the intracellular space until K$^+$ can be removed from the body.

If ECG changes are present, hyperkalemia is severe (>7 mEq/L), or both, the first step in treatment must be the infusion of Ca^{2+} to stabilize the cardiac muscle membrane potential; specifically, Ca^{2+} shifts the threshold potential to a less negative value to restore the difference between the resting and threshold potentials. The effects of intravenous Ca^{2+} occur within 1 to 3 minutes and last for 30 to 60 minutes. Calcium gluconate (10%, 0.6 mL/kg), infused slowly (over 5 to 10 minutes) under continuous electrocardiographic monitoring, is the preferred preparation of intravenous Ca^{2+}. Calcium chloride also can be used (10%, 0.2 mL/kg), but because it provides approximately three times the amount of Ca^{2+} per 10-mL dose, caution must be exercised in its administration to avoid potential Ca^{2+} toxicity.[122] Contraindications to administration of Ca^{2+} salts are digoxin intoxication or hypercalcemic states.

Somewhat more long-lasting effects (several hours) can be obtained by transferring extracellular K$^+$ into cells, thereby reestablishing a more physiologic transmembrane potential gradient. The first-line therapy is insulin with glucose,[122,123] the latter not necessary if the patient is already hyperglycemic. Glucose (1 g/kg) plus insulin (0.2 units/g of glucose) may be infused first as a bolus over 15 to 30 minutes and then over an hour until K$^+$ can be eliminated from the body. For example, a 10-kg child would require 10 g

dextrose with 2 units of insulin; therefore, 100 mL of $D_{10}W$ to which is added 2 units of insulin would be infused over 30 minutes and then at a rate of 100 mL/h. Of importance, this is an approximation and will need to be adjusted for individual patients based on close blood glucose monitoring. Because supraphysiologic doses of insulin (up to 20 units) are required to elicit a maximal K^+ shift in adults, and hyperosmotic glucose infusions alone may exacerbate hyperkalemia through fluid shifts and solvent drag, it may be unwise to treat nondiabetic hyperkalemic patients with glucose alone, expecting endogenous insulin release to adequately reduce plasma K^+ concentration.[124] The effect of insulin is seen within 10 to 20 minutes of administration and can last for hours and be expected to decrease K^+ levels by 0.5 to 1.5 mEq/L.

Administration of β2 agonists, and specifically albuterol, may also promote K^+ uptake by cells. In 11 children (aged 5 to 18 years) with end-stage renal disease, nebulized salbutamol (2.5 mg if the child weighed less than 25 kg, 5 mg if above) reduced the plasma K^+ concentration by 0.6 and 1 mM/L by 30 and 60 min, respectively, with effects lasting for up to 2 hours.[125] Transient side effects associated with this class of drugs include tachycardia, tremor, and mild vasomotor flushing. Caution is recommended for patients on β-blockers and those with known cardiac disease.

Finally, infusion of sodium bicarbonate ($NaHCO_3$; 8.4%, 1 to 2 mEq/kg IV over 30 minutes) may induce a transcellular shift of K^+ in patients with metabolic acidosis. However, it is ineffective in the acute treatment of hyperkalemic patients without acidosis.[124,126] Of note is that $NaHCO_3$ should not be mixed with solutions containing Ca^{2+} because of the possibility of precipitating calcium carbonate. The major toxicities of HCO_3^- therapy include Na^+ overload and precipitation of tetany in the face of preexisting hypocalcemia.

Ultimately, in cases of increased total body K^+ content, the cation must be removed from the body via renal or gut excretion. Net K^+ removal from the body in individuals with good renal function can be accomplished by stimulating flow-dependent K^+ secretion in the distal nephron, by volume expansion, administration of loop diuretics, or by a combination of these. Furosemide (1 mg/kg; maximum of 20 mg for patients not chronically on loop diuretics) promotes urinary K^+ losses via both its inhibition of NKCC2 in the TALH as well as its effect on increasing urinary flow rates in K^+ secretory sites of the distal nephron.[21,122]

However, in patients with renal insufficiency, dialysis may be necessary to reduce the total body K^+ burden. The rate of K^+ removal from the plasma depends on the gradient between the plasma and dialysate K^+ concentrations and can be maximized using a K^+-free dialysate. Hemodialysis is considered to be the most efficient means of removing K^+ in hyperkalemic patients and is able to remove 50 to 80 mEq/L of K^+ in a 4-hour session.[123,124,127] However,

peritoneal dialysis is more widely available and more easily applied to infants than is hemodialysis. Continuous venovenous hemofiltration provides another means of removing total body K^+ from hemodynamically compromised patients.

K^+ binding resins, such as sodium polystyrene sulfonate (Kayexalate 1 g/kg orally or per rectum), which exchanges bound Na^+ for cations including K^+, releasing Na^+ into the gut for absorption, are no longer recommended to reduce total body K^+ in the acute setting. In fact, salbutamol infusion has recently been reported to be more effective, faster, and safer than Kayexalate in the treatment of NOHK in preterm infants.[128] Kayexalate when administered with hypertonic sorbitol has been associated with intestinal obstruction in neonates and, when administered orally or by nasogastric tube to adults, necrosis of the GI tract.[128–130] Oral resin also has been associated with bezoar formation in infants with extremely low birth weights.[129] In addition, stool K^+ excretion in adults who received Kayexalate with laxatives was not significantly increased above that measured in patients given laxatives alone.[131]

Clinical Vignette 12.1

A 5-year-old boy with a history of multiple admissions for dehydration presents with vomiting and diarrhea for 1 day. He is afebrile with heart rate (HR) of 130/min, respiration rate of 18/min, blood pressure (BP) of 80/60 mm Hg, and oxygen saturation 100% on room air. His weight is 30 kg. His mother notes that at his last well child check, his BP was 100/70 mm Hg, and his weight was 33 kg. She states that he has always been small for his age. His physical examination is notable for a sleepy but arousable child with dry mucous membranes and diffuse muscle weakness. An IV line is placed, laboratory tests ordered, and he receives a bolus of normal saline. After the bolus, he is more alert, with HR 100/min and BP 85/60 mm Hg, but he still has diffuse muscle weakness. His laboratory chemistry results reveal Na^+ 137 mEq/L, K^+ 2.0 mEq/L, Cl^- 88 mEq/L, HCO_3^- 30 mEq/L, BUN 11 mEq/L, and creatinine 0.5 mEq/L. Noting his severe hypokalemia, dehydration, and relative hypochloremia, his physician orders urine electrolyte tests, which show Na^+ 25 mEq/L, K^+ 20 mEq/L, and Cl^- 64 mEq/L.

TEACHING POINTS

- This patient has severe dehydration, as evidenced by his approximately 10% weight loss and hypotension.
- Despite his dehydrated state, his kidneys fail to maximally conserve Na^+. In addition, he is hypokalemic and likely total body K^+-depleted, given his muscle weakness, and is wasting K^+ in his urine.

- His biochemical profile and urinary losses of Na$^+$, K$^+$, and Cl$^-$ are typical of furosemide administration.
- However, the absence of history of diuretic use should prompt this child's pediatrician to consider a diagnosis of Bartter syndrome, a possibility that is consistent with the boy's medical history of multiple admissions for dehydration and apparent failure to thrive.
- Bartter syndrome is caused by various mutations affecting transport in the TALH, summarized in this chapter. Bartter syndrome types I (loss-of-function mutation in NKCC2) and II (loss-of-function mutation in ROMK) typically manifest in the neonatal period, whereas type III (loss-of-function mutation in CLCNKB) often manifests with episodes of dehydration in a patient who has failure to thrive.
- Bartter syndrome results in reduced absorption of Na$^+$, K$^+$, and Cl$^-$ in the TALH, which is normally responsible for reabsorbing approximately 25% of the filtered load of Na$^+$. As a result, there is increased delivery of NaCl to the distal nephron, which ultimately results in polyuria and volume contraction.
- The urinary K$^+$ wasting seen in this disorder is due to increased distal Na$^+$ delivery and hyperaldosteronism, both of which enhance Na$^+$ reabsorption in the ASDN (thereby increasing the electrochemical gradient favoring K$^+$ secretion), and increased urinary flow in the distal nephron, which activates the BK channel.
- Despite the elevated levels of renin and angiotensin, patients with Bartter syndrome do not have hypertension because of vascular receptor desensitization.
- Other derangements observed in Bartter syndrome include hypocalcemia, hypomagnesemia, metabolic alkalosis, and hyperprostaglandinemia. Hypocalcemia and hypomagnesemia are due to decreased paracellular absorption in the TALH secondary to a reduced lumen positive potential (normally generated by K$^+$ secretion through the SK/ROMK channel).
- Whereas Bartter and Gitelman syndromes can both manifest with hypokalemic metabolic alkalosis, they can be distinguished on the basis of urinary calcium excretion: normocalciuria or hypercalciuria in Bartter syndrome and hypocalciuria in Gitelman syndrome.
- The molecular basis for the hyperprostaglandinemia is unclear; however, NSAIDs are known to improve polyuria and urinary salt wasting in some patients with Bartter syndrome.

REVIEW QUESTIONS

1. A 16-year-old girl is noted to have a plasma K^+ concentration of 7.0 mEq/L with peaked T waves on ECG. The *first* step of management should be:
   a. Administration of IV insulin with glucose
   b. Administration of IV sodium bicarbonate
   c. Administration of nebulized albuterol
   d. Administration of IV calcium gluconate
   e. Administration of IV furosemide

2. Severe hypokalemia *may be* associated with:
   a. Hypotension
   b. Renal concentrating defect
   c. Skeletal muscle weakness
   d. ST depression and appearance of U wave on ECG
   e. All of the above

3. K^+ is freely filtered in the glomerulus. The majority of filtered K^+ is reabsorbed in the _____, and the net urinary K^+ secretion, and thus excretion, occurs in the _____.
   a. TALH; distal nephron (distal convoluted tubule and collecting duct)
   b. Proximal tubule; distal nephron (distal convoluted tubule and collecting duct)
   c. Distal nephron (distal convoluted tubule and collecting duct); TALH
   d. Proximal tubule; TALH
   e. Distal nephron (distal convoluted tubule and collecting duct); proximal tubule

4. A 10-year-old patient with history of acute lymphoblastic anemia is noted to be in septic shock and disseminated intravascular coagulation. She is paralyzed with succinylcholine for intubation and placed on pressors for hypotension. Her sedation is maintained with propofol, and the patient requires multiple units of pRBCs for severe anemia. Arterial blood gas (ABG) reveals that she is acidotic, with an elevated lactate. Her ABG also reveals a K^+ of 7.5 mEq/L. The team sends off a sample to verify the K^+ result. You are concerned that the value is real because:
   a. Succinylcholine can promote K^+ release from muscle cells.
   b. The patient may have sustained acute kidney injury secondary to her hypotension.
   c. The patient received a large K^+ load via both intravascular hemolysis and pRBC transfusion.
   d. All of the above.

5. An 8-year-old boy with obstructive uropathy is noted to have chronic hypokalemia and non-gap metabolic acidosis. Despite his acidosis, his urine pH remains 6.0. His urine is negative for glucose and protein. Given his underlying uropathy, the patient *most likely* has:
   a. Type 1 RTA involving the inability of the proximal tubule to reabsorb HCO_3^-
   b. Type 1 RTA involving the inability of the distal nephron to secrete H^+
   c. Type 2 RTA involving the inability of the proximal tubule to reabsorb HCO_3^-
   d. Type 2 RTA involving the inability of the distal nephron to secrete H^+

6. A 2-week-old girl is brought to the emergency department for vomiting and lethargy. She is noted to have thready pulses and poor capillary refill. She has not yet regained birth weight. Samples for CBC, chemistry,

VBG, blood culture, urine culture, and CSF culture are sent to the laboratory, and the patient is started on IV antibiotics. Results are significant for acidosis, severe hyponatremia and hyperkalemia. Based on the patient's presumed diagnosis, you expect urine electrolytes to show:

a. FeNa <1%, TTKG > 8
b. FeNa <1%, TTKG > 8
c. FeNa <1%, TTKG < 4
d. FeNa >10%, TTKG < 4
e. FeNa >10%, TTKG > 8

    FeNa = fractional excretion of sodium; TTKG = transtubular potassium gradient.

7. Patients with nephrotic syndrome are predisposed to developing hypokalemia because of:
a. Treatment with loop diuretics
b. Impaired reabsorption of filtered K^+
c. Secondary hyperaldosteronism
d. Increased K^+ filtration by the glomerulus
e. Choices a and c

8. Bartter syndrome is characterized by the following derangements:
a. Hypernatremia, hypochloremia, hyperkalemia, hyperprostaglandinemia, metabolic alkalosis
b. Hyponatremia, hyperchloremia, hypokalemia, hypoprostaglandinemia metabolic acidosis
c. Hyponatremia, hypochloremia, hypokalemia, hyperprostaglandinemia, metabolic alkalosis
d. Hypernatremia, hyperchloremia, hyperkalemia, hyperprostaglandinemia, metabolic acidosis

ANSWER KEY

1. d
2. e
3. b
4. d
5. b
6. d
7. e

Disorders of mineral metabolism

FARAH N. ALI AND CRAIG B. LANGMAN

Mineral metabolism involves a complex interplay of ion and hormonal control by individual organs in support of overall total body homeostasis. The kidney is a vital participant in the maintenance of homeostasis of these essential ions. This chapter presents an overview of regulation of calcium, magnesium, and phosphorus homeostasis in the body and the role played by the kidneys in their regulation. Clinical disorders of the homeostasis affecting these ions and the evaluation and management of these disorders are also discussed.

CALCIUM METABOLISM

Calcium is a vital ion for many essential cellular metabolic functions and for skeletal development. The regulation of calcium balance is a complex, multicompartmental interplay of the gastrointestinal (GI) tract, kidneys, skeletal system, and numerous hormones. Dietary calcium is absorbed actively from the proximal GI tract, primarily in the duodenum and jejunum. The bioactive form of vitamin D, $1,25(OH)_2D_3$, formed in the kidneys, is the sole hormonal stimulus for intestinal calcium transport. Additionally, passive flux of calcium from intestinal lumen to blood may occur through the concurrent absorption of simple sugars, even in the absence of active vitamin D. The latter process is much less efficient and not well regulated. The skeletal system is the major site of calcium storage (99%); only 1% of calcium is stored in the intracellular and extracellular compartment (Figure 13.1).

Within the plasma, 40% of the calcium is bound to plasma proteins and is not ultrafiltrable across the glomeruli. Approximately 50% of serum calcium is found in the ionized form. The remainder (10%) of the calcium is complexed with anions, such as phosphate or carbonate. Of the plasma protein-bound fraction of calcium, 90% is bound to albumin and the remainder to globulins. Each gram of albumin, at the physiologic pH (7.4), binds 0.8 mg/dL of calcium. In the setting of hypoalbuminemia, the measured serum total calcium value must be corrected to account for low plasma albumin concentration. Corrected total serum calcium can be calculated in hypoalbuminemic patients by the following formula:

Corrected calcium = (4.0 − [plasma albumin] g/dL) × 0.8 + [serum calcium] mg/dL

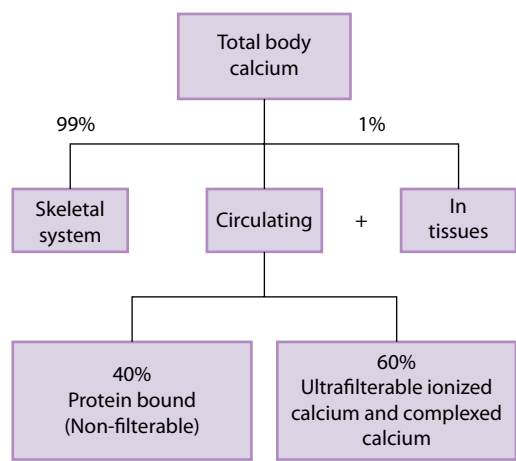
The acid-base status of the body affects ionized plasma calcium concentration substantially. During acidemia (excess hydrogen ion [H^+]), the negatively charged sites on the plasma proteins buffer the excess H^+, thus displacing the calcium ions from these sites and raising the ionized calcium level. Alkalemia has the opposite effect, decreasing the ionized calcium level.[1] An important clinical implication of this relationship is that aggressive correction of metabolic


Figure 13.1 Distribution of calcium within various compartments in the body.

Figure 13.2 Sites of reabsorption of calcium in the nephron.

acidosis in a patient with concomitant mild hypocalcemia can result in symptomatic hypocalcemia.

KEY POINTS

- Ionized calcium is the biologically active fraction of total body calcium.
- Metabolic alkalosis decreases serum ionized calcium concentration, and metabolic acidosis raises serum ionized calcium concentration.
- Rapid correction of metabolic acidosis in patients with borderline or low serum calcium level can precipitate tetany and cardiac dysrhythmia by lowering serum ionized calcium concentration.

RENAL HANDLING OF CALCIUM

Calcium homeostasis

Calcium homeostasis is maintained by three key hormones—parathyroid hormone (PTH), calcitonin, and vitamin D—which act on the GI tract, the kidneys, and the skeletal system (Table 13.1). The actions of these hormones are interrelated and interdependent.

Parathyroid hormone

PTH, an 84-amino acid–containing single-chain polypeptide, is produced by the chief cells of the parathyroid glands. The secretion of PTH from the parathyroid gland is regulated by the extracellular ionized calcium concentration. The cell membranes of the parathyroid gland chief cells have an extracellular calcium-sensing receptor (ECaR) that responds to the plasma ionized calcium.[5,6] A high plasma

calcium activates the ECaR and results in a decrease in PTH, whereas a reduction in plasma calcium inactivates the receptor and increases PTH secretion.

PTH acts on bone to stimulate the osteoclast-mediated release of calcium and phosphorus from the mineral matrix, in addition to providing a trophic action on bone mass accretion. In the kidney, PTH enhances calcium reabsorption in the distal tubular segment. It also inhibits the reabsorption of phosphate in the proximal convoluted tubule, with
Figure 13.3 Diagrammatic representation of a distal tubular cell showing the mechanisms involved in the active tubular reabsorption of luminal calcium in this segment. The tubular cells in this nephron segment have calcium (Ca^{2+}) channels (ECaC) on the apical aspects that facilitate transport of luminal calcium into the cell. Once within the cytosol, calcium combines with the calcium-binding protein calbindin-D28K (CaPB28K) that shuttles it to the basolateral aspect of the tubular cell. The sodium calcium exchanger 1 (NCX1) and the plasma membrane calcium adenosine triphosphatase (ATPase) (PMCA1b) pumps facilitate the transport of calcium out of the tubular cell at the basolateral surface.

resulting phosphaturia (Figure 13.2 and 13.3). In addition, PTH increases the activity of the enzyme 25-hydroxyvitamin D 1-α-hydroxylase in the proximal renal tubule, which mediates conversion of 25(OH) D_3 to $1,25(OH)_2D_3$ in the kidney. This is the active form of vitamin D; it increases intestinal calcium absorption. The action of vitamin D on the intestinal tract to increase the plasma calcium concentration takes place over several days. This contrasts with the impact of PTH secretion, which occurs within minutes.

The overall impact of these PTH-dependent processes is to maintain the blood calcium and phosphorus in the normal range. Taking advantage of these discoveries in the control of calcium homeostasis, an allosteric ECaR agonist ("calcimimetic") agent, cinacalcet hydrochloride (Sensipar), has been introduced for the treatment of secondary hyperparathyroidism in patients with chronic kidney disease (CKD).

KEY POINTS

- The extracellular calcium-sensing receptors of the parathyroid glands continuously sense ionized calcium levels in the plasma and respond by altering PTH levels.
- Calcimimetic agents or ECaR agonists are now available to treat patients with secondary hyperparathyroidism in CKD.

Vitamin D

Vitamin D is either ingested in the diet or produced from a common steroid precursor, 7-dehydrocholesterol, in the skin by the action of ultraviolet rays from the sun. Vitamin D ingested in the diet is absorbed in the proximal small intestine. To achieve biologic activation, vitamin D undergoes hydroxylation in the liver at the carbon-25 position by the cytochrome CYP2R1 to form $25(OH)D_3$ (Figure 13.4). The transformed compound, $25(OH)D_3$, undergoes further hydroxylation, at the carbon-1 position, in the kidney through the action of 25-hydroxyvitamin D 1-α-hydroxylase, a specific mitochondrial P450 enzyme CYP27A1. Although earlier work had suggested that the proximal renal tubule was the exclusive site of the 1-α-hydroxylase activity,[7,8] further observations using more sensitive probes suggest that the distal convoluted tubule, collecting duct, and papillary epithelia may also possess this enzyme activity.[9] Although $25(OH)D_3$ represents the largest circulating fraction of vitamin D and serves as the measure of its nutritional status, it does not possess any of the biologic functions of vitamin D.

Following its synthesis in the kidney, $1,25(OH)_2D_3$ and other hydroxylated metabolites of vitamin D are transported in blood by vitamin D–binding protein. The biologic actions of $1,25(OH)_2D_3$ are exerted after it binds the paranuclear vitamin D receptor (VDR) in target cells.[10] This receptor has been found in virtually

Table 13.1 Hormonal mediators of calcium and phosphorus balance

Mediator	Stimulus for secretion	Renal response	Bone response	Gastrointestinal response	Net effect on serum calcium	Net effect on serum phosphorus
Parathyroid hormone (PTH)	Hypocalcemia	Decreased phosphorus reabsorption (phosphaturia) Increased calcium reabsorption Upregulation of $1,25(OH)_2D_3$ production	Osteoclast activation and egress of calcium	Increased calcium absorption through up-regulation of $1,25(OH)_2D_3$	Increase	Decrease
Calcitonin	Hypercalcemia	Increased calcium and phosphorus excretion	Inhibition of osteoclast activity	No effect	Decrease	Decrease
1,25-dihydroxy-vitamin D	Hypocalcemia, Elevated PTH Hypophosphatemia	Increased calcium and phosphorus reabsorption	Increased osteoclast activation (variable)	Increased calcium and phosphorus absorption	Increase	Increase
Fibroblast growth factor-23 (FGF-23)	Excesses of dietary phosphorus intake	Decreased phosphate reabsorption (phosphaturia) Inhibition of 25-hydroxyvitamin D-1-α-hydroxylase		Reduced calcium absorption from effects on vitamin D	Unchanged	Decrease
Figure 13.4 Schematic diagram showing bioconversion of vitamin D in the body and its biologic actions. GI, gastrointestinal; PTH, parathyroid hormone.

all cells, although its precise biologic functions in some cells are not fully understood.

KEY POINTS

- 25(OH) D_3 represents the largest circulating fraction of the vitamin D endocrine system and serves as measure of nutritional adequacy.
- To assess nutritional adequacy or overdose of vitamin D, both 25(OH)D_2 derived from intake of ergocalciferol (synthetic) and 25(OH)D_3 need to be assayed.

Calcitonin

Calcitonin is a 32-amino acid–containing straight-chain peptide hormone produced by the parafollicular cells (also known as C cells) of the thyroid gland. Calcitonin demonstrates hormonal functions for modulating calcium and phosphorus metabolism, but its role as an important regulatory hormone in calcium metabolism is less than convincing. As with PTH, the primary target organs for the action of calcitonin are the kidney and the bone.[11] Calcitonin is secreted in response to increase in plasma calcium level. Its actions on the bone are to inhibit bone resorption and consequently reduce serum calcium levels. This physiologic action of calcitonin is sometimes used to treat hypercalcemia. In the kidneys, calcitonin increases urinary calcium and phosphorus excretion, but the magnitude of its phosphaturic action is less than seen with PTH.[12,13] Calcitonin also increases the renal production of 1,25(OH)$_2$D$_3$.[14]

KEY POINT

Calcitonin reduces serum calcium by inhibiting bone resorption, and in a minor role it increases urinary calcium excretion.

HYPOCALCEMIA

Hypocalcemia is defined as serum total calcium concentration of less than 8.8 mg/dL (2.2 mmol/L) in a patient whose serum albumin concentration is normal, or when the blood ionized value is less than 4.2mg/dL (1.05 mmol/L). Several formulas have been derived to "normalize" the serum total calcium in hypoalbuminemic states, but none is superior to measurement of the blood ionized calcium concentration. Broadly, hypocalcemia can be divided into disorders of parathyroid function, of vitamin D metabolism, or of their receptors. Table 13.2 lists the common causes of hypocalcemia seen in infants and children.

CLINICAL MANIFESTATIONS

The clinical manifestations of hypocalcemia are varied and are determined by the severity and rapidity of its onset (Table 13.3). Whereas mild hypocalcemia may remain asymptomatic, more severe or rapid-onset hypocalcemia results in neuromuscular irritability and tetany. Alteration of consciousness and seizures may occur in severe cases.

Neuromuscular irritability secondary to hypocalcemia can be elicited by the Chvostek and Trousseau signs. The Chvostek sign is performed by tapping the jaw with a reflex hammer, or by a firm finger tap. A twitch elicited in response

Table 13.2 Causes of hypocalcemia

Artifactual
- Low serum albumin
- Use of gadolinium-based MRI contrast agent

Lack of Vitamin D
- Nutritional deficiency
- Inadequate sunlight exposure
- Fat malabsorption

Defective Vitamin D Metabolism
- Anticonvulsant therapy
- Renal disease
- Hepatic disease

Vitamin D–Dependent Rickets
- Type I, 25-hydroxyvitamin D 1α-hydroxylase deficiency
- Type II, inactivating mutations of the vitamin D receptor (vitamin D resistance)

Lack of Parathyroid Hormone
- Congenital hypoparathyroidism
- Postparathyroidectomy state
- Postthyroidectomy state
- Hypomagnesemia

Parathyroid Hormone Resistance
- Pseudohypoparathyroidism

Abbreviations: MRI, magnetic resonance imaging.

Table 13.3 Clinical manifestations of hypocalcemia

Neuromuscular Irritability
- Paresthesias
- Muscular weakness
- Carpopedal spasms
- Positive Chvostek and Trousseau signs
- Tetany
- Seizures

Cardiovascular Dysfunction
- Prolonged QT interval
- Arrhythmias
- Left ventricular dysfunction
- Hypotension
- Cardiomyopathy

Skeletal System
- Poor bone mineralization
- Poor dentition

Miscellaneous
- Neuropsychiatric disturbances
- Papilledema

denotes a positive sign of neuromuscular irritability. The Chvostek sign is not specific for hypocalcemia. A Trousseau sign is elicited by applying a tourniquet or blood pressure cuff to the arm. A positive sign is indicated by carpal spasm following 3 minutes of inflation of the pressure cuff above the patient's systolic blood pressure. This sign is more specific for hypocalcemic tetany. A prolonged QT interval is noted in most cases of mild to moderate hypocalcemia, but other cardiac arrhythmias can be seen in severe cases of hypocalcemia.[15] Abnormalities of electrocardiogram (ECG) mimicking myocardial infarction have also been reported.[16] Long-standing hypocalcemia can result in digoxin-resistant left ventricular dysfunction and cardiomyopathy.[17,18] With long-standing hypocalcemia, abnormal dentition and cataracts may also be seen.

DISORDERS OF HYPOCALCEMIA

Hypoparathyroidism

Hypoparathyroidism or a low circulating level of PTH can be diagnosed in the setting of a normal serum magnesium concentration and results in hypocalcemia and hyperphosphatemia. A transient form of hypoparathyroidism may be seen in newborn infants through the second week of life. Risk factors for transient neonatal hypoparathyroidism include prematurity, low birth weight, infants of diabetic mothers, as well as babies born to mothers with hypercalcemia.[19]

Permanent forms of hypoparathyroidism occur in the velocardiofacial syndrome, which is a spectrum of disorders caused by gene deletions in the chromosome 22q11.[20] These disorders include the DiGeorge anomaly, which is associated with cardiac and facial defects, in addition to thymic and parathyroid hypoplasia of varying degrees. Familial hypoparathyroidism is a rare disorder that may be inherited as an isolated autosomal recessive, autosomal dominant, or X-linked recessive endocrinopathy.[21]

Hypoparathyroidism, sensorineural deafness, and renal dysplasia (HDR) comprise a distinct disorder that is inherited as an autosomal dominant disease. HDR is associated with mutations in dual zinc finger transcription factor, GATA3 (a transcription factor that specifically binds the DNA sequence A/T-GATA-A/G, hence the name GATA).[21,22] GATA3 is a transcription factor for vertebrate embryonal development. The molecular mechanism behind this defect's causing HDR is still undetermined. Activating mutations in the calcium-sensing receptor gene are associated with hypoparathyroidism and hypocalcemia.[21,23]

Pseudohypoparathyroidism

After PTH attaches to its cellular receptors, it activates guanine nucleotide regulatory proteins (Gs),

which in turn mediate activation of cyclic adenosine monophosphate (cAMP) for the cellular effects of PTH to be completed.[6] Pseudohypoparathyroidism is characterized by an end-organ resistance to PTH at any of the foregoing pathways. Findings of elevated circulating levels of PTH and hyperphosphatemia in the absence of renal dysfunction in a hypocalcemic patient are characteristic findings of this disorder. Two types of pseudohypoparathyroidism, with distinct clinical and laboratory markers, have been described.

KEY POINT

PTH level in hypoparathyroidism is low, and in pseudohypoparathyroidism it is elevated.

Type I pseudohypoparathyroidism is characterized by an absence of guanine nucleotide regulatory proteins (Gs). Type I pseudohypoparathyroidism includes McCune-Albright osteodystrophy, which is characterized by the clinical features of short stature, skeletal abnormalities, mental retardation, hypothyroidism, and hypogonadotrophism, in addition to end-organ PTH resistance.[1,24] Type II pseudohypoparathyroidism is associated with a yet-unknown defect downstream from activation of cAMP.[25] No characteristic phenotype has been reported. The two types of pseudohypoparathyroidism are distinguished by urinary levels of cAMP in response to exogenous PTH infusion (Ellsworth-Howard test). In type I pseudohypoparathyroidism, urinary cAMP does not increase with stimulation; in type II, the urinary cAMP levels increase in response to PTH.

Magnesium is required for adequate release of preformed PTH from the parathyroid gland under conditions of hypocalcemia.[26] Moderate to severe hypomagnesemia may lead to falsely low PTH levels. Peripheral resistance to the actions of PTH has also been considered a factor in the pathogenesis of hypocalcemia under these circumstances.[27] Correction of hypomagnesemia promptly results in correction of hypocalcemia and parathyroid resistance.

Vitamin D deficiency states

Vitamin D deficiency results in hypocalcemia, elevated PTH level, hypophosphatemia, and aminoaciduria. Nutritional vitamin D deficiency is common in the developing world. However, it is also recognized increasingly in the Western world, especially in patients with malabsorption of vitamin D resulting from abnormalities of structure or function of the GI tract.[28,29] Liver diseases

with an inability to 25-hydroxylate the parent vitamin D may also lead to vitamin D deficiency rickets and hypocalcemia. Apart from hypocalcemia and hypophosphatemia, diminished levels of 25-hydroxyvitamin D are the hallmarks of vitamin D deficiency rickets. Radiographs of the skeleton demonstrate the characteristic findings of rickets. Treatment consists of providing vitamin D supplements, but patients with liver disease require therapy with $1,25(OH)_2D_3$ (calcitriol). Healing of radiographic skeletal abnormalities can be noted by 6 to 8 weeks.

Vitamin D–dependent rickets

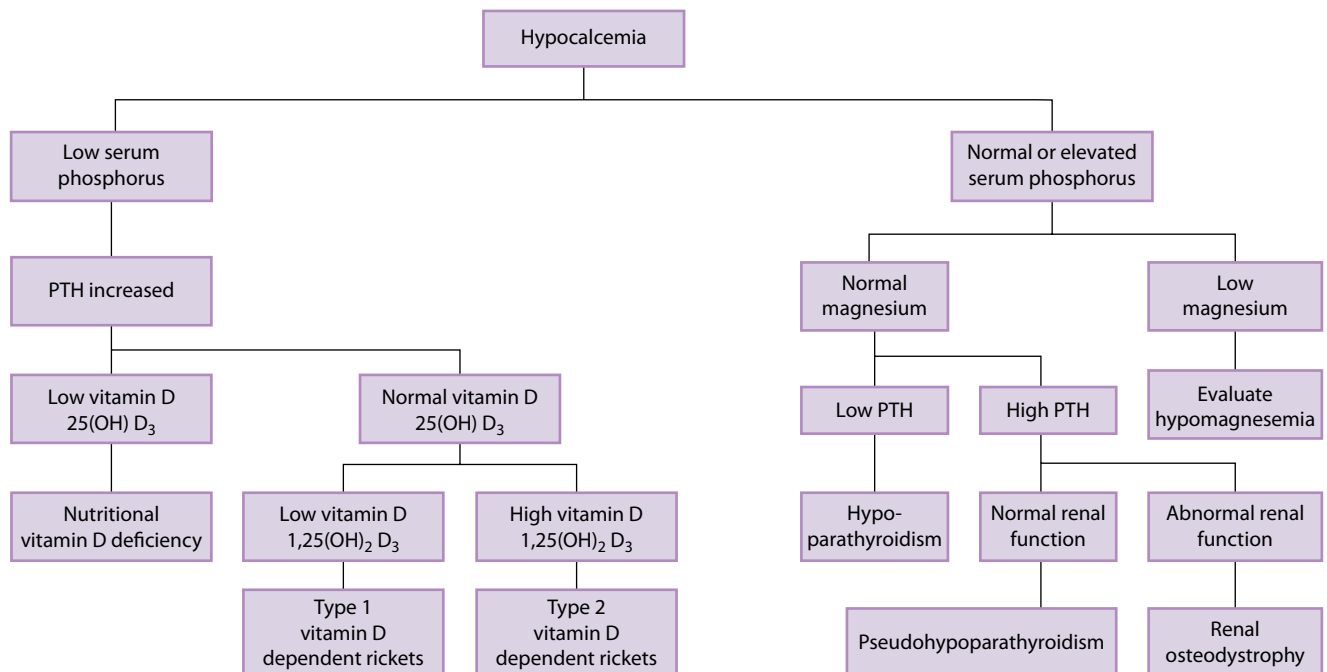
Vitamin D–dependent rickets (VDDR) is a heterogenous and rare metabolic disorder that is characterized by hypocalcemia and all the clinical and biochemical features of rickets. Two clinical variants of VDDR have been described (Figure 13.5). VDDR type I, also known as pseudovitamin D deficiency rickets, is an autosomal recessive disease associated with markedly diminished or absent synthesis of $1,25(OH)_2D_3$ resulting from deficiency of the
Figure 13.5 Schematic representation of the pathogenesis of type I and type II vitamin D–dependent rickets (VDDR).


Figure 13.6 A suggested algorithm for evaluation of children with hypocalcemia. PTH, parathyroid hormone.

25-hydroxyvitamin D_3 1α-hydroxylase enzyme in the kidney. Numerous mutations in the *CYP27B1* gene that encodes 25-hydroxyvitamin D_3 1α-hydroxylase in the kidney have been described in association with this disorder.[30] Patients with VDDR type I present in early infancy with muscle weakness, bony deformities (rickets), and hypocalcemic seizures.[31] The plasma level of $1,25(OH)_2D_3$ is low or absent, whereas the $25(OH)D_3$ level is elevated or normal. Exogenous administration of a physiologic dose of $1,25(OH)_2D_3$ (calcitriol) corrects the clinical, radiologic, and biochemical abnormalities associated with this disorder.

The clinical features of VDDR type II include bony deformities characteristic of rickets, poor linear growth, early onset of alopecia, and loss of teeth.[32] Some patients do not have alopecia.[33] Apart from hypocalcemia, patients have hyperparathyroidism and a high circulating level of $1,25(OH)_2D_3$. VDDR type II is caused by mutations in the vitamin D receptor gene.[34,35] Patients demonstrate end-organ resistance to vitamin D and are resistant to high-dose vitamin D therapy and supplementation with $1,25(OH)_2D_3$ (calcitriol). Long-term intravenous calcium supplementation has been shown to be effective in the treatment of VDDR.[36]

EVALUATION OF HYPOCALCEMIA

An evaluation of hypocalcemia should include concurrent measurement of serum ionized calcium, serum phosphorus, serum intact PTH, $25-(OH)D_3$, $1,25(OH)_2D_3$, and serum magnesium, as well as an evaluation of acid-base status (free-flowing venous blood is acceptable) and assessment of renal function. Values for urinary excretion of minerals and electrolytes may be needed in some circumstances. Figure 13.7 provides algorithms for evaluation of children and adults with hypocalcemia.

Serum phosphorus

Determination of serum phosphorus concentration aids in distinguishing the cause of low serum calcium levels beyond the neonatal age. In neonates, the serum phosphorus level is normally higher as a result of the limited ability of the neonatal kidney to excrete phosphorus, and It does not modulate in a fashion similar to that in older children. Hypocalcemia, coupled with hypophosphatemia, often points to an abnormality in vitamin D metabolism, whereas the presence of hyperphosphatemia points to a diagnosis of hypoparathyroidism, pseudohypoparathyroidism, or renal failure.

Serum magnesium

Magnesium is required for the secretion of PTH and should be evaluated in patients presenting with previously undiagnosed hypocalcemia. Hypomagnesemia is an especially common cause of hypocalcemia in neonates.

Parathyroid hormone

An elevated serum level of PTH may be seen in pseudohypoparathyroidism, chronic renal failure, vitamin D deficiency,

or in abnormalities of vitamin D metabolism. Low levels point to hypoparathyroidism.

Vitamin D level

Hypocalcemia in the setting of hypophosphatemia, and with elevations of serum PTH and alkaline phosphatase, suggests a disorder of vitamin D metabolism. Measurement of circulating levels of $25(OH)D_3$ and $1,25(OH)_2D_3$ should be performed to identify any nutritional deficiency of vitamin D, or defects in the metabolic pathways of vitamin D.

MANAGEMENT OF HYPOCALCEMIA

Treatment of hypocalcemia is usually urgent, especially in patients with neuromuscular irritability or seizures. Intravenous calcium therapy is required in these patients, whereas milder hypocalcemia may be amenable to oral treatment. Therapy also needs to be tailored to the underlying origin and pathogenesis of hypocalcemia.

Calcium supplements

Oral calcium supplements such as carbonate, citrate, and acetate salts of calcium are often used for long-term restoration and maintenance of blood calcium levels. The elemental calcium content of these compounds is variable. The GI calcium absorption rate of calcium is also highly variable, and absorption may be further impeded in vitamin D deficient states. An approximate starting dose for oral calcium supplementation is 5 to 20 mg elemental calcium/kg/dose, but the dose should be titrated by frequent assessment of blood calcium, to avoid hypercalcemia.

Vitamin D and analogues

The minimum daily requirement of vitamin D is 400 international units for babies and small children. High content of vitamin D is present in only few naturally occurring foods, such as fish (salmon), beef liver, cheese, egg yolks, and fortified dairy products, thus necessitating supplementation in most children. Vitamin D is available as ergocalciferol (vitamin D_2), and cholecalciferol (vitamin D_3). The two forms of vitamin D are considered bioequivalent. For treatment of nutritional vitamin D deficiency, ergocalciferol and cholecalciferol are the preferred supplemental compounds. For patients with other disturbances of vitamin D metabolism, hypoparathyroidism, or renal osteodystrophy, pharmacologic preparations are available that often bypass the need for kidney activation. Calcitriol, paricalcitol, and doxercalciferol are available in the United States for such therapy.

HYPERCALCEMIA

Hypercalcemia is defined as occurring when serum calcium values are greater than 10.6 mg/dL or when the blood ionized calcium is greater than 1.38 mmol/L. Broadly, hypercalcemia can be divided into disorders of parathyroid function, of vitamin D excess, or of their respective receptors. Numerous miscellaneous causes exist as well. Table 13.4 details the causes of hypercalcemia in infants and children.

CLINICAL MANIFESTATIONS

The symptoms of chronic hypercalcemia include muscle weakness, anorexia, nausea, vomiting, constipation, altered mental status, depression, hypertension, and weight loss. Additionally, polydipsia and polyuria may result from impairment in tubular concentrating ability. Nephrocalcinosis may occur with prolonged hypercalcemia and cause a progressive decrease in renal function. Nephrolithiasis may be present with persistent and long-standing hypercalcemia, and it can manifest with flank pain and hematuria. Skeletal involvement in hyperparathyroidism may lead to fractures. Infants may exhibit poor feeding, failure to thrive, and hypotonia. Some patients, however, may be asymptomatic, presenting only in response to incidental laboratory findings of elevated serum calcium concentrations.

DISORDERS OF HYPERCALCEMIA

Hyperparathyroidism

Primary hyperparathyroidism is a rare disorder in children, often manifesting in late childhood or early teens. Median age at presentation in a study was 16.8 years (range, 4 to 18.9 years).[37] Solitary benign adenomas of the parathyroid gland are the most common pathologic findings (65% to 85%), whereas diffuse hyperplasia of the glands accounts for the remaining 15% to 35% cases.[37–39] Among patients with diffuse parathyroid hyperplasia, the disorder can result from

KEY POINT

Hypophosphatemia and hypercalcemia point to the diagnosis of primary hyperparathyroidism.

Table 13.4 Causes of hypercalcemia

Artifactual Cause
- Increased serum albumin

Hyperparathyroidism
- Infant of mother with hypoparathyroidism
- Adenoma of parathyroid gland
- Multiple endocrine neoplasia

Heritable Disorders
- Calcium-sensing receptor disorders: familial hypocalciuric hypercalcemia
- Severe neonatal hyperparathyroidism
- Williams syndrome
- Jansen syndrome (a form of a metaphyseal dysplasia)
- Hypophosphatasia
- Idiopathic infantile hypercalcemia

Excess Vitamin D
- Surreptitious or intentional excess vitamin D intake
- Ectopic vitamin D synthesis:
  - Granulomatous disease (sarcoidosis, tuberculosis)
  - Subcutaneous fat necrosis in neonates

Malignancy-Associated Causes
- Paraneoplastic (PTH-rP or $1,25(OH)_2D_3$ excesses)
- Bone metastases with lysis

Drugs
- Vitamin D intoxication
- Vitamin A intoxication
- Thiazide diuretics
- Lithium therapy

Miscellaneous Causes
- Immobilization
- Hyperalimentation (with inappropriately high calcium)
- Hypophosphatemia
- Adrenal insufficiency
- Thyrotoxicosis
- Milk-alkali syndrome
- Down syndrome

Abbreviations: PTH-rp, parathyroid hormone–related peptide.

multiple endocrine neoplasia (MEN) or familial non-MEN. In neonates, hyperparathyroidism can manifest as neonatal severe primary hyperparathyroidism (NSHPT), which is discussed later.

Familial hypocalciuric hypercalcemia

Familial hypocalciuric hypercalcemia (FHH) is a benign disorder characterized by lifelong hypercalcemia, a normal PTH level, and lack of hypercalciuria. The parathyroid glands are normal in histologic structure, and subtotal parathyroidectomy does not cure the disorder.[40] FHH is inherited as an autosomal dominant disorder and results from heterozygous mutations in one allele for the gene that encodes the extracellular calcium-sensing receptor in the parathyroid gland and in the kidneys.[41] This condition leads to the characteristic findings of reduced urine calcium, despite the systemic hypercalcemia. Patients with FHH are asymptomatic, and no treatment is necessary. This disorder is commonly mistaken for primary hyperparathyroidism, and it is important to avoid unnecessary parathyroidectomy.

KEY POINTS

- FHH is a benign disorder.
- Inheritance: autosomal dominant.
- Despite hypercalcemia, urinary calcium excretion is low.
- PTH level is normal, and parathyroidectomy is not indicated.

Neonatal severe hyperparathyroidism

Severe hypercalcemia associated with hyperparathyroidism in neonates is caused by homozygous mutation of the calcium-sensing receptor and is termed neonatal severe primary hyperparathyroidism (NSHPT).[42] Whereas heterozygous mutation of the calcium-sensing receptor leads to benign familial hypercalcemia, NSHPT is associated with severe, life-threatening hypercalcemia in the neonatal period.[43] Clinical manifestations consist of feeding difficulties, respiratory distress, hypotonia, failure to thrive, and unexplained fractures. Radiography of the long bones reveals subperiosteal resorption, demineralization, and fractures. Onset in later childhood, and even in adults, has been reported.[43,44] Emergency parathyroidectomy is generally advocated to control severe hypercalcemia, but more conservative management with pamidronate has been reported in some cases.[44]

KEY POINTS

- NSHPT causes unresponsive hypercalcemia.
- It is caused by homozygous mutation of the calcium sensing receptor.
- PTH level is elevated.
- Parathyroidectomy is indicated.

Vitamin D excess states

Vitamin D intoxication is rare, but it may result from ingestion of milk products fortified with vitamin D or when excessive vitamin D is used as a supplement in children.[45,46] Other causes of vitamin D–mediated hypercalcemia include disorders causing extrarenal, ectopic production of $1,25(OH)_2D$, the active hormone of the vitamin D endocrine system. The latter category includes granulomatous diseases, such as sarcoidosis or tuberculosis, as well as subcutaneous fat necrosis, in which macrophage production of the active hormone may occur in an unregulated manner.[47–49]

> ### KEY POINTS
>
> - Accidental ingestion or incorrectly compounded vitamin D preparations can cause vitamin D intoxication and hypercalcemia.
> - PTH level is low.
> - It is important to assay vitamin D_2 and D_3 concentrations in serum in patients suspected of overdose of vitamin D.

Several mechanisms can cause hypercalcemia associated with malignant diseases.[50]. In 1987, the PTH-related peptide (PTH-rP), a gene product that is separate from PTH and causes hypercalcemia, was isolated from carcinoma of the lung.[51] The PTH-rP shares structural homology with the amino terminal portion of the PTH molecule and results in the humoral hypercalcemia of malignancy (HHM).[51,52] PTH-rP has been associated with numerous solid organ and hematologic malignant diseases.

A second cause of hypercalcemia of malignancy involves ectopic $1,25(OH)_2D_3$ production by the malignant cells.[53,54] Increased intestinal calcium absorption, osteoclastic bone resorption, and decreased renal calcium excretion have been implicated in the pathogenesis of hypercalcemia as a result of ectopic $1,25(OH)_2D_3$ production in malignant diseases.[50] A third cause of hypercalcemia of malignancy is tumor cell metastasis to bone, which produces lytic lesions and resultant hypercalcemia.

SYNDROMES ASSOCIATED WITH HYPERCALCEMIA

Williams syndrome

Williams syndrome is characterized by supravalvular aortic stenosis, elfin-like facies, and hypercalcemia. The disorder is caused by a 1.5-Mb deletion containing the elastin gene and flanking genes on chromosome 7q11.23.[55] Hypercalcemia is reported in 5% to 15% of patients with Williams syndrome.[56,57] The mechanism of the hypercalcemia remains obscure, but it may involve altered vitamin D metabolism.

Idiopathic infantile hypercalcemia

Idiopathic infantile hypercalcemia (IIH) is another distinct inherited clinical disorder that is characterized by failure to thrive, hypercalcemia, vomiting, and nephrocalcinosis. IIH results from loss-of-function mutations in the *CYP24A1* gene.[58] This gene regulates downstream catabolism of $1-25(OH)_2D_3$ into calcitroic acid through the enzyme 24-hydroxylase. In patients with IIH, clearance of $1-25(OH)_2D_3$ is dramatically decreased, resulting in high serum $1-25(OH)_2D_3$ levels, hypercalcemia, and suppression of PTH. This syndrome has been described in infants as well as in adults with kidney stones.[58,59]

Jansen syndrome

Jansen syndrome (metaphyseal dysplasia), which was previously classified as cartilage dysplasia, is also associated with hypercalcemia. Clinically, this disorder is characterized by a rachitic-appearing skeletal structure present from birth. Several mutations in the gene encoding the common PTH/PTH-rP receptor-1 have been associated with this disorder.[60] Hypercalcemia results from ligand-independent, autoactivation of this G-protein–coupled receptor. Despite the findings of hypercalcemia, PTH and PTH-rP are undetectable in this disorder.

EVALUATION OF HYPERCALCEMIA

Parathyroid hormone assay

Based on the plasma PTH level, patients with hypercalcemia can be segregated into those with low PTH and those with inappropriately normal or increased levels of PTH. The latter situations are found in primary hyperparathyroidism and in familial hypocalciuric hypercalcemia.

Vitamin D level

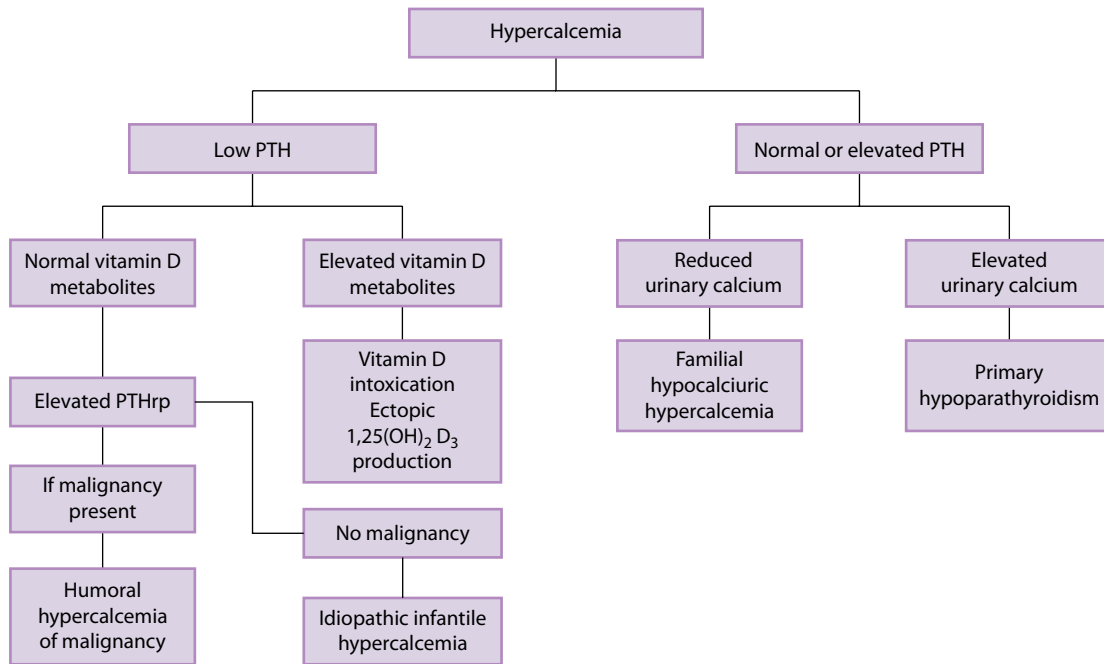
If a suppressed level of PTH is found in the diagnostic workup of a hypercalcemic patient, the differential diagnosis shifts to diseases associated with elevated circulating vitamin D metabolites. Normal levels of vitamin D metabolites, conversely, should prompt investigations of other sources of the hypercalcemia, such as a malignant disease. In the case of malignant disease, measurement of the serum PTH-rP level should be considered.


Figure 13.7 A suggested algorithm for evaluation of patients with hypercalcemia. Not all possible etiologies are shown in the algorithm. PTH, parathyroid hormone; PTHrp, parathyroid hormone–related peptide.

MANAGEMENT OF HYPERCALCEMIA

Treatment of hypercalcemia largely depends on the severity of the abnormality and the symptoms. In mild cases, no treatment may be necessary; serum calcium levels should be followed, and all calcium or vitamin D supplementation should be discontinued. Consideration of the use of a calcium-restricted diet may also be appropriate for treatment of mild hypercalcemia. Moderate hypercalcemia (serum calcium 12 to 14 mg/dL or 3 to 3.5 mmol/L) should be treated with saline diuresis, and calcitonin may also be considered for refractory cases. Hypercalcemic crises (serum calcium greater than 14 mg/dL or 3.5 mmol/L) require urgent attention and therapy.

Saline diuresis

Treatment of hypercalcemia should begin with hydration, using intravenous fluids appropriate for the child's age. In adults, normal saline is generally the recommended intravenous fluid for inducing diuresis. These patients often are dehydrated as a result of hypercalcemia-induced polyuria, and hydration is an important adjunct in their management. Additionally, volume expansion enhances renal calcium excretion and helps mitigate hypercalcemia. Addition of furosemide further reduces distal renal tubular calcium reabsorption and increases urinary calcium excretion. With diuresis alone, reduction in serum calcium level occurs gradually over several days. In general, fluid volume to be used should be age appropriate at 1.5 to 2 times normal maintenance. Such therapy should, however, be used with caution in infants and younger children because of the risk of inducing hypernatremia and fluid overload.

Calcitonin

Calcitonin induces hypocalcemia by inhibiting osteoclastic activity in the bones. Subcutaneous injection of calcitonin (Calcimar) results in a rapid decline in serum calcium level. Nasal spray of calcitonin has been approved for treatment of postmenopausal osteoporosis, but it is not yet approved for the purposes of treatment of hypercalcemia. The starting dose of calcitonin is 2 to 4 international units/kg, given every 12 hours, subcutaneously. Actions of calcitonin are short-lived, usually lasting 48 to 72 hours. Gradual resistance to therapy develops after extended use.

Bisphosphonates

Although bisphosphonates (pamidronate) have been used for of hypercalcemia in neonates and children, data on the long-term safety of these agents are unclear.[44] Bisphosphonates act by adsorbing onto hydroxyapatite of the bones, inhibiting bone resorption, reducing bone turnover, and increasing bone mineral accretion. The usual dose of intravenous pamidronate is 0.5 to 1 mg/kg in 0.9% saline infused over 2 to 4 hours. The therapeutic effect of pamidronate in decreasing serum calcium level is evident in 48 to 72 hours after the infusion is given, and it can last for 3 to 4 months. The drug is most helpful in patients with malignancy-induced hypercalcemia. Transient flulike symptoms consisting of muscle ache, fever, and lymphopenia are common. Other adverse effects include hypocalcemia, hypophosphatemia, hypomagnesemia, and acute kidney injury (AKI).

Corticosteroids

In the past, use of corticosteroids was advocated for the treatment of hypercalcemia, but the role of these drugs is limited at present. In general, corticosteroids are useful in treating hypercalcemia in conditions such as sarcoidosis or tuberculosis, where abnormal synthesis of $1\text{-}25(OH)_2D_3$ by macrophages drives hypercalcemia by enhancing GI calcium absorption.

Parathyroidectomy

Parathyroidectomy may be indicated in the treatment of recalcitrant hypercalcemia. Hyperparathyroidism caused by an adenoma or hyperplasia is a common indication for parathyroidectomy. The procedure is also indicated in patients with NSHPT or uncontrolled tertiary hyperparathyroidism (e.g., renal transplantation).

OTHER THERAPIES

Treatment of underlying malignant disease may be necessary for resolution of hypercalcemia in malignancy-associated hypercalcemia. Other therapeutic agents may include corticosteroids or mithramycin. Hemodialysis, using a low-calcium dialysate bath, should be considered for patients who are resistant to therapy or have life-threatening severe hypercalcemia.

MAGNESIUM METABOLISM

Magnesium is a dominant intracellular cation and is essential for metabolic processes. It is also an important component of bones and teeth. Bone and muscle are the major tissue pools for magnesium within the body. Bone accounts for approximately 60% of the total body magnesium stores, whereas the remaining 40% of magnesium resides intracellularly in soft tissues, with more than half in muscle cells. Liver is also a prominent store of magnesium.

RENAL HANDLING OF MAGNESIUM

Magnesium homeostasis

After its absorption from the small intestine, magnesium homeostasis is maintained through excretion by the kidney. Vitamin D, PTH, and increased sodium absorption in the intestine may directly enhance magnesium absorption. Conversely, calcium, phosphate, and increased intestinal motility decrease absorption of magnesium from the GI tract.[62] A small amount of magnesium is secreted into the GI tract normally, and its excretion is increased in diarrhea. Figure 13.8 depicts tubular sites of magnesium reabsorption.
Figure 13.8 Tubular sites of magnesium reabsorption in the nephron.

Chronic or acute metabolic acidosis increases urinary excretion of magnesium, whereas metabolic alkalosis decreases it. Other factors that inhibit renal magnesium reabsorption include expansion of the extracellular fluid volume, glucagon, calcium, low PTH levels, and diuretics. Loop diuretics such as furosemide inhibit the Na-K-2Cl transporter and diminish the paracellular reabsorption of magnesium by reducing the transepithelial voltage. Thiazide diuretics act primarily at the Na-Cl cotransporter in the distal convoluted tubule and may cause small and variable magnesium wasting. Volume contraction, magnesium deficiency, thyrocalcitonin, and elevated PTH levels enhance renal magnesium reabsorption.[61]

KEY POINT

The primary site of magnesium reabsorption in the renal tubules is in the thick ascending limb of the loop of Henle.

HYPOMAGNESEMIA

Hypomagnesemia may arise from either diminished intake or excessive excretion by the kidneys or the GI tract. Inadequate intake of magnesium may result from dietary deficiency or when an insufficient amount of magnesium has been provided during prolonged intravenous fluid

therapy. Malabsorptive states such as chronic diarrhea or celiac disease may also lead to magnesium deficiency. Excessive urinary excretion of magnesium may result from diuretic therapy, primary aldosteronism, hyperparathyroidism, postobstructive diuresis, acute tubular necrosis, diuresis following renal transplantation, and

nephrotoxic agents such as cyclosporine, cisplatinum, aminoglycosides, and amphotericin B. Several inherited disorders characterized by hypomagnesemia have also been identified. Functional deficiency of magnesium may be caused by intracellular shift of magnesium during respiratory alkalosis and treatment of diabetic ketoacidosis with insulin. Postparathyroidectomy "hungry bone syndrome," as well as refeeding of malnourished children, can also result in hypomagnesemia because of the incorporation of this ion into the regenerating tissues. Table 13.5 lists the causes of hypomagnesemia encountered in children.

CLINICAL MANIFESTATIONS

The symptoms of hypomagnesemia largely consist of increased neuromuscular irritability, including tremors, seizures, tetany, carpopedal spasms, and neuropsychiatric manifestations (Table 13.6). Positive Chvostek and Trousseau signs seen in hypocalcemia may also be elicited in patients with hypomagnesemia. Disorientation, nausea, anorexia, abnormal cardiac rhythm, and ECG changes, such as prolonged QT, U waves, or nonspecific T-wave changes, also may occur.[63] Hypocalcemia and hypokalemia are common biochemical findings encountered in hypomagnesemia. The degree of symptoms does not always correlate with the serum level of magnesium, however, possibly because magnesium is largely an intracellular cation and the serum level may not reflect the total body magnesium content.

Table 13.5 Causes of hypomagnesemia

Poor Absorption or Intake
- Protein-calorie malnutrition
- Chronic diarrhea
- Selective defect of magnesium absorption in the intestine

Magnesium Shift Into Cells
- Postparathyroidectomy hungry bone syndrome
- Insulin in treatment of diabetic ketoacidosis
- Respiratory alkalosis
- Refeeding in malnutrition

Renal Magnesium Wasting
- Inherited disorders
  - Hypomagnesemia with secondary hypocalcemia
  - Isolated familial hypomagnesemia:
    - Autosomal dominant
    - Autosomal recessive
- Familial hypomagnesemia with hypercalciuria and nephrocalcinosis (paracellin-1 mutations)
- Tubular sodium or chloride transport defects:
  - Gitelman syndrome
  - Bartter syndrome
- Drugs
  - Aminoglycosides
  - Cyclosporine
  - Cisplatinum
  - Amphotericin B
  - Dopamine
  - Insulin
  - Loop and thiazide diuretics
- States of diuresis
  - Postobstructive diuresis
  - Acute tubular necrosis: diuretic phase
  - Volume expansion
  - Osmotic diuresis
  - Post-renal transplant diuresis

Miscellaneous Disorders
- Hypoparathyroidism
- Phosphate deprivation
- Hypercalcemia
- Hyperthyroidism

Table 13.6 Manifestations of magnesium depletion

Neuromuscular
- Muscle weakness
- Positive Chvostek and Trousseau signs
- Spontaneous carpopedal spasm
- Seizures
- Psychosis

Cardiovascular
- Prolonged PR interval
- Widened QRS complex
- Inversion of T waves
- Life-threatening ventricular arrhythmias
- Enhanced toxicity of cardiac glycosides

Metabolic
- Resistant hypocalcemia
- Resistant hypokalemia
- Increased insulin secretion
- Carbohydrate intolerance

CLINICAL DISORDERS

Gitelman syndrome

Gitelman syndrome (see Chapter 41) is an autosomal recessive disorder characterized by metabolic alkalosis, hypokalemia, hypomagnesemia, and hypocalciuria. Other findings include increased urinary loss of magnesium and potassium.[64-66] Gitelman syndrome results from inactivating mutations in the *SLC12A3* gene (mapped to chromosome 16q) that encodes the thiazide-sensitive Na-Cl cotransporter present in the distal convoluted tubule of the kidney.[66] These patients usually present during childhood or adolescence and exhibit normal linear growth. Although the disorder is often asymptomatic, transient episodes of weakness and tetany secondary to profound hypomagnesemia can be observed. Variations in phenotype are common, even within the same family with identical gene mutations.[67] Adults with Gitelman syndrome occasionally develop chondrocalcinosis with deposition of calcium pyrophosphate dehydrate crystals.[68]

Bartter syndrome

Hypomagnesemia with secondary hypocalcemia

Hypomagnesemia with secondary hypocalcemia is an autosomal recessive disorder that manifests in the newborn period with seizures, tetany, and muscle spasms. This disorder is believed to result from a primary defect in intestinal magnesium transport.[71] Hypocalcemia results from parathyroid failure as a result of sustained magnesium deficiency. Mutations in a novel gene, *TRPM6*, encoding an ion channel expressed throughout the intestinal tract and within distal convoluted tubule cells, have been reported.[72] This disease can be fatal without the administration of high-dose oral magnesium.

Isolated familial hypomagnesemia

Isolated familial renal magnesium wasting is a rare but increasingly recognized disorder. The disorder has been reported as a dominantly or recessively inherited condition. In isolated dominant hypomagnesemia (IDH), low serum magnesium is seen in conjunction with renal magnesium wasting and hypocalciuria.[73] This disorder is distinguished from Gitelman syndrome by the absence of hypokalemic metabolic alkalosis. Patients with IDH can present in the neonatal period and early childhood with severe hypomagnesemia. Mutations in the *FXYD2* gene located on chromosome 11q23 that result in abnormality in the γ subunit of the basolateral Na$^+$-K$^+$-ATPase in the distal convoluted tubule have been proposed to be the abnormality in IDH.[74] Other clinicians have reported the lack of *FXYD2* gene mutation, a finding suggesting that IDH may be caused by other genetic mutations.[75] Isolated recessive hypomagnesemia (IRH) also appears in childhood with manifestations of hypomagnesemia, but it is not associated with hypocalciuria.[76] No candidate gene for this disorder has yet been identified.

Familial hypomagnesemia with hypercalciuria and nephrocalcinosis

Familial hypomagnesemia with hypercalciuria and nephrocalcinosis (FHHN) is an autosomal recessive disorder in which nephrocalcinosis is the cardinal finding. The biochemical abnormalities include hypomagnesemia with hypermagnesuria, and normal serum calcium with hypercalciuria. Some patients may also have findings of partial distal renal tubular acidosis.[77] Patients may present in early childhood with urinary tract infection, nephrolithiasis, polyuria, polydipsia, and failure to thrive. Manifestations of hypomagnesemia such as tetany and seizures are also common. Ocular abnormalities have been reported in these patients and include myopia, nystagmus, and chorioretinitis.[78] Patients with FHHN eventually progress to chronic renal failure in childhood or adolescence, and this feature distinguishes this disorder from other causes of hypomagnesemia such as Gitelman syndrome or isolated familial hypomagnesemia. Hyperparathyroidism, disproportionate to renal insufficiency, has also been reported, and it may be seen before onset of renal dysfunction. Therapy is aimed to reduce the progression of nephrocalcinosis and renal stones with thiazide diuretics. Renal transplantation is curative. Mutations in the gene *CLDN16*, located on chromosome 3q, which encodes for paracellin-1, a member of the tight junction proteins, have been reported in patients with FHHN.[79]

Autosomal dominant hypoparathyroidism

Autosomal dominant hypoparathyroidism may manifest in infancy with hypomagnesemia and hypocalcemia, with increased urinary excretion of magnesium and calcium. Defects in the *ECaSR* gene encoding the calcium/magnesium (Ca^{2+}/Mg^{2+})–sensing receptor in the parathyroid gland have been implicated in this disorder.[21] An activating mutation in this gene shifts the set point of the receptor and enhances the affinity of the mutant receptor for extracellular calcium and magnesium, thereby diminishing PTH secretion and reducing the renal tubular reabsorption of magnesium and calcium.

EVALUATION OF HYPOMAGNESEMIA

A thorough clinical history and examination and evaluation of serum magnesium, calcium, and phosphorus levels should be conducted in patients with hypomagnesemia. The focus of investigations is to determine whether the hypomagnesemia is the result of nutritional inadequacy, GI diseases, or excessive renal wasting. Kidney function and urinary evaluation and measurements of urinary calcium and magnesium excretions, preferably in a 24-hour sample, should be conducted. Fractional excretion of magnesium can be determined on a spot sample of urine, by using the following formula:

$$FEMg\ (\%) = [UMg \times PCr] / [(0.7 \times PMg) \times UCr] \times 100$$

where FEMg is the fractional excretion of magnesium (%), UMg is the urinary magnesium concentration (mg/dL), PMg is the plasma magnesium concentration (mg/dL), PCr is the plasma creatinine concentration (mg/dL), and UCr is the urine creatinine concentration (mg/dL).

Because only 70% of the plasma magnesium is ultrafiltrable (not bound to albumin), the plasma magnesium concentration is multiplied by a factor of 0.7. Fractional excretion of magnesium greater than 2.0% in patients with normal renal function suggests renal magnesium wasting. Patients with extrarenal loss of magnesium, such as with diarrhea or other GI disorders, have fractional excretion of magnesium lower than 1.5%.

KEY POINT

The initial evaluation of hypomagnesemia focuses on determining whether it is the result of GI disorders or renal disease.

MANAGEMENT OF HYPOMAGNESEMIA

HYPERMAGNESEMIA

Because of excellent renal modulation of magnesium homeostasis, hypermagnesemia rarely occurs in patients with normal renal function, except as an accidental toxic ingestion. Of course, patients with renal insufficiency often develop mild to moderate hypermagnesemia. Hypermagnesemia is defined as a serum magnesium level greater than 2.5 mEq/L. Sources of magnesium loads that may lead to elevated serum magnesium levels include laxatives (Milk of Magnesia), enemas, antacids, intravenous fluids with high magnesium load, accidental overdose with therapy, and neonates born to mothers treated with magnesium sulfate for pre-eclampsia. Addison disease may be associated with mildly elevated serum magnesium. A rare syndrome of decreased renal magnesium excretion and hypermagnesemia has also been reported.[82]

Symptoms of hypermagnesemia include hyporeflexia, flaccidity, respiratory depression, hypotension, disturbances in cardiac atrioventricular conduction, drowsiness, and coma. In addition to careful history taking to elucidate a cause, the evaluation generally includes serum and urinary measurements of calcium and magnesium. Treatment of hypermagnesemia includes intravenous calcium gluconate, exchange transfusion, and diuresis. Dialysis may be necessary for patients with renal failure.

PHOSPHORUS METABOLISM

Phosphorus is mainly stored in the body within the skeleton and teeth. Besides being a vital constituent of bone mineral, phosphorus is also required for vital intracellular metabolic processes, such as energy metabolism, protein

---

Table 13.7 Magnesium contents of commercially available supplements

Magnesium Salt	Brand names	Magnesium (mg/g)	Percent elemental magnesium (%)	Remarks
Magnesium oxide	MagOx; many other brands	603	60.3	Magnesium supplement
Magnesium hydroxide	Milk of Magnesia (MOM); other brands	417	41.7	Used as antacid
Magnesium citrate	Citroma; other brands	162	16.2	Used as bowel cleanser
Magnesium chloride	SlowMag; other brands	120	12.0	Magnesium supplement
Magnesium lactate	MagTab; other brands	120	12.0	Magnesium supplement
Magnesium sulfate	Numerous brands	99	9.9	Bowel cleanser; magnesium supplement; also available as a parenteral preparation
Magnesium aspartate	Numerous brands	75	7.5	Nutritional supplement
Magnesium gluconate	Numerous brands	54	5.4	Nutritional supplement

phosphorylation, and nucleotide and phospholipid metabolism. Phosphorus, as phospholipids, is an important component of cell membranes. Of the total body phosphorus, approximately 85% resides in the skeletal stores, and the remaining 15% is present in the soft tissues as an intracellular ion. A small fraction of the total phosphorus is found in the extracellular fluid. Within the plasma, phosphorus is present as organic compounds (phospholipids and phosphate esters), as inorganic phosphates (as HPO_4^{2-} or $H_2PO_4^-$), and as complexes with other ions, such as calcium and magnesium ions. Approximately 10% to 15% of plasma inorganic phosphorus is protein bound, and the remaining 85% to 90% is ultrafiltrable by the glomeruli. Whereas the adult phosphorus balance is zero, growing children have a positive phosphorus balance to meet the needs of skeletal growth.[1]

KEY POINTS

- Like calcium, bones are the main repository of phosphorus in the body.
- Phosphorus forms an important component of cellular energy transfer in the form of adenosine triphosphate (ATP).

Serum phosphorus is governed by a circadian rhythm, with a rapid decrease in levels early in the morning, a nadir before noon, and a peak after midnight. When measuring the serum phosphorus level, it is best to obtain a specimen in the morning fasting state to minimize the effect of dietary changes on the serum level. The normal serum concentration of phosphorus varies with age, with values higher in infants than in older children and adults (Table 13.8). Other factors that may affect the serum level include metabolic acidosis and intravenous calcium infusion, both of which may increase the serum phosphorus. Decreased serum phosphorus levels may result from intravenous infusion of glucose or insulin, acute respiratory alkalosis, and epinephrine administration.

Between 80% and 97% of the filtered phosphorus is reabsorbed by the renal tubules, mostly by the proximal tubules (70% to 80%), 5% to 10% in the distal tubule, and 2% to 3% in the collecting tubule (Figure 13.9). In the proximal tubule, phosphorus transport is coupled to sodium

Table 13.8 Serum phosphorus level in normal infants and children

Age group	Serum phosphorus level (mg/dL)
Infancy	4.8–7.4
Toddlerhood	4.5–5.8
Midchildhood	3.5–5.5
Adolescence to adulthood	2.4–4.5
Figure 13.9 Tubular sites of phosphorus reabsorption in the nephron.

transport, being unidirectional, against a gradient, and a transcellular secondary active process. Proximal tubular phosphate transport is mediated by the sodium-phosphate ($Na-P_i$) cotransporter present in the apical brush-border membrane. Three distinct types of $Na-P_i$ cotransporters— type I, type II, and type III—have been described in the renal tubules. Of these, the type IIa $Na-P_i$ cotransporter is believed to be the most significant phosphate reabsorption protein. The $Na-P_i$ cotransporter picks one phosphate ion along with three sodium ions and delivers these into the proximal tubular cells. Phosphorus exits the tubular cell by active basolateral Na-K-ATPase pumps.[83,84]

PHOSPHORUS HOMEOSTASIS

In adults, dietary intake results in a net intestinal absorption of 60% to 65% of the ingested quantity of phosphorus. In infants, this net absorption is higher and may exceed 90%. Most of the ingested phosphorus is absorbed from the duodenum and jejunum, through passive diffusion by a paracellular pathway. When the luminal concentration is low, phosphorus may also be absorbed actively by a sodium-dependent transcellular process. Once in the extracellular fluid compartment, phosphorus exists in equilibrium with the bone and soft tissue pools.

Vitamin D

Vitamin D plays an active role in phosphorus homeostasis. Hypophosphatemia causes an increase in renal $1,25(OH)_2D_3$ synthesis.[85,86] This leads to increased phosphorus and calcium absorption from the gut and increased mobilization of calcium and phosphorus from bone. These combined effects elicit an increase in serum calcium and phosphorus. Elevated serum calcium causes a decrease in PTH secretion,

which enhances renal phosphorus reabsorption and also increases renal calcium excretion. Hypophosphatemia also directly increases calcium excretion in the kidney. The net result of all these factors is an increase in serum phosphorus concentration, with relatively little change in the serum calcium. Hyperphosphatemia results in opposite effects by decreasing levels of $1,25(OH)_2D_3$ and increasing PTH levels, thereby decreasing the serum phosphorus level.[85,86]

Parathyroid hormone

PTH inhibits phosphate reabsorption in the proximal tubule by inhibiting phosphate transport by reducing the number of type IIa Na-P_i cotransporters (Na-Pi-IIa) and type IIc Na-P_i cotransporters (Na-Pi-IIc) on the luminal brush border of these cells. In contrast, with an absence of PTH (e.g., after parathyroidectomy), there is an increase in the number of Na-P_i cotransporters.[83] PTH mediates its actions in the proximal tubule through the type 1 PTH receptor.

Fibroblast growth factor-23

FGF-23 is a phosphaturic hormone distinct from PTH. FGF-23 is derived from osteocytes and osteoblasts in the bone, and its actions are mediated by binding to the FGF receptor -αKlotho complexes.[87,88] Similar to the actions of PTH, FGF-23 inhibits renal phosphate reabsorption by downregulating luminal expression of sodium-phosphate cotransporters type IIa and c (Na-Pi-IIa, Na-Pi-IIc) and sodium-dependent inorganic phosphate transporter (PiT2) in the apical brush-border surface of the proximal tubule.[83,88] FGF-23 also inhibits the synthesis of $1,25(OH)_2D$ in the kidney.

Missense mutations involving the *FGF23* gene cause autosomal dominant hypophosphatemic rickets. These mutations in *FGF23* result in an inability of FGF-23 to be cleaved and inactivated, thereby leading to phosphaturia and rickets.[88] Similarly, inactivating mutations in the *PHEX* gene, which regulates FGF-23 inactivation, leads to high FGF-23 levels and causes renal phosphate wasting in X-linked hypophosphatemic rickets (XLH).[88] Conversely, FGF-23 deficiency caused by mutations in *FGF23* result in familial tumoral calcinosis (FTC), which is characterized by hyperphosphatemia, elevated $1,25(OH)_2D$ level, and tumoral calcinosis.[89]

KEY POINTS

- FGF-23 and PTH both lead to phosphaturia, but by independent molecular mechanisms.
- Both PTH and FGF-23 downregulate luminal expression of two sodium-phosphate cotransporters: Na-Pi-IIa and Na-Pi-IIc.
- FGF-23 reduces $1-25(OH)_2D$ (calcitriol) synthesis.
- PTH increases $1-25(OH)_2D$ (calcitriol) synthesis.

HYPOPHOSPHATEMIA

Serum phosphorus levels in children vary by age (see Table 13.3), and these variations need to be considered in defining hypophosphatemia in children. Serum phosphorus may not reflect total body phosphorus levels because it is predominantly an intracellular ion. Both primary and secondary hyperparathyroidism may result in phosphaturia and consequent hypophosphatemia. Nonselective urinary phosphate wasting, leading to hypophosphatemia, can be seen in numerous renal diseases, such as Fanconi syndrome, distal renal tubular acidosis, postobstructive diuresis, and the diuretic phase of acute tubular necrosis.

Hypophosphatemia with reduced urinary phosphorus excretion may result from nutritional deficiency of phosphorus, malnutrition, impaired intestinal absorption from phosphorus-binding antacids, or intestinal disorders. Refeeding with a large carbohydrate load after prolonged malnutrition, as well as leukemic blast crisis, in which phosphate is incorporated into the proliferating cells, can lead to hypophosphatemia.[90] Respiratory alkalosis stimulates the formation of intracellular sugar-phosphate moieties and may cause hypophosphatemia with low urinary phosphorus. Intracellular phosphorus shift may also result from infusion of glucose, fructose, lactate and amino acids, exogenous administration of insulin, glucagon, androgens, and β-agonists.[91] Table 13.9 lists the causes of hypophosphatemia seen commonly in infants and children.

CLINICAL MANIFESTATIONS

Symptoms of low serum phosphorus generally result from decreased intracellular ATP and impaired tissue oxygen delivery, especially in hypophosphatemia of long duration. Symptoms may include anorexia, vomiting, paresthesias, myopathy, rickets, confusion, and seizures (Table 13.10). Life-threatening events, such as cardiac failure, ventricular arrhythmias, hypotension, red blood cell hemolysis, rhabdomyolysis, respiratory failure, and coma, may result from severe phosphorus deficits (less than 1.0 mg/dL).[92]

CLINICAL DISORDERS OF HYPOPHOSPHATEMIA

X-linked hypophosphatemic rickets

XLH, also known as familial hypophosphatemic rickets, is characterized by renal phosphate wasting, hypophosphatemia, growth retardation, and clinical manifestations of rickets. Serum calcium and PTH levels are normal, but the vitamin $1,25(OH)_2D_3$ level is low. The disorder is transmitted as an X-linked dominant disease and is caused by inactivating mutations in the *PHEX* gene (phosphate-regulating gene with homologies to endopeptidases on the X chromosome) in affected persons.[93,94] This mutation is believed

Table 13.9 Causes of hypophosphatemia

Poor Phosphate Intake or Absorption
- Malnutrition
- Anorexia nervosa
- Phosphate-binding antacids (e.g., calcium carbonate [Tums])
- Malabsorption
- Inadequate phosphate in intravenous hyperalimentation

Shift of Phosphate Into Cells
- Rapid infusion of large dose of carbohydrates (glucose, fructose)
- Endogenous or exogenous hormones
  - Insulin for correction of hyperglycemia
  - Catecholamines: epinephrine, dopamine, albuterol
  - Glucagon
  - Calcitonin
- Respiratory alkalosis

Cellular Incorporation of Phosphate
- Postparathyroidectomy hungry bone syndrome
- Leukemic blast crises
- Refeeding in malnutrition

Renal phosphate Wasting (Phosphaturia)
- Proximal renal tubular acidosis (Fanconi syndrome)
- Primary hyperparathyroidism
- Metabolic acidosis
- Diuretic therapy
- Glucocorticoid therapy
- Mineralocorticoid therapy
- Volume expansion
- Sodium bicarbonate infusion

Inherited Disorders
- *PHEX* mutation
  - X-linked hypophosphatemic rickets
- *FGF23* mutation
  - Autosomal dominant hypophosphatemia
- *SLC34A3* mutation
  - Hereditary hypophosphatemia with hypercalciuria
- *ENPP1* mutation
  - Autosomal recessive hypophosphatemic rickets

Miscellaneous Disorders
- Postrenal transplant hypophosphatemia
- Continuous renal replacement therapy: insufficient phosphate in the dialysate and/or replacement fluids
- Acute systemic infections

Table 13.10 Clinical and laboratory manifestations of phosphate depletion

Muscular
- Proximal myopathy
- Weakness
- Rhabdomyolysis

Gastrointestinal
- Dysphagia
- Ileus

Respiratory
- Hyperventilation
- Hypoventilation
- Respiratory muscle paralysis

Hematologic
- Hemolysis
- Impaired phagocytosis
- Impaired platelet function, thrombocytopenia

Renal
- Magnesuria
- Hypercalciuria
- Increased tubular phosphate reabsorption
- Increased $1,25(OH)_2D_3$ synthesis

Skeletal
- Bone pain
- Rickets or osteomalacia
- Pseudofractures or fractures

Neurologic
- Irritability
- Confusion
- Encephalopathy, coma

to prevent inactivation of FGF-23, a phosphaturic factor. Resultant increased FGF-23 concentration causes phosphaturia and the clinical manifestations of XLH (Figure 13.10). Treatment of XLH includes phosphate and calcitriol supplementation. Improvements in growth have been noted with such therapy, but nephrocalcinosis can be a side effect.[95,96]

Autosomal dominant hypophosphatemia

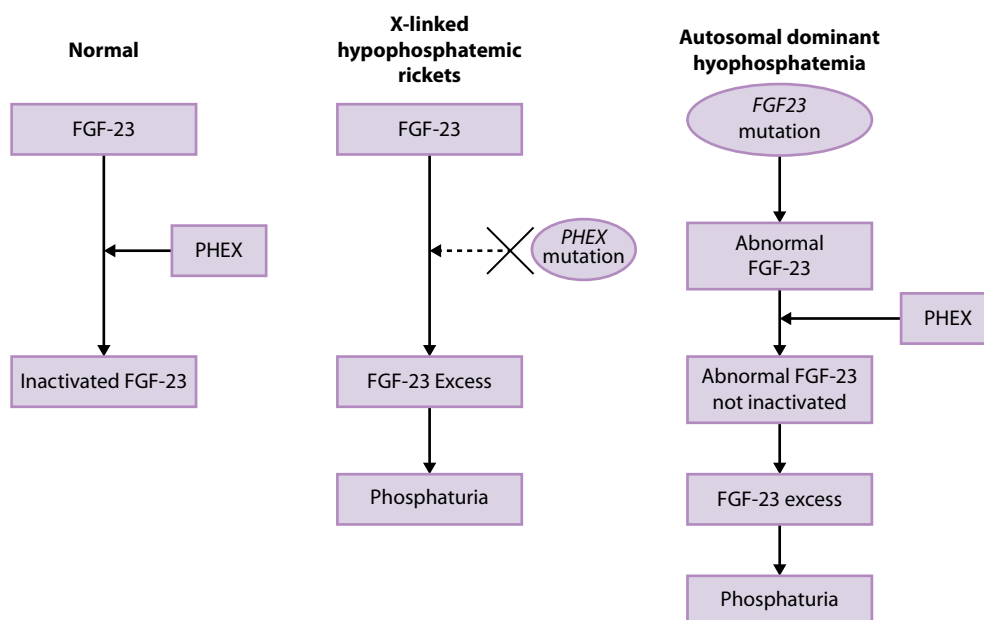
Autosomal dominant hypophosphatemia (ADH) is phenotypically a heterogenous disorder. Patients can present either in early childhood (1 to 3 years) or in the adolescent and adult age groups.[88,92,97] Clinical manifestations of children with ADH include muscle weakness, short stature, clinical rickets, and bone pain. Adults presenting with this disorder do not have any skeletal deformities, but they may have short stature, bone pain, and fatigue, and pseudofractures or stress fractures may be seen on radiographs.[97] In women, the disease may first manifest during or after pregnancy. Regression and resolution of hypophosphatemia in


Figure 13.10 Pathogenesis of hypophosphatemia in X-linked hypophosphatemic rickets and autosomal dominant hypophosphatemia. FGF-23, fibroblast growth factor-23; *PHEX,* phosphate-regulating gene with homologies to endopeptidases on the X chromosome.

affected persons have been reported. Serum calcium level is normal, PTH level is normal or marginally elevated, and $1,25(OH)_2D_3$ level is normal or modestly low. ADH is caused by missense mutations in *FGF23* that lead to the formation of a mutant FGF-23 molecule that is resistant to normal cleavage.[88,98,99] Excess FGF-23 accumulates and leads to phosphaturia and hypophosphatemia and the clinical manifestations of ADH.

Oncogenic osteomalacia

Tumor-induced osteomalacia (TIO), also known as oncogenic osteomalacia, is a paraneoplastic disorder that is characterized by phosphaturia, hypophosphatemia, and inappropriately low serum levels of 1,25-dihydroxyvitamin D_3.[100] TIO is caused by excessive production of FGF-23 by tumors, which are often of mesenchymal tissue origin.[101] Patients have severe bone pain and skeletal demineralization. Excision of the tumor is usually curative in TIO.

Hereditary hypophosphatemia with hypercalciuria

Hereditary hypophosphatemia with hypercalciuria (HHH) is another disorder of selective renal phosphorus wasting.[102] Clinical manifestations of HHH include short stature, phosphaturia, hypophosphatemia, hypercalciuria, nephrolithiasis, and rickets. The serum $1,25(OH)_2D_3$ level is elevated, whereas the PTH level is suppressed. HHH results from homozygous loss-of-function mutations in the *SLC34A3* gene encoding the renal type IIc cotransporter, NaPi-IIc.[103] Treatment with phosphorus supplementation improves rickets, despite ongoing phosphaturia.

Post–renal transplantation hypophosphatemia

Hypophosphatemia that can persist for up to several months is commonly seen after renal transplantation. Hyperparathyroidism associated with CKD persisting in the early course of transplantation had historically been considered the most likely suspect in the causation of phosphaturia and hypophosphatemia in these patients. It is now clear that persistence of elevated levels of FGF-23 has a major role in hypophosphatemia after renal transplantation.[104] Treatment consists of phosphate supplementation and adequate doses of vitamin D.

Idiopathic hypercalciuria

Renal phosphate wasting and hypophosphatemia was reported in a small group of children with idiopathic hypercalciuria.[105] Vitamin D levels were elevated in these patients, and phosphorus supplementation reduced calciuria and restored normal serum phosphorus values.

Hungry bone syndrome

Hungry bone syndrome refers to the transient phenomenon of hypocalcemia and hypophosphatemia seen due to increased avidity of bone for calcium and phosphorus after the resolution of long-standing primary or secondary hyperparathyroidism.[105] This disorder is commonly seen following parathyroidectomy in patients with primary or secondary hyperparathyroidism. Manifestations of hypophosphatemia as well as hypocalcemia can persist for weeks to several months. Oral supplemental calcium and vitamin

D therapy is needed for treatment of most patients with hungry bone syndrome. An occasional patient may require prolonged intravenous calcium supplementation and vitamin D to avoid life-threatening hypocalcemia. Hypophosphatemia is usually responsive to oral supplementation.

EVALUATION OF HYPOPHOSPHATEMIA

Disorders of hypophosphatemia can be classified as those with renal phosphate wasting and those with reduced urinary phosphorus. If the urinary phosphorus level is elevated, this suggests a phosphaturic mechanism, and serum PTH measurement is essential. Elevated PTH points to disorders of hyperparathyroidism, either primary or secondary. If the serum PTH level is normal or low, then it is necessary to determine whether the urinary losses are selective for phosphorus or whether nonselective phosphorus wasting, such as associated with Fanconi syndrome, may be present. FGF-23 measurement may be indicated in patients who have disorders associated with an increased FGF-23 level, such as TIO, XLH, and ADH. Bone radiography for evidence of osteoporosis and bone densitometry may also help in determining the impact of hypophosphatemia and phosphaturia on bone health. Tests that can be performed to document phosphaturia are discussed here.

Fractional excretion of phosphorus

Urinary phosphorus excretion and tubular reabsorption of phosphorus can be studied in a spot sample of urine by obtaining fractional excretion of phosphorus, by using the following formula:

$$FEPO_4\,(\%) = (UPhos \times PCr) / (PPhos \times UCr) \times 100$$

where $FEPO_4$ is the fractional excretion of phosphate (%), UPhos is the urine phosphorus (mg/dL), PPhos is the plasma phosphorus (mg/dL), PCr is the plasma creatinine (mg/dL), and UCr is the urine creatinine (mg/dL).

The fractional excretion of phosphate in normal children is 15% to 20%, and it is lower in growing infants. A fractional excretion of phosphate of more than 20% indicates phosphaturia.

Tubular reabsorption of phosphorus

Another derived index of phosphate excretion is tubular reabsorption of phosphate (TRP). TRP represents the percentage of the filtered phosphate that is reabsorbed in the renal tubules, by using the formula:

$$TRP(\%) = 100 - FEPO_{4\,(\%)}$$

Renal tubules reabsorb greater than 80% of filtered phosphate; therefore, TRP is 80% (or 0.8) in normal children. Higher values of TRP are expected in infants and growing children with high phosphorus accrual rates.[106] Both the fractional excretion of phosphate and TRP can be affected by renal function and plasma phosphorus concentration.

Tubular maximum rate of phosphate reabsorption

An index of renal phosphate excretion considered to be independent of renal function is the ratio of the TRP to the glomerular filtration rate (GFR). This index provides a theoretical lower limit of serum phosphorus below which all filtered phosphate would be reabsorbed. This index can be calculated either from a nomogram (Figure 13.11) or from the following formula[107,108]:

If TRP is 0.86 or lower, then:

$$TmP/GFR = TRP \times Serum\ phosphate$$

If the TRP is greater than 0.86 then:

$$TmP/GFR = 0.3 \times TRP / \{1 - (0.8 \times TRP)\} \times Pp$$

TmP/GFR in normal persons varies with age; it is high in younger children and decreases with age, and it ranges from approximately 4.4 to 5.4 mg/dL in young children and 2.5 to 4.5 mg/dL in adolescents.[108,109] Lower TmP/GFR reflects poor TRP (phosphaturia). Tests of TRP can be done on a spot sample of urine, but a short timed collection (2 to 4 hours) obtained with the patient in a fasting state is usually preferred to avoid variability related to dietary intake. A suggested algorithm for diagnosis of hypophosphatemia is given in Figure 13.12.

MANAGEMENT OF HYPOPHOSPHATEMIA

Treatment of hypophosphatemia in patients believed to have a normal total body phosphorus concentration may be deferred, unless clinical symptoms are present. Mild hypophosphatemia (greater than 2.5 mg/dL) may be treated with increased phosphate content in the diet. Milk and milk products are particularly high in phosphorus content, and their intake may be encouraged in such patients. Asymptomatic patients with moderate hypophosphatemia (1.5 to 2.5 mg/dL) may be treated with oral phosphorus supplementation (Table 13.11). Care should be taken not to provide calcium supplementation with meals because this may further exacerbate hypophosphatemia through binding of dietary phosphorus with calcium and thereby preventing its absorption.

Intravenous phosphorus infusion therapy is generally reserved for patients with symptomatic hypophosphatemia or a serum phosphorus level lower than 1 mg/dL. Sodium phosphate (phosphorus, 3.0 mmol/mL, and sodium, 4.0 mmol/mL) or potassium phosphate (phosphorus, 3.0 mmol/mL, and potassium, 4.4 mmol/mL) can be used for intravenous phosphate replacement (Table 13.12). It is important to remember that for every 1 mmol of phosphorus ordered as potassium phosphate, the patient will also receive approximately 1.47 mmol of potassium.

The usual dose for elemental phosphate for intravenous use is 0.08 to 0.2 mmol/kg, but higher doses can be used in monitored circumstances, such as in intensive care units.[110] Intravenous phosphate replacement
Figure 13.11 Nomogram for the calculation of renal tubular reabsorption of phosphate (TmPO4/GFR) from plasma phosphate concentration and the fractional reabsorption of phosphate (TRP). Inner aspect of the vertical axis on right and the left side represents data in SI units (mmol/L). Outer aspect of the vertical axis on right and the left side represents data in mass units (mg/100 mL). First step in using the graph is to calculate TRP, as detailed in the text. A straight line joining plasma phosphate concentration (left vertical axis), TRP (middle of the nomogram), and the right vertical axis gives the TmPO4/GFR. Lancet. 1975;2(7929):309–10.)

is infused over 4 to 6 hours, and the generally recommended rate of infusion is no more than 0.2 mmol/kg/h of elemental phosphorus. The phosphate infusions are formulated in normal saline- or dextrose-containing solutions and may be incorporated in the intravenous hyperalimentation. However, these infusions should not be mixed with calcium-containing solutions such as Ringer lactate, because of the risk of precipitation. Hypocalcemia, hypomagnesemia, and hyperphosphatemia can result following intravenous infusion of phosphate, and patients need close monitoring for these electrolyte abnormalities. Hyperkalemia and consequent cardiac toxicity can result from potassium phosphate infusion, even in patients with normal renal function. Rapid infusions may result in phosphaturia.[111]

HYPERPHOSPHATEMIA

Chronic hyperphosphatemia is an uncommon clinical disorder, except in patients with CKD. Acute hyperphosphatemia occurs in circumstances of AKI if a high phosphorus

dose is administered in the form of intravenous hyperalimentation or as phosphate enema (Fleet phosphate enema: monobasic sodium phosphate 19 g and dibasic sodium phosphate 7 g in 4.7 ounces).[112] Tumor lysis syndrome (TLS) is another frequent cause of acute hyperphosphatemia in children.[113] Endocrinopathies, such as hypoparathyroidism and pseudohypoparathyroidism, are well-known causes of hyperphosphatemia as well. Common causes of hyperphosphatemia in children are listed in Table 13.13.

CLINICAL MANIFESTATIONS

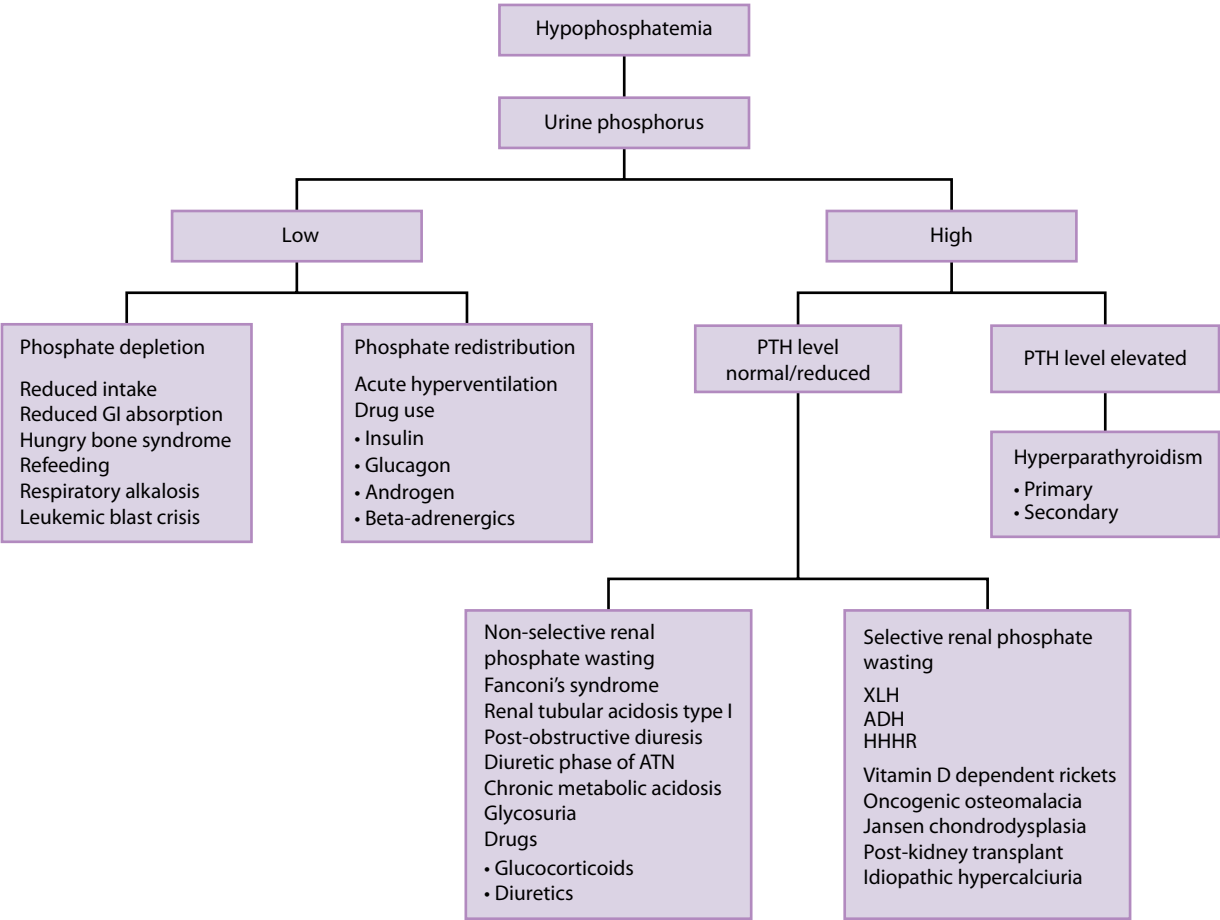
Patients with elevated serum phosphorus levels are frequently asymptomatic. Acute elevations in phosphorus usually cause hypocalcemia, and patients can become symptomatic with paresthesias, tetany, seizures, or cardiac arrhythmias.[114,115] Hypocalcemia is believed to result from chelation and precipitation of phosphorus and calcium ions in the soft tissues, especially when the calcium times phosphorus product is greater than 70.[114] Suppression of 1-25(OH)$_2$D$_3$ synthesis associated with AKI in these patients has been suggested as the other


Figure 13.12 A suggested algorithm for evaluation of hypophosphatemia in children. ATN, acute tubular necrosis; ADH, autosomal dominant hypophosphatemia; HHHR, hereditary hypophosphatemia with hypercalciuria and rickets; PTH, parathyroid hormone; XLH, X-linked hypophosphatemic rickets.

possible mechanism of hypocalcemia.[116] Symptoms may also result from metastatic tissue calcification and calciphylaxis syndrome characterized by rapid calcification in subcutaneous fat and small blood vessels, thus leading to painful necrosis.[117]

Table 13.11 Available oral preparations of phosphorus for treatment of hypophosphatemia

Formulation	Phosphate content	Sodium load	Potassium load
Neutra-Phos	250 mg/pack	7.1 mmol/pack	7.1 mmol/pack
Neutra-Phos K	250 mg/capsule	0	14.25 mmol/pack
K-Phos Original	150 mg/capsule	0	3.65 mmol/capsule
K-Phos Neutral	250 mg/tablet	13 mmol/tablet	1.1 mmol/tablet

CLINICAL DISORDERS

Kidney disease

Hyperphosphatemia is common in AKI, as well as in CKD. This is especially true if the GFR falls to less than 60 mL/min/1.73 m². Despite enhanced phosphate excretion mediated by elevations in PTH and FGF-23 by functioning nephrons, absolute excretion falls.[118] Hyperphosphatemia is worsened by enhanced dietary phosphorus intake. Whereas hyperphosphatemia is common in the oliguric phase of AKI, hypophosphatemia may be encountered during the nonoliguric phase.

Cytolytic disorders

Hyperphosphatemia is caused by a rapid release of intracellular phosphate during cellular breakdown; potassium and magnesium levels are also increased as a result of intracellular release. This is seen in TLS, rhabdomyolysis, and severe hemolytic anemia.[113,115] Underlying kidney dysfunction, caused by hyperuricemia or hyperphosphatemia, may be present in these patients.

Table 13.12 Preparations of potassium for parenteral use

Intravenous preparation	Sodium (mMol/mL)	Phosphorus (mMol/mL)	Potassium (mMol/mL)	Dose mMol/kg	Duration of infusion	Caution
Sodium phosphate, USP	3	4	0	Mild hypophosphatemia: 0.08–0.16 Moderate hypophosphatemia: 0.32–0.4 Severe hypophosphatemia: 0.6	Monitored (ICU): 6 h Ward: 24 h	Sodium overload
Potassium phosphate, USP	0	3	4.4	Mild hypophosphatemia: 0.08–0.16 Moderate hypophosphatemia: 0.32–0.4 Severe hypophosphatemia: 0.6	Monitored (ICU): 6 h Ward: 24 h	Hyperkalemia

ICU, intensive care unit.

Table 13.13 Causes of hyperphosphatemia

Artifactual Causes
- In vitro hemolysis of blood samples
- Hypertriglyceridemia

Increased Intake
- Phosphate-containing enemas
- Increased phosphate in intravenous nutrition
- Cows' milk feeding of premature infants

Endogenously Increased Phosphate Load
- Tumor lysis
- Malignant hyperthermia
- Rhabdomyolysis
- Hemolysis

Extracellular Shift of Phosphorus Acidosis
- Metabolic acidosis
- Respiratory acidosis

Impaired Renal Excretion
- AKI
- CKD
- End-stage renal disease

Hypomagnesemia

Endocrinopathies
- Hypoparathyroidism
- Pseudohypoparathyroidism
- FGF-23 deficiency
- Hypothyroidism
- Acromegaly
- Tumoral calcinosis

Miscellaneous Causes
- Hypomagnesemia
- Excess vitamin D intake (especially in renal insufficiency)
- Bisphosphonate therapy

Tumoral calcinosis

This inherited disorder results from mutations in the *FGF23* gene that cause impaired action of FGF-23 in the renal tubules and an inability to excrete phosphorus, with resultant hyperphosphatemia and widespread ectopic calcifications.[119] The clinical manifestations include periarticular calcifications located along the extensor surfaces of major joints.[117,120] Some cases may be associated with nephrolithiasis and dental abnormalities.[121] Serum calcium concentration is normal, and there is inappropriate lack of suppression of $1,25(OH)_2D_3$, resulting in enhanced renal phosphate reabsorption and hyperphosphatemia.[89,119] Some patients respond to the use of phosphate binders and reduction in dietary calcium and phosphorus.[117]

EVALUATION OF HYPERPHOSPHATEMIA

The evaluation of hyperphosphatemia should include evaluation of renal function, serum calcium, PTH level, vitamin D status, urinary phosphorus excretion, and serum FGF-23 level (Figure 13.13). Abnormal renal function may point to AKI or CKD as the cause of hyperphosphatemia. Secondary hyperparathyroidism in these patients is noted, especially in patients with CKD. Hypoparathyroidism can be diagnosed by presence of low serum PTH level, whereas PTH level is elevated in pseudohypoparathyroidism. Decreased urinary phosphate excretion denotes either renal impairment or other disorders (e.g., hypoparathyroidism) that are associated with increased renal tubular reabsorption of phosphorus. Because the spectrum of *FGF23* mutations in tumoral calcinosis is still evolving, FGF-23 serum levels may be included in the evaluation of selected cases of hyperphosphatemia.

MANAGEMENT OF HYPERPHOSPHATEMIA

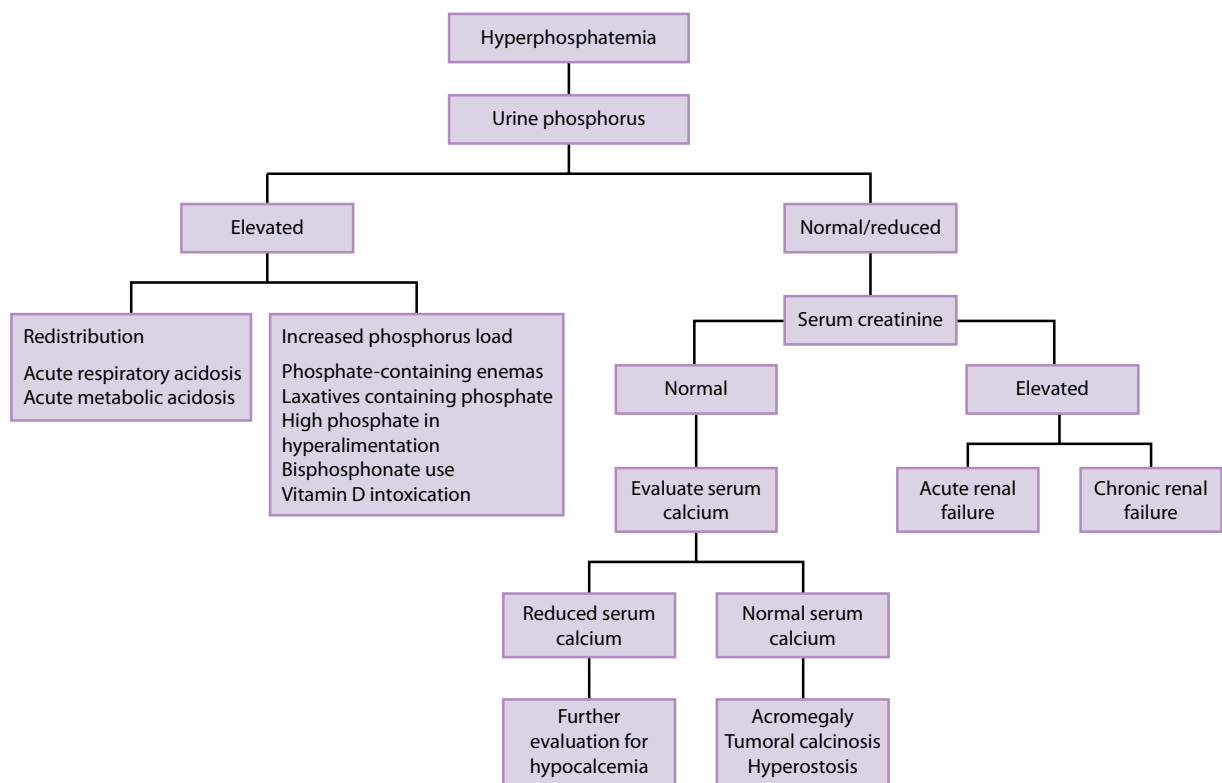
Treatment of hyperphosphatemia is directed toward managing the underlying cause. Oral calcium salts may


Figure 13.13 A suggested algorithm for evaluation of hyperphosphatemia in children.

assist in binding dietary phosphorus, prevent phosphorus absorption, and thereby lessen hyperphosphatemia. In patients with severely impaired kidney function, dialysis may be the only feasible treatment, but the efficiency of hemodialysis and peritoneal dialysis in removal of phosphorus is limited. Continuous renal replacement therapy (CRRT) with hemodiafiltration is able to remove phosphorus efficiently and may be useful in acutely sick patients, such as those with TLS or acute phosphorus intoxication. Caution should be exercised, as CRRT may also remove the therapeutically essential chemotherapeutic agents from patients undergoing treatment for malignant disease.

KEY POINTS

- Hyperphosphatemia is a common problem in CKD and AKI.
- Treatment is usually effective with phosphate binders, given orally.
- Hypoparathyroidism and disorders with low FGF-23 can result in hyperphosphatemia.

SUMMARY

The metabolism of calcium, phosphorus, and magnesium is interdependent and interrelated. The kidney plays an important role in maintaining the homeostasis of all three ions. Advances in our understanding of the hormonal control, cellular actions, and molecular mechanisms of their handling by the kidneys have resulted in a better understanding of many enigmatic clinical disorders (e.g., hypophosphatemic rickets) and the development of newer therapies (e.g., calcitriol). The scientific advance in understanding the biology of FGF-23 is beginning to have a profound impact on the pathogenesis of numerous disorders affecting the metabolism of phosphorus. Indeed, these findings may have significant pharmacotherapeutic applications, including addressing cardiovascular disease relating to aberrant mineral metabolism.

REVIEW QUESTIONS

1. All of the following hormones have a net effect of reducing serum phosphorus values except:
   a. Parathyroid hormone
   b. Calcitonin
   c. Calcitriol
   d. FGF-23
2. Which of the following conditions leads to hypocalcemia?
   a. Pseudohypoparathyroidism
   b. Jansen syndrome
   c. Vitamin A intoxication
   d. Thyrotoxicosis
3. When conducting an evaluation of hypocalcemia, which of the following blood levels WILL NOT be affected by recent administration of intravenous calcium therapy?
   a. Parathyroid hormone
   b. 25(OH) vitamin D
   c. Ionized calcium
   d. $1,25(OH)_2$ vitamin D
4. Hypophosphatemia in Fanconi syndrome leads to which of the following hormonal changes?
   a. Elevated blood FGF-23 levels
   b. Elevated blood cortisol levels
   c. Lowered blood levels of calcitriol
   d. No distinct pattern in calciotropic hormones
   e. Elevated blood levels of calcitonin
5. Which of the following segments of the kidney handle the majority of magnesium homeostasis
   A. Proximal tubule
   B. Thick ascending limb
   C. Thin ascending limb
   D. Distal convoluted tubule
   E. Collecting ducts
      a. D and E
      b. B and D
      c. A and C
      d. A and B
      e. All of the above
6. Which of the following is *not* associated with hypophosphatemia?
   a. Tumoral calcinosis
   b. Refeeding syndrome
   c. XLH
   d. Calcitonin therapy
7. Ionized calcium is the biologically active component of total body calcium and comprises:
   a. 50% of the total body calcium
   b. 1% of the serum calcium
   c. 1% of the total body calcium
   d. 50% of the serum calcium
8. The vast majority of phosphorus handling occurs in this part of the nephron:
   a. Proximal tubule
   b. Loop of Henle
   c. Distal tubule
   d. Collecting duct

9. Which of the following is *not* associated with hypomagnesemia?
   a. Chronic diarrhea
   b. Addison disease
   c. Gitelman syndrome
   d. Loop diuretics
10. When calculating the fractional excretion of magnesium, the plasma magnesium must be multiplied by 0.7 because:
   a. The majority of magnesium is albumin bound.
   b. The majority of magnesium is not ultrafiltrable.
   c. That is the ultrafiltrable percentage of magnesium
   d. That is the percentage of magnesium that is reabsorbed distally.

ANSWER KEY

1. c
2. a
3. b
4. d
5. d
6. d
7. d
8. a
9. b
10. c

Acid-base homeostasis

RAYMOND QUIGLEY

Acid-base homeostasis and disturbances can be some of the most complicated and challenging electrolyte problems encountered by the pediatric nephrologist. To assess and correctly treat the disturbances requires knowledge of acid-base chemistry, physiology, and pathophysiology. This chapter will briefly review the fundamentals of acid-base chemistry and physiology. Disturbances in acid-base homeostasis will be reviewed in a systematic approach so that the pathophysiology of the most complex cases can be understood. The historical development of the ideas behind acid-base homeostasis also will be reviewed to help understand how these concepts developed. Finally, the approach to clinical acid-base disorders will be briefly reviewed.

APPLIED ACID-BASE CHEMISTRY

It is useful to review definitions of some terms used in the discussions related to acid-base balance.[1–3] An acid is defined as a proton donor and a base as a proton acceptor. The following reaction depicts a generalized acid ionization equilibrium:

$$HA \leftrightarrow H^+ + A^- \tag{14.1}$$

where H^+ is the proton and A^- is the anion. The reaction kinetics can be summarized by the equation for the equilibrium association constant:

$$Ka = \frac{[H^+] \times [A^-]}{[HA]} \tag{14.2}$$

The anion of the acid is also known as the conjugate base, because it is capable of accepting a proton. The magnitude of the association constant is usually on the order of 10^{-4} to 10^{-8}, so a more convenient way to represent the constant is the pKa ($pKa = -logKa$). Thus, an acid with a Ka of 10^{-4} would have a pKa of 4.

The reaction for pure water is:

$$H_2O \leftrightarrow H^+ + OH^-$$
Because the concentration of water is constant, the denominator in calculating the equilibrium constant is left out by convention. Thus, instead of an association constant (Ka), the constant is referred to as Kw:

$$Kw = [H^+] \times [OH^-]$$

The value of Kw is approximately 10^{-14} (pKw = 14). Therefore, when water is neutral (i.e., $[H^+] = [OH^-]$), the concentration of H^+ ion is equal to that of OH^-, or 10^{-7} mol/L.

The pH scale is logarithmic and based on the H^+ concentration (ph = $-logH^+$). This means that water that is neutral has a pH of 7. In addition, as can be seen in the following derivation, the logarithmic form of Equation 14.2 becomes the Henderson–Hasselbalch equation:

$$log(Ka) = log\left\{ \frac{[H^+] \times [A^-]}{[HA]} \right\}$$

$$log(Ka) = log(H^+) + log\left\{ \frac{[A^-]}{[HA]} \right\}$$

and because pH = –log[H⁺] and pKa = –log(Ka), this becomes:

$$pH = pKa + \log\left(\frac{[A^-]}{[HA]}\right) \quad (14.3)$$

The applied and clinical utility of this equation is further discussed in the section on acid-base physiology.

KEY POINT

Acids are defined as proton donors and bases as proton acceptors.

Strong acids completely ionize, so that in Equation 14.1 the concentration of HA is nearly zero. Thus, the H⁺ ion concentration is equal to the amount of acid added to the solution. An example would be HCl. A solution of 1 mmol/L of HCl in water will result in a pH of 3 ([H⁺] = 10^{-3} mol/L, thus pH = 3). Weak acids do not completely ionize, so the amount of HA present becomes more significant. An example of a weak acid is lactic acid, which has a pKa of approximately 3.4 at 37° C. It should be pointed out that most weak acids would still be almost completely dissociated at a normal serum pH of 7.4 because their pKa is significantly less than 7.4. For example, lactic acid at a pH of 7.4 would dissociate with a ratio of 10,000 parts of lactate ions to 1 part of H-lactate.

Buffers are weak bases that are capable of binding free protons and thus stabilizing any changes in pH. The number of protons that the buffer can absorb would depend on the concentration of the buffer in the solution as well as the pKa of the buffer. As can be seen by examining Equation 14.3, when the concentrations of the acid form and the anion are equal (i.e., [A⁻] = [HA]), log [A⁻]/[HA] = 0 and the pH of the solution will be equal to the pKa. Thus, buffers will tend to keep the pH of a solution close to the pKa of the buffer.

In mammals, including humans, circulating bicarbonate serves as the primary buffer system.[2] As will be discussed later, the bicarbonate buffer system depends on and is regulated by the respiratory system. The Henderson–Hasselbalch equation will then be expressed as:

$$pH = pKa + \log\left(\frac{[HCO_3^-]}{[H_2CO_3]}\right) \quad (14.4)$$

One final point in basic acid-base chemistry is the fact that some acids have multiple equilibria. In particular, the phosphate ion can have up to three hydrogen ions attached to it. Each of the dissociation reactions has a different pKa.

$$H_3PO_4 \leftrightarrow H^+ + H_2PO_4^-$$

$$H_2PO_4^- \leftrightarrow H^+ + HPO_4^{-2}$$

$$HPO_4^{-2} \leftrightarrow H^+ + PO_4^{-3}$$
The respective pKa for each of these equilibrium reactions at 37° C is 2, 6.8, and 12. Therefore, at a normal blood pH of 7.4, most of the phosphate ions exist in the forms of HPO_4^{-2} and $H_2PO_4^-$. The ratio of these species in the blood can be determined by the Henderson–Hasselbalch equation as follows:

$$7.4 = 6.8 + \log\left(\frac{HPO_4^{-2}}{H_2PO_4^-}\right)$$

Thus, the ratio of $HPO_4^{-2}/H_2PO_4^-$ is 4:1 (i.e., $10^{0.6}$). The amounts of the other species of phosphate are essentially zero at a pH of 7.4.

ACID-BASE PHYSIOLOGY

Circulating bicarbonate is the primary buffering system against the threat of acidosis in humans and most mammals. Within normal parameters of bicarbonate and pCO₂ the serum pH is maintained at 7.4. This means that the H⁺ ion concentration is 40 nmol/L (40×10^{-9} mol/L) (see Equation 14.6). With an average adult human weighing 70 kg and having 42 L of total body water, this indicates that there are only approximately 1.68 μmol of H⁺ ions in the body. Thus, with the generation of acid at approximately 1 to 2 mmol (1000 to 2000 μmol)/kg of body weight per day, there is a very high turnover rate in this very small pool of H⁺ ions. So, one can see how the pH of the blood can quickly change with addition of acid or base.

BICARBONATE-CARBON DIOXIDE BUFFER SYSTEM

Bicarbonate in plasma acts as the first line of protection against acidosis by buffering the excess H⁺ generated. The bicarbonate buffering system in the blood is an "open" system, because it generates carbon dioxide, which can be quickly eliminated by the respiratory system. The relationship between bicarbonate buffering and carbon dioxide is depicted in the following reaction equations:

$$H^+ + HCO_3^- \longleftrightarrow H_2CO_3 \xleftrightarrow{\text{carbonic anhydrase}} H_2O + CO_2 \quad (14.5)$$
From Equation 14.5 it is clear that the bicarbonate buffering system is closely linked to carbon dioxide production and its eventual elimination through the lungs. It is also evident that alterations in the carbon dioxide concentration will cause the reactions in Equation 14.5 to shift. If the

patient hyperventilates and the pCO_2 decreases, the concentration of carbonic acid (H_2CO_3) will decrease and will lower the H^+ concentration, leading to respiratory alkalosis. The opposite is true for respiratory failure when the pCO_2 rises, causing an increase in the concentration of carbonic acid and a rise in the proton concentration, resulting in respiratory acidosis. The relationship between the concentrations of dissolved carbon dioxide and carbonic acid at 37° C is constant (in the presence of carbonic anhydrase) and is depicted in the following equation:

$$H_2CO_3 = 0.03 \times pCO_2$$

This is simply the conversion of pCO_2 in millimeters of mercury (mm Hg) to carbonic acid in millimoles per liter. Thus, the commonly written form of the Henderson–Hasselbalch equation becomes:

$$pH = pKa + \log\left(\frac{[HCO_3^-]}{[0.03 \times pCO_2]}\right) \qquad (14.6)$$

With a normal bicarbonate concentration of 24 mmol/L, pCO_2 of 40 mm Hg, and pKa of 6.1, the normal blood pH is 7.4.

To maintain these parameters within the normal range, the body must not only regulate the pCO_2 by the respiratory system but also must excrete acid that is generated by metabolic activity. Therefore, long-term homeostasis is determined by a balance between the generation of acid from the diet and from new bone formation and the excretion of acid, primarily through the kidney. In addition, short-term changes in the acid-base homeostasis can occur if the generation or excretion of either acid or base changes abruptly or if the respiratory status changes rapidly. This can lead to accumulation of acid or base, which is excreted, eventually, by the kidneys over time.

KEY POINTS

- Circulating bicarbonate is the first line of defense against acidosis.
- Respiratory compensation forms the second mechanism of acid-base homeostasis.
- Kidney provides the third and a delayed mechanism in maintaining acid-base homeostasis.
- Other buffer systems include bone and various cellular and circulating proteins.

GENERATION OF ACID

Our diet consists of a combination of carbohydrates, fats, and proteins.[4,5] In the normal state, carbohydrates and

fats are fully metabolized to carbon dioxide and water and therefore do not contribute to an acid load. Most amino acids are also neutral because the acid part of the amino acids is balanced by the amine moiety so that there is no net acid generation. The acid generated from our diet comes primarily from the metabolism of sulfur-containing amino acids (cysteine and methionine) to sulfuric acid. The typical Western diet results in daily generation of approximately 1 to 2 mmol of acid per kilogram of body weight.[4]

KEY POINTS

- Acid generation from our diet comes from the oxidation of sulfur-containing amino acids.
- Hydroxyapatite from growing bones also adds to acid load in children.

In addition, children generate acid from the production of hydroxyapatite $[(Ca)_{10}(PO_4)_6(OH)_2]$ in growing bone.[6] This adds to their acid generation so that the total amount generated is approximately 2 to 3 mmol of H^+ per kilogram of body weight, which is higher than that seen in adults (1 mmol of H^+/kg body weight).

ROLE OF KIDNEYS IN ACID-BASE HOMEOSTASIS

Renal bicarbonate reabsorption

The kidney is intimately involved in maintaining normal acid-base homeostasis.[7,8] The high filtration rate of the kidney is designed to excrete nitrogenous waste in the form of urea. However, this also means that an enormous amount of filtered bicarbonate would be lost in urine, if it was not reclaimed.[9] The proximal tubule is designed to reabsorb (or reclaim) 80% to 90% of the filtered load of bicarbonate and prevent bicarbonate loss. The mechanisms responsible for this are depicted in Figure 14.1.[10]

KEY POINT

The proximal tubule and thick ascending limb of Henle reabsorb the bulk of the filtered load of bicarbonate.

The first step in the reabsorption of bicarbonate is the secretion of protons into the proximal tubule lumen. This is achieved primarily by the sodium-proton exchanger (NHE_3) located in the luminal membrane, that derives its energy from the low intracellular sodium concentration maintained by the basolateral sodium-potassium ATPase (Na-K-ATPase).
Figure 14.1 Bicarbonate reabsorption by the proximal tubule involves a number of steps. First, protons are secreted into the tubule lumen by the sodium-proton antiporter (NHE3). The proton combines with bicarbonate to form carbonic acid that is converted by carbonic anhydrase (CA IV) to water and carbon dioxide. These diffuse into the cell and are converted back to carbonic acid that dissociates into a proton and bicarbonate. The bicarbonate is then transported into the blood stream by way of the sodium bicarbonate cotransporter (NBC1). (Reproduced with permission from: Fry AC, Karet FE. Inherited renal acidoses. Physiology (Bethesda). 2007;22:202–11.)

In addition, approximately one-third of the proton secretion is attributed to a luminal proton pump (H$^+$-ATPase).[11]

Once the proton is in the tubule lumen, it combines with the filtered bicarbonate to form carbonic acid. In the presence of carbonic anhydrase, it will eventually dissociate into carbon dioxide and water, as shown in Equation 14.5:

$$H^+ + HCO_3^- \longleftrightarrow H_2CO_3 \xleftrightarrow{\text{carbonic anhydrase}} H_2O + CO_2$$
The water and carbon dioxide molecules can then diffuse into the intracellular compartment of the proximal tubule, where the reverse reaction occurs to form carbonic acid that then ionizes to a proton and bicarbonate. Bicarbonate is then transported across the basolateral membrane, where it can then diffuse into the blood stream and the proton is available to be secreted back into the tubule lumen.

The thick ascending limb of Henle also reabsorbs bicarbonate. It is responsible for reclamation of approximately 10% of the filtered load of bicarbonate.[12,13] Thus, at a point when tubular fluid reaches the distal nephron, very little of the filtered bicarbonate is present in it.

Renal acid excretion

To prevent development of an excessive base deficit, the body also needs to excrete the acid that is continually generated from diet and the daily metabolic activities. This is accomplished in the collecting duct, as H$^+$ ion excretion.[14] The collecting duct is made up of several cell types. Most of the cells in the collecting duct are principal cells that are involved with reabsorption of sodium and excretion of potassium. The other cell types are alpha and beta intercalated cells. In general, there are more alpha intercalated cells that excrete acid, with the remainder beta intercalated cells that secrete bicarbonate into the tubule lumen for elimination.

The mechanism for excretion of acid (H$^+$) by the alpha intercalated cell is depicted in Figure 14.2.[10] The proton pump in the luminal membrane uses the energy directly from adenosine triphosphate (ATP) to pump protons into the tubule lumen for excretion. Inside the cell, carbonic anhydrase catalyzes the hydration of carbon dioxide into carbonic acid that ionizes into the proton and a bicarbonate ion (see Equation 14.5). Bicarbonate is transported via the basolateral membrane anion exchanger (AE1) and reabsorbed into the blood stream. The H-K-ATPase depicted in Figure 14.2 is primarily involved in retention of potassium. It is not clear if it plays an important role in the routine excretion of acid, but seems to be upregulated in the setting of potassium deficiency. Thus, the alpha intercalated cell of the collecting duct is responsible for secreting the 1 to 2 mEq/kg body weight of acid that is generated by the metabolism of the body.

KEY POINT

The alpha intercalated cells of the collecting ducts are responsible for actively secreting the acid (H$^+$) generated by metabolic activity.

Role of ammonia and phosphate in renal acid excretion

Once the protons (H$^+$) are secreted into the tubule lumen, it is critical to have buffers to accept the protons in the tubular luminal fluid (urine). To illustrate this point, consider that typical 70-kg adults must excrete 50 to 100 mmol of protons in their urine per day. If we relied solely on the protons that are dissolved in solution, this would require 5,000 to 10,000 L of urine if the urine pH were 5 (i.e., [H$^+$] = 10^{-5} mol/L). Urinary buffers allow protons to be excreted without having to lower the pH of the urine or have a large urine
Figure 14.2 Proton secretion in the alpha intercalated cell of the collecting duct is mediated by the proton pump (H$^+$-ATPase). Carbonic anhydrase (CAII) converts water and carbon dioxide into carbonic acid to provide the proton for secretion. Bicarbonate is transported into the blood stream by way of the anion exchanger (AE1). (Reproduced with permission from: Fry AC, Karet FE. Inherited renal acidoses. Physiology (Bethesda). 2007;22:202-11.)

Figure 14.3 Ammoniagenesis in the proximal tubule cell is critical for providing ammonia as a buffer for the excretion of acid. Glutamine (Gln) is taken up across both the apical and basolateral membranes and undergoes metabolism by glutaminase and glutamate dehydrogenase to provide two ammonia molecules for secretion. (Reproduced with permission from: Weiner ID, Hamm LL. Molecular mechanisms of renal ammonia transport. Annu Rev Physiol. 2007;69:317–40.)

volume. The primary buffers in our urine are ammonium ions and phosphate.

KEY POINT

Ammonia and phosphate are critical buffers in the urine that allow for the excretion of acid in a small amount of urine.

As shown in Figure 14.3, ammonia is generated in the proximal tubules of the kidney.[15–19] Glutamine is taken up by the proximal tubular cells through the apical and basolateral membranes and transported into the mitochondria. There, the enzyme glutaminase converts the glutamine into one glutamate and one ammonia molecule. Glutamate dehydrogenase can then produce a second molecule of ammonia by converting glutamate to α-ketoglutarate. The remaining α-ketoglutarate is then converted into carbon dioxide and water by enzymes in the Krebs cycle. These substrates are provided by the liver and are recycled to continue moving more ammonia precursors to the proximal tubule.

Although it used to be thought that much of the ammonia that is produced in the proximal tubule could move through the cell membrane as a gas, more recent studies have shown that it is secreted into the tubule lumen as ammonium ion by way of the sodium proton antiporter (NHE3).[15,16]

Ammonium is then recycled through the descending limb of Henle and the thick ascending limb in a process that keeps the medullary concentration of ammonium high[16] (Figure 14.4). It appears as though it may move partly as ammonia gas and ammonium ions into the collecting duct, where the protons secreted by the alpha intercalated cells will convert it to ammonium ion.[15] It then is excreted in the urine in the form of ammonium chloride.

The equilibrium reaction for ammonia and ammonium is shown in the following reaction equation:

$$NH_3 + H^+ = NH_4^+$$

The pKa for this reaction is approximately 9.0. Thus, at a pH of 7.4, most of the ammonia is in the form of ammonium. In addition, because the pKa is 9.0, NH_3 will tend to raise the pH of the urine. This can sometimes be confusing because the body will increase ammoniagenesis in the setting of acidosis. This can sometimes cause the urine pH to be higher than expected because of the high concentration of NH_4^+ in the urine.

The generation of ammonia by the proximal tubule can be upregulated in the presence of acidosis by a factor of as much as 5 to 10 over the baseline rate in adults.[20–23] The ability of the neonatal kidney to upregulate ammonium excretion is somewhat limited and can therefore prolong the recovery phase of acidosis in infants.[24,25] The upregulation of ammonium production and secretion serves as the
Figure 14.4 After secretion by the proximal tubule, ammonia is trapped in the medulla so that it can then be transported as ammonia and ammonium ions into the collecting duct lumen to act as a buffer for proton secretion. principal means of correcting acidosis that is due to nonrenal causes of acidosis.

As discussed previously, the phosphate ion exists in several forms depending on the pH of the solution. With a normal blood pH of 7.4, most of the phosphate ion is in the form of HPO_4^{-2}. However, as the tubular fluid travels from the glomerulus, through the various tubule segments, its pH becomes lower. This will convert more of the phosphate ion to the $H_2PO_4^-$ form. When the urine pH becomes 4.8, the ratio of $HPO_4^{-2}/H_2PO_4^-$ will then be 1:100. So there is a large potential for excreting acid in the form of phosphate. Phosphate accounts for the bulk of what is termed *titratable acid* in the urine.

Net acid excretion

The total amount of acid excreted by the kidneys is referred to as the net acid excretion (NAE) and is expressed as:

$$NAE = (U_{NH_4^+} + U_{TA} - U_{HCO_3}) \times V$$

where V is the urine flow rate, U_{NH_4} is the urine ammonium concentration, U_{TA} is the urine titratable acid concentration, and U_{HCO_3} is the urine bicarbonate concentration. Thus, the components of acid secretion can be thought of as bicarbonate reclamation to prevent bicarbonate loss, ammonium excretion, and titratable acid excretion. The titratable acid component is predominately phosphate, but may also contain some sulfate ions. The concept of NAE provides a framework for the approach to evaluating the patient's ability to excrete acid as will be seen below.

ACID-BASE DISORDERS

Because bicarbonate is the primary buffering system of the blood, the carbonic acid equilibrium reaction serves as a framework for thinking about acid-base disturbances in

clinical circumstances.[3,26-28] This is depicted in Equation 14.5:

$$H^+ + HCO_3^- \longleftrightarrow H_2CO_3 \xleftrightarrow{\text{carbonic anhydrase}} H_2O + CO_2$$
Expressed as the Henderson–Hasselbalch equation (Equation 14.6):

$$pH = pKa + \log\left(\frac{[HCO_3^-]}{[0.03 \times pCO_2]}\right)$$

where 0.03 represents the conversion factor from pCO_2 to $[H_2CO_3]$. Thus, changes in either pCO_2 or in the bicarbonate concentration will affect the blood pH.

CLASSIFICATION OF ACID-BASE DISORDERS

The terms *acidemia* and *alkalemia* refer to the pH values being lower or higher than normal, which is determined by the prevailing H^+ ion concentration. The terms *acidosis* and *alkalosis* refer to the *processes* that lead to the abnormal blood pH. These processes (acidosis and alkalosis) can be the result of either metabolic or respiratory disturbances. Therefore, there are four primary acid-base disorders: metabolic acidosis, metabolic alkalosis, respiratory acidosis, and respiratory alkalosis. Because of compensatory responses, primary acid-base disorders rarely exist alone.

PATIENT EVALUATION

It is critical to obtain a detailed history and physical examination for clues that will help in determining the underlying pathogenesis of the acid-base disorder and aid in developing an appropriate therapeutic plan.

As noted earlier, most acid-base disorders are of mixed nature because of the compensatory changes induced in an intact organism. To illustrate this, we will discuss a patient with diabetic ketoacidosis (DKA). When a patient with diabetes lacks insulin, the metabolism shifts to primarily using fatty acids instead of glucose. The production of ketoacids from this process will quickly exceed the kidney's ability to excrete the acid load, and metabolic acidosis will ensue. The respiratory system will then compensate by decreasing the pCO_2 with Kussmaul respirations, resulting in respiratory

---

KEY POINT

Metabolic acidosis leads to increased minute ventilation and decreased pCO_2 respiratory compensation.

---

alkalosis. In essence, the ratio of bicarbonate to carbonic acid (approximated as $0.03 \times pCO_2$) should remain at 20 to maintain a blood pH of 7.4 (see Equation 14.5). Thus, if the bicarbonate concentration falls by 50% to 12 mEq/L, the pCO_2 should decrease from 40 to 20 mm Hg to yield a blood pH of 7.4.

Assessment of acid-base status can be difficult when the correction is not complete, as is often the case. In the earlier example of the patient with DKA, the respiratory compensation is almost never complete. The pCO_2 might decrease to 30 mm Hg, and in that case the resulting pH would be 7.22. Thus, the patient would have a primary metabolic acidosis and a compensatory respiratory alkalosis. In some clinical circumstances, more than one acid-base disturbance may inherently exist, even without compensatory responses. The classic example of this is salicylate poisoning, which causes metabolic acidosis but also stimulates the respiratory center directly. The resulting respiratory alkalosis actually can cause the blood pH to be high early in the course of the intoxication.

Blood gas analysis

The assessment of the patient's acid-base status begins with obtaining a complete set of data that includes not only the serum bicarbonate concentration but also the pH and the pCO_2 in the blood. In most blood gas analyzers, the pH and pCO_2 are measured and the bicarbonate concentration is then calculated. If the electrolytes are measured using a serum chemistry autoanalyzer, the bicarbonate value might vary from the one obtained in the blood gas analyzer because of the different assay methodologies.[29] It is useful to check that the three pieces of data obtained are agreeable. If one of the values does not agree with the Henderson–Hasselbalch equation, there is a good chance there may be a laboratory error in the data.

Base deficit

Both the respiratory system and the kidneys regulate the acid-base status, and the contribution of each of them to the underlying acid-base problem must be determined. Clinicians rely on the base deficit calculated by most blood gas analyzers as a way to identify the nonrespiratory component of the acid-base disturbance. Base deficit is defined as the amount of bicarbonate (in milliequivalents per liter) that needs to be added or subtracted from the blood to give a pH of 7.4, when the pCO_2 is adjusted to 40 mm Hg.[2] Normal base deficit is –2 to +2 mEq/L. Metabolic acidosis is characterized by a base deficit of greater than 5 mEq/L. The base excess is the same as the base deficit multiplied by –1. These calculations are attempts to identify the primary acid-base disorder by separating the respiratory (carbon dioxide) component from the metabolic (bicarbonate) component.
Figure 14.5 Acid-base nomogram. The acid-base nomogram is critical in evaluating the acid-base status of the patient. These nomograms are based on data from animal studies as well as human cases.

Nomograms

In practice, the best way to understand the acid-base status of the patient is to plot the pH, pCO_2, and bicarbonate concentrations on an acid-base nomogram (Figure 14.5). The advantage of this method over relying on the base deficit is that the nomogram data are derived from animal models and actual patients. The nomogram thus provides the clinician with a clearer and a more realistic picture of the acid-base status of the patient. In addition, the acute or chronic nature of the disturbance also becomes evident. As can be seen in Figure 14.5, the areas that correspond to acute and chronic conditions are clearly separated. These nomograms are available on the World Wide Web as well as on mobile platforms (Acid Plus). After the data are plotted

on the nomogram, the primary acid-base disorder as well as evidence of compensation will be much more apparent. Although there are many rules of thumb for helping to determine these disorders, there are numerous exceptions to the rules and these can end up being misleading.

METABOLIC ACIDOSIS

One of the most common acid-base disturbances that the pediatric nephrologist is asked to evaluate is a patient with metabolic acidosis.[30] Metabolic acidosis occurs either when excess acid is generated or the base is lost at a rate that cannot be corrected by the kidney.[30]

The evaluation of patients with metabolic acidosis includes history as well as physical examination for clinical clues. Nonrenal loss of base (bicarbonate), such as in diarrhea, ingestion of a substance that would result in production of acids, or infusion of aminoacids, such as in total parenteral nutrition, should be looked at in the historical data.

INITIAL INVESTIGATIONS

It is critical to first assess the complete acid-base status of the patient with a blood gas analysis, so that a true diagnosis

KEY POINTS

- The acid-base status is best understood by plotting these data on an acid-base nomogram.

of acidosis can be ascertained. It is important to recognize that a low serum bicarbonate value may result from acute or chronic respiratory alkalosis. Also, a significant time delay between drawing the blood sample and analysis of the serum may result in the serum bicarbonate concentration to be lower than expected. The advantage of a blood gas analysis is that the sample is usually analyzed shortly after the blood is drawn and laboratory errors are minimized.

Anion gap

One of the primary tools used in evaluation of patients with metabolic acidosis is the anion gap.[31,32] Although reported in the 1970s, its interpretation has undergone considerable refinement.[33,34] The principle behind the anion gap is that the cations (positive charge) and the anions (negative charge) in the blood must be quantitatively the same to balance the electric charge (Figure 14.6A). The commonly measured cations sodium and potassium account for most of the cations, but there are many more that are termed *unmeasured cations*. These include calcium, magnesium, and gamma-globulin proteins. The commonly measured anions include chloride and bicarbonate. The unmeasured anions consist of primarily albumin but also phosphate, sulfate ions, and organic anions. In addition, there might be other anions present that are produced by the disease process, such as lactate or ketoacids, or from ingestion of a compound such as ethylene glycol.

The usual way to calculate the anion gap is:

$$\text{Anion Gap} = Na^+ - (Cl^- + HCO_3^-)$$

The concentration of potassium is ignored in the calculation of anion gap, because it is small compared to sodium and does not deviate much from approximately 4 mEq/L. The normal range for the anion gap is approximately 8 to 12 mEq/L. However, it is critical to understand how a particular laboratory measures these ions and defines the normal range. Evidence suggests that the newer methodologies for measuring ions with ion-selective electrodes results in higher chloride concentrations than in the previously used method of flame photometry.[35] This means that the normal anion gap range might be lower than previously reported.
Figure 14.6 **(a)** Normal anion gap in the serum. Cations must be balanced by the same amount of anions. Because the commonly measured ions do not account for all the ions in the blood, there are both unmeasured cations as well as anions in plasma. **(b)** Elevated anion gap metabolic acidosis. There are extra retained anions (e.g., lactate or ketoacids) that cause the chloride concentration to decrease. Thus, the calculated anion gap is increased. **(c)** Normal anion gap metabolic acidosis. As the bicarbonate concentration decreases, the chloride concentration increases to the same degree so that the calculated anion gap remains in the normal range, or from ingestion of a compound.

It is also important to realize that the bulk of the anion gap in normal individuals is made up of serum albumin.[36,37] The isoelectric point of serum albumin is 4.7. Therefore, at a normal serum pH of 7.4, albumin carries many negative charges and hence contributes to the anion gap. If the patient's albumin value is low, such as in nephrotic syndrome, the anion gap also will be low. This will be reflected in a higher than normal chloride concentration. This means that if a patient with nephrotic syndrome presents with a very low albumin value, normal chloride and bicarbonate concentrations and thus normal anion gap, he or she probably has an unmeasured anion that is elevated. In other words, the patient likely has an increased anion gap metabolic acidosis.

KEY POINTS

- Serum albumin constitutes the bulk of anion gap in normal individuals.
- The anion gap is affected by the serum albumin and serum pH.
- Anion gap in uncomplicated nephrotic patients is low.

The other effect that albumin has on the anion gap is that its charge will change depending on the pH of the serum.[38] When the patient is acidotic, albumin will contribute fewer negative charges and thus the anion gap will be slightly lower than normal. [38] If the patient is alkalotic, the opposite is true. The albumin molecule will have more negative charges that are not canceled by protons and thus will contribute to an elevated anion gap. It is not uncommon to be misled by a patient with respiratory alkalosis if the bicarbonate concentration is low because of metabolic compensation and the anion gap is elevated secondary to the increased negative charges on the albumin.

CLASSIFICATION OF METABOLIC ACIDOSIS

Traditionally, metabolic acidosis has been divided into two main categories: conditions with an increase in the anion gap and conditions with a normal anion gap (hyperchloremic acidosis). These are outlined in Tables 14.1 and 14.3. Clinical aspects of some of the more common conditions resulting in metabolic acidosis are discussed in the following section.

INCREASED ANION GAP METABOLIC ACIDOSIS

outline, the clinician should be able to analyze the information on the patient to determine the underlying cause of metabolic acidosis.

KEY POINT

The anion gap increases when unmeasured anions are retained. Often this is due to either volume depletion or some degree of acute kidney injury (AKI).

DIABETIC KETOACIDOSIS

One of the more common causes of an increased anion gap acidosis is DKA.[39] These patients have a lack of insulin that causes their metabolism to shift so that they metabolize fatty acids instead of glucose. This results in the production of ketoacids, acetoacetate, and β-hydroxybutyrate, which increases the anion gap. Acetone is also produced but does not contribute to the anion gap. As the production rate of acid quickly exceeds the kidney's ability to excrete it, the patient develops metabolic acidosis with a low bicarbonate concentration and normal chloride concentration, which results in an elevated anion gap (see Figure 14.6B).

If the patient remains well hydrated and is not volume depleted, the kidney is quite capable of excreting the ketoacids. However, because of the osmotic diuresis generated by the elevated glucose concentration, the patient quickly becomes volume depleted and usually develops some degree of AKI. Under these conditions, the ketoacids are retained and an elevated anion gap develops. Once the patient is volume expanded with normal saline (0.9% saline), the patient will then excrete these ketoacids and normalize the anion gap. With appropriate therapy of DKA, the increased metabolic acidosis may convert to normal anion gap acidosis.[40] The same principle applies to other forms of increased anion gap acidosis as well.

Because of its high glomerular filtration rate, the kidney is capable of excreting large amounts of filtered ions. If the body is retaining the ions and causing an increase in the anion gap, there is almost always volume depletion with or without some degree of acute kidney injury causing their retention.

LACTIC ACIDOSIS

Lactic acidosis is another of the increased anion gap acidoses, listed in Table 14.1, that deserves some discussion.[41] When glucose is metabolized in the presence of adequate oxygenation, the end products are water and carbon dioxide and there is no production of acid. However, lactic acid is produced in the setting of anaerobic glycolysis. This occurs during times of increased exercise, such as sprinting.[42] Because athletes have good tissue perfusion, the oxygen debt is eventually restored, and lactate is metabolized to water and carbon dioxide.[43,44]

The clinician often encounters lactic acidosis in the intensive care unit in patients with sepsis and multiorgan dysfunction.[45] Lactic acidosis in these patients persists as long as the tissue perfusion remains suboptimal. In these patients, in addition to increased tissue production of lactate, there is often a decreased renal function and compromised clearance of lactate via the kidney, as well. As a result, both enhanced production and retention of lactate result in increased blood lactate level.

Our understanding of lactic acidosis has progressed considerably in recent years. It is important to recognize that lactate itself is not toxic, but just a sign of poor tissue perfusion and cellular utilization of glucose. Thus, it becomes fruitless to try to remove the lactate by using various forms of renal replacement therapy. The lactic acidosis will improve only when the patient's tissue perfusion improves. Some studies suggest that monitoring the serum lactate concentration can provide information on the cardiovascular status of the critically ill patient.[46]

INBORN ERRORS OF METABOLISM

Another class of diseases that result in an elevated anion gap acidosis in pediatric patients is the inborn errors of metabolism.[47] Many of these diseases result in the production of organic acids that cannot be further metabolized and result in an elevated anion gap. These will usually manifest within the first several days or weeks of life and can sometimes cause hyperammonemia.

ETHYLENE GLYCOL INGESTION

A number of ingestions result in an increased anion gap acidosis. In particular, ethylene glycol ingestion can cause metabolic acidosis and acute kidney injury and can be lethal.[48] Thus, the recognition of the ingestion and treatment in a timely fashion is imperative. When the patient first ingests ethylene glycol, acidosis does not develop immediately. Because ethylene glycol is an alcohol, it results in the patient having central nervous system depression.

Not being an ion, by itself, ethylene glycol does not contribute to an anion gap. However, when the enzyme alcohol dehydrogenase metabolizes ethylene glycol there is a transient intermediary known as glycolic acid that has been

shown to be the anion responsible for the increased anion gap. This new substance is also very toxic to the kidney and other organs. The end product of the metabolism of ethylene glycol is oxalate. Urine of these patients often shows numerous oxalate crystals by microscopic evaluation.

Osmolar gap

Because the patient does not have an increase in the anion gap on presentation, ethylene glycol poisoning might go undetected until it is too late to treat. The way to determine quickly if there is a substance such as ethylene glycol in the blood is to examine the osmolar gap.[49] This is done by measuring the osmolality of the blood and also determining the calculated osmolality with the following equation:

$$\text{Calculated Osmolality} = 2 \times [\text{Na}^+] + \frac{\text{glucose}}{18} + \frac{\text{BUN}}{2.8}$$

where glucose is the serum glucose concentration in milligrams per deciliter and BUN is the blood urea nitrogen in milligrams per deciliter. Dividing the glucose by 18 and the BUN by 2.8 converts their units to millimoles per liter. Multiplying the sodium concentration by 2 will account for the accompanying anions with the sodium. So, the osmolar gap would then be the difference of the measured osmolality and the calculated osmolality, which is normally on the order of 8 to 12 mOsm/L.

Ethylene glycol and the other alcohols, ethanol, methanol, and isopropyl alcohol, have low molecular weights and would therefore contribute to an increase in the measured osmolality. Because they are not ions, they would not contribute to the calculated osmolality. Thus, an increased osmolar gap is very good evidence that the patient ingested one of these substances.

As the ethylene glycol is metabolized, the osmolar gap decreases and the anion gap will increase because of the formation of glycolic acid. This is also true for methanol (antifreeze poisoning) that is metabolized to formic acid, but ethanol and isopropyl alcohol are not metabolized to anions. Thus, a patient who has ingested ethanol or isopropyl alcohol and develops elevated anion gap acidosis usually has developed either ketoacidosis from starvation or has lactic acidosis as a result of respiratory or cardiac depression.

The treatment of ethylene glycol or methanol ingestion is aimed at reducing the production of the toxic compounds.[50] In the case of ethylene glycol, the toxin is glycolic acid, and in the case of methanol, it is formic acid. The enzyme alcohol dehydrogenase produces these compounds; thus, blocking the enzyme in the early phases of treating these ingestions is critical. Ethanol (alcohol) can be used for this purpose, because its affinity for the enzyme is much higher than that of ethylene glycol and methanol. Unfortunately, it is also a substrate and will need to be given continuously. Another inhibitor, fomepizole, also is used because it is a noncompetitive inhibitor.[49] Dialysis can be used to remove these compounds because they are low-molecular-weight compounds with a relatively small volume of distribution and have no protein binding.

5-OXOPROLINE–INDUCED METABOLIC ACIDOSIS

Another substance that recently has been found to cause increased anion gap acidosis is 5-oxoproline (also known as pyroglutamic acid).[51–53] This molecule is a result of metabolism involving the γ-glutamyl pathway. This is a metabolic pathway involved in the intracellular transport and metabolism of a number of amino acids. Glutathione is involved in these reactions. Although there are rare inherited defects that can result in excess 5-oxoproline, it also can develop in patients who are glutathione deficient and have chronic acetaminophen use.

NORMAL ANION GAP METABOLIC ACIDOSIS

The normal anion gap acidosis (Table 14.3) is often due to loss of bicarbonate or bicarbonate equivalents in the patients. Diarrheal disease and renal tubular acidosis (RTA) are two common forms of normal anion gap metabolic acidosis in childhood.

DIARRHEAL DISEASE

The most common diagnosis of normal anion gap metabolic acidosis in children is diarrhea. These patients lose massive amounts of bicarbonate equivalents in the stool, and serum bicarbonate concentration declines quickly. Because of volume depletion and activation of the renin-angiotensin-aldosterone system, the kidney attempts to conserve as much sodium as possible to maintain the volume status of the patient. Because the bicarbonate ions are in low concentration, the sodium is reabsorbed with chloride and the patient develops hyperchloremia. Thus, the anion gap (calculated as $\text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-)$) remains in the normal range (see Figure 14.6C).

RENAL TUBULAR ACIDOSIS

Another group of disorders that result in normal anion gap acidosis is RTA. RTA is discussed further in Chapter 42. The basic problem in these disorders is that the kidney cannot excrete the acid generated by normal metabolic activity on a daily basis, resulting in metabolic acidosis.

Urinary anion gap

Sometimes differentiating metabolic acidosis resulting from diarrheal disease and RTA is difficult. The primary

difference in these two forms of normal anion-gap acidosis is the source of bicarbonate loss and the renal response to the acidosis. As discussed earlier, the primary urinary buffer used for the excretion of acid is ammonium. If the patient becomes acidotic from gastrointestinal losses, the kidney has the capacity to increase ammonium excretion by four-fold or five-fold to help correct the acidosis. However, patients with RTA are not able to increase their ability to excrete ammonium.

Therefore, urinary excretion of ammonium can be used to differentiate these two disorders. Currently, most clinical laboratories do not measure urinary ammonium on a routine basis. Therefore, the amount of ammonium in the urine must be extrapolated by examining other ions in the urine. In a manner similar to serum anion gap, one can examine the urine anion gap for this purpose.[54] The principle is that the total cations and the anions in the urine must be equal in terms of their charges. This is summarized in the following equation:

$$Na^+ + K^+ + NH_4^+ = Cl^- + HCO_3^-$$
Because urinary bicarbonate is generally not measured in clinical laboratories, urine pH may be used to reflect the amount of bicarbonate. If the urine pH is less than 6.5, the amount of bicarbonate will be negligible. In addition, there are a number of unmeasured cations and anions such as calcium, magnesium, phosphate, and sulfate and many organic anions that are not accounted for in this calculation. This leaves the urine concentration of sodium, potassium, and chloride as the usual ions that are measured. Thus, the common method of calculating the urinary anion gap is:

$$Urinary\ anion\ gap = ([Na^+] + [K^+]) - [Cl^-]$$

Under normal conditions, the urinary anion gap will be zero. This is due to the fact that the ammonium present in the urine will be equal to the amount of unmeasured anions. However, when a patient has diarrhea, the amount of ammonium (excreted as with chloride) will increase greatly. In this condition, the amount of chloride will be greater than the sum of the sodium and potassium and the urinary anion gap will be negative. If the patient has RTA, the ability of the kidney to excrete ammonium will

be limited and the urinary anion gap will be positive (i.e., the sum of sodium and potassium will be greater than the chloride).

This approach has proved to be useful, but also has some limitations. If the patient has ketoacidosis, the amount of anions being excreted will be greatly increased and will cause the sodium and potassium excretion to increase as well. This will yield a positive urinary anion gap in a patient who might have normal renal function. Thus, another approach to estimate the ammonium in the urine is the urinary osmolar gap.[55,56] This can account for other unmeasured anions that could lead to misinterpretation of the urinary anion gap.

KEY POINT

Mixed acid-base conditions can be understood in many cases by comparing the change in the anion gap to the change in the serum bicarbonate concentration.

Delta anion gap

In many cases, the patient might have a combination of an increased anion gap acidosis and a normal anion gap acidosis. For example, if patients who have DKA also develop diarrhea, they could present with a mixed picture of a normal anion gap and increased anion gap. This can be somewhat confusing. The approach to take in this setting is to analyze the change in the anion gap and compare it to the change in the bicarbonate concentration. This has been termed the *delta anion gap* or the *delta delta gap*.[57,58]

The underlying concept of *delta anion gap* is that in the setting of an elevated anion gap acidosis, change in the anion gap should be equal to the decrease in the serum bicarbonate concentration. For example, if a patient presents with DKA and has the following electrolyte values: sodium, 132 mEq/L; chloride, 95 mEq/L; and bicarbonate, 12 mEq/L, the anion gap would be 25 mEq/L (132–95–12). If the normal anion gap is considered to be 12, then the delta anion gap (difference of observed and normal) would be 13 mEq/L. The change in bicarbonate would be the same (25 – 12 = 13). So this is clearly a pure increased anion gap acidosis.

Consider a patient with diarrhea as the cause of acidosis. He might present with the following electrolyte values: sodium, 132 mEq/L; chloride, 108 mEq/L; and bicarbonate, 12 mEq/L. This yields an anion gap of 12 mEq/L, which is in the normal range. Analyzing the differences in the observed and normal bicarbonate concentrations and the anion gap, it is clear that the change in bicarbonate (13 mEq/L) is much greater than the change in the anion gap (12 – 12 = 0). This indicates a normal anion gap acidosis.

Now consider the patient with DKA who also has diarrhea. She could present with the following electrolytes values: sodium, 132 mEq/L; chloride, 105 mEq/L; and

---

KEY POINT

The evaluation of a patient with a normal anion gap metabolic acidosis needs to include an estimate of the urinary ammonium excretion. This can be done by examining the urinary anion gap.

bicarbonate, 12 mEq/L. This yields an anion gap of 15 mEq/L. The difference in the bicarbonate concentration is 13 mEq/L, but the difference in the anion gap is now only 3. Thus, this would indicate a mixed picture of increased anion gap acidosis and normal anion gap acidosis.

Other conditions in which this approach can prove helpful is in the patient who has respiratory alkalosis in addition to a metabolic acidosis. An example would be the patient who presents with salicylate toxicity. As with any test in clinical medicine, there always will be exceptions to the rules. A recent study indicated that the use of the delta gap might not be as helpful as many investigators thought. The reason for some of the discrepancies might be that the normal range for the anion gap has been changing with the newer methodologies for measuring serum chemistries.[35]

METABOLIC ALKALOSIS

Metabolic alkalosis is less common in clinical practice than metabolic acidosis. However, alkalosis often can be associated with higher morbidity and mortality. Human physiology is designed to help prevent alkalosis. Recall that we have a high-filtration system for the excretion of urea that normally necessitates the reabsorption of large quantities of bicarbonate to prevent acidosis. A person who ingests a large amount of bicarbonate would quickly excrete the bicarbonate and would not sustain an alkalosis. Thus, one of the key points of metabolic alkalosis is the concept that it occurs in two phases. Metabolic alkalosis requires its generation, and then under conditions that promote the retention of bicarbonate, the alkalosis is maintained.[59] Metabolic alkalosis traditionally has been classified as chloride responsive and chloride nonresponsive and will be discussed along those lines in this chapter, as well.

> ### KEY POINTS
>
> - Metabolic alkalosis first must be generated and then sustained by abnormal clinical events.
> - Metabolic alkalosis can be approached as being chloride responsive versus chloride nonresponsive.

PYELORIC STENOSIS AND VOMITING

The classic example of metabolic alkalosis in children is a state of persistent vomiting, such as in patients with pyloric stenosis.[60] These patients lose gastric secretions, resulting in loss of H[+] ions (as hydrochloric acid), sodium, chloride, and volume. Under normal conditions, the pancreas secretes bicarbonate into the lumen of the intestines to neutralize the stomach acid and provide an optimal pH for intestinal and pancreatic enzymes to work. However, with the blockade at the pylorus and without gastric secretions, the unneutralized bicarbonate in the intestine is reabsorbed, leading to metabolic alkalosis. It should be pointed out that because of early diagnosis and prompt treatment of pyloric stenosis today, patients may not have as severe metabolic alkalosis as had been the case in past.[60]

Alkalosis associated with vomiting or prolonged nasogastric suction is also associated with hypokalemia. Hypokalemia results in these patients from two possible mechanisms. First, increased aldosterone secretion as a result of the volume depletion leads to distal tubular K[+] and H[+] secretion. Interestingly, because of increased distal H[+] secretion, sometimes these alkalotic patients may have acidic urine (paradoxical aciduria), with urine pH reaching below 5.5. Second, as enhanced proximal tubular sodium reabsorption is associated with chloride reabsorption, increased bicarbonate delivery to distal nephron promotes distal potassium secretion, to preserve electroneutrality. As a result of total body potassium depletion, patients with pyloric stenosis require careful repletion with potassium ion, in addition to volume.

ALKALOSIS IN EXTRARENAL CHLORIDE LOSS

Conditions that lead to nonrenal chloride loss also result in metabolic acidosis. Two commonly encountered clinical conditions associated with extrarenal chloride loss are cystic fibrosis and congenital chloride diarrhea.[61–63] As expected, the urinary chloride excretion in these conditions is very low.

CONTRACTION ALKALOSIS

Metabolic alkalosis can be observed under the conditions of volume depletion, and has been known as contraction alkalosis. Contraction alkalosis represents a classic form of chloride-responsive alkalosis, which is associated with low urinary chloride level. The chloride-responsive metabolic alkalosis seen in children can be seen in numerous clinical states associated with loss of chloride via renal and nonrenal routes. Cannon et al.,[64] who first described "contraction alkalosis," attributed it to sudden extracellular volume contraction. Traditionally, it has been thought that volume contraction promotes proximal tubular sodium and water reabsorption, along with that of bicarbonate, leading to metabolic alkalosis. Chloride depletion is now considered the pathogenic mechanism for contraction alkalosis. Some have even suggested that this condition be reclassified as "chloride depletion," rather than the traditional nomenclature of "contraction alkalosis."[65] Volume expansion and provision of chloride ions in the form of 0.9% saline allows

the patient to excrete the excess bicarbonate and thus mitigate alkalosis.

DIURETICS IN BARTTER AND GITELMAN SYNDROMES

Bartter syndrome and Gitelman syndrome lead to metabolic alkalosis secondary to urinary chloride loss resulting from defects in the thick ascending limb of Henle and the distal convoluted tubule.[66] Loop diuretics (such as furosemide) that cause urinary loss of chloride, often lead to metabolic alkalosis and can mimic Bartter syndrome. Thiazide diuretics inhibit chloride transport in the distal convoluted tubule and also cause alkalosis, but it is usually milder than that seen with the use of the loop diuretics. In these examples, the urine chloride is elevated and response to chloride repletion may be suboptimal.

CHLORIDE-NONRESPONSIVE METABOLIC ALKALOSIS

Some forms of metabolic alkalosis are termed *chloride unresponsive* because they generally have a high urinary chloride concentration and do not show resolution on volume expansion with 0.9% saline administration. The best example of this is primary hyperaldosteronism. In this condition, the patient is in a volume expanded state because of the retention of sodium in the collecting duct. Because of the high aldosterone concentration, the collecting duct actively secretes protons and potassium (H^+ and K^+), resulting in alkalosis and hypokalemia.

HYPOKALEMIC ALKALOSIS

Potassium depletion is a well-known cause of metabolic alkalosis. The pathophysiologic mechanism is complex and includes upregulation of the H-K-ATPase in the collecting duct to help reabsorb potassium as well as complex interactions with ammoniagenesis.

RESPIRATORY COMPENSATION IN METABOLIC ALKALOSIS

Severe metabolic alkalosis can result in respiratory acidosis, in an attempt to correct metabolic alkalosis by carbon dioxide retention. These patients may have slow and shallow breathing, and respiratory depression from metabolic alkalosis has been reported.[67,68]

RESPIRATORY ACIDOSIS

Respiratory acidosis occurs when the pCO_2 in the blood is elevated (hypercapnia) because of pulmonary disease and poor ventilator functions. Although this sounds fairly simple and straightforward, it can sometimes be difficult to determine if the patient has isolated ventilation problems. In particular, if the patient has chronic respiratory acidosis, the kidney can compensate with metabolic alkalosis, resulting in a mixed acid-base disturbance.

For example, if a patient has a pCO_2 of 60 mm Hg, the bicarbonate concentration will increase to 36 mEq/L and the blood pH will be 7.4. Thus, often one of the clues that a patient has chronic respiratory acidosis is the elevated bicarbonate in the absence of vomiting or other causes of metabolic alkalosis. In this example, the patient has a normal blood pH, even though there is significant respiratory failure. If such patients become critically ill and require intubation for respiratory support, they may manifest only metabolic alkalosis. This is because even though the pCO_2 can quickly become normalized on ventilator support, correction of bicarbonate will take some time. These patients also run the risk for becoming volume depleted because the urinary elimination of excess bicarbonate will be accompanied by sodium ion and require a large urine output.

Another acid-base disorder is the triple acid-base disorder. In the previous example, the patient has primary respiratory acidosis with a pCO_2 of 60 mm Hg. The patient also has metabolic alkalosis to compensate for this, with a bicarbonate concentration of 36 mEq/L. If the patient now develops diarrhea and has metabolic acidosis, there will be three concurrent acid-base disorders. This patient's bicarbonate concentration will be in the normal range of approximately 24 mEq/L (resulting from gastrointestinal loss of bicarbonate). However, the blood gas analysis will show that the patient is acidotic and will have a pH of 7.22 {6.1 + log [24/ (0.03 × 60)]}. On the surface this patient may appear to have acute respiratory acidosis, but detailed analysis will reveal a complex acid-base disturbance. The key here is the serum chloride and the anion gap.

RESPIRATORY ALKALOSIS

Respiratory alkalosis results from excessive removal of pCO_2 through lungs by hyperventilation (hypocapnia), induced accidentally or intentionally in a mechanically ventilated patient or due to psychogenic hyperventilation. Respiratory alkalosis can be acute or chronic in time course. Acute respiratory alkalosis is characterized by low pCO_2 level and an alkalemic blood pH. In contrast, chronic respiratory alkalosis has low pCO_2 level but the blood pH is normal or near normal. In the setting of acute respiratory alkalosis, the kidney has not had time to compensate and reduce the serum bicarbonate concentration. However, over a period of days, the kidney will excrete excess bicarbonate and bring the blood pH to a more normal level. The best way to determine the chronicity of this condition is to examine the acid-base nomogram (see Figure 14.5).

SUMMARY

As discussed previously, the acid-base homeostasis is determined by respiratory function and metabolic function. The challenge has always been to determine how much of a disturbance is due to the respiratory or the metabolic components. The fundamentals of acid-base physiology were developed during the early to mid-20th century. Much of this information is reviewed by Davenport.[2]

Henderson had expressed the ionization reaction for a general acid using the principle of mass action that had been developed in the late 19th century. Hasselbalch then converted the Henderson equation into the familiar logarithmic form that is well known as the Henderson–Hasselbalch equation. As techniques improved for the measurement of the components of the blood gases (i.e. pH and pCO^2) efforts to determine the two components, respiratory versus metabolic, began to develop. The first was the *standard base*. This was measured by taking the sample of blood and allowing it to equilibrate with gas to yield a pCO_2 of 40 mm Hg. Thus, a sample with a low standard bicarbonate would indicate a metabolic acidosis.

The concept of base excess was then developed. It is defined as the amount of acid or base needed to titrate the bicarbonate concentration to 24 mEq/L while keeping the pCO_2 at 40 mm Hg. The advantage to this approach was that it would also take into account the other buffers present in the blood sample, including hemoglobin. During this time, the approach taken by investigators in Boston was directed at estimating the predicted values of the blood gas determinants to understand the patient's acid-base disturbance, while the approach in Copenhagen was based on the measured base excess. This resulted in the "Great Trans-Atlantic Acid-Base Debate."[69] Currently, most physicians use the base excess approach.

More recently, Stewart reintroduced the concept of the "strong ion difference."[70] This is a more physico-chemical approach to the understanding of acid-base physiology. The merits of this approach continue to be debated.[71–74] Even the more practical tools that are used in the assessment of the patient with acid-base disorders have evolved. The acid-base nomogram (see Figure 14.5) used to be complicated and difficult to use, but mobile platform adoption and computing software are making its clinical applications easier.[75]

The causes of increased anion gap acidosis have shifted over time. The occurrence of paraldehyde overdose is rare, but the finding of 5-oxoproline overdose has been reported several times. Thus, the mnemonic for increased anion gap acidosis, MUDPILES, becomes less relevant. A new mnemonic for the 21st century designated GOLD MARK (see Table 14.2) has been proposed by Mehta and colleagues.[76]

Clinical Vignette 14.1

A 2-year-old patient with Leigh syndrome (mitochondrial defect) was admitted to the hospital and found to have the following serum electrolyte profile: sodium, 136 mEq/L; potassium 3.5, mEq/L; chloride 113 mEq/L; and bicarbonate 11 mEq/L. An arterial blood gas analysis showed blood pH 7.46, pCO_2 less than 16 mm Hg, and bicarbonate (calculated), 11 mEq/L. Urinalysis revealed a urine pH of 8.

TEACHING POINTS

- Because of a picture consistent with normal anion gap metabolic acidosis, hyperchloremia, and a high urine pH, the clinicians thought that the patient had proximal RTA.
- The treatment plan included starting the patient on bicarbonate replacement therapy.
- A closer look at the blood gas analysis, however, shows that the patient had respiratory alkalosis (alkalemia and low pCO_2). The patient had a high urine pH because of renal bicarbonate wasting in an attempt to lower the blood pH and not because of RTA.
- Treating this patient with bicarbonate supplementation would have exacerbated the clinical state, because the kidney would have had to excrete the extra bicarbonate load, along with added need for osmotic diuresis.
- This case highlights the need for complete set of data points for an accurate interpretation of acid-base status in a sick patient.

REVIEW QUESTIONS

1. A 3-year-old boy presents with a 3-week history of progressive eye swelling. He also has some swelling in his legs, and his mom reports his abdomen to be more distended. On examination, his blood pressure is 110/50 mm Hg and heart rate is 85 beats/min. He is afebrile. He has 2+ periorbital edema and 2+ pitting edema of his legs. His cardiac and lung examinations were normal. His urinalysis showed 4+ protein and is negative for blood. His serum chemistries are creatinine, 0.3 mg/dL; sodium, 132 mEq/L; potassium, 4.5 mEq/L; chloride 107 mEq/L; and bicarbonate, 25 mEq/L. This yields an anion gap of zero. Which of the following is the *most* likely cause of the low anion gap?
   a. The laboratory made an error.
   b. The serum calcium must be elevated.

c. His gamma-globulin fraction must be elevated.

d. His serum albumin is very low.

e. He has bromide intoxication.

2. A 1-year-old infant was admitted with a 3-day history of diarrhea. The laboratory analysis on the day of admission revealed sodium, 135 mEq/L; chloride, 115 mEq/L; and bicarbonate 15 mEq/L. After 2 days, the diarrhea has stopped and the patient has been volume expanded with 0.9% saline, the electrolytes were measured again and found to be sodium 138 mEq/L; chloride, 115 mEq/L; and bicarbonate of 17 mEq/L. The urinary electrolytes were found to be sodium of 35 mEq/L; potassium 75 mEq/L; and chloride of 105 mEq/L. The urine pH was 7.0. The *most* likely explanation for these findings is:

a. The patient has distal RTA.

b. The patient has cystinosis.

c. The 0.9% saline has caused dilutional alkalosis.

d. The ability to increase ammoniagenesis is impaired because of the patient's age.

3. A 15-year-old male patient has reportedly attempted suicide by drinking antifreeze containing ethylene glycol. His electrolytes were found to be sodium, 142 mEq/L; chloride, 111 mEq/L; and bicarbonate, 21 mEq/L. Other laboratory findings were glucose, 72 mg/dL, BUN, 28 mg/dL; and serum osmolality, 345 mOsm/kg water. The *best* evidence that he actually drank the ethylene glycol is:

a. The history of drinking antifreeze

b. The elevated anion gap

c. The high osmolar gap

d. No evidence for ethylene glycol ingestion

4. A 14-year-old female presents with a 3-week history of polyuria and polydipsia. The family also reports that she has lost 6 lb during this period. On examination, her blood pressure is 110/59 mm Hg, heart rate is 140 beats/min, and respiratory rate is 26 breaths/min. Serum chemistries demonstrated sodium, 132 mEq/L; potassium, 5.8 mEq/L; chloride, 98 mEq/L; and bicarbonate, 8 mEq/L (anion gap, 26). Her serum glucose was 820 mg/dL. Her urinalysis reveals no protein or blood, but had 4+ glucose. Her anion gap is *most* likely elevated because of:

a. Decreased serum albumin

b. Increased serum acetoacetate

c. Increased serum acetone

d. Increased serum calcium

e. Increased serum lactate

5. The primary source of acid in our diet is:

a. Fatty acids

b. Citric acid

c. Phosphate

d. Ascorbic acid

e. Sulfur-containing amino acids

6. A 10-kg patient generates 10 mEq of H^+/day that need to be excreted in her urine. If the patient's urine had no buffers and he made 1 L of urine, what would be the final pH of the urine?

a. 1

b. 2

c. 5

d. 6

e. Cannot calculate with the given information

7. A 6-week-old male infant has had nonbilious emesis for the past 2 days and appears volume depleted. The electrolyte values were sodium, 132 mEq/L; potassium, 2.8 mEq/L; chloride, 88 mEq/L; and bicarbonate 36 mEq/L. The *most* likely source for the loss of his potassium is:

a. Emesis

b. Stool

c. Urine

d. He has not lost any potassium, but it has shifted into the intracellular compartment

e. Sweat

8. A 2-year-old, ex–29-week preterm infant with bronchopulmonary dysplasia is being seen for diarrhea. He has lost 0.6 kg in the past 2 days and now weighs 9.5 kg. His blood pressure is 98/45 mm Hg, and his heart rate is 112 bpm. His respiratory rate is 32 breaths/min, and his lungs have coarse bronchi throughout. His skin turgor is decreased, with positive tenting. Laboratory studies revealed sodium, 136 mEq/L; potassium, 3.6 mEq/L; chloride, 90 mEq/L; and bicarbonate, 24 mEq/L. An arterial blood gas sample showed the pH to be 7.22 and pCO_2 to be 60 mm Hg. Serum creatinine is 0.5 mg/dL. The *most* likely explanation for these findings is:

a. The laboratory made an error in the ABG result.

b. The patient has acute respiratory acidosis that is uncompensated.

c. The patient has chronic respiratory acidosis with acute metabolic acidosis.

d. The patient must have had some vomiting.

9. A 3-year-old infant is being evaluated for stridor and hyperventilation. During the workup, serum electrolyte examination results revealed sodium, 138 mEq/L; potassium, 4.3 mEq/L; chloride, 108 mEq/L; and bicarbonate, 15 mEq/L. To assess the concern regarding the low bicarbonate, the *most* appropriate next step would be:

a. Perform a cortisone stimulation test.

b. Obtain arterial blood gas sample to assess pH and pCO_2.

c. Collect urine for anion gap.

d. Perform bicarbonate loading to determine transport maximum for bicarbonate.

10. A 13-year-old female presents for the evaluation of hypertension. Her blood pressure is 165/112 mm Hg. Her family history is positive for many individuals with hypertension, including her mother and two uncles. Her physical examination is otherwise normal. Laboratory values showed sodium, 145 mEq/L; potassium, 2.8 mEq/L; chloride, 99 mEq/L; and bicarbonate

36 mEq/L. An arterial blood gas has a pH of 7.5 and pCO_2 50 mm Hg. Her urinary electrolytes were sodium, 78 mEq/L; potassium 56 mEq/L; and chloride, 148 mEq/L. These laboratory values would indicate:

a. She is wasting chloride and should be given extra chloride.
b. She most likely has renal tubular acidosis.
c. She needs to be examined for chronic lung disease.
d. She has chloride-unresponsive alkalosis.

Water homeostasis

MELISSA A. CADNAPAPHORNCHAI

In *The Origin of Species* (1859),[1] Charles Darwin introduced the scientific theory of evolution, proposing that species continually adapt over time to their environments. Almost a century later, Homer Smith proposed that the concentrating capacity of the mammalian kidney was a major contributor to the evolution of various biologic species including humans.[2] Early protovertebrates resided in a saltwater environment whose composition was similar to that of their own extracellular fluid. Therefore, these animals could ingest salt water without affecting the composition of their *milieu intérieur*.[3] However, as early vertebrates migrated into freshwater streams, the development of a more water-impermeable integument was required to avoid fatal body fluid dilution by the hypo-osmotic freshwater environment. A vascular tuft or primitive glomerulus thus developed, enabling the fish to filter excess fluid from the blood. The subsequent development of proximal and distal tubules in vertebrates allowed for the preservation of sodium and the excretion of solute-free water, respectively. Importantly, there was now a means to uncouple sodium and water regulation.

As vertebrates progressed to dry land, conservation of fluid became critical for survival, requiring evolution of a sensitive mechanism to concentrate the urine. Mammals and birds are unique among vertebrates in possessing loops of Henle and in the ability to compensate for water loss by elaborating urine that is more concentrated than blood. Our understanding of water metabolism has greatly advanced in the past few decades with the identification and characterization of aquaporin (AQP) water channels and urea transporters, as well as improved conceptualization of the countercurrent concentrating mechanism. This chapter reviews urinary concentration and dilution

mechanisms, evaluation of disorders of water balance, and management of hyponatremia and hypernatremia in children.

DETERMINANTS OF URINARY CONCENTRATION AND DILUTION

The mammalian kidney maintains nearly constant plasma osmolality (POsm) and sodium concentration by mechanisms that independently regulate water and sodium excretion. Because fluid intake is typically not continuous, and sodium and its anions are the primary osmotic constituents of plasma, the mechanisms that control fluid and sodium balance must be distinct. Limitation of water intake results in concentration of plasma with production of urine that is hypertonic to plasma. Alternatively, high fluid intake results in dilution of plasma with production of urine that is more dilute than plasma. Thus, urine osmolality (UOsm) varies widely in response to fluid intake, ranging from less than 50 mOsm/kg H_2O to approximately 1400 mOsm/kg H_2O in humans, whereas total urine solute excretion is relatively constant. A comprehensive approach to disordered water metabolism requires a thorough understanding of the physiologic factors that regulate urinary concentrating and diluting capacity.

GLOMERULAR FILTRATION RATE AND PROXIMAL TUBULAR REABSORPTION

Glomerular filtration rate (GFR) and proximal tubular reabsorption are primarily important in determining the

rate of sodium and water delivery to the more distal portions of the nephron where renal concentration and dilution occur. Fluid reabsorption in the proximal tubule is isosmotic; therefore, tubular fluid is neither concentrated nor diluted in the proximal segment of the nephron. Approximately 70% of the glomerular filtrate is reabsorbed in the proximal tubules, with the remaining 30% entering the loop of Henle isotonic to plasma. A decrease in GFR or an increase in proximal tubular reabsorption has the following effects: (1) diminishes the amount of fluid delivered to the distal nephron, thereby limiting renal capacity to excrete free water; and (2) limits the delivery of sodium chloride (NaCl) to the ascending limb, where NaCl is reabsorbed without water to support the hypertonic medullary interstitium, thereby limiting the renal capacity to concentrate urine.

DESCENDING AND ASCENDING LIMBS OF THE LOOPS OF HENLE AND DISTAL TUBULE

In 1942, Kuhn and Ryffel proposed that a small difference in osmotic concentration (*einzeln effekt* or "single effect") at any point between fluid flowing in opposite directions in two parallel tubes connected in a hairpin manner can be multiplied many times along the length of the tubes.[4] In the kidney, such a gradient would lead to a high osmolar concentration difference between the corticomedullary junction and the hairpin loop at the tip of the papilla, with resulting concentration of the urine (Figure 15.1). Subsequent studies expanded on this concept.[5–7] The process by which the interstitial osmolality of the medulla is increased from iso-osmotic to hyperosmotic is called
Figure 15.1 The process of countercurrent multiplication. **(1)** At time zero, the fluids in the descending and ascending limbs and the interstitium are isosmotic to plasma. **(2)** Sodium chloride (NaCl) is reabsorbed from the ascending limb into the interstitium until a gradient of 200 mOsm/kg is reached. **(3)** Fluid in the descending limb equilibrates osmotically with the interstitium by water movement out of the tubule. **(4)** The hypertonic fluid is presented to the thick ascending limb with an increased solute concentration in the region near the tip of the system. Again, active NaCl transport along the ascending limb establishes a 200 mOsm/kg gradient increasing interstitial concentrations and by water abstraction descending limb contents. Concentrations near the tip begin to be higher than those near the base. **(5 to 7)** Continued operation of the countercurrent mechanism results in hypertonicity with the highest osmolality observed at the papillary tip. (From Koeppen BM, Stanton BA. Renal Physiology. St. Louis: Mosby; 1992.)

countercurrent multiplication. The term "countercurrent" refers to the opposite directions of flow in the descending and ascending limbs associated with the hairpin configuration of the loop of Henle. Critical to this process is the differential permeability to water and solutes occurring along the loop of Henle (Figure 15.2). Specifically, the descending limb is permeable to water, through aquaporin-1 (AQP1) water channels, and to a lesser extent to NaCl and urea. In contrast, NaCl is actively transported into the medullary interstitium from the thick ascending limb by the sodium-potassium–2 chloride (Na-K-2Cl) cotransporter but has minimal permeability to water because of a lack of AQP1.[8]

If we assume a hypothetic time zero when NaCl enters the medullary interstitium from the thick ascending limb, the interstitial osmolality is increased. This induces water movement from the descending limb into the interstitium. Active transport of NaCl into the interstitium continues in the thick ascending limb, thus stimulating further water movement from descending limb to interstitium along an osmotic gradient. As this process continues, interstitial osmolality is "multiplied" (see Figure 15.1). The maximum interstitial osmolality that can be achieved is directly proportional to the lengths of the loops (of Henle) and to the gradient achieved between ascending limb and interstitium. Thus, the majority of countercurrent multiplication occurs in the 30% of long-looped nephrons of the juxtamedullary and midcortical regions.

In humans, the maximal osmolality achieved at the papillary tip is 1200 to 1400 mOsm/kg H_2O and is, therefore, the maximum UOsm possible. However, the final osmolality of the urine is primarily determined by water permeability in the collecting tubules and not by the events in the loop of Henle.

MEDULLARY BLOOD FLOW

Medullary blood flow also alters the renal capacity to concentrate and dilute the urine. Although medullary blood flow represents only 5% to 10% of total renal blood flow, it is several times faster than tubular flow. Blood that enters the descending vasa recta becomes concentrated as water diffuses out of and solutes diffuse into the descending limb. The hairpin turn of the vasa recta does not allow the high-solute blood to leave the medulla. In the ascending portion of the vasa recta, water diffuses into the vasa recta and solute moves out, thus maintaining medullary hypertonicity. Therefore, circumstances that increase vasa recta flow, such as very high solute load, "wash out" the medullary interstitium and lead to impaired urinary concentrating ability.

ARGININE VASOPRESSIN

Arginine vasopressin (AVP), or antidiuretic hormone (ADH), is the primary determinant of final UOsm. AVP is
Figure 15.2 Differential permeability to water (H_2O) and sodium chloride (NaCl) along the nephron. H^+, hydrogen ion; HCO_3^-, bicarbonate; K^+, potassium; NH_3, ammonia. (From: Campbell NA; Reece JB, Taylor MR, et al. Biology: Concepts and Connections, 6th ed. Upper Saddle River, NJ: Pearson Education; 2009. Printed and electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.)

synthesized in magnocellular neurons of the paraventricular and supraoptic nuclei of the hypothalamus. Axons from these neurons project to the neural lobe of the hypophysis where AVP is stored. The precursor of AVP is a 164-amino acid peptide that is cleaved into three peptides (mature AVP nonapeptide, neurophysin, and copeptin) during its descent along the axons of the pituitary stalk. The hormone and associated peptides are released into the blood in response to several factors, including increased POsm and decreased effective circulating blood volume.[9,10] Copeptin is released into the blood in amounts equimolar to AVP. Because this peptide has a longer half-life and is easier to measure than AVP, copeptin a useful surrogate marker for AVP in research studies.[11]

KEY POINT

AVP or ADH is the primary determinant of final UOsm.

POsm is primarily generated by solutes that do not cross cell membranes (e.g., NaCl) and is the most important stimulus for AVP release under physiologic conditions. Osmoreceptor neurons in the circumventricular organum vasculosum of the lamina terminalis and in the anterior wall of the third ventricle sense changes in osmotic pressure that stimulate

magnocellular neurons to secrete AVP and the insular and cingulate cortex to induce thirst. AVP release is stimulated by very small changes in POsm (i.e., less than 1 mOsm/kg H_2O), before someone can even sense thirst (Figure 15.3A). This exquisitely sensitive threshold ensures that AVP is almost always present in the plasma, except when fluids are ingested in abundance.[12]

Plasma AVP concentrations in usual conditions of health range from undetectable to 3 pg/mL. However, changes in plasma AVP concentration lower than the lower detectable limit (approximately 0.5 pg/mL) can still have significant effects on UOsm. Arterial stretch, sensed by baroreceptors in the aortic arch and carotid sinus and transmitted to the central nervous system by the vagus and glossopharyngeal nerves, tonically inhibits AVP release. Arterial underfilling, secondary to peripheral vasodilation, decreased cardiac output, or intravascular volume depletion, eliminates this inhibition and leads to nonosmotic AVP release.[13,14] In contrast to POsm, relatively large changes in blood volume are required to stimulate AVP secretion (Figure 15.3B). AVP is also secreted in response to other nonosmotic stimuli such as pain, stress, and nausea, which can have a significant impact on water homoeostasis and serum sodium concentration (SNa).

AQUAPORIN-2

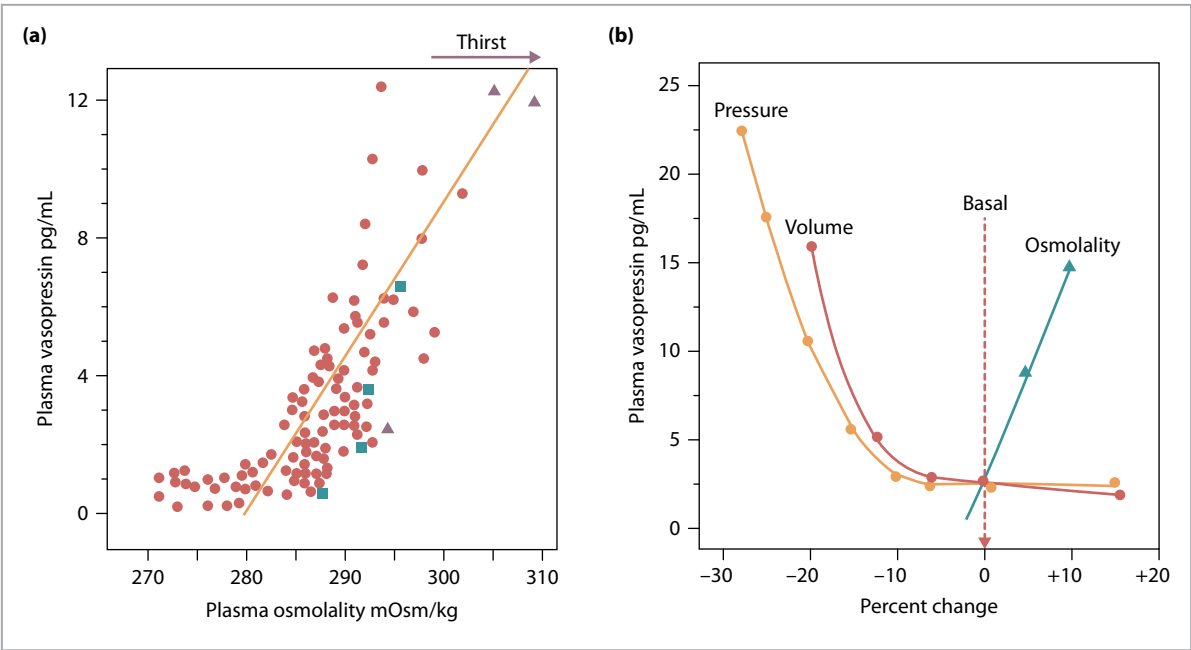
Similar to the loops of Henle, the cortical and medullary collecting tubules have permeability characteristics that


Figure 15.3 **(a)** Relationship of plasma arginine vasopressin concentration with plasma and urine osmolality in healthy adults in varying states of water balance. The level at which thirst begins is noted at the top of the figure. (**(b)** Comparative sensitivity of the osmoregulatory and baroregulatory mechanisms for vasopressin secretion. ((a) From Robertson GL, Athar S, Shelton RL. Osmotic control of vasopressin function. In: Andreoli TE, Grantham JJ, Rector FC Jr, editors. Disturbances in Body Fluid Osmolality. Bethesda, MD: American Physiological Society; 1977. p. 125; (b) from: Robertson GL, Berl T. Pathophysiology of water metabolism. *In* Brenner BM, Rector FC, Jr, editors. The Kidney, 5th ed. Philadelphia: Saunders; 1996.)

regulate the final osmolality of the urine. These segments are impermeable to the passive movement of NaCl; this characteristic is critical for the maintenance of the osmotic gradient of the medullary interstitium and subsequent generation of concentrated urine. The collecting tubule is the principal site of free water reabsorption, which occurs through the water channel AQP2 (Figure 15.4). Circulating AVP binds to its V_2 receptor on the basolateral surface of the principal cell of the collecting duct, a process inducing activation of an adenylyl cyclase–cyclic adenosine monophosphate (cAMP)–protein kinase A cascade that exerts dual effects. The short-term effect is phosphorylation of serine-256 of the C-terminal cytoplasmic domain of AQP2 that leads to the exocytosis of water channels from cytosolic storage vesicles and insertion into the apical membrane with subsequent water resorption.

Constitutively present basolateral AQP3 and AQP4 then permit passage of water into the systemic circulation.[15] The long-term effect occurs through phosphorylation of cAMP-response element binding protein in the nucleus, which leads to increased synthesis of AQP2. With resolution of the inciting factor, plasma AVP concentration diminishes, ultimately resulting in reclamation of AQP2 from the apical membrane to the cytoplasm.[16–18] Prostaglandins (e.g., PGE2) may impair the action of AVP; thus, prostaglandin

> POsm is primarily generated by solutes that do not cross cell membranes (e.g., NaCl) and is the most important stimulus for AVP release under physiologic conditions.

inhibitors are of benefit in nephrogenic diabetes insipidus (NDI), in which the V_2 receptor or AQP2 regulation is defective.

Urea transporters

Approximately half of the solute present at the papillary tip during antidiuresis is urea. As AVP stimulates water reabsorption from the cortical and outer medullary collecting tubules, the urea concentration in the tubular fluid markedly rises. In contrast, permeability to urea in the innermost segment of the medullary collecting tubule is relatively high in the basal state and is further increased by AVP through insertion of the urea transporters UT-A1 and UT-A3 into the luminal membrane. Therefore, at this site, urea diffuses into the interstitium and increases the interstitial osmolality. Urea accumulation in the medulla also indirectly depends on
Figure 15.4 Regulation of aquaporin-2 (AQP2) trafficking and expression in collecting duct principal cells. Vasopressin acts on V_2 receptors (V_2R) in the basolateral plasma membrane. Through the guanosine triphosphate (GTP)–binding protein (Gs), adenylyl cyclase (AC) is activated, which accelerates the production of cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP). cAMP then binds to the regulatory subunit of protein kinase A (PKA), which activates catalytic subunit of PKA. PKA phosphorylates AQP2 in intracellular vesicles. cAMP participates in the long-term regulation of AQP2 by increasing the levels of the catalytic subunit of PKA in the nuclei, which is thought to phosphorylate transcription factors, such as cAMP responsive element (CRE) binding protein (CREB-P) and C-Jun/c-Fos. Binding of these factors is thought to increase gene transcription of AQP2, thus resulting in synthesis of AQP2 protein, which in turn enters the regulated trafficking system. In parallel, AQP3 and AQP4 synthesis and trafficking to the basolateral plasma membrane occur. (From Nielsen S, Knepper MA, Kwon T-H, Frokiaer J: Regulation of water balance: urine concentration and dilution. *In* Schrier RW, editor. Diseases of the Kidney and Urinary Tract, 8th ed. Philadelphia: Lippincott Williams & Wilkins; 2007.)

active transport of NaCl in the ascending limb. The NaCl-driven rise in interstitial osmolality directly increases the activity of UT-A1 by an effect that is independent of AVP. Moreover, loop NaCl reabsorption dilutes the tubular fluid and enhances concentration of the medullary interstitium, thereby creating an osmotic gradient to allow water reabsorption in the collecting tubules. This increase in water reabsorption raises the tubular fluid urea concentration, which enhances the gradient for urea entry into the interstitium. Recirculation of accumulated urea from interstitium to thin ascending limb and descending limb tubular fluid occurs through the urea transporter UT-A2. This process allows the amount of urea in the early distal tubule to be similar to the amount filtered, even though 60% of the filtered urea was reabsorbed in the proximal tubule. Therefore, both urinary and interstitial urea concentrations are high in the presence of AVP. The elevation in medullary interstitial urea leads to increased interstitial osmolality, thereby directly augmenting urinary concentrating capacity, and it also promotes passive sodium reabsorption in the thin descending limb.

To summarize, the excretion of concentrated urine involves the following fundamental steps:

1. Creation of a hypertonic medullary interstitium by reabsorption of NaCl without water in the medullary ascending limb of the loop of Henle and, to a lesser extent, by urea entry into the interstitium from the medullary collecting tubule
2. Secretion of AVP with stimulation of AQP2 water channels in the collecting tubules, with associated reabsorption of free water

Urinary dilution also has two fundamental steps:

1. The reabsorption of NaCl without water in the ascending limb of the loop of Henle decreases the osmolality of the tubular fluid while increasing the osmolality of the interstitium.
2. The relative absence of AVP results in minimal water reabsorption in the collecting duct.

IMPAIRED URINARY CONCENTRATION AND DILUTION IN INFANTS

Although nephrogenesis is completed by 32 to 34 weeks of gestational age, tubular development continues throughout the first 2 to 3 years of life, and children demonstrate impaired urinary concentrating ability through 1 year of age. The preterm infant can achieve a maximal UOsm of approximately 600 mOsm/kg H_2O and the term infant approximately 800 mOsm/kg H_2O. It is well established that total body water is higher in neonates, especially those who are premature.[19,20] Under normal physiologic conditions, term infants excrete this excess water over the first week of life, thus accounting in part for the usual decrease

in weight observed in this interval.[21] Therefore, the ability to maximally concentrate urine is not critical at birth in the otherwise healthy term infant. However, in premature infants or term infants requiring intensive care, impaired urinary concentrating ability is associated with a high risk of water and electrolyte disturbances.[22] Contributing factors include resistance to AVP through reduced generation and increased degradation of cAMP, resulting in decreased expression of AQP2, as well as lower tonicity of the medullary interstitium.[23] Additional contributors include the low dietary solute intake of breast milk and commercially available infant formulas, the high anabolic state with ingested protein used for growth rather than urea synthesis, low sodium transport by the thick ascending limb of the loop of Henle, short loops of Henle, and immaturity of urea transporters leading to diminished medullary tonicity.[24–29] As anticipated, high-protein diets or urea supplements increase urinary concentrating ability in neonates.[30,31]

Impaired urinary dilution is also evident in infants in whom large free water loads (e.g., excessive dilution of formula) can lead to hyponatremia with seizures. Infants have diminished GFR compared with older children and adults. Therefore, there is limited delivery of the free water load to the distal nephron for excretion.

IMPAIRED URINARY CONCENTRATION AND DILUTION IN CHRONIC RENAL INSUFFICIENCY

As GFR declines, urinary concentrating and diluting abilities are limited by the decreased nephron mass. A higher solute load is imposed on each functioning nephron, and decreased tubular surface area limits medullary hypertonicity. UOsm is similar to that of plasma (isosthenuria). Because solute intake remains relatively constant, the obligate urine volume increases. When water intake exceeds excretion and other losses, hyponatremia and hypo-osmolality ensue.

CLINICAL ASSESSMENT OF WATER HOMEOSTASIS

Numerous sources of objective clinical and laboratory data are available to aid in the assessment of water balance in children. Perhaps the most important, however, is a detailed history. The history should include a review of fluid balance for the several days preceding clinical presentation, with particular attention to the nature and volume of the patient's usual intake and output and any recent changes. This includes review of formula preparation and administration in patients receiving liquid diets, as well as review of the nature and volume of administered parenteral fluids in hospitalized patients. Consideration of the patient's

ability to regulate fluid and solute intake independently is important. For example, an infant who is experiencing new and significant fluid and electrolyte losses through diarrhea relies on an attentive caregiver to provide appropriate enteral support to compensate for the stool losses. Any barriers to fluid intake such as vomiting or refusal to drink should be noted. The type and magnitude of losses, including gastrointestinal (vomiting, diarrhea, or other), urine, and insensible losses, should be assessed. Parents may relay concern for edema or abdominal distention suggestive of "third space" fluid accumulation.

A review of medications that could induce water or sodium loss (e.g., diuretics) or retention, is indicated. Recent brain trauma, surgical procedures or infection, or underlying brain malformations may increase the risk for abnormal regulation and secretion of AVP. Nonosmotic stimuli known to induce AVP secretion, including nausea, pain, or the postoperative state, should be noted. A family history of disordered water metabolism, such as diabetes insipidus (DI), should be reviewed.

The physical examination begins with evaluation of vital signs. Fever or tachypnea is associated with increased insensible water loss. Hypertension may suggest intravascular volume excess, whereas hypotension and tachycardia may indicate diminished effective circulating volume.

KEY POINT

A detailed history is critical to the accurate evaluation of disordered water homeostasis.

Comparison of the patient's current weight with a recent weight obtained when the patient was well (i.e., euvolemic) can provide invaluable information. Several physical findings alert the physician to the presence of intravascular volume depletion, including decreased skin turgor, sunken eyes or anterior fontanel, lack of tear production, dry mucous membranes, and delayed capillary refill. The degree of alterations correlates with the severity of intravascular volume depletion. These physical findings may not be as striking in the setting of hypernatremic dehydration because extracellular volume is maintained at the expense of intracellular volume. The presence and degree of peripheral edema, ascites, or anasarca should be noted. These findings may represent intravascular volume overload. However, these same clinical findings can occur in the setting of fluid "leak" from intravascular to third space, resulting in intravascular hypovolemia; thus, accurate interpretation of the constellation of physical findings may be necessary to reach an appropriate conclusion regarding the individual patient's volume status.

Strict recording of intake and output and daily weights in the hospitalized patient is necessary. An indwelling urethral catheter is often needed for accurate assessment of urine output, but its risks and benefits need to be considered in a given patient. Serial weight measurements are useful in the hospital setting.

LABORATORY ASSESSMENT OF WATER HOMEOSTASIS

URINE OSMOLALITY

UOsm is a measure of the solute concentration in urine. Assessment of UOsm routinely or under artificial conditions (e.g., water deprivation or water loading) provides data on the kidney's ability to maintain tonicity and extracellular fluid balance. Osmotically active particles include chloride, sodium, urea, potassium, and glucose. Glucose can significantly elevate UOsm, such as in uncontrolled diabetes mellitus.

Older children and adults can dilute urine to an osmolality of 40 to 80 mOsm/kg H_2O and can maximally concentrate to osmolality of 800 to 1400 mOsm/kg H_2O. Random UOsm is typically 300 to 800 mOsm/kg H_2O in healthy individuals. Urine specific gravity (USG) is another measure of the concentration of solutes in the urine, and it measures the ratio of urine density to water density (1.000). Studies in healthy adults suggest that at pH 7, USG of 1.010 is equivalent to approximately 300 mOsm/kg H_2O, and each increase in specific gravity of 0.01 correlates with approximately 200 mOsm/kg H_2O increase in UOsm.[32] Although there is good correlation between USG and UOsm from neonates through adults, the regression equations are significantly different in younger children, and maturation to adult values occurs by approximately 5 years of age.[33]

USG is significantly increased in the presence of high-molecular-weight substances, such as glucose, methanol, ethanol, and ethylene glycol, as well as contrast dye. The presence of these abnormal solutes also increases USG disproportionately in comparison with UOsm. Therefore, although USG provides a quick and an inexpensive assessment of urinary concentration in the generally healthy population, UOsm is more accurate and is preferred for evaluation of disordered water metabolism.

PLASMA OSMOLALITY

POsm or serum (SOsm) osmolality is a measure of the solute concentration per unit plasma or serum. From a practical standpoint, POsm and SOsm are generally very similar, and laboratory preference may dictate use. Osmoles per kilogram water defines osmolality, whereas osmoles per liter of solution defines osmolarity. Osmolality is a technically more precise expression because solute concentration expressed on the basis of weight is temperature independent.[34] However, at physiologic solute concentrations, these two measurements are comparable. Although basal POsm can vary among persons, the range in the general population

under conditions of normal hydration is 280 to 295 mOsm/kg H_2O.

Total osmolality is not always equivalent to *effective osmolality* (sometimes termed plasma "tonicity"). Only solutes that are impermeable to the cell membrane and remain relatively compartmentalized within the extracellular fluid are "effective" solutes (i.e., they are capable of creating osmotic gradients across cell membranes that can induce movement of water between the extracellular and intracellular fluid compartments). The concentration of effective solutes in plasma should be used to determine whether clinically significant hypo-osmolality is present. Sodium and its accompanying anions (chloride, bicarbonate) are the major effective plasma solutes, so hyponatremia and hypoosmolality are often, *but not always,* synonymous. Glucose and urea do not greatly affect POsm unless they are present in high amounts. POsm is calculated using the following formula:

$$POsm = [2 \times Na] + [glucose / 18] + [BUN / 2.8]$$

where POsm is measured in mOsm/kg H_2O, sodium concentration in mEq/L, and glucose and blood urea nitrogen (BUN) in mg/dL. Sodium concentration is multiplied by 2 to account for the accompanying anions. Glucose and BUN are divided by 18 and 2.8, respectively, to convert mg/dL to mmol/kg.

Toxic alcohols such as methanol, isopropyl alcohol, ethylene glycol, or polyethylene glycol increase POsm. In such cases, there may be a significant discrepancy between measured and calculated osmolality (the osmolal gap) that can provide an early clue to alcohol intoxication.

Hyponatremia is defined as plasma sodium concentration (PNa) or SNa concentration lower than 135 mEq/L. There are two critical pitfalls in the interpretation of PNa. First, PNa is a concentration and not an absolute value. Therefore, hyponatremia could reflect decreased total body sodium content, increased total body water, or both. Second, hyponatremia can occur in the setting of low, normal, or elevated plasma osmolality. It is essential to recognize the association of hyponatremia with normal or elevated POsm because hyponatremia does not require treatment in such situations.

KEY POINT

Hyponatremia can occur with normal, increased, or decreased POsm. In contrast, hypernatremia is always associated with hyperosmolality.

A marked elevation in plasma lipids or proteins can cause artifactual decreases in PNa in response to the larger relative proportion of plasma volume that is occupied by the excess lipids or proteins. This condition is termed pseudohyponatremia. Because the increased protein or lipid does not significantly alter the total number of solute particles in solution, the directly measured POsm is normal in such cases, and the patient is isotonic rather than hypotonic. This situation is observed in severe hyperlipidemia (e.g., serum triglycerides greater than 1500 mg/dL) and hyperproteinemia (e.g., serum total protein greater than 10 g/dL), which are rarely seen in the pediatric population, and with indirect-reading but not direct-reading ion-selective electrode potentiometry.[35]

In dilutional hyponatremia, effective solutes other than sodium are present in the plasma and induce water movement from intracellular to extracellular compartments; the result is a decrease in the measured sodium concentration with normal or elevated POsm. This condition occurs with hyperglycemia, radiographic contrast agents, and mannitol. In hyperglycemia, for every 100 mg/dL increase greater than normal in serum glucose, a decrease of 1.6 mEq/L is observed in measured SNa.[36] A more recent small study in adults suggested that a correction factor of a 2.4 mEq/L decrease in SNa per 100 mg/dL increase in glucose concentration may provide a better overall estimate of this association than the usual correction factor of 1.6, but this approach has not been widely adopted.[37]

In contrast, hypernatremia (PNa 145 mEq/L or greater) is always associated with hyperosmolality. It is again important to recognize that PNa is a concentration that can reflect increased total body sodium content, free water loss, or both.

URINE SODIUM CONCENTRATION

Determining urine sodium concentration (UNa) can be useful clinically, but it is influenced by multiple hormonal and other nonrenal factors. Because it is a concentration and not an absolute value, it is also subject to pitfalls in interpretation. For example, a child with NDI may demonstrate low UNa, but when interpreted in light of a urine volume of 10 L/day, the absolute amount of urine sodium excretion may be significant. UNa is affected by diuretics and sodium-containing parenteral fluids. The *fractional excretion of sodium (FENa)* can be used to correct for renal water reabsorption as follows:

$$FENa\ (\%) = \text{Quantity of } Na^+ \text{ excreted/Quantity of } Na^+$$
$$\text{filtered} = [(UNa \times SCr) / (SNa \times UCr)] \times 100$$

where sodium concentrations are expressed in mEq/L and creatinine (Cr) concentrations in mg/dL.

Values lower than 3% in neonates or 1% in older children suggest renal sodium conservation, as would be expected in the setting of an appropriate renal response to decreased effective circulating volume.

Elevated uric acid excretion can be observed in syndrome of inappropriate ADH secretion (SIADH) and cerebral salt wasting (CSW). The fractional excretion of uric acid may be useful for diagnosis in such cases, with normal values lower than 10%. It has been further suggested that the fractional

excretion of phosphate can help to distinguish SIADH (less than 20%) from CSW (greater than 20%).

To evaluate the amount of solute-free water that the kidney can excrete per unit time, one can determine the *free water clearance (CH₂O)*. If urine is hypo-osmotic to plasma, the total urine volume (V in mL/min or L/day) can be viewed as consisting of two components: one that contains all the urinary solute in a concentration isosmotic to plasma (the osmolal clearance or COsm) and one that contains the solute-free water that makes the urine dilute (CH_2O). Thus:

Urine flow (V) = osmolar clearance (COsm) + free water clearance (CH_2O)

$$CH_2O = V - COsm$$

$$CH_2O = V - [(UOsm / POsm) \times V]$$

A positive CH_2O denotes the excretion of excess free water. A negative CH_2O indicates reabsorption of excess free water. Positive CH_2O in hypertonic conditions or negative CH_2O during hypotonicity confirms an abnormal AVP-renal axis response.

HYPONATREMIA

Hyponatremia is defined as an SNa less than 135 mEq/L. It is one of the most common childhood electrolyte disturbances, affecting up to 25% of hospitalized children.[38–42] Although most cases of hyponatremia are mild and relatively asymptomatic, hyponatremia is clinically important because (1) acute severe hyponatremia can be associated with substantial morbidity and mortality, (2) adverse outcomes are higher in a variety of medical conditions with concomitant hyponatremia, and (3) overly rapid correction of chronic hyponatremia can cause severe neurologic deficits and death.

Hyponatremia occurs when the kidney does not appropriately excrete free water. This occurs with the following mechanisms: (1) diminished generation of free water in the loop of Henle and distal tubule; (2) increased water permeability in the collecting duct, most often from the inappropriate presence of AVP; and (3) excessive fluid intake. A combination of these factors can generate and maintain hyponatremia in any individual patient.

CLINICAL MANIFESTATIONS

As hyponatremia develops, there is an influx of water from the extracellular to the intracellular compartment, along the osmotic gradient. This fluid shift results in cellular swelling, which can lead to encephalopathy and cerebral edema. Hyponatremia is associated with a broad spectrum

KEY POINT

Hyponatremia occurs when the kidney does not appropriately excrete free water.

of clinical signs and symptoms, ranging from subtle and nonspecific findings (e.g., headache, nausea, vomiting) to behavioral alterations, weakness, decreased response to tactile and verbal stimuli, seizures, and cerebral herniation. The symptoms do not progress along a predictable course, and children are at particularly high risk of severe complications because of their high brain-to-skull ratio as compared with adults. Although adult brain size is achieved by approximately 6 years of age, adult skull size is not attained until approximately 16 years of age.[43] Thus, less severe cerebral edema may be associated with more severe complications in children. Hypoxia impairs brain cell volume regulation, decreases cerebral perfusion, and thereby increases the probability of developing neuronal lesions in the setting of hyponatremic cerebral edema.[44]

CLINICAL APPROACH TO HYPONATREMIA

The approach to hyponatremia involves:

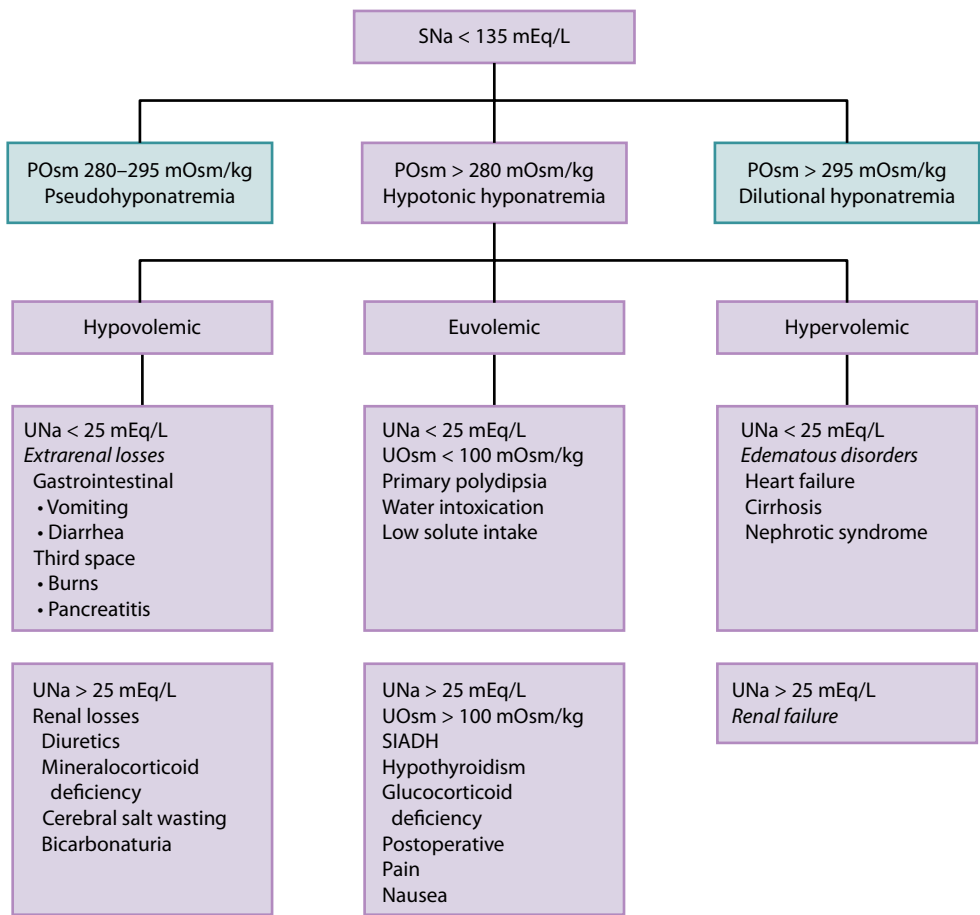
1. Confirm hypo-osmolality. As described earlier, exclusion of dilutional hyponatremia and pseudohyponatremia at this stage avoids unnecessary evaluation and intervention.
2. Obtain a detailed history. The history should include a detailed account of fluid balance, sources of sodium and water loss, free water ingestion or administration, change in weight, medications including diuretics, and underlying medical illnesses or conditions that could stimulate nonosmotic release of AVP (e.g., nausea, pain, postoperative state).
3. Determine the patient's volume status. Clinical assessment of the effective circulating volume provides important clues to the cause of hypo-osmolality (Figure 15.5). However, diminished effective circulating volume may have been restored with hypotonic fluids, and a detailed history is therefore critical in such cases.
4. Evaluate urine sodium excretion and osmolality. In the setting of significant hyponatremia, UOsm should be low, usually less than 100 mOsm/kg H_2O. If UOsm exceeds 100 mOsm/kg H_2O, then the kidney is not excreting free water appropriately. The UNa may then provide additional clues to the cause of the hyponatremia. In the presence of diminished effective circulating volume, the kidneys should be retaining sodium; hence the UNa is generally low (less than 25 mEq/L). In contrast, renal tubular dysfunction, diuretic use, SIADH, and other conditions with renal salt wasting are associated with UNa greater than 25 mEq/L. As noted previously, there


Figure 15.5 Clinical approach to hyponatremia. POsm, plasma osmolality; SIADH, syndrome of inappropriate antidiuretic hormone secretion; SNa, serum sodium concentration; UNa, urine sodium concentration; UOsm, urine osmolality.

are potential difficulties associated with the use of UNa alone. In particular in the hospital setting, timing of intravenous saline boluses, diuretic administration, and fluid or sodium restriction should be considered. FENa may be helpful in certain cases.

HYPOVOLEMIC HYPONATREMIA

With hypovolemic hyponatremia, diminished intravascular volume or effective circulating volume leads to baroreceptor-mediated release of AVP with associated AQP2-mediated free water retention. In some cases, diminished GFR is also

---

KEY POINT

If UOsm exceeds 100 mOsm/kg H_2O in the setting of hyponatremia, then the kidney is not excreting free water appropriately.

---

present and impairs urinary dilution by decreasing fluid delivery to the distal nephron for excretion. Hyponatremia is often exacerbated when the fluid deficit is replenished with hypotonic fluids. UNa is helpful to determine the source of solute losses (i.e., renal vs. extrarenal) that induced the hypovolemic state.

Extrarenal losses

Gastric contents and stool are hypotonic. Prolonged vomiting or diarrhea without fluid replacement would therefore be anticipated to cause hypernatremia. However, with low-solute fluid replacement (e.g., free water, tea, diluted juice, hypotonic parenteral fluids), hyponatremia ensues. Third space fluid loss (e.g., sepsis, burns, capillary leak, pancreatitis) with diminished effective circulating volume induces hyponatremia by a similar mechanism. The history and physical examination are critical to appropriate diagnosis in these settings. UNa is typically low, consistent with appropriate renal salt conservation in response to hypovolemia. An exception is ongoing vomiting, which can be associated with bicarbonaturia that causes obligatory urinary cation

(sodium) loss; in this case, the UNa may be elevated, but the urine chloride should be low.

Renal losses

Renal loss of sodium is associated with elevated UNa and may be seen in the following clinical conditions.

Diuretics: Diuretic-induced hyponatremia is more common with thiazide diuretics than with loop diuretics. This can be explained by the differences in the tubular site of action of these medications.[45] Loop diuretics inhibit NaCl reabsorption in the thick ascending limb of the loop of Henle. As noted previously, the reabsorption of NaCl without water in the medullary portion of this segment is the first step in the generation of the hyperosmotic gradient in the medullary interstitium. When a loop diuretic is administered, it impairs the accumulation of NaCl in the medulla. Thus, although the associated diuresis stimulates AVP secretion by intravascular volume depletion, the collecting tubule responsiveness to AVP is also reduced because of impairment in the medullary gradient.[45] Therefore, hyponatremia rarely occurs unless there is either diminished distal delivery of fluid as with decreased GFR or high water intake. In contrast, thiazide diuretics impair NaCl reabsorption in the distal convoluted tubule and leave the medullary concentration gradient intact. This means that thiazide-treated patients have limited ability to dilute the urine while still being able to concentrate the urine in the presence of AVP. Thiazides may also directly upregulate AQP2 abundance.[46] These factors contribute to a high risk of hyponatremia. Thiazide-induced hyponatremia typically develops within the first 1 to 2 weeks of therapy if diuretic dose and dietary intake remain constant. However, alterations in free water intake, as with intercurrent illness, may be associated with new-onset hyponatremia after several months of stable therapy. Patients who are susceptible to hyponatremia with thiazide diuretics often demonstrate recurrent hyponatremia when the thiazide is reintroduced.

Mineralocorticoid deficiency: In patients with primary mineralocorticoid deficiency, renal sodium wasting leads to intravascular hypovolemia with baroreceptor-mediated AVP secretion, AQP2-mediated water retention, and hyponatremia. Ingestion of water or administration of hypotonic intravenous fluids exacerbates the hyponatremia. Many patients in this setting demonstrate hyperkalemia in association with decreased urine potassium excretion. However, hyperkalemia is not a constant feature of primary mineralocorticoid deficiency in children.[47]

CSW: CSW has been described in the setting of subarachnoid hemorrhage, brain injury, meningo-encephalitis (most frequently tuberculous), and neurosurgical procedures.[48–50] Although it has been proposed that the initial inciting factor is an increase in brain or atrial natriuretic peptide, studies have not shown consistent elevation of these hormones in CSW.[51,52] In addition, the condition occurs primarily, but not exclusively, with central nervous system disease, a finding leading some authors to propose that the condition be termed "renal salt wasting" because the kidney is the end organ for salt excretion.[53–55] The hallmark of this condition is primary renal natriuresis, which leads to intravascular volume depletion with secondary neurohormonal responses including baroreceptor-mediated AVP secretion. AQP2-mediated water retention and activation of the renin-angiotensin-aldosterone system and sympathetic nervous system are also present in these patients. It can be clinically difficult to distinguish CSW from SIADH.[49] However, several features may be helpful. The key distinguishing feature of CSW is the history of intravascular volume depletion, whereas SIADH is associated with euvolemia. Although both conditions are associated with hypouricemia and elevated fractional excretion of uric acid, these abnormalities resolve with correction of hyponatremia in SIADH but persist in CSW.[56] However, the reliability of this finding to differentiate between CSW and SIADH requires further study, particularly in children.[49] It has been further proposed that the fractional excretion of phosphate can distinguish SIADH (less than 20%) from CSW (greater than 20%). Finally, fluid restriction should induce hypovolemia in the setting of ongoing renal salt loss in CSW, whereas this maneuver is a mainstay of treatment in SIADH.

EUVOLEMIC HYPONATREMIA

Euvolemic hyponatremia is caused by a relative or absolute excess of body water. Because otherwise healthy kidneys have great capacity to excrete free water, it is uncommon for excessive water ingestion to be the sole cause of hyponatremia, and most cases of euvolemic hyponatremia arise from a relative excess of AVP secretion.

KEY POINT

Because otherwise healthy kidneys have great capacity to excrete free water, it is uncommon for excessive water ingestion to be the sole cause of hyponatremia, and most cases of euvolemic hyponatremia arise from a relative excess of AVP secretion.

Syndrome of inappropriate antidiuretic hormone secretion

SIADH is a common cause of severe hyponatremia in hospitalized patients. It is caused by increased AVP secretion in the absence of an osmotic or hypovolemic stimulus and is most commonly seen in disorders of the central nervous or pulmonary systems or with medications (Table 15.1). The criteria were proposed in 1967,[57] and they have remained largely unchanged since that time (Table 15.2). It is not necessary for UOsm to exceed POsm to make the diagnosis of SIADH. In the setting of hypo-osmolality, AVP secretion should be suppressed, resulting in maximally dilute urine.

Table 15.1 Causes of syndrome of inappropriate antidiuretic hormone

Neurologic and Psychiatric Disorders
- Infections: meningitis, encephalitis, brain abscess
- Vascular: thrombosis, subarachnoid or subdural hemorrhage, temporal arteritis, cavernous sinus thrombosis, stroke
- Neoplasm
- Skull fracture/traumatic brain injury
- Psychosis
- Other: Guillain-Barré syndrome, acute intermittent porphyria, autonomic neuropathy, postpituitary surgery, multiple sclerosis, seizure disorder, hydrocephalus, lupus cerebritis

Drugs
- Intravenous cyclophosphamide
- Carbamazepine
- Vincristine, vinblastine
- Thiothixene
- Thioridazine, other phenothiazines
- Haloperidol
- Tricyclic antidepressants
- Serotonin reuptake inhibitors
- Monoamine oxidase inhibitors
- Bromocriptine
- Clofibrate
- Lorcainide
- General anesthesia
- Opiates
- Nicotine
- Desmopressin

Pulmonary Disease
- Pneumonia
- Tuberculosis
- Acute respiratory failure
- Positive pressure ventilation

Table 15.1 Causes of syndrome of inappropriate antidiuretic hormone (Continued)

Ectopic Production of AVP
- Carcinoma of lung, duodenum, pancreas, thymus, olfactory, neuroblastoma, bladder, prostate, uterus
- Lymphoma
- Sarcoma
- Leukemia

Miscellaneous Conditions
- Acquired immunodeficiency syndrome (AIDS)
- Idiopathic conditions

AVP, arginine vasopressin.

Therefore, UOsm greater than 100 mOsm/kg H_2O reflects inappropriate antidiuresis and is compatible with the diagnosis of SIADH. As noted in Table 15.2, SIADH is a diagnosis of exclusion. Measurement of plasma AVP is not required for the diagnosis of SIADH, for the following reasons: (1) AVP levels are inconsistently elevated in SIADH; (2) the plasma AVP assay suffers from variability related to sample processing and storage; (3) there is often a significant delay in obtaining results that limits clinical utility; and (4) plasma AVP should be relatively elevated in all forms of true hyponatremia, whether hypovolemic, hypervolemic, or euvolemic. It has been suggested that the ratio of copeptin to UNa can reliably distinguish hypovolemic hyponatremia from SIADH,[58] but this assay is not readily available at many centers and so is of limited clinical value currently. In SIADH, plasma uric acid concentration is typically decreased with increased fractional excretion of uric acid. UNa is greater than 20 mEq/L. The difficulties associated with differentiation of SIADH and CSW are described earlier.

Nephrogenic syndrome of inappropriate antidiuresis

Recent studies in children with hyponatremia have identified genetic mutations of the V_2 receptor associated with

Table 15.2 Criteria for diagnosis of syndrome of inappropriate antidiuretic hormone

- Decreased plasma osmolality (<275 mOsm/kg H_2O)
- Inappropriate urinary concentration (UOsm > 100 mOsm/kg H_2O with normal renal function) in the setting of plasma hypo-osmolality
- Clinical euvolemia
- Elevated urine sodium excretion (>20 mEq/L) with normal salt and water intake
- Absence of other causes of euvolemic hypo-osmolality (e.g., severe hypothyroidism, hypocortisolism)
- Normal renal function and absence of diuretic use

constitutive activation with increased AQP2 abundance in the absence of AVP binding.[59-62] These patients meet the clinical criteria for SIADH but have undetectable plasma AVP levels. The spectrum of symptoms of nephrogenic syndrome of inappropriate antidiuresis (NSIAD) has been shown to vary markedly within families, ranging from infrequent voiding to incidentally noted hyponatremia to recurrent hyponatremic seizures[63]; some affected patients may not manifest hyponatremia until adulthood.[64] *V2R* mutation analysis is indicated for diagnosis. Children with this condition have been successfully managed with fluid restriction and urea therapy.

Endocrinopathies

Endocrinopathies including glucocorticoid deficiency and hypothyroidism are associated with failure to suppress AVP, which leads to AQP2-mediated free water retention.[65,66] Although symptoms of these conditions are often nonspecific, usually these endocrinopathies can be quickly excluded as a cause of euvolemic hyponatremia through routine laboratory testing. Thyroid function tests are readily available in most laboratories, and a morning serum cortisol concentration lower than 10 µg/dL in an acutely ill patient suggests glucocorticoid deficiency. In some cases, a formal cosyntropin stimulation test may be needed. Hyponatremia caused solely by hypothyroidism appears to be uncommon,[67] particularly in children, but if present it relates at least in part to diminished GFR and cardiac output in the setting of severe myxedema.

Primary polydipsia

Patients with primary or psychogenic polydipsia have a primary increase in water intake and often present with complaints of polyuria or excessive thirst. Primary polydipsia is rare in childhood, but it does occur in otherwise healthy children including infants, in children with psychiatric disorders such as schizophrenia,[68,69] in response to anticholinergic or antipsychotic medications that cause dry mouth, and in hypothalamic disease in which thirst regulation is disordered. Because the kidneys' ability to excrete free water is intact, affected patients usually demonstrate normal or slightly reduced SNa with UOsm lower than 100 mOsm/kg H_2O. It is only with extreme water intake (e.g., 10 to 15 L/day in adults) or high-volume water ingestion over short periods of time that significant hyponatremia occurs. Other alterations that limit free water excretion, such as concomitant diuretic use or increased AVP secretion (e.g., nausea, postoperative state), may exacerbate the otherwise mild hyponatremia in primary polydipsia. As anticipated, animal models of chronic primary polydipsia are associated with suppressed AVP concentrations and diminished collecting duct AQP2 abundance, with decreased ability to upregulate AQP2 and concentrate the urine in response to acute water deprivation.[70]

Water intoxication

Water intoxication is a common cause of hyponatremia in children. Infants are at particular risk, not only because of a relatively diminished GFR that limits delivery of the free water load to the distal nephron for excretion, but also because they depend on others to provide a daily free water volume that can be appropriately managed by the infant kidney. Oral free water supplementation or excessive dilution of formula can quickly lead to hypo-osmolar hyponatremia in children dependent on a liquid diet. Because the infant's caloric intake depends primarily on the liquid diet, hunger drives the infant to accept the low-solute formula to the point of water intoxication. Such excessive oral free water supplementation is seen when the caregiver has not been properly educated regarding appropriate infant feeding, as well as in low-income settings where formula may be diluted intentionally to make the available supply last longer.[71,72] Cases of water intoxication have also been reported in infants and children with abusive or psychologically unstable caregivers.[72-74] Older children who depend on tube feedings can develop water intoxication when excess free water is administered through the feeding tube, either erroneously or intentionally. In otherwise healthy adolescents and young adults, significant acute hyponatremia with neurologic complications has been observed with ingestion of large volumes of free water over short periods of time, as in water-drinking contests or following 3,4-methylenedioxymethamphetamine (Ecstasy) use.[75] Ecstasy has also been demonstrated in experimental models and in case reports to stimulate AVP secretion, an effect that is more pronounced in women than in men.[76-79] In water intoxication, the urine should be maximally dilute in the setting of intact kidney function with suppression of plasma AVP concentration.

Reset osmostat

In this condition, the kidney retains its ability to concentrate and dilute urine appropriately. However, the threshold for AVP secretion is reset downward to a value less than 275 to 280 mOsm/kg H_2O, resulting in a stable but low SNa, usually approximately 125 to 130 mEq/L. This condition is quite rare in the pediatric age group but has been reported in the setting of congenital midline central nervous system defects[80] and quadriplegia.[81]

Miscellaneous conditions

Other nonosmotic stimuli for AVP release can result in euvolemic hyponatremia, particularly in the setting of free water ingestion or administration of hypotonic parenteral fluids. Pain and nausea are powerful stimuli for AVP secretion.[82,83] The postoperative state is also associated with nonosmotic AVP secretion that usually resolves by the third postoperative day, but it occasionally can persist to the fifth postoperative day.[40,43,84] Such patients are at particular risk of hyponatremia when they receive hypotonic parenteral

fluid support; therefore, frequent electrolyte monitoring is indicated.

HYPERVOLEMIC HYPONATREMIA

Hypervolemic hyponatremia is associated with edema formation secondary to renal sodium and water retention. Diminished effective circulating volume is common in edematous states, including congestive heart failure (by a primary reduction in cardiac output), nephrotic syndrome (by decreased oncotic pressure associated with hypoalbuminemia), and cirrhosis (by decreased peripheral vascular resistance associated with splanchnic vasodilation[85]). In such settings, hyponatremia has several mechanisms, including the following: (1) diminished effective circulating volume stimulates baroreceptor-mediated AVP secretion; (2) decreased GFR and increased proximal tubular NaCl and water reabsorption both limit the amount of fluid delivered to the distal nephron for excretion; (3) stimulation of thirst with hyponatremia is further exacerbated by intake of hypotonic fluids. Of these mechanisms, baroreceptor-mediated AVP secretion appears to be the most significant contributor to hyponatremia because administration of a vasopressin V_2 receptor antagonist (vaptan) largely reverses defective water excretion in heart failure and cirrhosis without improving tissue perfusion.[86–88] These effects are less clear in nephrotic syndrome.

Advanced renal failure can be associated with hyponatremia. As the urine becomes isosthenuric (approximately 300 mOsm/kg H_2O) with advancing renal failure, the ability to excrete a free water load is impaired despite appropriate suppression of AVP. Retention of ingested water results in hyponatremia. Although this condition lowers the effective serum osmolality and is thus clinically significant, the measured serum osmolality may remain in the normal or even high range because of the contribution of elevated BUN.

TREATMENT OF HYPONATREMIA

General considerations

Acute hyponatremia is associated with shift of water intracellularly to maintain osmotic equilibrium. When hyponatremia develops quickly (e.g., over several hours), cerebral edema and associated symptoms can result. In contrast, when hyponatremia develops over a more prolonged time period, brain cells extrude organic solutes ("idiogenic osmoles") from their cytoplasm, thus allowing intracellular osmolality to equal POsm without a marked increase in cell water.[89] This process minimizes brain edema and explains how only mild symptoms can be observed despite severe hyponatremia. This same phenomenon makes the brain susceptible to injury when the chronic hyponatremia is rapidly corrected or overcorrected. Rapid reversal of chronic hyponatremia can exceed the brain's ability to regain the lost idiogenic osmoles and can lead to osmotic demyelination.[90] A biphasic pattern occurs in osmotic demyelination

syndrome (ODS), with initial neurologic improvement on correction of hyponatremia, followed 1 to several days later by new, progressive, and in some cases, permanent neurologic damage. Findings may include confusion, pseudobulbar palsy, or pseudocoma, but many patients are asymptomatic. Magnetic resonance imaging (MRI) is the preferred modality to demonstrate the cerebral demyelinating lesions, which are best seen more than 2 weeks following correction of hyponatremia.

Management of acute hyponatremia

Brain herniation is typically observed with acute hyponatremia of less than 24 h duration or in the setting of underlying intracranial disorders. Hypoxia from hypoventilation or noncardiogenic pulmonary edema exacerbates hyponatremia-associated brain edema.[44] It has been suggested that a 4 to 6 mEq/L rise in SNa will reverse most serious neurologic manifestations of acute hyponatremia.[90] In the setting of acute *symptomatic* hyponatremia, hypertonic (3%) saline (514 mEq/L) is indicated. Assuming that total body water comprises approximately 50% of total body weight, 1 mL/kg of 3% saline will increase PNa by approximately 1 mEq/L. The goal of hypertonic saline therapy in acute symptomatic hyponatremia is to raise the SNa by approximately 1 mEq/L/h until: (1) the patient becomes alert and seizure-free; (2) PNa increases by 20 to 25 mEq/L; or (3) SNa of 125 to 130 mEq/L is achieved, whichever occurs first. If the child is having seizures or showing other evidence of increased intracranial pressure, the hypertonic saline infusion rate should target a rise in SNa of 4 to 8 mEq/L in the first hour or until seizure activity ceases. Following initial correction, acute hyponatremia can typically be rapidly normalized in forms of water intoxication. This often occurs spontaneously once AVP secretion is suppressed and excess free water ingestion is discontinued. Table 15.3 provides recommendations for management of acute symptomatic hyponatremia.

> ### KEY POINT
>
> In the setting of acute *symptomatic* hyponatremia, hypertonic (3%) saline (514 mEq/L) is indicated.

Management of chronic hyponatremia

It is clear from numerous animal and human studies that overly rapid correction of chronic hyponatremia can lead to iatrogenic brain damage.[91–93] However, the most appropriate rate and duration of correction of chronic hyponatremia remain a matter of debate. A consensus committee in adults recommended a correction rate of 4 to 8 mEq/L/day in patients with clinical factors suggesting a low risk of ODS and 4 to 6 mEq/L/day in patients with a high risk of ODS.[93] Risk factors for ODS in adults include hypokalemia, severe

Table 15.3 Management of acute symptomatic hyponatremia*

Indications	Acute water intoxication
	Known duration of hyponatremia less than 24–48 h
	Intracranial disorder or increased intracranial pressure
	Seizures or coma regardless of known chronicity
Therapy goals	Urgent correction by 4–6 mEq/L to prevent brain herniation and neurologic damage from cerebral ischemia
Treatment	Severe symptoms
	3% saline, 1–2 mL/kg IV over 10 min; may repeat × 2
	Adults: 3% saline, 100 mL IV over 10 min; may repeat × 2
	Mild to moderate symptoms
	3% saline, 0.5–2 mL/kg/h

* The rate of correction need not be restricted in patients with true acute hyponatremia, nor is relowering of excessive correction indicated. However, if there is any uncertainty about whether the hyponatremia is chronic versus acute, then the limits for correction of chronic hyponatremia should be followed.

Table 15.4 Measures to minimize risk of osmotic demyelination syndrome in correction of chronic hyponatremia

- Highest-risk population: serum sodium concentration <120 mEq/L for >48-h duration
- Increased vigilance indicated for specific risk factors:
  - Hypokalemia
  - Hypoxia
  - Malnutrition
  - Advanced liver disease
- Minimum correction of SNa by 4–8 mEq/L/day, with lower goal of 4–6 mEq/L/day if risk of ODS is high
- Maximum correction of SNa by 10–12 mEq/L/24 h or 18 mEq/L/48 h, with lower goal (8 mEq/L/24 h) if risk of ODS is high

Source: Verbalis JG, Goldsmith SR, Greenberg A, et al. Diagnosis, evaluation and treatment of hyponatremia: expert panel recommendations. Am J Med. 2013;126 (Suppl 1):S1–42.
Abbreviations: ODS, osmotic demyelination syndrome, SNa, serum sodium.

malnutrition, alcoholism, hypoxia, and advanced liver disease. However, the serum potassium concentration and the degree of the aforementioned medical conditions that increase the risk of ODS have not been defined, nor have the relevant risk factors in adults been correlated with risk of ODS in children. Guidelines for minimization of ODS are noted in Table 15.4. Sterns et al.[94] proposed a "rule of sixes" for management of severe hyponatremic symptoms ("sx"): "six a day makes sense for safety so six in 6 hours for severe sx then stop."

An unexpectedly rapid rate of correction of chronic hyponatremia can occur despite cautious management. This is particularly common in settings in which the pathogenic stimulus for excess AVP secretion is "turned off," such as fluid resuscitation in volume depletion, hydrocortisone treatment of cortisol deficiency, and discontinuation of thiazides. Excretion of maximally dilute urine can raise SNa by more than 2 mEq/L/h. It has therefore been suggested that goal correction rates fall short of rates associated with iatrogenic complications and that frequent monitoring of SNa (e.g., every 2 to 4 hours) and urine volume be instituted.

The longer the duration of hyponatremia and the lower the SNa, the higher is the risk of iatrogenic complications with overcorrection of SNa. Consideration should be given to reversing overcorrection of chronic hyponatremia when initial SNa was less than 120 mEq/L, particularly when known risk factors for ODS are present. In this setting, it is appropriate

to withhold ongoing measures designed to increase SNa (e.g., hypertonic saline) and to prevent further correction induced by urinary free water loss (e.g., replace urinary losses with 5% dextrose in water [D5W] or oral water).

The approach to treatment of hyponatremia should therefore consider (1) the underlying condition that precipitated the hyponatremia, (2) the presence of hyponatremia-associated neurologic symptoms, and (3) the duration of hyponatremia. With these considerations in mind, the discussion focuses on management of specific causes of hyponatremia.

Management of hypovolemic hyponatremia

With correction of volume depletion, the nonosmotic stimulus for AVP secretion is abolished, and the relative water excess corrects itself by water diuresis. Thus, appropriate monitoring of SNa and urine volume is indicated to avoid overcorrection of hyponatremia, which is frequently chronic. When intravascular volume depletion is evident, isotonic fluid resuscitation is indicated until euvolemia is restored. Such therapy is frequently initiated even before laboratory results are available. Hyponatremia secondary to gastrointestinal fluid loss is rarely of sufficient severity or acuity to require hypertonic saline. Once fluid resuscitation is completed, intravenous or enteral fluid support can be provided as needed, taking into account any ongoing gastrointestinal losses. Appropriate potassium supplementation is indicated in the setting of hypokalemia, which is commonly seen with emesis or stool losses. Potassium is exchangeable with intracellular sodium, so supplementation to correct hypokalemia raises SNa to the same degree as sodium repletion. Patients with acidosis (e.g., ongoing

stool bicarbonate loss) may require bicarbonate or acetate support to prevent expansion acidosis. Therapy specific to the underlying disorder should be pursued as appropriate.

Diuretic-induced hyponatremia is chronic. Discontinuation of the offending diuretic and repletion of sodium and potassium deficits reverse the associated hyponatremia. Caution should be exercised to ensure that overly rapid correction does not occur. Administration of potassium raises the SNa to a degree equivalent to that of administering sodium, so potassium dosage should be taken into account in the hyponatremia treatment plan. Enteral water or D5W can be used to slow the rate of correction if necessary.

Fluid resuscitation with isotonic saline is indicated in hypovolemic patients with CSW. Hypertonic saline can be used if altered mental status is present and is believed to relate to the hyponatremia, with correction rates as outlined earlier. Sodium supplementation, either intravenous or oral, may be needed because of ongoing natriuresis.

Mineralocorticoid deficiency is typically chronic. Volume repletion with isotonic saline is indicated. Fludrocortisone is used on a long-term basis for mineralocorticoid replacement and should minimize recurrent hypovolemic hyponatremia. Spontaneous aquaresis with rapid correction of hyponatremia can occur once volume status is restored; therefore, frequent monitoring of SNa is indicated.

Treatment of euvolemic hyponatremia

Treatment of SIADH should be directed to elimination of the source (e.g., discontinuation of offending medications, appropriate management of tumor, antibiotic treatment of pneumonia). Acute symptomatic hyponatremia in SIADH is most appropriately treated with hypertonic saline. It is critical to recall that patients with euvolemic hyponatremia secondary to SIADH may not respond to isotonic saline, and in some cases, such therapy causes the hyponatremia to worsen because urine sodium excretion increases while free water is retained. For most cases of mild to moderate hyponatremia related to SIADH, fluid restriction is the appropriate initial intervention. General recommendations in this regard include the following: (1) all fluid intake, including parenteral and enteral nutrition and fluid from medications, must be included in the fluid restriction; (2) the degree of restriction required depends on urine output (which may be decreased) and insensible fluid loss; (3) several days of restriction may be required before a significant increase in POsm is observed; and (4) sodium intake should not be restricted in these patients, who may have mild total body sodium depletion resulting from ongoing natriuresis. Predictors of poor response to fluid restriction alone include high UOsm (greater than 500 mOsm/kg H_2O) and low urine volume, findings that support the presence of significantly elevated plasma AVP concentration. Urea has been proposed as an alternative oral treatment for SIADH. Urea acts by inducing osmotic water elimination and by promoting passive sodium reabsorption in the ascending limb of the loop of Henle.[95] PNa and tonicity increase progressively, without associated hypertonicity. Reported adverse effects include gastrointestinal upset, poor compliance because of the undesirable taste of the medication, and development of azotemia at high doses. The administration of urea in SIADH can allow for a less strict regimen of fluid restriction. Low dietary solute intake limits free water excretion and should be avoided in patients with SIADH.

Vaptans, specific antagonists of the V_2 receptor, have been shown to increase renal free water excretion in adults with euvolemic and hypervolemic hyponatremia. Conivaptan is a V_1a/V_2 receptor antagonist available in intravenous form, whereas tolvaptan is a selective V_2 receptor antagonist available as an oral agent. In the SALT-1 and SALT-2 randomized placebo-controlled trials (Study of Ascending Levels of Tolvaptan in Hyponatremia) of tolvaptan versus placebo in adults with hyponatremia resulting from cardiac failure, liver failure or SIADH,[96,97] treatment with tolvaptan was associated with a progressive increase in SNa without requirement for water restriction. The largest increase in SNa occurred in patients with the lowest baseline SNa. Vaptans should not be used in conjunction with or immediately after other treatments for hyponatremia such as hypertonic saline because of the potential for excessively rapid correction of hyponatremia. The efficacy of vaptans in severe hyponatremia (SNa less than 120 mEq/L) has not been systematically studied, and current recommendations support hypertonic saline treatment in such cases. Vaptans have not been studied in children, but it is likely that clinical trials will be implemented in pediatric hyponatremia in the near future.

Patients with suspected NSIAD should undergo mutation analysis of the *AVPR2* gene to confirm the diagnosis. Fluid restriction and urea therapy are effective in the management of affected children.[61] Vaptans have not been shown to be effective in the few adult patients with NSIAD in whom they have been attempted.

If glucocorticoid deficiency is suspected, blood should be drawn for baseline plasma cortisol, and glucocorticoid replacement should be provided. Rapid water diuresis following administration of hydrocortisone is consistent with underlying glucocorticoid deficiency, and hyponatremia typically resolves without additional intervention. The associated aquaresis can be associated with rapid or overcorrection of chronic hyponatremia, so close laboratory monitoring is indicated.

The most appropriate treatment for hyponatremia secondary to hypothyroidism is thyroid hormone replacement. Because such hyponatremia is typically mild, fluid restriction can be helpful. Hyponatremic encephalopathy from myxedema is rare in general but particularly in childhood.

Management of primary polydipsia should target normal fluid intake. This can be difficult to accomplish, particularly in the setting of psychiatric disease or altered thirst regulation. Measures to decrease the sensation of

thirst (e.g., sour candies to stimulate saliva flow or ice chips to moisten the mouth) may be helpful. Although there are anecdotal reports of clozapine to reduce polydipsia and recurrent hyponatremia in adults with psychiatric disease,[98] similar findings have not been systematically described in childhood, in which clozapine use is rare. Chronic primary polydipsia is associated with impaired urinary concentration and diminished upregulation of AQP2 in rats in response to water deprivation,[70] so a progressive decrease toward normal fluid intake may be preferable in affected patients.

Water intoxication typically rapidly resolves once excess free water ingestion is discontinued. Because the urinary diluting mechanism is intact, SNa can rise rapidly in this situation. Given that most cases of water intoxication are acute, the risk of ODS is low. However, if there is concern for possible chronicity of the water intoxication, overly rapid correction should be avoided.

Treatment of hypervolemic hyponatremia

Diuretics and fluid and sodium restriction remain the primary treatments for edematous disorders. From a practical standpoint, however, compliance with fluid and sodium restriction is variable, and diuretics can induce electrolyte abnormalities and diminish effective circulating volume. Hyponatremia attributable to nonosmotic AVP secretion in these conditions is chronic and should be managed accordingly. Severely symptomatic patients with heart failure and rapidly falling or very low SNa can be managed with combined hypertonic saline and loop diuretics to prevent fluid overload. However, this treatment must be attempted cautiously. Typical therapies for management of cirrhosis with ascites include fluid and sodium restriction, diuretic therapy, and large-volume paracentesis. Management of nephrotic syndrome includes fluid and sodium restriction, diuretics, and 25% albumin support as clinically indicated.

Vaptans have perhaps their most ideal application in hypervolemic hyponatremia which has been unsuccessfully managed with fluid restriction. In contrast to loop diuretics, vaptans do not cause significant direct intravascular volume depletion and therefore do not stimulate neurohormonal responses of the renin-angiotensin-aldosterone and sympathetic nervous systems, and they do not deplete electrolytes. As noted previously, vaptans effectively induce renal free water excretion in adults with hypervolemic hyponatremia secondary to heart failure and cirrhosis. However, more recent studies in adults with autosomal dominant polycystic kidney disease who used oral tolvaptan at up to twice the maximum dose approved for hyponatremia raised concern for possible irreversible and potentially fatal liver injury,[99] a finding prompting the FDA to recommend limited duration of use in hypervolemic and euvolemic hyponatremia and avoidance of use with underlying liver disease. Conivaptan is not recommended in patients with cirrhosis and portal hypertension because blockade of the V_1a receptor in the splanchnic circulation can increase portal blood flow and precipitate variceal bleeding. Vaptans have not been systematically studied in nephrotic syndrome. As noted previously, these medications have not been studied or approved for use in children.

HYPERNATREMIA

Hypernatremia is defined as SNa greater than 145 mEq/L. It is less common than hyponatremia but has a broad reported prevalence of 1% to 14%, depending on the population studied.[100-102] Hypernatremia is frequently acquired in the hospital,[38] and it is seen most commonly in children with restricted access to free water and those with chronic disease, critical illness, or underlying neurologic disease. Gastroenteritis is reported to account for only approximately 20% of cases of hypernatremia in hospitalized children.[38] Similar to hyponatremia, many cases of hypernatremia are mild and relatively asymptomatic. However, hypernatremia is clinically important because (1) acute severe hypernatremia can be associated with substantial morbidity and mortality, (2) adverse outcomes are higher in a variety of medical conditions with concomitant hypernatremia, and (3) overly rapid correction of chronic hypernatremia can cause significant neurologic complications and death.

Hypernatremia occurs by the following mechanisms: (1) diminished urinary concentrating capacity with renal free water loss, (2) excess sodium ingestion, and (3) impaired thirst. One or a combination of these factors results in a relative free water deficit in an individual patient.

The body has two primary defense mechanisms against hypernatremia: AVP secretion and thirst. AVP is typically secreted when POsm exceeds 280 mOsm/kg H_2O, with maximal secretion greater than 290 to 295 mOsm/kg H_2O. The thirst mechanism provides a critical defense against hypernatremia because with intact thirst and free access to water, hypernatremia can be prevented in most cases even with concomitant impairment in urinary concentrating capacity or excess sodium ingestion.

Hypernatremia is always associated with elevated POsm.

KEY POINT

The thirst mechanism provides a critical defense against hypernatremia because, with intact thirst and free access to water, hypernatremia can be prevented in most cases even with concomitant impairment in urinary concentrating capacity or excess sodium ingestion.

CLINICAL MANIFESTATIONS

As hypernatremia develops, there is movement of water from the intracellular to the extracellular compartment along the osmotic gradient. This results in transient cerebral dehydration and cell shrinkage. Brain cell volume can decrease by as much as 10% to 15% acutely, with subsequent rapid adaptation. Within 1 hour, the brain increases the intracellular content of sodium, potassium, amino acids, and idiogenic osmoles. Within 1 week, the brain regains approximately 98% of its water content.

Hypernatremia is associated with a broad spectrum of neurologic signs and symptoms, ranging from subtle and nonspecific findings including agitation, irritability, lethargy, hypertonicity, and hyperreflexia to myoclonus, asterixis, chorea, seizures, and rhabdomyolysis. As in hyponatremia, the symptoms do not progress along a predictable time course. Physical findings of intravascular volume depletion may not be as striking in the setting of hypernatremic dehydration because extracellular volume is maintained at the expense of intracellular volume. Mortality is reported to be up to 15%, which is 15 times higher than age-matched mortality rates in children without hypernatremia.[38,43]

However, many deaths are not directly related to the hypernatremia, and this may instead reflect the overall severity of the underlying disease state.

CLINICAL APPROACH TO HYPERNATREMIA

The approach to hypernatremia involves the following (Figure 15.6):

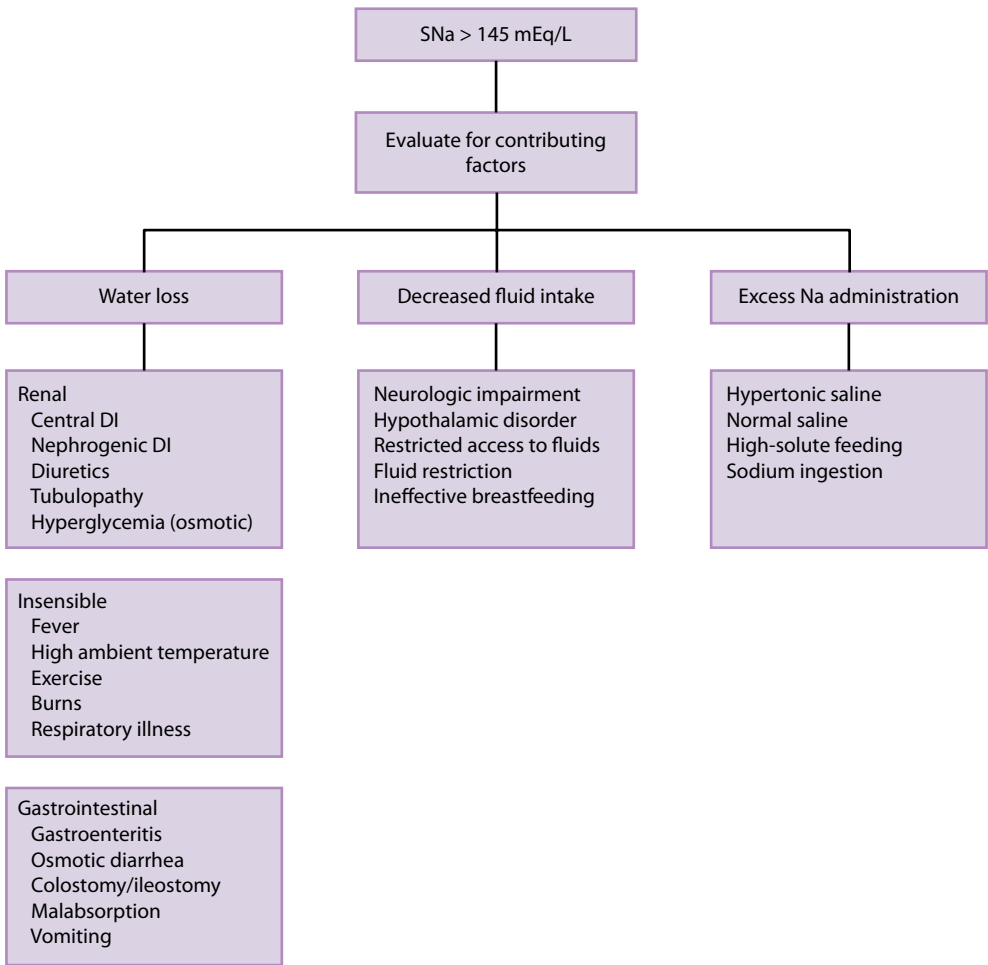
1. **Obtain a detailed history.** The history should include a detailed account of fluid balance, including recent intake and output. Assessment of intake should include consideration of both enteral and parenteral fluids and the associated free water and sodium content. Sodium supplementation should be reviewed. Consideration should be given to whether the patient's thirst mechanism is intact, whether full access to fluids was provided, and whether fluid ingestion is regulated by the patient or a caregiver. Assessment of output should include the nature and magnitude of both renal and extrarenal losses. Review of recent weights is often valuable. The medication history should be reviewed,


Figure 15.6 Clinical approach to hypernatremia. SNa, serum sodium concentration. DI, diabetes insipidus.

including diuretics. A family history of DI or tubulopathies should be obtained.

2. **Evaluate UOsm.** In the setting of significant hypernatremia, UOsm should be increased to greater than 800 mOsm/kg H$_2$O. If lower UOsm is present, then a renal concentrating defect is present.

The pathogenesis of hypernatremia is typically multifactorial and may involve free water loss, excess sodium administration, and impaired thirst.

KEY POINT

If UOsm is lower than 800 mOsm/kg H$_2$O in the setting of hypernatremia, then the kidney is not concentrating appropriately.

RENAL WATER LOSS

DI results from the inability to reabsorb free water. This can occur in patients with deficient AVP secretion (central DI or CDI) or when the collecting duct is unresponsive to AVP (NDI). Affected patients experience polyuria with subsequent polydipsia, increased thirst, and potentially hypernatremia.

CDI is most often acquired but can also be congenital. Congenital CDI occurs in patients with structural brain malformations that affect hypothalamic or pituitary function. Less commonly observed are autosomal dominant or recessive mutations of the gene encoding AVP-neurophysin II (NPII). Autosomal dominant mutations result from heterozygous AVP gene mutations that are believed to alter processing of the AVP precursor.[103] Accumulation of the misfolded AVP protein in the hypothalamic magnocellular neurons leads to eventual neuronal destruction. Affected patients demonstrate gradual development of DI over several months to years after birth. Autosomal recessive CDI is much less common but is associated with biologically inactive AVP.[103] Acquired forms of CDI are observed in several conditions associated with destruction or degeneration of vasopressinergic neurons. These include primary tumors (e.g., craniopharyngioma, germinoma) or metastases, infection (meningitis, encephalitis), histiocytosis, granulomatous disease, autoimmune disorders (lymphocytic infundibuloneurohypophysitis), and central nervous system trauma or surgical procedures.[104]

NDI can be congenital or acquired. Congenital NDI is caused by mutations in the *AVPR2* gene, which is located on chromosome Xq28 or by autosomal dominant or recessive mutations in the *AQP2* gene, which is located on chromosome 12q13 (less than 10%).[105] X-linked NDI is rare, affecting approximately 4 in 1,000,000 boys and men worldwide, but it accounts for 90% of congenital NDI. As anticipated with X-linked disease, males are affected, whereas females are carriers. Most *AVPR2* missense mutations result in a translated but misfolded V2R protein that remains trapped in the endoplasmic reticulum.[105] A few of the mutant receptors reach the cell surface but cannot bind AVP or trigger an intracellular cAMP signal. AQP2 mutant proteins are similarly trapped intracellularly.

Several forms of acquired NDI can affect children. Several of these conditions are known to be associated with impaired function of AQP2 water channels, including hypokalemia,[106] hypercalcemia,[107,108] obstructive uropathy,[109,110] and lithium administration.[111] Additional causes of acquired NDI include sickle cell disease and some primary renal diseases. There are also a variety of tubulopathies that have been associated with vasopressin resistance, including cystinosis and other causes of Fanconi syndrome, nephronophthisis, Bartter syndrome, and syndrome of apparent mineralocorticoid excess[112]; a small case series of affected patients has shown no associated mutations in *AVPR2* or *AQP2*.[113]

Patients with DI experience polyuria, which can be extreme (10 to 15 L/day in adults) and leads to increased thirst and polydipsia. When water access is unlimited, affected patients usually drink enough water to prevent significant hypernatremia. However, restricted water access (including a caregiver's lack of recognition of increased fluid needs), inability to keep fluids down (e.g., vomiting), a coexistent impaired thirst mechanism, or increased extrarenal losses may lead to severe hypernatremia over a matter of hours. Affected children often complain incessantly with attempts to limit their free water intake. Infants with congenital X-linked NDI often present within the first weeks of life with nonspecific symptoms including fever, vomiting, fussiness, and failure to thrive. First-time mothers may not recognize that urine volume is abnormally high. Mental retardation and intracranial calcifications were historically reported in affected male patients with X-linked NDI and are thought to relate to delayed diagnosis with recurrent episodes of dehydration.[114,115] Older children may experience enuresis or nocturia. Ongoing marked polyuria can lead to hydroureteronephrosis and megabladder, as well as functional obstructive uropathy, which in extreme cases can cause end-stage renal disease.

DI is diagnosed by demonstration of hyperosmolality with urine that is inappropriately dilute. With healthy kidneys, urine should be maximally concentrated in response to significant hypernatremia and hyperosmolality. UOsm lower than 800 mOsm/kg H$_2$O in the setting of hypernatremia or POsm greater than 290 to 295 mOsm/kg H$_2$O is consistent with DI. Male patients with X-linked NDI frequently manifest baseline UOsm of approximately 50 to 80 mOsm/kg H$_2$O. The discrepancy between UOsm and POsm is more prominent during fluid deprivation. However, if CDI or congenital NDI is suspected, it is dangerous to advise overnight fluid deprivation at home; instead, evaluation is most appropriately conducted in the hospital or clinic setting, where serial laboratory and urine output monitoring is readily available. A standardized fluid deprivation test includes serial measurement of weight, SNa, serum osmolality, urine

volume, and UOsm while the patient is fasted and deprived of fluids for up to 8 to 10 hours. The diagnosis of complete DI is confirmed when SOsm rises to more than 300 mOsm/kg H_2O with UOsm lower than 300 mOsm/kg H_2O. UOsm in the 300 to 750 mOsm/kg H_2O range suggests partial DI, whereas UOsm greater than 750 mOsm/kg H_2O excludes the diagnosis of DI. If DI is confirmed during the water deprivation test, a plasma sample should be obtained for AVP. The patient is then given vasopressin, often as desmopressin, to distinguish AVP deficiency from AVP unresponsiveness.

When CDI is confirmed, MRI of the brain with focus on the hypothalamic-pituitary region is indicated. CDI is often but not always associated with loss of the posterior pituitary "bright spot" on T1-weighted images. However, the bright spot can also be absent in normal persons.[116] DI may not be immediately apparent in patients with concomitant anterior pituitary–mediated adrenal glucocorticoid deficiency, which is often associated with free water retention. Glucocorticoid replacement may unmask CDI in such patients. It has been suggested that normal findings on brain MRI in CDI warrant ongoing surveillance for tumor, especially hypothalamic stalk lesions.[117] Treatment of CDI includes appropriate management of the primary disease, correction of any fluid deficit, and normalization of urine output with desmopressin. Desmopressin is an AVP analogue with significantly reduced pressor activity and longer half-life as compared with AVP; it can be administered intranasally or by subcutaneous injection. Because of the risk of hyponatremia with limited control of intranasal desmopressin dose, CDI can be managed in infancy with high-dose fluids either orally or by gastrostomy tube placed specifically for high-dose fluid support.

Treatment for congenital NDI has not changed for some decades, although a better understanding of the underlying mechanisms has evolved. Affected patients should be allowed constant access to fluids with high threshold for hypotonic parenteral fluid support when *ad libitum* oral fluid intake is not possible. It is critical to address the high free water need in such patients during parenteral fluid support. Low solute intake decreases the osmotic load for excretion, so dietary sodium restriction of 1 mmol/kg/day has been advocated. In this regard, families benefit from ongoing dietitian support as the child ages. Thiazide diuretics effectively decrease urine volume in congenital NDI. An initial thiazide-induced reduction in sodium reabsorption in the distal tubule increases sodium excretion, with extracellular fluid volume contraction. The associated decrease in GFR results in less fluid delivery to the distal nephron, thus limiting free water excretion. It has also been suggested that thiazides directly affect the AVP-AQP2 cascade, but further studies are needed to elucidate the mechanism.[118] Because hypokalemia is known to impair AQP2-mediated urinary concentration,[106] co-treatment with potassium-sparing diuretics such as amiloride or spironolactone is usually necessary.

Nonsteroidal anti-inflammatory drugs (NSAIDs) also decrease urine volume in congenital NDI by decreasing GFR. Prostaglandin E_2 is known to induce trafficking and phosphorylation of AQP2, and prostaglandin inhibition with NSAIDs inhibits endocytic retrieval of AQP2 from the apical membrane.[119] The individual contribution of these effects of NSAIDs to decreased urine volume in NDI is unclear. Indomethacin quite effectively decreases urine volume in congenital NDI, but some practitioners defer NSAIDs in very young children because of the risk of gastritis. Other NSAIDs such as ibuprofen and tolmetin are also effective in congenital NDI. Even with current optimal control of congenital NDI, urine volume is not normal. However, a reduction in urine volume of 50% can often be achieved. From a quality of life standpoint, the reduction in urine volume from 10 to 5 L/day is significant, although the patient remains markedly polyuric. V_2 receptor antagonists have been used in vitro as pharmacologic chaperones to rescue the cell-surface expression and functional activity of misfolded mutant V_2 receptors associated with specific mutations, but further studies are needed to assess the clinical relevance of these findings.[120,121] A similar approach with thiazides and NSAIDs can be used for management of polyuria caused by impaired urinary concentration associated with specific tubulopathies.

Lithium is the most common cause of acquired NDI in adults. A urinary concentrating defect occurs in approximately 55% of adults receiving long-term therapy, with 20% of patients producing more than 3 L urine per day. Lithium causes NDI by inhibition of adenylyl cyclase in principal cells in the collecting duct, with associated downregulation of AQP2 water channels.[111,122–124] Lithium also reduces UT-A1 protein abundance and interferes with the ability of AVP to phosphorylate UT-A1, thus reducing accumulation of inner medullary interstitial urea with diminished urinary concentrating ability.[125,126] Lithium-induced reduction of UT-B in the inner medulla decreases urea recycling and the efficiency of countercurrent exchange, further limiting urinary concentrating ability. Lithium-induced NDI can be irreversible if it is not quickly diagnosed and lithium is not subsequently discontinued. Amiloride can reduce lithium uptake into principal cells in the collecting duct, and this may lessen the inhibitor effect of intracellular lithium on water reabsorption.[127] Thus, co-treatment with lithium and amiloride is becoming widespread. Other medications known to induce a urinary concentrating defect include amphotericin B, cidofovir, demeclocycline, didanosine, foscarnet, ofloxacin, and orlistat.

Hypercalcemia, hypokalemia, low-protein diets, and obstructive uropathy are known to cause acquired NDI. These acquired forms are rarely as severe as congenital NDI but can result in significant polyuria. These conditions are associated with downregulation of AQP2 expression in the medulla of rat kidneys.[106–109,128,129] Hypokalemia and release of ureteral obstruction are also associated with reduced abundance of UT-A1, UT-A3, and UT-B protein in the

kidney medulla in rats.[130,131] These alterations all diminish urinary concentrating ability.

Hypernatremia from free water loss through the kidneys is also observed with excessive osmotic diuretic use and with severe hyperglycemia secondary to osmotic water loss.

EXTRARENAL WATER LOSS

Excess free water loss occurs with increased insensible losses, including fever, high ambient temperature, prolonged exercise, burns, and respiratory illnesses. Gastrointestinal water loss occurs in association with gastroenteritis, osmotic diarrhea, stool losses through ostomies, malabsorption, or vomiting. The history is critical in the evaluation of such losses. Primary treatment should be directed toward the precipitating factor.

DECREASED FLUID INTAKE

The thirst mechanism is perhaps the most powerful defense against hypernatremia. Children with structural brain defects with associated hypothalamic disease can have diminished or absent thirst leading to insufficient water intake. More commonly, however, decreased fluid intake is related to an imposed limitation on water. This is particularly common in infants, neurologically impaired children, and others who are unable to communicate the experience of thirst effectively and who therefore rely on attentive caregivers to provide appropriate free water support. Exclusively breast fed newborns of primiparous mothers are at particular risk for hypernatremic dehydration and may suffer from vascular complications, including renal vein thrombosis.[132,133] Prolonged fluid restriction has also been observed as a form of child abuse.[134]

EXCESS SODIUM ADMINISTRATION

Excess sodium administration is a less common cause of hypernatremia in childhood, but it can be observed both with parenteral administration of fluids with high sodium content and with enteral sodium ingestion. Repeated sodium bicarbonate administration for management of acidosis in the intensive care setting, particularly during prolonged code resuscitation, can result in hypernatremia. Infants and children who receive sodium supplementation for salt-losing disorders (e.g., salt-losing nephropathy) should undergo careful laboratory monitoring to ensure that the SNa remains within the normal range. Table salt is particularly concentrated (1 tsp salt = 104 mEq sodium). When table salt supplementation is prescribed for home administration for children, it is critical that parents measure rather than estimate each dose because salt poisoning can easily occur. Salt poisoning has also been described as a form of child abuse.[134]

TREATMENT OF HYPERNATREMIA

Treatment of hypernatremia requires provision of adequate free water to normalize the SNa. Hypernatremia is frequently accompanied by volume depletion; therefore, fluid resuscitation with isotonic crystalloid or colloid should be implemented before attempts to correct the free water deficit. Any offending agent (e.g., medication or salt supplementation) that is contributing to hypernatremia should be discontinued. As always, therapy directed toward the primary disease is indicated.

Following volume resuscitation, the composition of parenteral fluid therapy depends on the cause of the hypernatremia. For example, patients with sodium overload or a renal concentrating defect require more hypotonic fluid support than do patients with volume depletion and intact renal concentrating ability. Oral hydration should be instituted as soon as it is safely tolerated. Despite the best efforts of trained medical personnel, children with DI are often much better at self-correcting hypernatremia in response to thirst. Patients with acute hypernatremia that is corrected by oral free water supplementation appear to tolerate a more rapid rate of correction with less frequency of seizures than do patients receiving only parenteral fluid management. Serum electrolytes should be assessed every 2 hours until the patient is neurologically stable.

The free water deficit should always be calculated to devise an appropriate initial fluid management plan. Many pediatricians erroneously assume that simply providing a less hypotonic parenteral fluid than the SNa will correct the hypernatremia. The following formula is useful to determine the minimum amount of fluid necessary to correct hypernatremia:

$$\text{Free water deficit} = 4 \text{ mL} \times \text{Current body weight (kg)}$$
$$\times [\text{Desired change in SNa in mEq/L}]$$

This formula assumes that total body water is approximately 50% of total body weight. The fluid composition then dictates the amount of fluid required to correct the fluid deficit. For example, to correct a free water deficit of 3 L, 4 L of 0.2% NaCl in water or 6 L of 0.45% NaCl in water would be required because these solutions contain approximately 75% and 50% free water, respectively.[43] It is important to consider the patient's ability to tolerate the proposed quantity of fluid (e.g., in oliguric acute kidney injury). The calculated free water deficit does not account for ongoing losses or maintenance needs. Calculations for free water deficit and maintenance needs should be combined with estimation or quantification of ongoing losses to determine the best fluid management plan to correct hypernatremia in an individual child.

The rate of correction of hypernatremia depends on the severity and the cause of the hypernatremia. As noted earlier, the brain rapidly responds to hypernatremia with generation of idiogenic osmoles to maintain brain volume. Given the relative inability of the brain to extrude idiogenic

osmoles, rapid correction of hypernatremia can lead to cerebral edema. Although there are no clinical studies defining the optimal rate of correction of hypernatremia to avoid cerebral edema, empiric data suggest that a rate less than 1 mEq/L/h or 15 mEq/L/24 h is appropriate in the absence of hypernatremic encephalopathy.[43] If severe hypernatremia is present (SNa greater than 170 mEq/L), the target SNa should be higher than 150 mEq/L for the first 48 to 72 hours of therapy.[135] Laboratory studies should be monitored frequently (e.g., every 2 hours), with adjustments to the treatment plan as needed. Seizures occurring during correction of hypernatremia may indicate cerebral edema. Appropriate management includes slowing the rate of correction or consideration of hypertonic saline to increase SNa by a few milliequivalents per liter.[40] Such seizures are typically self-limited and do not necessarily portend adverse long-term neurologic outcome.[135]

SUMMARY

Hyponatremia and hypernatremia are commonly encountered in pediatric nephrology practice, particularly in hospitalized children. A thorough understanding of the physiologic processes that contribute to urinary concentration and dilution allows for recognition of the specific derangements that generate abnormalities of water metabolism in the individual patient. Appropriate therapy can then be tailored to the patient's needs, with minimization of the risk of potentially severe neurologic complications.

REVIEW QUESTIONS

1. A 3-month-old male infant presents with seizures. He is euvolemic on examination. Initial laboratory studies include serum sodium of 118 mEq/L with serum osmolality 240 mOsm/kg H_2O and urine osmolality 85 mOsm/kg H_2O. Further investigation should be directed toward:
   a. Family history of diabetes insipidus
   b. Home preparation of infant formula
   c. Central nervous system infection as a cause of SIADH
   d. History of sustained fever with increased insensible losses

2. A teenage male patient presents with altered mental status and is found to have a cerebrospinal fluid specimen positive for herpes simplex virus by polymerase chain reaction. He is mildly volume depleted and hypernatremic on admission. What is the most likely cause of his hypernatremia?
   a. Table salt ingestion
   b. Poor fluid intake related to altered mental status
   c. Nephrogenic diabetes insipidus
   d. Surreptitious diuretic use

3. After a few days the patient described in question 2 returns to his usual diet. He then develops hyponatremia with serum sodium of 125 mEq/L, SOsm 258 mOsm/kg H_2O, and UOsm 300 mOsm/kg H_2O. He is clinically euvolemic. He most likely has:
   a. Primary polydipsia related to increased thirst from hypothalamic dysfunction
   b. Pseudohyponatremia
   c. Central diabetes insipidus
   d. SIADH

4. A 4-week old male infant is admitted with hypovolemia, failure to thrive, and chronic irritability. He is hypernatremic (serum sodium of 159 mEq/L) with UOsm 50 mOsm/kg H_2O. The most likely cause of his hypernatremia is:
   a. Child abuse with chronic fluid deprivation
   b. Chronic diarrhea
   c. Nephrogenic diabetes insipidus
   d. Chronic vomiting

5. A 6-month-old male infant with known congenital X-linked nephrogenic diabetes insipidus has been vomiting everything he eats or drinks for the past 36 hours. On presentation, his weight is decreased 1 kg from baseline. His is afebrile with heart rate 165 bpm and capillary refill 4 seconds. Which of the following parenteral fluid therapies is most appropriate at this time?
   a. Fluid bolus with normal saline
   b. Fluid bolus with D5W
   c. D5 0.5 NS at maintenance rate
   d. D5 0.2 NS at maintenance rate

6. A 16-year-old female patient presents to the adolescent medicine clinic with fatigue and recent-onset headache. She is mildly volume depleted with weight stable from 1 month ago at 37 kg. Laboratory tests reveal serum sodium of 122 mEq/L, SOsm 250 mOsm/kg H_2O, urine chloride 47 mEq/L, and UNa 55 mEq/L. The most likely cause of her hyponatremia is:
   a. Surreptitious diuretic use
   b. Chronic laxative abuse
   c. Bulimia with chronic vomiting
   d. Primary polydipsia as a means to reduce hunger

7. A 3-year-old girl undergoes a water deprivation test for polyuria and polydipsia. Over the course of a 6-hour test, serum sodium increases from 139 to 142 mEq/L, and UOsm changes from 250 mOsm/kg H_2O to 850 mOsm/kg H_2O. The most likely cause of the polyuria is:
   a. Primary polydipsia
   b. Nephrogenic diabetes insipidus
   c. Partial nephrogenic diabetes insipidus
   d. Central diabetes insipidus

8. A 3-year-old boy undergoes a water deprivation test for polyuria and polydipsia. Over the course of a 6-hour test, serum sodium increases from 142 to 148 mEq/L, whereas UOsm remains lower than 100 mOsm/kg H_2O. dDAVP is administered and UOsm increases to 850 mOsm/kg H_2O. The most likely cause of the polyuria is:
   a. Primary polydipsia
   b. Nephrogenic diabetes insipidus
   c. Partial nephrogenic diabetes insipidus
   d. Central diabetes insipidus

9. A 12-month-old boy presents with hyponatremic seizures. He is euvolemic. The following treatment should be provided now:
   a. Hypertonic saline
   b. Fluid restriction
   c. Conivaptan
   d. Normal saline bolus

10. A 12-month-old boy presents with hypernatremic dehydration with associated seizures. Serum sodium is 162 mEq/L. Following fluid resuscitation, his fluid management plan should include:
    a. Administer normal saline because this has a lower concentration than the current serum sodium.
    b. Provide maintenance parenteral fluid support.
    c. Calculate and correct the free water deficit while providing additional support for maintenance and ongoing losses.
    d. Administer D5 0.2 NS at maintenance.

PART D

Glomerular and tubular diseases

Nephrotic syndrome

MICHELLE N. RHEAULT

Nephrotic syndrome (NS) is one of the most common glomerular disorders of childhood. It is characterized by proteinuria that is severe enough to cause hypoalbuminemia and edema. The first description of a nephrotic child was published in 1484, when Cornelius Roelans of Belgium described "swelling of the whole body of the child" as one of 52 common diseases of children.[1] Almost 250 years later, the kidney tubules were implicated in the pathogenesis of NS by Theodore Zwinger, who also described deterioration of renal function in some patients.[1,2] Richard Bright described NS in more detail in his classic text from 1827: however, the term "nephrotic syndrome" was not coined until 1929, in the writings of Henry Christian from Boston.[3,4] Outcomes for children with NS were uniformly poor before the introduction of antibiotics in the 1930s, with mortality rates of approximately 67%.[5] With widespread use of sulfonamides and penicillin to treat NS-associated infections, mortality dropped to 35% by 1950.[5] The watershed moment in the history of NS was the introduction of steroids for the treatment of this disorder in the 1950s, which led to clinical remission in a majority of treated patients and a drop in mortality to 9% by 1960.[5]

DEFINITIONS AND CLASSIFICATION

NS is a clinical description of a constellation of findings that can be caused by a large number of underlying primary and secondary disorders. The International Study of Kidney Disease in Children (ISKDC) defined NS as massive proteinuria (greater than 40 mg/m^2/h, or 1000 mg/m^2/24 h) leading to hypoalbuminemia (less than 2.5 g/dL), edema, and hyperlipidemia.[6] The urine protein-to-creatinine ratio greater than 2 also correlates well with nephrotic range or massive proteinuria. There are many ways to categorize patients with NS, including by age at presentation, by kidney pathologic features, and by clinical response to corticosteroid therapy. Presentation of NS at less than 3 months of age is termed congenital NS and is often caused by congenital infections or mutations in various podocyte proteins such as nephrin.[7,8] Infantile NS is defined as clinical presentation between 3 months and 1 year of age and often has a genetic basis as well (see Chapter 18). Childhood NS accounts for the majority of patients with NS and is defined as presentation between 1 and 18 years of age.

Children with NS can also be categorized by underlying renal pathologic features. Minimal change NS (MCNS) is the most common histopathologic finding in children with NS (Figure 16.1).[6] Kidney biopsy specimens from patients with MCNS have a normal appearance by light microscopy.[9] By electron microscopy, broadening and retraction of podocyte foot processes ("effacement") are evident. Foot process effacement is the hallmark pathologic finding in NS and is present in most, but not all, affected patients.[10,11] In addition to podocyte effacement by electron microscopy, biopsy samples from children with focal segmental glomerulosclerosis (FSGS) demonstrate light microscopic findings of segmental hyalinosis and sclerosis within some glomeruli or segmental glomerular collapse.[12] Other pathologic
Figure 16.1 Distribution of renal disorders in 521 children undergoing renal biopsy for diagnosis of nephrotic syndrome. FGS, focal global sclerosis; FSGS, focal segmental glomerulosclerosis; MCNS, minimal change nephrotic syndrome; mesangial GN, mesangial proliferative glomerulonephritis; MGN, membranous glomerulonephritis; MPGN, membrano-proliferative glomerulonephritis; prolif GN, proliferative glomerulonephritis. (Data from International Study of Kidney Disease in Children. Nephrotic syndrome in children: prediction of histopathology from clinical and laboratory characteristics at time of diagnosis. Kidney Int. 1978;13:159–65.)

findings in children with NS can include membranous nephropathy, diffuse mesangial sclerosis, World Health Organization class V lupus nephritis, immunoglobulin A (IgA) nephropathy, Henoch-Schönlein purpura nephritis, membranoproliferative glomerulonephritis, or mesangial proliferative glomerulonephritis (see individual chapters on these disorders).[13] Clinical response to corticosteroids has long been used as a means to classify children with NS because it predicts pathologic findings and long-term renal outcome.[6,14] Achievement of remission in response to corticosteroid therapy requires a marked reduction in urine protein to less than 4 mg/m^2/h or urine dipstick of 0 to trace protein for 3 consecutive days with resolution of edema. Terms used for clinical subclassification of NS are as follows:

Relapse: Relapse of NS is defined as recurrence of severe proteinuria (greater than 40 mg/m^2/h or urine protein dipstick 2+ or more for 3 consecutive days), often with recurrence of edema.[6]

Steroid-sensitive NS (SSNS): SSNS is defined as complete remission in response to corticosteroid therapy alone. SSNS suggests MCNS on histopathologic examination; 93.7% of steroid-sensitive children up to 6 years of age and 85.7% of steroid-sensitive children between 7 and 16 years of age demonstrate this lesion on kidney biopsy.[6] MCNS generally predicts excellent long-term renal outcome.

Steroid-dependent NS (SDNS): Some children who initially respond to steroids experience a relapse while still receiving steroids or within 2 weeks of discontinuation of treatment and are classified as having SDNS.

Frequently relapsing NS (FRNS): Finally, children who develop more than four relapses in 12 months are

classified as having FRNS. Children with SDNS and FRNS may have significant complications from prolonged corticosteroid therapy and may require treatment with other immunosuppressive agents.

Steroid-resistant NS (SRNS): Children with SRNS do not achieve remission despite 4 to 8 weeks of high-dose corticosteroid therapy.[15,16] Approximately 75% of children with SRNS have FSGS lesions on renal biopsy.[17] Failure to achieve remission with steroid therapy is a poor prognostic sign, and alternate therapies such as cyclosporine, mycophenolate, rituximab, and renin-angiotensin system blockade are often tried. No remission in response to any therapy in children with FSGS is associated with only a 47% renal survival at 3 years after presentation, whereas a partial remission (defined as a more than 50% reduction in proteinuria) is a favorable prognostic sign and is associated with 92% renal survival at 3 years.[18]

KEY POINT

SSNS is suggestive of MCNS on histopathologic examination and carries a good prognosis. Children younger than 6 years of age are more likely to have SSNS and MCNS than are older children.

EPIDEMIOLOGY

The prevalence of NS is estimated at approximately 16 cases per 100,000 children.[19,20] The annual incidence of NS has been estimated to range from 2 to 7 new cases per 100,000

children.[20–23] Whereas the overall incidence of NS appears to be stable, there is some evidence that the histopathologic pattern may be evolving, with more children demonstrating FSGS and fewer demonstrating MCNS, although the underlying reason for this shift is unclear.[21,24–27] In younger children with NS, boys outnumber girls by 2:1, but this gender disparity is not present in adolescents and adults, in whom the incidence among male and female patients is equal.[28]

Ethnic distribution

Ethnic, geographic, and racial differences in the incidence and histologic patterns in children with NS have been well characterized. In the United Kingdom, South Asian children have a more than fivefold higher incidence of NS than do white children.[22,29] NS appears to be less common among children in Africa; however, when it is present, FSGS lesions are more likely to be found on kidney biopsy.[30–32] NS in children in Sub-Saharan Africa may be more often caused by infections such as human immunodeficiency virus (HIV) infection, hepatitis B, and malaria, and NS is less likely to be steroid responsive than childhood NS in the United States or Europe.[33–35] In the United States, the distribution of NS tends to follow the racial and ethnic distribution of the surrounding community, although some population studies suggest a higher incidence of NS in African Americans.[21,24,36] African-American children presenting with NS are more likely to have SRNS and more rapid progression to end-stage kidney disease.[21,36,37] Biopsy studies have shown increased risk of FSGS in African Americans, with 44% to 47% of children presenting with NS demonstrating FSGS on kidney biopsy compared with 17% to 18% of white children.[21,24] African Americans with SRNS or FSGS are also less like to have an underlying genetic cause for their disease.[38] Sequence variants within the *APOL1* gene encoding apolipoprotein L1 were demonstrated to account for a large fraction of observed increased FSGS risk in African Americans.[39,40] The mechanism by which variants in *APOL1* contribute to increased risk of FSGS is unknown; *APOL1* is expressed in podocytes, and alterations in intrinsic podocyte function may be responsible.[41,42]

Age at presentation

The peak age of presentation of NS is 2 years, with approximately 60% to 70% of cases occurring in children less than 6 years old.[6,21] The age of initial presentation of NS is also an important predictor of histopathologic features and steroid responsiveness. In seminal reports from the ISKDC, MCNS was diagnosed in 87% of children presenting with NS at less than 6 years of age.[6] In the same study, the median age of diagnosis in patients with MCNS was 3 years, compared with 6 years for FSGS and 10 years for MPGN.[6] Thus, younger children with NS are more likely to have MCNS on biopsy, whereas older children are more

likely to have a less favorable diagnosis of FSGS. Younger children are also more likely to respond to steroids, with 86% of children younger than 6 years of age going into remission compared with 60% of children older than 6 years of age.[6]

PATHOPHYSIOLOGY OF EDEMA FORMATION

Edema, a state of total body sodium and water excess, is the most common presenting sign of NS and is the result of fluid accumulation in the interstitial space. The pathophysiology of edema formation in nephrotic patients has been studied and debated for almost 100 years.[43] There are two conflicting hypotheses to account for sodium and water retention in nephrotic patients: the "underfill" hypothesis and the "overfill" hypothesis. Both hypotheses are supported by clinical and experimental evidence, and in fact, it is likely that both mechanisms contribute to edema formation in individual patients at varying times in their disease course.[44]

UNDERFILL HYPOTHESIS

The underfill hypothesis suggests that hypoalbuminemia and the resultant decreased plasma oncotic pressure lead to leakage of fluid from the intravascular to the interstitial space and cause hypovolemia, renal hypoperfusion, activation of the renin-angiotensin-aldosterone system and vasopressin release, and secondary renal sodium and fluid retention. Hypoalbuminemia leads to edema by altering the Starling forces that govern the movement of fluid in the peripheral capillaries.[45] Briefly, the net movement of fluid between the capillary and the interstitial space compartments represents the algebraic sum of net outward hydrostatic pressure minus net inward oncotic pressure. Tissue oncotic pressure, although a smaller component in the Starling forces, provides an additional mechanism that promotes capillary fluid movement into the interstitial space. As shown in Figure 16.2, net hydrostatic pressure in healthy persons exceeds the oncotic pressure at the arterial end of the capillary and favors movement of capillary fluid into the interstitial space. This constant, slow leak of plasma water into the interstitial space is appropriate and necessary to provide substrate for cells not adjacent to the blood vessel. By the time blood flow reaches the venous end of the capillary bed, hydrostatic pressure decreases to venous pressure levels. Additionally, because of the fluid extravasation, capillary oncotic pressure increases slightly. The net pressure at the venous end of the capillary relationship favors movement of fluid back into the vascular space. However, not all the excess interstitial fluid is removed back into the capillary space, but is eventually removed by lymphatic drainage and returned back into the circulation.
Figure 16.2 Starling forces in the peripheral capillaries that determine the development of edema. The left side depicts normal oncotic and hydrostatic pressure dynamics, and the right side depicts the hypoalbuminemic state, such as nephrotic syndrome. Decreased capillary oncotic pressure resulting from hypoalbuminemia creates a greater net force (+25 mm Hg) across the arterial end of the capillary wall that allows transudation of fluid from the capillary. The net force generated at the venous end of the capillary that favors passage of fluid back into the capillary from the interstitial space is also lower in the nephrotic state, as compared with the normal condition (−5 mm Hg versus −20 mm Hg).

In NS, hypoalbuminemia results in a decrease in the capillary oncotic pressure, whereas capillary hydrostatic pressure remains unchanged, increasing the net driving force for fluid to move out of the capillary into the interstitial space. Furthermore, the net driving force that facilitates flow of fluid from the interstitial space into the venous end of the capillary is also diminished; consequently, less of the interstitial fluid returns to the capillary (see Figure 16.2), and edema formation results. Additionally, low circulating intravascular volume stimulates neurohumoral compensatory mechanisms in an attempt to replenish intravascular volume, including the sympathetic nervous system, the renin-angiotensin-aldosterone system, and vasopressin. In summary, hypoalbuminemia induces movement of fluid from the capillary space into the interstitial space and resultant edema formation.

Clinical evidence to support the underfill hypothesis includes high renin and aldosterone levels and low fractional excretion of sodium in NS, particularly in patients with severe hypoalbuminemia and MCNS.[46–48] Further support comes from studies demonstrating high basal vasopressin levels in patients with NS that can be suppressed by albumin loading, a finding suggesting that hypovolemia is a stimulus for vasopressin release and free water retention in this setting.[49,50] However, these findings are not consistent among all patients with NS, and some studies demonstrate normal or expanded blood volumes with suppressed renin values in these patients.[51,52] In addition, the initial oncotic pressure gradient that develops in response to acute hypoalbuminemia is lost over time because of a parallel decrease in interstitial oncotic pressure.[53,54] Incongruously, some patients and animal models with analbuminemia do not typically develop severe edema, a finding suggesting that hypoalbuminemia alone does not account for edema in nephrotic patients.[55,56] Evidence against a primary role of the renin-angiotensin-aldosterone system in driving sodium and fluid retention comes from studies showing minimal effect on edema and sodium excretion in nephrotic patients treated with angiotensin-converting enzyme (ACE) inhibition or aldosterone blockade.[57–59] Further evidence against the underfill hypothesis was generated in an elegant rat model whereby NS was induced in one kidney while normal contralateral kidney function was maintained.[60] These experiments

demonstrated sodium retention in only the nephrotic kidney and pointed to an intrinsic renal mechanism for sodium retention, rather than systemic effects.[60]

OVERFILL HYPOTHESIS

The alternate overfill hypothesis suggests that patients with NS have primary increased sodium reabsorption with resultant expanded circulatory blood volume and suppression of the renin-angiotensin-aldosterone system.[44] Some studies demonstrate increased expression and apical targeting of the epithelial sodium channel, ENaC, with increased sodium-potassium–adenosine triphosphatase (Na-K-ATPase) activity in the cortical collecting duct in nephrotic animals.[61–64] Modification of extracellular loops of ENaC by urine proteinases such as plasmin that are filtered by the nephrotic kidney activates ENaC and leads to sodium reabsorption.[65] This finding implies that proteinuria itself contributes to sodium retention by ENaC activation. In support of this hypothesis, urine from nephrotic patients, including children, demonstrates elevated plasmin levels that can activate ENaC in vitro.[66,67] Blockade of ENaC with amiloride, a competitive inhibitor, leads to increased sodium excretion.[66,68] Critics of the overfill hypothesis point to studies demonstrating low plasma volume, elevated plasma renin, and a natriuretic response to spironolactone in patients with NS and propose that overfill is more common in animal models of NS than in humans.[69] In addition, the clinical use of amiloride in nephrotic patients demonstrates only a mild diuretic effect.[70]

Clinically, it is important to distinguish whether an individual nephrotic patient is "underfilled" or "overfilled" because this influences management of the edema. Physical examination with particular emphasis on perfusion, pulse, and orthostatic blood pressures may help clarify volume status. Chest x-ray studies may also be useful to evaluate pulmonary vasculature for evidence of intravascular volume overload. It has also been suggested that patients with a fractional excretion of sodium that is lower than 1% and high relative urinary potassium excretion [$U_K/(U_K + U_{Na})$] of higher than 60% are more likely to have low intravascular volume and that these tests correlate with elevated renin, aldosterone, norepinephrine, and vasopressin levels.[47,71] A fractional excretion of sodium of 0.2% or more identifies volume expanded nephrotic patients.[72]

CLINICAL APPROACH

In a child with periorbital or generalized edema, a dipstick urinalysis demonstrating 3 to 4+ protein is sufficient to make a preliminary diagnosis of NS. Edema is generally seen in dependent parts of the body, such as ankles, but it can also be seen in the areas with low tissue resistance, such as the eyelids, scrotum, and labia. Periorbital swelling in the morning on awakening and ankle swelling later in the day for ambulating children are common. Scrotal, labial, and penile edema can result in significant discomfort and excoriation of skin in these areas (Figure 16.3). NS should be confirmed by a urine protein-to-creatinine ratio greater than 2 (mg/mg), a serum albumin concentration less than 2.5 g/dL, and the presence of hypercholesterolemia. Once the diagnosis of NS has been established, a thorough investigation for a possible cause must then be undertaken.

CLINICAL HISTORY AND PHYSICAL EXAMINATION

The clinical history and physical examination should focus on determining whether secondary causes of NS are likely to be present (Table 16.1). A thorough medication exposure

Figure 16.3 Severe scrotal and penile edema in a child with minimal change nephrotic syndrome.

Table 16.1 Causes of Nephrotic Syndrome in Children

Age at presentation	Causes
Congenital nephrotic syndrome (age <3 mo)	**Primary** Genetic: *NPHS1, NPHS2, WT1, LAMB2* (Laminin β2, Pierson syndrome), *PLCE1, COQ6, ARHGDIA* **Secondary** Infections: syphilis, toxoplasmosis, CMV, HIV, malaria, rubella, hepatitis B Maternal lupus Antenatal membranous nephropathy secondary to anti–neutral endopeptidase antibodies
Infantile nephrotic syndrome (age 3–12 mo)	**Primary** Genetic: *NPHS1, NPHS2, WT1, LAMB2, PLCE1, COQ6, LMX1B* (nail-patella syndrome) MCNS Galloway-Mowat syndrome Idiopathic conditions

Childhood nephrotic syndrome (age >1 yr)	**Primary**
	MCNS
	FSGS
	Idiopathic conditions
	Mutations in *NPHS2, INF2, ACTN4, TRPC6, LMX1B, CD2AP, MYO1E, PTPRO, WT1, COQ6, MYH9*
	Mesangial proliferative glomerulonephritis (IgM nephropathy, C1q nephropathy)
	MPGN
	Membranous nephropathy
	
	Secondary
	Systemic disease
	  Henoch-Schönlein purpura
	  IgA nephropathy
	  Systemic lupus erythematosus
	  LCAT deficiency
	Infections
	  Hepatitis B and C
	  HIV
	  Parvovirus B19
	Malignancy
	  Leukemia
	  Lymphoma (particularly Hodgkin disease)
	Medications/toxins
	  Nonsteroidal anti-inflammatory drugs
	  Penicillamine
	  Captopril
	  Tiopronin
	  Mercury
	  Pregnancy

Abbreviations: CMV, cytomegalovirus; FSGS, focal segmental glomerulosclerosis; HIV, human immunodeficiency virus; IgA, immunoglobulin A; IgM, immunoglobulin M; LCAT, lecithin cholesterol acyltransferase; MCNS, minimal change nephrotic syndrome; MPGN, membranoproliferative glomerulonephritis.

history is necessary because medications such as nonsteroidal anti-inflammatory drugs, captopril, and penicillamine have been shown to cause NS.[73–75] Risk factors and exposure to hepatitis B, hepatitis C, and HIV should be explored. Joint pain and swelling may be signs of systemic lupus erythematosus or Henoch-Schönlein purpura if a lower extremity purpuric rash is present. A history of gross hematuria may be associated with glomerulonephritis (membranoproliferative glomerulonephritis, IgA nephropathy, mesangial proliferative glomerulonephritis). Easy bruising, fatigue, weight loss, or night sweats may suggest a malignant disease. Cough or difficulty breathing may be a symptom of pleural effusion or pulmonary edema resulting from fluid overload. Menstrual history should be obtained in adolescent girls because Frasier syndrome, *WT1* mutations with 46XY gonadal dysgenesis, can be associated with FSGS and primary amenorrhea. Finally, the possibility of pregnancy should be entertained in postpubertal female patients. A careful family history should be obtained to determine whether any family members are known to have proteinuria or have required kidney dialysis or kidney transplantation to suggest familial NS.

Vital signs including blood pressure and weight should be obtained in all patients with NS. Hypertension is less common in children with MCNS than in those with other diagnoses.[13] Children should be carefully examined to determine the extent of edema, including an abdominal examination for ascites, the presence of periorbital and peripheral edema, and a genitourinary examination to evaluate for scrotal edema.

INVESTIGATIONS

Recommendations for laboratory studies at initial presentation are listed in Table 16.2.[76] A urinalysis is recommended to confirm proteinuria and for identification of significant hematuria or casts that may represent nephritis rather than primary NS. Hematuria is not always associated with nephritis, however, because microscopic hematuria can be demonstrated in 23% of children with MCNS and in 48% of children with FSGS.[13] Hypocomplementemia should prompt a kidney biopsy for evaluation for membranoproliferative glomerulonephritis or systemic lupus erythematosus. Additional screening studies for viral causes of NS such as parvovirus infection, hepatitis B, hepatitis C, and HIV infection should be considered in at-risk populations. Cytopenias on a complete blood count may suggest systemic lupus erythematosus, parvovirus B19 infection, or malignant disease. In anticipation of immunosuppressive treatment, placement of a PPD (purified protein derivative) or blood testing for tuberculosis with a quantiFERON-TB Gold test (Quest Diagnostics, Madison, NJ) should be considered for high-risk populations.[76,77] Finally, testing for immunity to varicella with varicella immunoglobulin G (IgG) titer is

Table 16.2 Initial evaluation of a child with nephrotic syndrome

General Tests
Urinalysis
First morning urine protein to creatinineratio
Serum electrolytes
BUN, creatinine
Serum albumin
Serum complement 3 (C3)
Complete blood count
Cholesterol level
PPD or serum screening for tuberculosis
Varicella titer

Tests for Selected Populations
ANA: if any systemic signs of lupus, if C3 is low, if age 10 yr or older
Hepatitis B, hepatitis C, HIV: if high risk or history of exposure
Parvovirus B19: if characteristic rash present, patient is anemic, or history of exposure
Kidney biopsy: if age 12 yr or older
Genetic testing: if family history of nephrotic syndrome or FSGS

Abbreviations: ANA, antinuclear antibody; BUN, blood urea nitrogen; FSGS, focal segmental glomerulosclerosis; HIV, human immunodeficiency virus; PPD, purified protein derivative.

recommended. Varicella exposure in a previously varicella-naïve patient should prompt treatment with varicella-zoster immunoglobulin within 96 h of exposure because varicella can be life-threatening in this population.[78] A renal ultrasound examination is not necessary in patients with an initial presentation of NS. However, gross hematuria in a nephrotic patient should prompt renal ultrasound with Doppler studies to evaluate for renal vein thrombosis.

KEY POINT

Children with NS should have a thorough history and physical examination performed, as well as limited laboratory screening to evaluate for secondary causes of NS.

KIDNEY BIOPSY

Most young children with NS are steroid responsive and do not require a kidney biopsy because it is overwhelmingly likely that they will have MCNS on histopathologic examination.[13] An initial trial of steroids at 2 mg/kg/day for 6 weeks is recommended, with biopsy reserved for

steroid-resistant patients. Kidney biopsy is also recommended for children older than 12 years of age because it is more likely that they will demonstrate pathologic features other than MCNS.[76] Finally, kidney biopsy should be considered in patients with atypical features, including age less than 1 year, gross hematuria, hypocomplementemia, or a suspected viral or malignant cause.

KEY POINTS

Clinical characteristics of MCNS are:

- Usual age of presentation: 2 to 6 years
- Absence of hypertension
- Normal renal function
- No gross hematuria, possible mild microscopic hematuria
- Normal complement profile
- Good response to corticosteroids, usually in 2 weeks

COMPLICATIONS

THROMBOEMBOLISM

Thromboembolism is a rare, but potentially life-threatening complication of NS that occurs in approximately 3% of affected patients.[79] Most thrombotic episodes are venous in origin; however, arterial thrombosis has been reported rarely (Figure 16.4).[80] The incidence of subclinical disease
Figure 16.4 A noncontrast computed tomography scan of a 12-year-old girl with nephrotic syndrome that shows a triangular area of infarction affecting the blood flow distribution area of the middle cerebral artery (arrow).

may be higher than previously recognized, with one study demonstrating pulmonary embolism (PE) in 28% of asymptomatic nephrotic children by computed tomography (CT) pulmonary angiography.[81] Symptomatic venous thromboembolism (VTE) most often occurs within the first 3 months after diagnosis of NS and can manifest as clots in the deep leg veins, ileofemoral veins, inferior vena cava, pulmonary veins, renal veins, and sagittal sinus.[80,82] The risk of VTE in nephrotic patients appears to be higher for children with congenital NS, adolescents, and children with membranous nephropathy.[80,83,84] Evaluation of a child with suspected thrombosis should be performed in an urgent manner and include imaging with Doppler or CT angiography to confirm the diagnosis. Clinical Vignette 16.1 describes a patient with PE in FSGS.

The pathophysiology of VTE in NS is likely multifactorial and includes both disease-specific and treatment-related factors (Table 16.3). Nephrotic-range proteinuria leads to loss of anticoagulation factors in the urine such as antithrombin III (ATIII) and protein S, thus shifting the nephrotic patient toward a prothrombotic state.[85,86] In addition, the liver increases synthesis of numerous procoagulant proteins such as factors I, II, V, VII, VIII, X, and XIII and fibrinogen.[85] Diminished fibrinolytic activity has also been reported in NS, with decreased plasminogen and tissue-type plasminogen activator and increased concentrations of inhibitors of fibrinolysis such as lipoprotein (a) and α_2-antiplasmin.[85,87] Thrombocytosis is common in children with NS, although the prothrombotic consequences of this abnormality alone are unclear.[88] Regardless of number, platelets from nephrotic patients have been shown to be hyperaggregable.[89,90] Hyperlipidemia and abnormal endothelial cell function have also been implicated in increased thrombosis risk in this population.[91,92] Children with inherited causes of thrombophilia such as factor V Leiden coincident with NS may be at increased risk of thrombosis,

Table 16.3 Risk factors for thromboembolism in nephrotic syndrome

Disease-Specific Risk Factors

Platelet hyperaggregability

Increased procoagulation factors I, II, V, VII, VIII, X, and XIII

Decreased anticoagulation factors ATIII and protein S

Diminished fibrinolytic activity: decreased plasminogen, increased lipoprotein (a) and α_2-antiplasmin

Hyperlipidemia

Endothelial cell dysfunction

General Risk Factors

Intravascular volume depletion

Presence of inherited thrombophilia (e.g., factor V Leiden, prothrombin G20210A)

Indwelling catheters

Presence of antiphospholipid antibodies

Abbreviations: ATIII, antithrombin III.

although the incidence of inherited thrombophilia in this population has not been studied.

Iatrogenic factors may also be responsible for an increased risk of thrombosis in nephrotic patients. Indwelling catheters increase the risk of VTE and should be used cautiously in children with NS. A large study showed that nearly 45% of VTE cases in children with NS were associated with indwelling catheters.[80] Diuretic use can cause intravascular volume depletion and increased blood viscosity, which predispose to thrombosis.[93]

Treatment of NS-associated thrombosis is generally initiated with heparin or low-molecular-weight heparin with transition to warfarin in some patients.[79] Because heparin requires ATIII for its mechanism of action, some children require supplementation with recombinant ATIII to maintain optimal anticoagulation effect.[94] There is no generally accepted pharmacologic prevention strategy for thrombosis in children with NS.[95] Prophylactic anticoagulation therapy should be considered for children who suffer relapses after earlier episodes of thrombosis while nephrotic.

KEY POINTS

Children with NS are at increased risk for VTE because of:

- Loss of anticoagulation factors in the urine
- Increased production of prothrombotic factors
- Diminished fibrinolytic activity
- Hemoconcentration due to diuretic therapy
- Iatrogenic factors, such as indwelling venous catheter use

INFECTIONS

Infection is the most common complication of NS, affecting approximately 17% of all NS hospitalizations.[96] It is also the most common cause of mortality in pediatric NS.[97] Parents and primary care providers should be counseled about the increased risk of infection in nephrotic children. Any fever or abdominal pain in a child with NS should prompt urgent evaluation in the clinic or emergency department.

Patients with NS are prone to develop bacterial infections for both disease-specific reasons and as a result of immunosuppressive therapies. Children with lower serum albumin levels appear to be at highest risk of infection.[98] In addition to loss of albumin in the urine, nephrotic patients lose components of the alternative complement pathway, including factors B and D.[99–102] This loss of opsonizing factors increases susceptibility to encapsulated organisms such as *Streptococcus pneumoniae, Haemophilus influenzae,* and *Escherichia coli.* Children with NS also demonstrate low serum IgG levels related to urinary losses as well as T-cell dysfunction that may contribute to risk of infection.[103–105]

The causative organisms for bacterial infections in children with NS may be shifting after the introduction of routine infant immunization with pneumococcal vaccine in 2000.[96,106]

The most common types of infection in nephrotic children are pneumonia, bacteremia, urinary tract infections, peritonitis, cellulitis, and meningitis. Pneumonia is an underrecognized cause of infection in patients with NS. Although early studies suggested that it was rare, more recent reports from the United States and Taiwan both found a high incidence of pneumonia in children hospitalized with NS.[96,107] The presence of severe edema in children with NS predisposes to the development of cellulitis, particularly in areas of skin breakdown. Spontaneous bacterial peritonitis is another common infection in nephrotic children, with an incidence of 2.6% to 5%.[103,108] Spontaneous bacterial peritonitis often manifests with fever, abdominal pain, and leukocytosis in the setting of abdominal ascites, which acts as an excellent culture medium.[103] The most common organisms are *S. pneumoniae* and *E. coli,* but others have been reported.[108,109] If peritonitis is suspected, then paracentesis should be performed to allow peritoneal fluid to be sent for white blood cell count and culture. Peritoneal fluid white blood cell count greater than 250/mm^3 in the setting of clinical signs of peritonitis is considered diagnostic.[98] Broad-spectrum antibiotics should be initiated until culture results are available.

The use of prophylactic antibiotics in children with NS remains controversial. Prophylactic penicillin has been recommended by some physicians to prevent infection, particularly in high-risk populations such as those children younger than 2 years old, those with SDNS or FRNS, or those with an earlier episode of pneumococcal infection.[110] Prophylactic antibiotics should be used with caution in children with NS because these drugs have been associated with resistant pneumococcal infections.[111,112] A Cochrane database review found no evidence of benefit for any prophylactic strategy to prevent infection in children or adults with NS.[113]

KEY POINT

Children with NS are prone to developing life-threatening infections including pneumonia, sepsis, peritonitis, and cellulitis from losses of components of the alternative complement pathway in the urine.

ACUTE KIDNEY INJURY

Acute kidney injury (AKI) is common in hospitalized adults with NS (34%) and somewhat less common in the pediatric population (8.5%).[96,114] The etiology of AKI is variable and includes prerenal AKI, acute tubular necrosis, interstitial nephritis, and medication nephrotoxicity, especially

resulting from calcineurin inhibitors. Children with NS may have intravascular volume depletion yet receive diuretics for total body fluid overload, thereby precipitating AKI. One randomized controlled trial found that the reversible nephrotoxicity rate for children with SRNS treated with cyclosporine was up to 50% and for tacrolimus was up to 33%.[115] Similarly, ACE inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) have been identified as potential causes of AKI in pediatric NS.[116,117] Antibiotics, particularly aminoglycosides, may have direct nephrotoxic effects or may cause interstitial nephritis.

Renal vein thrombosis may manifest as AKI, typically along with acute hypertension and gross hematuria. Finally, there appears to be an intrinsic decrease in glomerular filtration rate observed in patients with NS that is incompletely understood, but it is hypothesized that severe interstitial edema in the kidney may cause vascular or tubular obstruction.[118,119] Alternately, reduced glomerular permeability may also play a role.[120]

ENDOCRINE ABNORMALITIES

Hypothyroidism is a frequent complication in children with congenital NS as a result of losses of thyroid-binding protein in the urine, and levothyroxine supplementation is recommended for this population.[121] In older children, free thyroxine and thyroid-stimulating hormone levels are typically normal, although hypothyroidism has been documented in some patients with SRNS.[122]

Children with NS demonstrate decreased 25-hydroxyvitamin D levels in response to urinary excretion of vitamin D–binding protein.[123,124] Suboptimal vitamin D stores may lead to decreased 1,25-dihydroxyvitamin D levels or even secondary hyperparathyroidism and metabolic bone disease.[125,126] Children with SSNS have low vitamin D levels even when they are in remission, although the clinical significance is unclear.[127] Vitamin D supplementation for children with NS has been recommended by some groups, but it is typically reserved for patients with chronic kidney disease or secondary hyperparathyroidism.[128] Treatment with corticosteroids may exacerbate metabolic bone disease in this population.[129]

HYPERLIPIDEMIA AND ATHEROGENESIS

Hyperlipidemia is a universal finding in NS, including in MCNS. The characteristics of hyperlipidemia in NS are elevated total cholesterol (TC), low-density lipoprotein (LDL), very-low-density lipoprotein (VLDL), and intermediate-density lipoprotein cholesterol fractions. High-density lipoprotein (HDL) cholesterol fraction is usually unchanged, and the LDL/HDL cholesterol ratio is elevated. Serum triglyceride levels are usually normal or only slightly elevated.[130]

Hypoalbuminemia is believed to be the trigger for development of hypercholesterolemia in NS. An inverse relationship between plasma protein level and serum cholesterol level in patients with NS is well known. An even stronger inverse relationship was noted between oncotic pressure and TC level.[131] Indeed, infusion of albumin and other osmotically active molecules was shown to, at least transiently, reduce hepatic VLDL synthesis in patients with NS.[132] Although the precise sequence of events is unclear, the current view holds that hyperlipidemia in NS results from multiple abnormalities in lipid metabolism[130,133–137]:

- LDL receptor deficiency in peripheral tissues leads to diminished catabolism of LDL cholesterol.
- Increased hepatic 3-hydroxy-3-methyl glutaryl-CoA (HMG-CoA) activity causes enhanced hepatic cholesterol synthesis.
- Lecithin cholesterol acyltransferase (LCAT) deficiency from urinary losses reduces extrahepatic uptake of cholesterol and synthesis of HDL cholesterol.

An atherogenic lipid profile in adults with active NS is associated with an increased risk of cardiovascular events, such as myocardial infarction and coronary death.[138] A few reports of myocardial infarction have also been documented in children.[139] Although Zilleruelo et al.[140] found persistent lipid abnormalities in patients with NS, even in remission, long-term cardiovascular risk for children with SSNS is, however, unclear. One retrospective study did not demonstrate any increase in cardiovascular mortality or morbidity in adults with a history of SSNS.[141] Conversely, children with SRNS have a variety of abnormalities suggesting an increased risk for cardiovascular morbidity and mortality, including increased aortic pulse wave velocity, increased carotid intima media thickness, increased left ventricular mass, and hypertension.[142]

Treatment of hyperlipidemia in NS should include dietary counseling to limit dietary fat to less than 30% of total calories and cholesterol to less than 300 mg/day.[76] Most children with SSNS are not treated for their hypercholesterolemia because it is usually transient. Simvastatin and lovastatin are effective and well tolerated in children with persistent nephrotic range proteinuria, and these drugs cause an approximately 40% decrease in TC and LDL cholesterol, as well as a 30% to 40% decrease in triglycerides.[143,144] Because of a risk of rhabdomyolysis in children treated with statins, creatine kinase enzyme activity should be closely monitored.

OTHER COMPLICATIONS

Respiratory distress in children with NS may result from pleural effusions or decreased effective lung volume caused by ascites. Acute onset of respiratory distress and hypoxia should lead to investigation for pulmonary embolism. Although pulmonary edema is uncommon, it can occur during aggressive treatment of NS with albumin infusions. Patients at high risk for albumin infusion–related respiratory distress include those with decreased glomerular filtration rate, those not receiving adequate diuretics, and those receiving multiple albumin infusions per day.

Intussusception has been reported in children with NS who present with abdominal pain.[145] It is hypothesized that edema of the bowel wall may contribute to development of intussusception.[146] Alternately, peritonitis may induce intramural lymphoid hyperplasia with creation of a lead point for intussusception.[147] A high index of suspicion should be maintained for intussusception in nephrotic children with abdominal pain who do not appear to have peritonitis.

PRINCIPLES OF MANAGEMENT

Specific immunosuppressive treatments for MCNS and FSGS are discussed in Chapter 17. Principles of treatment of children with NS include management of edema, use of antiproteinuric agents, effective control of hypertension, and prevention of infections through appropriate immunizations.

EDEMA

Edema is one of the cardinal signs of NS and can sometimes be severe. The goal of edema management in NS is to prevent complications of severe edema such as respiratory distress and skin breakdown, and it can be achieved in most nephrotic children with fluid restriction and sodium restriction to less than 1500 to 2000 mg/day.[76] For children with anasarca or symptomatic edema, pharmacologic management may be necessary with diuretics and 25% albumin infusions. Diuretics should be initiated only in patients for whom significant intravascular volume depletion has been excluded or corrected. If necessary, 25% albumin is given intravenously over 1 to 4 h followed immediately by intravenous diuretics. Slowly increasing the serum albumin to the range of 2.5 to 2.8 g/dL is adequate to restore intravascular oncotic pressure with little clinical benefit from raising the serum albumin to normal levels. The 25% albumin infusions are generally restricted to once daily. Risks of aggressive albumin infusion or concomitant inadequate diuretic therapy include pulmonary edema, respiratory distress, acute hypertension, and congestive heart failure.[148]

KEY POINTS

- Therapy with 25% albumin infusions should be used only in patients with severe, symptomatic edema.
- Risks of 25% albumin infusions include pulmonary edema, hypertension, respiratory distress, and congestive heart failure.

Furosemide is the most commonly used diuretic for treatment of edema in NS. Furosemide, which is a loop diuretic, acts by inhibiting the sodium potassium-2 chloride (NKCC2) transporter in the thick ascending limb of the loop of Henle. Furosemide is highly protein bound (greater than 95%), with minimal glomerular filtration.[149] It is actively secreted through the organic acid pathway in proximal tubule cells to the tubular lumen, where it reaches the NKCC2 transporter.

Several factors can impair the ability of loop diuretics to function optimally in NS. First, hypoalbuminemia increases the volume of distribution of furosemide by allowing diffusion of free drug into the extravascular space. This, along with a decrease in furosemide that can be bound to albumin because of hypoalbuminemia, reduces the amount of albumin-bound drug that can be delivered to proximal tubule secretory sites.[150] Another factor that limits furosemide activity is binding of filtered albumin in the tubular lumen to secreted furosemide, which limits the free drug that is available to act on the NKCC2 transporter.[151] Several strategies are used to improve the diuretic effect in patients with NS, including more frequent dosing (every 6 to 8 h), higher doses, or even continuous dosing. Doses of up to 200% to 300% of normal are often required to achieve clinical effects, but this may increase the risk of ototoxicity, which correlates with peak levels.[151] Alternately, coadministration of furosemide with 25% albumin can improve efficacy by increasing renal perfusion and increasing delivery of furosemide. Another approach is to add a diuretic with a different mechanism of action for synergistic effects.[152] Metolazone, a thiazide diuretic, acts primarily in the distal tubule but also has some secondary effects on the proximal tubule, and it is often helpful in overcoming diuretic resistance in NS. Blockade of sodium reabsorption at several sites along the nephron can improve the overall diuretic effect.[153,154]

Diuretics should be used with caution in children with NS because of their potential for complications. Diuretic use is an iatrogenic risk factor for development of thrombosis.[93] AKI is increasingly common in nephrotic patients and can be precipitated by further volume depletion induced by diuretics.[96] Electrolyte disturbances induced by diuretics can range from mild to severe hypokalemia and metabolic alkalosis. Finally, hypercalciuria related to use of loop diuretics can cause nephrocalcinosis or kidney stones, particularly in patients who are receiving long-term therapy.[155]

ANTIPROTEINURIC AGENTS

ACEIs have been shown to slow the progression of proteinuric kidney disease in general and are currently recommended for use in all children with SRNS.[16,76] ACEIs and ARBs decrease proteinuria by decreasing intraglomerular pressure and through a direct alteration of glomerular permselectivity.[156,157] In addition, ACEI and ARBs have antifibrotic effects through inhibition of proinflammatory cytokines.[158] Several studies have demonstrated significant reduction in proteinuria in response to ACEI treatment in children with NS.[157,159,160] The reduction in proteinuria appears to be dose related. One prospective study demonstrated that nephrotic children treated with high-dose enalapril (0.6 mg/kg/day) had

greater reductions in proteinuria than did children treated with low-dose enalapril (0.2 mg/kg/day).[160] In most studies, ARBs or the combination of ACEIs and ARBs had similar effects on reduction of proteinuria.[161,162] Rebound proteinuria can be observed in children treated with ACEIs or ARBs. The ESCAPE trial (Effect of Strict Blood Pressure Control and ACE-Inhibition on Progression of Chronic Renal Failure in Pediatric Patients) demonstrated a 50% reduction in proteinuria for children with chronic kidney disease who were treated with ramipril, but proteinuria rebounded to baseline levels after 3 years of therapy.[163] The effect of rebound proteinuria on long-term renal outcomes is unclear.

ACEIs and ARBs are generally well tolerated in children. Adverse effects include hyperkalemia, hypotension, AKI, cough, and angioedema. Children treated with ACEIs or ARBs should have electrolytes and creatinine monitored routinely during therapy. Combination therapy with ACEIs and ARBs may increase the risk of adverse events.[164,165] Women of childbearing age should be counseled about risks of major congenital malformations in pregnancies exposed to ACEIs and ARBs.[166]

MANAGING HYPERTENSION

Systolic hypertension (defined as greater than the 98th percentile) on first presentation was documented in 21% of children with MCNS and in 49% of children with FSGS in the ISKDC study in the 1970s, but a higher frequency of hypertension has been reported more recently.[13,167,168] Hypertension may be exacerbated by therapies such as corticosteroids or calcineurin inhibitors. Posterior reversible encephalopathy syndrome can be observed in nephrotic children presenting with acute hypertension, headache, or seizures.[169] Children with chronic kidney disease should have blood pressures controlled to the 50th percentile for age and gender in an attempt to slow the progression of renal disease.[163] Children without chronic kidney disease, such as SSNS, should aim for blood pressures lower than the 90th percentile.[170] Nephrotic children and their families should receive low-salt diet education (less than 1500 to 2000 mg) and assistance with body weight management, if necessary. ACEIs or ARBs should be used as first-line pharmacologic therapy for hypertension because of their added antiproteinuric and antifibrotic effects.

IMMUNIZATIONS

Careful attention should be paid to immunization status in children with NS because they are susceptible to vaccine preventable diseases related to disease-specific effects as well as effects of immunosuppression. Live vaccines should be deferred for 3 months after therapy with cytotoxic agents such as cyclophosphamide. Children receiving at least 2 mg/kg/day of corticosteroids for more than 14 days should not receive live vaccines until 1 month after discontinuation of therapy.[78] Children receiving less than 2 mg/kg/day of corticosteroid may receive live vaccines. Children documented to be nonimmune to varicella based on titers or history should

be vaccinated as soon as appropriate. If exposed to varicella, nonimmune immunocompromised children should receive varicella zoster immune globulin prophylaxis.[78] Children with NS may develop severe, life-threatening varicella infection, and treatment with intravenous acyclovir should be considered at the onset of skin lesions.[76,171]

All children should complete their routine 13-valent pneumococcal vaccine series and also receive the 23-valent pneumococcal vaccine at age 2 years or older. There is evidence that invasive pneumococcal disease decreased in the United States after introduction of the 7-valent pneumococcal vaccine in 2000.[106,172] In children hospitalized with NS, the frequency of peritonitis decreased by 50% from 2000 to 2009, possibly because of vaccine effects, although further study is required.[96] Children with NS, even those in remission, and their families should receive inactivated influenza vaccine yearly.

SUMMARY

Advances in NS and podocyte research are happening at a rapid pace, with new FSGS-causative genes identified on a regular basis. The cause of MCNS remains elusive, but this subject is a large research focus. With the advent of next-generation sequencing, the initial evaluation of new patients with NS will probably soon include large gene panels to determine whether a child's disorder is likely to be steroid resistant.[173] The next 10 to 20 years will also likely see changes in the treatment of NS, with the development of podocyte-specific and nonimmunosuppressive therapies.[174]

Clinical Vignette 16.1

A 14-year-old boy presented to the emergency department with acute shortness of breath and hypoxia. Evaluation demonstrated a pulmonary embolism, and he was started on low-molecular-weight heparin with gradual improvement in his clinical status. Further investigation was notable for the classic features of NS, including proteinuria, hypoalbuminemia, and hyperlipidemia. There was mild leg edema on physical examination. A kidney biopsy demonstrated focal segmental glomerulosclerosis.

TEACHING POINTS

Most patients with NS present as a result of edema, but some patients may present initially with signs and symptoms of a complication such as infection or thrombosis. This may reflect a delay in diagnosis because the edema may be misdiagnosed (e.g., "allergies") or may not be appreciated. In other cases, the patient may have biochemical evidence of NS, but either mild or no discernible edema.

REVIEW QUESTIONS

1. The most likely finding on kidney histopathologic examination for a 2-year-old child with steroid-sensitive nephrotic syndrome is:
   a. Minimal change nephrotic syndrome
   b. Focal segmental glomerulosclerosis
   c. Membranous nephropathy
   d. Membranoproliferative glomerulonephritis
   e. Mesangial proliferative glomerulonephritis

2. Sequence variants in the following gene account for a large fraction of observed FSGS risk in African Americans:
   a. *NPHS2*
   b. *WT1*
   c. *MYH9*
   d. *APOL1*
   e. *COQ6*

3. Which of the following is *not* a component of the "underfill hypothesis" of edema formation in nephrotic syndrome?
   a. Decreased plasma oncotic pressure with leakage of fluid into the interstitial space
   b. Hypovolemia with renal hypoperfusion
   c. Activation of the renin-angiotensin-aldosterone system
   d. Vasopressin release
   e. Increased sodium reabsorption through ENaC

4. Children with an initial presentation of nephrotic syndrome should have all of the following performed, *except:*
   a. Complement C3 level
   b. Genetic testing for *NPHS2* mutations
   c. Serum albumin
   d. PPD
   e. Cholesterol level

5. The following factors cause increased risk for thrombosis in nephrotic syndrome, *except*:
   a. Increased production of protein S by the liver
   b. Loss of ATIII in the urine
   c. Platelet hyperaggregability
   d. Diminished fibrinolytic activity
   e. Hyperlipidemia

6. Complications of furosemide therapy for treatment of edema in nephrotic syndrome can include all of the following *except:*
   a. Hypokalemia
   b. Acute kidney injury
   c. Nephrocalcinosis
   d. Metabolic acidosis
   e. Thrombosis

7. Live vaccines (varicella, MMR) can be given to which population of children with nephrotic syndrome?
   a. Children receiving cyclophosphamide
   b. Children receiving 2 mg/kg/day of prednisone

   c. Children who have been off high-dose steroids for 1 month
   d. Children who have been off high-dose steroids for 1 week
   e. Children receiving 2 mg/kg/day of prednisone and exposed to varicella
8. Complications of 25% albumin infusions in nephrotic patients can include all of the following, **except**:
   a. Pseudotumor cerebri
   b. Respiratory distress
   c. Congestive heart failure
   d. Acute hypertension
   e. Pulmonary edema
9. Which of the following is most suggestive of a cause of nephrotic syndrome other than MCNS?
   a. Age 2 years
   b. No hematuria
   c. Anasarca
   d. Stage II hypertension
   e. Normal complement 3
10. After receiving intravenous furosemide, a 2-year-old girl with SSNS develops gross hematuria and hypertension. What study should be performed first to evaluate for the cause of the hematuria?
   a. Urine calcium-to-creatinine ratio
   b. Urine protein-to-creatinine ratio

   c. Lasix renogram
   d. Renal ultrasound with Doppler
   e. Voiding cystourethrogram

ANSWER KEY

1. a
2. d
3. e
4. b
5. a
6. d
7. c
8. a

Primary podocytopathies

RAED BOU MATAR, RUDOLPH P. VALENTINI AND WILLIAM E. SMOYER

Nephrotic syndrome is defined by the presence of high-grade proteinuria, hypoalbuminemia, and edema. Hyperlipidemia and hypercoagulability are common associated findings. Increased permeability of the glomerular filtration barrier (GFB) results in massive loss of protein in the urine that leads to the constellation of renal and extrarenal findings characteristic of the disease. Children with nephrotic syndrome commonly present with periorbital swelling, peripheral pitting edema, or ascites. If left untreated, these children are at risk for various complications, including systemic infections, thromboembolism, and pulmonary edema. As discussed in Chapters 10 and 16, a major contributor to the GFB is the *podocyte,* and disruption of podocyte physiology is an important cause of nephrotic syndrome. Nephrotic syndrome in the majority of children results from an abnormality in podocyte structure or function. In such cases, we refer to the disease as a *primary podocytopathy,* which is the subject of this chapter (Table 17.1). In children, the most common primary podocytopathies are minimal change disease (MCD) and focal segmental glomerulosclerosis (FSGS). Secondary podocytopathies are less common and include autoimmune diseases, drug effects, and infections.

KEY POINT

Nephrotic syndrome is caused by an injury to the podocyte that results in disruption of the GFB.

THE PODOCYTE

The podocyte, also known as the glomerular visceral epithelial cell, is a terminally differentiated, highly specialized cell located at the urinary side of the glomerular capillary tuft. It plays a central role in: maintenance of the GFB through preservation of a molecular filtration sieve, synthesis of the glomerular basement membrane (GBM), and regulation of other glomerular cell types. In many proteinuric diseases, the podocytes become the target of immunologic or nonimmunologic injury.[1] This leads to a disruption of the podocyte cytoskeleton and widespread foot process effacement. In FSGS, for example, podocyte depletion and detachment from the underlying basement membrane are prominent features.[2]

The kidney maintains homeostasis by facilitating the excretion of body fluids and waste products while retaining physiologically important macromolecules, such as albumin and other plasma proteins. This regulation is possible only in the presence of an intact complex functional structure, the GFB. An intact GFB prevents the passage of molecules larger than 42 Å in diameter or with a molecular

Table 17.1 Classification of the podocytopathies

Condition	Definition	Examples
Podocytopathy	Any proteinuric disease resulting from disruption of normal podocyte physiology	
Primary glomerulopathy	A glomerular disease with no systemic extrarenal involvement	Minimal change disease, focal segmental glomerulosclerosis, membranoproliferative glomerulonephritis, IgA nephropathy
Idiopathic podocytopathy	A primary glomerulopathy characterized by minimal glomerular inflammatory infiltration and a bland urinary sediment	Minimal change disease, focal segmental glomerulosclerosis, membranous nephropathy, mesangial proliferative glomerulonephritis
Secondary podocytopathy	A podocytopathy caused by an immune, inflammatory, or mechanical injury to the podocyte resulting from a systemic disorder or a decreased number of nephrons (hyperfiltration injury)	Podocytopathies secondary to hepatitis B, hepatitis C, HIV infection, drugs (heavy metals, penicillamine, gold), autoimmune diseases (systemic lupus erythematosus, Henoch-Schönlein's purpura, Sjögren's syndrome), and morbid obesity
Genetic podocytopathy	A glomerular disorder caused by a genetic defect that interferes with normal podocyte structure or function	*NPHS2, NPHS1, ACTN4, TRPC6* and *Myo1E* gene mutations

Abbreviations: HIV, human immunodeficiency virus; IgA, immunoglobulin A.

weight exceeding approximately 200 kDa.[3] The GFB has three components: the capillary endothelial cell, the GBM, and the glomerular epithelial cells (podocytes). First, the capillary endothelial cells contains pores, known as fenestrations, that are large enough to permit non–size-selective passage of macromolecules. However, these fenestrations contain glycoprotein assemblies that hinder the free filtration of macromolecules.[4] Second, the GBM is mainly composed of type IV collagen, laminin, and glycoproteins. It plays an important role in the restriction of fluid flux.[5] Third, the podocytes are terminally differentiated epithelial cells consisting of a cell body, major processes, and minor processes, also known as foot processes. Podocyte foot processes interdigitate with those of neighboring podocytes. Between the foot processes are highly specialized cell-cell junctions, known as slit diaphragms.[6] Many of the proteins forming or associated with the slit diaphragm have been implicated in the pathogenesis of genetic forms of nephrotic syndrome. These include nephrin,[7] podocin,[8] and TRPC6.[9,10] The slit diaphragm interacts with the actin cytoskeleton of the podocyte foot processes.[11] In view of the central role the podocyte plays in the pathogenesis of proteinuria, the term podocytopathies has become increasingly used to describe various glomerular disorders.

The charge selectivity of the GFB has been the topic of ongoing debate among the scientific community (further discussed in Chapter 10). Charge selectivity was initially supported by experimentally observing significant differences in the sieving coefficients between neutral and anionic proteins (particularly albumin),[12,13] This concept was challenged, however, when newer measurements of the albumin concentration in the Bowman space that used intravital two-photon microscopy were higher than previously thought. This finding suggested that a proportion of albumin is filtered and then reclaimed by the proximal tubular cells.[14] Studies of charge selectivity in animals with nephrotic syndrome have yielded conflicting results. Some experiments demonstrated a loss of charge selectivity,[15–17] whereas others failed to detect alterations in charge selectivity in patients with MCD or FSGS.[18] Dysregulation of anionic charge has also been detected in other cell membranes in patients with nephrotic syndrome, such as the membranes of red blood cells and platelets, thereby leading to a controversial belief that MCD may be a systemic disorder of cell membrane function.[19]

Glomerular diseases associated with podocyte injury (podocytopathies) have been traditionally classified based on the presence or absence of systemic disease or glomerular inflammation. *Primary glomerulopathies* involve glomerular lesions with no systemic extrarenal (systemic) involvement. Primary glomerulopathies include conditions associated with inflammatory glomerular lesions and an active urinary sediment (red blood cell or white blood cell casts), such as membranoproliferative glomerulonephritis (MPGN) and immunoglobulin A (IgA) nephropathy. In addition, primary glomerulopathies also include *idiopathic podocytopathies,* such as MCD, FSGS, and mesangial proliferative glomerulonephritis (MesProlif GN). Idiopathic podocytopathies are often characterized by minimal glomerular inflammatory infiltration and a bland urinary sediment (MCD and FSGS), with

MesProlif GN often showing some signs of glomerular inflammation. Despite the prevalent nomenclature, a significant proportion of the "idiopathic" podocytopathies have been attributed to underlying genetic mutations, hence the term *genetic podocytopathies*. *Secondary glomerulopathies,* conversely, are associated with systemic diseases such as viral infections (hepatitis B, hepatitis C, human immunodeficiency virus [HIV] infection), drugs (heavy metals, penicillamine, gold), and autoimmune diseases (systemic lupus erythematosus, Henoch-Schönlein purpura, Sjögren's syndrome).

EPIDEMIOLOGY

Nephrotic syndrome is the most prevalent pediatric glomerular disease. It affects 2 to 7 per 100,000 children annually worldwide and has a cumulative prevalence of 16 per 100,000 children.[20–24] The incidence of nephrotic syndrome in children peaks at the age of 2 years.[20,21] In 1978, a prospective study by the International Study of Kidney Diseases in Childhood (ISKDC) included 521 children between the age of 3 months and 16 years with newly diagnosed with nephrotic syndrome. This study provided invaluable insight into the clinicopathologic features of idiopathic nephrotic syndrome. As a result, the association between certain histopathologic features and steroid responsiveness was gradually established.[25]

An important observation is that the likelihood of having a specific underlying histopathologic lesion varies by age. For example, MCD is the underlying histopathologic feature in more than 90% of children with nephrotic syndrome who are less than 10 years of age. After the age of 10 years, minimal change histology is seen in only approximately 50% of cases. With the exception of the first year of life, the likelihood of MCD generally decreases as the age of disease onset increases. In contrast, the likelihood of FSGS, or resistance to steroid therapy, increases with age at presentation. This was illustrated by a classic ISKDC study of children with nephrotic syndrome who had undergone renal biopsy.[25] In that cohort, the median age at presentation for MCD was 3 years. In contrast, children with FSGS presented at an older age (median, 6 years).[25] None of the patients with MPGN presented before the age of 6 years.[25]

There is a male preponderance of approximately 2:1 among young children with idiopathic nephrotic syndrome. However, this difference disappears in adolescent children, who tend to have equal incidence in boys and girls.[20,21] Whereas MCNS and FSGS are more common in boys, MPGN has a female predominance.[25]

In addition to age and sex differences, ethnicity may also predict the underlying histopathologic features and response to therapy. In a case series of 42 children living in the United Kingdom, Asian children appeared to have a six times higher incidence of steroid-sensitive nephrotic syndrome (SSNS) compared to Europeans.[26] This difference was attributed to the higher incidence of atopy among Asian children. In a report from South Africa, conversely, steroid-sensitive nephrotic syndrome (SSNS) was relatively uncommon among African children (14.4%), even among those with underlying minimal change histologic features, only 44% of whom were responsive to steroids. In this cohort of African children, membranous nephropathy associated with hepatitis B virus was detected in 40% of the cases.[27] Genetic variation at the *MYH9* gene locus may also help explain the high rate of FSGS in African children.[28] In another study from Texas, a relatively high proportion (47%) of African-American children who presented with nephrotic syndrome had FSGS on histopathologic examination. This is in clear contrast to Hispanic and white children with nephrotic syndrome, of whom only 11% and 18% had FSGS on histopathologic examination, respectively.[29] Although Hispanics had the highest incidence of MCD, FSGS was the most common cause of nephrotic syndrome in African-American children.[29] Despite these differences in the underlying histopathologic characteristics, the overall incidence of nephrotic syndrome was found to be equally distributed across various ethnicities in the same report.[29] Similar findings were reported in another study from Kansas City.[22] However, in this study, African-American children appeared to have double the annual incidence of nephrotic syndrome as compared with white children.[22]

Familial forms of idiopathic nephrotic syndrome were first described in the literature in the early 1970s.[30–35] In a European survey of 1877 children with nephrotic syndrome, 3.3% had a family member affected by the disease.[32] Identical twins and other affected siblings tend to have a similar disease presentation, age at onset, underlying histologic features, and response to therapy.[34,35] More recently, various genes have been implicated in the pathogenesis of familial forms of the disease. These are discussed in more detail later.

PATHOGENESIS

MINIMAL CHANGE DISEASE

The exact etiology that underlies MCD remains unknown. Anecdotal evidence points to the presence of an unspecified systemic factor that disrupts the GFB, with resulting massive proteinuria and diffuse effacement of the podocyte foot processes. Classically, MCD has been considered primarily a disorder of cell-mediated (T-cell) immune regulation.[36]

However, more recent observations proposed an important contributory role for humoral (B-cell) immunity in the pathogenesis of the disease.[37]

At least two studies support the presence of an unidentified systemic factor in MCD. In the first study, serum collected from a patient with Hodgkin's lymphoma and MCD increased the in vitro permeability of cultured podocytes. The ability of the serum to increase podocyte permeability was abolished by treatment of the underlying Hodgkin's lymphoma.[38] In another report, kidneys transplanted from a patient with MCD into two recipients (with no proteinuria at baseline) resulted in transient proteinuria shortly after the transplant procedure that subsequently resolved spontaneously over a 6-week period.[39]

In 1974, Shalhoub et al.[36] suggested that abnormal T-cell monoclonal proliferation in nephrotic syndrome may produce a lymphokine that is toxic to the GBM. The central role of cell-mediated immunity in the pathogenesis of MCD has been supported by several observations. First, children with atopy appear to have a higher incidence of the disease.[40] Second, severe viral infections, known to suppress cell-mediated immunity, may sometimes induce remission of nephrotic syndrome.[36] Third, MCD appears to be more common among children with malignant diseases, particularly Hodgkin's lymphoma.[41] Fourth, medications known to suppress T-cell function, such as corticosteroids, dramatically induce remission in most children with MCD.[25]

In agreement with Shalhoub's hypothesis, T-cell function appears to be altered during active relapses of MCD.[42] Active MCD is associated with increased numbers of CD4+ and CD8+ memory T-cell subsets,[43] as well as with delayed cutaneous hypersensitivity reactions.[44] It also appears that the undifferentiated (CD34+) T-cells are involved in the pathogenesis of MCD, rather than the more mature (CD34−) cells.[45]

Clinical observations further support a role for T-cell–mediated autoimmunity in MCD. For example, viral upper respiratory infections commonly induce relapses in children with this disease. In addition, case reports indicated that SSNS may rarely be induced by a bee sting or a fire ant bite.[46,47] Bee stings may also precipitate a relapse in children with a known history of nephrotic syndrome.[48] Interestingly, a possible association between food allergies and the development of nephrotic syndrome has also been suggested in small case series. In a series of 42 patients with steroid resistant or steroid-dependent nephrotic syndrome (SDNS), 38% had positive skin testing and 29% had elevated serum IgE levels. Limiting certain antigens in the diet allowed for discontinuation of steroids for a period of 1 to 5 years in 7 of 27 patients with steroid-dependent disease. However, the benefit was not sustained because the majority of patients eventually had one or more relapses.[49]

Several studies attempted to identify cellular-immunity associated genes from peripheral blood mononuclear cells (PBMCs) that may be involved in the pathogenesis of MCD. Using a subtractive cDNA library, genes encoding cytoskeletal proteins and T-cell receptor components, such as Fyb/Slap, L-plastin, and grancalcin, were found to be upregulated during relapsing MCD.[50] Two additional reports yielded similar results using serial analyses of gene expression.[51,52] Collectively, these studies reflect a significantly altered transcriptome of PBMCs in patients with MCD. A subsequent proteomic analysis of PBMCs identified four proteins that were increased in relapsing MCD as compared with controls, three of which (L-plastin, α-tropomyosin, and annexin III) are known to be involved in cytoskeletal rearrangement.[53] Given the cross-sectional design of these studies, it is not possible to conclude that the aforementioned alterations in gene or protein expression are causally associated with MCD.

Cytokine release from T-cells has also been implicated in the pathogenesis of MCD.[54,55] Interleukin 13 (IL-13) gene expression appears to be enhanced in children with SRNS.[56] Moreover, overexpression of IL-13 in transfected rats induced albuminuria, hypoalbuminemia, and podocyte effacement with no structural glomerular lesion seen on light microscopy, thus closely resembling human MCD on histologic examination.[57] IL-13 in concert with other cytokines or microbial agents may trigger upregulation of CD80, a T-cell co-stimulation protein on the podocyte cell surface, and lead to the disruption of its cytoskeletal organization.[51] Further studies are needed before these mechanisms can be generalized to all children with MCD.

Humoral immunity, once considered irrelevant, may also play a role in the pathophysiology of MCD. This role is inferred from the observation that rituximab, an anti-CD20 (B-cell) monoclonal antibody, appears to alter the clinical course of some children with MCD.[37] Alternatively, the depletion of B cells by rituximab may favorably affect nephrosis by its disruption of the role of B cells in antigen presentation and subsequent cytokine production from T cells. Moreover, it has been known for decades that children with MCD have decreased serum IgG levels and increased serum IgM levels compared with the general population, a finding also suggesting humoral dysfunction.[58]

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

Despite similarities in the presentation, histopathologic features, and response to therapy between FSGS and MCD,[59] they are, in fact, two distinct pathologic entities. Podocyte injury is most probably the initial triggering event in both disorders. However, the underlying molecular mechanisms of injury or response to injury are vastly different between the two diseases. Some children who are initially diagnosed with MCD on a kidney biopsy may occasionally turn out to have FSGS on subsequent biopsies. This can be simply attributed to the focal nature of FSGS, and it raises

the possibility of sampling error on an initial biopsy specimen. However, children with focal global sclerosis, with no segmental lesions seen on biopsy, tend to be more responsive to steroids and may follow a course that more closely resembles that of MCD.[60] FSGS may be idiopathic (formerly known as primary), genetic (familial or sporadic), or secondary. Because testing for many of the known genetic mutations is not currently widely available, many patients with sporadic FSGS who are clinically categorized as having "idiopathic" FSGS may actually have underlying undetected genetic mutations.

Idiopathic focal segmental glomerulosclerosis

Injury to the podocyte (visceral epithelial cell) is thought to be the primary event leading to the development of idiopathic FSGS.[61,62] The initial injury results in effacement of the podocyte foot processes that, if severe, may progress to podocyte apoptosis. Because podocytes are generally unable to replicate, the resulting reduction in the number of podocytes leads to uncovered areas of the GBM. This is followed by formation of adhesions (synechiae) between the GBM and the parietal epithelial cells. Subsequently, filtered plasma proteins begin to accumulate in the area underlying the parietal epithelial cells (periglomerular space) and the subendothelial space, thus triggering interstitial inflammation, hyalinosis, and segmental sclerosis. Finally, advanced disease is characterized by the development of progressive global sclerosis and interstitial fibrosis.

The precise mechanisms underlying podocyte injury in FSGS are poorly understood. Immunologic, inflammatory, genetic, and toxic factors may all play a role. In many patients with FSGS, the injury appears to be mediated by a circulating factor. This notion was supported by several clinical observations. First, there is a relatively high rate of recurrence of FSGS following renal transplantation,[63] and plasmapheresis often improves proteinuria in transplant recipients with recurrence of disease.[64] Second, injection of serum from patients with collapsing glomerulopathy, a severe form of FSGS, into rats may result in transient proteinuria.[65] Third, transient proteinuria was reported in an infant born to a mother with active FSGS.[66]

The soluble urokinase plasminogen activator receptor (suPAR) has been identified as a candidate circulating factor in patients with FSGS.[67] In mouse models, overexpression of suPAR was associated with massive proteinuria, effacement of podocyte foot processes, and segmental glomerular lesions, similar to those seen in human FSGS.[68] In animal studies, suPAR-induced podocyte injury appears to be mediated by activation of β_3 integrin.[68] However, human studies correlating serum suPAR with clinical activity in idiopathic FSGS have yielded conflicting results. In one report, serum suPAR levels were elevated in 55% of children and in 84% of adults with active FSGS and were suppressed with successful immunosuppressive therapy.[68,69] In another

report, suPAR was specifically elevated in patients with FSGS, but not in other glomerular diseases such as MCD or membranous nephropathy.[68] However, the latter study was heavily criticized for failing to account for differences in glomerular filtration rate (GFR), a key confounding variable among participants in the study.[70] In contrast, a small single center study showed no difference in plasma suPAR levels between children with FSGS and those with other glomerular diseases, or even healthy controls.[71] Notably, high pretransplant serum levels of suPAR were found in a retrospective review of patients who developed post-transplant FSGS recurrence [67] However, because serum suPAR accumulates in advanced renal failure, it did not appear to have prognostic utility when obtained in adult renal transplant candidates. Urine suPAR has also been proposed as an alternate option for use in the pretransplant evaluation of patients with FSGS.[72]

Genetic variants of focal segmental glomerulosclerosis

Since the discovery of the nephrin gene in 1998,[7] growing numbers of patients with FSGS have been found to have gene mutations inherited in a mendelian fashion.[7,8,73,74] Such mutations may be detected in the majority of infants with congenital or infantile nephrotic syndrome, in children with familial FSGS, and even in a significant number of children with sporadic steroid-resistant FSGS. These genes are mainly involved in the formation or regulation of the slit diaphragm *(nephrin, podocin, alpha-actinin-4, TRPC6, CD2AP)* or regulation of podocyte differentiation and cytoskeletal stability.

NPHS2 encodes for podocin, a protein exclusively expressed in podocytes that constitutes an integral component of the glomerular slit diaphragm. *NPHS2* has been implicated in early-onset autosomal recessive familial FSGS.[8] In addition, *NPHS2* mutations have been described in children with sporadic SRNS and adults with autosomal recessive FSGS.[75] In a French multicenter study, *NPHS2* mutations were detected in 42% of patients with autosomal recessive SRNS and in 10.5% of patients with sporadic SRNS. Patients with a single mutation of *NPHS2* tend to present at an older age than do patients with multiple mutations.[76]

NPHS1 gene mutations are known to cause congenital nephrotic syndrome of the Finnish type.[7] However, *NPHS1* mutations have also been reported in older children and young adults with SRNS.[77,78]

Mutations in the *inverted formin 2 (INF2)* gene have emerged as important causes of autosomal dominant familial FSGS.[73] *INF2* encodes for a member of the formin family of actin-regulating proteins, an essential factor that promotes the stability of the podocyte's cytoskeletal structure. *INF2* mutations have been detected in 9% to 17% of families with late-onset familial FSGS,[79–81] but these mutations are relatively rare in sporadic FSGS.[79] In one study, mutations in *INF2* and *WT1* were identified as causative in 20% and 10%

of autosomal dominant SRNS, respectively.[82] *INF2* mutations have also been implicated in the pathogenesis of the neuropathy and glomerulopathy associated with Charcot-Marie-Tooth disease.[83]

ACTN4 encodes for α-actinin-4, a cytoskeletal protein that appears to be essential for podocyte structural integrity. *ACTN4* mutations were identified in 3.5% of children and adults with familial autosomal dominant FSGS and in less than 1% of those with sporadic FSGS.[84] Mutations in *ACTN4* are often reflected by distinct histologic features on electron microscopy, primarily in the form of electron-dense collections in the podocyte cytoplasm.[85]

The TRPC6 gene encodes for a calcium-permeable receptor, known as the canonical transient receptor potential six-ion channel. This channel appears to play an important role in the proper function of podocytes and slit diaphragms.[9] Mutations have been classically associated with late-onset familial autosomal dominant FSGS,[86] but they have also been reported in children with sporadic SRNS.[87,88]

Finally, two mutations in the *Myo1E* gene, encoding myosin 1E, were identified in two independent families from Italy and Turkey. Both families had multiple children with autosomal recessive steroid resistant FSGS.[74]

Secondary focal segmental glomerulosclerosis

HYPERFILTRATION INJURY

Podocytes are terminally differentiated cells that are generally unable to replicate. In response to nephron loss, such as in chronic kidney disease, renal dysplasia, or nephrectomy, compensatory changes develop in the remaining nephrons, which are manifested as glomerular hypertrophy and intraglomerular hypertension. The increase in the single nephron GFR initially serves to compensate for the reduced total number of nephrons. However, hyperfiltration often exacerbates podocyte shear stress and eventually leads to podocyte detachment from the GBM. The subsequent events that lead to segmental sclerosis are comparable to those described earlier in idiopathic FSGS. Histologically, the presence of glomerular hypertrophy and a patchy distribution of foot process effacement (less than 50% of the total glomerular capillary surface area) may help differentiate secondary forms of FSGS from idiopathic FSGS.[89]

OBESITY

Similarly, severe obesity may also lead to glomerulomegaly, hyperfiltration, and increased GFR, which infrequently progresses to secondary FSGS.[90] Hemodynamic factors, related to hyperfiltration and intraglomerular hypertension, may also account for the development of FSGS in patients with severe preeclampsia, anabolic steroid abuse,[91] pamidronate,[92] and interferon therapy.[93] Interestingly, prematurity and very low birth weight have been associated

with reduced nephron number and an increased risk for the subsequent development of secondary FSGS.[94,95]

OTHER RENAL DISEASES

Secondary FSGS may also develop as a consequence of healed inflammatory glomerular lesions, such as those resulting from vasculitis, lupus nephritis, IgA nephropathy or postinfectious nephritis. In the healing phase of glomerular inflammation, extracellular matrix deposition and fibrosis appear to be mediated primarily by overexpression of transforming growth factor-β (TGF-β) in an animal model.[96]

EVALUATION OF PATIENTS WITH PRIMARY PODOCYTOPATHY

Most children with nephrotic syndrome present with generalized pitting edema. Initial evaluation should be aimed at confirming the diagnosis, screening for complications, assessing the indications for a renal biopsy, and excluding secondary and familial forms of the disease.

CLINICAL HISTORY

Generalized swelling is usually first noticed in soft tissue regions with weak subcutaneous fasciae, such as the periorbital area, scrotum, or labia. Edema tends to accumulate in gravity-dependent areas, such as the lower extremities in ambulatory patients. The symptoms are frequently preceded by a triggering illness, such as a viral upper respiratory infection. A primary podocytopathy should be suspected in any child who develops progressive swelling with no systemic symptoms (e.g., arthralgias or skin rash) and no known triggers (medications or toxins). Clinical Study 17.1 describes the typical clinical presentation in a young child.

PHYSICAL EXAMINATION

Systemic hypertension is more common in children with FSGS and secondary podocytopathies when compared with children with MCD. Joint swelling, joint erythema, skin rash, and mouth ulcers are uncommon in primary podocytopathies and warrant evaluation for secondary causes, such as systemic lupus erythematosus.

LABORATORY STUDIES

The diagnosis of nephrotic syndrome is confirmed by detecting massive proteinuria (300 mg/dL or more) on urine dipstick, low serum albumin (less than 2.5 g/dL), and

commonly elevated serum cholesterol or triglycerides on blood chemistry studies. The proteinuria may be quantified by using a spot urine protein-to-creatinine ratio (normal, less than 0.2 mg/mg; nephrotic range, greater than 2.0 mg/mg). Microscopic hematuria is not uncommon in children with primary podocytopathies. Approximately 20% of children with MCD and 50% of those with FSGS manifest microscopic hematuria at initial presentation.[25] In contrast, gross hematuria is relatively rare in children with primary podocytopathies. Elevated blood urea nitrogen (BUN) or creatinine signals concurrent acute kidney injury, often related to intravascular fluid volume depletion, but it can also suggest an alternative diagnosis such as chronic glomerulonephritis or IgA nephropathy.[97]

> ### KEY POINT
>
> Gross hematuria, elevated blood pressure, elevated BUN or creatinine, and hypocomplementemia are uncommon in MCD and should raise the suspicion of an alternate cause.

Additional testing should include complement components (C3 and C4), antinuclear antibodies (ANA), and anti–double stranded (ds) DNA to evaluate for MPGN and lupus. Liver function tests along with serologic testing for hepatitis B virus (HBV), hepatitis C virus (HCV), and HIV may be indicated in sexually active adolescents or other at-risk children.

INDICATIONS FOR RENAL BIOPSY

A renal biopsy is often unnecessary at the initial presentation of children with nephrotic syndrome. Accumulating evidence has revealed that a thorough initial clinical evaluation of children presenting with nephrotic syndrome predicts, with satisfactory accuracy, the likelihood of subsequent clinical response to corticosteroid therapy.[25] The following criteria have been established that are consistent with a diagnosis of MCD and therefore predict a high probability (greater than 90%) of steroid-responsive disease: (1) children between the age of 1 and 10 years; (2) absence of hypertension, gross hematuria, or elevated serum creatinine; and (3) normocomplementemia. It is recommended that children who satisfy all the aforementioned criteria empirically receive an initial treatment course of daily corticosteroids without the need to obtain a kidney biopsy.[98]

> ### KEY POINT
>
> Children with the typical clinical and laboratory features of MCD may be treated empirically with steroids, without the need for a renal biopsy.

A kidney biopsy should be considered in children who do not fulfill the foregoing criteria or who do not respond to the initial or subsequent courses of corticosteroids. A renal biopsy has also been recommended for all children who are older than 12 years of age on presentation.[99] Older children also are at a greater risk for non-minimal change causes, such as FSGS or lupus nephritis.[99] Although some clinicians recommend a renal biopsy based on age, one could argue that an empiric trial of corticosteroids could be considered in a teenage child who does not fulfill any of the aforementioned criteria of hypertension, gross hematuria, azotemia, or hypocomplementemia. Because the best predictor of long-term prognosis is steroid responsiveness, it would be reasonable to postpone the biopsy and reassess the need for a potential biopsy after the initial 3 to 4 weeks of treatment with corticosteroids. A biopsy will also be required if the initial evaluation uncovers findings that point to a cause other than MCD. Such findings may include systemic hypertension, skin rash, pruritus, weight loss, arthralgias, positive viral serologic test results, or a positive serum ANA or anti ds DNA.

HISTOLOGIC CLASSIFICATION

MINIMAL CHANGE DISEASE

Histologically, MCD is defined by the absence of glomerular or tubulointerstitial abnormalities on light microscopy (Figure 17.1) and by the absence of immune deposits on immunofluorescence staining. However, the finding of mild mesangial hypercellularity or occasional globally sclerotic glomeruli does not exclude the diagnosis.[100] On electron microscopy, diffuse podocyte foot process effacement is usually prominent. In some cases of early FSGS, if none of the glomeruli examined on the initial kidney biopsy demonstrate segmental sclerosis, the histologic diagnosis may be labeled as MCD. Subsequently, segmental sclerotic lesions may be seen on a repeat biopsy specimen obtained months to years later. Such situations have led to the controversial belief by some investigators that MCD and FSGS may represent different stages of the same pathologic entity, as discussed earlier.

In children who present with nephrotic syndrome but no systemic symptoms, MCD is the most likely underlying histopathologic process.[25] This was illustrated by the original ISKDC cohort, which included 521 children who presented with symptoms of nephrotic syndrome. In this group, 77% were found to have MCD histologic features on the initial

The mesangium is not expanded. **(b)** Electron microscopy showing diffuse effacement of the podocyte foot processes over the urinary aspect of the glomerular basement membrane (arrows). The endothelial cells (E) are unremarkable, and there are no mesangial, subendothelial or subepithelial deposits.

renal biopsy. In the same cohort, 80% of children eventually diagnosed with MCD on renal biopsy presented with nephrosis before the age of 6 years. In contrast, only 50% of children with a histologic diagnosis of FSGS presented at such a young age.[25] In a more recent report, 88% of children who presented with nephrotic syndrome had MCD on renal biopsy.[101]

MINIMAL CHANGE DISEASE VARIANTS

Histologic variants have been proposed that resemble MCD on light microscopy but are distinguished by ultrastructural characteristics on electron microscopy or immunofluorescence. In view of the limited knowledge of the underlying pathophysiology, it remains unclear whether these disorders represent primary podocyte disorders, similar to MCD or FSGS, or separate pathologic entities with secondary involvement of the podocytes. The clinical significance of these variants lies in their lower response rate to corticosteroid therapy and their less favorable prognosis compared with classic histologic features of MCD.[102–104]

Mesangial proliferative glomerulonephritis

The MesProlif GN variant *of* MCD is characterized by variable degrees of mesangial proliferation.[105,106] In a series of 29 children with diffuse mesangial hypercellularity, the majority had associated microscopic or gross hematuria, and close to 50% had concurrent systemic hypertension. In the same cohort, 40% of children were steroid resistant, a proportion that far exceeds the 10% rate of steroid resistance that has been previously described in children with classic MCD.[106]

Immunoglobulin M nephropathy

IgM nephropathy is differentiated from classic MCD by the presence of electron-dense mesangial immune deposits that correspond to granular IgM staining on immunofluorescence staining.[103] These deposits must be differentiated from nonspecific mesangial IgM deposits, a relatively common finding in MCD that, in contrast to those seen in IgM nephropathy, do not correspond to electron-dense deposits on electron microscopy. The prognostic significance of a histopathologic diagnosis of IgM nephropathy remains uncertain. In a study that included 23 children with steroid-resistant or steroid-dependent IgM nephropathy, 88% of those treated with cyclosporine (7 of 8) achieved a partial or complete remission as compared with only 18% of those treated with cyclophosphamide (2 of 11).[107] In another large series of 110 children and adults with IgM nephropathy who were followed for a mean duration of 8 years, 29% were steroid resistant and 57% were steroid dependent. In the same cohort, 36% developed chronic renal insufficiency, and 23% reached end-stage kidney disease (ESKD) over the follow-up period, percentages that far exceed what would be expected in children with classic MCD.[104]

C1q nephropathy

In the absence of serologic evidence for systemic lupus erythematosus, diffuse mesangial electron-dense deposits associated with predominant C1q staining on immunofluorescence define *C1q nephropathy*. This histologic entity may be associated with MCD,[108] FSGS,[102] or mesangial proliferative lesions on light microscopy. Studies evaluating the prognostic significance of C1q nephropathy have yielded conflicting results. In a report of

12 children with C1q nephropathy, 8 of whom presented with nephrotic syndrome, most had steroid-dependent or steroid-resistant disease. The likelihood of progression to ESKD was very high, particularly in patients with steroid-resistant cases.[109] In contrast, only 3 of 61 children and adults with C1q nephropathy in another report developed renal insufficiency 8 to 15 years following the initial diagnosis.[110] In another review of 72 children and adults with C1q nephropathy, most (77%) of those with MCD histologic features, but only one-third of those with FSGS histologic features, were in complete remission at a mean follow-up of 5.5 years (range, 4 months to 21 years).[108]

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

As the nomenclature implies, FSGS is histologically characterized by glomerular fibrosis or mesangial collapse (glomerulosclerosis) that affects part of (segmental) the glomerular tuft (Figure 17.2). The lesions typically involve some but not all glomeruli (focal). In the initial stages of disease, most affected glomeruli are juxtamedullary and therefore may be missed on a renal biopsy that samples only cortical tissue.[111] Nonspecific mesangial IgM and C3 deposits

---

KEY POINTS

Histologic variants of FSGS include:

- Classic FSGS (FSGS not otherwise specified)
- Collapsing variant
- Tip variant
- Perihilar variant
- Cellular variant

Figure 17.2 Renal biopsy findings in a child with nephrotic syndrome resulting from classic focal segmental glomerulosclerosis. A photomicrograph of a glomerulus (periodic acid–Schiff stain ×40) shows a normal segment of the glomerulus (lower arrow) and the sclerotic (upper arrow) glomerular segment.

are frequently seen in the glomerular sclerotic lesions on immunofluorescence staining. In contrast, staining for IgG is usually negative.[112] Electron microscopy often reveals diffuse podocyte foot process effacement, which is particularly prominent in children with idiopathic FSGS.[113]

Several mutually exclusive histologic variants of FSGS have been described (Columbia classification), the prognostic significance of which is not entirely clear.[114]

Classic focal segmental glomerulosclerosis

The diagnosis of classic FSGS (FSGS not otherwise specified), the most common form of FSGS, is generally made on exclusion of all other histologic variants. In classic FSGS, segmental glomerulosclerosis is seen in one or more capillary loops and is associated with variable degrees of mesangial matrix expansion and hypercellularity.[89,115]

Collapsing variant

Collapsing variant FSGS is characterized by the global or segmental collapse of the glomerular capillary tuft (Figure 17.3). Collapsing FSGS has been associated with HIV infection[116] and parvovirus B19 infection.[117,118] It appears to be more common in children of African descent. Clinically, it is correlated with severe nephrotic syndrome that is generally resistant to immunosuppressive therapy and often carries a poor prognosis, almost invariably progressing to ESKD.[119] Because of differences in podocyte number between collapsing FSGS and the other variants, with apparent proliferation in the collapsing lesion versus podocytopenia in the others, it has been suggested that the collapsing variant is a distinct disease.[120] However, no differences in treatment regimen have been proposed.

Tip variant

Tip variant FSGS is defined by the presence of segmental involvement of the glomerular tuft at the origin of the proximal tubule, at which there is prominent tissue expansion by foam cells or hyaline material.[121] The remainder of the glomerular tuft appears normal by light microscopy, but diffuse podocyte foot process effacement is seen on electron microscopy. Clinically, tip variant has been correlated with an abrupt onset of steroid-sensitive nephrotic syndrome, resembling MCD.[121] Notably, in a small report in adults, as many as 55% of patients with tip variant FSGS on initial biopsy actually underwent spontaneous complete remission without the need for immunosuppressive therapy.[122]

Perihilar variant

Perihilar variant FSGS is distinguished by segmental sclerosis and hyalinosis in a perihilar pattern. Perihilar variant is seen predominantly in children with secondary FSGS.
Figure 17.3 Light and electron microscopy findings in a patient with collapsing focal segmental glomerulosclerosis. **(a)** Low-power photomicrograph (Jones stain ×20) shows two glomeruli with retracted and collapsed capillary tufts (CG). The capillary lumina are not preserved. **(b)** Higher-power photomicrograph (Jones stain ×40) of the same patient shows a glomerulus with collapsed capillary tuft, hyperplastic and hypertrophied epithelial cells, and thickened glomerular basement membrane (GBM). **(c)** An electron micrograph shows collapsed capillary loops with obliteration of the capillary lumina. Diffuse effacement of the podocyte (P) foot processes over the urinary aspect of the GBM is also noted. Abundant entrapped electron dense deposits (DD) are seen in the mesangium and on the inner sides of the collapsed glomerular capillary loops (arrow). No subepithelial deposits are present.

Cellular variant

Finally, cellular variant FSGS is diagnosed when at least one glomerulus shows segmental cellular proliferation. This lesion has been correlated clinically with a poor prognosis, similar to collapsing FSGS.[89]

Increasing incidence

Several studies have reported an increase in the incidence of FSGS in both children and adults over the last several decades.[22,29,123] It has been frequently debated, however, whether this trend can be simply explained by the more selective approach to obtaining renal biopsies in modern medicine. In the classic ISKDC cohort, renal biopsies were obtained on all patients who presented with nephrotic syndrome before or shortly after initiating therapy. In the current era, renal biopsies are generally performed only for children who to fail to respond to the initial 4- to 8-week course of steroids and therefore carry a far higher likelihood of having structural glomerular lesions, including FSGS. To minimize this bias, a study compared the incidence of FSGS in a well-defined geographic area between two periods of 8½ years extending from 1985 to 2002. Consistent with previous reports, the annual incidence of FSGS increased from 0.37 to 0.94 cases per 100,000-child population/year between

the two eras studied.[123] The basis behind this increase in the incidence of FSGS over time remains unknown.

In older children and adults, detecting occasional glomeruli with global sclerosis on renal biopsy is not uncommon. Focal global glomerulosclerosis (FGGS) is distinguished from FSGS by complete, rather than segmental, scarring of one or more sampled glomeruli. In the absence of significant associated interstitial changes, global sclerosis is considered a nonspecific finding and correlates with a more favorable long-term outcome when compared with FSGS histologic features.[60,124]

Secondary FSGS, a condition attributed to nephron loss, is associated with similar light microscopic findings as those seen in idiopathic FSGS, except for the prominent finding of glomerulomegaly. However, electron microscopy typically reveals focal podocyte foot process effacement in secondary FSGS, mainly confined to the sclerotic lesions, as opposed to the diffuse pattern seen in idiopathic FSGS.[89] Secondary FSGS may be seen in children with reflux nephropathy, renal dysplasia, sickle cell disease, glycogen storage diseases, and congenital heart disease.[125–127] In contrast to idiopathic FSGS, secondary FSGS typically manifests with a more gradual onset of proteinuria, which is usually in the subnephrotic range. Children with secondary FSGS are also less likely to have features of active nephrotic syndrome, such as edema, ascites, and hypoalbuminemia. The disorder is unlikely to respond to immunosuppressive therapy, but it is usually treated with angiotensin blockade and often has a more favorable outcome.[90,128]

SECONDARY PODOCYTOPATHIES

Podocyte injury may be the result of a systemic illness affecting multiple organs, the mechanism of which varies depending on the underlying origin. Secondary causes of childhood nephrotic syndrome include infectious agents, drugs, metabolic derangements, malignant diseases, and autoimmune diseases (Table 17.2).

Minimal change disease

LYMPHOMA

Nephrotic syndrome is infrequently reported in children and adults with Hodgkin's lymphoma. The timing of renal involvement is highly variable. The nephrotic symptoms may precede the diagnosis of Hodgkin's disease by up to several years,[129,130] may occur simultaneously,[131] or may even occur later during remission.[132] MCD appears to be the most common underlying histopathologic lesion in this setting. The nephrotic syndrome commonly remits with successful treatment of the underlying lymphoma.[133,134]

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Nephrotic syndrome, in the form of MCD or membranous nephropathy, with or without concomitant tubulointerstitial nephritis, is a rare side effect of nonsteroidal anti-inflammatory drugs (NSAIDs).[135–137] Glomerular disease has also been reported with the use of the newer selective NSAIDs,

Table 17.2 Primary and secondary podocytopathies in children

Primary Causes
- Minimal change disease (MCD)
- Focal segmental glomerulosclerosis (FSGS)
- MCD variants
  - Mesangial proliferative glomerulonephritis
  - Immunoglobulin M nephropathy
  - C1q nephropathy
- Membranoproliferative glomerulonephritis (MPGN)
  - MPGN type I
  - MPGN type II (dense deposit disease)
  - MPGN type III
- Membranous nephropathy

Genetic Causes*
- Nonsyndromic
  - *NPHS2* (podocin)
  - *NPHS1* (nephrin)
  - *IFN2* (formin)
  - *ACTN4* (α-actinin-4)
  - TRPC6 (TRPC6)
  - *Myo1E* (nonmuscle myosin-1E)
  - *PLCE1* (phospholipase Cε1)
  - *CD2AP* (CD2-associated protein)
- Syndromic
  - *WT1* (Denysh-Drash syndrome)
  - Mitochondrially encoded tRNA leucine 1 (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes).
  - *ITGB4* (epidermolysis bullosa)
  - *CD151* (epidermolysis bullosa, sensorineural deafness, nail dystrophy)
  - *SCARB* (action myoclonus–renal failure syndrome)
  - *LMX1b* (nail-patella syndrome)
  - Nonmuscle myosin IIA (*MYH9*; Epstein and Fechtner syndrome)
- *LAMB2* (Pierson syndrome)

Causes of Secondary Minimal Change Disease
- Lymphoma
- Nonsteroidal anti-Inflammatory drugs (NSAIDs)
- Gold salts
- Penicillamine, bucillamine
- Anti–tumor necrosis factor agents, such as infliximab and etanercept

Causes of Secondary Focal Segmental Glomerulosclerosis
- Human immunodeficiency virus (HIV) infection
- Leukemia and lymphoma

(continued)

* This is a limited list of the more common genetic causes of nephrotic syndrome. The reader is referred to www.omim.org for a more comprehensive and current list of genetic mutations that may cause nephrotic syndrome.

such as the cyclooxygenase 2 (COX-2) inhibitor, celecoxib.[138] However, in another report, celecoxib was successfully used as an alternative in an adult with NSAID-associated nephrotic syndrome without recurrence of the renal symptoms. This finding may suggest that a selective NSAID can sometimes be safely substituted with close monitoring for patients who require continued NSAID therapy.[139]

OTHER MEDICATIONS

In addition to NSAIDs, multiple other anti-inflammatory medications have been linked to the development of nephrotic syndrome. These include gold salts (especially parenteral formulations),[140] penicillamine,[141] bucillamine,[142] and anti–tumor necrosis factor agents, such as infliximab and etanercept.[143] Histologically, the glomerular toxicity of these agents may manifest as MCD, membranous nephropathy,[144] or immune complex glomerulonephritis, among others. In a case series of 33 patients with penicillamine-induced glomerulopathy, proteinuria did not clearly correlate with the dose or duration of therapy. However, 80% of the affected patients presented in the first year of therapy and most patients (close to 90%) had membranous nephropathy on renal biopsy.[141] Tiopronin, a thiol drug with marked structural similarity to penicillamine that is used to treat cystinuria, has also been associated with the development of membranous nephropathy.[145]

Focal segmental glomerulosclerosis

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Nephrotic syndrome is the most common presentation of HIV-related nephropathy.[146] In a large series of 71 children with HIV-1–related nephropathy from Africa, 39% had classic FSGS, and 26% had collapsing FSGS. The children with collapsing glomerulopathy had a worse outcome.[147] On electron microscopy, tubuloreticular inclusions may be seen, but they are not considered specific for HIV infection.[116] Fortunately, most children who receive antiretroviral therapy are expected to achieve partial or complete remission.[116] Persistent sterile pyuria has been correlated with declining renal function in HIV-infected children treated with indinavir.[148] In addition to FSGS, other forms of glomerular involvement have been reported with HIV, including immune complex kidney disease (HIVICK) and thrombotic microangiopathies.[149]

LEUKEMIA

A few case reports have identified acute lymphoblastic leukemia that developed in children treated for nephrotic syndrome.[150,151] The relative contribution, if any, of the immunosuppressive therapy to the risk of malignancy in these patients remains uncertain. Moreover, multiple case reports have been described of steroid-sensitive nephrotic syndrome, particularly FSGS or MCD, associated with chronic lymphocytic leukemia.[152–154] Case reports of membranous nephropathy have also been described in patients with acute myeloid leukemia.[155] Hematopoietic stem cell transplantation, with or without graft-versus-host disease, has also been linked to the development of nephrotic syndrome in several pediatric[156] and adult cases.[157–160]

DRUGS

Anabolic steroids, frequently abused to enhance athletic performance, have been associated with the development of secondary FSGS. In a retrospective review of 10 patients, prolonged use of anabolic steroids (8 to 20 years) was associated with significant proteinuria, which progressed to nephrotic syndrome in 3 patients. Renal biopsies revealed FSGS in the majority of cases. In the same report, glomerulomegaly and collapsing glomerulopathy were seen in 4 and 3 patients, respectively. Glomerulopathy improved after discontinuation of the offending agents.[91]

MITOCHONDRIAL DISORDERS

Minor renal tubular abnormalities are the most common renal manifestations of mitochondrial disorders, and these abnormalities affect up to 50% of children with known mitochondrial disease.[91] However, case reports have described glomerular disease in children with mitochondrial disorders, primarily in the form of steroid-resistant FSGS,[161,162] collapsing glomerulopathy, or crescentic glomerulonephritis.[163] Rarely, mutations in the *COQ2* gene leading to coenzyme Q10 deficiency, have been detected in patients with collapsing glomerulopathy associated with mitochondrial disease.[163] Characteristic features are detected on electron microscopy in children with *COQ2* gene mutations. These features include numerous structurally abnormal mitochondria located in the glomerular and tubular cells. These mitochondria appear enlarged, lack cristae, and have an electron-lucent central core.[163,164] Other closely linked mutations in the coenzyme Q10 pathway have also been described, including mutations in the *PDSS2*[165] and *COQ6* genes.[166] Mutations in the *COQ6* gene are also associated

with a syndrome of SRNS and sensorineural hearing loss.[166] Treatment with coenzyme Q10 supplements, also known as ubidecarenone, may help alleviate many of the manifestations of coenzyme Q10 deficiency.[161,167]

SICKLE CELL DISEASE

Renal manifestations of sickle cell disease include hematuria, tubular dysfunction, vascular compromise, and glomerular disease. Proteinuria develops in 25% of patients with SS disease.[168] Histologic patterns suggestive of secondary FSGS are often seen on renal biopsy, in concert with glomerular enlargement and hyperfiltration injury to podocytes.[168] Angiotensin-converting enzyme inhibitors (ACEIs) appear to be beneficial in this setting, by improving glomerular capillary hemodynamics and reducing proteinuria by more than 50% as illustrated in one study.[168] As would be expected with hemodynamic podocyte injury, the onset of proteinuria in sickle cell disease is gradual and not associated with significant swelling. Therefore, a child with sickle cell disease who presents with an acute onset of nephrotic syndrome should be evaluated for alternate causes.[169] In addition to FSGS, collapsing glomerulopathy and MPGN have also been described in patients with sickle cell disease.[170,171]

OBESITY

Nephrotic syndrome has been associated with severe obesity since the early 1970s.[172] With the emerging epidemic of obesity, the prevalence of obesity-associated glomerulopathy has increased by 10-fold over a 10-year period from 1986 to 1996.[90] *Obesity-induced glomerulopathy* has been attributed to an increase in GFR, hyperfiltration and intraglomerular hypertension.[90,173] In one report, for instance, the average GFR in severely obese adults was 145 mL/min compared with 90 mL/min in their nonobese counterparts.[173] More recently, lack of adiponectin, an adipose tissue–secreted hormone, has also been implicated in the underlying pathogenesis of glomerular injury in obese patients.[174] Glomerulomegaly and variable degrees of segmental or global sclerosis are the most common histologic lesions seen in obesity-related glomerulopathy.[90] By electron microscopy, increased width of individual foot processes, decreased density of podocytes, and decreased numbers of podocytes are prominent features of the disease.[175] Both weight loss and the use of ACEIs are effective treatment options.[176]

Secondary collapsing glomerulopathy

As previously detailed, HIV is by far the most common viral infection associated with collapsing glomerulopathy. Small case series and case reports have also implicated other viruses, such as parvovirus B19,[118] hepatitis C virus, and human T-lymphocyte virus type I (HTLV-I),[116] and cytomegalovirus (CMV).[119] although a causal relationship has not been established between these viruses and the associated collapsing glomerulopathy. Because

immunosuppressive therapy may be detrimental in patients with such viral infections, a thorough viral workup is warranted before labeling a child as having "idiopathic" collapsing glomerulopathy.[119]

TREATMENT OF PRIMARY PODOCYTOPATHIES

Since the introduction of corticosteroids in the early 1950s, the outcome for children with nephrotic syndrome has been dramatically altered. Over the following several decades, classic reports from the ISKDC and the Arbeitsgemeinschaft fur Padiatrische Nephrologie (APN) have served to improve the treatment of nephrotic syndrome further.[177–179] In one report, glucocorticoid therapy induced complete remission in 89% of children with nephrotic syndrome.[101] However, steroid responsiveness varied substantially according to the underlying histopathologic features. For instance, 95% to 98% of children with MCD responded to corticosteroid therapy as compared with only 20% of those with FSGS.[98,180] Several presenting features have been identified that may help predict the underlying histopathologic features and, therefore, the response to corticosteroids. Specifically, children between the age of 1 and 10 years, with normal renal function, no gross hematuria, no systemic hypertension, and no hypocomplementemia, are most likely to be steroid sensitive. As discussed earlier, it has been generally recommended that children who fulfill most or all of these features receive empiric treatment with glucocorticoids without resorting to a kidney biopsy.[99] Guidelines have been established for the initial and subsequent treatment regimens for children with nephrotic syndrome. Following the initial course of corticosteroids, the subsequent therapeutic approach varies considerably based on steroid responsiveness, frequency of relapses, and biopsy results, if a biopsy is deemed necessary. A widely used classification based on the response to steroids and frequency of relapses is detailed in Table 17.3.

STEROID-SENSITIVE NEPHROTIC SYNDROME

Guidelines for the treatment of childhood nephrotic syndrome were published in 2009 by the Children's Nephrotic Syndrome Consensus Conference, an expert panel of pediatric nephrologists (Table 17.4). These recommendations were developed for children 1 to 18 years of age with nephrotic syndrome. The panel recommended that the initial episode of nephrotic syndrome be treated with prednisone 2 mg/kg/day for 6 weeks (maximum, 60 mg per day), followed by 1.5 mg/kg/dose (maximum, 40 mg per dose) given every other day for 6 additional weeks. Prednisone should then be discontinued at the conclusion of the initial treatment course without the need for a tapering regimen.[99] Following this initial regimen, it is estimated that approximately 50%

Table 17.3 Clinical terminology based on response to corticosteroids and the frequency of relapses

Term	Definition
Nephrotic syndrome	The presence of edema, high-grade proteinuria (>40 mg/m^2/h or a urine protein-to-creatinine ratio >2.0) and hypoalbuminemia (<2.5 g/dL)*
Remission of nephrotic syndrome	Reduction in the spot urine protein-to-creatinine ratio to <0.2 mg/mg, or urine albumin dipstick readings that are negative or trace for 3 consecutive days
Relapse of nephrotic syndrome	Following remission, relapse is defined by an increase in the spot urine protein to creatinine (preferably obtained on a first-morning urine sample) to >2.0, or urine albumin dipstick readings exceeding 100 mg/dL (2+ or more) on 3 out of 5 consecutive days
Steroid-sensitive nephrotic syndrome (SSNS)	Remission in response to an initial 4–8-wk course of daily corticosteroid therapy
Steroid-resistant nephrotic syndrome (SRNS)	Persistent high-grade proteinuria following 4 wk of daily corticosteroids
Steroid-dependent nephrotic syndrome (SDNS)	Patients with SSNS who develop a relapse during gradual weaning of the dose of steroids, or within 2 wk of discontinuing steroid therapy
Frequent-relapsing nephrotic syndrome (FRNS)	Two or more relapses of nephrotic syndrome within a 6-mo period following initial therapy or four or more relapses within any 12-mo period

*   Hyperlipidemia and hypercoagulability are often associated findings, but they are not considered defining features of nephrotic syndrome.

of children will remain relapse free at 24-month follow-up. However, close to 30% are expected to develop a frequently relapsing course subsequently.[99]

Similar recommendations for the treatment of childhood nephrotic syndrome were published in 2012 by the Kidney Disease: Improving Global Outcomes (KDIGO) working group (see Table 17.4). The group recommended that oral prednisone be given initially for 4 to 6 weeks as a single daily dose of 60 mg/m^2/day or 2 mg/kg/day (maximum, 60 mg/day). This should be followed by alternate-day therapy of 40 mg/m^2/per dose or 1.5 mg/kg/dose (maximum, 40 mg on alternate days) to be continued for 2 to 5 months.[181] Unlike the Children's Nephrotic Syndrome Consensus

Table 17.4 Corticosteroid treatment protocols for nephrotic syndrome

Reference	Initial episode	Infrequent relapses	Frequent relapses
2009 Children's Nephrotic Syndrome Consensus Conference[99]	Prednisone, 2 mg/kg/day orally for 6 wk (maximum 60 mg/day) to be followed by 1.5 mg/kg/dose (maximum 40 mg/dose) given every other day for 6 additional wk (no taper)	Prednisone, 2 mg/kg/day until the urine dipstick for protein is trace or negative for 3 consecutive days; prednisone dose is then decreased to 1.5 mg/kg administered every other day for at least 4 wk	Prednisone, 2 mg/kg/day until the urine dipstick is trace or negative for 3 days; this is followed by 1.5 mg/kg on alternate days for an additional 4 wk; prednisone is then tapered over a period of 2 mo by 0.5 mg/kg
2012 Kidney Disease Improving Global Outcomes[181]	Prednisone, 60 mg/m^2/day or 2 mg/kg per day (maximum 60 mg/day) orally for 4–6 wk as a single daily dose; this is followed by alternate-day therapy of 40 mg/m^2/dose or 1.5 mg/kg/dose (maximum 40 mg on alternate days) to be continued for 2–5 mo, then tapered over 2–5 mo		Prednisone, 60 mg/m^2/day or 2 mg/kg/day (maximum 60 mg/day) orally until the child has been in remission for at least 3 days; this followed by alternate-day prednisone for at least 3 mo; prednisone is to be given on alternate days in the lowest dose possible to maintain remission without major side effects

Conference, the KDIGO group recommended tapering the alternate-day steroid dose over the course of 2 to 5 months. This recommendation was based on a systematic review revealing that prolonged duration of alternate-day therapy, up to 6 months, may reduce the risk of subsequent relapses of the disease.[182]

In patients with newly diagnosed disease, corticosteroids should be given for at least 12 weeks. This is because shorter courses of therapy have been associated with an increased risk of future relapses.[182] In a multicenter controlled trial, 61 children were randomized to receive either standard therapy, in the form of 4 weeks of daily steroids followed by alternate-day therapy, or a short course of daily steroids until they achieved full remission followed by alternate-day therapy. Only 19% of children who received the shorter course were in sustained remission at 2 years as compared with 41% with standard therapy. Moreover, the mean duration of remission in children receiving the shorter course was half of that of the children receiving a longer course.[177] Subsequent studies have further validated the beneficial effect of routinely using a relatively prolonged steroid regimen in the initial treatment of the disease because of its favorable impact on future relapses.[183–185]

Once-daily corticosteroid dosing appears to be as efficacious as twice-daily dosing.[182] A few studies have also inferred that calculating the steroid dose based on body weight, rather than surface area, may result in underdosing of young children who weigh less than 30 kg.[186] This potential underdosing does not appear to alter initial response to therapy, but it may increase the risk of future frequent relapses.[187]

Variations of the foregoing recommended regimens for the initial treatment of childhood nephrotic syndrome have been reported, with limited benefit. In a randomized controlled trial of 104 children, the use of the standard prednisone regimen was compared with standard glucocorticoids in addition to 8 weeks of cyclosporine A. Despite reduced rates of relapse in children treated with cyclosporine during the first year, there was no difference in sustained remission rates between the 2 groups at a follow-up period of 2 years.[188]

The majority of children with nephrotic syndrome will achieve complete remission within 4 weeks of therapy. In the original ISKDC cohort, 92% of children responded to steroid treatment. Of the initial responders approximately 75%, 94%, and 99% did so within the first 2 weeks, 4 weeks, and 8 weeks of therapy, respectively.[98] In a retrospective review of 103 children with idiopathic nephrotic syndrome, a shorter time to a response (less than 7 days) predicted a lower likelihood for an early relapse (within 3 months of discontinuing steroids). A shorter time to response was also associated with a lower risk for either a frequently relapsing or steroid-dependent course. In the same study, the median time to remission on steroids was 7 days.[189]

INITIAL RELAPSE OR INFREQUENTLY RELAPSING NEPHROTIC SYNDROME

More than 50% of children with nephrotic syndrome who respond to the initial course of steroids will develop at least one relapse of the disease.[99] Relapses are usually spontaneous, but they may sometimes be triggered by an upper respiratory infection. Relapses may occur during tapering of the prednisone dose or at some point following discontinuation of the medication. Some relapses (10% to 23%) may remit spontaneously.[190] The Children's Nephrotic Syndrome Consensus and the KDIGO groups define infrequent relapses as one relapse within 6 months of initial response, or one to three relapses in any 12-month period. Both groups recommended that patients with initial or infrequent relapses be treated with prednisone 2 mg/kg/day until the urine dipstick for protein is trace or negative for 3 consecutive days. The prednisone dose should then be decreased to 1.5 mg/kg administered every other day for at least 4 weeks.[99,181] These recommendations are based on a randomized controlled trial by the ISKDC that compared an 8-week regimen of steroids with another regimen of shorter duration (mean, 12 days). The 8-week regimen was associated with a markedly lower risk of relapse during treatment (8% vs. 40%) and a more prolonged relapse-free period after treatment.[179]

FREQUENTLY RELAPSING OR STEROID-DEPENDENT NEPHROTIC SYNDROME

In the ISKDC cohort, 30% of children with SSNS eventually developed a frequently relapsing course, defined as four or more relapses per year.[191] Moreover, relapses that occur while tapering steroids or within 2 weeks after discontinuing treatment indicate steroid dependence. Children with steroid dependence or frequent relapses often require prolonged courses of glucocorticoids. The goals of therapy for such children are focused on reducing the incidence of relapses, promoting a sustained remission, and limiting cumulative exposure to corticosteroids. To minimize toxicity, the lowest effective dose of glucocorticoids or steroid-sparing medications should be used to maintain remission. In the absence of significant glucocorticoid-associated adverse effects, extended treatment with low-dose alternate-day prednisone is generally the preferred option. Treatment with steroid-sparing medications, such as cytotoxic agents, calcineurin inhibitors, mycophenolate mofetil (MMF), or rituximab, is also frequently considered when these children manifest significant signs of corticosteroid toxicity.[99]

In the absence of signs of corticosteroid toxicity, the 2009 Children's Nephrotic Syndrome Consensus Conference recommended treatment of frequent relapses with prednisone 2 mg/kg/day until the urine dipstick is trace or negative for 3 days. This should be followed by 1.5 mg/kg on alternate days for an additional 4 weeks. Prednisone should then be tapered in 0.5 mg/kg increments over a period of 2 months.

Alternatively, children with frequently relapsing nephrotic syndrome (FRNS) or SDNS may be treated with oral cyclophosphamide, MMF, or cyclosporine A. Oral cyclophosphamide is prescribed at a dose of 2 mg/kg/day in addition to oral prednisone for a total of 12 weeks (cumulative dose, 168 mg/kg). The cyclophosphamide dose should be based on ideal body weight. MMF is prescribed at a dose of 400 to 600 mg/m^2/dose twice daily (maximum, 2 g/day) for 1 to 2 years along with a tapering dose of prednisone. A third option is cyclosporine A at a dose of 3 to 5 mg/kg/day divided twice daily for an average of 2 to 5 years.[99] Although a renal biopsy is not typically performed in FRNS or SDNS, it is recommended that it be performed before starting cyclosporine and periodically (approximately every 2 years) thereafter to document baseline renal histologic features, and monitor for cyclosporine-induced nephrotoxicity, respectively. There is currently insufficient evidence to support recommending one steroid-sparing medication over another. However, cyclophosphamide and MMF are probably the best options because of the side effect profile of cyclosporine (including nephrotoxicity) and the finding that relapse rates are high on tapering. Accordingly, the use of a specific agent depends on the tolerability and the potential for associated side effects.

Guidelines published by KDIGO are consistent with the previously discussed regimen, with only minor differences. The KDIGO group similarly suggested that children with FRNS or SDNS be treated with daily prednisone until the child has been in remission for at least 3 days. This treatment should be followed by alternate-day prednisone for at least 3 months. Prednisone is to be given on alternate days in the lowest dose possible to maintain remission without major side effects. Low-dose daily prednisone may also be given to maintain remission in children with SDNS, particularly when alternate-day therapy fails. In addition, the KDIGO group also suggested using daily prednisone during episodes of upper respiratory infections or other infections to reduce the risk of relapses in children with FRNS or SDNS who are already receiving alternate-day prednisone.[192] The recommendations for using low-dose alternate-day prednisone or daily prednisone for SDNS are based on small observational studies.[193,194]

Steroid-related side effects

Children with FRNS and SDNS often require prolonged courses of glucocorticoids and are at the highest risk of associated adverse effects. In addition, some patients with SRNS also require long courses of corticosteroids given on alternate days, thus putting them at significant risk for toxicity. Steroid-associated side effects are among the most common causes of iatrogenic morbidity in medicine. Accordingly, management of children with nephrotic syndrome requires in-depth knowledge of the impact, scope, and clinical implication of these adverse effects. A brief discussion of some of the more common toxicities is presented here.

GROWTH IMPAIRMENT

Glucocorticoids may induce suppression of growth hormone release, insulin-like growth factor I (IGF-I) activity, bone formation, and collagen synthesis.[195,196] However, studies that investigated the impact of prolonged corticosteroids therapy on linear growth in children with nephrotic syndrome have yielded conflicting results.

In a study of 85 children with SRNS with a minimum follow-up of 3 years, 38 children (45%) showed significant linear growth retardation. Higher doses of prednisone, a more prolonged duration of therapy, and older age were identified as risk factors for impaired growth.[197] In another report of 42 children with FRNS or SDNS with a mean follow-up of approximately 12 years, growth impairment correlated with the mean duration and cumulative dose of prednisone. Pubertal growth spurt was delayed in boys in this study, but not in girls. Children who continued to receive prednisone after puberty were at the highest risk for growth impairment. In contrast, early discontinuation of prednisone was associated with partial "catch-up" growth.[198]

Another report of 41 children with nephrotic syndrome also showed reduced final height in girls and boys. Similar to the previous study, delayed puberty was noted in boys, but not girls. Moreover, an abnormal pattern of growth hormone and gonadotropin release was observed in 6 of 8 children with growth impairment.[199] A third study by Leroy et al.[200] investigated the impact of corticosteroids and cyclosporine on the growth parameters of 64 boys with SDNS over a 10-year follow-up period. In concert with other reports, growth impairment was more pronounced in the children who received prednisone beyond 12 years of age. Catch-up growth in late puberty was common among study participants.[200] Conversely, in a small study of 41 children with SDNS followed for a mean of 4.2 years, prednisolone doses up to 0.75 mg/kg/day did not seem to adversely affect linear growth velocity.[201]

Steroid-sparing medications, such as alkylating agents, were associated with improved linear growth in one report.[202] The evidence for use of alternate-day corticosteroid therapy to minimize growth impairment is not conclusive. In one report, linear growth impairment did not occur with alternate-day steroid regimens,[203] whereas another study documented significant growth impairment in children who received alternate-day steroids.[198] Pending further evidence, we suggest using alternate-day steroid regimens when feasible to diminish the likelihood of growth impairment and other long-term adverse effects.

OSTEONECROSIS

Long-term use of corticosteroids has been associated with an increased risk of osteonecrosis of the femoral head. The underlying mechanism behind this association is not well understood. Fat microemboli involving the terminal bone arterioles have been implicated in the pathogenesis of osteonecrosis. Glucocorticoids may predispose patients to fat

microembolization by altering the structure of circulating lipoproteins, inducing fatty liver, or disrupting bone marrow fat cells.[204,205] An alternate theory, based on observations in animal models, suggests that corticosteroids may induce endothelial cell injury of the venules draining the bone, thereby leading to local stasis and subsequent bone necrosis.[206]

Osteonecrosis of the femoral head should be suspected in any child receiving corticosteroids who presents with hip pain, knee pain, or limping. In view of the insidious onset and the often low specificity of presenting symptoms, a high index of suspicion for osteonecrosis in children receiving long-term steroid therapy is crucial. The initial evaluation should include anteroposterior and frog-leg hip x-ray views. However, magnetic resonance imaging of the hip is far more sensitive and is often required for proper staging of the disease.[207]

CATARACTS

Posterior subcapsular cataracts have been reported in 10% to 56% of children receiving long-term corticosteroid therapy for nephrotic syndrome.[208–212] The development of this complication was associated with a higher total dose and longer duration of corticosteroids therapy in one study.[209] However, other studies found no such correlations.[208,210] Notably, cataracts have been reported even in children receiving alternate-day corticosteroid therapy.[210] Younger children who are exposed to prolonged courses of corticosteroids may be at the highest risk.[212] Cataracts associated with corticosteroids are often bilateral and progress slowly. In children receiving prolonged courses of corticosteroids, routine examination of the lens using an ophthalmoscope is recommended at each clinic visit. Cataracts may be detected as dark gray or black spots located in the posterior aspect of the lens. Even though most children with posterior subcapsular cataracts retain excellent visual acuity,[210,211] amblyopia has been infrequently reported.[212] Accordingly, children suspected to have cataracts should be promptly referred to an ophthalmologist for further evaluation and management.

Steroid-sparing medications

Prolonged courses of corticosteroids are often prescribed in children with FRNS or SDNS. In the absence of significant side effects, corticosteroids are usually prescribed at the lowest dose possible to maintain a prolonged remission. However, the development of steroid-related adverse effects often necessitates the addition of other immunomodulatory therapies, known as steroid-sparing medications. This strategy aims to maintain remission while further reducing the cumulative dose and duration of corticosteroid therapy. Treatment options in this situation include alkylating agents, MMF, and, less commonly calcineurin, inhibitors.[99] Steroid-sparing medications have been shown to be effective in maintaining remission while minimizing long-term steroid-related toxicities.[99]

ALKYLATING AGENTS

The effectiveness of cyclophosphamide and chlorambucil as steroid-sparing medications in the treatment of children with FRNS was verified in a meta-analysis of randomized controlled trials. In these trials, cyclophosphamide was given orally at a dose of 2 mg/kg/day for 8 to 12 weeks or chlorambucil was administered at a dose of 0.2 mg/kg/day for 8 to 12 weeks. Both medications were effective in maintaining a prolonged remission in 72% and 36% of the patients at 2 and 5 years, respectively.[213] However, cyclophosphamide appears to be less effective in children with SDNS compared with children with FRNS.[214–216] Moreover, children who are dependent on higher doses of steroids are less likely to respond to treatment with cyclophosphamide compared with children dependent on lower doses.[217]

In addition to oral use, intravenous regimens of cyclophosphamide have also been described in SRNS or SDNS. Two prospective studies compared the efficacy and safety of using monthly intravenous infusions of cyclophosphamide (pulse cyclophosphamide) at a dose of 500 mg/m^2/dose for 6 months in SDNS or FRNS with the conventional oral regimens described earlier. Intravenous pulse cyclophosphamide was equally effective and safe in both studies.[218,219] The efficacy of cyclophosphamide may be determined in some patients by certain genetic factors. For instance, the detection of specific polymorphisms in enzymes involved in the metabolism of cyclophosphamide, particularly glutathione-S-transferases, has been associated with increased efficacy of the drug.[220,221]

Side effects and outcome

The use of alkylating agents in the treatment of nephrotic syndrome has been associated with a significant risk of bone marrow suppression and infections. Other adverse effects, such as hemorrhagic cystitis, alopecia, or infertility, are more commonly seen in children who receive higher doses of cyclophosphamide (cumulative doses in excess of 200 mg/kg/treatment course), such as those used in oncologic protocols. Because such high doses are not recommended for children with nephrotic syndrome, these adverse effects are relatively uncommon in this setting.

In a meta-analysis of 38 studies (1504 children) evaluating the use of alkylating agents in FRNS, leukopenia developed in approximately one-third of children treated with cyclophosphamide or chlorambucil.[213] In view of these results, complete blood counts should be monitored periodically in

---

KEY POINT

Alkylating agents and MMF are effective steroid-sparing medications used in children with FRNS or SDNS to minimize steroid-induced toxicity.

children receiving either drug, and therapy with alkylating agents should be temporarily held if the white blood cell count drops to less than 3000/mm^3. In children who receive pulse (intravenous) treatment, the nadir blood counts often occurs 1 to 2 weeks following cyclophosphamide infusion. Accordingly, most nephrologists monitor complete blood counts at least once every 2 weeks in children receiving monthly pulse cyclophosphamide therapy.

In the same meta-analysis described earlier, serious bacterial infections were observed in 1.5% of children treated with cyclophosphamide and in 6.8% of those treated with chlorambucil.[213] Bacterial infections may occur in the presence or absence of concurrent leukopenia. Other infections, such as pneumocystis, fungal, or viral infections, may also occur. Severe cases of disseminated varicella infection have also been reported in nonimmune children with nephrotic syndrome who were treated with cyclophosphamide.[222,223]

The risk of infertility in patients treated with cyclophosphamide correlates with the total cumulative dose. At the currently recommended doses for children with nephrotic syndrome, the risk is considered trivial in adolescent girls and is relatively low in adolescent boys. In the same meta-analysis, long-term ovarian dysfunction was rare in treated girls and women. However, oligospermia and azoospermia were occasionally seen in adolescent boys and appeared to correlate with the total cumulative dose of cyclophosphamide.[213] In one study, for instance, 13 of 30 young men with nephrotic syndrome developed oligospermia or azoospermia, all of whom received oral cyclophosphamide for more than 16 weeks or received a total cumulative dose exceeding 300 mg/kg body weight, or both.[224]

The risk of malignant disease also appears to be very low. Only 14 cases of malignant disease were detected in the cohort of 1504 children included in the meta-analysis; all these cases occurred in patients receiving doses of alkylating agents that exceeded the currently recommended regimens. Chlorambucil appears to have a less favorable side effect profile, particularly in terms of a higher risk of infection and a potential for inducing seizures. Therefore, cyclophosphamide is considered the preferred alkylating agent for the treatment of FRNS or SDNS.[213]

CALCINEURIN INHIBITORS

The exact mechanism of action of calcineurin inhibitors (cyclosporine A and tacrolimus) in nephrotic syndrome is unknown. Calcineurin inhibitors suppress IL-2 production by blocking calcineurin, a calcium-dependent serine-threonine phosphatase, thereby inhibiting T-cell activation.[225] However, cyclosporine may also have a direct stabilizing effect on the podocyte cytoskeleton, thus further contributing to its antiproteinuric effect.[226] The effectiveness of cyclosporine in the treatment of SDNS and FRNS has been well established in several trials.[227–231] However, in view of the significant associated risk of irreversible nephrotoxicity, calcineurin inhibitors continue to be considered a third-line choice for FRNS and SDNS, after prednisone and alkylating agents.

Cyclosporine is used as a steroid-sparing medication at a starting dose of 4 to 5 mg/kg/day divided twice daily. The dose should then be adjusted to maintain serum trough levels of 100 to 200 ng/mL by high-performance liquid chromatography (HPLC) assay. Concurrent use of alternate-day prednisone is frequently needed to maintain a stable remission.[181] Two randomized controlled trials showed that cyclosporine was as effective as cyclophosphamide and chlorambucil in inducing remission and in reducing the need for prednisone in SDNS and FRNS. Unlike with alkylating agents, however, the effect of cyclosporine was not sustained once the treatment was stopped.[232,233] In a prospective clinical trial, 49 children with FRNS were successfully treated with cyclosporine for 2 years and were monitored for an additional 2 years after completion of treatment. Two years after stopping cyclosporine, 85% of the children had a relapse at least once, and 61% regressed back to a frequently relapsing course.[234] Hence, the majority of children who respond to calcineurin inhibitors can be expected to have a relapse after discontinuing the medication. Therefore, the treatment should generally be continued for at least 12 to 24 months.

In light of the previous results, prolonged courses of cyclosporine are commonly prescribed in children with FRNS or SDNS. However, the duration of therapy is often limited by the development of adverse effects, particularly chronic nephrotoxicity. Histologically, calcineurin-inhibitor–related renal toxicity manifests as tubulointerstitial fibrosis, classically in a "striped" pattern reflecting the blood supply. The risk of renal toxicity increases with the duration of therapy. In one report, interstitial fibrosis was found in 11% (2 of 18) of children who received cyclosporine for less than 2 years, but in 58% of children who received the drug for more than 2 years.[235] Other common side effects related to cyclosporine therapy include hypertension, tremor, hyperkalemia, gingival hyperplasia, and hypertrichosis.

The optimal duration of calcineurin inhibitor use in children with nephrotic syndrome remains a subject of significant controversy. Some experts recommended limiting treatment to a 2-year duration to reduce the risk of long-term nephrotoxicity.[235] Serial annual or biannual renal biopsies in children who receive the medication for a period in excess of 2 years have also been suggested.[228,236] If histologic evidence for progressive interstitial fibrosis is detected on biopsy, serious consideration should be given for tapering the calcineurin inhibitor and transitioning to an alternative steroid-sparing medication. It has been suggested that in some cases toxicity is not apparent clinically and is observed only on biopsy. Because of a lack of sufficient evidence, however, the 2012 KDIGO group did not support the practice of performing serial renal biopsies in children receiving long-term calcineurin inhibitors for nephrotic syndrome with no laboratory evidence of progressive renal dysfunction.[181] Further studies are needed to clarify the role, if any, of serial biopsies in this setting. Nevertheless, frequent monitoring of renal function, proteinuria, and cyclosporine levels is

still considered crucial to screen for early signs of potential nephrotoxicity.

Tacrolimus, also known as FK 506, is a calcineurin inhibitor with a mechanism of action similar to that of cyclosporine. It has been frequently used as an alternative to the older cyclosporine A to avoid cyclosporine-associated cosmetic side effects (gingival hyperplasia and hypertrichosis). Support for its efficacy in the treatment of FRNS and SDNS comes from small retrospective case series.[237] Tacrolimus is usually started at a dose of 0.1 mg/kg/day, divided twice daily. The dose is adjusted to target serum trough levels of 5 to 10 mg/L. Once remission is achieved, the dose is titrated to the lowest possible amount to sustain remission. Although tacrolimus has a generally similar side effect profile compared with cyclosporine, gum hypertrophy and hypertrichosis do not occur with tacrolimus use.

Unfortunately, tacrolimus has been associated with a higher risk of neurotoxicity compared to cyclosporine.[238,239] Tacrolimus has also been associated with a higher risk of insulin-dependent diabetes mellitus compared with cyclosporine. Even though tacrolimus-associated insulin dependency is most often transient and resolves with discontinuation, it may occasionally become permanent.[240,241]

Levamisole is an antihelminthic and is the only immunostimulatory medication with known efficacy in the treatment of FRNS and SDNS. The efficacy and safety of levamisole have been validated in a randomized placebo controlled trial of 61 children with FRNS. After tapering and discontinuing corticosteroids, only 4 children developed a relapse in the treatment group as compared with 14 children in the placebo group when patients monitored for a period of 112 days.[242] Retrospective case series have yielded similar results confirming the efficacy of levamisole use in SDNS.[243–246] In a retrospective study of 51 children with FRNS or SDNS, the efficacy of a 6-month course of levamisole was equivalent to an 8- to 12-week regimen of cyclophosphamide. Both medications reduced the relapse frequency and the total exposure to corticosteroids.[247] Levamisole is usually prescribed at a dose of 2.5 mg/kg on alternate days for 4 to 12 months. Levamisole appears to be generally safe in children at the conventionally prescribed doses. Reported adverse effects include neutropenia, agranulocytosis, flu-like symptoms, seizures, and, rarely, disseminated vasculitis.[248,249] Levamisole was withdrawn from the United States market in 2000 because of the risk of agranulocytosis,[250] but it is still available in many countries worldwide.

MYCOPHENOLATE MOFETIL AND MIZORIBINE

MMF and mizoribine have been frequently used in the management of children with FRNS and SDNS. The exact mechanism of action of MMF and mizoribine in the treatment of glomerular diseases remains unknown. MMF inhibits T- and B-lymphocyte proliferation through noncompetitive inhibition of inosine monophosphate dehydrogenase (IMPDH), thereby leading to depletion of guanosine triphosphate and deoxyguanosine triphosphate.[251] Clinically,

this effect is specific to T and B lymphocytes because all other cells in the body are capable of regenerating purines by a separate scavenger pathway and therefore are generally unaffected. In addition, MMF preferentially suppresses Th2 cytokines in the kidney, particularly IL-4.[252] MMF also inhibits mesangial cell proliferation,[253] and it interferes with the adhesion of activated lymphocytes to endothelial cells.[254]

In comparison with calcineurin inhibitors and alkylating agents, MMF has a generally favorable side effect profile. Most importantly, MMF is not nephrotoxic, and this property renders MMF a very attractive choice for patients with FRNS and SDNS. Evidence to support the effectiveness and safety of MMF and mizoribine in the treatment of FRNS and SDNS comes from small observational case series and retrospective studies.[255–260] In these studies, MMF reduced the need for corticosteroids and the relapse rate by 40% to 70%. Mizoribine appears to be more effective in children less than 10 years of age.[261] In a study of 46 children treated with MMF after remaining steroid dependent despite previous regimens of levamisole and cyclophosphamide, 43% were able to discontinue corticosteroids, and an additional 27% required lower doses of steroids to maintain remission. At a mean follow-up of 3.5 years, 54% of these children required no further alternative immunosuppression.[255]

As is the case with calcineurin inhibitors, relapses are common after MMF is discontinued. In a multicenter study of 33 children with FRNS by the Southwest Pediatric Nephrology Study Group, the relapse rate was decreased in patients receiving MMF from 1 episode every 2 months to 1 episode every 14.7 months. However, in the same series, remission was maintained in only 25% of children with FRNS after stopping MMF.[258]

MMF appears to be less effective in inducing remission when compared with cyclosporine.[262,263] In a multicenter, open-label, crossover trial of 60 children with FRNS, 85% of patients remained relapse free while receiving cyclosporine (1-year duration) as compared with only 64% of patients receiving MMF. In this trial, low serum levels of mycophenolic acid (MPA), an active metabolite of MMF, were correlated with a higher risk for relapse.[264] When considering the choice of MMF versus other immunosuppressive agents, these differences in efficacy should be carefully weighed against the potential for renal (calcineurin inhibitors), hematologic, and gonadal toxicities (alkylating agents).

MMF is usually prescribed at a dose of 400 to 600 mg/m^2/dose twice daily (25 to 36 mg/kg/day; maximum dose 1 g twice daily). Adverse reactions associated with MMF include diarrhea, vomiting, leukopenia, anemia, and sepsis. In addition, mizoribine is also known to be associated with hyperuricemia. Most adverse effects are dose dependent and are more common among children less than 6 years of age and transplant recipients.[265] In one study, for example, adverse effects led to stopping MMF in 54% of renal transplant recipients.[266] Enteric-coated mycophenolic acid is an alternative to MMF that is associated with fewer

gastrointestinal side effects.[267,268] Because most children require the use of a liquid suspension, enteric-coated mycophenolic acid has limited use in the pediatric population. In light of the significant risk for leukopenia or anemia, periodic monitoring of blood counts in children receiving MMF or mizoribine has been suggested.

In children receiving MMF for the treatment of nephrotic syndrome, gastrointestinal and hematologic side effects appear to be less common. This feature was illustrated in 4 studies evaluating the use of MMF in childhood nephrotic syndrome that included a combined total of 110 children. None of the study participants reported dose-limiting gastrointestinal symptoms, none developed leukopenia, and only 3 children developed mild anemia that required reducing the MMF dose.[256,260,269,270]

RITUXIMAB

Rituximab is a monoclonal antibody that targets CD20, a B-cell surface marker, thus leading to the depletion of B cells.[271] The rationale for the use of rituximab in glomerular diseases came from evidence that proposed a crucial role for B cells in the regulation of cell-mediated immune response.[272] The efficacy of rituximab in SDNS was evaluated in a single randomized trial and in multiple small observational case series. In a randomized, open-label, controlled trial of 54 children with steroid-dependent and calcineurin-dependent idiopathic nephrotic syndrome, rituximab allowed the temporary withdrawal of prednisone and calcineurin inhibitors in 63% at 3 months and in 50% at 9 months while maintaining a stable remission.[273] Other smaller observational studies yielded similar results, providing further support for its role in the treatment of refractory SDNS.[274-277] Most studies used 1 to 4 infusions of rituximab (375 mg/m² per infusion) given 2 weeks apart during a period of disease remission. Relapses are common, particularly during recovery of B-lymphocyte counts.[278]

The use of MMF as a preferred maintenance medication following rituximab therapy has been suggested. In a prospective nonrandomized controlled pilot study, 9 children with SDNS were treated with rituximab followed by MMF and were compared with 7 children treated only with rituximab. At 1 year of follow-up, 3 of the 9 children in the MMF group had relapses, as compared with 6 of 7 in the control group.[279] In summary, evidence from a single randomized trial and multiple observational studies supports the use of rituximab in the management of refractory SDNS. However, given the current paucity of evidence on the long-term safety of this agent in nephrotic syndrome, rituximab use should be reserved for children with significant steroid-related toxicity who fail to respond to conventional steroid-sparing drugs.

Short-term adverse effects associated with rituximab include infusion-related reactions in the form of myalgias, fever, chills, pruritus, respiratory distress, hypotension, or anaphylaxis. Long-term but rarer adverse effects include infections, fatal pulmonary fibrosis,[280] and progressive multifocal leukoencephalopathy (PML).[281] PML is a rare demyelinating disorder that results from reactivation of latent JC polyoma virus. This delayed complication of rituximab (mean, 5.5 months) carries a 90% mortality rate, based on adult studies.[282]

STEROID-RESISTANT NEPHROTIC SYNDROME

As previously discussed, most children (80% to 90%) with nephrotic syndrome respond well to an initial 8 weeks of corticosteroid therapy. The lack of a response to an adequate initial course of steroid therapy defines SRNS. Various underlying genetic mutations have been identified in 25% to 52% of children with SRNS.[283-285] Other important causes of steroid resistance include nonadherence to the prescribed medications, inappropriate dosing, inadequate gastrointestinal absorption, concurrent infections, or underlying malignant diseases.

A response to corticosteroids beyond 8 weeks of therapy is uncommon but not impossible. Moreover, such a delayed response has been occasionally reported with intravenous pulse glucocorticoids.[286] Conversely, delayed resistance to steroids is not uncommon in children who are initially steroid responsive.[287] Whether early or delayed, resistance to steroid therapy universally represents an ominous prognostic sign, predicting a 5-year risk of progression to ESKD of more than 50% in some studies.[288-290]

The treatment of children with SRNS is often very challenging. It requires carefully weighing the risk of comorbidities and progressive renal insufficiency in children with unremitting nephrotic syndrome against the potential for nephrotoxicity and serious adverse effects related to immunosuppressive medications. Various therapeutic options has been developed for the treatment of SRNS and may be classified into three major categories (Tables 17.5 and 17.6):

- Supportive therapy
- Immunomodulatory therapy
- Nonimmunosuppressive therapy

Supportive and adjunctive therapies for steroid-resistant nephrotic syndrome

Children with SRNS require close monitoring and supportive medical care. This includes careful monitoring for infectious and thrombotic complications, electrolyte abnormalities, and volume status. In addition, supportive measures include antihypertensive medications, immunizations, and treatment of edema and dyslipidemia. An overview of the general medical care of children with nephrotic syndrome is presented next, followed by a review of the recommended immunizations. Please refer to Chapter 16 for a detailed discussion of the management of edema and dyslipidemia in these children.

Table 17.5 Components of supportive therapy for children with steroid-resistant nephrotic syndrome

General medical care	Management of edema	Management of hyperlipidemia
Identification and treatment of suspected thrombosis:	Moderate restriction of dietary salt intake	Limit dietary saturated and trans fat
Asymmetric swelling in extremity		Increase intake of complex carbohydrates and fiber, including whole grains, fruits, and vegetables
Respiratory distress		
Acute oliguria		
Gross hematuria		
Neurologic symptoms		
Identification and treatment of suspected infection:	Avoidance of excessive fluid intake	Regular exercise regimen (30–45 minutes of moderately intense exercise daily)
Cellulitis		
Peritonitis		
Sepsis		
Maintenance or restoration of intravascular volume	Elevation of extremities	HMG Co-A reductase inhibitors (statins)*
Maintenance of adequate protein intake (130%–140% of RDA)	Judicious use of albumin and diuretics (only for severe edema)	
Immunizations	Head-out water immersion	

Abbreviations: HMG-CoA, 3-hydroxy-3-methylglutaryl–coenzyme A; RDA, recommended dietary allowance.
*Patients more than 8 years of age.

GENERAL MEDICAL CARE

Children with SRNS are at a high risk for infectious and thrombotic complications. Common infections in children with active nephrotic syndrome include pneumonia, bacteremia or sepsis, peritonitis, urinary tract infection, and cellulitis.[291] Frequent, careful evaluation for skin infections and skin breakdown is crucial in patients with refractory edema. Prophylactic antibiotics are generally not recommended, but signs of cellulitis such as skin erythema, tenderness, or induration should be promptly evaluated and treated with systemic antibiotics. Skin breakdown can be prevented by frequent repositioning of bedridden patients.

Skin breakdown is of particular concern in boys with severe scrotal edema. Asymmetric swelling of the lower extremity should raise a suspicion for deep vein thrombosis. Thrombotic complications may also manifest with an acute onset of respiratory distress, suggesting pulmonary embolism. The development of acute neurologic deficits may suggest a thrombotic stroke. Careful monitoring of volume status is essential, particularly in children who are maintained on diuretics. Despite generalized salt and water retention, children with SRNS commonly show signs of intravascular fluid depletion and hemoconcentration, both of which generally respond well to intravenous albumin

Table 17.6 Treatment options for children with steroid-resistant nephrotic syndrome

Immunosuppressive	Immunostimulatory	Nonimmunosuppressive
Cyclosporine	Levamisole*	ACE inhibitors/angiotensin receptor blockers
Tacrolimus	—	Vitamin E*
Mycophenolate mofetil	—	Galactose*
Pulse IV methylprednisolone	—	—
Rituximab	—	—
Plasma exchange and immunoadsorption*	—	—
Azathioprine*	—	—

Abbreviations: ACE, angiotensin-converting enzyme.
* Less commonly used or controversial.

infusions.[292] In contrast, most children with refractory FSGS develop systemic hypertension. ACEIs are frequently used to control hypertension in view of their antiproteinuric and long-term renoprotective properties.[293–295] Intravenous albumin infusions should be avoided in children with uncontrolled hypertension because of the risk of exacerbating the blood pressure elevation and inducing congestive heart failure (see Chapter 16).

INFECTIONS AND IMMUNIZATIONS

Before the initiation of steroid therapy, a purified protein derivative (PPD) test should be requested in children with newly diagnosed nephrotic syndrome, to exclude tuberculosis. In children who receive daily or alternate-day corticosteroids at a dose that exceeds 2 mg/kg/day *or* exceeds 20 mg/day for more than 14 days, the American Academy of Pediatrics recommends that all live vaccines should be delayed for at least 1 month after discontinuing corticosteroids. If the dose of corticosteroids exceeds the aforementioned threshold but the duration of treatment is less than 14 days, live vaccines may be administered immediately after discontinuing corticosteroids.[296] Conversely, live vaccines are effective and may be administered safely to children who are receiving lower doses of steroids (less than 2 mg/kg/day *and* less than 20 mg/day). Varicella immunization is particularly important in children with newly diagnosed nephrotic syndrome, given the high risk of morbidity and mortality associated with this infection.[222,223,297–299] To ensure an adequate response, varicella immunization is preferably postponed until the patient is in remission or receiving alternate-day corticosteroids. In children who are in a stable remission, including those receiving alternate-day corticosteroids, varicella vaccine has been shown to be safe and effective, and it has a relatively low risk of inducing a relapse of the disease.[300–302] Immunosuppressed children who are exposed to varicella should receive passive immunoprophylaxis in the form of the varicella-zoster immunoglobulin (VZIG) within 4 days of the exposure. VZIG may prevent or minimize the morbidity associated with varicella infection in this setting. VZIG has not been shown to be effective if it is given more than 96 hours after exposure to varicella.[303] Passive immunoprophylaxis is not recommended in children who have previously completed the two-dose regimen of the varicella vaccine.

Rare cases of vaccination-induced relapses of nephrotic syndrome have been reported.[304] This has led to significant anxiety among parents and health professionals regarding administration of immunizations to children with nephrotic syndrome who are in a stable remission. Based on the available evidence, these concerns do not seem justified because the risk of future infections will likely far outweigh the remote possibility of triggering a relapse. Indeed, in a multicenter study, 29 children with nephrotic syndrome, half of whom were receiving alternate-day prednisone treatment, were immunized with 2 doses of varicella. Of these children, 91% showed serologic evidence of a protective immune response for at least 2 years. None of administered

vaccination doses were linked to relapses or other adverse events in this study (also see Chapter 6).[300]

The 2009 Children's Nephrotic Syndrome Consensus recommended that all children with nephrotic syndrome receive the 23-valent polysaccharide pneumococcal vaccine (PPSV23) and the heptavalent conjugated pneumococcal vaccine (PCV7).[99] However, PCV13, a polysaccharide-protein conjugate vaccine that immunizes against 13 pneumococcal serotypes, was introduced in 2010 and has since replaced the PCV7. Accordingly, we suggest that children with nephrotic syndrome receive the PCV13 vaccine in addition to the PPSV23 at the time of initial diagnosis. Children, who are actively nephrotic or receiving immunosuppressive medications, and their household contacts should also receive the annual inactivated influenza vaccine. The group also recommended delaying live vaccines until the dose of prednisone dose has been reduced to less than 2 mg/kg/day (and less than 20 mg total/day). Live vaccines should also be postponed for 3 months following the conclusion of cytotoxic therapy and for 1 month after the conclusion of treatment with other immunosuppressive agents.[99]

Immunomodulatory therapies for steroid-resistant nephrotic syndrome

As previously discussed, children with refractory nephrotic syndrome are at a markedly increased risk of progression to ESKD. Aside from supportive therapy and treatment of the associated comorbidities, the management of children with SRNS is directed toward two main objectives: (1) complete or partial resolution of proteinuria and (2) halting the progression of renal insufficiency. Therapeutic options are categorized into: immunosuppressive, immunostimulatory, and nonimmune mediated treatments (see Table 17.6).

KEY POINT

Children with SRNS and identified causative genetic mutations are unlikely to respond to immunomodulatory therapy.

Children with SRNS and identified genetic mutations are unlikely to respond to immunomodulatory therapies. This was demonstrated in a study of 91 patients with SRNS or congenital nephrotic syndrome. Genotyping revealed various mutations in 43 of these patients, none of whom attained complete remission with immunosuppressive therapy and only 2 of whom achieved a partial response.[283] In another report of 29 patients with SRNS and identified homozygous or compound heterozygous mutations in *NPHS2,* none achieved complete remission following treatment with cyclosporine A or cyclophosphamide.[305] A third study reported disease-causing mutations in 37 of 110

patients with SRNS. None of the 37 patients achieved a complete remission with immunosuppressive therapy.[285]

CYCLOSPORINE A

Cyclosporine A is widely used in the treatment of SRNS and is one of the most effective therapies available for this disease. Cyclosporine is generally started at a dose of 150 mg/m²/per day or 4 to 5 mg/kg/day divided twice daily. The dose is titrated to maintain a trough drug level in the range of 100 to 200 ng/mL by HPLC assay. The efficacy of cyclosporine has been demonstrated in several randomized controlled trials,[306–308] as well as observational series.[227,309,310]

In a meta-analysis of 3 randomized trials that included a total of 49 children with SRNS, cyclosporine was more effective in inducing partial or complete remission compared with placebo or no treatment, regardless of the underlying histopathologic features (relative risk [RR], 5.5). Analysis of the subset of patients with FSGS on renal biopsy yielded similar results (RR, 5.8), but the beneficial effect in this subset did not reach statistical significance.[311] In the same meta-analysis, the rate of complete and partial remission in response to cyclosporine therapy was 36% (8 of 22) and 45% (10 of 22), respectively. Furthermore, these data are also consistent with multiple observational studies that showed rates of complete remission with the use of cyclosporine in the range of 46% to 84%.[227,309] In a case series of 65 children with SRNS, the rate of remission varied with the underlying histopathologic features, from 30% in FSGS to 46% in MCD.[227]

> ## KEY POINT
>
> Calcineurin inhibitors are frequently effective in the treatment of SRNS. However, long-term therapy is limited by concerns of irreversible nephrotoxicity.

The addition of pulse intravenous methylprednisolone to cyclosporine may increase the cumulative rate of children achieving remission. In a retrospective study of 52 children with biopsy-confirmed FSGS, the combined use of pulse intravenous methylprednisolone and cyclosporine was associated with an 84% cumulative rate of sustained complete remission, compared with only 64% in those who received alternate-day oral prednisone therapy and cyclosporine.[309] In the same report, all 14 children who were diagnosed with MCD by renal biopsy achieved complete remission in response to cyclosporine therapy, regardless of whether it was combined with oral or intravenous corticosteroids.[309]

Cyclosporine appears to be more effective in SRNS compared with either cyclophosphamide or MMF. A multicenter randomized controlled open-label trial compared treatment with cyclosporine with intravenous cyclophosphamide in 32 children with SRNS. At 12 weeks of follow-up, 3 of 17 children (18%) had complete or partial remission in the cyclophosphamide treatment group compared with

9 of 15 children (60%) in the cyclosporine group, thus significantly favoring cyclosporine over cyclophosphamide. The incidence of adverse events was similar between the 2 groups, with the most common complications being infections, systemic hypertension, and Cushing syndrome.[312] In another randomized controlled trial of 138 children and adults with SRNS, a 12-month course of cyclosporine was compared with a combination of intravenous dexamethasone and MMF. Forty-six percent (33 of 72) of patients were in partial or complete remission after 12 months in the cyclosporine group as compared with 33% (22 of 66) in the dexamethasone/MMF group. However, this difference did not reach statistical significance.[313] In the same report, no significant difference was found in the rate of sustained remission between the 2 groups at 26 weeks of follow-up after discontinuing immunosuppression.[313]

Adverse reactions that have been attributed to cyclosporine therapy include nephrotoxicity, systemic hypertension, hyperkalemia, metabolic acidosis, elevated serum creatinine, infections, tremor, seizures, gingival hypertrophy, and hypertrichosis. Nephrotoxicity is of particular concern because it is irreversible and frequently limits the long-term use of cyclosporine. It manifests in the form of progressive interstitial fibrosis on renal biopsy, classically in a striped pattern. In one study, interstitial fibrosis was found on renal biopsy in 11% of children who received the medication for less than 2 years and in 58% of children who received it for more than 2 years.[235] Other factors that were associated with an increased risk of nephrotoxicity included the presence of renal insufficiency at baseline, FSGS histopathologic features, dosage exceeding 5.5 mg/kg/day, and high-grade proteinuria for more than 30 days.[235,314]

Limiting the duration of cyclosporine therapy to reduce the potential for nephrotoxicity has been suggested. However, the optimal duration of therapy remains a subject of considerable debate. In children with SRNS who respond to cyclosporine therapy, an attempt to wean the medication or switch to an alternative non-nephrotoxic option (e.g., MMF) may be reasonable after 1 to 2 years.[235] However, performing serial renal biopsies to monitor for nephrotoxicity in children who receive long-term cyclosporine therapy was not supported by the 2012 KDIGO group, and it remains controversial.[181]

Systemic hypertension may also be linked to calcineurin inhibitors and has been attributed to overactivity of the sodium chloride cotransporter in the distal convoluted tubule.[315] In addition, features of type IV renal tubular acidosis, including hyperkalemia and metabolic acidosis, may be seen in children receiving cyclosporine. Cyclosporine-induced neurotoxicity ranges from a mild tremor that resolves with continued therapy to an acute confusional state, psychosis, or seizures.[316] Seizures related to cyclosporine toxicity have been seen concomitantly with systemic hypertension and imaging findings suggestive of posterior reversible encephalopathy syndrome (PRES).[317,318] Finally, children who develop significant cosmetic adverse effects related to cyclosporine, such gingival hyperplasia or

hypertrichosis, may benefit from transitioning to tacrolimus as an alternative agent.

In summary, cyclosporine is currently one of the most effective immunosuppressive agents used in the treatment of SRNS. It is generally well tolerated in the short term, but the risk of progressive irreversible nephrotoxicity limits its long-term use. Accordingly, children who initially respond to cyclosporine therapy should be transitioned to an alternative immunosuppressive agent within 2 years, if feasible.

TACROLIMUS

Tacrolimus, also known as FK 506, is a calcineurin inhibitor with a mechanism of action similar to that of cyclosporine. Toxicities associated with tacrolimus are similar to those seen with cyclosporine. However, unlike cyclosporine, tacrolimus has not been associated with gum hypertrophy or hypertrichosis, thus rendering it an attractive alternative for children with intolerable cosmetic side effects linked to cyclosporine. However, tacrolimus has been associated with a higher incidence of neurotoxicity and glucose intolerance when compared with cyclosporine.[238,239] In transplant recipients, tacrolimus has also been associated with a higher risk of insulin-dependent diabetes mellitus compared with cyclosporine. Tacrolimus-associated insulin dependency is often transient, resolving with discontinued use, but it may rarely become permanent.[240,241] Tacrolimus is usually started at a dose of 0.1 mg/kg/day divided twice daily. The dose is adjusted to maintain target serum trough levels of 5 to 10 mg/L.

The efficacy of tacrolimus in the treatment of SRNS was demonstrated in a small randomized trial and in several observational reports. A randomized controlled open-label trial compared tacrolimus with cyclosporine for the treatment of SRNS. After 6 months of treatment, complete remission was achieved in 86% (18 of 21) of children who received tacrolimus as compared with 80% (16 of 20) of children who received cyclosporine. The rates of complete remission were also similar between the 2 groups at 12 months of therapy. However, more children developed relapses with cyclosporine as compared with tacrolimus (RR, 4.5).[319] Several other observational studies in children with SRNS, most with relatively short-term follow-up (less than 1 year), reported complete remission rates ranging between 40% and 94% with tacrolimus therapy.[320–325] In a single-center report of 19 children with SRNS treated with tacrolimus followed for an average duration of 55 months, complete remission was observed in 11 patients and partial remission in 6 patients. The mean time to induction of remission with tacrolimus was 8 weeks in this study.[323] Tacrolimus was generally well tolerated in the foregoing studies, with no reports of diabetes mellitus or severe neurotoxicity. However, given the paucity of long-term follow-up data, the long-term safety of tacrolimus in the treatment of SRNS remains uncertain.

In conclusion, limited evidence from a single randomized controlled trial and several observational reports have illustrated the effectiveness and short-term safety of tacrolimus use in SRNS. Tacrolimus appears to have similar efficacy in the treatment of SRNS compared with cyclosporine. However, cyclosporine continues to be the preferred calcineurin inhibitor by many nephrologists, primarily because of the longer-term experience with its use in SRNS. However, tacrolimus is an attractive alternative in children who develop intolerable cosmetic side effects related to cyclosporine use.

MYCOPHENOLATE MOFETIL

MMF is known to suppress lymphocyte proliferation through inhibition of purine synthesis.[251] However, the specific mechanism of action of MMF in glomerular diseases remains unknown. Evidence for the benefit of MMF in childhood SRNS comes from a single randomized controlled trial and several observational case series. In a multicenter trial, 138 children and young adults were randomized to receive a 12-month course of either cyclosporine or a combination of MMF and intravenous dexamethasone. Partial or complete remission was attained in 33% (22 of 66), compared to 46% (33 of 72) in the cyclosporine-treated group, a difference that did not reach statistical significance.[313] Because the study did not include a group that received dexamethasone monotherapy, it was not possible to attribute the beneficial effect solely to MMF. In a retrospective study of 52 children, 34 of whom were previously resistant to cyclosporine, MMF treatment for at least 6 months induced complete or partial remission in approximately 60% of the cases.[326] In another report of 24 Chinese infants (less than 2 years of age) with SRNS, MMF was used for 6 to 12 months along with a stepwise tapering regimen of daily prednisone therapy; complete remission was achieved in 15 patients and partial remission in 6.[327] In a third study, 9 children and young adults with SRNS were pretreated with weekly intravenous pulse methylprednisolone therapy (15 mg/kg) for 4 to 8 weeks. This was followed by a regimen of MMF and ACEIs or angiotensin receptor blockers (ARBs). Proteinuria, assessed using spot urine protein-to-creatinine ratios, decreased by 43% when compared with baseline in treated patients, a reduction that was sustained after 24 months of observation.[295] An open-label, 6-month trial of MMF in 18 adults with steroid-resistant FSGS showed a marked improvement in proteinuria in 44% (8 of 18), which was sustained in 50% (4 of 8) of the patients for up to 1 year after discontinuing therapy.[328] Considering the observational design of these studies, it was not possible to account for multiple confounding variables. Hence, a causal association between MMF treatment and the observed benefits cannot be ascertained.

MMF may also be helpful in sustaining remission in children who were previously treated successfully with cyclosporine A. This concept was illustrated by an observational study that included 18 children with SRNS in complete remission on cyclosporine. The addition of MMF allowed for successful discontinuation of cyclosporine in 16 children. Of these children, only 21% developed relapses at a mean follow-up of 7 years.[270] In contrast, children who did not respond to cyclosporine monotherapy are unlikely to respond to a combination of MMF and cyclosporine.

This was illustrated by an observational study of 27 adults with cyclosporine-resistant SRNS. At 5 years of follow-up, MMF therapy did not induce complete remission in any of the cyclosporine-resistant patients and was associated with partial remission in only 4 patients (14%). MMF also failed to delay the progression of renal insufficiency in these patients.[329]

In summary, based on several observational studies, MMF appears to be less effective than cyclosporine in children with SRNS. MMF may be more suitable as an adjunct to pulse methylprednisolone or to help sustain remission in children who were previously successfully treated with a calcineurin inhibitor. Randomized controlled trials are needed to define the role of MMF in the treatment of SRNS further.

RITUXIMAB

Rituximab is a monoclonal antibody against CD 20, a B-cell surface marker. It causes rapid depletion of B cells and suppresses immunoglobulin production. Traditionally, nephrotic syndrome has been considered a disorder of T-cell dysregulation. However, more recent evidence suggested a role for B-cell dysfunction in the pathogenesis of the disease.[330] This led to a growing interest in rituximab as a potential treatment option for SRNS refractory to other therapies. The exact mechanism by which rituximab may be effective in nephrotic syndrome is uncertain. Proposed mechanisms include late induction of regulatory T cells,[331,332] podocyte cytoskeletal stabilization,[333,334] and reduction of suPAR levels.[335] The effect of rituximab may be monitored by enumerating cells that express CD 19, another B-cell surface marker.[336]

Multiple observational studies and case reports have suggested a beneficial role for rituximab in the treatment of children and adults with SRNS.[279,337–345] More recently, an open-label, randomized controlled trial investigated the efficacy of rituximab in 31 children with SRNS who were resistant to calcineurin inhibitors.[346] The control group continued to receive calcineurin inhibitors and prednisone, whereas the intervention group received the same standard therapy in addition to 2 infusions of rituximab 375 mg/m^2 administered 2 weeks apart. If feasible, prednisone and tacrolimus were gradually tapered and sequentially discontinued within 6 to 8 weeks. At 3 months of follow-up, the rate of proteinuria was not significantly different between the 2 groups. Three patients in each group achieved remission (defined as a protein excretion less than 1 g/m^2/day) and were successfully weaned off all medications. All 6 children who showed a response to therapy had a history of delayed resistance to corticosteroids. In this study, severe allergic reactions to rituximab were reported in only 2 patients, but minor reactions were common.[346] This study was powered to detect a 70% difference in proteinuria between the 2 groups and was evaluated for treatment-related effects for only a relatively short duration of 3 months. Therefore, a delayed or more modest effect related to rituximab could have been missed. Similarly, late adverse effects may have

also been missed. In conclusion, the current evidence is not sufficient to recommend for or against the use of rituximab in SRNS. Randomized controlled trials are needed to outline its role in this regard more definitively.

PULSE INTRAVENOUS METHYLPREDNISOLONE

Pulse intravenous methylprednisolone, in isolation or combined with other immunosuppressive therapy, has been used for decades to induce remission in children with SRNS. In the early 1990s, Mendoza et al.[347] described an 18-month protocol of intravenous high-dose methylprednisolone (30 mg/kg) given three times/week for the first 2 weeks, then weekly for the next 8 weeks, then every other week for the following 8 weeks, then every 4 weeks for 8 doses, followed by every other month for an additional 4 doses.[347] Cyclophosphamide or chlorambucil was added for children who have not responded by 10 weeks of therapy or who had experienced relapse when reducing the frequency of pulse steroids. In the initial cohort, 52% (12 of 23) of children achieved full remission at a mean follow-up of 46 months.[347] Prolonged follow-up of children treated with this protocol (mean, 6.3 years) revealed sustained complete remission in 66% (21 of 32).[348] Multiple variations of this protocol have been subsequently reported with varying success, reporting rates of complete remission in the range of 38% to 82%.[349–353] Moreover, based on a retrospective review, intravenous methylprednisolone therapy, when added to oral cyclosporine, may improve the rate of remission in children with SRNS.[309]

However, despite the generally satisfactory response to the use of intravenous pulse methylprednisolone, the original Mendoza protocol is not commonly used in current practice because of its high cumulative dose of corticosteroids, which has been linked to serious short-term and long-term adverse effects including cataracts (22%), growth retardation (17%), impaired glucose tolerance, and systemic hypertension.[347] The introduction of newer relatively safe and effective alternatives, such as calcineurin inhibitors and MMF, has further reduced the need for intravenous pulse corticosteroids in the treatment of children with SRNS.

ALKYLATING AGENTS

In view of the availability of safer and more effective alternatives, alkylating agents, including cyclophosphamide and chlorambucil, are no longer recommended for the treatment of SRNS. A meta-analysis of five randomized studies evaluated the efficacy of alkylating agents in the treatment of SRNS. The meta-analysis concluded that there was no significant benefit associated with the use of oral or IV cyclophosphamide in children with SRNS over prednisone alone.[311] Two ISKDC studies reported in 1974 and 1996, compared treatment with oral cyclophosphamide plus prednisone with prednisone alone. The studies included a total of 84 patients and found no significant differences in the number of patients who achieved a complete or partial remission between the two groups.[286,354] Children who received cyclophosphamide, however, responded in a

shorter period of time (mean, 38.4 days as compared with 95.5 days with prednisone).

In another report, 30 patients with SRNS received treatment with either chlorambucil or indomethacin. No significant differences were found in the number of patients who achieved complete remission or those who developed ESKD with either treatment.[355] As previously detailed, the efficacy of cyclosporine was superior to that of intravenous cyclophosphamide in a randomized controlled trial of 32 children with SRNS.[312]

PLASMAPHERESIS AND IMMUNOADSORPTION

Plasma exchange or plasmapheresis is frequently used in children who develop recurrences of FSGS after renal transplant. The benefit observed in transplant recipients has been attributed to the removal of circulating permeability factors, such as suPAR. In children with refractory idiopathic FSGS in native kidneys, treatment with plasma exchange has been reported in small case series and case reports to have varying success. In a report of eight children with steroid-resistant idiopathic FSGS, six sessions of plasma exchange were completed over a 2-week period. Proteinuria decreased significantly in only two of these patients and was sustained in only one of these.[356] In another report of 9 children with cyclosporine-resistant FSGS, two of whom had recurrent disease after renal transplantation, five patients achieved complete remission, and one patient achieved partial remission. However, three of these patients had relapses within 2 years.[357] Multiple other case reports in children and adults with FSGS have also suggested benefit with the use of plasma exchange, although often combined with other immunosuppressive therapies.[358–363]

Despite the widespread use of plasma exchange in recurrent FSGS after kidney transplantation, the evidence for its use in native kidney FSGS remains relatively limited. In one controlled trial, 14 patients with native kidney FSGS were randomized to receive tacrolimus only or tacrolimus with 15 sessions of plasmapheresis. No significant differences were found in proteinuria between the 2 groups at 6 months and 12 months of follow-up (unpublished data).[364]

AZATHIOPRINE

The current evidence does not justify the use of azathioprine in the treatment of SRNS. A prospective randomized double-blind placebo-controlled trial that included 31 children with SRNS compared the use of a combination of azathioprine and steroids with steroids alone. The study did not detect any benefit from the addition of azathioprine.[365] Azathioprine also did not offer any advantage when it was used in two subsequent small case series of patients with SRNS.[366,367]

LEVAMISOLE

Levamisole has been frequently used in the treatment of both FRNS and SDNS worldwide. Its use has also been infrequently reported in children with SRNS. This was illustrated in two small observational studies. The first included five children with SRNS who were treated with levamisole 2.5 mg/kg on alternate days. Two of these children also received cyclosporine A. None of the five children with SRNS experienced a remission. Serious adverse reactions were reported in two patients, in the form of agranulocytosis and a severe psoriasis-like cutaneous reaction.[368] The second study included six children with SRNS who were treated with levamisole at 2 mg/kg/day. Levamisole treatment was associated with a marked improvement in proteinuria (from 1.53 g to 0.11 g/day) and decreased need for corticosteroids (from 9086 to 1505 mg).[245] In the latter report, neutropenia developed in 15% of children treated with levamisole. In the absence of randomized controlled trials, there is thus little evidence to support the use of levamisole in children with SRNS.

Nonimmunosuppressive therapy for steroid-resistant nephrotic syndrome

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

ACEIs and ARBs are recommended in children with refractory nephrotic syndrome for their antiproteinuric, antihypertensive, lipid-lowering, and long-term renoprotective effects. Several mechanisms have been proposed for the antiproteinuric effect associated with the use of ACEIs and ARBs. Reduction in the intraglomerular filtration pressure, alteration in glomerular permselectivity, and antifibrotic and lipid-lowering effects all may contribute to reducing proteinuria. First, ACEIs and ARBs acutely reduce the glomerular capillary hydraulic pressure and filtration pressure across the GFB by blocking the vasoconstrictor effect of angiotensin II on both the afferent and efferent glomerular arterioles.[369,370] Second, ACEIs and ARBs alter the permselectivity of the GFB independently of hemodynamic changes,[371,372] thereby providing an explanation for the continued improvement in proteinuria up to several months following the initiation of ACEIs and ARBs.[373] Third, angiotensin II appears to promote the release of profibrotic factors, such as transforming growth factor-β (TGF-β) and epidermal growth factor (EGF), an effect that is mediated by the angiotensin I receptor (AT1 receptor). Hence, ACEIs and ARBs block the release of profibrotic factors and can slow the progression of glomerular and tubulointerstitial fibrosis in chronic kidney disease.[374] Fourth, the use of ACEIs and ARBs is associated with a prominent lipid-lowering effect that exceeds what would be expected in response to decreased proteinuria.[375–377] Angiotensin blockade–induced correction of dyslipidemia may also

---

KEY POINT

ACEIs and ARBs are recommended in children with refractory nephrotic syndrome for their antiproteinuric, antihypertensive, lipid-lowering, and long-term renoprotective effects.

contribute to the delayed progression of chronic kidney disease in proteinuric diseases.[378]

The beneficial effects of ACEIs and ARBs in proteinuric kidney diseases are well established in large controlled adult studies.[379–381] The benefits appear to be enhanced by concurrent dietary sodium restriction.[382] In children, multiple observational studies have illustrated the antiproteinuric effects of ACEIs and ARBs in SRNS.[294,295,377,383] In a randomized uncontrolled prospective crossover trial of 25 children with SRNS, high-dose (0.6 mg/kg/day) and low-dose enalapril (0.2 mg/kg/day) reduced proteinuria by 52% and 33%, respectively.[293] Moreover, a prospective observational study investigated the use of losartan in 52 children with proteinuria, 22 of whom had associated hypertension. Proteinuria decreased by 34% at a 6-week follow-up visit. Further reductions in proteinuria in the range of 64% to 67% from baseline were noted at 3 subsequent visits between 4.5 months and 2.5 years later.[294]

In a case series, 13 children with SRNS received enalapril at a dose of 0.2 to 0.6 mg/kg/day combined with low-dose prednisone given on alternate days. Total urinary protein and albumin excretion were reduced by 80% and 70%, respectively. In the same study, urine protein electrophoresis showed a shift to a more albumin-selective proteinuria in children treated with enalapril.[383] In another case series of 9 children with SRNS, the combined use of MMF and angiotensin blockade resulted in a 72% reduction in proteinuria at 6 months of follow-up compared with baseline, a benefit that was maintained for at least 24 months. Both total cholesterol and triglycerides also markedly improved.[295]

Adverse effects associated with ACEIs and ARBs include decreased GFR, hyperkalemia, cough, and, rarely, angioedema. The decrease in GFR is most pronounced in children with decreased renal perfusion, such as those with bilateral renal artery stenosis. In conditions with decreased renal perfusion, angiotensin II maintains the filtration pressure through efferent vasoconstriction. ACEIs and ARBs block this defense mechanism and may result in a precipitous drop in the GFR. ACEIs and ARBs may also induce or exacerbate hyperkalemia, most likely through blockade of angiotensin II–induced release of aldosterone. Monitoring of renal function and electrolytes is suggested 5 to 7 days after initiating ACEIs and ARBs and after increases (usually of 50% or more) in the prescribed dose. ACEIs and ARBs should be discontinued in the event of a significant elevation in serum creatinine (greater than 30%) from baseline value or significant hyperkalemia.

ANTIOXIDANTS

Induction of reactive oxygen species (ROS)[384] and reduced antioxidant enzyme activity[385] have been implicated in the pathogenesis of nephrotic syndrome in animal models. In addition, accumulation of lipid peroxides, a product of oxidative damage, were documented in the renal cortex,[386] glomeruli,[387,388] and urine of animals with glomerular injury.[386–388] The use of ROS scavengers partially ameliorates glomerular injury in some animal models of nephrotic syndrome.[386,389–391]

Total serum antioxidant activity is reduced in children with nephrotic syndrome.[392–394] Total serum antioxidant activity was also significantly lower in children with SSNS who developed subsequent relapses of the disease compared with those with sustained remission.[394] In addition, malondialdehyde, a marker of oxidative stress, is significantly elevated during active disease.[392–394] Antioxidants, such as ascorbic acid and vitamin E, were elevated in some reports,[395] but unchanged in others.[392,393] It remains unclear whether these findings are related to an increase in oxygen free radical generation or suppressed antioxidant defense mechanisms.

The use of vitamin E as an ROS scavenger in the treatment of childhood FSGS was investigated in a small open-label controlled trial. Eleven children with biopsy-proven FSGS, 8 of whom were steroid resistant, were treated with vitamin E 200 IU twice daily. Nine children with other glomerular diseases and high-grade proteinuria were used as controls. After approximately 3 months of therapy, vitamin E was associated with a significant quantitative reduction in proteinuria (from a mean protein to creatinine ratio of 9.7 to 4.1) in the FSGS group, but not in the controls.[396] A subsequent randomized placebo-controlled trial of vitamin E in children with IgA nephropathy yielded similar results, a finding suggesting that the beneficial effect may be generalized to other glomerular diseases, rather than being specific to idiopathic FSGS.[397] Despite these findings, reproduction of these results in long-term randomized controlled studies will be required before vitamin E may be recommended for the treatment of children with SRNS.

GALACTOSE

In vitro and in vivo evidence suggests that galactose binds avidly to a circulating permeability factor in some patients with FSGS. Binding to galactose may induce rapid inactivation and clearance of the permeability factor. Intravenous and oral administration of galactose in a patient with post-transplant FSGS recurrence resulted in sustained suppression of permeability activity.[285] This study was followed by a case report of an adult with refractory SRNS who was successfully treated with oral galactose, which resulted in remission of the disease and reduced permeability factor activity.[398] Partial remission of nephrotic syndrome was also reported with oral galactose therapy in a toddler with IgM nephropathy and an adolescent girl with mesangioproliferative glomerulonephritis, both of whom were previously refractory to multiple immunosuppressive medications.[399] A prospective study is under way to investigate the role of galactose in SRNS further.

OTHER TREATMENT-RELATED ADVERSE EFFECTS

Drug-induced hypertension

Systemic hypertension is common in children with nephrotic syndrome who are maintained on immunosuppressive medications. In this setting, the elevated blood

pressure is more likely to be related to the use of corticosteroids or calcineurin inhibitors than to the underlying glomerular disease. The hypertensive effect of corticosteroids is thought to be mediated by an increase in the vasoconstrictor response to endogenous catecholamines[400–402] and to angiotensin II.[401,402] Renal salt retention, mediated through corticosteroid-induced direct activation of mineralocorticoid receptors, may also play a contributory role.[403] Tacrolimus, in contrast, may induce systemic hypertension through activation of sodium chloride cotransporters (NCCs) in the distal convoluted tubules. Tacrolimus-induced hypertension is often associated with hyperkalemia, hypercalciuria, and metabolic acidosis, a syndrome that resembles familial hyperkalemic hypertension (Gordon syndrome), a genetic disease characterized by overactivity of NCC.[315] Similarly, cyclosporine A has been associated with systemic hypertension. However, the underlying mechanisms behind the hypertensive effect of cyclosporine remain undetermined.

In children with persistent proteinuria, ACEIs and ARBs are the preferred antihypertensive medications in view of their antiproteinuric and long-term renoprotective effects. Careful monitoring of electrolytes and renal function is imperative in children with nephrotic syndrome who are treated with ACEIs and ARBs, particularly children with severe anasarca and intravascular volume depletion who are at high risk for acute kidney injury or hyperkalemia.

Based on more recent studies, up to 50% of children with nephrotic syndrome who are treated with calcineurin inhibitors may develop systemic hypertension.[231,237] Classically, calcium channel blockers have been considered the first-line choice in children with calcineurin inhibitor-induced hypertension. However, since uncovering the underlying tubular mechanisms behind the hypertensive effect of tacrolimus, selective blockade of NCC by using thiazide diuretics has been proposed as an alternative.[315] Clinical trials are needed to determine the efficacy of thiazide diuretics in the treatment of calcineurin inhibitor–induced hypertension.

Drug-induced dyslipidemia

The effect of glucocorticoids on lipid metabolism has been debated in multiple adult studies. After controlling for autoimmune disease activity, diet, physical activity, and other confounding factors, low to moderate doses of glucocorticoids do not appear to adversely affect lipid profiles in adults[404,405] or in children with systemic lupus erythematosus.[406,407] In children with SSNS, glucocorticoids are likely to improve the lipid profiles paradoxically by reducing proteinuria.

Cyclosporine has been associated with elevated triglyceride and lipoprotein A levels, along with an undesirable fall in high-density lipoprotein cholesterol independent of prednisone in renal transplant recipients.[408] However, this effect is more difficult to isolate in children with nephrotic syndrome who are treated with calcineurin inhibitors. Moreover, the antiproteinuric benefit of calcineurin inhibitors in children with nephrotic syndrome will likely outweigh any risk of drug-related dyslipidemia.

COMPLICATIONS OF THE PODOCYTOPATHIES

The development of acute kidney injury, as well as common infectious, thromboembolic, cardiovascular, and pulmonary complications of nephrotic syndrome, is discussed in detail in Chapter 16. The following sections discuss some of the less common complications that include anemia, endocrine abnormalities, and trace element deficiencies.

ANEMIA

Anemia related to erythropoietin deficiency or iron deficiency has been described in children with refractory nephrotic syndrome. The anemia has been attributed to urinary losses and increased catabolism of both erythropoietin and transferrin.[409,410] The anemia improves following induction of remission of the disease, but it may also be responsive to exogenous erythropoietin therapy.[411]

ENDOCRINE ABNORMALITIES AND DEFICIENCY OF TRACE ELEMENTS

Many circulating hormones, vitamins, and trace elements are bound to serum albumin or other binding proteins. In children with active nephrotic syndrome, massive losses of these binding proteins can result in endocrine abnormalities or deficiency symptoms. For example, substantial losses of vitamin D–binding proteins in nephrotic syndrome can result in signs and symptoms of vitamin D deficiency. Secondary hyperparathyroidism with low levels of 25-hydroxy-vitamin D and 1,25-hydroxy-vitamin D have also been detected in children with nephrotic syndrome.[412,413] However, the free and physiologically active fraction of 1,25-hydroxy-vitamin D usually remains normal.[414] This may explain why only a subset of children with nephrotic syndrome develops symptomatic vitamin D abnormalities that require supplementation.[415]

Studies evaluating bone mineral density in children with nephrotic syndrome produced variable results. In an uncontrolled prospective evaluation of 100 children with nephrotic syndrome using dual-energy x-ray absorptiometry (DEXA), osteoporosis was detected in 22%.[416] The low bone mineral density in these children was partially reversed following calcium and vitamin D supplementation.[417] Conversely, Leonard et al.[418] reported similar bone mineral content of the spine in 60 children with nephrotic syndrome and 195 healthy controls. In the same study, the whole body mineral content was increased in children with nephrotic syndrome. These differences were attributed to steroid-induced weight gain, an undesirable adverse effect of corticosteroids that is also associated with increased bone density.[418]

Urinary losses of binding proteins for cortisol and thyroxine may lead to reduced total blood levels of these hormones in children with nephrotic syndrome.[419,420] However,

the unbound hormonal fractions remain normal, and symptomatic hypothyroidism or adrenal insufficiency seldom occurs.[413,420] One exception to this rule involves infants with congenital nephrotic syndrome. Unlike other children with nephrotic syndrome, these infants develop massive urinary losses of binding proteins that commonly lead to clinical hypothyroidism and often require supplementation.[421–423] Clinically important hypocortisolism has also been reported in an infant with congenital nephrotic syndrome.[423]

In addition to endocrine abnormalities, deficiencies of zinc and copper have been described in patients with nephrotic syndrome. Zinc and copper are lost into the urine through urinary losses of their associated binding proteins—albumin and ceruloplasmin, respectively[413,424,425] (see Chapter 6).

PROGNOSIS

LIKELIHOOD OF ACHIEVING REMISSION

The initial response to steroid therapy is considered the most important long-term prognostic indicator in childhood nephrotic syndrome. This was illustrated in a multicenter study of 389 children with idiopathic nephrotic syndrome who were treated with prednisone and were followed for up to 17 years. Most (76%) children who responded to the initial course of glucocorticoids and were in remission for at least 6 months remained in remission for the entire follow-up period or had relapses rarely. In contrast, children who failed to respond to the initial 8-week course of corticosteroids developed ESKD in 21% of the cases. Moreover, children who failed to respond to both the initial steroid course and subsequent therapies over a period of 6 months developed ESKD in 35% of the cases. Children who responded to the initial course of glucocorticoids but who later developed frequent relapses within the subsequent 6-months period had a more favorable outcome, with 63% eventually becoming relapse free after an average follow-up of 3 years.[191]

In the initial ISKDC cohort, 78% of children who were treated with corticosteroids achieved complete remission.[98] However, the likelihood of responding to corticosteroids differed by the underlying histopathologic features. The steroid-response rate was 93%, 30%, 56%, and 7% in children with MCD, FSGS, MesProlif GN, and MPGN, respectively. None of the children with membranous nephropathy responded to corticosteroids in the ISKDC cohort.[98] Furthermore, the likelihood of response to steroids varied by age at presentation, with lower response rates seen in older children. This finding is not surprising because a higher age at presentation has been correlated with histopathologic features with poor steroid responsiveness, such as FSGS, MPGN, or membranous nephropathy.[25]

In our current era, a range of effective options may be offered to children who fail to respond to the initial course of corticosteroids. However, many of these children, particularly those with familial disease, may have an identifiable underlying genetic defect that profoundly reduces their probability of responding to immunosuppression. It appears that children with SRNS attributable to the identified genetic mutations to date are unlikely to achieve remission in response to immunosuppressive therapy. This was illustrated in a study of 91 children with SRNS, of whom 43 had identified disease-causing mutations. None of the 43 patients with identified disease-causing mutations achieved complete remission in response to cyclosporine, and only 2 achieved partial remission.[283] Similarly, immunosuppressive therapy failed to induce complete remission in any of 66 patients with SRNS and detected genetic mutations who were included in two other reports.[285,305]

The long-term prognosis of children who are responsive to cyclosporine has not been extensively studied. In a multicenter prospective report, 71% (22 of 31) of children with SRNS who initially attained complete remission in response to cyclosporine continued to require immunosuppressive therapy at 5 years of follow-up. Of these 22 patients, 19 remained on cyclosporine, and 7 developed frequent relapses.[426] Unfortunately, relapses are common during tapering or after discontinuing cyclosporine therapy. By the end of 12 months of cyclosporine treatment, 3 of 6 children who initially responded developed a relapse in one study.[307] The substitution of MMF may reduce the rate of relapse during cyclosporine tapering. In a study of pediatric SRNS, MMF was added sequentially to 18 children who achieved complete remission on cyclosporine A. This was followed by the successful discontinuation of cyclosporine in 16 children. At a mean follow-up of 7 years, only 21% of these children eventually developed relapses. In this study, renal function parameters improved significantly following discontinuation of cyclosporine.[270]

Most studies that have investigated the efficacy of immunosuppressive medications did not include genetic testing. As a result, it is not possible to estimate the response rate of children with nongenetic forms of SRNS to various immunosuppressive medications. When genetic and nongenetic forms of the disease are taken into account, the rates of achieving complete remission in children with SRNS have been reported at 52% for pulse steroids (Mendoza protocol),[347] in the range of 36% to 84% with cyclosporine,[227,306–310] and 40% to 94% with tacrolimus.[319–325.] In light of these statistics, it appears highly likely that children with SRNS, particularly those with nongenetic forms of the disease, will achieve remission in response to at least one of the foregoing immunosuppressive options.

KEY POINT

Clinical response to steroids with entry into complete remission predicts a favorable long-term outcome in children and adults with primary podocytopathies.

RELAPSE RATE

The majority of children with SSNS (70%) will experience at least one relapse of their disease. However, the probability of developing relapses declines over time. By 8 years following the initial diagnosis, 80% (311 of 389) of children from the original ISKDC cohort with steroid-sensitive MCD had no further relapses.[191] In the same study, the best outcome was seen in children who responded to initial therapy with prednisone and subsequently remained in remission for at least 6 months. Of those, 75% remained in remission or developed rare relapses throughout the follow-up period (mean, 9.4 years).[191]

END-STAGE KIDNEY DISEASE AND TRANSPLANT RECURRENCE RISK

Persistent high-grade proteinuria that is unresponsive to corticosteroids or other immunosuppressive medications predicts a high risk for progressive renal insufficiency. In the ISKDC cohort of 389 children with MCD, 21% of those who did not respond to the initial course of prednisone progressed to ESKD at a mean follow-up of 9.4 years.[191] Moreover, 35% of those who had unremitting proteinuria for 6 months following the initial prednisone course progressed to ESKD. Overall, 4% to 5% of the ISKDC cohort of children died or progressed to ESKD.[191]

Similar to the foregoing observations in children with MCD, steroid responsiveness also predicted a more favorable outcome in children[289,427] and adults[290] with FSGS. In a report of 60 children with FSGS, 58% of whom were African American, the risk of ESKD was reduced by 90% in those who achieved complete remission at a median follow-up of 33 months.[289] In another retrospective review of 92 children with steroid-resistant FSGS, including 33 patients with late steroid resistance, the lack of an initial response to corticosteroids was also identified as an important risk factor for progression to chronic kidney disease. Other risk factors identified in this study included asymptomatic proteinuria at presentation, baseline renal insufficiency, higher percentage of segmentally sclerotic glomeruli on biopsy, and a high degree of tubulointerstitial fibrosis.[427]

Renal transplantation is considered the treatment of choice in most children with nephrotic syndrome who progress to ESKD. In children with FSGS, however, recurrence of the disease has been reported in 20% to 56% of pediatric allograft recipients.[428–430] In a report by the North American Pediatric Renal Transplant Cooperative Study database (NAPRTCS), recurrent FSGS resulted in the loss of the allograft in 6.1% of children by 5 years after transplantation.[431] Risk factors for FSGS recurrence include a younger age at onset (less than 15 years), rapid progression to ESKD (within 3 years), mesangial proliferative histopathologic features, and a previous history of recurrence.[60,432–434] FSGS recurrence after renal transplantation has also been infrequently reported in children with identified genetic mutations in *NPHS2*[435,436] or *TRPC6*.[437] Effective treatment options include corticosteroids, plasma exchange,[63] and cyclosporine.[438]

MORTALITY RISK

A dramatic reduction in the mortality rate of children with nephrotic syndrome followed the introduction of antibiotics in the 1940s and corticosteroids in the 1950s. Despite these enormous advances, children with nephrotic syndrome, particularly those who are refractory to conventional therapies, remain at a considerable risk of mortality. Death is often related to disease complications. In the ISKDC study that included 389 children with biopsy-proven MCD, 10 children died (2.6%) over a follow-up period of 5 to 15 years. The deaths were attributed to infection in 6 of these 10 children,[439] a finding highlighting the importance of early recognition and treatment of the infectious complications of nephrotic syndrome.

ADULTS WITH A HISTORY OF CHILDHOOD NEPHROTIC SYNDROME

Three studies described the clinical course of adults who had a history of childhood SSNS. In the first study, which described adults at a mean duration of 22 years after their initial diagnosis, 33% (14 of 42) reported at least 1 relapse during adulthood, but all had normal renal function. As would be expected, a complicated course and the need for steroid-sparing medications during childhood predicted adult relapses.[440] The second study included 15 adults with persistent biopsy-proven childhood MCD with a frequently relapsing or steroid-dependent course. These patients were evaluated at a median duration of 24 years since initial diagnosis. Similar to the previous report, all patients had normal renal function, but 80% were still being treated with an immunosuppressive medication. The prevalence of treatment-related complications was relatively high. The most common complications were hypertension (47%), osteoporosis (33%), and cataracts (20%).[441] In a third study, which investigated the adult outcome of 117 patients with a history of childhood SSNS, 42% reported at least one relapse during adulthood. A younger age at disease onset (less than 6 years) and a higher number of relapses during childhood were identified as risk factors for continued relapses into adulthood. Steroid-related side effects, particularly in the form of obesity or osteoporosis, were detected in 44% of adults who continued to experience relapses.[442] In summary, these studies clearly demonstrate that the burden of nephrotic syndrome, as well as treatment-related complications, carries over into adulthood in many patients. This finding highlights the importance of appropriate transitioning of patients with nephrotic syndrome to an adult nephrologist for continued follow-up and monitoring.

SUMMARY

Nephrotic syndrome is one of the most commonly encountered kidney diseases in children. Advances in genetic testing and molecular diagnostics have allowed for better classification of the disease. Moreover, animal and human research studies have contributed to an improved understanding of the underlying pathophysiology. However, many questions remain unanswered in terms of the pathogenesis behind the primary glomerular injury, as well as the mechanisms of edema and dyslipidemia. Furthermore, the pathways by which the most commonly used medications, such as corticosteroids, exert their effect have not been fully elucidated. Despite the monumental improvements in the mortality and morbidity of children with this disease, many children with refractory SRNS, particularly those with underlying genetic mutations, may not fully respond to the currently available therapeutic options. Unfortunately, such children continue to face significant challenges in regard to their quality of life, and they remain at increased risk for treatment-related toxicities as well as infectious, thrombotic, and cardiovascular complications. Additional research is needed to promote a deeper understanding of the underlying pathogenesis and to provide a wider spectrum of safe and effective treatments.

Clinical Vignette 17.1

Anthony is a 2-year-old boy with a known history of seasonal allergies who presents to his primary physician with bilateral periorbital swelling of 5 days' duration. His mother initially "self-treated" his facial swelling with over-the-counter diphenhydramine, with minimal response. He does not appear to be in any discomfort and maintains normal activity. His appetite is slightly decreased. His mother has not noticed any changes in his voiding pattern or urine color. His facial swelling appears to be worse in the morning and improves as the day progresses. No apparent triggers are reported, but the mother recalls a transient brief episode of runny nose and dry cough that resolved spontaneously approximately 1 week before the current presentation.

In the office, he appears well and in no acute distress. His blood pressure is 102/56 mm Hg, and his heart rate is 77 beats/min. His physical examination is notable for bilateral periorbital swelling, abdominal fullness with a positive fluid wave but no tenderness, and significant pitting pretibial edema bilaterally. No skin rash or joint abnormalities are noted on examination. A urine dipstick was obtained in the office that shows 4+ protein (greater than 2000 mg/dL). Chemistry panel shows hypoalbuminemia (albumin, 2.1 g/dL) and hypercholesterolemia (total cholesterol, 340 mg/dL). Serum complement levels, blood urea nitrogen, creatinine, and electrolytes are normal.

Anthony is referred to a pediatric nephrologist, who discusses with the family the most likely diagnosis, MCD, as well as the recommended initial empiric therapy (corticosteroids), expected adverse effects, and alternatives to therapy. He is started on oral prednisolone, 2 mg/kg/day, of which he completes 6 weeks, followed by 1.5 mg/kg/dose given on alternate days for an additional 6 weeks. His urine dipstick turns negative for protein approximately 6 days after starting prednisolone therapy, and his generalized swelling completely resolves 3 days later.

REVIEW QUESTIONS

1. A 3-year-old boy presents with bilateral periorbital swelling and abdominal distention. Blood pressure is 104/66 mm Hg. Urine dipstick revealed 4+ proteinuria and moderate blood. You discuss the likelihood of response to steroid therapy with the family. Children who are *least* likely to respond to corticosteroids include:
   a. Asians
   b. African Americans
   c. Hispanics
   d. Native Americans
   e. Whites

2. A 16-year-old female patient with morbid obesity is being referred by her primary physician for evaluation of persistent proteinuria. Physical examination is significant for morbid obesity and acanthosis nigricans. Urinalysis showed 2+ proteinuria but no other abnormalities. She is normotensive. A spot urine protein-to-creatinine ratio on a first morning urine specimen was 1.6 mg/mg. You anticipate that her renal biopsy will *most likely* show:
   a. Glomeruli of large diameter
   b. Subepithelial and subendothelial dense deposits
   c. Diffuse foot process effacement
   d. Splitting and proliferation of the glomerular basement membrane
   e. Increased number and density of podocytes

3. Acceptable options for the treatment of children with steroid-resistant nephrotic syndrome include all of the following *except:*
   a. Oral cyclophosphamide
   b. Mycophenolate mofetil
   c. Tacrolimus
   d. Cyclosporine
   e. Use of angiotensin-converting enzyme inhibitors for refractory proteinuria

4. A 6-year-old girl presents with progressive generalized swelling of 2 weeks' duration. She has no reported changes in her urine color. Blood pressure measurements in the office are normal. Laboratory workup reveals high-grade proteinuria and severe hypoalbuminemia. Serum complement levels are normal. You suspect minimal change disease, and you inform parents that her prognosis is *most closely* linked to the following parameter:
   a. Presence or absence of systemic hypertension on presentation
   b. Age at onset less than 10 years
   c. Grade of peripheral edema on initial presentation
   d. Clinical response to oral prednisolone
   e. Detection and degree of microscopic hematuria on initial urine dipstick

5. A 12-year-old boy with history of steroid-resistant nephrotic syndrome presents for follow-up. He has been treated with cyclosporine, prednisone, lisinopril, and amlodipine for the last 5 months. His cyclosporine levels have been monitored periodically and have been consistently in the therapeutic range. Laboratory workup obtained this morning again showed therapeutic cyclosporine level, persistent high-grade proteinuria, and hypoalbuminemia. His serum creatinine is elevated at 1.5 mg/dL. You also note that his most recent previous creatinine level obtained 8 weeks ago was 0.8 mg/dL. The *most appropriate* next step in the management of this patient is to:
   a. Admit to the hospital for albumin and Lasix infusions.
   b. Discontinue lisinopril.
   c. Stop cyclosporine therapy and replace with tacrolimus.
   d. Encourage oral hydration and repeat kidney function tests in 1 week.
   e. Arrange for a repeat renal biopsy.

6. A 17-year-old African-American male patient is recently diagnosed with primary focal segmental glomerulosclerosis (FSGS). A *high likelihood* of steroid response has been associated with the following histologic variant:
   a. Tip lesion
   b. Collapsing glomerulopathy
   c. Perihilar variant
   d. Cellular variant
   e. Classic variant

Nephrotic syndrome in the first year of life

CHRISTER HOLMBERG AND HANNU JALANKO

Nephrotic syndrome (NS) in the first year of life manifests unique clinical and causal challenges. NS occurring in the first 3 months of life is defined as the congenital nephrotic syndrome (CNS); NS with onset between 4 and 12 months is known as infantile NS (INS), and NS appearing after the first year is recognized as childhood NS. In the youngest patients, mutations in the podocyte-associated genes or the syndromic disorders are the most common causes of NS. In contrast, minimal change nephrotic syndrome (MCNS) is the most prevalent form of NS later in childhood.

MCNS and some secondary forms of NS are often treatable, unlike NS resulting from gene mutations or syndromes. Overall, NS during the first year of life is an uncommon but severe disease. The affected children usually develop end-stage renal disease (ESRD) and require treatment with dialysis and renal transplantation (RTx). Classification of NS in the first year of life, based on primary and secondary causes is given in Table 18.1.

> ### KEY POINT
>
> NS during the first year of life is an uncommon but severe disease. Affected children develop ESRD and require treatment with dialysis and RTx.

PODOCYTE FUNCTION AND PROTEINURIA

Each of our kidneys contains approximately one million nephrons that filter 100 to 200 L of plasma from the glomerular capillaries daily into the urinary space. Most of the ultrafiltrate is reabsorbed by the renal tubules and collecting ducts. Normally, blood cells and plasma proteins are not lost into the urine. The glomerular capillary wall forms an efficient filtration barrier, which consists of three layers: fenestrated endothelium, the glomerular basement membrane (GBM), and the epithelium or podocyte layer.[1]

Podocytes are specialized neuron-like cells that possess a cell body, major and minor processes, and foot processes that attach to the GBM (Figures 18.1 and 18.2). The foot processes are linked by a specialized structure, the slit diaphragm (SD). Although all these components contribute to the regulation of renal filtration, the SD plays the most important role in preventing urinary protein losses. The main component of the SD is nephrin, a 1241-residue cell adhesion protein of the immunoglobulin family. Nephrin consists of an extracellular part with eight immunoglobulin-like modules and one type-III fibronectin domain.[2] The

> ### KEY POINTS
>
> - Podocytes are now being recognized as an important cell structure in the glomerular filtration barrier.
> - SD is the most important structure involved in preventing loss of protein from the glomerular capillaries into the urinary space.
> - SD is chiefly composed of nephrin, which forms a zipper-like barrier across the foot processes.

Table 18.1 Classification of nephrotic syndrome in the first years of life

Primary causes

1. Podocytopathies (restricted to the kidney)
   - Nephrin gene defect (*NPHS1*)
   - Podocin gene defect (*NPHS2*)
   - Phospholipase Cα1 gene defect (*PLCε1*)
2. Syndromes
   - Wilms tumor gene 1 defect (*WT1*)
   - Laminin β2 gene defect (*LAMβ2*)
   - Cation channel defect (*TRPC6*)
   - Coenzyme Q synthetase disturbances (*PDSS2*)
   - PHB-propenyl transferase defect (*COQ2*)
   - RhoGDIβ defect (*ARGHDIA*)
   - Nail-patella (*LMX1B* gene defect)
   - Lowe (*OCRL* gene defect)
   - Herlitz junctional epidermolysis bullosa (*LAMβ3* gene defect)
   - Galloway-Mowat (gene defect unknown)

Secondary causes

- Infections (syphilis, cytomegalovirus, human immunodeficiency virus)
- Immunologic (infantile lupus erythematosus/maternal)
- Idiopathic nephrotic syndrome
Figure 18.2 Electron microscopy of the glomerular capillary wall. **(a)** Capillary wall with normal podocyte foot processes and the slit diaphragms. **(b)** Normal slit diaphragm (SD) between podocyte foot processes.

extracellular part of one nephrin molecule binds to nephrin from an adjacent foot process (homophilic binding), as well as to other SD proteins, such as Neph1. These components form a zipper-like structure of the SD that is visible with electron microscopy (Figure 18.3). The intracellular part of nephrin contains nine tyrosine residues, which may be phosphorylated and are important in signal transduction from the SD into the podocyte.[3]

Besides nephrin, the proper function of the SD involves additional components, such as Neph1, Neph2, Neph3, and FAT.[4–6] These SD proteins, especially nephrin and Neph1, interact with adapter proteins podocin, CD2AP, and ZO-1 located in the cytosolic part of the foot processes.[7,8] These adapter proteins link the SD proteins to the actin cytoskeleton, which is vital to podocyte morphology (see Figure 18.3). Podocin belongs to the stomatin family and binds nephrin to lipid rafts, thus contributing to signal transduction.[8] Mutations in the podocin gene, *NPHS2*, and in the nephrin gene, *NPHS1*, are the two most common causes of primary CNS.[9]
Figure 18.1 **(a)** Illustration of cross section of a glomerular capillary showing the three glomerular cells: podocyte (epithelial cell), endothelial cell, and mesangial cell. **(b)** Illustration of cross section of a capillary wall showing the three layers of the glomerular filtration barrier: fenestrated endothelium, basement membrane, and epithelial layers comprising the podocyte foot processes and the slit diaphragm.
Figure 18.3 Illustration depicting a simplified model of the slit diaphragm and podocyte foot process. Anchoring of nephrin, Neph1, and podocin to the podocytes and formation of the slit diaphragm are shown.

GENETIC MUTATIONS IN NEPHROTIC SYNDROME

NPHS1 (NEPHRIN)

In 1956, Hallman's group described the first patients with NS whose clinical features are compatible with *NPHS1* gene mutation.[10] Norio[11] showed that this autosomal recessive disease occurs in 1 in 8200 newborns in Finland. In the late 1990s, Kestilä et al.[2] located the gene responsible for CNF on chromosome 19q13.1 and named it nephrotic syndrome gene 1 *(NPHS1);* its gene product was named nephrin.

Two main mutations are present in the Finnish children: Fin-major and Fin-minor.[2,3] Approximately 60% of Finnish patients are homozygous for the Fin-major mutation, 20% are compound heterozygotes for the Fin-major and Fin-minor mutations, and 10% are homozygous for the Fin-minor mutation.[12] The Fin-major mutation is a

two–base pair deletion in exon 2, which causes a frameshift and an early translational stop. The Fin-minor is a nonsense mutation in exon 26. Both of these mutations lead to a total absence of nephrin in the SD filaments by electron microscopy. Today, more than 200 different *NPHS1* mutations have been described worldwide (www.biobase-international.com), including nonsense and missense mutations, frameshifts, small insertions or deletions, and splice-site changes. Most are individual mutations located quite evenly along the gene and often lead to a severe form of CNS. However, studies have also described "mild" mutations leading to an unusual phenotype.[13] Although Fin-major and Fin-minor mutations are rare outside Finland, the 1481delC mutation is common in Mennonites and leads to a truncated protein of 547 residues, and homozygous nonsense mutation R1160X in exon 27 frequently occurs in Maltese children.[14,15]

Clinical features

Pregnancy with an affected fetus is usually uneventful. A high concentration of α-fetoprotein (AFP) in the amniotic fluid during the second trimester is often a sign of fetal proteinuria.[16] However, this finding is not diagnostic for homozygous *NPHS1* mutation, because fetal carriers of the Fin-major or Fin-minor mutation also may have a temporarily high concentration of AFP.[17] Amniotic fluid AFP may be elevated in other disorders, such as the presence of neural tube defects. Thus, only genetic testing is diagnostic. At birth, the amniotic fluid is often stained with meconium and the placenta is usually more than 25% of the newborn's weight; the child may be born prematurely.[18]

KEY POINTS

- The gene product of NPHS1 is nephrin and is present in SDs.
- Fin-major and Fin-minor were the two earliest described mutations in *NPHS1* in Finland. These are rare mutations in non-Finnish populations.
- More than 200 mutations have been recorded in the *NPHS1*, worldwide.
Figure 18.4 **(a)** Electron microscopy showing capillary wall of a patient with congenital nephrotic syndrome secondary to *NPHS1* mutation, demonstrating aberrant podocyte foot processes, with effacement. **(b)** "Empty" podocyte slit, without the (SD) filament is seen in a higher resolution.

Severe proteinuria is often evident right after birth, and NS develops within the first days or weeks. Children with *NPHS1* mutations have no extrarenal malformations, but growth and development may progress slowly. Protein deficiency may cause affected children to exhibit muscular hypotonia and mild atrophic brain changes. Some patients with *NPHS1* mutation have exhibited athetoid cerebral palsy, the cause of which is unknown.[19] Renal function is initially normal, unless the patient is severely dehydrated, and an ultrasound reveals oversize kidneys (as much as twice their normal size). Left untreated, a patient with *NPHS1* mutation grows insufficiently, is prone to thrombotic and infectious complications, and usually dies during the first year of life.

Renal pathology

By light microscopy, the glomeruli show mesangial expansion and degenerative changes. Dilated proximal tubules, interstitial fibrosis, and glomerular sclerosis develop over time. Electron microscopy reveals effacement of foot processes, as is common in all proteinuric disorders (Figure 18.4).[20] A total absence of the SD filaments by electron microscopy due to absence of nephrin also may be seen (Figure 18.4B). Scanning electron microscopy may show loss of normal podocyte architecture and an aberrant podocyte structure (Figure 18.5).
Figure 18.5. **(a)** Scanning electron microscopy (SEM) of a normal glomerular capillary wall showing podocyte soma and filaments. **(b)** SEM of a patient with congenital nephrotic syndrome resulting from *NPHS1* mutation showing aberrant podocyte structure and a lack of primary and secondary epithelial branching that normally covers the glomerular basement membrane.

PODOCIN

In 2000, Boute et al.[7] reported a new podocyte gene, *NPHS2,* in autosomal recessive steroid-resistant nephrotic syndrome (SRNS) and its gene product was named podocin.[7] Podocin is an intracellular linker protein that interacts with nephrin and serves as a scaffold for the SD. Mutations in the *NPHS2* can lead to typical CNS, but also may manifest later in life as steroid-resistant NS.[21] Researchers have described more than 100 pathogenic mutations. In one report on 80 European families, *NPHS2* mutations accounted for 39% of the CNS cases and 35% of the INS cases. Hinkes et al.[22] found *NPHS2* mutations in 18% of more than 400 patients in a worldwide cohort of SRNS ranging in age from birth to 21 years. Severe truncating mutations resulted in early onset of NS (from birth to 9.1 years; mean 1.75 years). Overall, *NPHS2* mutations account for approximately 20% of sporadic and 40% of familial cases of SRNS.[21] The *R138Q* mutation is common in Europe, and patients with homozygous mutations develop NS early in life. Nephrin expression may be distorted in CNS resulting from *NPHS2* mutations.[15,21]

KEY POINT

Mutations in the podocin gene, *NPHS2,* and in the nephrin gene, *NPHS1,* are the two most common causes of primary CNS.

KEY POINTS

- NS caused by *NPHS2* mutations is more variable with less severe proteinuria than NS caused by *NPHS1* mutations.
- FSGS is the most common renal pathology seen in *NPHS2* mutation (podocin).

Clinical features

NS resulting from *NPHS2* mutations may exhibit less severe proteinuria than NS caused by *NPHS1* gene mutation.[23] Renal failure develops at a mean age of 6.6 years, significantly later than in *NPHS1* mutations.[22] Only podocytes express podocin, and affected children show no extrarenal malformations, although some patients with cardiac anomalies have been reported.[24] With regard to renal histology, focal segmental glomerulosclerosis (FSGS) is the most common pathologic process noted, but MCNS and mesangial proliferative glomerulopathy have also been reported.[21,24]

WT1 GENE MUTATION

The Wilms tumor suppressor gene *(WT1)*, located on chromosome 11p13, encodes for transcription factor WT1 of the zinc finger family, which is located in the podocytes. WT1 regulates numerous target genes that are important for renal morphogenesis and also development of genitalia in fetal life.[26] These include some of the podocyte proteins, such as nephrin. Researchers have described a variety of *WT1* mutations that affect renal development or predispose to tumor formation.[27] These disorders include the Denys-Drash syndrome (DDS), Frasier syndrome, and WAGR syndrome (Wilms tumor, aniridia, genitourinary anomalies, and mental retardation).[27–31]

DDS is characterized by male pseudohermaphroditism, 46,XY karyotype, and diffuse mesangial sclerosis (DMS) noted in renal biopsy. Patients with DDS have a high risk for Wilms tumor. DDS results from heterozygous mutations in exons 8 and 9 of *WT1,* of which over 60 germline mutations have so far been described. The most prevalent of these mutations is *R394W,* located at zinc finger 3.[32] In most patients with DDS, *WT1* expression in podocytes is either absent or reduced.[27]

Clinically, DDS can be categorized into (1) genotypic males with all three abnormalities; (2) genotypic males with nephropathy and ambiguous external, internal, or both genitalia only; and (3) genotypic females with glomerulopathy and Wilms tumor only. Proteinuria and NS develop usually during the first few months of life, ESRD occurs within a year, and DMS is histologically evident.[28]

WT1 analysis in young patients with NS is important for early detection and tumor prophylaxis. Nephropathy is usually discovered at the age of a few months, sometimes at birth. To avoid the development of Wilms tumor, bilateral nephrectomy is recommended in all patients with DDS nephropathy resulting from *WT1* mutations at the time of developing ESRD.[33] RTx is usually the treatment of choice. *WT1* mutations also may cause isolated DMS.[32,34]

Frasier syndrome is also an autosomal dominantly inherited condition in which females present with amenorrhea, streaked gonads, 46,XY karyotype, and progressive nephropathy leading to ESRD. Proteinuria is usually detected between 2 and 6 years of age, and kidney biopsy reveals FSGS. Frasier syndrome results from point mutations in intron 9 of *WT1* and is characterized by male pseudohermaphroditism and glomerulopathy.[35] Indeed, patients with 46,XY exhibit complete male-to-female gender reversal. Frasier syndrome is associated with gonadoblastomas but not with Wilms tumor.

Mutations in *WT1* also can cause an isolated kidney disease with NS. The histopathologic diagnosis in these cases may be DMS or FSGS.[36] In a recent study, *WT1* mutations were observed in 5 of 110 (4.5%) of patients with SRNS. All patients were less than 5 years of age at onset of NS.[37] In a worldwide cohort of 164 cases of sporadic SRNS, 15 patients exhibited seven different mutations exclusively in exons 8 and 9 of *WT1*, suggesting that screening for *WT1* exons 8 and 9 in patients with sporadic SRNS is sufficient to detect pathogenic mutations.[38]

PHOSPHOLIPASE Cε1 GENE (*PLCε1*) MUTATIONS

PLCε1 belongs to the phospholipase family of proteins that catalyse the hydrolysis of phosphoinositides, which are involved in a broad range of intracellular functions.[39] *PLCε1* was found to associate with IQGAP1, a protein that interacts with nephrin. The precise function of *PLCε1* in podocytes, however, remains unclear.

In 2006, Hinkes et al.[40] identified mutations in *PLCε1* as a cause of early-onset NS. The age at onset in the 12 patients varied from 2 months to 4 years, and the age at ESRD was from 5 to over 13 years. No extrarenal manifestations were observed, and kidney histologic examination showed DMS in most patients. Two siblings with a missense mutation exhibited characteristics of FSGS. Interestingly, two other affected individuals responded to immunosuppressive therapy, making this the first report of a molecular cause of NS that may have resolved after therapy. In a subsequent study, Gbadegesin et al.[41] identified 40 children from 35 families with idiopathic DMS from a worldwide cohort of 1368 children with NS. The age of onset varied from 1 month to 6 years. Truncating mutations in *PLCε1* were detected in 10 of 35 (29%) of the families, and, interestingly, *WT1* mutations were seen in only 3 of 35 (8.5%) of the families. Except in one family, all the mutations detected were homozygous loss-of-function mutations. One child had two compound heterozygous mutations. Fourteen children were placed on corticosteroid or cyclosporine (CsA) therapy, but none responded. Age at ESRD varied from 8 months to 5 years.

Thus far, the results show that *PLCε1* mutations are a major genetic cause of isolated DMS, and subjects with this type of histologic lesion should be screened for *PLCε1* mutations. Such mutations also may lead to FSGS with a relatively

---

KEY POINTS

- Bilateral nephrectomy is highly recommended in patients with DDS because of the high risk for Wilms tumor.
- Patients with Frasier syndrome have a high risk for gonadoblastoma but not Wilms tumor. Therefore, bilateral nephrectomy is generally not necessary.

KEY POINT

PLCε1 mutations usually have DMS pathology, but FSGS also can be seen.

late onset of proteinuria. *PLCε1* mutations, however, remain an infrequent cause of FSGS. A Dutch study found no *PLCε1* mutations in 19 cases of childhood-onset FSGS.[42] Similarly, no *PLCε1* mutations were found in 125 Spanish patients with SRNS ranging from congenital to adult onset.[43] Interestingly, some individuals with *PLCε1* mutations may remain asymptomatic, implying that modifier genes may interact with *PLCε1* to cause DMS or FSGS.

LAMβ2 GENE MUTATIONS (PIERSON SYNDROME)

The *LAMβ2* gene encodes for the laminin β2-chain expressed in the GBM, eye, and central nervous system.[44] Pierson syndrome (OMIM 609049) consists of CNS (with DMS histology), ocular changes (microcoria, lens cornea, and retina abnormalities and possibly blindness), and in surviving children, neurologic deficits (hypotonia and psychomotor retardation). Pierson syndrome usually results from biallelic truncated mutations in the *LAMβ2*, but variants also exist, as do milder forms of cases involving *LAMβ2* mutations. Matejas et al.[45] reviewed the findings of 51 patients from 39 families with *LAMβ2* mutations. The age of most of the patients at diagnosis was younger than 3 months, and only four patients were older than 1 year; their age at ESRD onset was mainly under 1 year (from 1 week to 16 years). Renal biopsy showed DMS histology in 73%, FSGS in 14%, and minimal changes in 8% of the patients. Neurodevelopmental deficits were observed in 82% of the patients, and all but two patients had some ocular abnormalities. Among patients with isolated NS, *LAMβ2* mutations are rare. However, in patients with CNS without *NPHS1* or *NPHS2* mutations, and especially in those with eye abnormalities, this syndrome should be considered.

KEY POINTS

- Pierson syndrome manifests as CNS, eye abnormalities, neurologic manifestations, DMS, or, sometimes FSGS.
- Pierson syndrome is caused by *LAMβ2* mutations that encodes for the lamininβ2-chain of the GBM.

RARE MUTATIONS CAUSING CONGENITAL NEPHROTIC SYNDROME

A few other gene defects associated with podocytopathies may cause NS during the first months of life, although these presentations are much less common than those described previously.[9] Mutations in the cation channel gene *TRPC6*, *PDSS2* coding for coenzyme Q synthetase, *COQ2* for PHB-propenyl transferase, and *ARHGDIA* regulating RHO GTPase activity in podocytes all can cause NS.[46–50] *PDSS2*

and *COQ2* defects lead to mitochondrial disorders with several extrarenal symptoms, and *ARHGDIA* mutations have been associated with early NS accompanied by the rapid development of ESRD and DMS.

The Galloway-Mowat syndrome, first described in 1968, consists of congenital microcephaly, CNS, and hiatal hernia.[51,52] Subsequently, additional anomalies have been described, including dysmorphic clinical features, as well as ocular, limb, cardiac, and diaphragmatic anomalies.[53] The gene responsible for Galloway-Mowat syndrome has not yet been isolated. CNS has been described in single patients with nail-patella syndrome, Lowe syndrome, Herlitz junctional epidermolysis bullosa, and sialic acid storage disease.[54–58]

NONGENETIC FORMS OF CONGENITAL AND INFANTILE NEPHROTIC SYNDROME

NS in newborn infants has been described in association with a multitude of neonatal infections, such as cytomegalovirus infection, toxoplasmosis, congenital rubella, and human immunodeficiency virus infection.[59–62] Congenital syphilis can cause membranous nephropathy that is curable by penicillin therapy.[63] These reversible or treatable diseases need to be ruled out in all patients with CNS. Lupus erythematosus with nuclear antibodies, hypocomplementemia, and glomerulonephritis, but with poor response to therapy has been described in infants.[64] Membranous nephropathy resulting from fetomaternal alloimmunization with neutral endopeptidase antibodies and CNS also has been reported.[65] It is important to remember that idiopathic NS with minimal change histology, which is by far the most common form of childhood NS, usually occurs in toddlers and school-age children but can sometimes present during the first year of life.

DIAGNOSTIC EVALUATION

EVALUATION OF RENAL DISEASE

NS is sometimes difficult to detect in infants, but edema, hypoproteinemia, hypoalbuminuria, hyperlipidemia, and heavy proteinuria are the cardinal signs. The serum albumin level is typically less than 15 g/L (<1.5 g/dL), and proteinuria

---

KEY POINTS

- NS is sometimes difficult to detect in infants, but edema, hypoproteinemia, hyperlipidemia, and heavy proteinuria are the cardinal signs.
- Heavy and constant proteinuria (5 to 100 g/L) inevitably leads to life-threatening edema, and protein substitution by parenteral albumin infusions is mandatory.

Table 18.2 Diagnostic points in a child with nephrotic syndrome during the first year of life

Clinical manifestation	Possible disorder
Large placenta	*NPHS1*, intrauterine proteinuria
Nephrotic syndrome during the first month	*NPHS1*, infections
Ocular malformations	*LAMβ2*, syndromic disorders
Genital malformations	*WT1*
Neurologic problems	*LAMβ2, PDSS2, COQ2, ARGHDIA* syndromes
High creatinine during first months	*NPHS2, WT1*
Renal ultrasound-large kidneys	*NPHS1*
Ultrasound—small kidneys	DMS/*WT1*

is in nephrotic range. Other serum proteins can be lost into the urine, thus lowering immunoglobulin G, transferrin, apoproteins, LPL, antithrombin III, ceruloplasmin, vitamin D–binding protein, and thyroid-binding globulin. The severity of proteinuria, however, varies and can be modest initially. Serum creatinine and cystatin C can be normal during the first weeks or months, and ultrasound can show the nonspecific finding of large hyperechoic kidneys (Table 18.2).[19]

ROLE OF RENAL BIOPSY

The indications for renal biopsy remain unclear. Histologic lesions such as FSGS, MCNS, and DMS, as well as glomerular mesangial expansion, are not specific to the gene defect involved. On the other hand, clinical findings and histologic examination together can suggest the cause. The severity of the histologic lesions also helps in developing treatment strategies.

ESTABLISHING GENETIC DIAGNOSIS

The etiologic diagnosis is helpful in choosing therapy and assessing prognosis, following associated symptoms, and genetic counseling for the family. Examination should include possible renal and nonrenal malformations, genital abnormalities (karyotype), and neurologic and ocular defects, because these may compel the search for a mutation in the most likely gene. In newborns, a placental weight greater than 25% of birth weight is typical of classic *NPHS1* mutation, but may occur in other entities with congenital NS.

Patients with CNS or INS should first be screened for mutations in *NPHS1* and *NPHS2*. In a large study of early-onset NS, 74% of all patients presenting during the first week of life carried an *NPHS1* mutation and 11% had an *NPHS2* defect.[23] Conversely, *NPHS2* mutations accounted for 37%

of those seen after the first month, and only 16% carried an *NPHS1* mutation. In this study, 5.6% had a *WT1, LAMε2,* or *PLCε1* mutation, and 18.7% had no known mutations. If a kidney biopsy shows FSGS histologic findings, the patient shows signs of renal failure, or both, screening for *NPHS2* mutations is always the first option. On the other hand, all cases with DMS histology require *WT1* and *PLCε1* analyses. Individually sequencing several genes can be time-consuming and costly. However, next-generation genetic analysis of several genes simultaneously is now available at a reasonable price.

TREATMENT

MAINTAINING HOMEOSTASIS AND GROWTH

The magnitude of the protein losses into the urine is crucial for therapeutic decisions in infants with NS. Heavy and constant proteinuria inevitably leads to life-threatening edema, and protein substitution by parenteral albumin infusions is mandatory (Table 18.3). On the other hand, patients with moderate proteinuria (2 to 5 g/L) may be managed without parenteral albumin substitution, especially if proteinuria is associated with renal failure and reduced urinary output. Daily albumin infusions are necessary in severe NS and can be administered in one to three infusions per day together with 0.5 mg/kg furosemide, initially in three 2-hour infusions and later as one 6-hour infusion at night. Normally, 20% to 25% albumin, depending on which is available, is infused (3 to 4 g/kg/day) through a permanently placed

Table 18.3 Treatment strategies in children with nephrotic syndrome in the first year of life

- Exclude and treat infectious/immunologic causes
- Maintain the patient without severe edema (IV albumin)
- Provide sufficient calories (nasogastric tube/ gastrostomy)
- Administer ACE inhibitors (and indomethacin) especially in cases with moderate proteinuria
- Begin anticoagulation to avoid thrombotic complications
- Treat consequences of other protein losses (thyroxine, balanced fat diet, active treatment of infections)
- Early nephrectomy and dialysis in children with uremia, delayed growth and development, frequent infections, or reduced quality of life
- Renal transplantation when the patient has attained a sufficient weight (>10 kg for extraperitoneal placement)

deep-vein catheter. One should aim for normal growth and a nonedematous state. If protein loss is less severe, only a few infusions per week may be needed to maintain the fluid balance and albumin concentration at approximately 1.5 g/dL (15 g/L).[19,66]

Infants with severe NS have traditionally been treated with a high-energy (130 kcal/kg/day) and high-protein (3 to 4 g/kg/day) diet, although neonates with CNS can manage for some time with breast milk or cows' milk formulas. Glucose polymers are administered to increase energy intake, and a mixture of rapeseed and sunflower oil serves to balance lipid levels. The children also receive vitamin D_3 (10 to 30 µg/day), multivitamin preparations, magnesium, and calcium. Most infants need a nasogastric tube or gastrostomy to ensure their energy intake.[67,68]

> ## KEY POINT
>
> Most infants with CNS need a nasogastric tube or gastrostomy to provide adequate caloric intake.

Patients with constant proteinuria often have low levels of serum thyroid-binding globulin; for such patients, thyroxine substitution is recommended. An imbalance of plasma coagulation factor levels contributes to hypercoagulability and raises the risk for thrombosis; in such cases, warfarin, (and aspirin) therapy are recommended. Antithrombin III (50 U/kg) may be administered before surgical procedures. Prophylactic use of immunoglobulins has been recommended to prevent the consequences of urinary immunoglobulin loss, but in our hands this has proved to be ineffective. Similarly, the use of prophylactic antibiotics may increase the likelihood of infection with resistant organisms.[69] Immunization programs should be performed after nephrectomy and before RTx. Patients with NS warrant a high degree of vigilance for septic infections.

> ## KEY POINTS
>
> - Thyroxine replacement is required for most patients with CNS.
> - Hypercoagulability needs to be addressed.

MEDICAL MANAGEMENT OF PROTEINURIA

In the great majority of infants with genetic NS, proteinuria fails to respond to medication. However, a few patients with *NPHS1* with "mild" mutations have reportedly responded to antiproteinuric medication with angiotensin-converting enzyme (ACE) inhibitors and indomethacin.[12,66] Thus, in non-Finnish patients with less severe mutations, a 3- to 4-month course of ACE inhibitor or angiotensin II (ATII)

blocker with indomethacin may be worth trying. In patients with SRNS resulting from *NPHS2* mutations, antiproteinuric therapy has proved ineffective. In general, patients with NS often receive ACE inhibitors or ATII blockers, especially if the clinical findings support the diagnosis of idiopathic NS.

> ## KEY POINTS
>
> - For children with heavy proteinuria, early bilateral nephrectomy, dialysis, and subsequent renal transplantation is often the therapy of choice.
> - A few patients with *NPHS1* with "mild" mutations have reportedly responded to antiproteinuric medication with ACE inhibitors and indomethacin.
> - Antiproteinuric therapy in SRNS resulting from *NPHS2* mutations has proved to be ineffective.

Prednisone is the drug of choice in patients with nongenetic forms of NS. In practice, because the genetic analysis of patients with NS takes time, prednisone is often administered on admission, except in neonates with severe CNS. Some studies have reported success with single patients, but most of these had no known gene mutation.[9,24]

Recent data suggest that CsA might improve proteinuria, mainly in patients with *WT1* mutations.[40,70–73] CsA directly stabilizes the podocyte actin cytoskeleton by inhibiting the degradation of synaptopodin.[74] Some patients with FSGS and *NPHS2* mutations as well as patients with DMS and *PCLε1* mutations have also responded to CsA.[40,71,72] In addition, one report indicates that a patient with a coenzyme Q10 deficiency responded to coenzyme Q10 supplementation.[75] However, the long-term results of these medications and the magnitude of their side effects remain unclear.

DIALYSIS

As long as the child grows and develops normally and the quality of life is acceptable for the patient and family, conservative therapy for NS and for progressive uremia can continue.[19,66] However, thrombotic events and infections may occur, and the risk for permanent neurologic complications is greatest during this period. In infants with moderate proteinuria, unilateral nephrectomy may be indicated to reduce proteinuria and the need for IV albumin replacement. On the other hand, for children with heavy proteinuria, early bilateral nephrectomy, dialysis, and subsequent RTx is often the therapy of choice.[68] In patients with *NPHS1* with Fin-major or Fin-minor mutations, and in those who fail to respond to ACE inhibitors, we usually perform bilateral nephrectomy and begin peritoneal dialysis (PD) when the patient has attained a weight of about 7 kg. The PD catheter is inserted before initiation of PD.[67] The diet and medication administered to the proteinuric child are optimized following nephrectomy, some centers providing additional

IV albumin for the first 2 to 3 days after nephrectomy to normalize serum albumin.[19]

With aggressive therapy, growth and development can be normalized during PD in infants with minimal comorbidities.[68] However, long-term PD therapy is suboptimal for the child and the child's family and early RTx is recommended.[76]

RENAL TRANSPLANTATION

In most centers, RTx is performed after an infant with NS has reached the weight of approximately 10 kg. The donor kidney usually comes from a living (parental) or deceased adult donor. The graft can be placed intraperitoneally or extraperitoneally depending on the preferred technique. Transplanting an adult kidney into an infant requires large amounts of fluids (2500 mL/m^2/day) to provide adequate perfusion of the graft.[77] Extra fluids are continued for several months after the surgery. RTx and the postoperative therapy in infants is otherwise quite similar to that in older recipients.

KEY POINT

Transplanting a dult kidney into an infant requires excessive fluids (2500 mL/m^2/day) to provide adequate perfusion of the graft.

Today, the long-term results of RTx in infants, when performed in experienced centers, are comparable to those in older children.[78,79] Long-term patient and graft survival rates are over 90%. The likelihood that NS will recur in the allografts of patients with a genetic form of NS is minimal. However, recurrences have occurred in patients with *NPHS1* (Fin-major homozygotes) and *NPHS2* mutations. One-third of the Fin-major homozygotes develop anti-nephrin antibodies to this previously absent protein after RTx. The cause of recurrence in *NPHS2* is elusive. Most of these patients responded to plasma exchange, cyclophosphamide, anti-CD20 monoclonal antibodies (Rituximab), or a combination of these.[80]

LONG-TERM OUTCOME

With the first CNS children having reached adulthood, we know that with aggressive therapy from birth, children without comorbidities can enjoy normal growth and development.[68,81,82] Final height in 105 Finnish children transplanted at a mean age of 4.5 years was –1.2 standard deviation (SD) in boys and –1.7 SD in girls (45% of patients CNS of the Finnish type), puberty was normal, and psychomotor development was acceptable.[83-88] Moreover, families with an infant with CNS living in developed societies with adequate social support seemed to cope well.[76]

SUMMARY

NS in the first year of life is a rare, usually severe disease that in most cases can be treated only with RTx after nephrectomy of the diseased native kidneys. However, the long-term outcome for these children critically depends on early diagnosis and early institution of supportive treatment with subsequent PD and RTx.

REVIEW QUESTIONS

1. Congenital nephrotic syndrome is *best defined* as:
   a. Nephrotic syndrome during the first year of life
   b. Nephrotic syndrome during the first 6 years of life
   c. Nephrotic syndrome during the first 3 months of life
   d. End-stage renal disease and proteinuria in infancy
   e. Proteinuria and hematuria with uremia at birth

2. The *most common* causes of congenital nephrotic syndrome are:
   a. *WT1* mutations
   b. *WT1* and *PLCε1* mutations
   c. Neonatal infections
   d. Galloway-Mowat syndrome
   e. *NPHS1* and *NPHS2* mutations

3. Which of the following is *most important* in regulating glomerular protein filtration?
   a. The capillary endothelium
   b. Mesangial cell function
   c. The basement membrane
   d. The slit diaphragm
   e. The podocyte cell bodies

4. Congenital nephrotic syndrome secondary to *NPHS1* mutation:
   a. Is most commonly seen in Turkish children
   b. Is caused by a mutation in the podocin gene
   c. Usually manifests after the first 3 months of life
   d. Is caused by a nephrin gene mutation
   e. Reacts to cyclosporin A medication

5. Congenital nephrotic syndrome secondary to *NPHS2* mutation:
   a. Presents during the first month of life
   b. Is characterized by severe NS and ocular malformations
   c. Is caused by a mutation in the podocin gene
   d. Shows DMS in renal biopsy
   e. Reacts to ACE inhibitors and indomethacin

6. The *most typical* symptoms of congenital nephrotic syndrome is (are):
   a. Severe nephrosis during the first 3 months of life
   b. Malformations and end-stage renal failure
   c. Hematuria, high fever, and a typical rash
   d. Proteinuria and gastrointestinal malformations
   e. Edema, high creatinine level, and high blood pressure during the first months of life

7. Congenital nephrotic syndrome is *most effectively* treated by:
   a. Dialysis and early renal transplantation
   b. ACE inhibitors and indomethacin with cyclosporin A
   c. The patients recover spontaneously
   d. Penicillin
   e. High-dose immunosuppression

8. Which of the following *best represents* the long-term outcome of congenital nephrotic syndrome?
   a. Remains poor, with death during the first years of life
   b. Has improved, because most patients respond to the medication
   c. Is poor regardless of intervention, because the disease mostly reappears in the graft
   d. Is good with early support, dialysis, and renal transplantation
   e. Is poor because graft survival is still only 50% at 5 years

Membranoproliferative glomerulonephritis

CARLA M. NESTER AND DANNIELE G. HOLANDA

As advances are made in our understanding of the mechanistic underpinnings of membranoproliferative glomerulonephritis (MGPN), the classification and nomenclature of MPGN as a clinicopathologic entity is being revisited. Children with MPGN may present with nephritic syndrome, nephrotic syndrome, asymptomatic proteinuria, or a nephritic-nephrotic clinical picture. Despite an increased understanding of its pathogenesis, optimal treatment of MPGN remains uncertain.

HISTORICAL PERSPECTIVE AND NOMENCLATURE

MPGN is the pathologic term used to describe a pattern of glomerular injury noted on kidney biopsy. When the ultrastructural abnormalities that characterize MPGN are present on the kidney biopsy in the absence of immune deposits, the term membranoproliferative *pattern* is often preferred, instead of membranoproliferative *glomerulonephritis*. MPGN pattern is commonly seen in the late phase of thrombotic microangiopathy, chronic allograft rejection, and radiation-induced glomerulonephritis.

The term *secondary* MPGN applies when the characteristic pathologic findings are seen in renal biopsy in association with a defined disease process (e.g., systemic lupus erythematosus, hepatitis B or hepatitis C). The list of secondary causes of MPGN is extensive (Table 19.1). MPGN is designated *idiopathic* (or simply MPGN) when there is no evidence for an underlying disease. The secondary forms of MPGN are more common in adults, and the idiopathic forms of MPGN are more common in children. This chapter will focus on the idiopathic forms of MPGN in children.

Historically, MPGN has been classified into three morphologic types based on the location of the immune deposits noted on electron microscopy of the kidney biopsy sample (Figure 19.1): types I, II, and III. Type I, often referred to as *MPGN* (without the Roman numeral designation), is the most common variant and is characterized predominantly by the presence of subendothelial immune complex deposits. The immune complexes identified by immunofluorescence may include immunoglobulin, complement, or a combination of the two. The presence of immune deposits has led to the presumption that an important aspect of the pathogenesis of MPGN I is immune complex–mediated inflammation, with subsequent complement activation from chronic antigen stimulation.

The pathologic feature characteristic of MPGN II is the presence of distinct, dense, osmiophilic, sausage-shaped intramembranous deposits on electron microscopy. The historical term *MPGN II* as a disease entity is a misnomer because only 25% of patients with this disorder demonstrate any glomerular proliferative changes that are characteristic of MPGN.[1–6] In keeping with this distinctive pathologic picture, the dense deposit disease (DDD) is considered the

KEY POINTS

- MPGN classification is based on the location of immune deposits seen on electron microscopy of the kidney biopsy sample.
- The nomenclature of MPGN is in flux and is likely to be reconsidered.
- The term *C3 glomerulopathy* (C3G) is being proposed to capture a subgroup of patients with renal morphologies that manifest within the spectrum of MPGN.

preferred term. Additional criteria for the disease definition of DDD include the presence of predominant complement component 3 (C3) deposits on immunofluorescence staining of the kidney biopsy.[5,7–12]

Type III MPGN, considered by some to be a morphologic variant of type I and by others to represent a distinct category, has a more complex distribution of immune deposits. The electron microscopy of MPGN III not only demonstrates subendothelial and occasional intramembranous deposits but also includes subepithelial deposits.

The MPGN nomenclature, mainly types I and III, is in flux. In 2007, Servais et al. suggested that it may be important mechanistically, therapeutically, and prognostically to differentiate MPGN based on the predominant immunostaining, as opposed to the location of the deposits.[14] As noted previously, the diagnostic immunostaining requirement for DDD was a predominant C3 pattern on renal biopsy. Servais et al. hypothesized that the important pathologic distinction for all of the MPGNs was not the *location* of the deposits, but the *specificity*. The authors supported their theory by demonstrating that a significant proportion of the patients with C3 only on the kidney biopsy

Table 19.1 Secondary causes of membranoproliferative glomerulonephritis

Rheumatologic disorders	Genetic disorders
Systemic lupus erythematosus	Alpha-1–antitrypsin deficiency
Sjögren's syndrome	Hereditary complement deficiencies
Henoch Schönlein purpura	Down syndrome
Rheumatoid arthritis	Gaucher disease
Sarcoidosis	Kartagener syndrome
Psoriasis	Sickle cell disease
Takayasu arteritis	Partial lipodystrophy
Polyarteritis	Wiskott-Aldrich syndrome
Hypocomplementemic urticarial vasculitis	Prader-Willi syndrome
Infection	Turner syndrome
Infected ventricular shunt	Hereditary angioedema
Endocarditis	Familial Mediterranean fever
Visceral abscess	Addison disease
Tuberculosis	Gastrointestinal disease
Lyme disease	Chronic active hepatitis
Mycoplasma	Cirrhosis
Hepatitis B or C	Celiac disease and sprue
Human immunodeficiency virus	Diabetes mellitus
Hantavirus	Ulcerative colitis
Filariasis	Renal disease
Malaria	Alport syndrome
Schistosomiasis	C1q nephropathy
Candida endocrinopathy	PCKD
Malignancy	POEMS syndrome
Amyloidosis	Cushing's disease
Plasma cell dyscrasia	Immunoglobulin deposition disease
Leukemia or lymphoma	Radiation nephritis
Epithelial tumors	Other
Malignant melanoma	Bone marrow transplantation
Desmoplastic tumors	Immunoglobulin deficiency
Ovarian tumors	Drug abuse
Castleman disease	Organizing pneumonia
Figure 19.1 Classification of membranoproliferative glomerulonephritis (MPGN) by location of electron-dense deposits. MPGN I deposits are classically subendothelial and occasionally intramembranous. The defining deposits of MPGN II (dense deposit disease [DDD]) are the elongated, sausage-shaped intramembranous deposits. MPGN III has the most complex array of deposits, including subendothelial, intramembranous and subepithelial. Podocyte pathology is not depicted in this cartoon; however, it may be present in each of the MPGNs.

Figure 19.2 Immunofluorescence pattern in dense deposit disease. There is a strong capillary wall staining of C3 as well as mesangial C3 staining.

immunostaining had genetic mutations in complement genes, an acquired complement abnormality, or both.[14–22] Servais et al. further proposed that distinguishing a group of MPGN patients with a primary complement abnormality facilitates a more directed treatment approach.

The term *C3 glomerulopathy* (C3G) has been proposed as a new categorization of the diseases that would include entities formerly classified as MPGN I or MPGN III and MPGN II, all with C3 predominance on immunofluorescence (Figure 19.3). This recategorization of MPGN pathologic subtypes, based on the presence of *isolated* or *predominant* C3 deposits on kidney biopsy, has been embraced by several other authors.[13,23–26] The updated nomenclature includes two major categories: MPGN (alternatively called *immune complex MPGN* or simply *MPGN*), types I or III and C3G. C3G is currently separated into two subcategories: DDD and C3 glomerulonephritis (C3GN). Those who do not have the characteristic dense deposits noted in DDD are designated as C3GN (regardless of whether the MPGN pattern is type I or II). Gale

et al.[15] suggested CFHR5 nephropathy as another subcategory of C3G. CFHR5 nephropathy meets the histologic criteria of C3G yet has a well-described, unique, genetic, complement-based etiology.[15] A consensus statement on the definition of these terms, recapping our current understanding of the underlying pathologic processes, and identifying knowledge gaps was recently issued.[13]

Undoubtedly, the published literature is based on a heterogeneous description of patients who may or may not share the degree of disease characteristics previously presumed. When discussing epidemiology, treatment, and prognosis in this chapter, we use the older nomenclature for our primary discussion. However, to facilitate understanding of the disease process, newer terminology will also be included.

EPIDEMIOLOGY

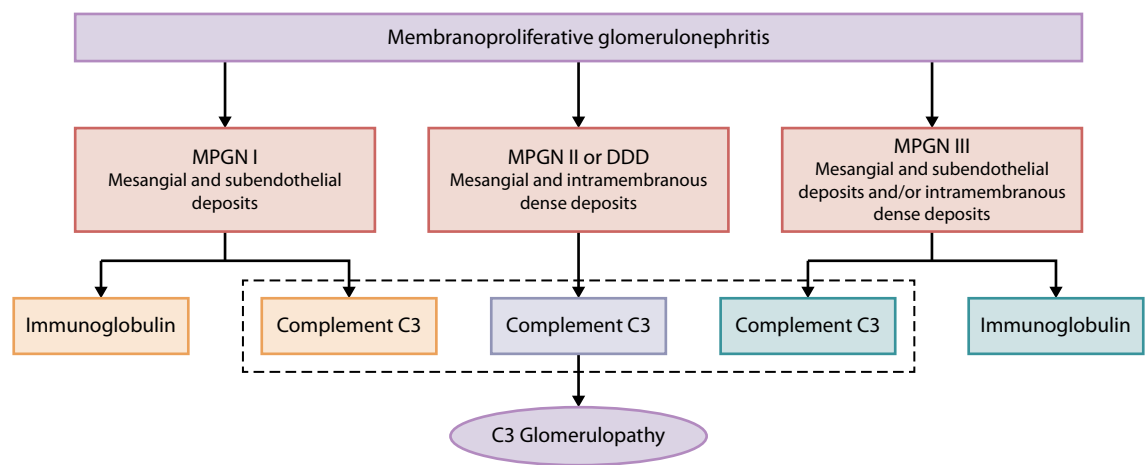
Although MPGN was originally reported in children, it is seen less frequently in children than in adults.[27–29] The true incidence of MPGN remains unknown. Estimates of prevalence have been extrapolated from data in patients who underwent kidney biopsy for indications of abnormal kidney function, proteinuria, hematuria, or a combination of these. The diagnosis of MPGN is reported in 5% to 10% of U.S. patients and 9.6% of U.K. patients undergoing a kidney biopsy for the evaluation of glomerular diseases.[28,30–34]


Figure 19.3 Renal pathology in membranoproliferative glomerulonephritis (MPGN). Three types of MPGN have historically been recognized: MPGN I, dense deposit disease [DDD], and MPGN III. MPGN I is often referred to as immune complex MPGN when immunoglobulin is the primary immunostaining. When C3 is the predominant immunostaining, regardless of the electron microscopy findings, C3 glomerulopathy is the preferred term.

Whereas MPGN is the most common primary glomerulonephritis in developing countries, it appears to be on the decline in some industrialized countries.[29] Hygienic, environmental, and socioeconomic factors are presumed to play a role in this disparity, but no firm relationships have been established. Local practice pattern, including indications for performing a kidney biopsy, may affect the reported incidence estimates.

MPGN is one of the least common types of glomerulonephritides in children. Three single-center reviews support the adult predominance and demonstrate ethnic differences. Nawaz et al.[28] presented a 5-year review of biopsies performed in their center. Of 348 biopsy samples, 13% were designated as MPGN, with an adult-to-pediatric ratio of 4:1.[28] Golay et al.[27] reported from their center that 5.25% of 666 biopsies were classified as MPGN, with 25% in children. In contrast, Kawamura et al.[29] reported that

only 1.2% of 6369 biopsies were MPGN, 30% of which were in children.

Many reports suggest that the global incidence of MPGN in adults has not changed substantially over time. However, a declining incidence of MPGN in children from industrialized countries has been reported.[29,35–37] The reasons for this decline of MPGN in children have not been identified.

The incidence of C3G as a subset of MPGN is unknown. Undoubtedly, a number of C3G cases were previously designated as MPGN I, II, or III. Disease-specific data are impossible to tease out from previously published literature. The initial study of Servais et al.[22] described 19 cases over a 33-year period, 5 of which were in patients under the age of 18. In a follow-up study, they reported an additional 134 cases, 39% occurring in children.[14]

In the United States, idiopathic MPGN predominantly affects whites. Type I disease affects women more often than men, but a nearly equal sex distribution is seen in MPGN type II. On the other hand, in a multicenter French report, both type I and type II/DDD were more common in male patients.[14] As in the United States, the French group reported that MPGN I was more common in adults and DDD was more common in children. DDD tends to affect children between 5 and 15 years of age. As noted previously, secondary forms of MPGN lesions are also more common in adults and the epidemiology parallels that of the underlying disease.

KEY POINTS

- The incidence of MPGN may be declining in the industrialized countries.
- Light microscopy of MPGN demonstrates intense cellularity of the glomeruli, with increase in mesangial cell and cytoplasm.
- Silver stain may demonstrate a "double-contoured" glomerular basement membrane.
- Immunofluorescence shows capillary loop and mesangial deposition of C3 and immunoglobulin G (IgG).
- Electron microscopy findings are variable, depending of the type of MPGN.

PATHOLOGY

A combination of light microscopy, immunofluorescence, and electron microscopy is necessary to define and stratify MPGN into the generally accepted variants. The

characteristic light microscopy renal biopsy findings are as follows:

1. Light microscopy shows cellular (proliferative) glomeruli, with a lobular appearance. This morphologic picture results from an extensive mesangial cell and endothelial cell proliferation. These findings in older literature were also referred to as mesangiocapillary glomerulonephritis (see Figure 19.1 and 19.4A to C).
2. Glomerular basement membranes are thickened and double contoured because of interposition of the mesangial cytoplasmic extensions into the basement membranes and new basement membrane formation in response to immune complex deposition (see Figure 19.1 and Figure 19.4D). This morphologic finding

in light microscopy is sometimes referred to as "tram-tracking". These findings are better demonstrated with stains that highlight the basement membrane, such as Jones methenamine silver stain.

Immunofluorescence microscopy demonstrates a granular to thick semilinear (or pseudolinear) pattern of immune deposits consisting of either IgG and C3 or isolated C3 deposits (see Figure 19.2). Lesser degrees of IgA, IgM, and C1q may be present. Electron microscopy has a variable pattern of electron-dense deposits, depending on the subtype of MPGN.

Based on location, quality, and specificity of immune deposits on immunofluorescence and electron microscopy findings, MPGN is further classified by the by these methods into three distinct subtypes (Table 19.2). MPGN I is
Figure 19.4 Light microscopy in membranoproliferative glomerulonephritis. **(a)** The glomerulus stained with hematoxylin and eosin (H&E) stain shows increased glomerular cellularity. The lobulated appearance of the capillary tuft results from an increase in mesangial cell numbers and increased endocapillary hypercellularity. Several neutrophils are seen infiltrating the glomerular tuft. **(b)** The glomerulus stained with periodic acid–Schiff (PAS) stain demonstrates glomerular tuft lobulation and mesangial cell proliferation. Capillary wall thickening is also noted. **(c)**. A glomerulus stained with trichrome stain showing mesangial proliferative changes. Arrow points to the lobulated glomerular tuft with very few open capillaries. Close inspection of the glomerular basement membranes shows numerous areas of double-contoured appearance. **(d)**. The Jones methenamine silver stain is ideal for outlining glomerular basement membrane (black, or argyrophilic). This figure shows thickened glomerular basement membranes and double contours or tram-rack of the basement membrane (arrows). This appearance results from proliferation and interposition of the mesangial cytoplasm, almost splitting the basement membrane, or to the presence of immune deposits along the contour of the basement membrane, as is seen in the dense deposit disease.

Table 19.2 Classification of membranoproliferative glomerulonephritis based on immunofluorescence microscopy and electron microscopy findings

	Electron microscopy microscopy	Immunofluorescence
MPGN type I	Granular and/or thick linear interrupted pattern of deposits with either IgG and C3 or isolated C3 deposits. Lesser degrees of IgA, IgM, and C1q may be present.	Subendothelial deposits
MPGN type II	Granular and/or band ("ribbon")–like C3 deposits.	Long, dense, band ("ribbon")-- like or "sausage"-shaped deposits in the lamina densa of the glomerular capillary basement membrane and subendothelial space
MPGN type III	Granular to the semilinear pattern of deposits with either IgG and C3 or isolated C3 deposits. Lesser degrees of IgA, IgM and C1q may be present.	Subendothelial, intramembranous and subepithelial deposits

characterized by presence of subendothelial electron-dense deposits (see Figures 19.1 and 19.5), MPGN II has ribbon-like or sausage-like electron-dense deposits in the lamina densa (see Figures 19.1 and 19.6), and MPGN III has electron-dense deposits in the subendothelial, intramembranous, and subepithelial areas (see Figures 19.1 and 19.7)

PATHOGENESIS

A detailed understanding of the pathogenesis of MPGN I, II, and III is not yet established. It is likely that a diverse set of pathogenic pathways lead to the pathologic findings seen in MPGN. In some cases, MPGN is a manifestation of an underlying disorder, such as chronic antigen exposure and subsequent kidney injury from immune complex deposition and complement activation. This is designated as the

Figure 19.5 Electron microscopy pathologic finding of membranoproliferative glomerulonephritis I. Arrow indicates subendothelial deposits.

secondary form of MPGN (see Table 19.1). The idiopathic MPGN is not associated with any apparent underlying disorder. It remains unclear whether abnormalities in the complement cascade will eventually be identified in some of these patients.

Two primary mechanisms have been proposed for the pathogenesis of idiopathic MPGN. In both of them, involvement of complement cascade plays a central role. In the first proposed mechanism, immune complex deposition in the glomeruli activates the classic pathway of complement. Immune activation of component C1 (active form: C1qC1rC1s) leads to the cleavage of C4 and C2. Cleavage of C4 and C2 leads to the generation of C4b and C2a and the subsequent formation of C4b2a, the classic pathway C3 convertase (Figure 19.8). The C3 convertase cleaves C3

Table 19.3 Clinical features at membranoproliferative glomerulonephritis presentation

	Children* (%)	Children and adults† (%)
Hematuria	33 (100%)	83 (58.8%)

into C3a, an anaphylatoxin, and C3b, which joins the C3 convertase to form the C5 convertase (C4b2aC3b). The C5 convertase cleaves C5 into C5a (another anaphylatoxin) and C5b. The cleavage product C5b is the first protein of the terminal complement complex. The joining of C5b to C6, C7, C8, and C9 generates the membrane attack complex (MAC). Production of MAC causes cell activation or damage to the glomerular capillary wall.

KEY POINTS

- MPGN is mediated by an activated complement system.
- Some patients have circulating C3-nephritic factor(s), which is an antibody that combines with the C3 convertase and prevents its catabolism. This results in an "always on" alternative complement pathway and downstream activation.
- Rare patients with MPGN may have inherited complement gene abnormalities.

In addition to MAC-induced tissue damage, the cleavage products C3a and C5a are potent anaphylatoxins. Anaphylatoxin generation triggers the accumulation of white blood cells capable of releasing oxidants and proteases that facilitate glomerular damage. In addition, anaphylatoxin activity plays a role in precipitating mesangial proliferation. Mesangial proliferation leads to the classic clinical

findings of MPGN: hematuria, proteinuria, and a reduction in glomerular filtration.

To understand the second mechanism of MPGN, it is necessary to understand normal function of the alternative pathway (AP) of complement (see Figure 19.8). Through this pathway, complement is activated as part of innate immunity, in the absence of immune complexes. C3b (produced by spontaneous hydrolysis of C3) is the first protein of the AP. It reacts with factor B and properdin to form the AP C3 convertase (C3bBb). As in the classic pathway, the C3 convertase cleaves C3 to C3a and C3b. This step is known as the amplification loop of the AP. This amplification loop facilitates accelerated cleavage of additional C3. Additional C3b molecules combine with the AP C3 convertase to form the AP C5 convertase (C3bBbC3b). The end-result of AP activation is also MAC and anaphylatoxin production.

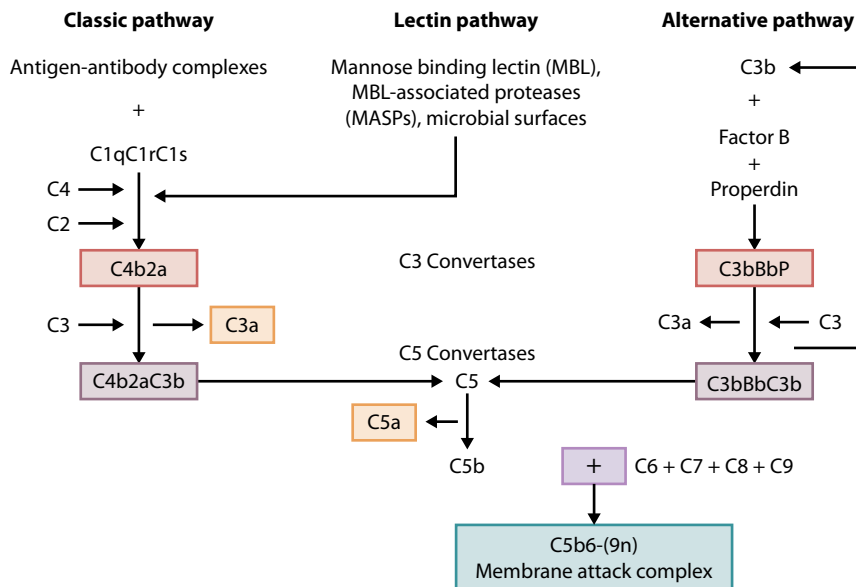
The second pathologic mechanism for MPGN involves an underlying primary complement abnormality. In this instance, injury is not associated with activation of the classic pathway of complement but results from dysregulation of the AP. The final steps are the same: formation of complement breakdown products, anaphylatoxin, and the terminal complement complex (C5b-9). However, the underlying initiating event of disease is the loss of normal control of the AP leading to uncontrolled AP activity. Dysregulation of the AP may be primarily at the C3 convertase (presence of circulating C3 nephritic factors), at the C5 convertase or terminal complement pathway (denoted by elevated C5b-9), or both. Because the AP has an amplification loop,


Figure 19.8 The complement cascade. The classical pathway, lectin pathway and the alternative pathway generate C3 convertase. Downstream complement activation eventually leads to the formation of the membrane attack complex (MAC).

uncontrolled activity can result in marked complement activity.

Two important discoveries have helped define the underlying disease mechanism in the second scenario. The first was the discovery of the C3 nephritic factors.[38] C3 nephritic factors are antibodies that bind to and prevent the normal breakdown of the AP C3 convertase, leading to AP dysregulation (Figure 19.9). The interaction of C3 nephritic factors with the AP C3 convertase leads to a constantly activated state of the AP.[38–41] A more active AP leads to an amplified production of C3 breakdown products. C3 breakdown products are deposited on the glomerular basement membrane, triggering a cascade of complement inflammatory responses. Why some patients develop circulating C3 nephritic factor remains unknown. C3 nephritic factors are present in up to 50% of MPGN I patients and in as many as 85% of patients with DDD.[25,42–44] C3 nephritic factors have been reported in 45% of C3GN patients.[14]

Genetic complement abnormalities also play an important role in the pathogenesis of MPGN, although these occur with less frequency than C3 nephritic factors. Both familial and sporadic forms of genetic complement abnormalities are well-documented in MPGN.[17–19,21,25,45,46] One large cohort found that genetic mutations in the complement regulatory proteins factor H (CFH), factor I (CFI), or membrane cofactor protein (MCP) were present in 16.8%, 17.2%, and 19.6% of idiopathic MPGN I, DDD, and C3GN patients, respectively. The association of gene mutations of complement regulatory proteins and MPGN has been substantiated in multiple ethnic groups.[24,47–51] Mutations in the complement factor H–related proteins CFHR1, CFHR3, and CFHR5 have been implicated in C3GN.[15,16,18,52] These mutations are primarily present in proteins that normally regulate the AP, and their impact is likely via dysregulation of

the AP. Consistent with the relative low frequency of genetic abnormalities in this disease population, there are very few reports of multiple family members being affected.

CLINICAL MANIFESTATIONS

Clinical manifestations of MPGN vary, depending on the severity of the disease (see Table 19.3). Idiopathic MPGN often presents with high-grade proteinuria, nephrotic syndrome, hypertension, and glomerular hematuria (see Table 19.2).[1,7,9,35,42,53–56] MPGN accounts for more than 7% of children and 12% of adults with idiopathic nephrotic syndrome. Gross hematuria can simulate clinical features of poststreptococcal glomerulonephritis in some at initial presentation. Hypocomplementemia, with low C3 is common, but C4 also may be low in an occasional patient. Respiratory illness may precede onset in some patients with MPGN. Children tend to have a more acute presentation and a slower decline in renal function than adults. Rapidly progressive disease is also well described in children. In contrast to adults, children are more likely to have hematuria at onset and less likely to have renal insufficiency.[42] Hypertension is present in half of children at presentation, and renal dysfunction occurs in 25% to 50% of patients.

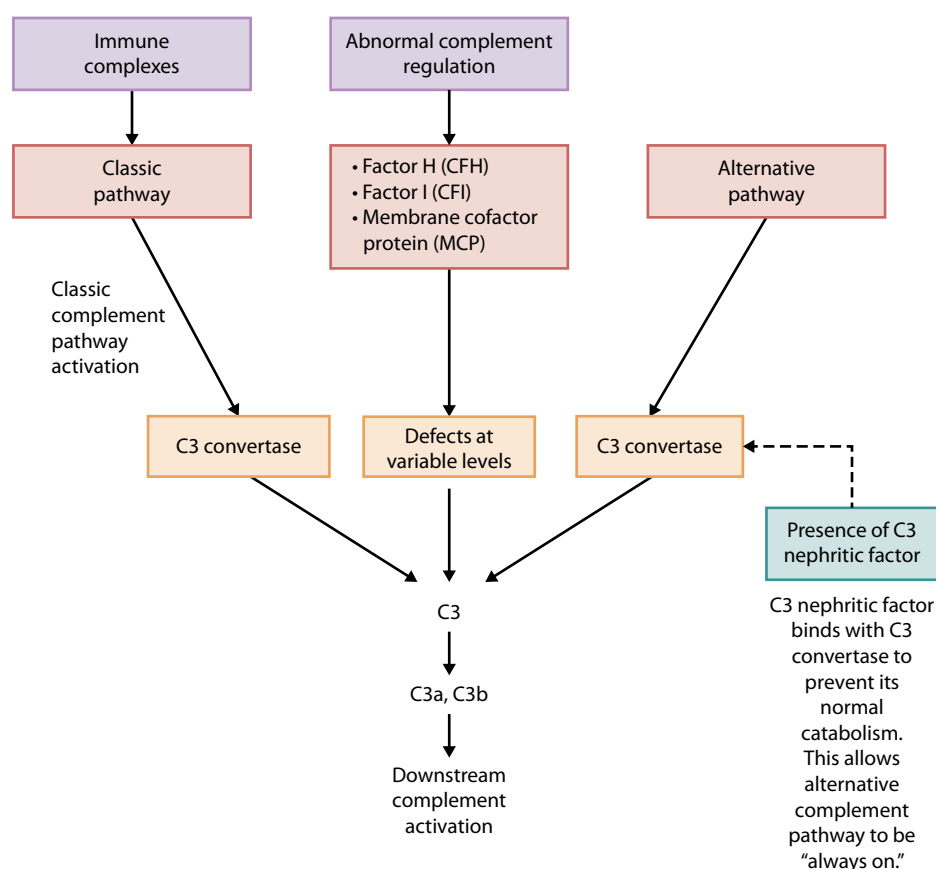
Clinical manifestations of the different types of MPGN are indistinguishable on presentation. Patients with DDD may have unique chronic clinical complications. These patients may have ophthalmologic findings of drusen, which are electron-dense deposits in the retina between the collagenous layer of the Bruch membrane and the retinal pigmented epithelial cells.[57] Presence of drusen carries an approximately 10% risk for long-term visual problems.[58]


Figure 19.9 Pathogenesis of complement pathway dysregulation and activation in membranoproliferative glomerulone-phritis (MPGN). Inherited defects of complement pathways that are associated with MPGN are listed but are not shown in relation to the site of their dysregulation.

Occasionally, patients with DDD also develop acquired partial lipodystrophy, a disease characterized by the loss of fat from the face, neck, shoulders, arms, forearms and thorax.[58] Lower extremities are generally spared.

> ## KEY POINTS
>
> - Despite morphologic subtypes, clinical manifestations of MPGN are indistinguishable.
> - MPGN can manifest with gross hematuria, proteinuria, and low serum complement C3 level features that can be mistaken for poststreptococcal glomerulonephritis.
> - Nephrotic syndrome, hypertension, and renal dysfunction are common findings of MPGN.

EVALUATION

Renal biopsy with light microscopy, immunofluorescence, and electron microscopy studies establishes the diagnosis of MPGN and allows its classification into the subtypes of MPGN I, MPGN II, or MPGN III. Further investigations are generally guided by the patient's exposure history, potential comorbid conditions, and clinical examination. The goal of the workup is to determine if there is an underlying or treatable disease process. For instance, identifying systemic lupus erythematosus or a monoclonal gammopathy in a patient with MPGN offers a specific treatment target.[59] Although diseases that are associated with MPGN (see Table 19.1) may be considered, a practical approach includes a much more limited laboratory evaluation (Table 19.4, top). If no associated disease is identified, the patient's disease is labeled idiopathic MPGN and treatment will be based on current knowledge about its treatment and response to therapy. Care must be taken to rule out a postinfectious glomerulonephritis (PIGN) process as the cause of MPGN. Postinfectious MPGN is most often a self-limited glomerular disease that requires only supportive care. Whereas extreme presentations of PIGN may require immunosuppression and renal replacement, this presentation is unusual enough that it should trigger close follow-up to ensure that the diagnosis is not actually idiopathic MPGN that was triggered by an infection.

As a result of our better understanding of the role of complement in the pathogenesis of MPGN and related diseases, and with the publication of the C3G consensus statement,

Table 19.4 Evaluation of patients with membranoproliferative glomerulonephritis*

Immunoglobulin dominant immunostaining		
Infection	**Organ dysfunction**	**Immune abnormality**
HCV, HBV, HIV	Liver function studies	ANA, ANCA, ENA
ASO	Chest x-ray	Rheumatoid factor
Tick-borne viral studies	Renal ultrasound	Cryoglobulins
Blood cultures	Protein electrophoresis	C3, C4, CH50
		C3 nephritic factor
Evaluating MPGN with C3 Dominant† Immunostaining		
Autoantibodies and protein deficiencies	Serum complement activity assays	Screen for genetic variants and/or copy number variation
C3 nephritic factors	Alternative pathway function	CFH
FHAA		CFI
FBAA	C3 breakdown products	MCP
FH level	C5 breakdown products	C3
FB level		CFB
Properdin level	Terminal complement cascade activity	CFHR1-5
CD46 expression on leukocytes	Hemolytic assay	Copy number variation in the CFH-CFHR region
Western blot for FHR proteins		

* The investigations for immunoglobulin dominant forms are designed to identify secondary associations (see Table 19.1) that may influence a treatment plan. The workup of C3 dominant glomerulonephritis remains the most controversial and is likely to change as the pathologic mechanisms behind disease become better defined.
† Dominant refers to 2 orders of magnitude over other positive stains.
ANA, antinuclear antibody; ANCA, anticytoplasmic autoantibody; ENA, extractable nuclear antigens; C4, complement C4; CH50, classical pathway 50% activity; FHAA, factor H autoantibody; FBAA, factor B autoantibody; CFH, factor H, CFI, factor I; MCP, membrane cofactor protein; CFI, factor I; CFHR1-5, complement factor H related 1, 3, 3, 4 and 5.

recommendations are to evaluate the patient according to the specificity of immune staining on immunofluorescence.[13] Accordingly, if the patient has a predominant C3 deposition pattern on immunofluorescence, the assumption is that the patient's disease is driven by an abnormal complement system. In this case, it is appropriate to assess complement proteins and genes to define the disease pathogenesis. Table 19.4 (bottom) outlines a comprehensive complement system evaluation. Although this workup serves to further define a given patient's pathologic process and complement abnormality, the absence of approved, directed therapeutics (unapproved anticomplement therapy to be discussed later) limits the clinical usefulness of this workup at this time. It is anticipated, however, that understanding the underlying pathologic condition will allow directed therapy in the near future.

It is worth noting that C3 predominance is often present by immunofluorescence in a patient with PIGN who requires a kidney biopsy (as is low peripheral C3 at presentation). Most often, knowledge of the clinical course will facilitate separation from C3G. If there is confusion, per consensus, PIGN is ruled out by a steady improvement of glomerular signs and normalization of the peripheral C3

over the subsequent 12 weeks. If either is still abnormal after 12 weeks, it is appropriate to reassign the patient's diagnosis to C3G and continue to follow the patient for chronic glomerulonephritis.

TREATMENT

The treatment of the secondary MPGNs is dictated by the cause. In some cases, the focus is treating the primary disease while monitoring the kidney response to this primary therapy. In cases of MPGN associated with lupus nephritis, treatment is guided by trial data and based on the histologic class of lupus. Finally, in other cases, a standard approach to a proliferative glomerulonephritis (e.g., high-dose steroids) may be used. Treatment of idiopathic MPGN has not been uniformly satisfying, and available options are based primarily on retrospective reviews and case reports. No up-to-date randomized controlled trials are available to guide care. The small number of patients studied and the relatively short follow-up time further compromise the usefulness of available data. Finally, because most trials, to date, included patients

with all three types of MPGN (and patients with C3G), analysis of treatment results are likely to be confounded.

Treatment strategies for idiopathic MPGN have included corticosteroids, immunosuppressive agents, antiplatelet regimens, plasma exchange, and biologic agents. As with all glomerular diseases, patients should receive therapy to maintain a normal blood pressure and minimize proteinuria using angiotensin-converting enzyme inhibitors or angiotensin receptor blockers. In addition, growth and development should be monitored closely, with a focus on appropriate chronic kidney disease markers and nutrition.

> ### KEY POINTS
>
> - There is no clear consensus on the treatment of MPGN.
> - The International Study of Kidney Diseases (ISKD) protocol for alternate-day steroids for 2 years or more is often used in children.
> - The value of steroid-sparing therapies has yet to be confirmed in randomized controlled trials.

CORTICOSTEROIDS

Retrospective and prospective studies have demonstrated a beneficial effect of steroid therapy on renal survival in pediatric patients with MPGN.[60,61] Steroid use was tested in the International Study of Kidney Disease in Children trial (ISKDC), a prospective, multicenter, randomized trial of 80 children, with predominantly type I MPGN (before the new classification), heavy proteinuria, and glomerular filtration rates of 70 mL/min/1.73 m^2 or greater.[62] The patients were randomized to receive either 40 mg/m^2 of prednisone every other day or placebo for a mean duration of treatment of 41 months. Treatment failure (30% increase in serum creatinine) occurred less frequently (40%) in patients treated with prednisone than in those who received placebo (55%). Of the treatment group, 61% versus 12% of the placebo group had stable renal function at the end of the study. Similar results have been reported in the combined adult and pediatric cohorts.[63] It is unclear what impact a presumed heterogeneous population of patients may have had on treatment outcome. It is important to note that the reported success of steroid use in MPGN involves alternate-day therapy, used for 24 to 40 months.[60,62] Nonetheless, steroids remain the mainstay of therapy for MPGN. Because treatment failures were as high as 40%, and because a protracted course of steroid therapy is not without adverse effects, other treatment options have been evaluated. Particularly, it appears that non-nephrotic children may forego steroid treatment without compromising long-term kidney function.[26]

ANTICOAGULANTS

Anticoagulants (heparin, warfarin, aspirin, dipyridamole), combined with or without steroids have been inconsistently successful, and long-term benefit has not been established.[53]

CYCLOPHOSPHAMIDE

In one study, 19 pediatric and adult patients with MPGN were treated with a prolonged regimen of pulse methylprednisolone, oral prednisone, and cyclophosphamide.[27] Of these, 15 achieved complete remission and 3 achieved a partial remission. Despite this success, the side effects of cyclophosphamide limit its usefulness as a primary treatment agent. In practice, cyclophosphamide is generally reserved for patients with rapidly progressive renal failure or a recent deterioration in renal function, especially those with crescentic histopathology.

MYCOPHENOLATE MOFETIL

Mycophenolate mofetil (MMF) is an inosine monophosphate dehydrogenase inhibitor, which inhibits the proliferation of T and B cells. Such an inhibitory action is expected to limit inflammatory reaction in the kidney, particularly as it applies to anaphylatoxin response. MMF was proposed for the treatment of MPGN as a steroid-sparing option. Few data exist to determine MMF's efficacy as a primary agent, but MMF is being increasingly used for treating patients with other forms of immune-mediated renal disease, particularly those resistant to steroids.[64] In idiopathic MPGN, preliminary studies suggest that the combination of MMF and corticosteroids can, in the short term, reduce proteinuria and may preserve renal function.[28,29]

CYCLOSPORINE

The role of calcineurin inhibitors for treating idiopathic MPGN is unclear. Two studies have suggested there may be some benefit from cyclosporine, particularly if high-grade proteinuria is present.[65,66] Bagheri et al.[67] used cyclosporine to treat 18 patients with MPGN who were resistant to steroids, aspirin, and dipyridamole. Long-term reductions in proteinuria with preservation of renal function were observed in 17 of the patients, suggesting that cyclosporine can be considered in corticosteroid-resistant primary MPGN.

PLASMA EXCHANGE

The data for plasma therapy in MPGN I are limited. Plasma therapy for C3GN is supported by data derived from

experimental animal models.[68,69] Support for effectiveness in humans comes from a handful of case reports.[21,70,71] As a treatment strategy in humans, plasma therapy has appeal either as a mechanism for removing abnormal disease-causing proteins (i.e., C3 nephritic factors), or replacing deficient proteins (e.g., genetic complement factor H deficiency). A number of issues make this a less palatable option. Among the deterrents to the routine use of this therapy are (1) the fact that the vast majority of patients with MPGN do not have genetic mutations causing protein deficiencies, (2) we lack scientific proof that reducing the C3 nephritic titer is protective of renal health, and (3) the risks of placing a catheter, especially given the lack of evidence for effectiveness. Currently, plasma therapy remains a fourth- or fifth-line consideration for the treatment of MPGN.

RITUXIMAB

Rituximab, a chimeric IgG1 monoclonal antibody that specifically targets the CD20 surface antigen expressed on B lymphocytes, has been considered for the treatment of MPGN. Similar to plasma therapy, the purported mechanism relates to the reduction of an abnormal complement-related circulating protein.[72] Few convincing examples of its success, however, are reported in the literature.[73]

ECULIZUMAB

Over the last decade, great advances have been made in our understanding of the complement-mediated renal diseases such as C3G and, to a lesser extent, MPGN. Given the role of complement dysregulation in the pathogenesis of these diseases, anticomplement treatment makes theoretical sense. A therapeutic role for eculizumab, an anti-C5 therapy (i.e., anti-C5a and anti-C5b) is supported by a number of case reports, especially in C3G.[50,74–76] The larger of these reports was a prospective, uncontrolled trial in six adults with native or recurrent post-transplant DDD or C3GN.[50] At the conclusion of a 1-year course of eculizumab, a clinical improvement was observed in three of the patients. Alternatively, a handful of reports have cataloged the failure of eculizumab in C3G.[76] Eculizumab is currently not approved by the U.S. Food and Drug Administration for MPGN or C3G, and the expense of this agent limits its availability off label. Trial data to support its efficacy are required to determine the role of eculizumab in the treatment of MPGN

OUTCOME

The natural history of MPGN is variable. Some patients appear to have a single nephritic-nephrotic episode followed by relative preservation of their kidney function and minimal, if any, residual signs of glomerular disease, such

as hematuria, proteinuria, and hypertension.[77–79] More frequently, patients have a chronic relapsing and remitting course of nephritis and nephrotic syndrome. Progression to end-stage renal disease (ESRD) is common, regardless of MPGN subtype.[1,7,42,43,80,81] Unfortunately, it is not possible to predict who will progress to ESRD. Habib et al. suggested that crescents or significant kidney dysfunction at presentation increases the risk for progression to ESRD.[1,14,82] In a small cohort of children, severe tubulointerstitial damage was the best predictor of outcome.[83] Others have failed to document a relationship with presentation and disease progression.[84] Reports have been variable regarding outcomes in relation to treatment regimens employed.[14]

TRANSPLANT

Given the presumed heterogeneity of the historical MPGN populations, it is not surprising that the post-transplant recurrence estimate is difficult to establish. Historical estimates have ranged from 2% to 20% for MPGN. Higher estimates are reported for DDD.[85] The North American Pediatric Renal Transplant Cooperative Study performed a retrospective cohort study of 8000 pediatric transplant recipients (including 75 children with DDD); 11 of 29 grafts lost in patients with DDD patients were due to DDD recurrence. Histologic recurrence of DDD is reported to be as high as in 90% patients. Higher estimates of recurrence have been reported in more contemporary cohorts of MPGN, making MPGN one of the more common glomerular diseases to recur in kidney transplants.[42,86–92]

COMPLICATIONS

The complications that result from MPGN disease are primarily related to the features of chronic glomerular disease and include chronic kidney disease, effects on growth, hypertension, bone health, and cardiac status. In patients treated with immunosuppression, each of the immune suppressants comes with its own set of cautions and side effects (e.g., infertility, cystitis, bone changes, gum and renal abnormalities, risk for cancer). The use of these agents in this setting is not unique to their use in other settings, with the exception that patients with significant renal dysfunction may have accentuated side effects of agents that are classically renally excreted.

SUMMARY

MPGN comprises a heterogeneous group of diseases that share distinct kidney biopsy pathologic findings. MPGN is an important renal disease in children. Progressive renal disease is common, with approximately 50% renal survival at 10 years in some affected children. Idiopathic MPGN is more common in children and young adults, whereas MPGN lesions are more commonly secondary to chronic infections in adults. New insights into the role of complement regulation in renal injury are adding to our understanding of the cause of injury in the C3G subcategory of MPGN. Randomized control trials for the treatment of MPGN are limited, and the mainstay of therapy includes standard renal protective agents (antihypertensive and antiproteinuric treatments). Small cohort studies guide adding anticellular immunosuppression. More data are required for the use of anticomplement therapy in patients with C3G. Transplant recurrence is frequent. Genetic studies currently do not have a clinical role, but in the future may help define targeted therapies.

Clinical Vignette 19.1

An 8-year-old boy presented with a 2-week history of fatigue and poor appetite and 5-day history of intermittent painless gross hematuria. He had no history of rash or joint pains. The review of systems was otherwise negative, with no history of recent infections. His medical history was negative for any illness.

Physical examination was significant for a moderately ill–appearing boy who was afebrile, with a blood pressure of 124/88 mm Hg. Lung, abdomen, skin, and joint examinations were normal. The patient had 1+ edema of ankles bilaterally. The urine was tea colored, and was positive for blood and protein. The urine protein-to-creatinine ratio was 2.0 His serum creatinine was 1.8 mg/dL, and serum albumin was 1.8 g/dL (normal 3.8 to 5.4 g/dL). Complement C3 was 14 mg/dL (normal greater than 90 mg/dL), and C4 was normal. Antinuclear antibody, antineutrophil cytoplasmic antibodies, and antistreptolysin were negative. Epstein-Barr virus and cytomegalovirus polymerase chain reaction results were negative. Because of rising serum creatinine and evolving oliguria, a renal biopsy was done and revealed diffuse proliferative changes and a lobulated appearance of the glomerular capillary loops. Silver staining revealed "tram-track" appearance of the glomerular basement membrane. There was no evidence of chronic tubulointerstitial damage. Immunofluorescence staining showed an isolated C3 deposition along the capillary loops, and electron microscopy demonstrated findings of diffuse foot process effacement, subepithelial deposits, with an occasional "hump," and subendothelial electron-dense deposits. Tubuloreticular inclusions were absent. The biopsy was consistent with MPGN .

The patient was treated with three daily doses of pulse intravenous methylprednisolone (10 mg/kg/doses) and then continued on high-dose steroids for 1 month. Over the subsequent 6 weeks, his C3 values increased, at 63 mg/dL at 2 weeks and 74 mg/dL at 3 weeks; the levels remained at low normal for the next 6 months. After 1 month of high-dose steroids, he was placed on a weaning dose of oral steroids to complete his course of immune suppression by 12 weeks after presentation. The patient was followed in clinic for 2 years with no recurrence of gross hematuria, proteinuria, or hypertension. His serum creatinine returned to normal by 3 months after presentation (0.4 mg/dL), and his ratio of urine protein to creatinine returned to normal by 12 months. Microscopic hematuria persisted for 12 months.

TEACHING POINTS

- This clinical case makes several important points relevant to the diagnosis and management of patients with MPGN.
- This patient simulated the clinical manifestations of poststreptococcal glomerulonephritis, which is the most common cause of hypocomplementemic acute glomerulonephritis in children. Although this patient did not have history of preceding infectious event before onset of gross hematuria, many patients with MPGN have history or laboratory evidence of recent viral or even streptococcal infection.
- Advancing acute kidney injury and progressive proteinuria, as was the case in this patient, should suggest the possible diagnosis of MPGN in a hypocomplementemic patient with glomerulonephritis. Indeed, these clinical findings led to his renal biopsy and eventual diagnosis of MPGN. The renal biopsy showed a proliferative glomerulonephritis with subepithelial and subendothelial C3 immune deposits.
- Interestingly, the biopsy also showed subepithelial "humps," indicating that a postinfectious onset could not be completely ruled out.
- A normal serum C4 and ANA points away from the diagnosis of systemic lupus erythematosus, in which a diffuse proliferative picture can also be seen in the renal biopsy. Often, patients with MPGN may continue to demonstrate low to low-normal levels of complement level for an extended time, as was the case in this patient.
- Given the acute oliguric presentation and renal dysfunction, intravenous steroids were used to treat this patient. Those with persistent hypocomplementemia and proteinuria can be considered for alternate-day, long-term steroid therapy, per the ISKDC protocol.

REVIEW QUESTIONS

1. What is the *major* distinguishing pathologic feature of the MPGN kidney biopsy?
    a. Immunoglobulin deposition on immunofluorescence
    b. Mesangial interposition into the glomerular basement membrane
    c. Mesangial cell proliferation
    d. Podocyte effacement

2. Why was the name MPGN II changed to dense deposit disease?
    a. Only 25% of patients actually had MPGN.
    b. MPGN II is the only MPGN with intramembranous deposits.
    c. Dense deposits were the sole disease-defining characteristic.

3. Which is the classic laboratory finding in MPGN patients?
    a. Low platelet count
    b. Hypocomplementemia
    c. Genetic abnormality
    d. Positive bacterial cultures

4. Which of the following is *not* a known cause of secondary MPGN?
    a. Systemic lupus erythematosus
    b. Viral infection
    c. Licorice intoxication
    d. Immunoglobulin deficiency

5. Name the required immune deposit location for dense deposit disease.
    a. Subendothelial deposits
    b. Intramembranous deposits
    c. Subepithelial deposits
    d. Mesangial deposits.

6. What is the ratio of MPGN presentation in children compared to that in adults?
    a. ¼:1
    b. ½:1
    c. ¾:1
    d. 1:1

7. The *most* likely pathologic cause of dense deposit disease is:
    a. A genetic mutation
    b. An autoantibody
    c. A protein inhibitor
    d. An exposure

8. What is the risk for end-stage renal disease for a patient with MPGN?
    a. 25%
    b. 50%
    c. 75%
    d. 100%

9. Of the MPGN diseases, which is the *most* likely to result in end-stage renal disease?
    a. DDD
    b. MPGN I
    c. MPGN III
    d. C3GN

10. What is the risk for recurrence after transplant for MPGN?
    a. 25%
    b. 50%
    c. 75%
    d. 100%

11. Which treatment for MPGN is supported by a randomized controlled trial?
    a. Steroid therapy
    b. None
    c. Mycophenolate mofetil
    d. Rituximab

12. What is the presentation biomarker that is associated with the *greatest* likelihood of advancing to end-stage renal disease?
    a. Proteinuria greater than 2 g
    b. Degree of interstitial fibrosis on presentation biopsy
    c. Degree of creatinine elevation at time of kidney biopsy
    d. Unknown

Membranous nephropathy

GEORGES DESCHÊNES

Membranous nephropathy (MN) is an uncommon disorder in children. It is an immune complex glomerulonephritis characterized by thickened glomerular basement membrane (GBM), presence of subepithelial immune deposits, and lack of cellular proliferation or infiltration within glomeruli.[1] The subepithelial immune deposits always contain immunoglobulin G (IgG) and frequently complement C3.[2] Proteinuria and nephrotic syndrome are the common manifestation of the disease at onset.[3] Although the idiopathic form of the disease is much more common in adults, secondary disorders, such as systemic lupus erythematosus (SLE) and infectious diseases, are common causes of MN in children.[4] This chapter discusses the clinical manifestations, renal biopsy characteristics, etiologies and therapy of children with MN.

was noted to be 22% in children 13 to 19 years of age in whom biopsy was performed for the diagnosis of nephrotic syndrome, suggesting that it might be more common in older children.[10] MN is an uncommon cause of end-stage renal disease (ESRD) in children. The 2013 U.S. Renal Data System data indicate that MN accounted for only 0.6% of pediatric ESRD patients in the United States.[11] There is no gender or racial predilection for childhood MN.[6]

A higher incidence of MN has been formerly reported from endemic geographic regions with a high prevalence of hepatitis B or malarial infection.[9,12] However, with control of hepatitis B with immunization and effective treatment and prevention of malaria, the incidence of MN resulting from these infectious causes appears to be significantly declining.[13,14]

EPIDEMIOLOGY

MN is an uncommon cause of proteinuria in childhood, while it remains a leading cause of nephrotic syndrome in adults.[5,6] In the International Study of Kidney Disease in Children (ISKDC) MN was seen in only 1.5% of the 521 children with nephrotic syndrome (12 weeks to 16 years).[7] In a Japanese study, 163 children (3 to 15 years) had kidney biopsies to investigate hematuria or proteinuria; the incidence of MN was 6.7%.[8] The incidence of MN among 463 Taiwanese children (younger than 17 years) who underwent biopsy for primary glomerular disease, was 11.7%.[9] In one study from the United States, the incidence of MN

RENAL PATHOLOGY

LIGHT AND IMMUNOFLUORESCENCE MICROSCOPY

Thickening of the glomerular wall is the main feature of MN on light microscopy, using trichrome or hematoxylin-eosin staining (Figure 20.1A). Staining with basement membrane stains, such as Jones silver stain or periodic acid–Schiff stain, shows that the GBM is thickened and exhibits argyrophilic projections, known as "spikes" that extend toward the epithelial aspect (see Figure 20.1B). This picture results from the fact that the subepithelial immune deposits sit in
Figure 20.1 **(a)** Light microscopy (hematoxylin and eosin stain) showing thickened glomerular capillary wall (arrows) in a patient with membranous nephropathy. Absence of cellular or mesangial matrix proliferation is the hallmark of membranous nephropathy. **(b)** Jones silver–stained renal biopsy showing typical spikes of membranous nephropathy. Arrows point to the site of immune deposits (which do not stain) with proliferation of surrounding glomerular basement membrane giving rise to the morphologic picture of spikes.

between the projections of GBM and are not stained by the GBM stain (Figure 20.2). Glomeruli may be affected in a segmental fashion.

Immunofluorescence shows IgG and C3 deposits along the periphery of the glomerular capillary wall. Primary or idiopathic MN is characterized by deposition of IgG4 and IgG1.[15] In contrast, secondary forms of MN primarily demonstrate IgG1, IgG2, and IgG3 in the immunofluorescence staining.[15,16] Tubular atrophy and interstitial fibrosis can be seen in long-standing and severe disease and correlate with the progression to chronic kidney disease (CKD) and ESRD.[17] Long-standing and progressive MN eventually leads to sclerosis of glomeruli. Immune deposits may be seen in mesangial location, and occasionally crescents may be associated with MN.[18]

ELECTRON MICROSCOPY

Depending on the duration of the disease, electron microscopy may demonstrate a variable pattern in MN (Figure 20.3).[19] Early MN (stage I) is characterized by finely granular, discontinuous electron-dense deposits that are located along the epithelial aspect of the GBM, under the epithelial cell foot processes. Over time, the GBM proliferates and surrounds the electron-dense deposits (stage II). Basement membrane stains (silver stain) at this stage result in the typical picture of spikes noted in light microscopy. Eventually, GBM proliferation envelopes the electron-dense deposits and incorporates them into the GBM (stage III). Finally, the electron-dense deposits in the GBM demonstrate resorption or dissolution and GBM repair ensues (stage IV). The site of electron-dense deposits in the GBM at this stage is often represented by a scalloped appearance. These stages of evolution of immune deposits in MN are depicted in Figure 20.3 and described in Table 20.1.

KEY POINTS

- The definition of MN relies on the characteristic renal histologic findings.
- Electron microscopy provides histologic staging of the disease.

CLINICAL FEATURES AND DIAGNOSIS

The diagnosis of MN should be suspected in patients with steroid-resistant nephrotic syndrome, especially in those in whom the onset of nephrotic syndrome occurs after 10 years of age. Proteinuria, which can be nephrotic or subnephrotic range, is the clinical hallmark of MN and is associated with low serum albumin in almost all patients.[3,6] Although microscopic hematuria is commonly observed in children with MN, gross hematuria has been described in up to 40% of children with idiopathic MN.[4,6,20] Hypertension at presentation is uncommon in children with MN. Renal function is usually normal at onset in children with MN, but renal dysfunction and development of CKD may be noted during disease progression.[20] Serum complement C3 and C4 are normal in the primary or idiopathic form of MN, but can be low in MN as a result of SLE. Differences between MN in children and adults are summarized in Table 20.2. A secondary cause of MN should be diligently sought in children.
Figure 20.2 Electron microscopy staging of membranous nephropathy. **(a)** Stage 1: Initial subepithelial electron dense-deposits. **(b)** Stage 2: Basement membrane enveloping electron-dense deposits (arrow head). The projection of basement membrane between the deposits gives rise to the characteristic spikes in the silver-stained sections in light microscopy. **(c)** Stage 3: Electron-dense deposits incorporated into the basement membrane. **(d)** Stage 4: Repair of the basement membrane and resolution of the dense deposits, giving rise to scalloped electron-lucent appearance (arrow) along the endothelial aspect of the glomerular basement membrane. (Reproduced with permission from: Yokoyama H, Yoshimoto K, Wada T, et al. Electron-dense deposition patterns and the outcomes of idiopathic membranous nephropathy in Japanese. Med Electron Microsc. 2002;35:81–6.)
Figure 20.3 A diagrammatic representation of the four stages of membranous nephropathy, demonstrating the life cycle of the subepithelial immune deposits.

Table 20.1 Electron microscopy classification of membranous nephropathy

Stage	Definition
I	Scattered subepithelial deposits without significant thickening of the GBM. Foot process effacement seen.
II	Widely distributed subepithelial deposits. Spikes are seen between the electron-dense deposits. The GBM is thickened.
III	GBM fuses over the deposits and envelopes them. Deposits become intramembranous in location.
IV	Resorption of deposits, leaving behind irregularly thickened lamina densa of the GBM.

Source: Churg J, Sobin LH. Renal disease: classification and atlas of glomerular diseases. Tokyo: Igaku-shoin, 1982, p. 52.
Abbreviation: GBM, glomerular basement membrane.

KEY POINTS

- Nephrotic syndrome and proteinuria are hallmarks of MN.
- Gross hematuria is common in children and raises the possibility of associated renal vein thrombosis.

CAUSES OF MEMBRANOUS NEPHROPATHY

MN is an immune complex glomerulonephritis that exhibits characteristics of an autoimmune disease in adults, as well as in many children. Although most cases are characterized as being idiopathic, discovery of numerous glomerular antigens and circulating antibodies to these antigens has redefined the notion of idiopathic MN. MN in children is often secondary to an underlying disorder. Table 20.3 lists the causes of MN and brief descriptions of some of the common causes of MN are provided in the following section.

PRIMARY OR IDIOPATHIC

Except in areas where the hepatitis B virus infection is endemic, the primary or idiopathic form of the disease is the most frequently observed etiology in adults.[4] Many patients with the primary or idiopathic MN have an autoimmune disease in which the kidneys are the specific target organ of the autoantibodies (see discussion of pathogenesis).[21] One such target podocyte antigen is phospholipase A2 receptor (PLA2R). Most adult

Table 20.2 Demographic, clinical, and morphologic differences between pediatric and adult forms of membranous nephropathy

Disease features	Pediatric membranous nephropathy (%)	Adult membranous nephropathy (%)
Disease type or subtype		
Proportion of primary nephrotic syndrome cases that have MN	<5 in younger children and 5–20 in adolescents.	15–30
MN cases that have primary ("idiopathic") disease	Minority	Majority
Proportion of primary MN that is PLA$_2$R-associated	45 (more common in adolescents)	70–80
Demographic and clinical features		
• Male predominance	Variable	Yes
• Nephrotic syndrome	40–75	75
• Hypertension	<10	30
• Thromboembolic events	<5	10–20
• Spontaneous remission	Common	30
• Progressive renal impairment	<25	30–40
Pathologic features		
• Mesangial deposits	Up to 50	30
• Segmental distribution of deposits	Occasional	Very rare

  - Captopril
  - Nonsteroidal anti-inflammatory drugs (NSAIDs)
  - Gold
  - Probenecid
  - Penicillamine
  - Lithium
  - Mercury
- Malignancy
  - Leukemias
  - Lymphomas
  - Solid organ malignancies
- Miscellaneous disorders
  - Renal transplantation (de novo)
  - Bone marrow transplantation
  - Sickle cell disease

patients (70%) with idiopathic MN have autoantibodies against PLA2R.[22] Whether this antibody test can serve to definitively differentiate primary from secondary forms of MN in adults and children is being investigated.

In children below 5 years of age, cationic bovine serum albumin (cBSA) originating from the trypsin digestion of cow's milk or beef protein in the gut has been linked to the development of MN.[23] It is possible that many of the idiopathic forms of MN will eventually be recognized as autoimmune disorders with glomerular or exogenous antigens serving as the causal triggers for the immune response.

KEY POINTS

- The most common cause of MN in adults is primary.
- Primary is now characterized as an autoimmune disorder.
- Approximately 70% of patients with primary MN have circulating antibodies against PLA2R, a podocyte antigen.
- cBSA, as a planted antigen, may cause MN in young children.

SYSTEMIC LUPUS ERYTHEMATOSUS

MN occurs in 20% of the children with SLE nephropathy and may be indistinguishable from the idiopathic MN by light microscopy in the renal biopsy.[24] Mixed proliferative and MN pathology also can be seen in patients with SLE, and clinical manifestations consist of proteinuria and nephrotic syndrome.

RENAL AND ALLOGENEIC BONE MARROW TRANSPLANTATION

In children, recurrence of MN in a renal allograft has not been reported. By contrast, de novo membranous nephropathy leads to graft loss in 60% of patients.[87] In adults, recurrence of MN in renal transplants has been reported in approximately 30% cases, whereas de novo disease is noted much more commonly in protocol transplant biopsies.[25] The recurrent form of transplant MN occurs early in the course of transplantation and can be associated with graft loss in 50% cases. De novo disease, conversely, occurs later in the transplant course, and may be asymptomatic or associated with mild proteinuria. Hepatitis C infection may be seen in patients with de novo transplant MN.[25] Rarely, MN also has been reported in allogeneic bone marrow transplantation and is usually associated with graft-versus-host disease.[26]

MEMBRANOUS NEPHROPATHY IN THE NEONATE

MN has been well described in neonates as a result of maternal syphilitic infection.[27] Prematurity, hepatitis and splenomegaly, respiratory distress, skin lesions, especially over the soles and palms, cerebrospinal fluid abnormalities, jaundice, and periostitis are possible findings of neonatal syphilis. When associated with MN, these neonates exhibit massive proteinuria and nephrotic syndrome.[27]

Rarely, neonatal MN also may occur as a result of the placental transfer of anti–neutral endopeptidase (NEP) IgG antibodies from the mother to the fetus. These mothers lack NEP because of gene deletion and have undergone previous alloimmunization because of blood transfusion, prior pregnancy or miscarriage.[28] Patients present early in the neonatal course with severe proteinuria and nephrotic syndrome.

NEP was the first podocyte antigen discovered to be associated MN.

VIRAL INFECTIONS

Hepatitis B virus (HBV) infection in children is a common cause of MN in some geographic regions of the world where HBV infection is endemic.[9,13] This results from glomerular co-deposition of viral antigens and their cognate antibodies.[9] Universal HBV vaccination of children has led to a decreased incidence of HBV-related MN.[13]

Another viral cause of MN in children is the human immunodeficiency virus (HIV) infection. HIV-associated MN is far less frequent than HIV-associated nephropathy or collapsing glomerulopathy.[29] Epstein-Barr virus (EBV) infection also, rarely, has been reported to be responsible for MN in children.[30]

DRUGS AND TOXINS

Drugs and toxins can lead to MN. Of the drugs in clinical use, captopril and nonsteroidal anti-inflammatory drugs (NSAIDs) have been well described to cause MN.[31,32] Treatment of adults with rheumatoid arthritis with gold salts has been reported to cause MN.[33] Isolated pediatric cases of MN have been reported after use of D-penicillamine and bucillamine.[33–35]

PATHOGENESIS OF MEMBRANOUS NEPHROPATHY

Heymann nephritis is an experimental model of MN that has been studied extensively since the 1950s.[36] In experimental models, as well as in human disease, subepithelial deposition of immune complex formation is the histologic hallmark of MN. The presence of immune complexes in this location sets the stage for complement activation and subsequent podocyte injury. The pathogenesis of subepithelial immune complex formation in experimental and human MN can involve one of the three possible mechanisms discussed in the following section.

Podocyte antigen–induced in situ immune complex formation

Studies done in the 1970s and 1980s demonstrated that circulating antibodies can bind in situ to glomerular antigens in Heymann nephritis and lead to the development of subepithelial immune deposits.[37] These antibodies are thought to traverse the GBM and bind to antigens present on the basal surface of podocytes. In Heyman nephritis, the antibodies bind to Gp330, also known as megalin.[38]

Megalin is not the target antigen in human MN since it is not present on the surface of human podocytes. In a seminal discovery in 2002, fetomaternal alloimmunization to NEP, a podocyte antigen, caused MN in a newborn.[28] The mother of the patient did not possess the NEP antigen and had been alloimmunized during a previous pregnancy. Passive transfer of antibodies in this fetus resulted in severe neonatal MN that was confirmed by renal biopsy. Subsequently, Beck et al.[39] demonstrated that antibodies directed against a podocyte antigen, M-type PLA2R, were present in 70% of idiopathic MN in adults, but not in secondary MN. More recently, antibodies to another podocyte antigen, thrombospondin type-1 domain-containing 7A (THSD7A), were detected in a subset of adult idiopathic MN patients who are negative for anti-PLA2R antibodies.[40]

It is possible that additional autoantibodies to podocyte antigens will be discovered. The role of testing for these autoantibodies in diagnosis, prognosis and management is not defined.

Planted antigen-antibody immune complex formations

cBSA, when injected into rabbits, leads to nephrotic syndrome with pathologic findings of MN.[41] cBSA is believed to navigate across the GBM along an electrostatic charge gradient (since it is positively charged). It is then trapped (or "planted") in the subepithelial region, and interacts later with antibodies generated by the host to form immune complex.

The demonstration of MN in children who develop antibodies to cBSA has substantiated the existence of planted antigens as a pathogenic mechanism of MN in patients.[23] Planted cBSA in these children with MN has been suggested to orignitate from trypsin digestion of cow's milk or beef protein in the gut. The cBSA is readily absorbed via the more permeable gastrointestinal tract of the infant and is
Figure 20.4 Pathogenesis of podocyte injury in membranous nephropathy. Autoantibodies to inherent podocyte antigens (PLA2R) or the planted (cBSA) antigens attach to the appropriate antigen site on the podocytes. The immune complexes detach from the podocytes and form the subepithelial deposits. Local complement activation results in formation of the membrane attack complex (MAC), which leads to sublethal podocyte injury. (Based on: Beck LH Jr, Salant DJ. Membranous nephropathy: from models to man. J Clin Invest. 2014;124:2307–14.)

subsequently trapped in the subepithelial space of the glomerular capillary wall. The development of antibodies to cBSA results binding to the planted antigen (cBSA) in the glomerular capillary wall and the development of MN.

Circulating immune complex formation

Evidence for circulating immune complexes (CICs) as the pathogenic mechanism of subepithelial immune complex formation in MN is scant. An experimental model using ferritin-antiferritin antibody–induced MN has provided some evidence that immune complexes may be formed along the endothelial side of the glomerular capillary wall and then translocate into the subepithelial space.[42] The presence of CICs in HBV-associated MN has been suggested as a human equivalent of circulating immune complex–induced MN.[43]

PODOCYTES INJURY AND COMPLEMENT ACTIVATION

After formation of in situ immune complexes on the basal aspect of podocytes, these immune complexes dislodge from podocyte surfaces and migrate onto the epithelial aspect of the GBM to form the subepithelial immune deposits.[44] Eventually, these antigen-antibody immune complexes lead to complement activation and formation of the terminal complement (C5b-9) membrane attack complex

(MAC). MAC in sublytic concentration is instrumental in inducing podocyte injury via mechanisms that involve cellular calcium influx, oxidative injury, and disruption of the actin cytoskeleton (Figure 20.4).[44,45] The consequences of these cellular events within the podocytes are simplification of the podocyte cell structure, loss or displacement of slit diaphragms, podocyte detachment, and development of proteinuria.[44–46] Indeed, MAC excretion has been well documented in the urine of patients with idiopathic MN that improves or disappears on treatment with immunosuppressive agents.[47] It has been suggested that MAC also may be involved in the tubulointerstitial damage observed in patients with MN.[48]

KEY POINT

Podocyte injury in MN results from local complement activation and formation of MAC.

MANAGEMENT

There is no clear consensus on the treatment of children with MN. Immunosuppressive therapies have been recommended on the belief that MN is an autoimmune disorder.

All of the immunosuppressive regimens are associated with significant side effects, including renal toxicity associated with calcineurin inhibitor therapy, and need to be chosen carefully. Evidence-based data with the use of immunosuppressive treatments in children are lacking, and therapy decisions are often based on the safety and efficacy data obtained in in adults. Supportive therapies for treatment of edema, use of antiproteinuric agents, prevention of infections, and treatment of hypertension need to be considered in all patients with MN. These therapies are briefly discussed in the following section and are described in detail in Chapters 16 and 17.

IMMUNOSUPPRESSIVE REGIMENS

There are no definitive guidelines for the treatment of idiopathic MN in children; the approach is largely based on trials in adults. Prolonged corticosteroid therapy, alkylating agents, calcineurin inhibitors, and rituximab have been used in treating MN. However, the most appropriate strategy for treatment has yet to emerge. This is further complicated by the fact that spontaneous improvement of nephrotic syndrome and proteinuria is common (approximately 30%) in MN. A brief review of the immunosuppressive agents used for treatment of MN is given later, which relies heavily on the experience in adult patients.

KEY POINTS

- Immunosuppressive regimens are the primary form of therapy in MN.
- Corticosteroid therapy as a monotherapy is not recommended.

Corticosteroids

Corticosteroids as a monotherapy are ineffective in the treatment of adult patients with MN. An early study compared using 8 weeks of alternate-day corticosteroids with placebo. Corticosteroids produced a significantly slower decline in glomerular filtration rate (GFR), with doubling of creatinine at 3 years in 24% in the treatment arm and 36% in the placebo arm.[48] The Medical Research Council Trial in the United Kingdom, using short-term prednisone therapy did not find any difference in renal function or proteinuria at 36 months between the treatment and placebo arms.[49] Another randomized controlled 6-month trial of alternate-day corticosteroids also failed to demonstrate any beneficial effects of the therapy.[50] Based on the lack of definitive evidence of benefit, the Kidney Disease Improving Global Outcomes (KDOQI) guidelines do not recommend corticosteroids as a monotherapy for treatment of MN.[51]

Corticosteroids and alkylating agents in cyclical therapy

Alkylating agents (chlorambucil and cyclophosphamide), used cyclically with steroids for 6 months, were shown to be effective in inducing remission of nephrotic syndrome by Ponticelli et al.[53] Being a cyclical therapy, the Ponticelli regimen uses monthly cycles of intravenous steroids and alkylating agent. In the first month, intravenous pulse prednisolone is administered daily for three doses and then oral methylprednisolone (0.5 mg/kg/day) is used for 27 days. In month 2, oral chlorambucil is administered in a dose of (0.15 to 0.2 mg/kg/day). Alternatively, oral cyclophosphamide (2 mg/kg/day) can be used for 30 days. These cycles are repeated for a total of 6 months. In a recently reported randomized controlled trial of adults with MN with declining function, immunosuppression consisting of 6 months of therapy with prednisolone and chlorambucil in a format similar to that in the Ponticelli regimen was found to slow the decline of renal function compared to the control group.[53] Although effective, alkylating agents can be associated with significant side effects and infectious complications.

Calcineurin inhibitor therapy

Cyclosporine, a calcineurin inhibitor, is effective in reducing proteinuria in patients with MN. In some randomized controlled trials, cyclosporine was superior to placebo in preserving renal function.[54,55] In the controlled study by Alexopoulos et al., [56] complete remission of nephrotic syndrome after 6 months of therapy was higher when cyclosporine was combined with corticosteroids (19% vs. 5%).[5 6] However, the partial remission rate was similar in the two groups. Failure to respond to cyclosporine after 6 months of treatment was noted in 17% of the combination group (cyclosporine and corticosteroids) and in 15% of patients in the cyclosporine monotherapy group. The dose of cyclosporine used in this study was 2 to 4 mg/kg/day in two divided doses, and the dose was adjusted to keep the plasma cyclosporine level at approximately 100 ng/mL.

Cyclosporine should be used cautiously in patients with decreased renal function. Comparing the Ponticelli regimen, cyclosporine, and supportive care, the U.K. randomized controlled trial demonstrated a higher risk for decline in renal function in patients receiving cyclosporine.

The appropriate duration of cyclosporine therapy in MN is unclear. KDIGO guidelines recommend at least 6-months of therapy in those who respond and possible extension of therapy to 1 year.[52] Relapses of proteinuria and nephrotic syndrome occur in 40% to 50% of patients after discontinuation of cyclosporine.

The mechanism by which cyclosporine reduces proteinuria in nephrotic states, including MN, is poorly understood. Possible mechanisms include suppressing the immune system, selective vasoconstrictive action on the afferent arteriole, and enhancing the selectivity of the glomerular capillary barrier.[57] More recently, cyclosporine has

been shown to have a stabilizing effect on the actin cytoskeleton of podocytes.[58,59]

Tacrolimus is also effective in controlling proteinuria in MN. The dose of tacrolimus in the randomized controlled trial by Praga et al.[60] was 0.05 mg/kg, given twice daily for 12 months and then tapered over 6 months. Remission of proteinuria occurred in 58%, 82%, and 94% after 6, 12, and 18 months of treatment, respectively. This compared with the remission rate of 10%, 24%, and 35% in the control group at 6, 12, and 18 months, respectively.

In a head-to-head comparison of tacrolimus and cyclophosphamide, Xu et al.[61] reported a remission rate of 65.1% in the tacrolimus group compared to a 44.2% remission rate in the cyclophosphamide group after 2 months of treatment. Both groups also received low-dose steroids. Mean time to partial or complete remission of proteinuria was 2.2 months in the tacrolimus group and 3.9 months in the cyclophosphamide group. However, the response was similar after 6 months of treatment, but there were fewer side effects in the tacrolimus arm of the study. Similarly, Chen et al.[62] noted that compared to the group receiving cyclophosphamide plus prednisone, tacrolimus plus prednisone provided a higher remission rate at 6 months (85% vs. 65%), but the remission rate was similar at 12 months of treatment. In the Cochrane meta-analysis of 39 studies in adults, there was no clear superiority of cyclosporine over alkylating agents (cyclophosphamide).[63] The number of studies using tacrolimus in this meta-analysis was too small to make any specific recommendations.

As is the case with cyclosporine, the relapse rate after discontinuation of tacrolimus is high. Patients on either of the two calcineurin inhibitor therapies become "dependent" on such treatments and therefore at risk of long-term nephrotoxicity.

Mycophenolate mofetil

Mycophenolate mofetil (MMF) is a potential therapeutic choice for some patients with MN.[64] However, the type of patients with MN who may benefit from MMF therapy remains unclear at this time. Using historical controls of MN patients who had been treated with daily cyclophosphamide (1.5 mg/kg/day), Branten et al.[65] treated a group of 32 adult MN patients with MMF (1 g twice daily). MMF reduced proteinuria comparable to the response with cyclophosphamide, but 38% of patients treated with MMF had relapse of nephrotic syndrome on cessation of treatment compared to 13% in the cyclophosphamide group. Of the patients treated with MMF, 16% failed to respond to the therapy. Dussol et al.[66] evaluated MMF monotherapy in adults for 12 months (randomized controlled) and compared it to symptomatic treatment along with angiotensin-converting enzyme inhibitor (ACEI) therapy. Although proteinuria improved in both groups, none of the MMF patients developed complete remission of proteinuria at 6 months.

Being an immunosuppressive agent, MMF may be considered in patients with idiopathic or primary MN with circulating anti-PLA2R antibodies. However, given the paucity of available data and a high relapse rate after discontinuation of therapy, the therapeutic role of MMF in the treatment of MN is unclear.

Rituximab

Rituximab is a monoclonal antibody that binds to the CD20 antigen on B cells, resulting in their deletion. Rituximab was approved by the U.S. Food and Drug Administration (FDA) in 1997 for treatment of non-Hodgkin's lymphoma and later for chronic lymphocytic leukemia, rheumatoid arthritis, granulomatosis with polyangiitis (Wegener granulomatosis), and microscopic polyangiitis.[67]

In an open-label clinical trial of rituximab, Fervenza et al.[68] treated 15 patients with MN using two doses intravenously 2 weeks apart (1 g/dose). They noted a mean of 48% reduction in proteinuria in 66% of patients, which occurred gradually over 12 months. However, 33% patients failed to respond. Disappearance of anti-PLA2R circulating antibodies has been noted after treatment with rituximab.[69] Ruggenenti et al.[70] extended their previously reported study on safety and efficacy of rituximab in 100 MN patients. Follow-up of rituximab (375 mg/m^2) therapy over 29 months resulted in a complete remission of proteinuria in 27% patients, and another 38% achieved partial remission. In this study, 35% patients did not fulfill the criteria for a partial or complete remission, but were noted to have a reduction in the degree of proteinuria. Remission with rituximab therapy was gradual and was attained over a median of 7.1 months. An important finding was that complete remission was associated with a significant improvement of GFR of approximately 13 mL/min/1.73 m^2. Interestingly, of those who achieved partial or complete remission, 27% had recurrence of proteinuria that ranged from 7 through 116 months (median 42 months) after rituximab treatment.

Interestingly, Fervenza et al.[68] found no relationship between the response rate and the number of B cells in the blood or CD20 cells in the kidney biopsy. Randomized controlled trials of rituximab use in MN are lacking, and recommendations related to its use in children cannot be made with confidence.

Adrenocorticotropin hormone gel therapy

Adrenocorticotrophin hormone (ACTH) was approved by the FDA for clinical use in 1952. A new formulation of ACTH in gel was approved by the FDA for treatment of edematous states (nephrotic syndrome) in 2010.[71] HP Acthar Gel (ACTH; Mallinckrodt, St. Louis, MO) is obtained from porcine pituitary gland and is currently the only approved product available in the United States. It has been shown to reduce proteinuria in a variety of kidney disorders, including MN.[72-74] There is some optimism about the use of ACTH gel therapy in the treatment of MN, but recommendations in children are currently inappropriate in view of a complete lack of substantial data.

SUPPORTIVE THERAPY

Supportive treatment of MN should be considered in all nephrotic patients for relief of edema, curtailing proteinuria, and preventing complications. These measures are also discussed in Chapters 16 and 17.

KEY POINT

Supportive therapy should be considered as an adjunct to immunosuppressive treatment in all patients with MN.

Antiproteinuric and renoprotective therapy

ACEIs and angiotensin receptor–blocking agents (ARBs) are well accepted as adjuncts in nephrotic patients to curb proteinuria. Apart from their antiproteinuric impact, ACEIs and ARBs are also renoprotective. Treatment with ACEIs, ARBs, or both is effective in achieving complete or partial remission in patients with MN and should be considered in all patients with MN.[75]

Managing hypertension and cardiovascular risks

Hypertension should be effectively controlled to lower cardiovascular risk and to slow progression of renal disease. Because of their antiproteinuric as well as antihypertensive effects, ACEIs and ARBs are the preferred initial therapy for hypertension in MN patients. Intensified blood pressure control, with a target between the 50th and 95th percentiles has been recommended in patients with CKD for optimal renoprotection, and should be the goal in patients with MN.[76] Hypercholesterolemia is common in MN and is routinely treated with statins in adults. The role of statins in children with nephrotic syndrome is not clearly defined.[77]

Managing edema

Diuretics are important in the management of edema in most nephrotic patients, including those with MN. Although not studied specifically in MN, a combination of furosemide, thiazides, and potassium-sparing diuretics can be considered for relief of edema. These therapies are also discussed in Chapters 16 and 17.

Prevention of thromboembolism

The prolonged nephrotic syndrome that occurs in some patients with membranous nephropathy increases the risk of thromboembolic complications. Renal vein thrombosis has been reported to be especially common in patients with MN.[78] Zhang et al.[79] studied renal computed tomography (CT) venography and pulmonary CT angiography in 512 patients (9 to 81 years of age) with nephrotic syndrome of all causes, 80 of whom were children. Pulmonary embolism or renal vein thrombosis was diagnosed in 35% patients. MN as the cause of nephrotic syndrome was the leading cause of these two thromboembolic complications (48%) in this study. Thrombotic complications involving other large vessels have also been reported in patients with MN.[80] The annual incidence of venous thrombosis (mostly pulmonary embolism and deep vein thrombosis) in adult patients with nephrotic syndrome has been estimated to be 1.02%, and the risk for arterial thrombosis (mostly myocardial infarction) has been estimated to be 1.45%.[81] These observations point to the importance of preventing thromboembolism in patients with MN.

Nephrotic children who may be at high risk for thromboembolic complications are difficult to identify. But the severity of proteinuria has been identified as a risk factor for thromboembolism in children.[82] There are no definitive guidelines for employing anticoagulants or antiplatelet agents in nephrotic syndrome, including in MN. For established thromboembolism, intravenous heparin therapy is the traditional approach, but low-molecular-weight heparin (enoxaparin [Lovenox]) may offer an alternative in some patients. If indicated, heparin may be necessary as long as the nephrotic state persists in these patients or at least for 3 to 6 months. Thrombolysis may be needed in patients with arterial thromboembolic events.[83]

Prevention of infections

Infections such as spontaneous bacterial peritonitis or sepsis may occur in children with MN. Strategies for preventing these infectious complications in nephrotic patients are discussed in Chapters 16 and 17 and should be employed in these MN patients. These include pneumococcal vaccinations and intravenous immunoglobulin in select patients.

NATURAL HISTORY OF MEMBRANOUS NEPHROPATHY

The natural history of MN is unique in that spontaneous remission of proteinuria and nephrotic syndrome in untreated patients is relatively common. The second clinically relevant aspect of the natural history of MN in adults is that progression of renal dysfunction occurs slowly and over many years. Noel et al.[78] followed 116 patients with MN for a mean of 4.5 years (2 months to 21 years) without any treatment. Of these, 23.5% developed clinical remission of nephrotic syndrome, some with residual mild-to-moderate proteinuria. Remission was noted more commonly in patients with stage I electron microscopy renal biopsy findings.

In a cohort of 116 patients with idiopathic MN from the Mayo Clinic, 72 patients did not receive any treatment and 42 patients received various immunosuppressive therapies.[84] Of the untreated patients, 57% had remission of proteinuria, 10% had persistent proteinuria, and 33% continued to have nephrotic syndrome. In contrast, in the treated group, 40% developed remission, 12% had persistent proteinuria, and 48% had persistent nephrotic syndrome. In an Italian study of 107 patients who received only diuretics or antihypertensive medications and were followed for a mean duration of 52 months, 65% of patients followed for at least 5 years developed clinical remission of proteinuria.[85] Serum creatinine in the entire group increased from a mean of 1.1 ± 0.5 mg to 1.4 ± 1.2 mg during the observational period. Polanco et al.[86] observed a multicenter cohort of 328 patients with nephrotic syndrome secondary to MN. Spontaneous remission of nephrotic syndrome occurred in 32% over a mean interval of 14.7 ± 11.4 months. Remission was more likely in patients with lower baseline proteinuria. Relapse of nephrotic syndrome occurred in only 5.7% of patients, and reduction of proteinuria by 50% in the first year was associated with remission of nephrotic syndrome.

Given the possibility of spontaneous remission in adult patients with MN, conservative therapy, such as with ACEIs, ARBs, and diuretics, has been recommended by some.[75] However, clinical, renal biopsy, or laboratory characteristics of patients who might respond to such a therapeutic approach remain unclear.

SUMMARY

MN is a relatively unusual cause of nephrotic syndrome in children. The underlying etiology varies in different regions of the world because of differences in the prevalence of infections such as hepatitis B and HIV infection and autoimmune disorders, especially lupus. The majority of adult idiopathic MN is due to autoantibodies to PLA2R. Children may develop MN as a result of autoantibodies to cBSA or alloantibodies to NEP. Treatment, determined by the underlying cause, includes antiviral agents and immunosuppressive medications.

Clinical Vignette 20.1

An 8-year-old girl was noted by her parents to have facial swelling. She was diagnosed with nephrotic syndrome. Daily oral prednisone for 4 weeks at a dose of 60 mg/m²/day and three additional intravenous pulses of methylprednisolone did not produce remission of proteinuria, and she was considered to have steroid-resistant nephrotic syndrome. Renal biopsy was performed, which showed typical findings of MN with thickening of the GBM and presence of spikes in the basement membrane on silver staining. Immunofluorescence showed IgG and C3 deposits. Electron microscopy demonstrated subepithelial electron-dense deposits characteristic of stage II classification. Estimated GFR was in the normal range. Viral serologic findings and polymerase chain reaction results were negative, and no drug or toxic exposure was detected. Serum complement levels were normal, anti-DNA autoantibodies were negative, and anti-PLA2R and anti-BSA antibodies were negative.

Treatment of MN was begun with tacrolimus and alternate-day prednisone. She was also started on anticoagulation with low-molecular-weight heparin. Complete remission of proteinuria and nephrotic syndrome was achieved in 4 weeks. Anticoagulation was stopped after the recovery of serum albumin to a normal level. Enalapril was started for renoprotection. Prednisone was stopped in 9 months, and tacrolimus was discontinued 26 months after initiation.

The patient relapsed with nephrotic-range proteinuria 4 months after discontinuing tacrolimus, while she was still taking enalapril. Tacrolimus was restarted, and full remission was again noted in 8 weeks. The trough level of tacrolimus was maintained less than 8 ng/L. Because of a decrease in GFR, despite complete remission of proteinuria, enalapril had to be discontinued. Prednisone was not restarted in this relapse.

A second renal biopsy was performed in year 3 after onset of the disease because of the decline in GFR and suspected nonadherence to therapy. Tubular atrophy and interstitial fibrosis were observed in 20% of the biopsy field, possibly as a result of tacrolimus therapy. The patient was started on rituximab therapy, to minimize the tacrolimus dose. B-cell depletion lasted 6 months. Unfortunately, her proteinuria reappeared following B-cell repletion.

TEACHING POINTS

- In children, MN is classically discovered following the investigation of steroid-resistant nephrotic syndrome. The diagnosis relies on the renal biopsy findings, especially the findings of immunofluorescence staining and electron microscopy.
- This patient was investigated thoroughly for a secondary cause of MN, as well as autoantibodies, and was eventually diagnosed to have idiopathic MN.

- Addition of tacrolimus to prednisone achieved a clinical and biochemical remission of proteinuria. Enalapril was used as a renoprotective and antiproteinuric agent, but it did not result in significant improvement in proteinuria.
- Unfortunately, MN in this patient continued to have a relentless chronic clinical course and she became "dependent" on tacrolimus therapy.
- Development of CKD, characterized by chronic interstitial disease in this patient could be attributed to persistent proteinuria and tacrolimus therapy. It is possible that she will develop ESRD.
- The choice of rituximab instead of cyclophosphamide as a B cell–depleting agent was based on the report of Beck et al.[69] despite the absence of anti-PLA2R autoantibodies. This therapy choice over cyclophosphamide was favoured in view of the lack of gonadal toxicity in females with rituximab.

REVIEW QUESTIONS

1. Membranous nephropathy is:
   a. The leading cause of nephrotic syndrome in adults
   b. The leading cause of nephrotic syndrome in children
   c. Idiopathic in most cases, whatever the patient age
   d. Mainly associated with lupus nephropathy
2. The diagnosis of membranous nephropathy relies on:
   a. Nephrotic-range proteinuria
   b. The age at onset of nephrotic syndrome
   c. Renal biopsy findings of thickened glomerular capillary wall, immunopathology, and electron microscopy showing subepithelial deposits
   d. Low circulating C3 and C4 in the plasma
3. The treatment of idiopathic membranous nephropathy includes all *except:*
   a. Prednisone + calcineurin antagonists
   b. Prednisone + alkylating agents
   c. Immunosuppression and ACE inhibitors
   d. Immunosuppression and ARBs
   e. Complement blockade by eculizumab
4. Circulating anti-PLA2R antibodies are seen in patients with:
   a. Membranous nephropathy associated with systemic lupus erythematosus
   b. Membranous nephropathy associated with drugs and toxins
   c. Primary or idiopathic membranous nephropathy
   d. Membranous nephropathy associated with hepatitis B
5. Corticosteroids, as a monotherapy, can produce long-lasting remission in patients with membranous nephropathy.
   a. True
   b. False

Acute glomerulonephritis

DIEGO H. AVILES AND V. MATTI VEHASKARI

Acute glomerulonephritis is a well-described complication of streptococcal and other infections in children. The narrative of hematuria and edema (dropsy) following scarlet fever provided a clinical description of acute glomerulonephritis, and for over a century this condition was known as the Bright disease.[1] It is likely, however, that many of the patients with Bright disease actually had some form of chronic glomerulonephritis. The term *acute postinfectious glomerulonephritis* (APIGN) refers to the broad group of acute nephritis that follows a variety of infectious events. APIGN may result from a variety of other bacterial and viral infectious agents, such as staphylococci, pneumococci, *Yersinia, Mycoplasma pneumoniae*, influenza virus, adenovirus, coxsackie virus, Epstein-Barr virus, varicella virus, mumps virus, measles virus, and parvovirus B19 (Table 21.1). APIGN can also occur in states of chronic bacterial infections, such as acute endocarditis, ventriculoatrial shunt infections, and deep-seated abscesses.

The term *acute poststreptococcal glomerulonephritis* (APSGN) is reserved for acute glomerulonephritis that develops after infection with group A β-hemolytic streptococci (GAS). Although generally a self-limited disease, APSGN may lead to life-threatening complications such as severe hypertension and encephalopathy, acute kidney injury (AKI), need for dialysis, and pulmonary edema. This chapter will primarily focus on the clinical aspects of APSGN. Viral infections resulting in glomerulonephritis are discussed separately in Chapter 29.

EPIDEMIOLOGY

APSGN may occur at any age, but it is more commonly encountered between the ages of 2 and 15 years.[2–5] Peak incidence in a recent study from New Zealand was noted to be between 5 and 9 years of age.[4] Occurrence of APSGN below 2 years of age has been reported, but is rare.[6] Most studies report a slight male preponderance.[3–5] Global prevalence of severe GAS-associated systemic disease (rheumatic fever and APSGN) remains a public health concern. Estimated prevalence of severe GAS associated systemic illnesses is at least 18.1 million cases (mostly rheumatic fever), with 1.78 million new cases occurring annually.[7] With improvement in living standards, the incidence of APSGN has significantly declined in the Western world. This declining trend in APSGN was well documented in the United States from 1961 to 1988 in a regional study from Memphis, Tennessee by Roy and Stapleton.[5] In a comparative analysis of APSGN in Florida, Ilyas and Tolaymat[6] noted that the prevalence of the disease had decreased from 2.18 in 100,000 population in the 1959 to 1973 cohort, to 0.64 in 100,000 population in the 1999 to 2006 cohort. ASPGN, however, remains a public health concern in some global regions.[3,5,7-9] For example, the endemic incidence of APSGN reported from Santiago, Chile in the decade of the 1980s was 37.5 in 100,000, which decreased to 15.3 in the decade of 1990s.[3] During GAS epidemics, the prevalence of APSGN was recorded to be 103.8 in 100,000 population in this study. In another recent study

Table 21.1 Microorganisms associated with acute postinfectious glomerulonephritis

Bacterial infections
- Group A β-hemolytic streptococcus
- Staphylococci
- *Streptococcus pneumoniae*
- *Yersinia*
- *Mycoplasma pneumoniae*
- *Mycobacterium tuberculosis*
- Syphilis
- Brucellosis
- *Rickettsia rickettsii*
- *Granulicatella adiacens*

Viral infections
- Hepatitis B
- Hepatitis C
- HIV-1 infection
- Cytomegalovirus (especially in immunocompromised and kidney transplant patients)
- Parvovirus B19
- Influenza virus
- Adenovirus
- Coxsackie virus
- Epstein-Barr virus
- Varicella virus
- Mumps virus

Parasitic infections
- Malaria
- Schistosomiasis

Fungal infections
- Histoplasmosis
- Cryptococcosis
- Coccidioidomycosis

from Auckland Metropolitan area in New Zealand, annual incidence of APSGN was estimated to be 9.7 in 100,000.[4] This study also established an inverse relationship between incidence of APSGN and socioeconomic status. Association with overcrowding and low socioeconomic status has been established in other studies.[3]

KEY POINTS

- APSGN is the most common form of acute glomerulonephritis encountered in children, worldwide.
- APSGN is uncommon in children younger than 2 years of age.
- The peak incidence of APSGN is 5 to 9 years.

APSGN follows upper respiratory or skin infection with GAS. A bimodal distribution of APSGN is well described. Pharyngotonsillitis is a more common antecedent to APSGN in temperate climates and occurs during winter and spring months. Impetigo-associated APSGN, on the other hand, is more common during summer and autumn months and occurs more frequently in the tropical regions with warm and humid climate.[3,6] Interestingly, a trend of decreasing impetigo-associated APSGN has been observed since the 1960s in the United States in several studies.[4,5] A recent study from Florida noted that antecedent pharyngitis has replaced skin infection as the main source of streptococcal infection in APSGN.[4] Pharyngitis-associated APSGN was noted in 64% of the recently observed cases (1999 to 2006 cohort), whereas impetigo-associated APSGN formed the bulk (66%) of APSGN cases in the earlier era (1957 to 1973) in this study.[4] Epidemic outbreaks of APSGN may occur, especially in overcrowded and poor sanitation conditions.[3,9]

KEY POINTS

- Tonsillopharyngitis as a source of GAS infection is more common in the United States and developed countries.
- Pyoderma as a source of GAS is more common in Australia and less developed countries.

Studies of epidemic and nonepidemic APSGN have well documented that subclinical disease is common.[10–17] Siblings of affected patients are more at risk for asymptomatic APSGN, but parents also can be affected.[12,13] Screening of family members of index cases within 7 days revealed abnormal urinalysis in 22.3% of siblings, and definitive diagnosis of APSGN was made in 9.4% of the siblings. Prospective screening of family contacts by Rodríguez-Iturbe et al.[12] demonstrated that asymptomatic cases of APSGN are four times more common than symptomatic cases and that the attack rate in siblings was 37.8%.

CLINICAL MANIFESTATIONS

The onset of clinical APSGN usually has a dramatic clinical presentation that occurs 7 to 14 days after pharyngotonsillitis and as long as 6 weeks following impetigo.[14] Scabies is often present in those manifesting pyoderma. Scarlet fever may be a manifesting feature of some cases.[11] The primary infection may remain undetected in some cases. Typical initial

Table 21.2 Clinical manifestations and laboratory findings of acute poststreptococcal glomerulonephritis in children

Clinical and laboratory findings	Berrios et al.[3] (%)	Ilyas and Tolaymat[6] (%)	Roy and Tapleton[5] (%)
Edema	100	78 (data derived)	83 (S) 82.6 (P)
Arterial hypertension	97	75 (data derived)	42.3 (S), 80.6 (P)

Mild/moderate	52	40	88.1 (S), 91.7 (P)
Severe	0.5	Not reported	Not reported
Chest x-ray: Pulmonary edema	Not reported	50	Not reported

Abbreviations: P, pyoderma-associated acute poststreptococcal glomerulonephritis (APSGN); S, sore throat–associated APSGN; ASO, anti-streptolysin O.

manifestations of APSGN consist of a combination of gross hematuria, oliguria, hypertension, mild lower extremity, periorbital edema, and a modest impairment in the renal function (Table 21.2). Dull abdominal pain or flank pain and malaise may be present. Mild fever can be seen in approximately half of the patients, often attributed to an underlying tonsillopharyngitis, and hepatomegaly may be noted in some.[6] As shown in Figure 21.1, gross hematuria may last for a few weeks, but microscopic hematuria in APSGN can

persist for several months to a year in some patients. Proteinuria in APSGN is short-lived and disappears in 4 to 6 weeks. Persistence of proteinuria should raise suspicion about the diagnosis and may be an indication for a renal biopsy in these patients.

Painless gross hematuria with brownish (the color of cola or tea) discoloration of urine is present in up to 50% to 90% of the patients and may be the only manifestation at presentation.[2,3,5,6,15] Significant leukocyturia may be seen in some patients with APSGN. Proteinuria is common (25% to 75%), and frank nephrotic syndrome is seen in 3% to 27%.[3,5,15] Oliguria and edema are observed in 80% to 100%, and pulmonary edema secondary to fluid overload may be seen on chest radiographs (Figure 21.2) in approximately half of patients.[3,6,10] Azotemia with modest elevation of serum creatinine is noted in 40% to 80% of patients on presentation, and severe azotemia requiring dialysis occurs in fewer than 1% cases.[3,5,6,15] Occasionally, a quickly rising serum creatinine level may represent transition to a crescentic form of glomerulonephritis.[16] Characteristically, serum C3 level is very low, often 20% of normal, in patients with APSGN.

KEY POINTS

- Edema, hematuria (cola-colored urine), and hypertension are the characteristic manifestations of APSGN.
- Pulmonary edema may be seen in up to 50% cases on chest radiograph.
- Leukocyturia, with a positive test for leukocyte esterase, may be present.
- Azotemia, proteinuria, and severely low complement C3 level are characteristic of APSGN.
Figure 21.1 Time course of clinical manifestations of acute poststreptococcal glomerulonephritis.
Figure 21.2 Chest radiograph of a patient with poststreptococcal glomerulonephritis showing pulmonary edema.

Hypertension is an almost a universal finding in patients with clinical APSGN, being present in 80% to 90% cases.[3,5,6,15] Occasionally, patients may present with severe hypertension and hypertensive encephalopathy as the only manifestation of APSGN.[17] Radiographically defined posterior reversible encephalopathy syndrome (PRES) has been reported as a presenting manifestation in patients with APSGN.[18] Magnetic resonance imaging findings of multiple abnormal foci of increased density in white and gray matter suggestive of a vasculitic lesion have also been reported in some patients with APSGN.[19] Whether these patients had PRES rather than true vasculitis is unclear.

PATHOLOGY

A diagnostic renal biopsy is generally not necessary in children suspected to have APSGN. Adults, on the other hand, may have APIGN as a result of infective agents other than GBS and renal biopsies are generally recommended.[20] Light microscopy in the acute phase of APSGN shows diffuse endocapillary cell proliferation and narrowing of the glomerular capillary lumens (Figure 21.3A).[15,20,21] Infiltration of the glomeruli with neutrophils and monocytes is a characteristic finding in early biopsies, but monocytes may be more abundant in later stages of APSGN.[15] Glomerular crescents and a clinical presentation of rapidly progressive glomerulonephritis (RPGN) can be seen rarely in patients with APSGN.[22]

Immunofluorescence microscopy reveals coarsely granular staining of the capillary loops with IgG and complement C3. The presence of IgM and IgA is variable.[14] Three distinct immunofluorescence patterns, symbolizing the nature of immune deposits visualized in the glomeruli, described by Sorger et al.[23] are starry sky (generalized distribution), tree stalk (mesangial), and garland (capillary wall). The starry sky pattern denotes IgG, IgM, and IgA, combined with C3 deposition in the endocapillary-mesangial distribution.
(a)
(b)

Figure 21.3 Acute poststreptococcal glomerulonephritis. **(a)** Light micrograph showing a glomerulus with endocapillary proliferation in a patient with acute poststreptococcal glomerulonephritis. Glomerular capillaries are obliterated in many areas as a result of endothelial cell swelling. Numerous neutrophils (arrows) are noted in the glomerulus. **(b)** Electron micrograph showing a characteristic large subepithelial deposit or "hump" (arrow) in a patient with poststreptococcal glomerulonephritis. (Photomicrographs courtesy of Dr. Randall Craver, Louisiana State University.)

This pattern is usually seen in the early phase of the disease—within the first few weeks. The tree stalk, or mesangial pattern, consists mainly of C3 deposition along the mesangium. The garland type of immune deposits may be more characteristic of patients with heavy subepithelial immune deposits, often associated with severe proteinuria.[23] After the acute phase, mesangial hypercellularity with positive immunofluorescence may persist for months to years, despite clinical recovery.[21]

KEY POINTS

- Renal biopsy is not necessary in the diagnosis of APSGN in children.
- Severe endocapillary proliferation and narrowing of glomerular capillary lumens are characteristic.
- Distinct immunofluorescence patterns with IgG and C3 deposition are seen along the glomerular capillary wall.
- "Humps" of electron-dense deposits in subepithelial location are characteristic of APSGN.

The hallmark of APSGN is electron microscopy finding of large subepithelial deposits (humps), believed to be immune complexes (see Figure 21.3B). Electron-dense deposits can sometimes be noted in the subendothelial or even intramembranous regions.[24] Subepithelial electron-dense deposits are also seen in membranous glomerulopathy, which is distinguished from APSGN by lack of any glomerular endocapillary proliferation and inflammatory infiltrate.

PATHOGENESIS

Infection by GAS elicits an antibody response in most patients, and in some it leads to the development of non-suppurative complication, such as acute rheumatic fever or APSGN. Epidemiologic data suggest that the clinically affected patients of APSGN are outnumbered by those who are asymptomatic, by a ratio of 1:4. Therefore, not all infected patients develop clinical disease, suggesting that apart from the bacterial virulence and nephritogenicity, host factors may be equally important in the pathogenesis of APSGN. The last two decades have produced some of the groundbreaking information about our understanding of the nephritogenicity of GBS and pathogenesis of APSGN.

NEPHRITOGENICITY OF STREPTOCOCCI

Most cases of APSGN are associated with group A streptococcal infections, although epidemics with group C streptococci have been reported.[25] Zoonotic infection involving an equine source of streptococcus also has been reported, less commonly.[26] The glomerular inflammatory lesions in APSGN, are believed to result from the host immune response to the preceding streptococcal infection. Not all strains of streptococci result in APSGN, and the causative organisms are referred to as nephritogenic strains. Lancefield M serotypes 1, 2, 3, 4, 12, 18, and 25 are most commonly seen with pharyngitis-associated APSGN, whereas serotypes 2, 49, 55, 57, and 60 are commonly encountered with skin infection–associated APSGN.[27] GAS that cause pharyngotonsillitis and pyoderma can also be typed using characteristics of the *emm* gene sub-family in their chromosomes.[28]

KEY POINTS

- Not all strains of GAS cause nephritis.
- Strains causing APSGN are referred to as *nephritogenic strains*.
- Nephritogenic GAS strains do not cause rheumatic fever.

NEPHRITOGENIC ANTIGENS

In the past, the streptococcal M antigen has been considered as the primary nephritogenic antigen involved in the glomerular inflammatory response in APSGN.[29] Newer evidence, however, does not support the relevance of M antigen as a nephritogenic antigen.[30] Elegant studies done in the last two decades have focused on two separate antigens that may be associated with the nephritogenic potential of the streptococci. Evolving consensus suggests that both antigens may be involved in the pathogenesis of APSGN. These two streptococcal antigens are nephritis-associated plasmin receptor (NAPlr) and streptococcal pyrogenic exotoxin B (SpeB). Once deposited in the glomerular structures, both of these antigens induce complement activation, promote glomerular tissue injury, and induce chemoattractants and inflammatory response in the mesangial and endocapillary sites.[31]

KEY POINTS

- Streptococcal M antigen is not considered to be the nephritogenic antigen.
- NAPlr and SpeB streptococcal antigens are involved in the pathogenesis of APSGN.

Nephritis-associated plasmin receptor

Yoshizawa et al. isolated a 43-kDa protein from GSA, which they designated as NAPlr.[32–34] NAPlr is highly similar to previously reported streptococcus plasmin(ogen) receptor Plr, or glyceraldehyde-3-phosphate dehydrogenase (GAPDH). NAPlr induces an antibody response in the infected host, which has been well documented in patients with APSGN. NAPlr has been shown to be localized to the endothelial aspect of the GBM and the mesangium in the glomeruli.[33] This localization has been noted in 100% of APSGN patients within 2 weeks of onset of the disease and disappears beyond 90 days. Also, the anti-NAPlr antibodies persist in the host for a prolonged period and can be detected at lower levels for as long as 10 years after the onset of APSGN. The NAPlr antigen is restricted by the GBM because of its anionic charge.

In APSGN, NAPlr binds to the plasmin and prevents its breakdown in the glomerular tissues, which results in local tissue injury. Plasmin is known to have multiple physiologic roles, which include fibrinolysis, extracellular matrix turnover, cell migration, wound healing, angiogenesis, and activation of metalloproteins.[34] Plasmin-induced glomerular tissue damage may be mediated by degrading extracellular matrix proteins, such as fibronectin or laminin. The proposed net effect of these interactions is damage to the GBM.[32–34] Yoshizawa's investigative group proposed that NAPlr bound to plasmin also encourages endocapillary and mesangial proliferation and inflammatory response in APSGN (Figure 21.4).[34] Additionally, impaired GBM permeability might allow the NAPlr to transgress from the endothelial aspect of the GBM into the subepithelial space, where it may bind with the anti-NAPlr antibody to give rise to *in situ* immune complex formation. Alternatively, immune complexes of NAPlr and anti-NAPlr antibody could be preformed on the endothelial side and then migrate to the subepithelial area, where they form the humps seen in the renal biopsy of patients with APSGN.

Pyrogenic exotoxin B

SpeB is a cationic extracellular cysteine proteinase generated by proteolysis of a zymogen precursor (zSpeB) and is produced by the nephritogenic GAS.[35–37] As with NAPlr, SpeB has been demonstrated to be present in the biopsy samples of patients with APSGN, and high titers of antibodies to SpeB are seen in sera of APSGN patients during convalescence. Another feature that SpeB shares with NAPlr is that it also acts as a plasmin-binding receptor, can activate metalloproteinases, and can degrade human fibronectin.[38] In contrast to NAPlr, SpeB is a cationic antigen and has the potential to move across the intact anionically charged GBM. Indeed, SpeB is the only streptococcal antigen that has been documented to be co-deposited with IgG and complement C3 in the subepithelial humps that are the hallmark of APSGN.[38]

CIRCULATING IMMUNE COMPLEX FORMATION

The role of circulating immune complexes in the pathogenesis of APSGN is controversial. In the 1960s and 1970s, the presence of glomerular immune complexes was considered to be the evidence for "trapped" circulating antigen-antibody complexes in APSGN. The experimental correlate cited for this pathogenetic mechanism was the serum sickness model of acute glomerulonephritis induced in rabbits by a single injection of bovine serum albumin.[39,40] This experimental model is also characterized
Figure 21.4 Illustrative patterns of complement C3 immunofluorescence observed in renal biopsy samples from patients with postinfectious glomerulonephritis. **(a)** Mesangial pattern: Mesangial C3 deposits are present, particularly toward the axial region of the glomerulus. **(b)** Garland or capillary wall pattern: Heavy C3 deposits are present along the glomerular basement membrane (GBM). **(c)** Starry sky or diffuse pattern: Many small deposits of C3 are present along the GBM and in the mesangium. by self-limited acute proliferative glomerulonephritis characterized by complement and IgG deposition, and hypocomplementemia.

Presence of circulating immune complexes in APSGN has been documented in several older reports.[41–43] In a year-long study of 30 children with APSGN from Taiwan, Lin[43] reported a high level of circulating immune complexes, using Raji cell radioimmune assay.[43] Circulating immune complexes were noted to be highest in the first 3 days after the onset of gross hematuria, and the levels gradually returned to baseline normal by 9 months. Some evidence to suggest that these circulating immune complexes contain streptococcal antigens has been presented, but these findings have not been verified or explored further with more direct techniques, or any of the more modern investigative techniques.[44] Evidence supporting the involvement of circulating immune complexes in APSGN with the newly discovered nephritogenic streptococcal antigens (NAPlr and SpeB) has yet to be presented convincingly.

COMPLEMENT ACTIVATION

Hypocomplementemia and profoundly low levels of complement C3 are common findings in APSGN.[45] Complement C4 level, on the other hand, is generally normal. The immune complexes in renal biopsy samples of patients with APSGN also demonstrate complement C3, along with C5b-9 membrane attack complex and IgG in them.[46] Deposition of early classic complement pathway components (C4 and C1q) is generally lacking.[47] These findings largely suggest that alternative complement activation pathway is likely to be involved in APSGN. However, Wyatt et al.[45] presented some evidence of classic pathway involvement in patients with APSGN, despite normal serum C4 level. Hisano et al.[47] provided evidence for activation of both the alternative pathway and lectin pathway in the biopsies of patients with APSGN.

KEY POINTS

- Complement activation is the hallmark of APSGN.
- Alternative complement pathway is the predominant pathway for complement activation in APSGN.
- Lectin pathway may be involved in some.

Host susceptibility factors

Host susceptibility and disease-modifying factors for APSGN are not fully understood. Increased frequency of HLA-DRW4 and HLA-DRB1*3011 has been reported in APSGN patients,[48,49] Whether this represents a true susceptibility to APSGN in these patients remains unclear. Similarly, a higher prevalence of eNOS4a (eNOS4a/a and eNOS4a/b) genotype has been noted in patients with APSGN, compared to healthy controls.[50] These findings suggest that "aa" and "ab" genotypes or "a" allele of eNOS4 have a greater likelihood of developing APSGN.

KEY POINT

Host susceptibility factors remain unclear but may be important in the pathogenesis of APSGN.

Final pathways of glomerular inflammation and injury

Irrespective of initiating streptococcal antigen, the final common pathway of setting up glomerular inflammation and injury in APSGN is likely to be multifaceted (Figure 21.5).[20] These pathogenetic complement-activating mechanisms include a combination of (1) glomerular in situ immune complex formation by antibodies directed against planted cationic bacterial antigens, such as SpeB, (2) entrapment of circulating bacterial antigen-antibody immune complexes; (3) deposition of bacterial antigens, such as NAPlr, that bind to plasminogen, inducing local tissue injury, (Figure 21.6). Once the complement activation and plasmin-induced local tissue injury are initiated, multiple chemoattractants in the glomerular space promote inflammation and injury.[20,34] Host response and susceptibility characteristics may modify the inflammatory response, injury, and clinical manifestation of APSGN.

EDEMA AND HYPERTENSION

Fluid overload is frequently present in APSGN, even in a mild disease. It is mostly the consequence of inappropriate tubular sodium (Na) reabsorption, not the result of reduced GFR. Proximal tubular avidity for Na during the acute phase of APSGN has been well described.[51] Fractional excretion of Na (FeNa) of 0.5 or less is common in APSGN, especially in patients developing hypertension.[52,53] These observations indicate that enhanced tubular Na absorption underlies the development of fluid overload and hypertension in these patients.[52] Plasma renin activity has been reported to be low or normal in the early phase of APSGN, perhaps reflecting a state of plasma volume expansion in these patients.[53,54]

KEY POINTS

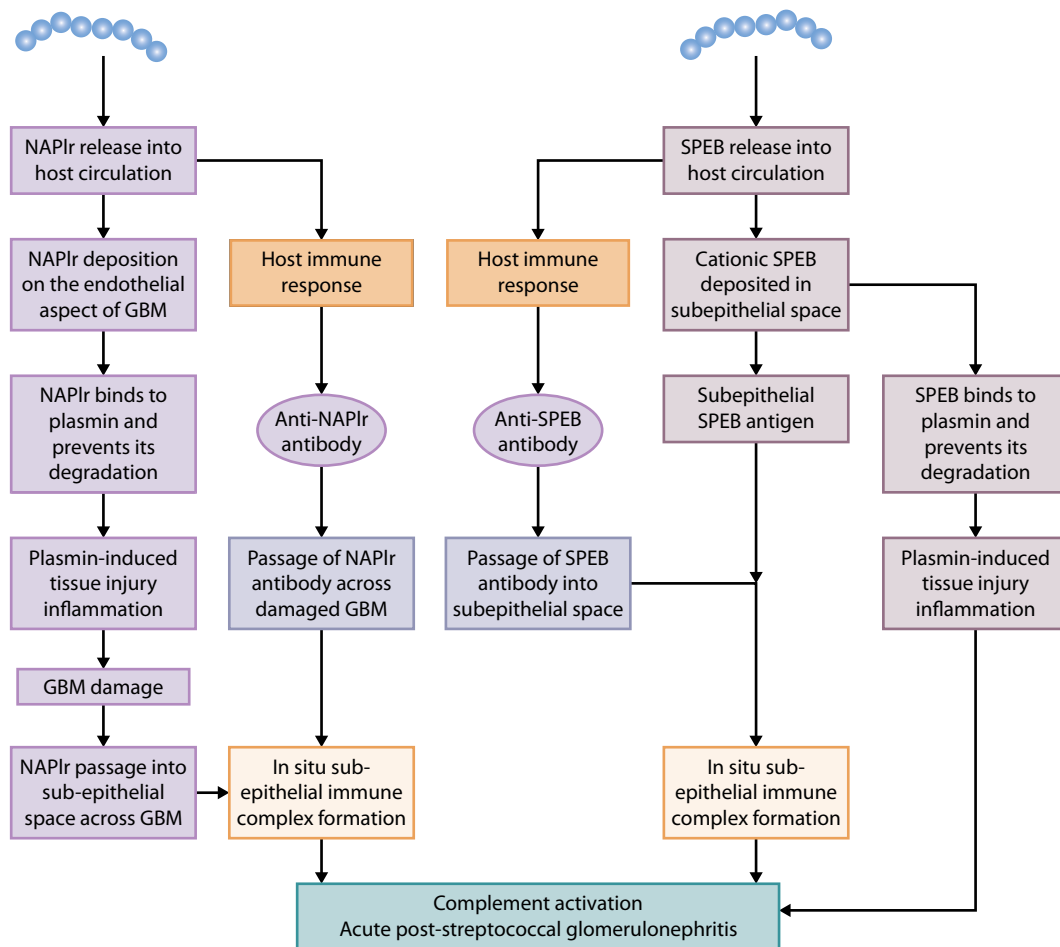
- ASPGN is characterized by increased tubular Na reabsorption, fluid retention, and a low FeNa.
- Plasma renin activity is low to normal.


Figure 21.5 Mechanisms through which streptococcal antigens, nephritis-associated plasmin receptor (NAPlr) and strepto-coccal pyrogenic exotoxin B (SpeB), induce glomerular injury in acute poststreptococcal glomerulonephritis. Both antigens induce a host antibody response, which leads to in situ immune complex deposition. NAPlr also induces endocapillary inflammation and injury by binding to plasmin. SpeB being cationic in charge can also directly move into the subepithelial location to form in situ immune complexes. In contrast, because NAPlr is anionic in charge, it requires glomerular basement membrane (GBM) permeability to change via plasmin-induced injury to transgress into the subepithelial sites. Concepts based on data in references 33, 34, 37, and 48.

DIFFERENTIAL DIAGNOSIS

Several renal diseases may mimic clinical manifestations of of ASPGN. These include other immune complex glomer-ulonephritides such as IgA nephritis, nephritis associated with systemic lupus nephritis (SLE), membranoprolifera-tive glomerulonephritis (MPGN), and Henoch-Schönlein nephritis. IgA nephritis, in particular, is easy to misdiag-nose as APSGN because of the presentation of gross hema-turia with respiratory infection. However, gross hematuria in IgA nephropathy occurs within 24 to 48 hours of onset of upper respiratory tract infection (usually viral) and is often referred to as *synpharyngitic* hematuria. Clinical and labo-ratory features distinguishing APSGN and IgA nephropa-thy are listed in Table 21.3.

Nephritis may be the first sign of SLE, sometimes even before extrarenal manifestations appear. Presence of hypo-complementemia in SLE nephritis can further complicate the clinical distinction between the two clinical disor-ders. However, presence of antinuclear antibody and anti–double-stranded DNA antibody in SLE can be a diagnostic differentiation of SLE from APSGN. MPGN can manifest with clinical features similar to those of APSGN, includ-ing gross hematuria, edema, increased serum creatinine, hypertension, and presence of hypocomplementemia. However, the clinical course of APSGN is one of progres-sive improvement in contrast to that of MPGN, which is characterized by progressive worsening of proteinuria, nephrotic syndrome, edema, and presence of severe hyper-tension. A renal biopsy is eventually necessary to clinch the diagnosis.

Table 21.3 Clinical and laboratory features distinguishing acute nephritic syndromes of immunoglobulin A nephropathy and acute poststreptococcal glomerulonephritis

Clinical and laboratory findings	APSGN	IgA nephropathy
Latent period from URI to onset of gross hematuria	10-14 days. Longer with pyoderma	Synpharyngitic association: Within 48 hours of onset of URI
Oliguria	Common	Not common
Increased serum creatinine	Common	Not common
Edema	Present	Absent
Hypertension	Present	Usually absent
Group A streptococcal infection	Positive bacteriologic evidence	Usually negative, often viral
Serologic evidence for streptococcal infection	Positive	Negative
Serum complement C3	Low, recovers by 6-8 wk	Normal

DIAGNOSIS OF ACUTE POSTSTREPTOCOCCAL GLOMERULONEPHRITIS

Patient history

Streptococcal pharyngitis typically precedes the development of gross hematuria and other symptoms of APSGN by 7 to 14 days. In temperate climates, a history of recent skin infection should be ascertained; this may have occurred several weeks before the onset of nephritis. In addition, any infectious disease during the preceding month should be recorded (see Table 21.1), as well as infections in family members and other daily contacts.

Throat culture

Throat culture for GAS should be obtained, even though positive findings may not be always present by the time of the patient's presentation. It should also be recognized that up to 20% of healthy individuals are streptococcal carriers.[55,56]

Streptococcal antibody titers

Streptolysin O is a toxin secreted by the streptococcus, which is present in all streptococci, but its gene expression varies.[57] Anti–streptolysin O (ASO) antibody titer is elevated in patients with recent streptococcal infection, but a preferred method is to demonstrate a rising titer of the serum ASO antibody at an interval of 2 weeks. Other antigens against which host antibody titer can be measured as evidence of recent streptococcal infection include anti-DNase B and antihyaluronidase antibodies.

The streptozyme panel, which includes antibodies against five streptococcal antigens, is a more sensitive test than the commonly used ASO titer. ASO antibody titer tends to be higher in APSGN associated with tonsillitis or pharyngitis, whereas in impetigo-associated disease the anti-DNase B antibody or antihyaluronidase antibody (included in the streptozyme panel) is more consistently positive, even in the absence of elevated ASO titer.[57–59] In acute glomerular nephritis secondary to nonstreptococcal infections, specific antibody titers should be obtained, when possible.

Complement studies

Low complement C3 is central in the diagnosis of APSGN. Typically, it is markedly decreased (less than 40 mg/dL) from the very onset of the disease and normalizes in 2 to 8 weeks.[45,60,61] Persistence of low complement C3 beyond 8 weeks likely indicates a diagnosis other than APSGN. Approximately 15% of patients with APSGN do not demonstrate a low C3 level, perhaps reflecting a transient complement utilization and rapid recovery in these patients.[61] Complement C4 levels, in contrast, are normal in most patients with APSGN, but can be transiently low in some patients, especially in the first 1 to 2 weeks.[61] Apart from APSGN, low complement C3 is also seen in SLE and MPGN (Table 21.4). Some

Table 21.4 Acute glomerulonephritis associated with C3 hypocomplementemia

- Acute poststreptococcal glomerulonephritis
- Membranoproliferative glomerulonephritis
- Nephritis associated with systemic lupus erythematosus
- Glomerulonephritis associated with subacute bacterial endocarditis
- Glomerulonephritis associated with ventriculoatrial shunt infection

patients with atypical APSGN may exhibit persistent urinary abnormalities, along with abnormalities of complement C3 and C4. Some of these patients may have inherited abnormalities of complement-regulating proteins and persistent activation of alternative complement pathway.[62]

RENAL BIOPSY

A diagnostic renal biopsy is not necessary in most typical cases of APSGN. An exception is a rapid deterioration of renal function, raising a suspicion of MPGN, SLE-associated nephritis, rapidly progressive glomerulonephritis, and IgA nephropathy. Persistently low complement C3 beyond 8 weeks, or prolonged proteinuria also indicate a need for tissue diagnosis in order to rule out chronic glomerulonephritis, such as MPGN or C3-associated nephropathy.

Table 21.4 presents a two-step approach to the diagnosis of acute glomerulonephritis. If the clinical presentation is strongly suggestive of APSGN, the first step may confirm the diagnosis and render the second step unnecessary. If APSGN appears unlikely, or is ruled out by the initial laboratory result, a more extended evaluation, possibly including renal biopsy, will be necessary.

Table 21.5 Evaluation of acute nephritic syndrome

Initial evaluation when APSGN is strongly suspected
- Urinalysis and urine microscopy
- Blood count (rule out hemolytic-uremic syndrome)
- Blood urea nitrogen, creatinine, electrolytes, serum albumin
- Quantify proteinuria (urine protein:creatinine ratio)
- Throat culture
- Culture of skin infections
- Streptococcal antibody titers (ASO, antihyaluronidase, antistreptokinase, anti-NAD, anti-DNase B)
- Complement C3, C4
- Chest radiograph to rule out pulmonary edema

Further evaluation of acute nephritis if APSGN not present or is unlikely
- Hepatitis B panel, hepatitis C titer
- HIV-1 antibody
- ANA (full lupus panel if ANA is positive)
- ANCA
- Anti-GBM antibody titer
- Renal biopsy as indicated

Abbreviations: ANA, anti-nuclear antibody; ANCA, anti-neutrophil cytoplasmic antibody; ASO, anti–streptolysin O; GBM, glomerular basement membrane; HIV, human immunodeficiency virus,

MANAGEMENT

SUPPORTIVE THERAPY

The mainstay of treatment of APIGN consists of supportive therapy. Children without volume expansion, hypertension, electrolyte problems, or decreased kidney function need only close follow-up. Patients who develop moderate-to-severe hypertension, renal impairment, or hyperkalemia generally require hospitalization for monitoring fluid and electrolyte balance as well as for managing hypertension.

ANTIBIOTICS

Antibiotic treatment after the onset of APSGN does not alter the course of the disease. In epidemics, antibiotic prophylaxis given to family members may reduce the risk for spread of APSGN.[3,5,63] During epidemics of GAS infection, universal penicillin prophylaxis to all children has been shown to prevent transmission of nephritogenic strains of GAS and protect against glomerulonephritis.[64–66] Routine prophylaxis of general population and outside the household contacts, however, is not recommended.

In a large-scale prospective study, treatment of 4782 patients with culture-proved GAS tonsillopharyngitis, treatment with oral penicillin V resulted in GSA eradication rate of 84%.[67] APSGN sequelae occurred in only five (0.1%) of the treated patients in this study, reaffirming that appropriate and timely treatment of GAS infection prevents development of APSGN.

FLUID OVERLOAD AND HYPERTENSION

When present, hypertension is the result of sodium retention and volume expansion. Therefore, treatment is directed at sodium restriction and diuretic therapy, in addition to antihypertensive medication, if necessary. The combination of a loop or thiazide diuretic with a calcium channel blocker is usually effective. Caution should be exercised with the use of angiotensin-converting enzyme inhibitors or angiotensin receptor blockers because of the risk for hyperkalemia or acute kidney injury. Interestingly, in two studies the use of captopril was noted to be therapeutically efficient in reducing blood pressure without any significant change in renal function.[68,79] Serum potassium was, unfortunately, not monitored in these studies.

HYPERKALEMIA

Hyperkalemia is commonly seen in patients with APSGN, especially if renal function is compromised and daily intake of potassium remains unchecked. Hyporeninemic hypoaldosteronism seen in patients with APSGN has
Figure 21.6 The putative nephritogenic bacterial antigens in acute postinfectious glomerulonephritis (APSGN) cause glomerular injury through multiple potential mechanisms that include the following: **(1)** passive glomerular entrapment of circulating bacterial antigen-antibody immune complexes; **(2)** glomerular in situ immune complex (IC) formation by antibodies directed against planted cationic bacterial antigens or intrinsic glomerular antigens via molecular mimicry; and **(3)** glomerular in situ localization of circulating cationic bacterial antigens without immunoglobulin, potentially promoting plasmin activation in the mesangium and glomerular basement. Any combination of these mechanisms may act in concert and initiate complement cascade activation via the alternative and lectin pathways. The resultant complement activation in glomeruli leads to the generation of chemotactins C3a and C5a, recruitment of neutrophils and monocytes, and leukocyte-mediated injury. In addition, locally activated plasmin degrades the glomerular basement membrane directly or through the activation of metalloproteinases and may promote inflammation. Predisposing host factors such as genetic susceptibility and dysregulation of the alternative complement pathway may contribute to pathogenesis. *GAPDH,* glyceraldehyde-3-phosphate dehydrogenase; *NAPlr,* nephritis-associated plasmin receptor; *SpeB,* streptococcal pyrogenic exotoxin B. (Reproduced with permission from: Nasr SH, Radhakrishnan J, D'Agati VD. Bacterial infection-related glomerulonephritis in adults. Kidney Int. 2013;83:792–803.

been suggested to be the cause of hyperkalemia in these patients.[70] Mildly elevated serum potassium level can be treated with restriction of potassium intake in the diet, and use of potassium exchange resin sodium polystyrene sulfonate (Kayexalate®) orally. Severe hyperkalemia should be treated as an emergency using an inhaled β_2-adrenergic stimulant salbutamol, intravenous bicarbonate, intravenous glucose and insulin, or calcium carbonate, as appropriate. Salbutamol inhalation can provide a quick response (30 minutes) and lower serum potassium to a more manageable level, and its effect can last up to 2 hours.[71] Rare cases of life-threatening or symptomatic hyperkalemia require treatment with dialysis, in conjunction with pharmacologic therapy.

Dialysis

In addition to treating hyperkalemia, hemodialysis or continuous venovenous hemofiltration may be necessary to treat severe cases of uremia or volume overload, especially if diuretic-unresponsive anuria or oliguria is present. Most patients requiring dialysis support for management of fluid overload, hyperkalemia, and uremia in APSGN have severe renal disease with crescentic renal pathology.[72]

TREATMENT OF CRESCENTIC ACUTE POSTSTREPTOCOCCAL GLOMERULONEPHRITIS

A rapidly progressive clinical course with crescents in the renal biopsy represents therapeutic challenges, such as fluid overload, hypertension, hyperkalemia, and potential for long-term renal damage. Apart from supportive management, there are no clear, evidence-based, and well-accepted guidelines for treatment of such patients. Treatment with quadruple therapy consisting of prednisone, azathioprine, cyclophosphamide, dipyridamole, and heparin was not shown to be superior to supportive therapy alone in a study by Roy et al.[73] In another nonrandomized study of crescentic APSGN, steroids, with or without cyclophosphamide, did not provide any convincing therapeutic advantage.[23]

CLINICAL COURSE AND PROGNOSIS

The acute morbidity of ASPGN is well known and clinically challenging in some patients.[77] However, several long-term studies in children have documented an excellent long-term outcome in a majority of patients with this disease.[74–76] Potter et al.[74] followed 760 patients, of whom 41 were adults, for 2 to 6 years after onset of APSGN. Of these, only 1.8% patients had persistent urinary abnormalities and only one patient had developed chronic kidney disease (CKD) . In half of the patients, urinary abnormalities disappeared on their own in the following 2 years of observation. Hypertension was present in only 1.4% patients.

Clark et al.[75] prospectively followed a cohort of 36 children with biopsy-proven APSGN between 1962 and 1970. After a mean follow-up of 9.5 years (range, 5.4 to 12.4 years), although minor urinary abnormalities were noted in 20% cases, no one developed CKD and hypertension was noted in only one patient, who also had history of recurrent pyelonephritis. Similarly, Popović-Rolović et al.[76] found hypertension in 3.4%, proteinuria in 2.3%, and microhematuria in 2.3% of APSGN patients after follow-up of 10 to 17 years.

Prognosis of APSGN in adults has been reported to be less optimistic compared to that in children. Lien et al.[77] followed 57 adult patients with APSGN for a period of 1 to 14 years (mean, 7 years). Of these, 5 patients died, 2 with CKD. Glomerular obsolescence was noted on repeat renal biopsy in 3 of the 11 patients who underwent biopsy for evidence of ongoing proteinuria, hematuria, or abnormal renal function. Chugh et al.[78] reported that of the 192 patients (142 adults and 51 children) followed in India up to 10 years (mean, 4.8 years), 10 patients developed CKD or end-stage renal disease (ESRD). Hypertension was noted in 15% of patients during follow-up. Similarly, Srisawat et al.[79] noted that 14% of their patients with APIGN developed ESRD, none had APSGN, and all had other infective causes for acute glomerulonephritis. In summary, adults with APSGN need to be followed more closely and for a longer time than children.

SUMMARY

Despite a decrease in the incidence, APSGN is still one of the most common kidney diseases in children. The disease is relatively benign in most children, but it can have considerable early morbidity in some, such as hypertensive encephalopathy and hyperkalemia. In most cases, the diagnosis is easily made and treatment consists of supportive measures. Full recovery is expected in most children. Atypical cases may present diagnostic challenges and severe cases require a renal biopsy. Improving overcrowding and poor living conditions can reduce the burden of the disease worldwide.

Clinical Vignette 21.1

A 10-year-old African-American boy presented to the emergency department with the complaints of passing dark brown urine and swelling around his eyes since waking up the same morning. On further questioning, the patient reported having a slight sore throat within the previous month but a throat culture was not obtained. He denied any such previous illness.

His physical examination revealed moderate periorbital and pretibial edema and a few bilateral basal

pulmonary crackles. His blood pressure was 150/102 mm Hg. Laboratory evaluation demonstrated normal CBC; serum sodium, 138 mmol/L; potassium, 5.2 mmol/L; chloride, 106 mmol/L; bicarbonate, 18 mmol/L; blood urea nitrogen (BUN), 20 mg/dL, creatinine, 1.7 mg/dL; and urine with 3+ and 2+ protein. The patient was admitted to hospital for treatment of his hypertension and further diagnostic evaluation.

The patient's hypertension responded to intravenous furosemide and oral calcium channel blocker (amlodipine) therapy. The day after admission his blood pressure was 128/80 mm Hg; serum creatinine, 1.5 mg/dL; BUN, 35 mg/dL; and electrolytes within normal limits. The ASO titer was positive at 1:400 (international units/mL), and his complement C3 level was low at 30 mg/dL (normal is greater than 90 mg/dL). The antinuclear antibody (ANA) test was negative and throat culture was negative for GAS. Based on the clinical presentation and laboratory results, the diagnosis of APSGN was made. On the third day, his serum creatinine was 1 mg/dL. He was discharged from the hospital the following day on oral amlodipine therapy. Antibiotics were not prescribed in view of negative throat culture results.

At a follow-up appointment 1 week after discharge, a serum creatinine was 0.7 mg/dL. Four weeks later the patient's basic metabolic panel and serum C3 level were normal, and urinalysis shows microscopic hematuria only. His blood pressure in the outpatient clinic was 96/66 mm Hg, and his amlodipine therapy was discontinued.

TEACHING POINTS

- The apparent short duration of illness and decreased renal function point toward acute disease such as APSGN, rapidly progressive glomerulitis, or an exacerbation of a previously undiagnosed chronic glomerulonephritis, such as IgA nephropathy and MPGN. Absence of signs of systemic disease makes generalized vasculitis unlikely.
- The presence of proteinuria, hematuria, hypertension, azotemia, and low C3 points to three possibilities: APSGN, MPGN, and nephritis of SLE. A negative ANA suggests that the patient is unlikely to have SLE nephritis. A declining serum creatinine was shown on day 2; although this is a positive development, the possibility of MPGN could not be ruled out in that time frame. However, further decline of serum creatinine on day 3 made the diagnosis of APSGN more likely.
- Had the serum creatinine continued to rise, MPGN would have been the more likely diagnosis at that time and he would have needed a diagnostic renal biopsy.
- Treatment of this patient was mainly directed at control of his blood pressure, and a combination of diuretics and calcium channel blockers was sufficient to normalize it.

- Antibiotics were not prescribed for this patient because throat culture was negative for GAS. If the throat culture would have been positive, oral antibiotics would have been appropriate from a public health perspective to eradicate the infection in this patient and prevent its transmission to others in his circle of contacts.
- The parents of this child should be informed that he may continue to have microscopic hematuria for a number of months, even though he has no active renal disease. His overall prognosis should be excellent.

REVIEW QUESTIONS

1. The typical "deposits" in acute poststreptococcal glomerulonephritis seen by electron microscopy are in which of the following locations?
   a. Mesangial
   b. Subendothelial
   c. Subepithelial
   d. Intramembranous

2. Typical glomerular anti-IgG immunofluorescence in acute poststreptococcal glomerulonephritis shows which of the following patterns?
   a. Linear along capillary loops
   b. Granular along capillary loops
   c. Granular in mesangium
   d. No immunofluorescence

3. Acute postinfectious glomerulonephritis most commonly follows infection by which of the following organisms?
   a. Group A β-hemolytic streptococcus
   b. Group B β-hemolytic streptococcus
   c. Group C β-hemolytic streptococcus
   d. Group C streptococcus

4. Which of the following is true regarding scabies-associated acute postinfectious glomerulonephritis?
   a. The latent period is longer than in tonsillitis-associated disease.
   b. It is usually not caused by group A β-hemolytic streptococcus.
   c. Complement C3 is typically not decreased.
   d. An antigen from *Sarcoptes scabiei* is present in the glomeruli.

5. Which of the following statements is true regarding the epidemiology of acute poststreptococcal glomerulonephritis?
   a. It is more common in affluent societies.
   b. During epidemics, subclinical disease is more common than symptomatic disease.
   c. Epidemics are usually caused by non–group A streptococci.
   d. Antibiotic prophylaxis is not effective.

6. A 9-year-old boy presents with symptomless gross hematuria. He has had a sore throat for 2 days. His basic metabolic panel is normal. Which of the following is the *most* helpful diagnostic test?
   a. Complement C3 level
   b. Complement C4 level
   c. Throat culture
   d. ASO titer

7. A 6-year-old girl has painless gross hematuria and puffy eyes. She denies any recent illness. Her BP is 139/76; BUN, 34 mg/dL; creatinine, 1.3 mg/dL; serum albumin, 2.9 g/dL; and complement, C3 23 mg/dL. Urine is positive for blood and protein. Which of the following is the *most* appropriate treatment?
   a. Amoxicillin
   b. Intravenous steroids
   c. Chlorothiazide or furosemide
   d. Observation only

8. A 9-year-old boy presents with puffy eyes and headache. He remembers having a recent sore throat. His BP is 150/90 mm Hg, and he has mild periorbital and pretibial edema. Blood urea nitrogen (BUN) is 30 mg/dL; creatinine, 1.3 mg/dL; and complement C3, 20 mg/dL. Intravenous nicardipine and furosemide are started to control his hypertension. The next day his metabolic panel shows sodium, 132 mmol/L; potassium, 4.8 mmol/L; chloride, 100 mmol/L; carbon dioxide, 20

mmol/L; BUN, 60 mg/dL; and creatinine, 3.2 mg/dL. Which of the following is the *most* appropriate next step?
   a. Hemodialysis
   b. Continuous venovenous hemofiltration
   c. Renal biopsy
   d. Intravenous steroid treatment
9. Hypertension in acute postinfectious glomerulonephritis is mainly due to which of the following?
   a. Activated sympathomimetic nervous system
   b. Decreased glomerular filtration rate
   c. Elevated plasma renin level secondary to nephritis
   d. Increased fluid volume expansion resulting from increased tubular sodium absorption

Rapidly progressive glomerulonephritis and vasculitis

FRANCA IOREMBER AND V. MATTI VEHASKARI

Rapidly progressive glomerulonephritis (RPGN) is a rare clinical disorder characterized by sudden and rapid deterioration of kidney function over days or weeks and by histologic findings of glomerular injury associated with extensive "crescent" formation. Glomerular crescents are cellular or fibrotic, crescent-shaped formations outside the glomerular capillary tuft in the Bowman space that ultimately result in global glomerular sclerosis. Some crescents may occasionally be seen in severe forms of glomerulonephritis, but in a stricter sense the term *crescentic glomerulonephritis* is used only when crescents affect more than 50% of the glomeruli in an adequate kidney biopsy.[1,2] This definition is arbitrary, however, and patients with a lesser degree of crescent formation may progress to full-blown RPGN. The diagnosis of RPGN must be made promptly because a delay in the initiation of therapy can lead to irreversible renal injury and loss of kidney function. The best predictors of outcome for all types of crescentic glomerulonephritis are the severity of kidney dysfunction at presentation and the initiation of therapy.[3,4] Another poor prognostic indicator is the severity of crescents present in the renal biopsy.[3–6]

CLASSIFICATION

RPGN is classified into three broad categories (Table 22.1) based on pathologic and immunopathologic features: (1) immune complex–mediated crescentic glomerulonephritis, (2) pauci-immune crescentic glomerulonephritis, and (3) anti–glomerular basement membrane (anti-GBM) antibody disease. As noted in Table 22.1, several specific diseases can result in RPGN and are classifiable into one of the three distinct categories.

Childhood RPGN is frequently caused by vasculitis, which includes immune complex–mediated disorders, such as Henoch-Schönlein purpura (HSP) nephritis and lupus nephritis, and all of the conditions included under the classification of pauci-immune RPGN.

KEY POINTS

Three types of RPGN are:

- Immune complex–mediated disease
- Pauci-immune disease
- Anti-GBM antibody disease

Consensus criteria for classification of vasculitides for the pediatric population were developed by the European League Against Rheumatism (EULAR) and the Pediatric Rheumatology European Society (PReS) in 2006.[7,8] This classification uses vessel size to categorize vasculitis into large-, medium-, and small-vessel

Table 22.1 Causes of rapidly progressive glomerulonephritis*

Immune Complex RPGN (45% of Pediatric Cases)
- Systemic vasculitis
  - HSP
  - SLE
- Isolated renal disease
  - IgA nephropathy
  - MPGN type 1 and 3
  - Dense deposit disease (DDD)
  - APIGN

Pauci-immune RPGN (42% of Pediatric Cases)
- ANCA-associated vasculitis (AAV)
  - Microscopic polyangiitis
  - Granulomatosis with polyangiitis (formerly Wegener granulomatosis)
  - Eosinophilic granulomatosis with polyangiitis (formerly Churg-Strauss syndrome)
  - Renal limited disease
  - Drug-induced disease
  - ANCA-negative vasculitis

Anti-GBM Antibody–Associated RPGN (12% of Pediatric Cases)
- Idiopathic (autoimmune anti-GBM antibodies)
- After renal transplantation in Alport syndrome
- Combined anti-GBM and ANCA

Abbreviations: AAV, ANCA-associated vasculitis; ANCA, anti–neutrophil cytoplasmic antibodies; APIGN, acute postinfectious glomerulonephritis; GBM, glomerular basement membrane; HSP, Henoch-Schönlein purpura; IgA, immunoglobulin A; MPGN, membranoproliferative glomerulonephritis; RPGN, rapidly progressive glomerulonephritis; SLE, systemic lupus erythematosus.

* Vasculitides not associated with RPGN are not included.

Table 22.2 Classification of pediatric vasculitis

Predominantly large-vessel disease
- Takayasu arteritis

Predominantly medium-vessel vasculitis
- Childhood polyarteritis nodosa
- Cutaneous polyarteritis
- Kawasaki disease

Predominantly small-vessel vasculitis
- a. Granulomatous
  - Granulomatosis with polyangiitis
  - Eosinophilic granulomatosis with polyangiitis
- b. Nongranulomatous
  - Microscopic polyangiitis
  - Henoch-Schönlein purpura
  - Isolated cutaneous leukocytoclastic vasculitis
  - Hypocomplementemic urticarial vasculitis

Other vasculitides
- Behçet disease
- Vasculitis secondary to infection (including hepatitis B associated–polyarteritis nodosa), malignant diseases, and drugs including hypersensitivity vasculitis)
- Vasculitis associated with connective tissue diseases
- Isolated vasculitis of the central nervous system
- Cogan syndrome
- Unclassified

diseases (Table 22.2). In general, RPGN largely results from small-vessel vasculitides. Most other forms of vasculitis are rarely, if ever, a cause of acute renal disease, with the exception of polyarteritis nodosa (PAN) and Kawasaki disease, both of which may manifest with renal disease that is histologically distinct from RPGN. PAN predominantly affects medium-sized blood vessels, causes necrotizing vasculitis, and often spares the glomeruli.[9,10] The major renal manifestation of Kawasaki disease is tubulointerstitial nephritis. This chapter discusses the clinical, pathologic, and management aspects of diseases that cause RPGN.

EPIDEMIOLOGY

RPGN is a rare disease in all populations, especially in children. Most incidence estimates come from biopsy materials. In a large study of 632 renal biopsies with crescentic glomerulonephritis, only 11.6% were pediatric cases.[3] Overall, pauci-immune crescentic glomerulonephritis was the predominant subtype in adults and made up 60% of the total number of cases. In children, the number of immune-complex mediated and pauci-immune RPGN were similar, each accounting for 45% and 42% of cases respectively. Anti-GBM disease comprised 12% of the total number of pediatric patients in this study. In another pediatric report of 33 cases of RPGN from India, immune complex–mediated crescentic glomerulonephritis accounted for 45.5%, whereas pauci-immune

KEY POINTS

- Most types of RPGN are caused by small-vessel vasculitides.
- Pauci-immune RPGN is more common in adults.
- In children, distribution of immune-complex mediated and pauci-immune RPGN is almost equal.
- Anti-GBM disease is rare in children.

disease comprised the remaining 54.5% cases.[11] RPGN affects more whites than African Americans in a ratio of 7:1, with no gender predilection.[3,12,13]

Whereas the overall incidence of all RPGN in the general population is unknown, the incidence of pauci-immune glomerulonephritis has been estimated at 4 per million.[14] The annual incidence of RPGN secondary to anti–neutrophil cytoplasmic antibody–associated vasculitis (AAV) in both European and North American populations is approximately 10 to 20/million, with a peak age of onset at 65 to 74 years.[13] In Japan, the annual incidence is reported to be as high as 22.6/million.[15] Available data suggest significant geographic differences among AAV subtypes. Data from Europe, India, and Japan have shown that granulomatosis with polyangiitis (GPA, formerly known as Wegener granulomatosis) is the most common subtype of AAV in Europe and India, whereas microscopic polyangiitis (MPA) predominates in Japan.[13,15–18] These regional differences may be explained by genetic and environmental risk factors.[19]

Available data estimate the annual incidence of anti-GBM disease at 1 case per million in the general population, and this disorder is even less common in children.[20–24] The peak age of incidence is in the third decade in young men, and a second peak, in the sixth and seventh decades, affects both sexes equally.[25]

PATHOGENESIS AND PATHOLOGY

Glomerular crescents are the hallmark in all forms of RPGN, crescents are the hallmark findings in all forms of RPGN, and they need to be documented for the diagnosis in an adequate renal biopsy. The percentage of glomeruli with crescents on renal biopsy correlates with the severity of renal failure and with long-term prognosis.[3,26,27] Glomerular crescents can be of two types: (1) cellular crescents; and (2) crescents with varying degrees of fibrin organization, including fibrocellular and fibrous crescents.[28] Cellular crescents develop first and eventually organize into fibrous crescents as the disease progresses. Ultimately, the entire glomerular tuft may be replaced by fibrous material, with resultant cessation of filtration and glomerular death (global sclerosis).

KEY POINTS

- Glomerular crescents crescents are the hallmark of RPGN.
- The initiating event in crescent formation is disruption of the glomerular capillary wall.
- Crescents are derived from proliferating parietal cells and podocytes, as well as from recruitment of circulating monocytes, neutrophils, and macrophages.
Figure 22.1. Light microscopy showing a glomerulus with cellular crescent (arrow). Compression of the glomerular tuft (G) by the crescent is also evident. (Figure courtesy of Dr. Bhaskar Kallakuri, Department of Pathology, Georgetown University Hospital, Washington DC.)

Cellular crescents are defined by the presence of two or more layers of cells in a crescent-shaped formation in the periphery of the Bowman space (Figure 22.1). These cells are derived from proliferating parietal cells and podocytes and from recruitment of circulating monocytes and macrophages. There is also evidence of local proliferation of macrophages within the Bowman space.[29–31] The initiating event in crescent formation appears to be disruption of the glomerular capillary wall, which is a common pathway for all types of RPGN.[3,32] Lysis of the GBM results from release of serine proteinases and matrix metalloproteinases derived from activated monocytes and neutrophils infiltrating into the glomerular tuft.[3]

Disruption of the glomerular capillary wall allows passage of plasma coagulation factors to leak into the Bowman space. These factors result in the formation of fibrin on contact with a tissue factor, a transmembrane protein expressed in different cell types, including monocytes and macrophages. The tissue factor has been shown to also possess proinflammatory properties, thus facilitating further macrophage and T-cell recruitment from the circulation into the Bowman space.[3,33,34] Other chemotactic factors such as fibrin, monocyte chemoattractant protein-1 (MCP-1), macrophage colony-stimulating factor, and macrophage migration-inhibitory factor also play major roles in cellular recruitment.[28] Macrophage-derived proinflammatory cytokines including interleukin-1 (IL-1) and tumor necrosis factor-α (TNF-α) exacerbate glomerular injury and promote further macrophage infiltration and glomerular cell proliferation (Figure 22.2).[28] The entry of T cells and fibroblasts into the Bowman space, as occurs through tears in the GBM, leads to progressive deposition of collagen and transition from cellular crescents into fibrocellular and eventually fibrous crescents. This transition may be orchestrated by transforming growth factor-β (TGF-β). Within a week or so, a gradual loss of macrophages, T cells,

Factors involved in the
pathogenesis of glomerular
crescents
Figure 22.2 A diagrammatic representation of pathogenesis of crescents in rapidly progressive glomerulonephritis. The initiating event in crescent formation appears to be disruption of the glomerular capillary wall. Lysis of the glomerular basement membrane results from release of serine proteinases and matrix metalloproteinases derived from activated monocytes and neutrophils infiltrating into the glomerular tufts. Cells forming crescents are derived from proliferating parietal cells and podocytes, as well as from recruitment of circulating monocytes and macrophages.

and fibroblasts from the Bowman space occurs, a process mediated by apoptosis that leads to glomerular scarring (Figure 22.3).[3,28,35,36] In general, crescent formation is less common in immune-complex glomerulonephritides than in other forms of RPGN-causing conditions.

IMMUNE COMPLEX MEDIATED RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

Immune complex glomerulonephritides may, in their most severe form, also progress to RPGN. Two of the most common diseases, HSP and systemic lupus erythematosus (SLE), are systemic vasculitides, but the renal disease in both disorders is triggered by immune complex deposition in the glomeruli. Other immune complex diseases that have the potential to develop into RPGN include immunoglobulin A (IgA) nephropathy, acute postinfectious glomerulonephritis (APIGN), and membranoproliferative glomerulonephritis (MPGN) including C_3 nephropathy.[3] More than 90% of cases of APIGN result from streptococcal infections. RPGN

is uncommon in all of the foregoing diseases and probably occurs in fewer than 10% of all cases. RPGN may be encountered in any type of MPGN, but it is not clear whether the risk of RPGN is influenced by the type of MPGN.

KEY POINTS

- HSP and SLE are the two most common causes of immune complex–mediated RPGN in childhood.
- Rarely, other glomerulonephritides may also progress to RPGN.

The initiating pathogenetic events are the accumulation of immune complexes in glomeruli and the activation of complement coagulation factors and other mediators of glomerular injury. If the disorder is severe enough, crescent formation follows, as described earlier. The immune complexes may be either preformed circulating complexes that are trapped in the glomerular filter or complexes formed in situ.[37,38] In the latter case, a circulating antigen may possess affinity to the glomerular capillary wall, with secondary binding of antibody.

The characteristic finding on renal biopsy in immune complex–induced RPGN, in addition to crescents, is the presence of immune deposits in the glomeruli. The immune complexes are often easier to identify in the better-preserved glomeruli. The location and type of immune material are specific to each primary disease, thus giving rise to mesangial or granular capillary loop immunofluorescence with antibodies against appropriate immunoglobulins. The exception is MPGN type 2, in which only complement C3 is seen by standard immunofluorescence. In advanced disease, the underlying primary disease may no longer be recognizable on renal biopsy because of the extensive glomerulosclerosis.

PAUCI-IMMUNE CRESCENTIC GLOMERULONEPHRITIS

Pauci-immune crescentic glomerulonephritis is the most common cause of RPGN in adults and also a common cause of RPGN in children.[3] The three commonly described vasculitides in this category are (1) microscopic polyangiitis, (2) GPA (formerly Wegener granulomatosis), and (3) eosinophilic granulomatosis with polyangiitis (EGPA; formerly Churg-Strauss syndrome). Most cases of pauci-immune glomerulonephritis involve inflammation and necrosis of small blood vessel walls. Renal biopsy characteristically shows glomerular crescents and vasculitis of small vessels, with paucity or absence of immunoglobulins by immunofluorescence. Common to most of these small-vessel vasculitides is the presence of circulating anti–neutrophil cytoplasmic
Figure 22.3 Microscopic polyangiitis demonstrating vasculitis lesions. **(a)** and **(c)** Fibrinoid necrosis (long arrows) and fragmentation of nuclei or leukocytoclasia (short arrows) affecting small blood vessels (venulitis). The inflammatory infiltrate in the affected areas consists of a mixture of neutrophils and mononuclear leukocytes. **(b)** Glomerulus with similar fibrinoid necrosis (arrow) and an acute inflammatory reaction. **(d)** Masson trichrome–stained glomerulus demonstrating residual chronic segmental sclerosis (arrow) after acute inflammatory glomerular disease in rapidly progressive glomerulonephritis. (From Jennette JC, Falk RJ, Hu P, et al. Pathogenesis of antineutrophil cytoplasmic antibody-associated small-vessel vasculitis. Annu Rev Pathol. 2013;8:139–60.)

antibodies (ANCAs) that target specific antigens in cytoplasmic granules.[39-44] The term *ANCA-associated vasculitis* (AAV) is often used to describe these vasculitides. Rarely, AAV may be induced by drugs, such as hydralazine and propylthiouracil. AAV is a frequent cause of pulmonary-renal syndromes.[45,46]

<div style="border:1px solid #000">

KEY POINTS

- Pauci-immune RPGN usually results from small-vessel vasculitides.
- Three common types are:
  - Microscopic polyangiitis
  - GPA (formerly Wegener granulomatosis)
  - EGPA (formerly Churg-Strauss syndrome)
  - Circulating ANCA is present in more than 70% of cases.

</div>

ANCA test results are negative in approximately 10% to 30% of patients with pauci-immune RPGN, and anti–endothelial cell antibodies are found in more than 50% of these cases, thus suggesting their pathogenic and clinical significance.[43] These patients tend to exhibit fewer extrarenal

symptoms compared with ANCA-positive patients.[44] Some patients with pauci-immune glomerulonephritis have no evidence of systemic vasculitis or other organ involvement and are referred to as having renal limited vasculitis (RLV). Several cases of RLV have been reported in the pediatric literature.[47]

The pathophysiologic mechanisms in pauci-immune glomerulonephritis are complex and involve both humoral and cellular immune systems. The hallmark of AAV is the formation of ANCA against granular cytoplasmic antigens, including proteinase-3 (PR3) and myeloperoxidase (MPO). Whereas GPA is predominantly associated with cytoplasmic antibodies directed against PR3 (cytoplasmic ANCA or cANCA), MPA and EGPA are more often associated with perinuclear antibodies against MPO (perinuclear ANCA or pANCA).[48-50] Lysosomal membrane protein-2 (LAMP2) has been proposed as another major target for ANCA, but this hypothesis remains controversial.[51-53] Granulomatous inflammation is present in GPA and EGPA but not in MPA.[48-50]

The precise cause of ANCA autoimmunity is unclear, but once in the circulation, ANCA activates neutrophils and monocytes. This process is facilitated by neutrophil priming with cytokines that causes the release and display of antigens on the surface of neutrophils, where they interact with ANCA. Once ANCA

binds to antigens, neutrophil activation is induced by Fc receptor engagement.[48,50,53] Activated neutrophils release factors that activate the alternative complement pathway, thereby leading to the generation of C5a, which recruits and activates additional neutrophils.[50,54,55] This inflammatory amplification loop generates the localized necrotizing inflammation in blood vessels, including in renal vessels. T lymphocytes and monocytes are further recruited into the site of severe injury and replace neutrophils that have undergone leukocytoclasia during acute inflammation. Mild vascular injury may resolve with vessel wall remodeling, but with more severe injury fibrosis and sclerosis may result.[50] The formation of extravascular granulomatosis in AAV may occur as a result of intense localized inflammation, caused by activated extravascular neutrophils, that leads to tissue necrosis and fibrin formation.

ANTI–GLOMERULAR BASEMENT MEMBRANE DISEASE

Anti-GBM disease is rare in all age groups and is characterized by the presence of circulating autoantibodies to the GBM and linear deposition of immunoglobulin G (IgG) along the GBM and alveolar basement membrane.[25,56] Anti-GBM disease is the most aggressive form of RPGN and may involve the kidneys alone (Goodpasture disease), or be accompanied by pulmonary hemorrhage (Goodpasture syndrome). In anti-GBM disease, the primary target of the circulating IgG autoantibodies is the noncollagenous 1 (NC1) domain of the α_3-chain of type IV collagen, with specific binding to the E_A and E_B epitopes.[57,58] All IgG subclasses (1 through 4) are known to be present in patients with anti-GBM disease who have moderate to severe renal injury requiring dialysis. In patients who have pathogenic anti-GBM autoantibodies but normal kidney function, IgG1, IgG2, and IgG4 predominate. Natural anti-GBM IgG antibodies are also known to be present in the sera of healthy individuals and are predominantly of the IgG2 and IgG4 subclass.[20,59] The circulating antibody level in anti-GBM disease correlates with the severity of renal disease and serum creatinine concentrations.[20,60] Anti-GBM antibodies
Figure 22.4 Immunofluorescence staining showing immunoglobulin G linear staining of the **(a)** glomerular and **(b)** alveolar basement membrane in a patient with Goodpasture syndrome. (Reproduced with permission from Williamson S, Phillips C, Andreoli S, et al. A 25-year experience with pediatric anti–glomerular basement membrane disease. Pediatr Nephrol. 2011;26:85–91.)

have been reported to coexist with ANCA in approximately one-third of cases of crescentic glomerulonephritis in both adults and children.[61–64] Lung and kidney involvement (pulmonary-renal syndrome) may be associated with anti-GBM antibodies alone, with a combination of ANCA and anti-GBM antibodies, or with ANCA alone.

The pathogenesis of vascular tissue injury in anti-GBM disease is similar to that in AAV.[25] Circulating anti-GBM IgG attacks the NCI domain of α_3-chain of type IV collagen present in both the kidney and the lungs, and this process leads to crescentic glomerulonephritis and pulmonary hemorrhage. In contrast to AAV, in which immunoglobulin deposits occur only at the sites of vascular injury, anti-GBM disease and immune complex glomerulonephritis are characterized by deposits of immunoglobulin throughout the involved vasculature.[50]

Unless the diagnosis is made early and therapy is instituted promptly, anti-GBM disease rapidly progresses to renal failure and end-stage renal disease (ESRD), with a fatal outcome in approximately one-half of all cases. In almost all patients, circulating IgG autoantibodies can be detected by enzyme-linked immunosorbent assay (ELISA). Renal biopsy typically shows necrotizing crescentic glomerulonephritis and linear deposition of IgG, and less frequently C3, along the GBM (Figure 22.4). Rarely, RPGN due to anti-GBM antibodies occurs in patients with Alport syndrome who receive a kidney transplant. The anti-GBM antibodies develop in these recipients because the type IV collagen present in the transplanted kidney is perceived as a foreign antigen by the recipient, who lacks it in the native kidney.[65,66]

CLINICAL MANIFESTATIONS

Table 22.3 depicts the clinical and laboratory findings in different types of RPGN. The clinical presentation of RPGN limited to the kidney can vary from asymptomatic

---

KEY POINTS

- Anti-GBM disease is the least common form of RPGN in both children and adults.
- Anti-GBM disease results from circulating IgG autoantibodies that target the noncollagenous 1 (NC1) domain of the α_3-chain of type IV collagen in the GBM and the alveolar basement membrane.

++, More than 50% of patients; +, fewer than 50% of patients; aGBM, anti–glomerular basement membrane antibody disease; ANA, antinuclear antibody; APIGN, acute post-infectious glomerulonephritis; cANCA, cytoplasmic anti–neutrophil cytoplasmic antibody; EGPA, eosinophilic granulomatosis with polyangiitis; GPA, granulomatosis with polyangiitis; HSP, Henoch-Schönlein purpura; MPA, microscopic polyangiitis; MPGN, membranoproliferative glomerulonephritis; pANCA, perinuclear cANCA, cytoplasmic anti–neutrophil cytoplasmic antibody; RLV, renal limited vasculitis; SLE, systemic lupus erythematosus.

proteinuria and hematuria in early stages to life-threatening renal failure requiring dialysis or hypertensive crises. Vague constitutional symptoms, such as malaise and loss of appetite, may be present and may precede other disease manifestations. Gross hematuria is present in many patients, especially in patients with IgA nephropathy, APSGN, or MPGN. Symptoms and signs may evolve over days to weeks.

Extrarenal symptoms may predominate initially in many patients with RPGN. The most common extrarenal symptoms include malaise, fever, weight loss, arthralgias, and upper respiratory tract symptoms.[67–69] Characteristic skin lesions are often present in HSP and SLE. Respiratory tract symptoms and signs in children with GPA include sinusitis, epistaxis, hemoptysis, nasal and oral ulcers, otitis media, hearing loss, and pulmonary nodules or infiltrates. A retrospective analysis of pediatric patients with GPA showed that constitutional symptoms, glomerulonephritis, and upper and lower respiratory tract symptoms predominated at the initial diagnosis.[69,70] Arthritis, eye and skin involvement, and hypertension were less common.

In pediatric EGPA, pulmonary and cardiac involvement is more common than in adults. The most common respiratory findings are asthma and sinusitis, which are present in 91% and 77% of children, respectively.[71] Eosinophilia is frequently present. Additional pulmonary findings in these patients include eosinophilic pleural effusion and eosinophilic microabscesses.[72]

In anti-GBM disease, arthralgia and myalgia are less common symptoms, and hypertension is also uncommon, except in the presence of severe renal failure. Hemoptysis is seen as a result of alveolar hemorrhage in these patients.[25,56,73] The relative involvement of the kidneys and lungs in anti-GBM disease is variable. Although most patients present with both renal and alveolar disease, isolated renal involvement occurs in 30% to 40% of all cases. Occasionally, patients may present with pulmonary hemorrhage alone, without overt renal disease, although they may have urinary abnormalities.[73] The conditions to be considered in the differential diagnosis of RPGN are listed in Table 22.3.

DIAGNOSTIC EVALUATION

The diagnosis of RPGN must be made rapidly to enable early institution of therapy. Evaluation should start with a thorough history and a physical examination. Laboratory investigations taken into consideration in the investigations

Table 22.4 Evaluation of suspected rapidly progressive glomerulonephritis

Laboratory Tests
- Complete blood count
- Comprehensive metabolic panel
- Peripheral blood smear (to rule out HUS)
- Urinalysis, urine protein-to-creatinine ratio
- Complement C3 and C4 and total complement
- ANA (full lupus panel if ANA positive)
- ANCA (cANCA and pANCA)
- Anti-GBM antibody titers
- Streptococcal antibody titers (ASO, anti-DNase B and antihyaluronidase)
- Culture of throat and skin lesions (for suspected APSGN)

Radiologic Imaging
- Chest x-ray study
- Renal ultrasound examination
- Computed tomography scan of orbit, sinuses, trachea, and chest

Tissue Diagnosis
- Renal biopsy

Abbreviations: ANA, antinuclear antibody; ANCA, anti–neutrophil cytoplasmic antibody; APSGN, acute poststreptococcal glomerulonephritis; ASO, anti–streptolysin O; cANCA, cytoplasmic anti–neutrophil cytoplasmic antibody; GBM, glomerular basement membrane; HUS, hemolytic-uremic syndrome, pANCA, perinuclear anti–neutrophil cytoplasmic antibody.

Figure 22.5 Subglottic narrowing (arrow) in a patient with granulomatosis with polyangiitis.

subacute bacterial endocarditis, and malignant diseases.[74,75] The international guidelines for ANCA testing recommend screening for ANCA by immunofluorescence test (IFT). If results are positive, ANCA testing by ELISA is required.[76] IFT is more sensitive for ANCA, and ELISA is more specific for cANCA and pANCA.

In suspected APSGN, streptococcal antibody titers should be obtained. Erythrocyte sedimentation rate (ESR) and C-reactive panel, although nonspecific, may help establish the presence of inflammation. Radiologic studies should include a renal ultrasound examination, which may show enlarged echogenic kidneys. A chest x-ray study and computed tomography (CT) scan of the orbit, sinuses, trachea, and chest may be necessary in suspected GPA. Imaging studies of the upper airway may identify subglottic stenosis (Figure 22.5). Radiography of the chest may also demonstrate infiltrative pulmonary disease (Figure 22.6), pulmonary hemorrhage, pleural effusions, or granulomatous lesions.

A renal biopsy is essential for tissue diagnosis. It provides information necessary for categorization of RPGN and to

of RPGN are listed in Table 22.4. The goals of evaluation are to identify the underlying immunopathologic mechanisms and determine the activity and severity of renal involvement. Laboratory investigations should include the following: complete blood count; comprehensive metabolic panel; complement C3, complement C4, and total complement; ANA, ANCA, anti-GBM antibodies; urinalysis, and quantitative measurement of urinary protein excretion. Radiologic investigations is indicated in patients with pulmonary manifestations or if the diagnosis of GPA is being actively considered.

ANCA is usually of the IgG class, although IgA and immunoglobulin M (IgM) ANCAs have been described.[74] Although ANCA is strongly associated with pauci-immune crescentic glomerulonephritis, a negative ANCA test result does not exclude the diagnosis. Approximately 90% of patients with GPA have a positive test result for ANCA, mostly for PR3-ANCA (cANCA), whereas 70% of MPA patients have a positive test result for ANCA, mostly to MPO (pANCA). Of EGPA patients, only 50% are ANCA positive, but this varies with stage of renal and lung involvement.[74] ANCA has been reported in other nonvasculitic disorders, including SLE, rheumatoid arthritis, inflammatory bowel disease, autoimmune hepatitis, tuberculosis,

Figure 22.6 Chest x-ray film of a patient with granulomatosis with polyangiitis (Wegener granulomatosis) showing bibasilar pulmonary infiltrates, especially on the left side.

determine the severity of renal involvement. Inability to obtain a renal biopsy because of a patient's instability should not delay the initiation of therapy.[2]

TREATMENT

Treatment of RPGN must be initiated as soon as the diagnosis is suspected and sometimes even before a renal biopsy is obtained. The aims of early treatment of RPGN are to halt disease progression, reverse renal injury, induce remission, and preserve renal function. In general, the treatment can be arbitrarily divided into two phases: (1) induction of remission and (2) maintenance of disease remission.

INDUCTION OF REMISSION

Standard treatment strategies involve the use of corticosteroids, immunosuppressive agents, and plasmapheresis. More recent experience with therapeutic agents such as rituximab, mycophenolate mofetil (MMF), leflunomide, antibodies to cytokines, and signal transduction inhibitors is encouraging.

Glucocorticoids

High-dose corticosteroids form part of the initial therapy for crescentic glomerulonephritis in most regimens.[2,3,77–79] The rationale for the use of high-dose steroids in the form of "pulse methylprednisolone" includes the rapid anti-inflammatory properties of this regimen and the possible effect on reduction of ANCA-producing plasma cells in AAV. Kidney Disease Improving Global Outcomes (KDIGO) recommends the use of pulse methylprednisolone as an initial therapy in RPGN in combination with cyclophosphamide.[79]

An intravenous dose of methylprednisolone 10 mg/kg/day (maximum dose, 500 mg daily) is given for 3 days, followed by oral prednisone at a dose of 2 mg/kg/day (maximum, 60 mg daily), which is tapered over several months. There is no evidence that 1000 mg of methylprednisolone is more effective than 500 mg.[79] A meta-analysis involving 983 patients showed that long-term low-dose glucocorticoid therapy administered for more than 12 months reduced relapse rates.[80]

Cyclophosphamide

Cyclophosphamide, an alkylating agent, is the most common immunosuppressant used in combination with glucocorticoids for the treatment of patients with RPGN. Cyclophosphamide has been shown to be effective in inducing remission in these patients, and KDIGO recommends its use as part of the initial therapy in patients with crescentic glomerulonephritis.[79] Oral and parenteral routes are equally effective in inducing remission. A randomized trial of more than 140 patients with newly diagnosed AAV compared pulse with oral cyclophosphamide for the induction of remission.[81,82] Pulse intravenous cyclophosphamide was as effective as the oral route in inducing remission, with the advantage of a reduced total cumulative cyclophosphamide dose and fewer cases of leukopenia. The recommended dose of intravenous cyclophosphamide is 0.5 to 0.75 g/m^2, given every 3 to 4 weeks for 3 to 6 months. The cyclophosphamide dose should be adjusted to keep the leukocyte count between 3 and 5 10^3/μL at 2 weeks after treatment. Other regimens for intravenous cyclophosphamide pulse therapy also exist. Oral cyclophosphamide is usually given at a dose of 1.5 to 2mg/kg/day for 3 months and not more than 6 months.[77,79] The oral cyclophosphamide dose should also be adjusted to keep the leukocyte count between 3 and 5 10^3/μL. Currently, there is no convincing evidence that longer treatment with cyclophosphamide reduces relapse rates. In patients who are dialysis dependent and who have severe renal damage on histologic examination, the mortality rate appears to be increased.[83] Therefore, in patients who are dialysis dependent at 3 months after initiation of therapy and who have no evidence of ongoing extrarenal manifestations of vasculitis, cyclophosphamide should be discontinued.[79,83]

Plasmapheresis

The use of plasmapheresis as an adjunctive therapy in the management of RPGN has attracted interest since the 1980s. Plasmapheresis aims to remove antibodies in patients with anti-GBM disease or AAV. A randomized trial of high-dose methylprednisolone or plasma exchange as adjunctive therapy for severe renal vasculitis showed that high-dose methylprednisolone was less effective in facilitating renal recovery as compared with plasma exchange.[84] Early plasmapheresis in combination with corticosteroids and cyclophosphamide has been shown to improve renal outcomes in patients with

RPGN associated with severe renal failure.[84–,88] In patients with RPGN associated with pulmonary hemorrhage, the addition of plasmapheresis to induction therapy significantly improved patient survival.[87–90] More recent meta-analyses demonstrated an improvement in the risk of ESRD in patients with renal vasculitis in whom plasmapheresis was added to induction therapy.[81,91] Currently, the EULAR and KDIGO recommend the addition of plasmapheresis to initial induction therapy with corticosteroids and cyclophosphamide in patients with RPGN associated with severe renal disease and pulmonary hemorrhage.[79,92] Duration of plasmapheresis therapy is not clearly defined, but 7 to 14 sessions have been performed in various studies.[84,86,87,89]

Newer induction therapies

Although current therapies have dramatically reduced the mortality associated with RPGN, induction of remission is often slow, requiring 3 to 6 months of therapy, by which time renal tissue damage and chronic kidney disease commence. Furthermore, approximately 20% to 30% of patients fail to achieve complete remission, and relapse is common, even after full remission.[93] Drug toxicity and infection rates also remain high with current induction agents. Alternative immunosuppressive medications such as rituximab and MMF have attracted attention as potential remission-inducing agents. A head-to-head comparison of rituximab and cyclophosphamide as induction therapy for AAV demonstrated that rituximab was effective in inducing remission in severe AAV and had a better side effect profile.[94] Based on these findings, the Food and Drug Administration (FDA), in April 2011, approved rituximab (in combination with glucocorticoids) as a front-line agent for treating adult patients with GPA and MPA. In patients with refractory cases of AAV, rituximab has also been shown to be effective in inducing remission.[95,96] Data on MMF as an effective remission-inducing agent are weak and insufficient to support its use as induction therapy for crescentic glomerulonephritis. Other emerging agents currently being investigated include TNF-α antagonists, high-dose intravenous immunoglobulin, antithymocyte globulin, and alemtuzumab.

Maintenance therapy

Maintenance therapy should be initiated in patients who have achieved remission. The toxicity of long-term use of cyclophosphamide makes this drug an unattractive option for use as a maintenance agent for patients with crescentic glomerulonephritis. Current options for maintenance therapy include azathioprine, MMF, leflunomide, and methotrexate.[92] Available evidence supports the use of azathioprine as a first-line agent for maintenance of remission in crescentic glomerulonephritis. A randomized controlled trial in 144 patients with AAV showed that withdrawal of cyclophosphamide and substitution with azathioprine after induction of remission did not increase relapse rates.[97] Another randomized study compared azathioprine and

MMF for maintenance of remission in AAV and found that MMF was less effective than azathioprine for maintaining remission in these patients.[98] KDIGO currently recommends azathioprine as first-line maintenance therapy. In patients who do not tolerate azathioprine, MMF can be substituted. If patients are intolerant to both azathioprine and MMF, methotrexate may then be considered. Methotrexate is not safer than azathioprine and should not be used in patients with a glomerular filtration rate of less than 60 mL/min/1.73 m².[99] Maintenance therapy should be continued for at least 18 months in patients who remain in remission.[79]

> ## KEY POINTS
>
> Maintenance therapies for RPGN include:
> - Azathioprine
> - MMF
> - Methotrexate

The foregoing recommendations are largely based on studies in adults with pauci-immune RPGN. Because immune complex RPGN is common in children and has a better prognosis, it is possible that a less intensive treatment regimen may be sufficient in selected pediatric cases.

CLINICAL COURSE AND PROGNOSIS

RPGN constitutes a medical emergency. In the absence of prompt therapy, morbidity, mortality, and the risk of progression to ESRD are high. With the introduction of immunosuppressive therapy and tools for early diagnosis, the clinical course and prognosis of vasculitis has dramatically improved over the last several decades.[100,101] The current patient survival rate for AAV ranges from 75% to 100% at 5 years.[101] Severe kidney injury at presentation, a higher Birmingham Vasculitis Activity score, a higher white blood cell count, and lower hemoglobin levels are poor prognostic factors in long-term survival.[4,11,102]

The histologic predictors of poor renal survival are a low percentage of normal glomeruli, a high percentage of crescentic glomeruli, extensive tubular atrophy, and interstitial fibrosis at the time of biopsy. The percentage of normal glomeruli at biopsy is the best predictor of dialysis independence over time.[5,6,103,104] Similar findings also have been published in the pediatric population.[11,105–107] Children with immune complex crescentic glomerulonephritis have better renal survival and are more likely to be dialysis free at follow up than are children with pauci-immune glomerulonephritis. A single center study of children with crescentic glomerulonephritis showed a renal survival of 94% at 3 years in those with immune complex glomerulonephritis compared with 63% in those with pauci-immune glomerulonephritis.[105]

KEY POINTS

- Treatment of RPGN is a medical emergency.
- Treatment can be initiated if the diagnosis is suspected and a renal biopsy cannot be urgently obtained.
- Delay in treatment is a risk factor for chronic kidney disease and ESRD.

COMPLICATIONS

Crescentic glomerulonephritis is associated with serious adverse events related to the disease itself and to immunosuppressive therapy. Target organ damage resulting from the disease process includes renal failure, as well as respiratory failure secondary to pulmonary hemorrhage and edema. The intensity of immunosuppression during the induction phase of therapy is associated with a high risk of infection with bacterial, fungal, viral, and parasitic organisms.[107,108] Approximately 10% to 20% of patients will die of serious infections in the first 3 months of therapy.[47] Overall, the leading causes of death in the first year of diagnosis are infections and active vasculitis.[101,108] Factors that increase the risk of infection include leukopenia, immune dysfunction induced by therapy, and renal failure. High cumulative doses of cyclophosphamide are associated with irreversible gonadal failure causing infertility and an increased risk of malignant diseases such as nonmelanoma skin cancer and urinary tract cancers.[108] Osteoporosis, hypertension, and weight gain are some of the adverse effects of high dose steroid exposure. These complications must be discussed with patients and their families before therapy is initiated.

SUMMARY

RPGN is a rare but devastating disease that may result in ESRD or death if it is left untreated or if treatment is significantly delayed. Its highly variable presentation, depending on the specific diagnosis and extent of organ involvement, may cause diagnostic difficulties. The index of suspicion should therefore be high whenever a patient presents with nephritic syndrome, acutely worsening kidney function, or systemic manifestations consistent with vasculitis, pulmonary hemorrhage, or granuloma formation. Although current treatment regimens have greatly improved the outlook, evolving new medications, especially biologic agents, are likely to improve the prognosis further.

Clinical Vignette 22.1

A 10-year-old girl presented with a 4-week history of worsening malaise, weight loss, and intermittent fevers. She was diagnosed with sinusitis by her pediatrician 6 weeks earlier and received two courses of oral antibiotics, with no improvement. On physical examination, she was not in any distress. Her blood pressure was 130/90 mm Hg. She had paranasal tenderness, and there was no pedal edema. The rest of her physical examination was unremarkable. Laboratory data revealed blood urea nitrogen of 76 mg/dL and creatinine of 4.5 mg/dL, normal electrolytes, and serum albumin of 3.0 g/dL. Hemoglobin and hematocrit was 8.7 g/dL and 28%, respectively. Urinalysis shows hematuria and proteinuria with a urine protein-to-creatinine ratio of 1.8 mg/mg. Renal biopsy was performed urgently, and results show necrotizing glomerulonephritis, with 70% of glomeruli exhibiting fibrocellular crescents (Figure 22.7). Immunofluorescence was negative. Electron microscopy did not reveal any electron-dense deposits. The diagnosis of rapidly progressive glomerulonephritis was established.

TEACHING POINTS

Based on the biopsy findings, the patient in Clinical Vignette 22.1 has pauci-immune rapidly progressive glomerulonephritis. Further characterization revealed negative serologic results for antinuclear antibodies (ANAs), anti–glomerular basement membrane antibodies, and myeloperoxidase (MPO) antibodies, but the proteinase-3 (PR3) antibody level was high at 701 absorbance units arbitany units/mL (normal, 0 to 19). Chest x-ray was normal. A high-resolution CT scan of the chest, however, revealed multiple bilateral mostly peripheral and vasocentric lung nodules and wedged peripheral
Figure 22.7 Proliferation of parietal epithelial cells forms a nearly circumferential epithelial crescent surrounding a collapsed glomerular tuft. (Courtesy of Dr. Randall Craver, Louisiana State University, Baton Rouge, LA.)

densities. There were areas of early cavitation in both upper and left lower lobes, and subglottic tracheal narrowing (see Figure 22.5) was also noted. Collectively, these findings suggested granulomatosis with polyangiitis, formerly known as Wegener granulomatosis. Renal biopsy confirmed the presence of severe proliferative glomerulonephritis with cellular crescents.

Induction therapy was initiated with high-dose methylprednisolone pulses and cyclophosphamide. The patient received three pulses of methylprednisolone and then was transitioned to oral steroids. Cyclophosphamide was given parenterally every 4 weeks for 6 months. Remission was achieved by 14 weeks of therapy. After cyclophosphamide infusions, azathioprine was initiated as maintenance therapy. The patient remained in remission 16 months after diagnosis. Follow-up CT scan of her chest after 5 months of therapy showed complete resolution of her lung lesions. Her kidney function and hematologic indices remained normal. Her upper respiratory tract symptoms also resolved.

REVIEW QUESTIONS

1. The diagnosis of RPGN requires which of the following?
   a. Low complement C3 and deteriorating renal function

b. Glomerular crescents on biopsy and positive ANCA
c. Glomerular crescents and deteriorating renal function
d. Glomerular crescents and linear anti-IgG immunofluorescence

2. A 13-year-old girl has hemoptysis and is found to have serum creatinine of 8.5 mg/dL. Which of the following test results is most likely to be abnormal?
   a. ANA
   b. Anti-GBM antibody
   c. Complement C3
   d. ANCA

3. A 15-year-old girl is found to have proteinuria and serum creatinine of 1.8 mg/dL. A week later her s-Cr is 4.8 mg/dL. Her hepatitis C titer is positive. Her renal biopsy shows crescents in 12 of 18 glomeruli. Immunofluorescence is most likely to show which of the following capillary loop patterns?
   a. Linear staining for anti-IgG, negative for C3
   b. Granular staining for IgG and C3
   c. Granular staining for C3, negative for IgG
   d. Granular staining for IgG, negative for C3

4. Which of the following statements is true regarding RPGN in children?
   a. It is less common than in adults.
   b. The most common cause is anti-GBM antibodies.
   c. It is a frequent complication of APSGN.
   d. It is ANCA positive in most cases.

5. A 17-year-old patient has chronic sinusitis, cough, and oral ulcers. Chest x-ray study shows nodular lung densities. Laboratory evaluation reveals positive cANCA. Which of the following is the most likely diagnosis?
   a. Granulomatosis with polyangiitis
   b. Systemic lupus erythematosus
   c. Dense deposit disease
   d. Microscopic polyangiitis

6. Which if the following is true of PAN?
   a. It predominantly involves small vessels.
   b. It predominantly involves medium-size vessels.
   c. It is a common cause of crescentic glomerulonephritis.
   d. Renal histology is indistinguishable from RPGN.

7. Which of the following is the currently recommended regimen for initiation therapy of severe RPGN?
   a. Cyclophosphamide and high-dose steroids only
   b. Cyclophosphamide, high-dose steroids and plasmapheresis
   c. High-dose steroids and plasmapheresis only
   d. Cyclophosphamide and plasmapheresis

8. RPGN caused by which of the following primary diseases is least likely to result in ESRD?
   a. Goodpasture disease
   b. Granulomatosis with polyangiitis
   c. IgA nephropathy
   d. Eosinophilic granulomatosis with polyangiitis

9. Which of the following is true of ANCA?
   a. It is present in all patients with pauci-immune RPGN.
   b. It activates neutrophils by binding to surface antigens.
   c. pANCA is predominantly seen with GPA.
   d. It is produced in response to known antigenic stimuli.

10. An 11-year-old girl has a 6-week history of malaise and weight loss. Serum BUN and creatinine are 75 mg/dL and 6.4 mg/dL, respectively. Electrolytes are unremarkable. She is suspected to have RPGN; additional laboratory evaluation is pending. The most appropriate next step is:
    a. Start intravenous fluids and monitor kidney function.
    b. Arrange an immediate renal biopsy.
    c. Start cyclophosphamide and high-dose steroids.
    d. Start intermittent hemodialysis.

Immunoglobulin A nephropathy and Henoch-Schönlein purpura nephritis

M. COLLEEN HASTINGS AND ROBERT J. WYATT

Immunoglobulin A (IgA) nephropathy (IgAN) is the most common chronic glomerulonephritis in childhood, and Henoch-Schönlein purpura (HSP) is the most common vasculitis diagnosed in children and has nephritis as its most frequent chronic manifestation.[1,2] Because of shared pathogenic features, IgAN and HSP nephritis (HSPN) are discussed together in this chapter.[3]

In 1969, Jean Berger[4] reported IgA deposition in the mesangial region of glomeruli from children and young adults who were experiencing macroscopic hematuria during viral upper respiratory infections. In that report, Berger also described similar IgA deposits in patients with HSP. Some children diagnosed with HSPN subsequently have one or more episodes of macroscopic hematuria in the absence of rash, joint, or abdominal symptoms.[5] Meadow and Scott[6] reported identical twins with simultaneous adenovirus infections; one of them developed the clinical phenotype of HSP, the other had isolated macroscopic hematuria, and both had mesangial IgA deposits. HSP has occurred in children who previously had one or more episodes of isolated macroscopic hematuria with an interval between the episode and onset of HSP as long as 12 years.[7,8]

EPIDEMIOLOGY

Few studies have determined population-based incidence for IgAN in children and adolescents. Many have relied on inferences from the percentage of cases in renal biopsy series. In Memphis, Tennessee and Seoul, Korea, the reported biopsy series incidence is approximately 10%,[1,9] whereas in Japan it is considerably higher, ranging from 24% to 30%.[10,11] In an Italian registry, IgAN and HSPN together accounted for approximately 30% of pediatric renal biopsy diagnoses.[12]

In central and eastern Kentucky, from 1985 through 1994, the incidence of IgAN was 5.6 cases per million persons per year for children 1 to 9 years of age and 10.2 cases per million persons per year for those 10 to 19 years of age.[13] The reported incidence of IgAN in Italy for children under the age of 15 years was 3.1 cases per million persons per year from 1992 through 1994. For children under the age of 15 years in Venezuela, the incidence of IgAN was only 0.3 cases per million persons per year in 1998.[14] From 1983 to 1999, the incidence was 45 cases per million persons per year for children under age 15 in Yonaga City, Japan.[15] The increased incidence in Japan compared to other areas of the world may reflect a true racial or ethnic difference in incidence.[16] However, additional explanations include increased detection through school screening programs, better diagnostic acuity of Japanese primary care physicians, and an aggressive approach of Japanese pediatric nephrologists toward biopsies for children with isolated microscopic hematuria or low levels of proteinuria.

Data from adult biopsy series suggested that IgAN is rare in persons of African descent and very few cases of IgAN have been reported from the continent of Africa.[17,18] However, in Shelby county (Memphis), Tennessee, for the period 1985 through 1995, the incidence of IgAN was higher for African-American children than white children (5.7 vs. 3.0 cases per million persons per year).[19] We continue to

diagnose a significant number of African-American patients with IgAN.[20]

Population-based incidence for HSP from different regions was more than 100 cases per million persons per year, or at least 20-fold higher than that of IgAN.[1] However, because only 20% to 40% of children with HSP develop nephritis, which is often mild, the incidence of persistent HSPN appears similar to or even lower than that of IgAN.[1]

North American and European pediatric studies of IgAN find a male-to-female predominance of approximately two to one.[21,22] However, Japanese data that include school screening programs found no gender predominance.[15] Males and females are affected equally with HSP, but for HSPN there appears to be a slight male predominance of approximately 1.5 to 1.[1,23–27]

PATHOLOGIC FEATURES

Renal histologic features in HSPN are strikingly similar to those in IgAN.[28,29] In both IgAN and HSPN, IgA is the dominant or codominant immunoglobulin that deposits mainly in the glomerular mesangium.[23,30] Only the IgA1 subclass is found in the deposits.[31]

The Oxford classification (Table 23.1) was developed to define lesions that may predict outcome of IgAN.[32,33] Figure 23.1A to E show some of the pathologic features examined as prognostic markers in the Oxford cohort that included both adult and pediatric patients. Light microscopic features in IgAN and HSPN are quite variable: glomeruli may have normal histologic findings, mesangial proliferation and expansion without glomerular sclerosis or other chronic changes, endocapillary proliferation, focal segmental glomerulosclerosis with or without mesangial proliferation, focal necrosis (affecting a minority of glomeruli), adhesion of the glomerular tuft to Bowman's capsule and formation of crescents, or a combination of these. The presence of chronic tubular and interstitial injury is not often seen in the initial biopsy sample for pediatric IgAN and HSPN, but when present indicates progressive disease.[34]

> ### KEY POINTS
>
> - IgAN and HSP are both characterized by dominant deposition of IgA in the glomerular mesangium.
> - Most consider these two disorders as part of the same clinical spectrum.

Figure 23.1F shows this mesangial pattern as demonstrated by direct immunofluorescence. These deposits almost always can be seen by electron microscopy, typically in the paramesangial region where the basement membrane covers the mesangium. The immune deposits also may occur in the capillary loops, particularly during the early phase of aggressive HSPN and IgAN.[35,36] IgG, IgM, and complement C3 deposits are frequently seen on immunofluorescence, but IgA may be the sole immunoglobulin present in approximately 15% of biopsy samples.[37] Electron microscopy usually shows electron-dense material corresponding

Table 23.1 Oxford classification of immunoglobulin A nephropathy (MEST score)

Biopsy variable	Definition	Score
Mesangial hypercellularity	<4 mesangial cells/mesangial area = 0 4–5 mesangial cells/mesangial area = 1 6–7 mesangial cells/mesangial area = 2 >8 mesangial cells/mesangial area = 3 The mesangial hypercellularity score is the mean score for all glomeruli. If more than half the glomeruli have more than three cells in a mesangial area, this is categorized as M1.	M0 ≤ 0.5 M1 > 0.5
Endocapillary hypercellularity	Hypercellularity secondary to increased number of cells within the glomerular capillary lumina causing narrowing of the lumina	E0: Absent E1: Present
Segmental glomerulosclerosis	Any amount of the tuft involved in sclerosis, but not involving the whole tuft or the presence of an adhesion	S0: Absent S1: Present
Tubular atrophy/interstitial fibrosis	Percentage of cortical area involved by the tubular atrophy or interstitial fibrosis, whichever is greater	T0: 0–25% T1: 26%–50% T2: >50%

Source: Adapted from Cattran DC, Coppo R, Cook HT, et al. The Oxford classification of IgA nephropathy: rationale, clinico-pathological correlations, and classification. Kidney Int. 2009;76,534–45.
Figure 23.1 Pathologic characteristics of immunoglobulin A nephropathy. **(a)** Periodic acid–Schiff (PAS) stain shows mesangial hypercellularity, with four or more cells per mesangial area (arrow). **(b)** PAS shows segmental endocapillary proliferation with occlusion of the capillary lumen (arrow). **(c)** PAS shows segmental glomerulosclerosis and adhesion, with focal accumulation of hyaline and obliteration of the capillary lumen (arrow). **(d)** Trichrome stain shows tubular atrophy and interstitial fibrosis, with severe interstitial scarring and loss of tubules (arrow). **(e)** PAS shows a glomerular crescent; a circumferential layer of epithelial cells surrounds the glomerular tuft (arrow). **(f)** Immunofluorescence stain with fluorescein-conjugated anti-IgA antibodies) shows diffuse mesangial staining for IgA (arrow). **(g)** Electron micrograph of a glomerular capillary tuft in a specimen fixed in osmium tetroxide shows electron-dense material in the mesangial area (arrow), a finding that is consistent with the accumulation of immune complexes. (Reproduced with permission from: Wyatt RJ, Julian BA. IgA nephropathy. N Engl J Med. 2013;368:2402–14.)

to immunodeposits on immunofluorescence microscopy. These are generally in mesangial and paramesangial areas but are occasionally in subepithelial and subendothelial portions of glomerular basement membranes.[38]

Children seem to have fewer chronic-appearing lesions at the time of biopsy than adults with IgAN. Comparing kidney biopsy samples obtained from Japanese children to those from Japanese adults with IgAN, pediatric patients had increased glomerular hypercellularity although adult patients had more mesangial matrix expansion without hypercellularity; more adhesions, crescents, or both; and more tubulointerstitial damage.[39] Pediatric biopsy samples from the Oxford cohort also had more mesangial and endocapillary hypercellularity but less segmental glomerulosclerosis and tubulointerstitial injury compared to biopsy samples obtained from adult subjects.[40]

PATHOGENESIS

The multiple hit hypothesis has been proposed to explain the pathogenesis of IgAN as well as HSPN (Figure 23.2).[1,41,42] The initiating or first hit is the presence in the serum of galactose-deficient (or underglycosylated) IgA1 in which in some of the carbohydrate side chains (O-glycans) at the hinge region terminate in N-acetylgalactosamine (GalNAc) or sialylated GalNac, rather than galactose. IgA1 differs from IgA2 and the other immunoglobulins in that it has a hinge region that contains O-linked glycans composed of N-acetylgalactosamine (GalNAc) linked to galactose (Figure 23.3).[43–45] Attachment of the galactose requires β1,3 galactosyltransferase. Galactose-deficient IgA1 can be detected in serum samples from patients with IgAN and HSPN by an increased affinity for binding to various lectins such as *Helix aspersa* that are specific for terminal GalNAc.[45,46]

The second hit involves generation of antiglycan antibodies that recognize the terminal GalNac residue on galactose deficient-IgA1. These antibodies may be either IgG or IgA.[47] This points to IgAN being an autoimmune disorder. The third hit consists of the formation of nephritogenic circulating immune complexes containing galactose-deficient IgA1 and antiglycan antibody.[48] These complexes then deposit in the glomerular mesangium by virtue of decreased clearance from the circulation, increased affinity for binding to mesangial structures, or both.[49–51]

KEY POINTS

- A multi-hit hypothesis has been suggested to explain the pathogenesis of IgAN.
- The primary abnormality in IgAN is the presence of galactose-deficient (or underglycosylated) IgA1 in the serum of these patients.

The fourth hit incorporates all of the pathways of glomerular injury after deposition of the nephritogenic complexes in the mesangium and activation of the mesangial cells. Some of these mechanisms include the secretion of extracellular matrix components,[52] induction of nitric oxide synthase,[53] and the release various mediators of renal injury such as angiotensin II,[54] proinflammatory and profibrotic cytokines,[52,54] and growth factors.[53] Most, if not all, of these mechanisms of injury are not specific to IgAN.

GENETICS

In 1985, Julian et al.[55] described a pedigree containing eight patients with IgAN who descended over 200 years from one of the earliest settlers of Pike County, Kentucky. Many similar pedigrees were subsequently described from eastern Kentucky and northern Italy.[56–58] A study of the French Society of Nephrology described 40 families in which two or more first-, second-, or third-degree relatives had IgAN, with five families having a member with HSP.[59] In addition, 18 other families had one member with IgAN and one or two with HSP.

KEY POINTS

- Familial IgAN has been reported from several parts of the world, but most cases of IgAN are sporadic.
- No gene or gene product has yet been identified as pathognomonic for IgAN.
- Serum galactose-deficient IgA1 level is elevated in approximately 75% patients with IgAN and is a heritable trait.

Gharavi et al.[60] used members of 30 pedigrees from Italy and Kentucky to demonstrate linkage to a locus on chromosome 6 in 60% of the pedigrees. This locus at 6q22-23 was named *IgAN1*. However, no gene or gene product from that locus of pathogenic importance for IgAN has yet been identified.

Antiglycan antibodies (IgG or IgA)

Decreased clearance of IgA1-antiglycan antibody immune complexes

Increased circulating immune complexes

Mesangial deposition of nephritogenic immune complexes

Mesangial cell activation

Inflammatory mediators causing glomerular damage

Abnormal circulating galactose-deficient IgA1

Circulating immune complex formation (galactose-deficient IgA1-antiglycan antibodies)

Figure 23.2 Schematic representation of the multi-hit pathogenesis of immunoglobulin A nephropathy.
Figure 23.3 Structure of human immunoglobulin A1 (IgA1). IgA exists in several forms in the circulation: monomers, dimers, trimers, larger polymers, and secretory IgA. The IgA1 dimer is composed of two monomers linked by a joining chain. Each heavy chain has two N-linked (attached to a nitrogen molecule) glycan (carbohydrate) side chains and a hinge region between the first and second constant-region domains (Cα1 and Cα2, respectively). This hinge region is longer in IgA1 than in IgA2, and the longer IgA1 segment is rich in proline, threonine, and serine amino acid residues. Within the IgA1 hinge region, three to six glycans are attached to an oxygen molecule of a serine or threonine residue (O-linked). The dimer depicted has five O-linked glycans at each of the four hinge regions. The numbered amino acids indicate the six most common sites of attachment of O-glycans. The composition and number of the O-glycans differ substantially among the IgA1 molecules in a person, constituting microheterogeneity for the structure of the hinge region. The numbers below the position indicators show the frequency (percentage) of the compositional variations of an IgA1 myeloma protein that mimics the structure of poorly glycosylated IgA1 in patients with IgA nephropathy. As compared with healthy persons, patients with IgA nephropathy have more circulating IgA1 molecules with O-linked hinge-region glycans that do not include galactose (galactose-deficient IgA1). Panel B shows O-glycan variants of IgA1. Synthesis of the O-linked glycans proceeds in a stepwise manner, starting with attachment of N-acetylgalactosamine to some of the hinge-region serine or threonine amino acids. The glycan is normally extended by attachment of galactose. Sialic acid can be attached to N-acetylgalactosamine, galactose, or both. If sialic acid is attached to N-acetylgalactosamine before attachment of galactose, subsequent attachment of galactose is not possible. An imbalance in the activities or expression of specific glycosyltransferases in patients with IgA nephropathy accounts for the increased production of galactose-deficient O-linked glycans in the IgA1 hinge region with increased sialic acid residues. Cα denotes constant-region domain on alpha heavy chain, CL constant-region domain on light chain, VH variable region on heavy chain, and VL variable region on light chain. Squares indicate N-acetylgalactosamine, circles galactose, and diamonds sialic acid. (Reproduced with permission from: Wyatt RJ, Julian BA. IgA nephropathy. N Engl J Med. 2013;368:2402–14.)

Serum galactose-deficient IgA1 level is a heritable trait in whites with IgAN and HSPN nephritis and in Asians and African Americans with IgAN.[61–63] Approximately 75% of patients with IgAN have a level above the 90th percentile for healthy controls and approximately 30% to 40% of first-degree relatives of patients with IgAN also have significantly elevated serum galactose-deficient IgA1 level.[61,64] The majority of first-degree relatives with elevated serum galactose-deficient IgA1 levels do not develop clinical manifestations of IgAN of HSPNs.[61,65] This suggests that additional factors are necessary for the disease to be clinically expressed.

Genome-wide association studies (GWAS) have the capablity to detect common susceptibility for complex traits without *a priori* mechanistic hypotheses.[66] A GWAS comprising a discovery cohort of 1194 IgAN cases and 902

controls of Chinese Han ancestry and follow-up cohorts of Han Chinese (740 cases, 750 controls) and European ancestry (1273 cases, 1201 controls) found five susceptibility loci. Three were on chromosome 6p21 in the major histocompatibility complex, and one was on chromosome 1q32 in the complement factor H (CFH) gene cluster. A single deletion of *CFHR1,3* (complement factor H–related proteins 1 and 3) conferred a 30% reduction in the risk for developing IgAN. The fifth locus was on chromosome 22q12 in a region encoding oncostatin and leukemia inhibitory factor, which are cytokines involved in mucosal immunity and inflammation. All five loci were replicated in a meta-analysis comprising 12 cohorts of Asian, European, and African-American ancestry.[67]

CLINICAL PRESENTATION

In the United States, 75% of children and adolescents with IgAN present with macroscopic hematuria.[22,34,67] Such episodes typically occur during an upper respiratory tract infection, with macroscopic hematuria clearing after a period of 2 to 4 days. Children also may present with microscopic hematuria with or without proteinuria or, more rarely, isolated proteinuria. Gross hematuria is not generally seen before the age of 3 years.[68]

Approximately 10% of children presenting with macroscopic hematuria have an acute kidney injury, but fewer than 5% have chronically impaired renal function at diagnosis.[22,34] Before the widespread use of normative blood pressure data based on gender, age, and height percentiles, hypertension at presentation of pediatric IgAN appeared to be unusual. The use of such normative data suggests that approximately 25% of pediatric patients in the United States are hypertensive at presentation.[69] However, severe hypertension in children presenting with normal renal function is rare. As a result of school screening programs, the majority of cases in Japan are detected with asymptomatic microscopic hematuria, proteinuria, or both.[10,15] Some children detected by screening will subsequently have a typical episode of macroscopic hematuria during an upper respiratory tract infection.

Figure 23.4 Classic distribution of Henoch-Schönlein purpura rash in the lower extremities in a child.

Fewer than 10% of children with IgAN present with overt nephrotic syndrome.[22,70] IgAN and steroid-responsive idiopathic nephrotic syndrome have occurred in the same child, and the clinical manifestations of one may appear several years after the other.[71,72] Treatment with corticosteroids should be directed toward the steroid-responsive idiopathic nephrotic syndrome and not withheld because of the presence of IgAN.[72]

The peak incidence of HSP is between 4 and 6 years of age, although individuals may present later in childhood or even as adults.[73] The child initially manifests with a typical rash that spreads from lower extremities up toward the buttocks and can be seen on the trunk and extensor surfaces of upper extremities (Figure 23.4). Scalp edema has been described in some patients. Other manifestations include abdominal pain or arthritis. Joint swelling and pain may be a dominant clinical manifestation in some. Intussusception may be seen in some patients with HSP, which manifests with intermittent abdominal pain and gastrointestinal bleeding. Urinalysis is often normal at the time of presentation, even in some who subsequently develop severe nephritis. HSPN may actually develop after all other manifestations of HSP have resolved.[73] Thus, it is imperative that all patients with

---

KEY POINTS

- Synpharyngitic macroscopic hematuria is common in children with IgAN.
- Ten percent of children present with acute kidney injury.
- Hypertension is common in children at presentation (approximately 25%).
- Nephrotic syndrome is uncommon (less than 10%).

KEY POINTS

- The peak incidence of HSP is seen in early childhood (4 to 6 years of age).
- Nephritis in HSP can occur after the nonrenal manifestations have subsided.
- Urinalysis may be normal early in the course of HSP.
- Proteinuria and nephrotic syndrome require close monitoring.
- Persistent proteinuria, nephrotic syndrome, and renal dysfunction are indications for a renal biopsy and treatment.

HSP should have a urinalysis performed every other week for at least 2 months from onset. Approximately 25% of children with HSPN will have macroscopic hematuria.[1,74] Approximately 10% to 20% of pediatric patients with HSPN will develop nephrotic syndrome.[75-77]

EVALUATION AND DIAGNOSIS

Serum galactose-deficient IgA1 and antiglycan antibodies levels show some promise as diagnostic markers, but at the present time assays appropriate for use in the clinical laboratory are not available.[78] With no specific serologic marker for IgAN, diagnosis remains dependent on examination of cortical renal tissue obtained via kidney biopsy. In contrast, the diagnosis of HSPN is based on the presence of typical clinical features of HSP and clinical evidence of nephritis.[79] In HSPN, renal biopsy is usually reserved for patients with significant proteinuria who may require treatment. The renal biopsy findings in HSPN and IgAN are indistinguishable,[80] although patients with HSPN are more likely to have significant crescentic involvement.[1,23]

Initial laboratory tests for evaluation of suspected IgAN should include serum creatinine and albumin, serum complement C3, fluorescent antinuclear antibody (to exclude systemic lupus erythematosus [SLE]), urinalysis, and quantitation of urinary protein excretion by either a timed urine collection or random ratio of urine protein to creatinine. Except in the rare instance of preexisting deficiencies of an individual complement component or regulatory protein, serum concentrations of C3 and C4 are normal in both IgAN and HSPN.[23,81-83] For HSPN, perinuclear antineutrophil cytoplasmic antibodies (p-ANCA) and cytoplasmic ANCA (c-ANCA) and platelet counts may be necessary. Although the serum IgA level is usually above the mean and often significantly elevated in IgAN and HSPN, the sensitivity of the assay is too low for its use as a diagnostic test for either condition.[23,81,84]

The differential diagnosis of IgAN includes C1q nephropathy, IgG nephropathy, and SLE.[85-87] Poststreptococcal acute glomerulonephritis rarely manifests with a rash that appears similar to the HSP rash, and this diagnosis should be entertained when the serum C3 level is depressed.[88] Another unusual presentation is HSPN with typical systemic manifestations but without mesangial immune complex deposition.[81]

OUTCOME

The outcome for pediatric patients with IgAN ranges from complete resolution of all clinical signs of disease to end-stage renal disease (ESRD).[22,34,36,69,81,89-91] At least one-third of pediatric patients with IgAN eventually have a normal urinalysis result, including some with severe histologic changes such as focal segmental sclerosis and crescents[69] or nephrotic syndrome.[22,34,69,81,89] In 181 Japanese children

with IgAN with a mean follow-up time of 7.3 years, 50.3% had achieved a clinical remission, 13.2% had persistent isolated hematuria, 32.6% had persistent hematuria and proteinuria, and 4% had advanced to ESRD at the time of last clinical examination.[92] The same group retrospectively analyzed 96 Japanese children with minor glomerular abnormalities, focal mesangial proliferation, or both, who did not receive medication for treatment of IgAN and found that 57 achieved spontaneous remission with a mean time from onset to remission of 5.9 ± 0.4 years.[93]

KEY POINTS

- IgAN may progress to ESRD in 20% of cases.
- In unselected cases of HSPN, ESRD is seen in 3% of cases.

Kidney survival data for pediatric IgAN indicate that about 20% of patients eventually progress to ESRD, as often as adults.[2-5] In 2007, in a Memphis cohort of 67 white patients, predicted renal survival was 91% at 10 years and 80% at 20 years.[94] These findings are similar to predicted renal survival in a Finnish pediatric cohort (n = 55), with 93% renal survival at 10 years and 87% renal survival at 20 years.[95]

In Japan, 5% of pediatric patients with IgAN reached ESRD by 10 years from diagnosis in cohorts analyzed in the late 1980s.[90,91] Yata et al.[96] reported actuarial renal survival from the time of apparent disease onset in children diagnosed from 1976 to 2004 as 96.4% at 10 years, 84.5% at 15 years, and 73.9% at 20 years, with improved renal survival in those children diagnosed between 1990 and 2004 (98.8% at 10 years and 98.8% at 15 years). Studies of renal survival in pediatric patients with IgAN are summarized in Table 23.2.

Precise outcome for HSPN is difficult to determine because of wide differences in severity of cases reported from various tertiary care hospitals.[98-102] Data from "unselected" patients suggest that the risk for ESRD is approximately 1% for all children with HSP and 3% for those with HSPN.[75,77,98] Clearly, some pediatric patients with HSPN will progress to ESRD.[24,25,98] In Germany, 22% of patients with HSPN were predicted to reach ESRD by 10 years from onset.[24]

PROGNOSIS

The optimal primary endpoint for studies of prognostic markers and treatment of glomerular diseases is progression to ESRD or a surrogate marker that closely associates with this end point. For pediatric patients with IgAN, clinical markers at diagnosis that associate with progressive loss of kidney function, ESRD, or both are magnitude of proteinuria and severe histologic features on kidney biopsy.[2-4]

Numerous studies of adults with IgAN have indicated that hypertension and renal function at time of presentation are important prognostic indicators.[102]

The use of serial measurements of urinary protein excretion averaged over 6-month intervals after renal biopsy has better prognostic value than a single measurement of proteinuria at the time of diagnosis.[103] In an adult population of Chinese patients with IgAN, time-averaged urinary protein excretion greater than 1.0 g/day was associated with a risk for ESRD that was 46 times the risk among patients with values of less than 0.5 g/day.[104]

Hypertension has been significantly related to progression in only one pediatric report.[34] However, blood pressures greater than 140/90 mm Hg are usually associated with loss of renal function in adult cohorts.[106-111] Proteinuria and hypertension were used in an adult study together to accurately predict decline in glomerular filtration rate and risk for dialysis or death.[111,112]

Numerous adult studies that have associated poor renal function at the time of diagnosis with development of ESRD.[115,116] There are not enough large pediatric studies that have evaluated baseline renal function and progression of disease in children. It is reasonable to assume that a child with impaired renal function at the time of diagnosis would be at increased risk for development of ESRD.

Hematuria, whether macroscopic or microscopic, does not correlate with prognosis, and early studies suggesting that gross hematuria was associated with better outcome were likely affected by lead time bias.[116] Two reports that both included the patients from Memphis suggested that African Americans had a significantly worse outcome than whites.[22,34] However, for Memphis patients diagnosed since 1990 there was no difference in outcome based on race.[20] Our most recent kidney survival data for the entire Memphis IgAN cohort also shows no difference in progression to ESRD based on gender.

The Oxford cohort was developed to determine histologic predictors of progression.[32,33] Patients with estimated glomerular filtration rate (eGFR) less than 30 mL/min/1.73 m^2 (CKD4) were excluded from the study, and progression to ESRD or more than 50% decline from entry eGFR was used as the primary outcome measure during validation for this biopsy classification schema. The Oxford cohort included 206 adult and 59 pediatric patients with IgAN from 17 centers (located in Asia, Europe, and North America) and required urinary protein excretion greater than 500 mg/day and more than 12 months of follow-up time.

Mesangial hypercellularity (M), segmental glomerulosclerosis/adhesion (S), and tubular atrophy and interstitial fibrosis (T) were the histologic features independently associated with loss of renal function (see Figure 23.1). Endocapillary proliferation (E) was associated with progression in patients not treated with corticosteroids or other immunosuppressive drugs. Grading of these four histologic features constitute the MEST score.[33]

Coppo et al.[40] verified the MEST with a subgroup analysis of the data from the pediatric patients in the Oxford cohort. Other groups have applied this classification schema to their cohorts of children with IgAN. In a Swedish study, the mesangial hypercellularity score greater than 0.5, the presence of endocapillary hypercellularity, or tubular atrophy/interstitial fibrosis of greater than 25% was significantly associated with a poor renal outcome, but segmental glomerulosclerosis was not.[117] Shima et al.[118] found in 161 Japanese children with newly diagnosed IgAN from 1977 to 1989 that mesangial hypercellularity score, endocapillary hypercellularity, tubular atrophy, and crescents were significant predictors of renal outcome in a univariate analysis.

Severe histologic findings and nephrotic syndrome are markers of poor prognosis for HSPN.[23,101] Logistic regression analysis in a German cohort found that renal insufficiency at presentation and nephrotic syndrome were significant independent predictors of outcome.[25] Although many clinicians feel that younger children are less likely to have severe or progressive HSPN, age at presentation does not significantly associate with outcome.[24,25,99]

TREATMENT STRATEGIES

There are no solid, evidence-based guidelines for the treatment of pediatric IgAN and HSPN.[72] This is due to factors such as (1) the small number of patients at single centers; (2) the difficulty, time, and expense in organizing randomized controlled trials (RCTs); and (3) progression from normal function to ESRD may take several decades. In addition, distinct treatment strategies may be applied to acute and chronic phases of disease.

Rapidly progressive or severe crescentic IgAN and HSPN are usually treated with high-dose intravenous methylprednisolone pulses followed by oral corticosteroids and sometimes other immunosuppressive agents, such as cyclophosphamide.[120–123] All published data on this approach are from uncontrolled case series. This treatment may be effective in some instances, but a poor outcome cannot be avoided if the glomerular lesions are too far advanced before therapy is begun.[72]

Treatment with an angiotensin-converting enzyme inhibitor (ACEI) or angiotensin receptor blocker is recommended as initial therapy for with IgAN.[123] A recent RCT in children and young adults showed that ACEI treatment was associated with better prognosis.[124] Our group and others now use this approach for both hypertensive and normotensive pediatric patients.[71,125] In an RCT of mycophenolate mofetil (MMF) for pediatric and adult patients with IgAN, many patients had such significant reduction in proteinuria in response to 3 months of ACEI and fish oil treatment that they were no longer eligible for randomization to MMF or placebo.[126]

KEY POINTS

- Treatment of rapidly progressive nephritis should be undertaken urgently. Intravenous methylprednisolone is the initial drug of choice.
- Use of ACEIs or angiotensin receptor blockers is the recommended therapy in early IgAN.

Although there are no RCTs supporting the approach, corticosteroid therapy is indicated for pediatric patients with IgAN or HSPN who have the nephrotic syndrome.[72] An RCT for adult and pediatric patients with IgAN compared alternate-day prednisone, fish oil capsules, and placebo and showed no significant advantage with respect to time to ESRD for any arm of the trial.[127] Current Kidney Disease: Improving Global Outcomes (KDIGO) guidelines for glomerular disease suggest that corticosteroids should be initiated in high-risk patients only if proteinuria remains above 1 g/day after supportive care has been optimized for 3 to 6 months and only if GFR remains above 50 mL/min/1.73 m^2 (level 2C evidence).[123] The Therapeutic Evaluation of Steroids in IgA Nephropathy Global Study (TESTING Study) is an RCT currently enrolling patients 14 years or older with proteinuria higher than 1 g/day to evaluate the use of methylprednisolone versus placebo in patients with IgAN already on maximal RAS blockade (http://clinicaltrials.gov/show/NCT01560052). Coppo[128] postulated that there may be a legacy effect—that is, benefit to early and aggressive treatment of mild IgAN with low-grade proteinuria at presentation that might prevent sclerosis and interstitial fibrosis leading to loss of GFR later in the course of the disease.

SUMMARY

As illustrated in the following case report, some patients who originally have HSPN will enter a chronic phase in which the clinical phenotype is that of IgAN. Patients with HSPN and IgAN with persistent proteinuria, flares, or both characterized by macroscopic hematuria during viral illness appear to be at risk for eventual progression to ESRD. In such cases decisions about treatment are difficult and sometimes not supported by evidence from RCTs. Future advances will depend on delineation of the earliest pathogenetic mechanisms in IgAN and HSPN with specific therapy targeted toward such mechanisms.

ACKNOWLEDGMENTS

Clinical Vignette 23.1

A previously well 5-year-old white male presented with the typical features of HSP: purpuric rash distributed on the lower limbs, swollen ankles, abdominal pain, and microscopic hematuria. Two weeks later he developed macroscopic hematuria. He had transient hypertension with a maximum blood pressure of 120/85 mm Hg that resolved without treatment. Pertinent laboratory tests included hemoglobin, 11.3 g/dL; platelet count, 519 ×

10^9/mL; serum creatinine, 0.5 mg/dL; serum albumin, 2.8 g/dL; serum cholesterol, 242 mg/dL; complement C3, 92 mg/dL (normal); and a negative antinuclear antibody test. The urinalysis had a specific gravity of 1.015 with 2+ protein and a sediment that showed too numerous to count (TNTC) red blood cells (RBCs), 5 to 10 white blood cells (WBCs) per high-power field (hpf), and several granular casts/hpf. Random ratio of urine protein to creatinine increased from 0.62 to 4.1 over the next 7 days. Renal biopsy showed diffuse mesangial proliferative glomerulonephritis with focal sclerosis in 9% and cellular crescents in 12% of the glomeruli. Immunofluorescence showed mesangial deposition of IgA (3+), IgG (2+), complement C3 (3+), and properdin (2+). Alternate-day prednisone was begun at a dose of 40 mg/m^2 every other day and continued in a tapering dose for 18 months. At this era, an ACEI was not used for treatment of nonhypertensive glomerular disease. One month after treatment was stopped the urine had TNTC RBC/hpf, but the ratio of urine protein to creatinine was normal (0.13).

The child was not seen again until age 10, when he had an episode of macroscopic hematuria associated with exercise. At this time he had no rash or joint or abdominal symptoms. His serum creatinine was 0.5 mg/dL, and the ratio of urine protein to creatinine was 2.8. Alternate-day prednisone was again begun at 40 mg/m^2 per dose, and a fish oil supplement (MaxEPA) was added. After 4 months he was lost to follow-up until he returned at age 14 after another episode of macroscopic hematuria during a flulike illness. His serum creatinine level was 0.9 mg/dL and albumin was 3.1 g/dL. Urinalysis showed specific gravity of 1.020 with 2+ protein. Microscopic examination of unspun urine showed TNTC RBCs/hpf, 20% of which were dysmorphic. The ratio of urine protein to creatinine was 4.1. A second renal biopsy showed diffuse mesangial proliferation with 20% obsolescent glomeruli, but minimal focal sclerosis and no crescents. There was minimal interstitial fibrosis. The immunofluorescence pattern was similar to that of the first biopsy sample except for the presence of IgM with 1+ intensity. He was normotensive, with no HSP rash. With no therapeutic intervention, 2 weeks after the biopsy the ratio of urine protein to creatinine fell to 1.07 and 10 mg per day of the ACEI fosinopril was begun.

One year later he had yet another episode of macroscopic hematuria with a viral illness. Over the next 2 months his serum creatinine increased from 0.7 to 2.2 mg/dL and albumin fell to 2.9 g/dL; the ratio of urine protein to creatinine was up to 5.9. A third renal biopsy was performed that showed diffuse mesangial proliferation with 10% of the glomeruli having cellular crescents. Several glomeruli showed segmental sclerosis and fibrous adhesions to Bowman's capsule. Alternate-day prednisone at 40 mg/m^2 per dose and MMF (initial dose of 600 mg/m^2/day, advanced to 900 mg/m^2/day)

were started. The prednisone was discontinued after 10 months and MMF after 14 months when the serum creatinine was 0.7 mg/dL; albumin, 3.2 g/dL; and ratio of urine protein to creatinine, 2.5. Three years later, at age 17, he developed macroscopic hematuria again and nephrotic syndrome shortly after undergoing a tonsillectomy. Serum creatinine was 1.7 mg/dL; albumin, 2.0 g/dL; and ratio of urine protein to creatinine, 4.6. He had severe edema with ascites. He slowly improved after treatment with alternate-day prednisone, MMF, fosinopril, and losartan. At the last follow-up, he continued to have microscopic hematuria with a serum creatinine of 1.1 mg/dL; serum albumin, 3.4 g/dL, and ratio of urine protein to creatinine, 0.75.

TEACHING POINTS

This patient presented at 5 years of age with classic clinical features of HSPN. Five years later, he developed episodes of recurrent gross hematuria that were preceded by exercise and flu-like illnesses. HSP-like rash was absent in these hematuria events. The clinical course of this patient is reminiscent of a transition from HSPN to IgAN. Interestingly, the first renal biopsy of this patient documented that 9% of glomeruli were affected by chronicity changes indicated by focal glomerular sclerosis, a finding that is less likely to be present during acute phase of HSP nephritis. It can, therefore, be argued that even though this patient presented with classic clinical features of acute HSPN, it is more likely that he had an underlying IgA nephropathy of much longer duration. Although an accurate MEST score for IgAN (Oxford classification) was not developed for this patient, histologic features, presence of renal insufficiency at presentation, and nephrotic syndrome are considered indicators of poor outcome in HSPN-IgAN spectrum of disorders. [23,25,101,117,118]

From a therapeutic perspective, remission of proteinuria after steroid therapy for HSPN provided clinical relief to the patient. Yet the renal disease in this patient progresses, as documented by the second renal biopsy, development of nephrotic syndrome, and onset of CKD. This patient did not receive the benefit of ACE-inhibition as an anti-proteinuric and renoprotective therapy, since such a therapy was not considered to be the standard of care in the era of this patient's clinical presentation. At present, ACE inhibition and ARB therapies should be considered as a part of ongoing management of IgA nephropathy, unless contraindications for their use exist.

REVIEW QUESTIONS

1. Which of the following histopathologic features is *not* included as a part of the Oxford classification?
   a. Mesangial hypercellularity
   b. Endocapillary hypercellularity
   c. Segmental glomerulosclerosis
   d. Tubular atrophy/interstitial fibrosis
   e. Crescent formation

2. The increased incidence of IgA nephropathy in Asian countries such as Japan may be due to all of the following, *except:*
   a. True racial or ethnic differences in incidence
   b. Increased detection through school screening programs
   c. An aggressive approach by pediatric nephrologists in these countries for performing renal biopsies in children with isolated microscopic hematuria or low levels of proteinuria
   d. Increased serum levels of immunoglobulin A in these populations

3. On renal biopsy, IgA nephropathy is characterized by which of the following:
   a. Dominant or codominant deposition of immunoglobulin A, mainly in the glomerular mesangium
   b. Subepithelial humps
   c. Patchy foot process effacement
   d. Prominent subendothelial deposits
   e. Apple-green birefringence under polarized light

4. A multi-hit hypothesis may explain the pathogenesis of IgA nephropathy. The first hit is thought to be due to:
   a. The presence in the serum of galactose-deficient (or underglycosylated) IgA1 in which in some carbohydrate side chains (*O*-glycans) of the hinge region terminate in *N*-acetylgalactosamine (GalNAc) or sialylated GalNac rather than galactose
   b. The generation of antiglycan antibodies recognizing this terminal GalNac
   c. The formation of nephritogenic circulating immune complexes containing galactose-deficient IgA1 and antiglycan antibody
   d. Secretion of extracellular matrix components, induction of nitric oxide synthase, and the release various mediators of renal injury such as angiotensin II, proinflammatory and profibrotic cytokines, and growth factors

5. Which of the following statements is *false*?
   a. Serum galactose-deficient IgA1 level is elevated in approximately 75% patients with IgA nephropathy; this is a heritable trait.
   b. The majority of first-degree relatives with elevated serum galactose-deficient IgA1 levels do not develop clinical manifestations of IgA nephropathy of HSP nephritis.

   c. A locus at 6q22-23 named IgAN1 is associated with the production of galactose-deficient immunoglobulin A.
   d. Susceptibility loci for IgA nephropathy have been found on chromosome 6p21 in the major histocompatibility complex and on chromosome 1q32 in the complement factor H (CFH) gene cluster.

6. In the United States, the percentage of children who have gross hematuria at the time of presentation with IgA nephropathy is approximately:
   a. 10%
   b. 25%
   c. 50%
   d. 75%
   e. 90%

7. The peak incidence of Henoch-Schönlein purpura is between ages:
   a. 1 to 3 years
   b. 2 to 4 years
   c. 4 to 6 years
   d. 6 to 8 years
   e. 10 to 12 years

8. The percentage of children with IgA nephropathy who present with overt nephrotic syndrome is:
   a. Less than 10%
   b. 10% to 25%
   c. 25% to 50%
   d. 50% to 75%
   e. Greater than 75%

9. The diagnosis of IgA nephropathy is dependent on:
   a. Serum galactose-deficient IgA1 and antiglycan antibody levels
   b. Serum immunoglobulin A levels
   c. Low C3 levels
   d. Genetic testing for IgAN1
   e. Examination of cortical renal tissue obtained via kidney biopsy

10. A normal urinalysis may eventually be seen in what percentage of pediatric patients diagnosed with IgA nephropathy?
    a. 10%
    b. 20%
    c. 33%
    d. 70%
    e. 90%

11. All of the following features may predict loss of renal function in children and adults with IgA nephropathy, *except:*
    a. Serial measurements of urinary protein excretion averaged over 6 month intervals after renal biopsy
    b. Severe histologic features on kidney biopsy
    c. Hypertension
    d. Renal function at time of presentation
    e. Persistent hematuria

12. The mainstay of treatment for persistent proteinuria in the setting of IgA nephropathy is:
    a. High-dose intravenous corticosteroids
    b. Low-dose oral corticosteroids
    c. Angiotensin-converting enzyme inhibitors or angiotensin receptor blockers
    d. Tonsillectomy
    e. Cyclophosphamide

Thrombotic microangiopathies

JOHN D. MAHAN AND STEPHEN CHA

INTRODUCTION

Thrombotic microangiopathies (TMAs) are diverse clinical conditions characterized by endothelial injury and microvascular thrombotic lesions that often involve the kidneys and can affect a variety of organs, such as the nervous system and the gastrointestinal (GI) tract. The most common forms of TMA encountered during childhood are the hemolytic uremic-syndrome (HUS), and to a significantly lesser extent thrombotic thrombocytopenia (TTP). All TMAs, especially HUS, are characterized by the triad of microangiopathic hemolytic anemia, thrombocytopenia, and microvascular thrombosis in the kidneys and other organs.

HISTORICAL DEVELOPMENTS

HUS was first described by Gasser in 1955, and the systemic character of HUS was subsequently defined.[1] Kaplan and Drummond[2] identified several distinct entities that can manifest as HUS and emphasized that HUS was a syndrome with a common pathologic outcome. HUS is now considered as a part of the broader group of TMA. TTP, first described by Moschcowitz[3] in 1925, is a distinct clinicopathologic condition that can mimic the clinical characteristics of HUS. Indeed, although these criteria seem distinct, in real life the clinical forms are often incomplete or changing during the course of the disorder, complicating a precise separation of the two entities and their evaluation and treatment.

The TMAs can occur as sporadic disorders, in epidemic outbreaks, or in a genetic or familial pattern.[4–7] Although HUS and TTP are uncommon diseases, they represent common causes of acute kidney injury (AKI) in infants and children, in both the developed and undeveloped countries.[8] Although most children experience complete recovery of renal function after a single TMA disorder, chronic kidney disease (CKD) characterized by hypertension, proteinuria, renal insufficiency, or a combination of these complicates a significant minority of the survivors. Children with severe clinical disease and those with an inherited form of HUS often progress to end-stage renal disease (ESRD).

The discovery that endothelial cell injury underlies this broad spectrum of TMA disorders has come into focus during the last two decades. In the 1980s, Karmali et al.[9] defined the presence of microvascular injury in diarrhea-associated HUS and the critical role of a verotoxin produced by specific strains of *Escherichia coli*. This verotoxin was subsequently found to be a member of a family of toxins first identified with *Shigella* and known as Shiga toxin (Stx). This relationship and the eventual link of TTP to abnormally high levels of ultra-large Von Willebrand factor (vWF) multimers caused by congenital or acquired reductions in ADAMTS13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13) activity was established at approximately

the same time.[10] A decade later, Warwicker et al.[7] confirmed the association of atypical HUS (aHUS) to defects in a region on chromosome 1 that contains the genes for several complement regulatory proteins. Mutations in complement factor H (CFH), complement factor I (CFI), membrane cofactor protein (MCP, CD46), factor B, C3, and thrombomodulin have now been found to cause many of the familial cases of aHUS.[4] These discoveries have allowed a more comprehensive understanding of the pathogenesis, evaluation, and treatment of the entire spectrum of TMA disorders and provide a more rational and effective approach to the care of these children with complicated disease.[4,11]

NOMENCLATURE

TMA encompasses a number of different clinicopathologic disorders, most prominently HUS and TTP (Table 24.1). The nomenclature of TMA, and particularly of HUS, has evolved over the last decade. HUS caused by Stx-producing *E. coli* (STEC) and usually preceded by a diarrheal prodrome had been previously designated as D-positive HUS (diarrhea-associated. All other forms of HUS that were not associated with preceding diarrhea were classified as D-negative HUS.

With the development of a better understanding of the pathogenesis of HUS, the classification of HUS into subtypes is also undergoing a redefinition. The D-positive HUS caused by the STEC is now referred to as the STEC-HUS. Nondiarrheal, or D-negative HUS, on the other hand, comprises multiple clinical entities that have varied causes and pathogenesis. The term *atypical HUS* (aHUS) is now beginning to be used in a more restricted manner to indicate the genetic, or familial, form of TMA resulting from a dysfunctional regulation of the complement cascade. With increasing availability of genetic testing, it is likely that more patients with the familial, or genetic, form of aHUS will be detected. HUS from pneumococcal infection is a less common but a well-recognized clinical form of TMA. HIV infection–associated TMA is an important infection-triggered disorder seen in both children and adults. Drugs, malignancies, and pregnancy-associated TMA are sometimes encountered in specific clinical circumstances.

DIAGNOSTIC CRITERIA FOR THROMBOTIC MICROANGIOPATHIES

TMA is characterized by the triad of hemolytic anemia, thrombocytopenia, and organ dysfunction, especially renal dysfunction. Hemolytic anemia in TMA is microangiopathic, with peripheral smear of blood demonstrating burr cells, helmet cells or schistocytes, and teardrop cells (Figure 24.1). Anemia is thought to be due to direct

mechanical injury of the red blood cells (RBCs) caused by thrombosis in the microvascular circulation. Because anemia is nonimmune in nature, the direct Coombs test is negative in all cases, except *Streptococcus pneumoniae*–associated HUS (explained later). Hemolysis is further confirmed by an elevated serum lactic dehydrogenase (LDH) level and elevated reticulocyte count. Thrombocytopenia is modest in most at onset, but can rapidly reach below 50,000/mm^3. Blood urea nitrogen (BUN) and serum creatinine may be elevated at presentation, and BUN may be elevated out of proportion to rise in creatinine (Cr) (BUN/Cr ratio greater than 20) in some patients because of the presence of dehydration caused by the diarrheal disease.

SHIGA TOXIN–PRODUCING *ESCHERICHIA COLI*–ASSOCIATED HEMOLYTIC-UREMIC SYNDROME

EPIDEMIOLOGY

STEC-HUS is the most common form of HUS noted during childhood. Since 2001, *E. coli* O157 and non-O157 STEC infections resulting in human illness have been designated as notifiable illness in the Nationally Notifiable Diseases Surveillance System in the United States, resulting in more complete data acquisition on the disease. Annually, 110,000 cases of diarrhea caused by *E. coli* are identified in the United States. Of this, approximately 3200 (3%) require hospitalization.[12] HUS develops in 5% to 8% of patients affected by STEC in the United States. A meta-analysis of the published reports observed that of the patients with *E. coli* O157:H7 diarrheal disease, 17.2% patients in small studies (fewer than 50 cases) and 4.2% in large studies (more than 1000 cases) developed HUS.[13] Children below 5 years of age infected by STEC are disproportionately susceptible to development of HUS and may have an infection rate of up to 15%.[14,15]

STEC-HUS accounts for 90% of all cases of HUS in childhood.[16] The overall incidence of STEC-HUS in the United States, including in adults, is 1.5 per 100,000 population.[14] However, STEC-HUS is more common in children younger than 5 years of age, wherein its incidence has been reported to be as high as 6.5 cases per 100,000 population.[14]

Median age of STEC-HUS in one study from the United States was 4 years (range, 3 months to 64 years). The disease was dominant in the age group younger than 18 years, and only 12% of total patients in this study were over 18 years of age.[16] A similarly high incidence of STEC-HUS in children younger than 5 years of age also has been reported from other geographic regions.[6,15,17] A recent epidemic of

STEC-HUS in Germany caused by *E. coli* O104:H4, however, was, characterized by an exceptionally high incidence in adults (median age, 42 years) and older children and may reflect a changing epidemiologic trend.[18] In part, this demographic shift has been attributed to the type of vector (salad) involved in the transmission of *E. coli* in this epidemic.

KEY POINTS

- HUS secondary to *E. coli* infection is the most common form of HUS in children (90%).
- STEC-HUS occurs in 1.5 to 2 patients per 100,000 population.
- STEC-HUS is more common in children younger than 5 years of age (6.5 per 100,000 population.)

Peak incidence of STEC-HUS occurs in the summer months of May through September, but sporadic cases occur throughout the year.[16] Equal sex distribution of the STEC-HUS has been recognized in most studies.[16] One study reported a significantly low incidence of STEC-HUS in African-Americans.[19] A decreasing trend in STEC-HUS was reported in the United States by the Centers for Disease Control and Prevention (CDC) in 2011, compared to the 2006 to 2008 era, but the trend appears to have halted in 2013.[20]

MICROBIOLOGY OF *ESCHERICHIA COLI* INFECTION

The most common *E. coli* serotype identified in patients with hemorrhagic colitis and HUS in the United States is O157:H7.[13,16,17,21] *E. coli* serotypes are diverse, and by now over 200 different types of STEC have been characterized.[21] Non-O157:H7 *E. coli,* such as O111 and O104:H4 and even nonserotypable *E. coli,* are an emerging subgroup of *E. coli* that can cause outbreaks of enterocolitis and HUS.[22–24] The important characteristic of *E. coli* that results in HUS is the ability to produce the Shiga toxin. Because Stx-producing *E. coli* frequently causes symptoms of hemorrhagic diarrhea, the term *enterohemorrhagic E. coli* is sometimes used to identify it. Studies have shown that 0.3% to 0.9% of stool samples submitted for routine culture are STEC positive, and approximately 50% of these are the *E. coli* O157:H7 strain.[25] In patients with diarrhea due to *E. coli* O157:H7, it can be recovered in 100% of stool samples if the culture is obtained in the first 2 days and the yield declines to 33% after 7 days.[3,26]

Cattle are the largest reservoir for STEC, in which it may cause bloody diarrhea but usually by a commensal organism.[27] Undercooked hamburgers have been the vector of several epidemics of HUS in the United States and Canada. Other potential vectors of STEC include domestic animals (sheep), wild animals (deer, seagulls), humans, water, other

beverages, and other food sources. Transmission of STEC commonly occurs through ingestion of contaminated food products (beef, fruit, and produce washed in contaminated water), visits to dairy farms and petting zoos, and exposure to airborne organisms.[28, 29] Contact with contaminated dirt also has been implicated in the transmission of these bacteria.[29] Person-to-person spread of *E. coli* O157:H7, especially in day care and family groups, is well known.[30]

<div style="border:1px solid #000;padding:10px;background:#f0e0ef;">

KEY POINTS

- *E. coli* serotype O157:H7 is the most common pathogen associated with STEC-HUS.
- Other serotypes may be involved in STEC-HUS.

</div>

SHIGA TOXIN

STEC was first linked to acute colitis in humans by Riley et al.[31] in 1983 and to epidemic HUS in children by Karmali et al.[9] in 1985. The Stx family of toxins elaborated by *E. coli* are also referred to as *verotoxins* because of their observed toxicity in monkey kidney vero cells.

The Stx produced by STEC is composed of a biologically active subunit A and a receptor unit B. The B subunit is composed of five subunits, through which the toxin binds to specific glycoprotein receptors on susceptible cells.[33] STEC produce two types of Stx, known as Stx1 and Stx2, and each have their subvariants, Stx1c, Stx2c, Stx2d, Stx2e, Stx2f, and Stx2g.[3,32] STEC toxins are structurally similar to the toxins produced by *Shigella dysenteriae* type 1, and are thus named Shiga toxins (or Shiga-like toxins). Some strains of STEC can produce both types of Stx1 and Stx2 toxins. Stx2 has been shown to be a more toxic and virulent form of Shiga toxin in mice. The STEC toxins are potent inhibitors of protein synthesis in endothelial cells.[32]

PATHOGENESIS OF SHIGA TOXIN–PRODUCING *ESCHERICHIA COLI* HEMOLYTIC-UREMIC SYNDROME

In humans, STEC infection causes both bloody and nonbloody diarrhea. Only approximately 5% to 8% of children with STEC-associated hemorrhagic colitis develop HUS.[14,15,26] Virulence factors such as enterocyte attachment factors affect the ability of these organisms to produce human disease.[32–34] The severity of the colitis usually correlates with the clinical severity of the HUS.[35]

After a person ingests contaminated or poorly cooked food, STEC results in colitis that can be associated with bloody diarrhea. Stx and lipopolysaccharides produced by these organisms are then absorbed from the colonic mucosa into the systemic circulation

(Figure 24.2).[36] In the past, endotoxemia caused by Stx was difficult to demonstrate.[37] Recent findings of circulating Stx in some patients with HUS by Brigotti et al.[38] support the hypothesis of endotoxemia-induced pathogenesis of HUS. The role of leukocytes and RBCs in the carriage of Stx from the gut to kidney and other organs also has been in demonstrated in STEC-HUS.[38,39]

Through its subunit B, Stx binds to the glycoprotein galabiosyl ceramide and globotriosyl ceramide (Gb3) receptors on the surface of GI epithelial and endothelial cells (Figure 24.3). The active fragment of Stx (subunit A) is internalized into the cells and interferes with ribosomal protein synthesis through depurination. This leads to apoptosis of the affected cells and eventual cell death.[9,40–42] Apart from glomerular endothelial cells, Gb3 receptors for Stx are also present on podocytes and mesangial cells.[39] Stx binding to glomerular and renal tubular cells can be quite unpredictable because of variable cellular Gb3 expression on these cells. Stx binding or Gb3 expression has not been shown to be greater in the glomeruli or renal tissue of younger subjects compared to older subjects.[43]

<div style="border:1px solid #000;padding:10px;background:#f0e0ef;">

KEY POINTS

- Stx subunit B attaches to GB3 receptor on the GI epithelial cells and other host cells.
- Subunit A is internalized and interferes with cellular protein synthesis.
- Stx endotoxemia has been difficult to demonstrate but may be present.

</div>

The receptor-mediated internalization of the Stx is essential in cellular injury and inducing a prothrombotic state.[39] Endothelial cells, in response to subunit A demonstrate altered gene expressions, increased prothrombotic protein production, and release of von Willebrand (vW) multimers into the circulation that cause platelets to adhere to these multimers and form microvascular clots.[44] Other cells, such as monocytes and neutrophils, are induced by Stx to release proinflammatory mediators such as interleukin-1 and tumor necrosis factor (TNF) and upregulate adhesion molecules that can augment adherence to endothelial cells, further enhancing the vascular and cellular injury in HUS.[43–46] As endothelial surfaces are injured, platelet and coagulation factor deposition results in microvascular thrombi formation and, ultimately, the TMA that characterizes HUS.[47] Documentation of hypocomplementemia, with low C3 complement, along with increased levels of activated factor B and soluble membrane attack complex (MAC) detected during active HUS in some patients suggest a possible role for alternative complement activation in the pathogenesis of STEC-HUS.[48–50]
Figure 24.2 Pathogenesis of Shiga toxin–producing *Escherichia coli* hemolytic-uremic syndrome–related acute kidney injury.

Most studies suggest that antibiotic treatment of STEC-mediated gastroenteritis is associated with a higher incidence of HUS, presumably as a result of release of Stx into the circulation.[51,52] Based on in vitro experiments in mice, induction of bacteriophages in *E. coli* by antibiotics (quinolones) has been proposed as a mechanism for this enhanced Stx production.[53] However, in a meta-analysis of clinical reports and studies, treatment with antibiotics failed to demonstrate an increased likelihood of HUS with antibiotic use in STEC diarrhea.[54]
Figure 24.3 A diagrammatic representation of cellular events leading to microvascular thrombosis and organ injury in Shiga toxin (Stx)–producing *Escherichia coli* hemolytic-uremic syndrome.

CLINICAL MANIFESTATIONS

STEC-HUS primarily affects young children, in whom the disease is also more severe. STEC-HUS is more common in the summer and autumn months and may occur both sporadically and in localized epidemics. Some studies have reported a higher incidence of HUS among rural than urban populations in the United States and in other countries.[3,5,17] Siegler et al.,[55] on the other hand, did not see a significant difference in the incidence of STEC-HUS in urban and rural settings.

Three clinically indistinct phases, diarrheal prodrome, onset of HUS, and recovery phase or progression to ESRD, are noted in the course of STEC- HUS in children.

Diarrheal prodrome

Signs of GI illness, characterized by abdominal pain, vomiting, and diarrhea, precede the onset of STEC-HUS. A diarrheal prodrome is noted in 85% to 95% of patients with STEC-induced HUS, and usually lasts 3 to 4 days.[6,16,17,55] Although stools are usually bloody, some may have only streaks of blood visible in the diarrheal stool.[55] Severe cases may be associated with intussusception or intestinal perforation.[56,57] GI manifestations may be minimal or transient.

Acute disease phase

HUS evolves in 5 to 7 days after onset of diarrheal prodrome.[6,16,17,55] Anorexia, weakness, pallor, and jaundice are the presenting manifestations in many children with HUS. These findings represent development of profound anemia

as a result of microangiopathic hemolysis. Platelet count of approximately 75,000/mm³ is common at presentation. Normal platelet count has been reported in 13% patients with HUS.[58] As thrombocytopenia becomes more significant, purpura or petechiae may develop

---

KEY POINTS

- Onset of STEC-HUS can be sudden, 4 to 6 days after diarrhea.
- Oliguria, paleness, and puffiness are early manifestations.
- Neurologic manifestations can occur in 30% patients with STEC-HUS.

Oliguria or hematuria may be the initial recognition of HUS by many parents of the affected children. These manifestations may evolve over a few hours to a few days, depending on the severity of the disease. Progressive and severe renal injury is usually associated with anuria. Oligoanuria, as a manifestation of AKI in HUS, has been reported in 50% to 60% patients and eventual need for dialysis arises in 40% to 50% of patients with STEC-HUS.[56,59] Duration of necessary dialysis varies from 1 to 2 weeks in most patients. Hyponatremia secondary to fluid overload (dilutional hyponatremia), high anion gap metabolic acidosis, and hyperkalemia may be seen at presentation.

Central nervous system symptoms, such as lethargy, irritability, seizures, cortical blindness, paresis, and coma, have been reported in 25% to 30% of affected children.[16,60,61] Complications of renal insufficiency, such as hypertension, electrolyte disturbances, and uremia, may contribute to the CNS symptoms, as well. Evidence of other significant organ system damage in HUS may become apparent as the condition progresses. Pancreatic injury in some patients with HUS can lead to hyperglycemia and diabetes mellitus.[62]

Recovery phase

Once oliguria and AKI set in, dialysis support for treatment of hypervolemia, electrolyte disturbances, and hypertension may be necessary for 1 to 2 weeks. It is uncommon for dialysis to be required beyond 4 weeks in most patients, unless associated complications occur or progression to ESRD is impending. Recovery of platelet count often precedes renal recovery by 3 to 5 days. Urine output can increase rapidly in patients headed toward recovery of renal function. Sometimes a phase of polyuria can be seen while recovering from oligoanuric HUS. Mild proteinuria can be seen in the recovery phase and may persist for several months, but nephrotic-range proteinuria is unusual. Prolonged anuria indicates severe renal disease that may lead to nonrecovery of renal function and development of ESRD. Sequential renal ultrasound evaluations may demonstrate declining renal size in these patients over 6 to 8 weeks of the disease.

ATYPICAL HEMOLYTIC-UREMIC SYNDROME

HUS without any accompanying diarrheal illness has, in past, been classified as D-negative HUS. One subcategory of D-negative HUS, characterized by severe clinical disease, frequent progression to ESRD, recurrent disease episodes, and sometimes familial occurrence, is now recognized as a separate clinical disorder and is designated the atypical hemolytic uremic syndrome (aHUS). Complement dysfunction resulting from mutations in one or multiple complement regulatory proteins is recognized as the underlying mechanism in these patients.

INCIDENCE AND DEMOGRAPHICS

The incidence of aHUS is not known precisely. It is estimated that aHUS comprises 5% to 10% of all cases of childhood HUS, and more than 1000 cases have been reported worldwide.[63] The incidence of aHUS in the United States, derived indirectly from the Synsorb Study, has been estimated to be 2 in 1,000,000 population, representing 11% of all cases of HUS in the study.[64] These data may, indeed, be an under-representation of true incidence in the general population.

The initial presentation of aHUS may occur as early as the first day of life to as late as adulthood. In the International Registry of Recurrent and Familial HUS/TTP data, 60% of the reported cases were younger than 18 years of age, whereas in the French national study, 42% patients were younger than 18 years of age.[65,66] The mean age of presentation in the French series was 1.5 years.[66] Early presentation of the disease has been reported to be especially common in patients with the CFH gene mutations.

The male-to-female sex ratio was nearly equal in the International Registry patients (M/F, 125:131).[65] The French series also showed an equal male-to-female ratio (M/F, 47:42) in children younger than 18 years of age, but there was a preponderance of females among the adult patients with aHUS (M/F, 32:93).[66]

KEY POINTS

- aHUS is a rare disorder (1 to 2 per 1,000,000 population) and accounts for fewer than 10% of all cases of HUS in childhood.
- Family history of aHUS may be present in 30% cases.
- Genetic mutations in complement-regulating proteins or complement cause this disorder.

A family history of aHUS may be present in approximately 30% of patients.[65–67] A recognized trigger of an episode of aHUS is recorded in 30% to 50% patients and varies from a trivial viral respiratory infection, otitis media, or sinusitis in the majority of patients to severe systemic infectious diseases in the minority. Precipitation of an episode of aHUS also has been noted after exposure to certain drugs, hypertension, or pregnancy. Diarrheal illnesses can occasionally trigger aHUS, making it difficult at presentation to distinguish aHUS from STEC-induced HUS in such cases.

ATYPICAL HEMOLYTIC-UREMIC SYNDROME AS A COMPLEMENT DYSFUNCTION DISORDER

Many, but not all, patients presenting with the clinical features of aHUS demonstrate mutations of the alternative complement pathway. Inherited deficiency or dysfunction of factor H or factor I, factors that exert inhibitory control over the alternative complement pathway, are the most commonly described genetic defects of complement regulation associated with aHUS.[65–69] Other less frequent genetic defects in complement regulation associated with an aHUS include factor B and reduced expression of membrane cofactor protein (MCP, CD46).[70–73] Recently, mutations affecting diacylglycerol transferase an enzyme present in endothelial cells, also has been described as a cause of aHUS.[74] Some of these patients do not manifest clinical disease until adulthood, even though the genetic predisposition is present, when a triggering event occurs.

COMPLEMENT CASCADE AND ITS REGULATION

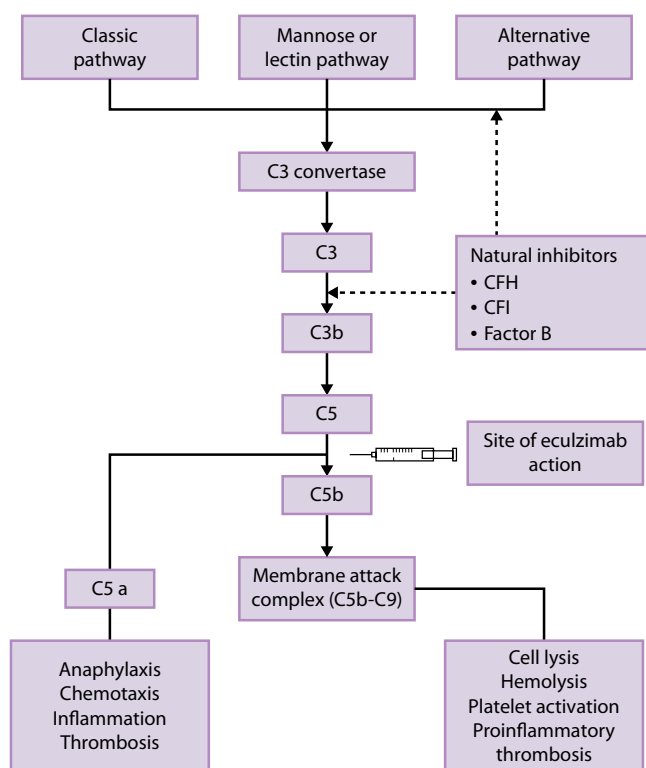
Complement serves as an important mediator of immune responses. The entire complement pathway is composed of over 30 protein molecules that are synthesized in the liver. The complement pathway participates in tissue inflammation by generation of chemoattractants in areas of inflammation, opsonization of bacteria, and bacterial cell lysis. Three separate mechanisms can initiate the complement cascade: (1) classical pathway, (2) lectin pathway, and (3) alternative pathway. Although all three pathways are initiated by different triggers, they all result in generation of a common effector molecule called C3 convertase (Figure 24.4). C3 convertase is responsible for enzymatic degradation of complement C3. This part of the complement cascade is known as the early complement pathway. After C3 convertase is generated, complements C5 through C9 are activated, leading to the formation of MAC, and C5a. MAC is involved in cell lysis and activation of platelets and is prothrombotic


Figure 24.4 Diagrammatic representation of complement pathways showing the inhibitory control sites by complement factor H (CFH) and complement factor I (CFI). Site of action of eculizumab is also shown.

and proinflammatory. C5a, on the other hand, promotes anaphylaxis, chemotaxis, inflammation, and thrombosis. This segment of complement pathway beyond the formation of C3 convertase is also known as the terminal complement pathway.[75]

If not regulated, the complement cascade can result in unregulated generation of proinflammatory molecules detrimental to the host. Several circulating and tissue-bound proteins provide an inhibitory control mechanism on the complement pathway and prevent unwarranted complement activation that can be harmful to the host.

GENETICS OF ATYPICAL HEMOLYTIC-UREMIC SYNDROME

Genetic mutations in one or more of the complement regulatory proteins have been documented in 40% to 60% of individuals with aHUS.[65–73] These disorders represent an incomplete gene penetrance, and additional triggers, such as an infection, drugs, or bone marrow transplant, are often necessary to precipitate an episode of aHUS in susceptible individuals. Concurrent multiple complement-regulating gene defects also have been described in some individuals with aHUS, and such patients appear to have the greatest risk for progression to ESRD, as well as recurrence after renal transplant.[72]

COMPLEMENT REGULATION PROTEINS AND ATYPICAL HEMOLYTIC-UREMIC SYNDROME

Without the appropriate inhibitory control in the complement activation process, excessive C3 convertase and eventually C5a and C5b can occur. C5a induces significant changes in endothelial cells to a prothrombotic, inflammatory phenotype capable of chemotactic effects on circulating leukocytes. The C5b fraction leads to generation of the MAC, a molecular assembly that leads to lysis of endothelial and other cells. The end-result of complement activation is vascular injury and development of a prothrombotic state, leading to TMA.[65,72]

Although a number of complement regulatory protein defects have been characterized and the phenotype-genotype correlation well established, understanding of the broad range of mutations and their phenotypic outcome is still evolving. Some of the defined complement regulatory protein defects leading to aHUS include the following:

1. **Complement factor H:** CFH is one of the proteins that bind to C3b and the C3 convertase formed in the alternative pathway at the cell surface and degrades both of them.[76] Diminished CFH allows unchecked C3 convertase formation on endothelial cells. Mutations in CFH are the most common genetic defect noted in aHUS, accounting for 20% to 30% of all cases (Table 24.2).[65–68]
2. **Antibodies to complement factor H:** Autoantibodies to CFH can result in a nonfunctional or poorly functional CFH and lead to aHUS. In large studies, these antibodies have been identified in 3% to 7% of patients with aHUS.[65,66,76]

3. **Complement factor I:** CFI is a serene protease that cleaves C3b and C4b. In its absence there is increased C3 convertase formation and initiation of the both the proximal and terminal parts of the complement cascade. Mutations that result in decreased CFI activity have been reported in 4% to 9% of patients with aHUS.[65,66,76]
4. **Membrane cofactor protein:** Membrane cofactor protein (MCP, also known as CD46) is an important cofactor for CFI in degrading C3b and C4b.[71,75,76] Mutations in MCP have been documented in 7% to 19% of patients with aHUS.[65–68,76]
5. **Complement C3:** Complement C3 plays a central role in the complement cascade as the precursor protein for C3 convertase. A gain in function mutation affecting complement C3 can result in the enhanced formation of C3 convertase and activation of complement cascade.[76] C3 mutations have been reported in 4% to 9% of patients with aHUS.[65–68,76]
6. **Thrombomodulin:** Thrombomodulin (TM), encoded by the *THBD* gene, is involved in the inactivation of C3b by CFI.[75,76] THBD gene mutation is involved in fewer than 5% of patients with aHUS.[65–68]
7. **Factor B:** Factor B is involved in the alternative complement pathway, where it is cleaved by factor D into Ba and Bb. The subfraction Bb results in the formation of C3 convertase of the alternative pathway. This is an uncommon complement dysfunction caused by gain in function mutation of the gene regulating factor B. Factor B mutations account for 0% to 3% of aHUS.[76]
8. **Undefined genetic mutations:** In each of the three large genetic studies, reported so far, 30% to 60% of patients with aHUS did not have any known genetic mutation.[65–68]

CLINICAL MANIFESTATIONS

Most children have their first episode of aHUS before 2 years of age. Mean age of presentation of children with aHUS in the French series was 1.5 years. Family history of the aHUS may be present in 30% of patients.[65,66]

The episode of aHUS is often preceded by an infective event or exposure to specific drugs or occurs during pregnancy in adult women. Occasionally, viral and other diarrheal illness may trigger aHUS, making the differentiation from STEC-induced HUS difficult at presentation.

Onset of clinical symptoms, such as pallor and decreased urine output, indicative of hemolytic anemia and renal dysfunction, can occur insidiously but may also appear abruptly following an illness. The classic diagnostic triad of hemolytic anemia, thrombocytopenia, and renal failure, evolves in most patients (70% to 80%).[63,65,66] Extrarenal manifestations, particularly neurologic and cardiovascular involvement, are common, especially in aHUS patients with CFH mutations.[65,66] Reduced complement C3 level is present in approximately 30% to 50% of patients, most notably in aHUS secondary to complement C3 mutations and CFH mutations.[65,66]

CLINICAL OUTCOME OF ATYPICAL HEMOLYTIC-UREMIC SYNDROME

The clinical course of aHUS can be characterized by recurrent episodes of hemolysis and renal dysfunction. A relapsing pattern has been reported in 10% to 60% of cases, depending on the type of genetic mutation.[65,66] Most relapses (80%) occur within the first year of onset of aHUS.[66] Recurrences of aHUS are most commonly observed in patients with CFH gene mutations.[65] The International Registry of Recurrent and Familial HUS/TTP reported that ESRD or death occurred within the first 3 years of the onset of aHUS in 70% of patients.[65] Of all the genetic mutations in complement regulation, aHUS associated with MCP mutations has the most favorable outcome, with ESRD or death reported in fewer than 10% patients.[65,76] Interestingly, the prognosis of aHUS in patients without any identifiable mutation does not appear to be better than that seen in those with well-documented gene mutations.[65,66,77]

HEMOLYTIC-UREMIC SYNDROME IN PNEUMOCOCCAL DISEASE

An atypical form of HUS (D-HUS) caused by invasive *S. pneumoniae* infection termed SpHUS is an uncommon but well-described clinical disorder. Because many of these patients also suffer from significant *S. pneumoniae* systemic disease and may even have concurrent disseminated intravascular coagulopathy (DIC), recognition of aHUS in these patients may be difficult. A high index of suspicion is an important key to the diagnosis of SpHUS in such sick patients.

INCIDENCE AND DEMOGRAPHICS

SpHUS is a rare form of HUS. Over a 21-year period, only 14 patients with SpHUS were reported from the Children's Hospital of Philadelphia, suggesting occurrence of 0.63 cases per year.[78] In another study

Table 24.3 Acute complications of hemolytic-uremic syndrome

Organ system	Complication
• Neurologic	• Irritability
	• Seizures
	• Coma
	• Cerebral infarction
	• Cortical blindness
	• Paresis

	• Stricture
• Pancreas	• Pancreatitis
	• Pancreatic failure (diabetes mellitus)
• Liver	• Hepatocellular injury
• Testes	• Infarction
• Skeletal muscles	• Myopathy

from the United Kingdom, a total of 45 patients were reported nation-wide over a 7-year period.[79] This suggests a yearly incidence of 6.4 new cases of SpHUS per year in the entire United Kingdom. Based on hospital discharge data over a 5-year period, SpHUS comprised 4.6% of all HUS cases admitted to hospitals in the United States.[80]

SpHUS generally occurs in young children. Median age of presentation in the United Kingdom was 13 months (range, 5 to 39 months).[79] In two studies reported from the United States, the mean age of presentation was 22 months (range, 4 to 62 months) and 27 months (range, 4 to 56 months).[78,81] In an analysis of 58 other reported cases, Brandt et al.[82] found the mean age of presentation to be 16.2 months. A slight female dominance has been reported by some.[70,80] Seasonal distribution in cases from the United Kingdom suggests that majority (74%) of cases occurred between October and March.[79]

SITE OF INFECTION AND BACTERIOLOGY

In more than 75% of patients with SpHUS, the primary source of infection is in the lungs, usually pneumonia. The second most common source of infection is meningitis. Empyema, as a complication of pneumonia, has been noted commonly in these patients and may represent the invasive nature of this organism.[78–83] Specific serotypes of *S. pneumoniae* may be relevant in the etiopathogenesis of SpHUS. Two separate studies of SpHUS have noted a high prevalence of infection by *S. pneumoniae* serotype A19.[78,81]

PATHOGENESIS

Klein et al.,[84] in 1977, proposed that the neuraminidase produced by *S. pneumoniae* exposes the hidden or cryptic Thomsen-Friedenreich antigen (T-antigen) present normally on RBCs, platelets, endothelial cells, glomeruli, and hepatocytes. This observation was based on the finding that the T-antigen was found exposed on the RBCs and the glomeruli in two children who died of pneumococcal sepsis and pneumonia. Klein et al. proposed that once neuraminidase exposes the T-antigen on the RBCs, platelets, and endothelial cells, these sites react with the naturally occurring circulating serum immunoglobulin M (IgM) antibodies to the T-antigen. This may lead to complement activation, vascular injury, and development of TMA, although there is now evidence that the pathogenesis is more complex than this straight forward explanation.[85,86]

A role for CFH, a potent inhibitor of alternative complement pathway activation, in the pathogenesis of SpHUS has been speculated by some.[87,88] These investigators suggest that desialylation of RBCs and endothelial cells by pneumococcal neuraminidase also may destroy binding sites for CFH on these host cells that could promote complement activation.

KEY POINTS

- Neuraminidase in *S. pneumonia* exposes the T-antigens on RBCs and other cells.
- Naturally occurring IgM antibodies against T-antigen react with the exposed T-antigen to initiate cellular damage and hemolysis.

CLINICAL FEATURES

In contrast to classic *E. coli*-induced HUS, patients with SpHUS are younger and usually sicker. Acute renal injury, evidenced by oliguria and rise of serum creatinine may lead to the incidental discovery of TMA in some of these patients. A higher proportion of patients with SpHUS (up to 80%) require supportive dialysis, and there is a higher frequency of serious extrarenal complications.[78,79,81,82]

One of the distinguishing features of SpHUS is that these patients have a positive direct Coombs test. This distinguishes SpHUS patients from those with other forms of TMA and can be used as a screening test in suspected cases with *S. pneumoniae*–induced HUS.

KEY POINT

Renal failure needing dialysis or continuous renal replacement therapy is very frequent (80%) in SpHUS.

THROMBOTIC MICROANGIOPATHIES IN OTHER INFECTIONS

HUS has been reported in a variety of infectious diseases that may be associated with diarrhea, such as *Salmonella, Shigella, Yersinia,* and *Campylobacter* infections.[89,90] Some viral infections, such as the human immunodeficiency virus (HIV), Coxsackie virus, influenza virus, Epstein-Barr virus, and rubella virus, have been associated with HUS.[91–94]

HIV-associated TMA may manifest abruptly and at any stage of HIV infection. The pathogenesis of TMA in HIV infection remains unclear. Some patients have been reported to have deficiency of ADAMTS13, whereas others have normal plasma levels.[94] Endothelial injury by the virus or antiretroviral drugs remains a possibility. Oliguric renal failure and ESRD can result after a relatively short clinical course.[90,94,95]

DRUG-INDUCED THROMBOTIC MICROANGIOPATHIES

TMA, in particular the classic HUS phenotype, has been reported in association with some drugs and malignancies. Clinically, these cases mimic patients with aHUS. Calcineurin inhibitors (cyclosporine and tacrolimus), commonly used in renal and other transplants, are well known causes of TMA.[96] Chemotherapeutic agents, such as mitomycin C, cytosine arabinoside, cisplatinum, and gemcitabine, have been associated with drug-induced HUS.[97] Antiplatelet drugs, such as ticlopidine and clopidogrel, can cause HUS.[98] Antiangiogenesis treatment of malignancies also has been associated with a TMA disorder. TMA has been reported after treatment with biologic agents that block the activity of vascular endothelial growth factor (VEGF).[99]

THROMBOTIC THROMBOCYTOPENIA

TTP is an uncommon but life-threatening form of TMA that rarely occurs in children. The clinical manifestations and some of the laboratory features of TTP can, at times, be indistinguishable from those of HUS. The differentiation may be complicated further by the fact that neurologic and other organ dysfunction also can be encountered in children with HUS.

KEY POINTS

- SpHUS is an uncommon form of HUS and may be under-recognized.
- The highest incidence is in children younger than 3 years of age.
- Complicated pneumonia is a common association.
- Presence of a positive direct Coombs test, in addition to other features of HUS, is diagnostic for spHUS.

INCIDENCE AND DEMOGRAPHICS

The true incidence of TTP in childhood remains uncertain. The Oklahoma TTP-HUS Registry recently analyzed their experience over the 17 years (1996 to 2013) during which 79 patients were diagnosed to have TTP.[100] The incidence of TTP in children (younger than 18 years) in this group was 0.09 in 1,000,000 children per year. This compared to the incidence of 2.88 in 1,000,000 per year in adults. These observations suggest that that only 3% of patients with TTP are younger than 18 years of age. Most of the children affected by TTP are older, in contrast with STEC-HUS, in which most patients are younger than 5 years of age.[100,101] The sex distribution of TTP in children is reported to be similar to that seen in adults, with TTP more common in females.

KEY POINTS

- TTP is mostly a disease of the adult population.
- In TTP, females are affected more than males.

PATHOGENESIS

The role of von Willibrand factor (vWF) in the pathogenesis of TTP has been well characterized in the last decade. vWF is synthesized by endothelial cells and megakaryocytes and stored as ultra-large vWF multimers in Weibel-Palade bodies in the endothelium and as a granules in platelets. vWF is secreted as multimers into the plasma compartment but remains associated with the endothelial cell surface, providing binding sites for platelets and promoting platelet aggregation. Stress or injury to endothelial cells, and vasopressin, lead to increased vWF release.

The vWF cleaving protease known as ADAMTS13 (a dysintegrin and metalloprotease with thrombospondin-like motifs type 13) is now recognized to be critical in maintaining intravascular clotting homeostasis.[11,102] ADAMTS13 cleaves the vWF multimers by proteolytic degradation.[102] Lacking adequate concentration of ADAMTS13 enzyme in plasma, the plasma multimers of vWF accumulate and promote platelet aggregation and formation of thrombi within the vascular tree (Figure 24.5). These thrombi usually lack fibrin and are composed mostly of platelet aggregates.[102] The platelet-rich microvascular thrombi of TTP are typically found at the arteriolar-capillary junction, a site characterized by high sheer stress. The vascular beds usually affected by microvascular thrombosis in TTP are in the brain, heart, spleen, kidneys, pancreas, adrenals, lungs, and eyes.

Inherited deficiency of ADAMTS13 is now well established as a cause of TTP in children. Several mutations in the gene encoding ADAMTS13 have been described and are associated with development of the inherited variant of TTP.[102–105] The inherited form of TTP seen during childhood is also known as Upshaw-Schulman syndrome, named after the initial discoverers of the defect.[105,106]

TTP in adults usually results from acquired IgG antibodies directed against ADAMTS13.[107,108] Circulating immune complexes containing ADAMTS13 have been documented in about a third of these patients.[109] TTP is considered by some to be an autoimmune disorder.
Figure 24.5 Pathogenesis of thrombotic thrombocytopenia. Left side of the cartoon demonstrates the role of ADAMTS13 in breaking down vWF in normal individuals. Right side of the cartoon shows the generation of platelet thrombi in TTP. Absence or inactivation of ADAMTS 13 leads to accumulation of von Willibrand factor multimers in plasma, promotes adherence of platelets to vWF multimers, and develops microvascular thrombosis.

KEY POINTS

- TP is caused by deficiency or absence of vWF factor–cleaving protease known as ADAMTS13.
- Mutations in *ADAMTS13* gene can result in the congenital form of TTP in children and adults known as Upshaw-Schulman syndrome.

CLINICAL FEATURES

Upshaw-Schulman syndrome

Inherited TTP resulting from genetic mutation and absence of ADAMTS13 (Upshaw-Schulman syndrome) often manifests with neonatal hyperbilirubinemia secondary to microangiopathic hemolytic anemia. In a review of 43 patients with the Upshaw-Schulman syndrome from Japan, 43% patients had history of neonatal hyperbilirubinemia that required exchange transfusion.[110] Recurrent episodes of TTP and associated AKI are common in these patients, and ESRD develops in approximately 20%.[111] Even with congenital deficiency of ADAMTS13, more than half of the patients are diagnosed later in life (15 to 45 years).[110,111] TTP in these patients is usually triggered by infection or pregnancy.

Antibody-mediated thrombotic thrombocytopenia

The clinical and laboratory criteria used by Moschcowitz[3] to describe patients with the TTP pentad are

- Features of systemic illness, such as fever
- Microangiopathic hemolytic anemia
- Thrombocytopenia
- AKI
- Neurologic involvement

Classic (antibody-mediated) TTP is seen in older adolescents and adults and affects females more than males. At presentation, the clinical pentad noted here is not observed universally and may be seen in only 40% to 50% of cases. The triad of microangiopathic hemolytic anemia, thrombocytopenia, and neurologic manifestations, on the other hand, is the most common manifestation and is seen in 80% to 90% of patients.[112] Clinical presentation of patients with TTP can be quite dramatic, with neurologic manifestations such as headache, confusion, seizures, or coma.[111,112] Most patients also have nonspecific clinical complaints, such as fever, malaise, and nausea. Involvement of the GI system can manifest as abdominal pain, pancreatitis, and GI bleeding.[112–114] AKI requiring renal replacement therapy evolves quickly in 40% to 75% of cases.[110,111] Thrombocytopenia-related petechial manifestations or even frank bleeding diatheses also can be seen.

KEY POINTS

- All features of the TTP pentad are seen in only 40% to 50% of cases.
- Renal disease is seen less commonly in TTP than HUS.
- Extrarenal manifestations are common.
- The acute mortality rate of TTP is high.

DIFFERENTIATING HEMOLYTIC-UREMIC SYNDROME FROM THROMBOTIC THROMBOCYTOPENIA

The majority of children (85% to 95%) with STEC-HUS display a GI prodrome, and neurologic involvement and seizures are less common (15% to 30%). In contrast, fever, feeling of being unwell, and neurologic symptoms dominate in TTP. ADAMTS13 assay allows a clearer distinction between TTP and HUS. Plasma ADAMTS13 levels are very low in TTP patients and are normal (greater than 10%) in patients with HUS. Antibodies to ADAMTS13 are seen in acquired forms of TTP, whereas these are absent in inherited forms of TTP.[114]

PATHOLOGY OF THROMBOTIC MICROANGIOPATHY

Vascular pathology

Irrespective of the underlying cause of TMA, the characteristic pathologic lesions consist of endothelial cell injury and small vessel thrombosis, platelet aggregation, vascular injury, and organ dysfunction.[1,115,116] The endothelial cells are swollen, they may be detached from the underlying basement membrane, and the subendothelial space is filled with amorphous material and fibrin. Platelet-fibrin thrombi are present within the vascular lumen and hinder vascular blood flow. Pathologic studies demonstrate that fibrin vascular thrombi tend to predominate in HUS and that platelet thrombi are more prominent in the vascular injury associated with TTP.[11]

Renal pathology

The morphologic findings of renal injury in HUS and all forms TMAs consist of glomerular, arteriolar and interlobular arterial endothelial cell injury and thrombosis and signs of tubular cell injury and acute tubular necrosis (ATN). Glomerular thrombi and thrombosis affecting the interlobular arteries are classic features of HUS (Figure 24.6).[117–119] The extent of ATN can be variable and may be prominent in some. Earliest electron microscopy findings consist of endothelial cell swelling, vacuolization, and separation of the endothelial cell from the basement membrane with "fluffy" and fibrillar material and platelet fragments appearing under the separated endothelial cells. Later, mesangial matrix and cell expansion, endothelial cell necrosis, and small and larger vessel occlusion with platelet and fibrin thrombi are evident.[119,120] Positive staining for fibrinogen, C3, and IgM in the vascular lesions is characteristic.[118]

As the acute phase of the disease wanes and renal biopsies are obtained during follow-up of patients with CKD secondary to TMA, most patients demonstrate varying degrees of glomerular sclerosis and chronic tubulointerstitial damage and fibrosis.
Figure 24.6 Light microscopy showing a glomerulus affected by thrombosis (arrow) in Shiga toxin–producing *Escherichia coli* hemolytic-uremic syndrome.

KEY POINTS

- Endothelial damage is the hallmark of TMA.
- Microvascular thrombosis affects glomeruli, arterioles, and interlobar arteries of the kidney.

EVALUATION AND DIAGNOSIS

A general diagnostic evaluation pathway of a patient with suspected TMA is shown in in Figure 24.7. Clinical and laboratory diagnostic techniques are essential in establishing the diagnosis of various types of TMA.

Urinalysis

The urinalysis typically demonstrates hematuria, proteinuria, and cellular casts, although early in the course hematuria may be the only abnormality. Urine also may be visibly brown or muddy in some cases.

Hematologic profile

All patients have evidence of microangiopathic hemolytic anemia with low hemoglobin and peripheral smear demonstrating evidence of fragmented RBCs (see Figure 24.1) and schistocytes. Thrombocytopenia with evidence of new large platelets and a high mean platelet volume is generally seen. The reticulocyte count is typically elevated in response to intravascular hemolysis, although eventually, as renal insufficiency develops, the reticulocyte count will be low.

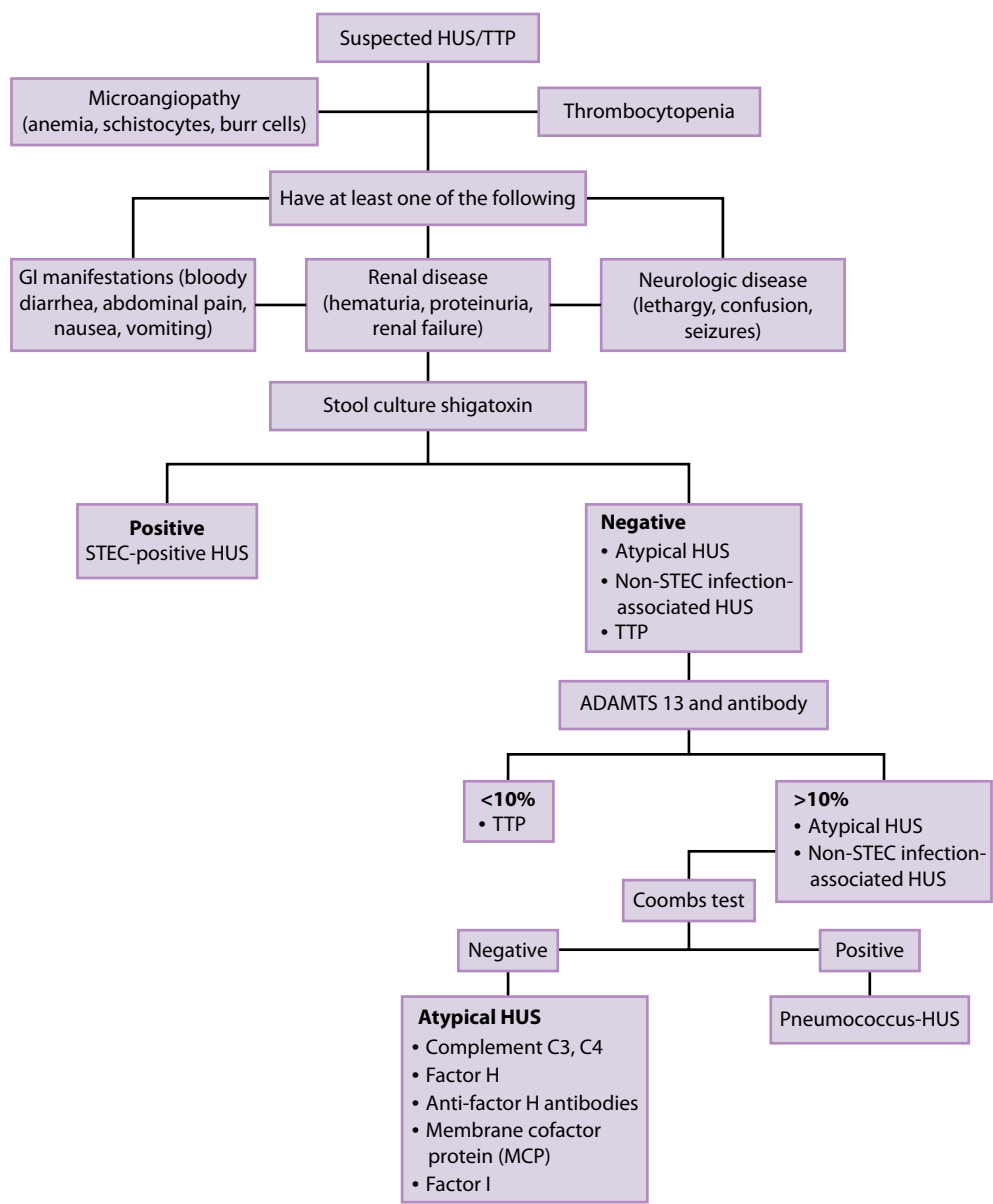
The leukocyte count is often elevated early in the course of HUS.[121] The direct and indirect Coombs tests are negative in STEC-HUS and aHUS, but the direct Coombs test is positive in SpHUS. The plasma


Figure 24.7 Diagnostic evaluation pathway in patients with thrombotic microangiopathy. *GI*, gastrointestinal; *HUS*, hemolytic-uremic syndrome; *STEC*, Shiga toxin–producing *Escherichia coli*; *TTP*, thrombotic thrombocytopenic purpura.

haptoglobin is low and indirect bilirubin high. Plasma LDH is elevated as a result of red cell lysis. The prothrombin and partial thromboplastin times are normal. Evidence of activation of the fibrinolytic system (increased levels of fibrin degradation products) is commonly seen, when assessed.

STOOL CULTURE AND SHIGA TOXIN ASSAY

Evidence of STEC infection can be determined by stool culture, detection of Stx in stool, and/or polymerase chain reaction (PCR) assays for Stx in the stool. CDC recommendations include collection of stool as early as possible after onset of diarrhea for detection of STEC and other pathogens.[122] In extenuating circumstances the stool sample may be stored for 24 hours in an unpreserved manner or in transport medium for up to 48 hours. Stx in testing on the bacterial culture obtained in broth provides better diagnostic yield than testing on the stool itself.[122] Immunoassay or PCR testing for Stx is now possible using several commercially available kits. It has been observed that stool culture alone on sorbitol MacConkey agar failed to detect a positive culture in 28% cases of STEC infection, and PCR for detection of the Stx gene missed 11% cases.[123] The CDC as well as other experts recommend using at least two methods for detection of STEC and Stx.[122–124] Newer research studies, including detection of Stx on the surface of circulating

neutrophils, offer other promising methods for more rapid detection of Stx-mediated HUS in the future.[125] DNA-based Stx gene detection has not yet been approved by the U.S. Food and Drug Administration.

> ## KEY POINTS
>
> - Stool culture should be inoculated on appropriate media for detection of STEC.
> - Assaying Stx on cultured organisms rather than on stool itself gives better results.
> - Stx assay and stool culture give better diagnostic yield for STEC than either one alone.

Renal function

The degree of kidney injury may be quite variable but usually manifests over 5 to 7 days after first evidence of renal involvement.[6,16,18,55] Laboratory evidence of acute renal failure injury in more severely affected patients include elevated BUN and creatinine, hyperkalemia, metabolic acidosis, hypocalcemia, hyperphosphatemia, and hyperuricemia.

Other organ dysfunction

Other less frequent laboratory findings, typically seen in more severely affected patients, include elevations of liver enzymes, creatine kinase, amylase, and lipase. For patients with pregnancy-associated HUS or HUS seen with medications, vasculitides, or other secondary disorders, the diagnosis is usually not difficult to establish.

Complement assay

The European Pediatric Study Group for HUS has defined the algorithm that should be followed for diagnosis of aHUS and its treatment. After ruling out the possibility of STEC-HUS and SpHUS, complement studies need to be obtained in all cases in which aHUS is being considered. It is important to note that despite being a disorder of dysregulated complement pathways, a normal serum complement C3 level does not always rule out aHUS.[126] Other studies that need to be considered in these patients include CFH and CFI plasma assay; antibody against CFH, MCP (CD46) expression on mononuclear leukocytes; and gene mutation analysis for CFH, CFI, MCP, factor B, and C3.

ADAMTS-13 AND ANTIBODY ASSAY

In patients considered to have TTP, plasma level of ADAMTS13 and antibody to ADAMTS13 (also known as inhibitor) should be determined before plasmapheresis is undertaken. The congenital or inherited form of TTP should be suspected in newborns with severe jaundice and hemolytic anemia of unclear cause. Severe deficiency of ADAMTS13 (less than 10%), without any antibody detection should be considered as presumptive evidence of this disorder and an indication for plasma infusion therapy. Congenital TTP can manifest at any age and may be considered even in older children. Presence of antibody to ADAMTS13 suggests the diagnosis of acquired (classic) form of TTP.[127]

MANAGEMENT OF SHIGA TOXIN–PRODUCING *ESCHERICHIA COLI* HEMOLYTIC-UREMIC SYNDROME

Most children with STEC-HUS recover with appropriate supportive care and management of acute renal failure. Supportive management of volume deficit or excess, anemia, hypertension, and electrolyte abnormalities is the mainstay of treatment of established HUS.

ANTIBIOTIC USE

Antibiotic therapy is not indicated for D positive HUS or idiopathic HUS and has been associated with worse outcome in some studies and been shown to be of no benefit or harm in most studies.[51,52] Often, in diarrhea-associated HUS, by the time the child presents with signs of HUS, the diarrheal illness is resolving and stool cultures may actually be negative.

INTRAVASCULAR VOLUME

Judicious volume expansion early in the course of HUS has been demonstrated to attenuate the degree of renal impairment.[128–130] Serum albumin is often low in these children, and replacement with intravenous albumin may be useful; however, no controlled studies using this intervention have been reported.[131] Most importantly, once acute renal failure and oliguria have set in, fluid balance needs to be maintained with judicious use of intravenous and oral fluid intake to avoid fluid overload and associated complications.

ANEMIA AND THROMBOCYTOPENIA

Treatment of anemia with judicious RBC transfusions is usually directed to keep the hemoglobin level greater than 8.0 mg/dL. Erythropoietin administration may be useful to maintain the hemoglobin count in case of prolonged renal insufficiency. Platelet transfusions may increase microvascular thrombosis, and are generally not recommended in TMA.[132] Platelet transfusion, however, may be clinically indicated in a minority of patients, especially in those who may require surgery. In one study, platelet transfusions based on clinical needs in STEC-HUS was not associated with adverse outcome.[133]

ACUTE RENAL INJURY

Management of acute oliguric renal failure requires (1) strict attention to fluid balance, (2) treatment of hypertension, and (3) correction of metabolic disturbances, such as hyperkalemia, metabolic acidosis, hypocalcemia, and hyperphosphatemia.[8,17,84,85] Dialysis support becomes necessary once anuria or significant oliguria develops in a patient with evidence of progressive renal insufficiency. In most young children, peritoneal dialysis (PD) is the modality of choice.[8] The advantage of PD in these patients is that it is technically easy, and placement of the dialysis catheter can be done by the bedside in the intensive care unit. Continuous renal replacement therapy (CRRT) also can be used in the treatment of AKI associated with HUS and may be especially suited in patients with intra-abdominal complications, such as pancreatitis or colitis. Regional citrate anticoagulation is preferred over heparinization in such patients because of the potential risk for bleeding. When dialysis is required, it is generally needed for 5 to 7 days, although some patients have recovered after more than a month of dialysis support, albeit with evidence of some chronic renal insufficiency. Providing adequate nutrition is important in all cases of HUS with significant AKI and may require parenteral nutritional therapy until the GI tract has recovered.

ECULIZUMAB IN SHIGA TOXIN–PRODUCING *ESCHERICHIA COLI* HEMOLYTIC-UREMIC SYNDROME

There is new interest in the use of eculizumab, a monoclonal antibody to C5, for the treatment of STEC-HUS. The rationale for this therapy is the observation that alternative complement pathway is likely to be involved in the pathogenesis of STEC-HUS.[51] Reports of children with severe STEC-HUS who received this drug have been encouraging, with reversal of hematologic abnormalities and improvement in neurologic symptoms with this therapy.[134] However, a subsequent clinical trial of eculizumab with plasma exchange in the German STEC-HUS epidemic did not establish superiority of eculizumab and plasma exchange over plasma exchange alone.[135,136] At present, the use of eculizumab has not been accepted universally for treatment of STEC-HUS but may be considered for the most severe cases, especially with neurologic manifestations.

KEY POINT

Although eculizumab has been used in STEC-HUS, its efficacy in this disorder is unclear at this time.

OTHER THERAPIES

For STEC-HUS, other therapies such as intravenous streptokinase, intravenous gamma-globulin, Stx-binding antitoxins, and corticosteroids have been shown to have no impact on clinical outcome.[137–140] Recent experience with plasma infusions and plasmapheresis in STEC-HUS in Germany has revived interest in these treatments for resistant or very sick patients with STEC-HUS.[135,136]

PREVENTING HEMOLYTIC-UREMIC SYNDROME

Prevention strategies are most useful to minimize exposure to STEC and include appropriate meat processing, food handling, and preparation.[141] All parts of food, especially meats, must be cooked to a core temperature of 70° C. Salads and sprouts are a common source of spread of STEC, and their cultivation, washing, and storage need to be carefully supervised in the supply chain. Simple measures, such as hand and food washing as well as avoidance of ingestion of raw and rare beef, remain effective strategies for prevention of acquisition of STEC infections and HUS.

MANAGEMENT OF ATYPICAL HEMOLYTIC-UREMIC SYNDROME

Patients with aHUS may present with an infection-triggered hemolytic crisis, acute onset of renal dysfunction, or neurologic complications, such as seizures. Supportive care, including dialysis therapy should be individualized. Some of the specific treatment options to be considered in this disorder are outlined in the following section.

PLASMAPHERESIS

Expert opinion favors providing plasmapheresis as the most effective initial therapy in aHUS.[125] This recommendation stems from the observation that high mortality rate, neurologic complications, and ESRD are common in this group of patients. Plasmapheresis should be begin within 24 hours of the presumptive diagnosis of aHUS. Fresh frozen plasma is used for plasmapheresis, and the treatment is continued until the platelet count normalizes.

ECULIZUMAB

Eculizumab has now been established as the standard of care for patients with aHUS.[145] This humanized monoclonal IgG2/4 antibody functions as a terminal complement inhibitor by binding to C5, thus blocking the production of C5a and C5b, activated complement proteins that trigger the TMA response (see Figure 24.4). Early initiation of eculizumab therapy

is associated with more rapid control of aHUS disease manifestations and has been reported to improve short-term and long-term outcomes.[143] In the prospective phase 2 trial of eculizumab, treatment over 26 weeks resulted in a mean increase in platelet count of 73×10^9 and a relapse-free clinical course in 80% of patients. Chronic dialysis was discontinued in four of five patients in the trial. A sustained increase in estimated glomerular filtration rate (GFR) and decrease in proteinuria were noted in the treated patients, and earlier start of therapy was associated with a better renal outcome.[142]

Eculizumab is administered weekly until normalization of the platelet count and the microangiopathic anemia improves. The pediatric dose recommendations for eculizumab are 600 mg per dose for children below 40 kg body weight and 900 mg per dose in those weighing above 40 kg body weight. Eculizumab is administered in a solution strength of 5 mg/mL and can be diluted with normal saline from its original strength of 10 mg/mL concentration. Infusion should last over 35 minutes, and patients need to be premedicated to prevent any cytokine-mediated or allergic manifestation. The half-life of eculizumab is 12.1 days.[144] Frequency of follow-up infusions is every 2 to 4 weeks, based on the clinical response. At this point, eculizumab is considered to be a life-long treatment for aHUS. Discontinuation of eculizumab has been associated with recurrence of disease, and most clinicians continue antibody therapy indefinitely.[145] Further studies are needed to determine the appropriate dosage, timing, and frequency of eculizumab infusions to preserve renal function and prevent HUS relapses and establish specific treatment parameters for specific genetic conditions.

LIVER TRANSPLANTATION

Failure rate in kidney transplantation in patients with aHUS attributable to disease recurrence is as high as 80% to 90%, especially in patients with CFH and CFI mutations.[146] Transplantation of a healthy liver, alone or with a kidney transplant, has been seen as an option for replacing deficient complement CHF or CFI. Early experience with such liver transplantation strategies in these patients was disappointing, but recent clinical successes have generated renewed interest in liver or combined liver and kidney transplantation in patients with aHUS.[147,148] At present, the recommendation of the Consensus Study Group is to consider liver only transplantation in patients in whom the renal function has recovered, and the dual liver and kidney transplantation in those with ESRD.[147] Plasmapheresis, plasma replacement, and eculizumab therapy in the perioperative period may evolve as adjuncts in improving patient and graft survival in aHUS.[149]

> ### KEY POINTS
>
> - Liver transplant may provide definitive therapy for correcting complement dysfunction in some patients with aHUS.
> - Role of liver transplantation in aHUS is not clearly defined and needs to be evaluated.

MANAGEMENT OF THROMBOTIC THROMBOCYTOPENIC PURPURA

General and supportive care of patients with TTP, as outlined earlier, should be considered in all patients. This includes institution of dialysis therapy, if needed. Neurologic, cardiac, and GI manifestations should be addressed appropriately.

PLASMAPHERESIS AND PLASMA THERAPY

Prompt institution of plasmapheresis is now regarded as the most appropriate initial treatment of TTP in adults and the one that is associated with best outcomes.[150] Plasmapheresis has been able to decrease the mortality in TTP from 94.5% to 13% in the last two decades.[151] The purpose of plasmapheresis is twofold: (1) To remove the anti-ADAMTS13 antibody in the acquired type of TTP and (2) to provide new source of ADAMTS13 via the fresh frozen plasma used in the plasmapheresis. Superiority of plasmapheresis over plasma infusions has been well established in the acquired form of TTP.[152]

Daily 1.5 blood volume plasmapheresis is usually initiated in patients with TTP after the diagnosis is presumptively considered. Fresh frozen plasma is used as the replacement fluid. Rise of platelet count is used as a guide to the success of plasmapheresis and is usually continued for a few days beyond normalization of the platelet count.[153]

In the inherited form of TTP (Upshaw-Schulman syndrome), periodic plasma infusion therapy is able to provide the plasma ADAMTS13 that is lacking.[154] Several case reports of long-term use of this therapy resulting in prolongation of life and preventing ESRD have been reported in the literature.[157] Although many patients require frequent plasma infusions, some may need it only during acute infections that might precipitate these events.[154]

RITUXIMAB

Rituximab, a monoclonal antibody directed to CD20 on the surface of β cells, has recently been reported to

be effective in TTP. In the phase 2 safety trial, rituximab given in a dose of 375 mg/m^2 within 3 days of the diagnosis of TTP was compared with the standard therapy consisting of plasmapheresis and steroids.[156] Rituximab was continued weekly for 4 doses. Median time to sustained normalization of platelets was 12 days, and by the second dose, 68% of cases had a platelet count greater than 50,000/mm^3. Of the 37 patients in the rituximab group, 4 developed a relapse of TTP at a median duration of 27 months. In comparison, the plasmapheresis group developed a relapse in 21 of the 38 patients at a median duration of 18 months. The relapse rate TTP in this study was reduced from 55.2% to 10.8% with rituximab. In retrospective analysis, Westwood et al.[157] reported on their use of rituximab as an adjunct, in addition to protocol plasmapheresis. They were able to achieve remission in 95% of patients in the rituximab therapy group. Earlier treatment with rituximab (less than 3 days) was shown to be more effective in reducing hospitalization, achieving a faster remission, and decreasing the need for plasmapheresis treatments. Relapse of TTP occurred in 13.4% patients at a median duration of 24 months. ADAMTS13 levels normalized in 3 months after initiation of rituximab in all patients.

The role of rituximab in inducing remission in patients with TTP, alone or in addition to plasmapheresis, is evolving and may become an acceptable modality of treatment in these patients.

CORTICOSTEROIDS AND OTHER IMMUNOSUPPRESSIVE AGENTS

Corticosteroids have been used as immunosuppressive therapy for TTP since the 1960s.[158] Even after the development of plasmapheresis as a treatment of choice in acute TTP, corticosteroids have continued to be adjunct therapeutic agents to decrease the recurrence of TTP and reduce their clinical severity.[154] Controlled, randomized studies on the efficacy of steroids are lacking, and data from small series do not allow fair evaluation of such a regimen.[159] Similarly, other immunosuppressives, such as cyclosporine and cyclophosphamide, also have been used in clinical studies, but their therapeutic role remains unclear.[159]

PROGNOSIS OF THROMBOEMBOLIC MICROANGIOPATHIES

SHIGA TOXIN–PRODUCING *ESCHERICHIA COLI* HEMOLYTIC-UREMIC SYNDROME

The prognosis of STEC-HUS is generally good. Most children recover fully from the acute episode without obvious sequelae and without subsequent relapses.[104] Acute mortality in children with STEC-HUS is reported as 2% to 5%.[55,59] The cause of death in children with STEC-HUS is usually due to neurologic complications, such as a stroke, or GI complications, such as intestinal perforation and ischemic necrosis of the bowel.[55,59] Autopsies performed in children dying early in the course of illness have shown presence of brain edema and infarction in most patients.[160] Although acute renal failure itself is rarely a cause of death in STEC-HUS patients in the present era, this was reported as a leading cause of mortality in children before the 1970s.[58]

Evidence of CKD, such as proteinuria and decreased GFR, may be seen in up to 30% to 50% of children who recover from STEC-HUS. During a median follow-up of 6.5 years (range, 1 to 16 years), Siegler et al.[55] noted the presence of proteinuria or decreased GFR in 31% of cases, and combined proteinuria and decreased GFR in 12.5% of children who recovered from STEC-HUS. ESRD occurred in 3.6% of patients in this series extending over 20 years. In the more recent epidemic, STEC-HUS associated with a contaminated water supply in Canada (Walkerton epidemic), the overall renal outcome was better, with none of the children experiencing abnormal GFR or significant proteinuria.[161] In Argentina, where STEC-HUS is endemic, ESRD has been reported in 3.4% and proteinuria with decreased GFR in 16.1% of children followed over a mean duration of 13 years (range, 10 to 19.6 years).[59] Although long-term studies have yet to be reported, the short-term data from the German epidemic of *E. coli* O104:H4 documented ESRD in 1% of patients and CKD (stage 3 and 4) in 3.3% of cases.[23]

Hypertension may develop after recovery from HUS, sometimes requiring multiple medications for adequate control of blood pressure. In large series, the incidence of residual hypertension has ranged from 6.5% to 17.7%.[55,57] The incidence of hypertension has been noted to be higher in children with more severe disease that is characterized by oliguria exceeding 10 days.[162] Neurologic sequelae, such as seizures, delayed development, and hemiparesis, have been reported in 7% to 9% of cases. Despite a high incidence of seizures at onset, residual seizures in the short-term studies in the German epidemic of *E. coli* O104:H4 was only 3.3%.[23]

In a large cohort of STEC-HUS from Utah, predictors of adverse outcome such as residual neurologic sequelae, hypertension, renal disease, or death have been reported to be age younger than 2 years, leukocyte count greater than 20,000/mm^3, and presence of anuria in the diarrheal prodrome.[56] Others have also reported duration of oliguria to be a predictor of CKD with recovery of renal function occurring in 92.8% of those with oliguria lasting fewer than 10 days and in only 69.2% patients with oliguria longer than 10 days.[59]

A significantly lower platelet count was reported to be associated with acute neurologic complications in the German outbreak.[23]

ATYPICAL HEMOLYTIC-UREMIC SYNDROME

High early mortality and ESRD are the hallmarks of patients with aHUS secondary to dysregulation of complement pathways. Mortality rate during the presenting episode depends on the type of genetic mutation in the patient. It has been reported to be as high as 30% in patients with CFH mutations and the best early survival (100%) has been reported with MCP mutations.[163] Similarly, development of ESRD is also variable and occurs in 60% to 70% patients with CFH, CFI, or C3 gene mutations. Those with MCP gene mutations appear to have a better prognosis for ESRD (6% to 19%).[63,65,72,163] Recurrence of aHUS and graft loss in 3 years is also high in these patients.[72] These findings suggest a heterogeneity in the clinical outcome and the importance of genotype-phenotype correlation in patients with aHUS.

STREPTOCOCCUS PNEUMONIAE–ASSOCIATED HEMOLYTIC-UREMIC SYNDROME

SpHUS occurs in the background of invasive pneumococcal disease, and most patients are significantly sick. Early mortality rate in these patients has ranged from 3% to 11%.[79,81] Hospital length of stay of patients with SpHUS is generally longer than STEC-HUS. In one comparative study, median hospital stay for SpHUS was 21 days, versus 8 days in STEC-HUS.[80] A greater need for dialysis therapy (70% to 75%) in SpHUS has been well recognized, and ESRD has been reported in 23% to 28% patients.[81,82]

THROMBOTIC THROMBOCYTOPENIA

High mortality of TTP at onset is well known. Amorosi and Ultmann[164] reviewed 255 previously reported patients and 16 of their own patients in 1966 and noted that 72% of patients died by 90 days of onset. After introduction of plasmapheresis, the immediate mortality rate declined to 29% by the 1990s and currently stands at 10% to 13%.[150-152] Even after a successful treatment of the clinical disease at onset, recurrences of TTP are common and often occur within the first year. With maintenance therapy using rituximab, the relapse rate has been reduced to 13.4%.[157] Early mortality usually results from neurologic or cardiovascular disease associated with TTP.

SUMMARY

HUS is a clinical syndrome characterized by the triad of microangiopathic hemolytic anemia, thrombocytopenia, and renal injury. Although there are many distinct causes of HUS in children, up to 90% of cases are related to GI infection (diarrhea-associated HUS) with STEC or *Shigella*. Supportive care is essential to good outcome, and the course and outcome are related to the underlying cause. With diarrhea-associated HUS, mortality is now less than 5% but a large number of survivors exhibit signs of proteinuria, hypertension, or renal insufficiency and deserve continued follow-up.

Improved public health prevention strategies remain the best option to decrease the frequency of diarrhea-associated HUS in children. Early detection of STEC infection offers promise to provide opportunities to minimize disease severity. For children with established STEC colitis, supportive care is the mainstay. HUS continues to be a challenge in terms of prevention; even for severely affected children, appropriate supportive management of acute renal insufficiency and nonrenal complications can provide a good outcome.

Children with diarrhea-negative HUS are a more heterogeneous group. aHUS resulting from inherited complement disorders is emerging as a distinct entity. Treatment with eculizumab and liver transplantation provides new hope in such patients. SpHUS caused by *S. pneumonia* infection may be an under-recognized clinical disorder. Management of TTP is also undergoing rethinking with the use of rituximab as a possible maintenance therapy, after prompt plasmapheresis has stabilized the patient's clinical course.

Clinical Vignette 24.1

A 19-month-old white boy was admitted from the emergency department (ED) with a 5-day history of low-grade fever, anorexia, and watery diarrhea. His parents reported eating at a barbecue 2 days before his GI symptoms started. On the day of admission his stools were streaked with blood. In the ED he was noted to be pale, fatigued, and slightly dehydrated. He had intermittent abdominal colic and vomited once.

Initial laboratory studies showed proteinuria and microhematuria on urinalysis. Hemoglobin was 11.0 mg/dL; white blood cell (WBC) count, 22,400/mm³; platelets, 177,000/mm³; reticulocyte count, 5.6%; and LDH 4980 units/L. Serum creatinine was 1.0 mg/dL; BUN, 34 mg/dL; sodium, 134 mmol/L; potassium, 3.8 mmol/L; bicarbonate, 18

mmol/L; chloride, 98 mmol/L; calcium, 8.8 mg/dL; phosphorus, 4.8 mg/dL; and albumin, 2.8 mg/dL. Liver transaminases, amylase, and lipase were normal. Creatine kinase was elevated, at 448 units/L. Bacterial stool cultures were sent for examination. The stool was positive for fecal WBCs.

Intravenous hydration was initiated on admission. On hospital day 2 his hemoglobin was 8.3 mg/dL and platelets 74,000/mm³. His stool culture was positive for *E. coli* O157:H7. A rectal prolapse needed to be reduced with use of sedation. His serum creatinine increased to 1.8 mg/dL and urine output declined to less than 0.5 mL/kg/h. A PD catheter was inserted on the third hospital day because of anuria and progressive azotemia. Severe hypertension was treated with short-acting and long-acting calcium channel blockers. He was started on intravenous erythropoietin for anemia but required two RBC transfusions to maintain his hemoglobin above 8.0 mg/dL during the first week on PD. Total parenteral nutrition (TPN) was initiated on hospital day 5, and he subsequently required insulin therapy for control of hyperglycemia. At that time his lipase was elevated, at 1266 mg/dL.

On hospital day 6, on the third day after starting PD, hydrothorax was noted and PD was discontinued for 2 days. Hydrothorax did not reoccur on restarting PD. His TPN and insulin therapy were able to be discontinued on hospital day 22 after resumption of oral intake. PD was performed for 29 days before substantial urine output returned, and PD was able to be discontinued.

By hospital day 35 his urine output and oral intake were good and serum creatinine was 1.2 mg/dL. His PD catheter was removed on day 36, and he was discharged to home the following day on enalapril 1.25 mg twice daily. His serum creatinine was 0.9 mg/dL at 6 months after resolution of HUS.

Three years after his recovery, further renal impairment was noted, with no evidence of active HUS. His hypertension worsened, and he developed progressive renal insufficiency. He received a successful renal transplant 14 years after his recovery from acute HUS and is now doing well, with no signs of recurrent HUS.

TEACHING POINTS

- This boy's clinical presentation was typical for diarrhea-associated HUS. His initial complete blood count had only mild anemia and an elevated WBC count. Thrombocytopenia, anemia, and renal dysfunction became more impressive over the next few days, and dialysis was started once severe oliguria was noted in this setting.

- He did not receive antibiotic therapy. RBC transfusions and erythropoietin were employed. Platelet transfusion was not employed.

- His blood pressure was difficult to manage and required acute management. He continued to require antihypertensive therapy at the time of discharge, and his renal function has not normalized.

- Long-term outcome of this case was characteristic of the subset of children who do not experience complete recovery of HUS and stresses the need for continued follow-up of affected patients.

REVIEW QUESTIONS

1. Which of the following molecules is involved in the pathogenesis of pneumococcal HUS?
   a. Factor H
   b. Globotriosyl ceramide (Gb3)
   c. Membrane cofactor protein (CD46)
   d. Neuraminic acid
   e. von Willebrand factor cleaving protease ADAMTS13

2. Which of the following laboratory findings is associated with pneumococcal HUS but not seen in atypical HUS?
   a. Hypocomplementemia
   b. Microangiopathic hemolytic anemia
   c. Normal or slightly elevated prothrombin time
   d. Positive result of a Coombs test
   e. Positive result of a peanut lectin activity test

3. Which of the following is associated with a poor outcome in pneumococcal HUS?
   a. Family history of aHUS
   b. History of recurrent pneumococcal infections
   c. Meningitis
   d. Serotype of *S. pneumoniae*
   e. Severity of thrombocytopenia

4. In the treatment of a patient with pneumococcal HUS, which of the following approaches should be avoided?
   a. Calcium channel blockers
   b. Continuous venovenous hemofiltration
   c. Hemodialysis
   d. Peritoneal dialysis
   e. Transfusion of unwashed packed red blood cells

5. In the comparison of children with pneumococcal HUS and STEC-HUS, which of the following is *true*?
   a. Children with pneumococcal HUS are not more likely to require acute dialysis.
   b. There is no gender predisposition in STEC-HUS.
   c. Children with pneumococcal HUS are more likely to be younger at presentation.
   d. Children with pneumococcal HUS are less likely to develop chronic kidney disease.
   e. Children with STEC-HUS are more likely to require red blood cell and platelet transfusions.

6. In children with STEC-HUS, which of the following *E. coli* serotypes is most commonly identified?
   a. O157
   b. O104
   c. O97
   d. O144
   e. Nontypable
7. What is the *most* accurate statement about the Shiga-like toxin that results in diarrhea-associated HUS?
   a. It binds to ceramide receptors on susceptible cells.
   b. It binds only to endothelial cells.
   c. It binds to the T antigen on RBCs.
   d. It inhibits ADAMTS-13.
   e. It is only toxic in cows.
8. TMA has been associated with which of the following medications?
   a. Calcineurin inhibitors
   b. Cyclophosphamide
   c. Eculizumab
   d. Erythropoietin
   e. Rituximab
9. Which of the following is the *most common* long-term sequela of STEC-HUS?
   a. CKD stage 3 to 5
   b. ESRD

c. GI malabsorption
d. Proteinuria
e. Seizures
10. What is the *most commonly* defined genetic abnormality in individuals with aHUS?
   a. C3
   b. Factor H
   c. Factor I
   d. Factor 2
   e. Thrombomodulin

ANSWER KEY

Tubulointerstitial nephritis

ROSSANA BARACCO, GAURAV KAPUR, AND TEJ K. MATTOO

Approximately 80% of the renal parenchyma consists of renal tubules and the interstitium. These structures provide support and hold together the nephrons and the renal vasculature. Inflammatory lesions of these structures, or tubulointerstitial nephritis (TIN), constitute a heterogeneous disorder that is commonly involved in renal pathologic findings.[1] Progressive tubulointerstitial damage correlates well with progression of renal disease and deterioration of glomerular and tubular functions.[2–4]

DEFINITION AND CLASSIFICATION

TIN is characterized by inflammatory infiltrate, edema, and fibrosis affecting renal tubules and the interstitium.[5] Clinicopathologically, TIN may be acute or chronic in onset.

- *Acute tubulointerstitial nephritis (ATIN)* is characterized by an acute inflammatory cell-mediated response that is associated with a rapid decline in renal function.
- *Chronic tubulointerstitial nephritis (CTIN),* also called *chronic tubulointerstitial nephropathy,* is characterized by a protracted onset and a slow decline in renal function.[6]

These two types of TIN may represent a continuum in the spectrum of initial acute inflammatory cell-mediated response that transforms into interstitial fibrosis over time. This transition to fibrosis can occur quickly, sometimes as early as a week after onset of the disorder.[4] TIN is defined as primary in origin when the inflammation is limited to the tubules and the interstitium and glomeruli and vessels are either not involved or show minor involvement. Secondary TIN results from diseases that initially involve glomerular or vascular structures.[6]

EPIDEMIOLOGY

The precise incidence of TIN is unclear. It accounts for 8% to 27% of the reported cases of acute kidney injury (AKI) in adults and up to 7% in children.[7–11] A lower reported incidence of primary TIN in children may represent a lack of recognition of the disorder in routine renal biopsies.[12] Among 171 army recruits in Finland who underwent renal biopsy for proteinuria or hematuria, two cases had TIN and the reported incidence was 0.7 per 100,000 population.[13] TIN is estimated to account for 22% to 33% of cases with chronic kidney disease (CKD) in adults.[14,15] CTIN is commonly seen in association with obstructive uropathy and vesicoureteral reflux (VUR), both of which are significant causes of CKD and end-stage renal disease (ESRD) in children.[16–20]

ACUTE TUBULOINTERSTITIAL NEPHRITIS

ETIOLOGY

ATIN may occur in four distinct clinical settings (Table 25.1): exposure to drugs, infections, immunologic disorders, and idiopathic. Drugs and infections are the two leading causes of ATIN in children.[26–29]

KEY POINTS

- TIN is characterized by an inflammatory infiltrate, edema, or fibrosis of renal tubules and the renal interstitium.
- Multiple antigens can cause ATIN by becoming targets of an immune reaction that is characterized by cell-mediated interstitial damage.

Drug-induced acute tubulointerstitial nephritis

Exposure to drugs is the most common cause of ATIN in adults.[24,25] The list of drugs reported to cause ATIN is ever expanding (Table 25.2). Of these, penicillins, nonsteroidal anti-inflammatory drugs (NSAIDs), rifampin, and sulfonamide derivatives account for the majority of reported cases.[30] Drug-induced ATIN is a rare idiosyncratic reaction and occurs in only a small subset of patients exposed to any specific medication. It is not dose-dependent and typically occurs with repeated exposure to the drug. Structurally similar drugs may induce cross-reactivity, as evidenced by recurrent ATIN after cephalosporin administration in individuals with previous penicillin-induced ATIN.[30] The mechanisms by which drugs can induce ATIN include binding of the drug to the tubular basement membrane (TBM) and forming antigenic heptans, drug mimicking a normally present antigen in the TBM, drug being trapped in the interstitium and acting as a trapped or "planted" antigen, or forming antigen-antibody complexes in circulation that are trapped in the interstitium (Figure 25.1).

Infection-associated acute tubulointerstitial nephritis

Infection-associated ATIN may complicate the clinical course of many bacterial, viral, fungal, and parasitic infections (see Table 25.1). It may occur as a result of direct invasion of the renal interstitium (pyelonephritis) or as an immune-mediated reaction to a systemic infection. Polyoma BK virus–induced interstitial nephritis has been reported in renal transplant patients and in a child receiving chemotherapy for leukemia.[30,31] Primary infection with this virus or reactivation of the latent virus in immunosuppressed patients in the renal epithelium is believed to induce interstitial nephritis. The presence of typical

Table 25.1 Etiologic classification of acute tubulointerstitial nephritis

A. DRUG EXPOSURE (see Table 25.2 for drug list)
- Immunologic mechanisms: Antibiotics, anti-inflammatory drugs (NSAID), diuretics
- Toxic mechanisms: Aminoglycosides
- Unknown mechanisms

B. INFECTIONS

Reactive (sterile), infective agent not in renal parenchyma

- Bacteria: *Yersinia pseudotuberculosis, Mycoplasma, Streptococcus pneumoniae*, β-hemolytic streptococcus, *Salmonella*
- Viruses: Rubeola virus, Epstein-Barr virus, human immunodeficiency virus, hepatitis viruses
- Parasites: *Toxoplasma gondii, Leishmania donovani*

Infectious interstitial nephritis

- Bacteria: Acute bacterial pyelonephritis, *Leptospira, Mycobacteria, Treponema pallidum*
- Viruses: Cytomegalovirus, adenovirus, polyoma virus (BK)
- Fungi: *Candida, Histoplasma capsulatum, Aspergillus* sp.
- Rickettsiae: *Rickettsia rickettsii, Rickettsia conorii, Rickettsia prowazekii*
- Parasites: *Plasmodium* spp., *Schistosoma* sp..

C. IMMUNOLOGIC
- Anti-TBM antibodies
  - Primary anti-TBM nephritis
  - Secondary anti-TBM nephritis
    - Membranous GN
    - Anti-GBM disease
    - Miscellaneous GN
- Immune complex deposition
  - Primary immune complex nephritis
  - Secondary Immune complex nephritis
    - SLE
    - Sjögren syndrome
    - Membranous GN
    - MPGN
    - Miscellaneous GN
- T-cell mechanisms
  - Primary T-cell nephritis
    - Allograft rejection
    - TINU
    - Sarcoidosis
  - Secondary T-cell nephritis
    - Associated with nephropathies
    - Tubulointerstitial nephritis

D. IDIOPATHIC

Abbreviations: GBM, glomerular basement membrane; GN, glomerulonephritis; MPGN, membranoproliferative glomerulonephritis; SLE, systemic lupus erythematosus; TBM, tubular basement membrane; TINU, tubulointerstitial nephritis with uveitis.

Table 25.2 Drugs associated with acute tubulointerstitial nephritis

Antimicrobial Agents	Nonsteroidal Anti-inflammatory Drugs	Diuretics
Acyclovir	Alclofenac	Chlorthalidone
AMPICILLIN[*,†]	Azapropazone	Ethacrynic acid
Amoxicillin	ASPIRIN	FUROSEMIDE[†]
Aztreonam	Benoxaprofen	Hydrochlorothiazide[†]
Carbenicillin	Diclofenac	Indapamide
Cefaclor	Diflunisal[†]	Tienilic acid[†]
Cefamandole	Fenclofenac	Triamterene[†]
Cefazolin	FENOPROFEN	**Miscellaneous**
Cephalexin	Flurbiprofen	ALLOPURINOL[†]
Cephaloridine	IBUPROFEN	α-Methyldopa
Cephalothin	INDOMETHACIN	Azathioprine
Cephapirin	Tetracycline	Bethanidine[†]
Cephradine	Vancomycin	Bismuth salts
Cefixitin	Ketoprofen	Captopril[†]
Cefotetan	Mefenamic acid	Carbimazole[†]
Cefotaxime	Meloxicam	Chlorpropamide[†]
CIPROFLOXACIN	Mesalazine (5-ASA)	Cyclosporine
Cloxacillin	NAPROXEN	CIMETIDINE
Colistin	Niflumic acid	Clofibrate
Cotrimoxazole[†]	Phenazone	Clozapine
Erythromycin	PHENYLBUTAZONE	Cyamethazine[†]
Ethambutol	PIROXICAM	D-penicillamine
Foscarnet	Pirprofen	Fenofibrate[†]
Gentamicin	Sulfasalazine	Gold salts
Indinavir	Sulindac	Griseofulvin
Interferon	Suprofen	Interferon
Isoniazid	TOLEMETIN	Interleukin-2
Lincomycin	ZOMEPIRAC	OMEPRAZOLE
METHICILLIN[†]	**ANALGESICS**	PHENINDIONE[†]
Mezlocillin	Aminopyrine	Phenothiazine
Minocycline	Antipyrine	Phenylpropanolamine
Nafcillin	Antrafenine	Probenecid
Nitrofurantoin[†]	Clometacin[†]	Propranolol
Norfloxacin	Floctafenine[†]	Propylthiouracil
Oxacillin[†]	Glafenine[†]	Ranitidine
PENICILLIN G[†]	Metamizole	Streptokinase
Piperacillin	Noramidopyrine	Sulfinpyrazone
Piromidic acid	**ANTICONVULSANTS**	Warfarin
Polymyxin acid[†]	Carbamazepine	
Quinine	Diazepam	
RIFAMPICIN[†]		
Spiramycin[†]		
SULFONAMIDES		
Teicoplanin

basophilic or amphophilic intranuclear inclusions on renal biopsy is diagnostic. Distinguishing polyoma viral infection from allograft rejection is critical in the management of these patients.

Immunologically mediated acute tubulointerstitial nephritis

Antibodies, immune complexes, or T cells may mediate ATIN by immune mechanisms.[7] Primary TIN resulting from anti-TBM antibody[32,33] and immune complex deposition is rare.[34] Linear deposits of immunoglobulin G (IgG) and complement along the TBM, with relative sparing of glomeruli and vessels, characterize primary anti-TBM nephritis.[7] Systemic lupus erythematosus (SLE) is the most important cause of ATIN seen in association with glomerulonephritis in children,[19] and the degree of tubulointerstitial lesions has been proposed to predict renal outcome in lupus nephritis.[35] Secondary ATIN also may be seen in association with membranous glomerulonephritis, shunt

nephritis, and immunoglobulin A (IgA) nephropathy.[7] Patients with glomerular and tubulointerstitial involvement have worse renal function than those with isolated glomerular involvement.[36] ATIN also has been described as an extraintestinal manifestation of Crohn disease.[37] Allograft rejection, TIN with uveitis (TINU), and sarcoidosis manifest with predominant tubulointerstitial damage mediated by T cells.[7]

PATHOGENESIS

The immune mechanisms producing tubulointerstitial damage, like any other immune-mediated reaction, have an antigen recognition phase, immune regulatory phase, and effector phase (Figure 25.2).

ANTIGENS

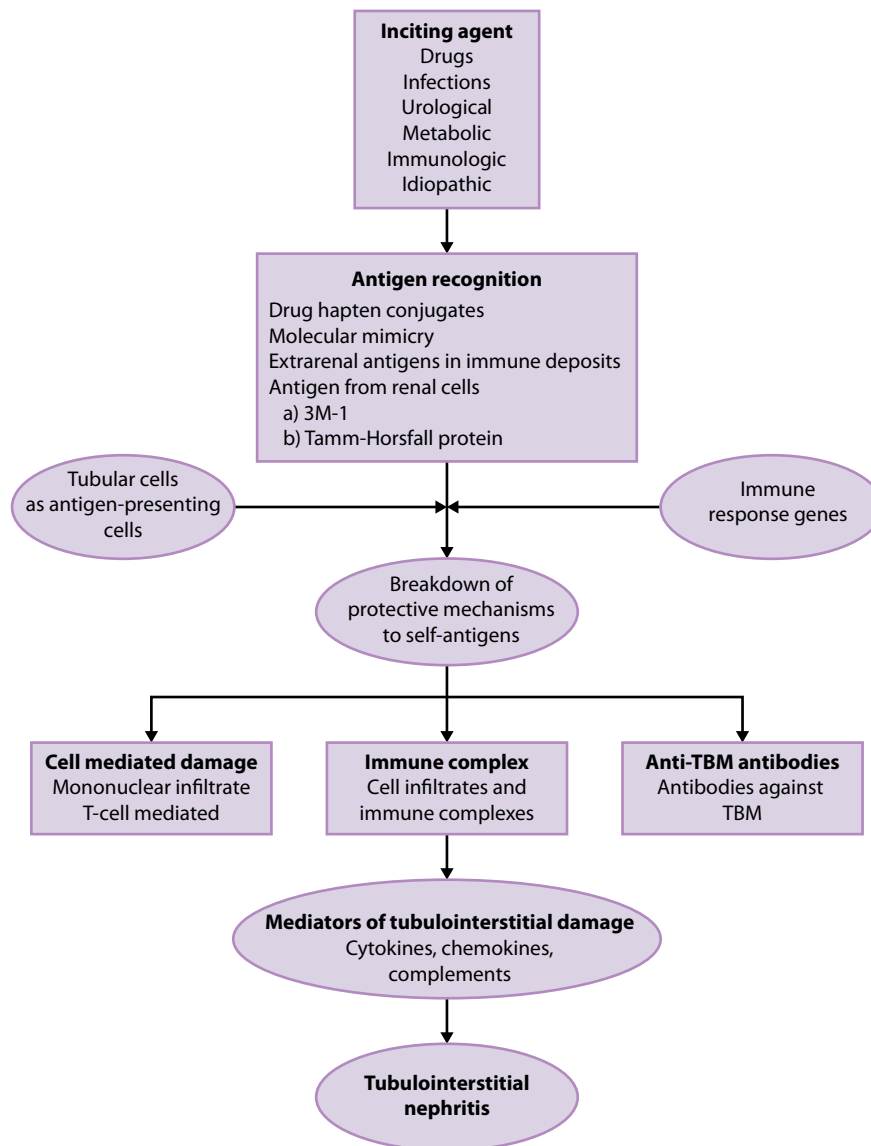
The antigens causing ATIN may be derived from the interstitial cells or may be planted into the interstitial


Figure 25.2 Pathogenesis of tubulointerstitial nephritis. *TBM*, tubular basement membrane.

microenvironment from the circulation. The nephrito-genic antigens derived from the renal cells and the TBM include 3M-1 antigen,[38] Heymann nephritis protein (gp330, megalin)[39] and Tamm-Horsfall protein.[40–42] 3M-1 (TIN antigen) is the antigen of anti-TBM disease and has been characterized and mapped to chromosome 6 in humans.[38] Immunohistochemical studies have indicated that TIN anti-gen is defective in kidney tissues of patients with juvenile nephronophthisis.[42] Genetic deletion of the TIN antigen gene has been identified to cause TIN resulting in CKD.[43] Allotypic differences in the expression of the gene may occa-sionally result in anti-TBM disease in renal transplants of these patients.[44,45] Tamm-Horsfall protein may be an incit-ing antigen, especially following lower tract obstruction.[46]

Molecular mimicry of infectious agents,[47,48] drugs acting as haptens,[49] and toxic damage to the interstitium exposing cryptic nephritogenic neoantigens,[50] are other mechanisms whereby tubulointerstitial antigens may become targets.

Studies also have shown that induction of TIN could be a consequence of viral proteins, as in renal disease related to the Epstein-Barr virus (EBV)[51] and human immunodefi-ciency virus (HIV).[52] Experimental evidence suggests that native renal cells can process and present the antigen to T cells[53,54;] upregulate cell surface proteins, including intra-cellular adhesion molecule 1 (ICAM)[55] and vascular cell adhesion molecule 1 (VCAM)[56;] and enhance production of cytokines and chemokines.[57] Induced class II major histo-compatibility complex (MHC) expression by renal tubular cells in response to inflammation or proinflammatory cyto-kines[49,58] may promote autoimmune injury by facilitating expression of self-antigens.

IMMUNE RESPONSE

Genetic factors play a role not only in antigen expression[59] but also in immune response to a particular antigen[60] (immune

response genes). Successful recognition of antigens leads to activation of nephritogenic T cells, which sequentially activates the nephritogenic immune response. Regulation of autoimmune B-cell and T-cell response may occur either during the maturational phase or by a fully differentiated effector mechanism. Interstitial nephritis is relatively uncommon, because nephritogenic B-cell and T-cell activation is self-limited by downregulatory events.[60,61] These regulatory events include complementary interactions in immune system[61] or regulation of target antigen presentation.[62] The immune response genes carried by specific individuals are important in determining the host immune response. Suppressor T cells are an important component of the immunoregulatory process. Models of autoimmune interstitial nephritis provide evidence for peripheral inactivation of autoreactive clones regulating suppressor T cells.[63] Breakdown of the tolerance to self-parenchymal antigens is needed for spontaneous TIN, and the details of these mechanisms need to be elucidated.

EFFECTOR MECHANISMS

Cell-mediated response

The predominant effector mechanism in acute interstitial nephritis is cell-mediated immunity. The majority of the infiltrating cells (>50%) in TIN are T lymphocytes; the CD4/CD8 ratio is at least 1, and the infiltrating T cells and tubular epithelial cell express class II MHC. Studies in animal models of TIN have revealed that nephritogenic helper T cells producing interstitial nephritis are usually CD4 and class II restricted,[64] whereas the effector cells are usually CD8 and class I restricted.[65,66] They induce toxic cellular damage by releasing inflammatory cytokines or by direct cell-mediated cytotoxicity by releasing proteases.[65]

Antibody-mediated response

Antibody-mediated damage is less common and may occur as anti-TBM nephritis or immune complex–mediated TIN. Human anti-TBM nephritis has been reported in patients who received drugs such as methicillin, those who underwent renal transplantation, or in cases without an underlying abnormality.[31,45,67,68] Immune complex and complement deposition are seen in patients with SLE.[69] Tamm-Horsfall protein[37,38] and Heymann antigen of brush border[36] have been implicated in local immune complex formation in the interstitium. Tamm-Horsfall protein is localized in the interstitium in the setting of urinary tract obstruction or reflux nephropathy, suggesting that it may be a target antigen in previously damaged kidneys.[70]

Amplification of tubular damage and interstitial fibrosis

Infiltration of T cells or antibody-mediated damage triggers processes that augment and amplify tubulointerstitial injury and inflammation. These include chemoattraction of inflammatory cells such as eosinophils and macrophages, release of soluble factors, and activation of the complement cascade. The soluble factors include chemokines, complement, luminal proteins, cytokines (profibrotic and proinflammatory), and proteinases.[71] Interstitial fibrosis is the final common pathway, especially for diseases associated with glomerular proteinuria or presence of inflammatory cells in the tubulointerstitium.[72,73] Transforming growth factor beta (TGF-β) is the most important profibrotic cytokine.[74] Specific inhibition of TGF-β in ureteral obstruction[75] reduces renal fibrosis. Myofibroblasts play an important role in elaboration of interstitial fibrosis and may evolve from differentiation of tubular epithelial cells into fibroblasts (epithelial to mesenchymal transformation), resident interstitial cells, macrophages, or endothelial cells.[71] Immune-mediated mechanisms of various cytokines may trigger this transformation, as well as result in tubular cell damage. Thus, tubular atrophy and interstitial fibrosis coexist.

PATHOLOGY

Renal biopsy findings in ATIN demonstrate a mononuclear cell infiltrate within the interstitium, most prominently observed in the cortical interstitium (Figure 25.3A).
Figure 25.3 (a) Light microscopy showing acute interstitial inflammatory infiltrate consisting of mononuclear cells in a patient with acute interstitial nephritis. The patient presented with acute kidney injury and proteinuria. (b) Inflammatory cell infiltration into the tubules resulting in tubulitis.
Figure 25.4 Granuloma in the renal interstitium in a patient with sarcoidosis.

The presence of infiltrating lymphocytes between tubular epithelial cells (tubulitis) is common in severe cases (see Figure 25.3B). The interstitial mononuclear infiltrate consists mostly of T lymphocytes, and B cells and plasma cells constitute a minor fraction. Eosinophils may be present, especially in drug-induced ATIN. Interstitial granulomas with giant cells may be seen with medication-associated TIN (methicillin, thiazides) and sarcoidosis (Figure 25.4). Variable degrees of tubular necrosis and regeneration are usually present. The glomeruli are generally normal, but associated nephrotic syndrome with minimal change has been reported in TIN caused by NSAIDS.[21] In ATIN secondary to infections, neutrophils may dominate as the cell type. Interstitial edema may be observed. Based on immunofluorescence findings on renal biopsy, ATIN can be classified into three subtypes:

1. No antibodies or immune deposits (pauci-immune)
2. Immune complex deposits present along the basement membrane (Figure 25.5)
3. Linear immunofluorescence staining for IgG and complement along the TBM, also known as anti–tubular basement disease (Figure 25.6)[22,23]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Clinical manifestations of ATIN can range from asymptomatic proteinuria to renal failure (Table 25.4). Many patients have constitutional symptoms such as fever (especially during infection-associated ATIN), fatigue, anorexia, weight loss, nausea, and vomiting.[26–29] Approximately 30% to 40% of patients with ATIN have nonoliguric AKI.[11] ATIN should be suspected in any patient who presents with AKI

of unclear cause. With drug-induced ATIN, the patient may exhibit other features of allergic process such as rash, fever, or eosinophilia. The classic triad of fever, arthralgia, and rash occurs in fewer than 10% of such patients.[24,76] Such signs are even less common in ATIN resulting from NSAIDS.[73]

> ### KEY POINTS
>
> - Patients with ATIN generally present with nonoliguric AKI.
> - ATIN related to drug exposure may be associated with fever, rash, and eosinophilia.
> - Urinary excretion of eosinophils (eosinophiluria) should be looked for in these patients by staining the urinary sediment with an appropriate stain.
> - Renal biopsy is the gold standard for establishing the diagnosis of ATIN.

In drug-induced TIN, renal manifestations develop on average 10 days after starting the medication; however, they can occur as early as one day and as late as months after the inciting medication is started.[78] The urinary abnormalities in ATIN consist of microscopic or macroscopic hematuria, sterile pyuria, and white blood cell casts. Mild proteinuria, usually less than 1 g/day is frequently observed. Nephrotic syndrome has been associated with TIN caused by NSAIDS,[78] and nephrotic-range proteinuria has occasionally been reported with nephropathies induced by lithium, ampicillin, and rifampicin.[79] Eosinophiluria, which is defined as the presence of eosinophils greater than 1% of total urinary leucocytes (by Hansel stain), is seen in only approximately 25% of patients. However, eosinophiluria also can be seen in other forms of renal injury and inflammation and is not, by itself, diagnostic of ATIN.[80] Renal ultrasound reveals normal or enlarged kidneys, depending on the degree of interstitial edema. Clinical manifestations of acute TIN in adults reported in two separate studies are shown in Table 25.3.

Renal tubular epithelial cell damage and abnormalities in tubular function are common; sometimes these abnormalities may be limited to specific tubular segments.[25] Fanconi syndrome and tubular acidosis are seen rarely in ATIN but are relatively more common in CTIN. Urinary β_2 microglobulin excretion is elevated[81,82] and could reflect renal inflammatory activity. Urinary biomarkers have been studied in ATIN; among them, monocyte chemotactic peptide-1 (MCP-1) has been identified to correlate well with acute lesions, such as interstitial edema and inflammatory infiltration, seen in kidney biopsy samples of patients with drug-induced ATIN.[83] N-acetyl-β-D-glucosaminidase (NAG), has been proposed to correlate with more rapid progression of renal dysfunction in patients with CTIN.[84] In
Figure 25.5 **(a)** Immunofluorescence microscopy showing intense staining of the tubular basement membranes (TBMs) and Bowman capsule with IgG in a finely granular pattern. The glomerular tufts (G) are negative for immunofluorescence staining. Inset shows the TBMs with finely granular staining pattern at 400× magnification. **(b)** Electron microscopy showing atrophic tubular epithelium and thickened TBM with scattered electron-dense deposits. view of the nonspecific nature of the clinical and laboratory features of ATIN, a kidney biopsy is often indicated to confirm the diagnosis.

TREATMENT

Eliminating the inciting drug or agent

The therapy of ATIN should begin by eliminating the possible inciting factors, such as drugs or infections. In choosing therapeutic options, potentially cross-reacting drugs (e.g., penicillin by cephalosporin) should be avoided. Many patients with mild ATIN may show recovery of their renal

Table 25.3 Clinical and laboratory features at presentation in adult patients with acute tubulointerstitial nephritis

disease after discontinuation of the inciting drug, and no further treatment may be necessary. Supportive care involving maintenance of fluid balance, monitoring of blood chemistry, and dialysis may be necessary for patients with renal dysfunction.

Corticosteroids

The role of corticosteroids in the treatment of ATIN remains unclear[9,24,30] because of conflicting studies, some of which revealed no benefit with corticosteroids[76] and others reported improvement of serum creatinine and decreased need for dialysis.[24,85,86] A study in children observed improvement in renal function within 1 week of initiation of corticosteroid therapy after a period of observation with no spontaneous recovery.[87]

A small prospective study showed that children with ATIN who received prednisone had a faster recovery of renal function.[88] There is a need for prospective randomized controlled trials to address this. We recommend administering corticosteroids when the renal function is not improving after removing the offending agent or if there is significant inflammatory infiltration seen in the biopsy sample. Corticosteroids are generally administered daily as oral prednisone (2 mg/kg/day) for 4 weeks, followed by gradual tapering.[19,22,30]

Methylprednisolone intravenous pulse therapy (5 to 10 mg/kg/dose) for 1 to 3 days, followed by oral prednisone has been used in severe cases of ATIN, especially those with severe AKI.[19,30] There is no available evidence to suggest that cyclosporine or cyclophosphamide is of benefit in patients resistant to steroids.[30]

Mycophenolate mofetil

Mycophenolate mofetil (MMF) has been used in a limited number of case reports and small studies in patients with ATIN in whom corticosteroids alone were not effective.[89–91] Although encouraging, sufficient data are not available to make recommendations about MMF in patients with ATIN.

PROGNOSIS

The prognosis for recovery of renal function after ATIN in children is usually excellent.[26,28,29,78] Poor prognosis in ATIN is associated with the presence of tubular atrophy.[24,30,78] However, data on relationship of interstitial fibrosis[19,30,92–94] and degree of cellular involvement and

tubulitis[19,30,95] with the outcome of ATIN are unclear. Poor recovery of renal function also has been reported in patients with protracted oliguria lasting over 3 weeks, and in the presence of a preexisting renal disease.[24,95] There is no obvious correlation between peak serum creatinine or clinical severity of the disease at presentation with long-term outcome of ATIN.[19,24]

CHRONIC TUBULOINTERSTITIAL NEPHRITIS

ETIOLOGY

Chronic tubulointerstitial nephritis (CTIN) results from numerous infectious, metabolic, structural, toxic, or hereditary factors. CTIN is commonly seen in children in association with obstructive uropathy and VUR. Interstitial damage and progressive fibrosis in these disorders may result from renal immune responses that amplify tubulointerstitial injury, induced by high urinary tract pressures in the setting of infection.[19] Some drugs, such as calcineurin inhibitors (cyclosporine and tacrolimus) are particularly likely to cause CTIN, whereas others can cause both ATIN and CTIN. CTIN secondary to chronic cyclosporine toxicity is characterized by tubular atrophy, interstitial fibrosis, and vascular hyalinosis and sclerosis.[96] With the exception of cisplatinum, none of the drugs that cause AKI commonly results in CKD.[6] Conditions that may be associated with CTIN are listed in Table 25.5. The hyperosmolar, acidic, and hypoxic environment of the renal medulla favors precipitation of many metabolites (e.g., calcium, uric acid, and oxalate), resulting in tubulointerstitial injury and CTIN.[1]

PATHOLOGY

Unlike ATIN, CTIN is a slowly progressive disorder characterized by renal tubular atrophy and interstitial fibrosis. Interstitial inflammatory cell infiltration may be minimal or even absent. The deposited extracellular matrix consists of a combination of collagen I, III, and V from interstitial fibroblasts and type IV derived from endothelial and tubular cells.[7] Tubular atrophy with thickened and wrinkled TBM is generally present. In contrast to ATIN, glomeruli in CTIN often show ischemic changes with shrinking of the glomerular tuft and wrinkling of the Bowman capsule (Figure 25.7).[7] Periglomerular fibrosis is also commonly seen. The end result of CTIN can be small and shrunken kidneys with prominent parenchymal scarring and pelvicalyceal dilatation.

Table 25.4 Common clinical manifestations of tubulointerstitial nephritis

Symptoms
- Fever
- Nausea
- Anorexia
- Abdominal Pain
- Vomiting
- Weight loss
- Growth Failure (CTIN especially)
- Eye pain (TINU)
- Polyuria
- Rash (usually with allergic drug reactions)

Investigations
- Urinalysis
  - Hematuria
  - Proteinuria (modest), urine protein excretion is usually less than 1.0 g/day
  - Leukocyturia, eosinophiluria, white cell and tubular cell casts
- Blood chemistry
  - Increased creatinine
  - Predominant segmental tubular defects
    - Proximal tubular defects: Proximal RTA, Fanconi syndrome
    - Distal tubular defects: Hyperkalemia, sodium wasting, distal RTA
    - Medullary defects: Sodium wasting, polyuria
  - Anemia: Normochromic normocytic
  - Eosinophilia
  - Increased erythrocyte sedimentation rate

Radiology
- Ultrasonography
  - Enlarged hyperechoic kidneys (ATIN)
  - Small contracted kidneys (CTIN)

Renal biopsy
- Diagnostic gold standard

ACTIN, acute tubulointerstitial nephritis; *CTIN*, chronic tubulointerstitial nephritis; *RTA*, renal tubular acidosis; *TINU*, tubulointerstitial nephritis with uveitis.

KEY POINTS

- CTIN is often the end result of numerous types of renal injuries and inflammatory processes.
- Urinary obstruction and VUR are commonly associated with CTIN in children.
- Growth failure and inability to concentrate urine may be the only presenting manifestations of CTIN in children.
Figure 25.7 Glomerulus in a patient with chronic tubulointerstitial nephritis showing periglomerular fibrosis and ischemic glomeruli with collapsed capillary lumens.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The clinical, laboratory, and radiologic manifestations of CTIN are similar to those observed in ATIN (see Table 25.5).[19] However, individuals with CTIN may have no evidence of renal disease, may have asymptomatic proteinuria, or may be first diagnosed as a result of the onset of CKD. Nonspecific symptoms such as weight loss, fatigue, anorexia, and vomiting may be present, and polyuria and polydipsia may be prominent features of the illness. Growth retardation may be a prominent manifestation of CTIN in children.[19] Polyuria resulting from inability to concentrate urine because of chronic tubular dysfunction is a common manifestation and may lead to nocturnal enuresis and urinary frequency.

Renal ultrasound usually reveals small, hyperechogenic kidneys. In association with CKD, skeletal radiographs may reveal changes of renal osteodystrophy. Generally, CTIN tends to progress more slowly than other forms of renal disease.[11] A kidney biopsy is often needed to confirm the diagnosis.

TREATMENT

There is currently no known effective therapy for CTIN. As in ATIN, when an offending agent is identified it should be discontinued and supportive care initiated. For example, calcineurin inhibitor therapy may be associated with CTIN in renal transplants as well in native kidneys, where this class of drugs may be used as steroid-sparing agents. However, the damage may be irreversible and the disease course self-perpetuating.[19] Management of hypertension and prevention of further renal damage in the form

of infection or from nephrotoxic agents are the focus of treatment. The beneficial effect of angiotensin-converting enzyme inhibitors (ACEIs) in CTIN-induced proteinuria can be predicted, but these have yet to be confirmed in clinical studies.[9]

TUBULOINTERSTITIAL NEPHRITIS UVEITIS

Dobrin et al.[97] described the association of tubulointerstitial nephritis with uveitis and granulomas in the bone marrow. This uncommon condition is now recognized as a separate clinicopathologic entity and is known as tubulointerstitial nephritis uveitis (TINU) syndrome.

TINU tends to affect young women, but the disorder has been reported in both sexes, as well as in older patients.[98] Cases of familial TINU have been described,[99,100] suggesting an underlying genetic component. An association between TINU and certain human leukocyte antigens (HLAs) has been reported. Levinson et al.[101] found HLA-DQA1*01, HLA-DQB1*05, and HLADRB1*01. Renal lesions are characterized by acute interstitial nephritis with predominant T-cell infiltration into the interstitium. Ocular disease is commonly bilateral and is characterized by anterior uveitis. Ocular manifestations may occur before, simultaneous with, or up to several months subsequent to the onset of renal disease.[100] Manifestations of uveitis include ocular pain, redness, photophobia, itching, and visual impairment, and can be the presenting manifestation of the disorder. However, recent studies suggest that uveitis is underdiagnosed in patients with TIN, as it is asymptomatic in 50% to 58% of patients.[87,100] A prospective study of children with TIN recommends that patients with TIN be evaluated by an ophthalmologist even if there are no ocular complaints and followed at 3-month intervals for at least 1 year.[97] Fever and other nonspecific symptoms such as fatigue and anorexia also may be present.[88]

Laboratory findings of TINU are notable for markedly elevated ESR, normocytic and normochromic anemia, elevated creatinine, and elevated immunoglobulins. Patients with TINU have been reported to have serologic evidence of autoantibodies, including antinuclear antibody (ANA), rheumatoid factor, and cytoplasmic antineutrophil cytoplasmic antibodies (c-ANCA). TINU has also been reported in association with herpes zoster, EBV infection, toxoplasmosis, and insect bites, as well as systemic diseases such as hyperthyroidism and hypothyroidism, rheumatoid arthritis, and lymphadenopathy. In children and adolescents with this syndrome, TIN spontaneously resolves and its long-term prognosis is good, but uveitis often relapses. Systemic steroids may be required for treatment of both uveitis and TIN.[87]

KEY POINT

Patients with ATIN should have an ophthalmologic evaluation, because uveitis can be asymptomatic.

SUMMARY

TIN is an important cause of AKI and should be considered in patients with no obvious cause for renal failure. History of infection, drug ingestion, skin rashes, or other constitutional symptoms may be present. The clinical features are nonspecific, and strong clinical suspicion is needed to make a diagnosis, which, depending on the clinical course of the patient, may need to be confirmed by renal biopsy. Patients with TIN should be evaluated for uveitis even in the absence of ocular symptoms. Studies support the role of systemic corticosteroid therapy in ATIN. Elimination of the causative agent such as medication and instigation of supportive care are recommended. The prognosis for ATIN is usually good, and very few patients progress to CTIN. On the other hand, CTIN indicates chronic progressive renal damage that involves interstitial fibrosis and glomerular and tubular damage. Recent research has focused on various factors involved in the pathogenesis of TIN and, with better understanding of the immunologic process involved, may help in determining the best targets for treatment.

Clinical Vignette 25.1

A 16-month-old girl with no significant medical history presented to the emergency department (ED) with fever, fussiness, vomiting, and diarrhea. Five days before presentation she had been seen at her pediatrician's office for fever and upper respiratory tract symptoms. She was prescribed oral azithromycin for otitis media. Fevers continued and her mother gave her around-the-clock ibuprofen. She then developed vomiting and non-bloody diarrhea, significantly decreased oral intake, and increased fussiness. The mother noted no wet diapers for 1 day before bringing her to ED. In the ED, she was afebrile, tachycardic with a heart rate of 142 beats/min. Her blood pressure was normal at 106/62 mm Hg, and on examination she looked dehydrated. Relevant laboratory test results revealed serum potassium, 5.2 mEq/L; bicarbonate, 17 mEq/L; blood urea nitrogen, 60 mg/dL; and creatinine, 5.2 mg/dL. Complete blood count showed a white blood cell count of $18.0 \times 10^3/\mu L$; hemoglobin, 11.8 g/dL; and platelets 540,000/μL. Complement levels were normal, and serology studies, including ANA and ANCA titers, were negative. After three normal saline boluses her hydration status improved; however, she remained anuric. She was admitted, and her blood chemistry on the next day showed further deterioration in blood chemistry values, including renal function.

A kidney biopsy was done, and a peritoneal dialysis catheter was placed at the same time. Kidney biopsy showed severe interstitial nephritis; the interstitium was edematous and markedly expanded with severe inflammatory infiltrate and many eosinophils. Immunofluorescence was negative. Intravenous methylprednisolone was given for 3 days followed by oral prednisone 2 mg/kg/day. After 2 days of methylprednisolone the patient began producing small amounts of urine. She continued to slowly improve and was weaned off dialysis 10 days later. She received prednisone 2 mg/kg/day for 1 month, after which it was slowly weaned over the course of 5 months. Her renal function on follow-up has been normal for 4 years.

TEACHING POINTS

- Patients with ATIN usually have nonoliguric AKI, but this patient was anuric on presentation, with rapidly deteriorating renal function.
- The diagnostic value of renal biopsy in such patients is demonstrated by this case. The renal biopsy was remarkable for severe interstitial inflammation with significant amount of eosinophils, a picture typically seen in drug-induced ATIN.
- She had a history of taking two different medications (ibuprofen and azithromycin), either of which could have been the responsible for her ATIN.
- Another confounding aspect of her presentation was the symptoms suggestive of a viral infection, which included diarrhea, vomiting, and lethargy.
- Significant dehydration is likely to have added a prerenal component to her AKI.
- Treatment with corticosteroids resulted in clinical improvement. Whether this improvement was because of the removal of the offending agent or a result of corticosteroids that she received is difficult to ascertain.
- The patient has now been labeled as being allergic to both ibuprofen and azithromycin, the two drugs potentially inciting ATIN in this patient.

REVIEW QUESTIONS

1. Which of the following is true regarding drug-induced ATIN?
   a. ATIN secondary to NSAIDs can present as nephrotic syndrome.
   b. The triad of fever, rash, and arthralgia is present in the majority of patients with drug-induced ATIN.
   c. Eosinophiluria is pathognomonic for ATIN.
   d. Renal injury always develops soon after starting the offending drug.
   e. Drug-induced ATIN is dose-dependent.

2. The typical features on light microscopy of a kidney biopsy in a patient with ATIN are:
   a. Tubular atrophy and interstitial fibrosis with minimal interstitial inflammatory cell infiltration
   b. Diffuse endocapillary proliferation with crescents and necrosis
   c. Diffuse thickening of the glomerular basement membrane
   d. Diffuse mesangial proliferation
   e. Interstitial mononuclear cell infiltration with variable degrees of tubular necrosis and regeneration

3. A 15-year-old boy with a history of obstructive uropathy who received a kidney transplant 8 years ago has an elevated creatinine level. Renal biopsy shows interstitial stripe fibrosis and tubular atrophy. These findings are characteristic of:
   a. Interstitial nephritis secondary to BK virus
   b. Acute cellular rejection
   c. Calcineurin inhibitor chronic interstitial damage
   d. Interstitial nephritis secondary to NSAIDs use
   e. Chronic transplant nephropathy

4. A 5-year-old girl presents with fever, fatigue, and abdominal pain and is admitted to the hospital because of AKI with a creatinine value of 1.3. According to history obtained, she had been taking amoxicillin for 4 days for strep throat. Her physical examination is normal; her urinalysis reveals a specific gravity of 1.009, negative findings for blood and protein, 10 to 20 white blood cells, and no casts. You suspect ATIN secondary to amoxicillin. Which of the following is the next *best* step in her management?
   a. Schedule her for a renal biopsy.
   b. Discontinue amoxicillin and follow creatinine trend.
   c. Administer pulse corticosteroids followed by oral prednisone.
   d. Check eosinophils in the urine, if negative, continue workup looking for other causes of AKI.
   e. Change amoxicillin to a cephalosporin.

5. Which of the following urinary biomarkers has been associated with the acute changes seen in ATIN?
   a. N-acetyl-β-D-glucosaminidase (NAG)
   b. Kidney injury molecule-1 (KIM-1)
   c. Neutrophil gelatinase-associated lipocalin (NGAL)
   d. Monocyte chemotactic peptide-1 (MCP-1)
   e. $β_2$-Microglobulin

6. A 10-year-old boy presents with nonoliguric AKI. He has a renal biopsy performed that shows severe interstitial inflammation with predominant mononuclear cell infiltrate and no granulomas; immunofluorescence is negative. There is no history of medication use or evidence of any viral or bacterial infection. The patient receives corticosteroids and his renal function returns to normal. Regarding further evaluation and follow-up, which of the following is the *most* accurate statement?
   a. He will need follow-up with a nephrologist for at least 1 year.
   b. He can follow up with his primary care physician for yearly checkups only and does not need specialty care.
   c. He needs an ophthalmology evaluation now and every 3 months for the next year in addition to follow-up with a nephrologist.
   d. He needs follow-up with a rheumatologist because of the possibility of underlying autoimmune disease.

7. A 12-year-old girl, previously healthy, presents with nausea and vomiting. She has been taking ibuprofen for a knee injury for the last 7 days. She has mild pitting edema on both lower extremities. Her laboratory results reveal significant proteinuria with a ratio of urine protein to creatinine of 5.9, elevated serum creatinine of 3.5 mg/dL, normal electrolytes, and a low serum albumin of 2.0 g/dL. You suspect ATIN secondary to NSAIDs and stop the medication. Over the next 2 days her creatinine continues to rise and you decide to perform a renal biopsy. Which of the following would be the *most* appropriate step in her management while you wait for the results of her biopsy?
   a. Administer albumin followed by furosemide
   b. Administer intravenous fluids
   c. Check complements and serologic findings and test for viral and bacterial infections
   d. Start intravenous methylprednisolone 10 mg/kg
   e. Start mycophenolate mofetil

8. Which of the following condition can cause secondary tubulointerstitial nephritis?
   a. Membranous nephropathy
   b. Inflammatory bowel disease
   c. Systemic lupus erythematosus
   d. IgA nephropathy
   e. All of the above

9. Regarding CTIN, which of the following statements is true?
   a. In children, the most common cause of CTIN is lupus nephritis.
   b. NSAIDs are the most common causes of drug-related CTIN in children.
   c. CTIN progresses rapidly to end-stage renal disease.
   d. Polyuria, polydipsia, and nocturnal enuresis may be the only manifesting symptoms in children with CTIN.
   e. Corticosteroids are effective in the treatment of CTIN.

10. Regarding prognosis of ATIN in children, which of the following statements is true?
    a. The recovery of renal function depends on the severity of disease at presentation.
    b. Prognosis is independent from the presence of tubular atrophy.
    c. Prognosis is worse in patients with underlying renal disease and when there is prolonged oliguria (more than 3 weeks).
    d. Most children with ATIN progress slowly to CTIN.
    e. All of the above.

Kidney in systemic diseases

Lupus nephritis

CARLA M. NESTER, DAVID B. THOMAS, AND DEBBIE S. GIPSON

Systemic lupus erythematosus (SLE) is a rheumatologic disease associated with significant morbidity and mortality in children.[1–11] It is a chronic autoimmune, inflammatory disease well known for affecting multiple organ systems including the kidney. Presenting symptoms and disease-defining clinical parameters are protean[12,13] (Table 26.1). The pathology of SLE is complex, and disease results from a combination of an inherent susceptibility to the environment and genetically determined abnormalities in the immune system. Although SLE is less common in children than in adults, renal involvement *(lupus nephritis)* in children is more common and more severe than in adults.[14] Lupus nephritis is seen in 60% to 80% of children at presentation, depending on the patient's age and ethnicity.[15,16] When lupus nephritis is not part of the initial constellation, it is likely to evolve and often becomes one of the most significant prognostic factors for long-term morbidity and mortality in a child with this disease.[17–20]

estimated prevalence in the general population of 50 per 100,000 when all ages are included.[24] Variations in the reported prevalence of SLE are likely to be influenced by referral bias, as well as the ethnic makeup of the selected populations studied. The relative risk of SLE in nonwhite pubescent girls compared with white pubescent girls has been estimated to be 7 for Asian girls, 4.5 for African-American girls, and 3 for Hispanic girls.[18] The burden of SLE in the African-American and Hispanic populations is compounded by an increased severity and worse prognosis.[21,25]

KEY POINTS

- Renal involvement in lupus is both more common and more severe in children than in adults.
- The relative risk of SLE is higher in Asian, African-American, and Hispanic girls and women.

EPIDEMIOLOGY

SLE is significantly more common in girls and women than in boys and men.[21] The female-to-male ratio rises from 2:1 in prepubertal children, to 4.5:1 in adolescence, and finally to approximately 10:1 in adults.[22,23] The prevalence of SLE in children is estimated to be as high as 10 per 100,000 individuals, compared with an

PATHOGENESIS

A complete understanding of the pathologic underpinnings of SLE remains to be defined. The production of pathogenic autoantibodies represents the hallmark of SLE and indicates that a major component of the pathology is loss of *immune tolerance*.[26] The acceptance of self-antigens is known as tolerance. Normally, B cells

Table 26.1 Clinical manifestations of systemic lupus erythematosus in children*

* Renal disease is seen in more than 50% patients. Data are representative of an Asian population.

that are able to recognize an individual's own antigens are tightly controlled and eliminated. SLE is characterized by a global loss of self-tolerance and activation of autoreactive T and B cells.[27] The results are the production of pathogenic autoantibodies and tissue injury. Autoantibodies are produced to self-antigens such as DNA, nuclear proteins, and certain cytoplasmic proteins.[28] The stimulus for generation of these autoantibodies is likely fostered by a failure to clear apoptotic debris containing nuclear proteins and chromatin effectively.[29] These self-antigens are then recognized by the abnormal, self-reactive B cells. B-cell and T-cell cooperation leading to B-cell activation results in the creation of both effector and memory B cells. Effector B cells release immunoglobulin G (IgG) autoantibodies into the circulation that form antigen-antibody complexes. These complexes accumulate in the small vessels of organs, where they stimulate local inflammation by activating complement pathways and by binding of Fc receptors, thus leading to mast cell degranulation and local infiltration of macrophages and neutrophils. This aberrant immune regulation provides the backdrop for maladaptive responses to environmental antigens.

As another measure of the complexity of SLE, there are now more than 60 genetic loci associated with this disease (Table 26.2).[30–60] The genetic susceptibility to SLE is supported by familial aggregation, the disease concordance rate in twins, and the increased sibling risk for SLE.[61–66] The genetic contribution appears to involve multiple loci with small to modest individual effect.

KEY POINT

Lupus nephritis results from aberrant immune regulation and is influenced by both environmental factors and genetic risk.

Because SLE may affect the vascular, glomerular, and tubulointerstitial compartments of the kidney to differing degrees, lupus nephritis can manifest in a variety of histologic patterns. Glomerular involvement results not only from the deposition of immune complexes but also from glomerular response and injury caused by antigen specificity and complement stimulation. The pathologic classification of lupus nephritis is based on the criteria set forth by the International Society of Nephrology (ISN) and the Renal Pathology Society (RPS).[67,68] This

* These genes, which are involved in immune complex processing, T- and B-cell signally, interferon pathways, Toll-like receptor function, and multiple other pathways, have been implicated in the pathogenesis of systemic lupus erythematosus.

classification system is a refinement of the historical World Health Organization (WHO) classification system, with the major advances being (1) elimination of the normal biopsy category, (2) elimination of the subcategories of membranous class V lupus, (3) sharper delineations among all the classes, and (4) the addition of subclasses to the diffuse proliferative (class IV) lupus nephritis category. Although the ISN classification is the preferred system, familiarity with the WHO classification system is essential because most available trial data are based on this older classification.

PATHOLOGY

The WHO classification of lupus nephritis has been in use in clinical studies since the 1980s (Table 26.3). In 2003, the ISN and RPS provided further refinement of the pathologic classification of lupus nephritis (Table 26.4). An abbreviated version of this classification for clinical use is given in Table 26.5.

Class I lupus nephritis is minimal mesangial lupus nephritis. The glomeruli are normal by light microscopy, but there is evidence of renal involvement by immune

Table 26.3 World health organization classification of systemic lupus erythematosus (modified in 1982)

Class I	**Normal glomeruli**
	a. Nil (by all techniques)
	b. Normal by light microscopy, but deposits by electron or immunofluorescence microscopy
Class II	**Pure mesangial alterations (mesangiopathy)**
	a. Mesangial widening and/or mild hypercellularity (+)
	b. Moderate hypercellularity (++)
Class III	**Focal segmental glomerulonephritis (associated with mild or moderate mesangial alterations)**
	a. With active necrotizing lesions
	b. With active and sclerosing lesions
	c. With sclerosing lesions
Class IV	**Diffuse glomerulonephritis (severe mesangial, endocapillary, or mesangiocapillary proliferation and/or extensive subendothelial deposits)**
	a. Without segmental lesions
	b. With active necrotizing lesions
	c. With active and sclerosing lesions
	d. With sclerosing lesions
Class V	**Diffuse membranous glomerulonephritis**
	a. Pure membranous glomerulonephritis
	b. Associated with lesions of category II (a or b)
	c. Associated with lesions of category III (a–c)
	d. Associated with lesions of category IV (a–d)
Class VI	**Advanced sclerosing glomerulonephritis**

+, ++, an integer scoring system of 0, + = 1, ++ = 2, etc., with increasing number reflecting worsening hypercellularity.

Table 26.4 Detailed International Society Of Nephrology/Renal Pathology Society 2003 classification of lupus nephritis

Class I	**Minimal mesangial lupus nephritis**	
	Normal glomeruli by light microscopy, but mesangial immune deposits by immunofluorescence	
Class II	**Mesangial proliferative lupus nephritis**	
	Purely mesangial hypercellularity of any degree or mesangial matrix expansion by light microscopy, with mesangial immune deposits	
	A few isolated subepithelial or subendothelial deposits possibly visible by immunofluorescence or electron microscopy, but not by light microscopy	
Class III	**Focal lupus nephritis[a]**	
	Active or inactive focal, segmental, or global endocapillary or extracapillary glomerulonephritis involving <50% of all glomeruli, typically with focal subendothelial immune deposits, with or without mesangial alterations	
Class III (A)	Active lesions: focal proliferative lupus nephritis	
Class III (A/C)	Active and chronic lesions: focal proliferative and sclerosing lupus nephritis	
Class III (C)	Chronic inactive lesions with glomerular scars: focal sclerosing lupus nephritis	
Class IV	**Diffuse lupus nephritis[b]**	
	Active or inactive diffuse, segmental, or global endocapillary or extracapillary glomerulonephritis involving ≥50% of all glomeruli, typically with diffuse subendothelial immune deposits, with or without mesangial alterations; this class is divided into diffuse segmental (IV-S) lupus nephritis when ≥50% of the involved glomeruli have segmental lesions, and diffuse global (IV-G) lupus nephritis when ≥50% of the involved glomeruli have global lesions; segmental is defined as a glomerular lesion that involves less than half of the glomerular tuft; this class includes cases with diffuse wire loop deposits but with little or no glomerular proliferation	
Class IV-S (A)	Active lesions: diffuse segmental proliferative lupus nephritis	
Class IV-G (A)	Active lesions: diffuse global proliferative lupus nephritis	
Class IV-S (A/C)	Active and chronic lesions: diffuse segmental proliferative and sclerosing lupus nephritis	
Class IV-G (A/C)	Active and chronic lesions: diffuse global proliferative and sclerosing lupus nephritis	
Class IV-S (C)	Chronic inactive lesions with scars: diffuse segmental sclerosing lupus nephritis	
Class IV-G (C)	Chronic inactive lesions with scars: diffuse global sclerosing lupus nephritis	
Class V	**Membranous lupus nephritis**	
	Global or segmental subepithelial immune deposits or their morphologic sequelae by light microscopy and by immunofluorescence or electron microscopy, with or without mesangial alterations	
	Class V lupus nephritis possible in combination with class III or IV, in which case both classes will be diagnosed	
	Class V lupus nephritis possibly showing advanced sclerosis	
Class VI	**Advanced sclerotic lupus nephritis**	
	≥90% of glomeruli globally sclerosed without residual activity

[*] Indications and grading (mild, moderate, severe) tubular atrophy, interstitial inflammation and fibrosis, severity of arteriosclerosis, or other vascular lesions, when seen in the biopsy.
[a] Indicates the proportion of glomeruli with active lesions and with sclerotic lesions.
[b] Indicates the proportion of glomeruli with fibrinoid necrosis and cellular crescents.
[c] Class V may occur in combination with class III or IV, in which case both classes will be diagnosed.
Figure 26.1 Class I (ISN/RPS 2003) minimal mesangial lupus glomerulonephritis. Glomeruli are normal by light microscopy but are positive for immune complex deposition by immunofluorescence microscopy.
Figure 26.2 Class II (ISN/RPS 2003) mesangial proliferative lupus glomerulonephritis: only mesangial proliferation (more than three mesangial cells per mesangial area in a 3-μm section) with any degree of matrix expansion by light microscopy, positive immunofluorescence microscopy, and electron microscopy for immune complex deposition (original magnification: 200×, periodic acid–Schiff stain).

into active (A) and chronic (C) lesions. The active lesions include endocapillary hypercellularity, leukocyte infiltrates, karyorrhexis, necrosis, cellular crescents, and hyaline thrombi. The chronic lesions are characterized by sclerosis, adhesions, or fibrous crescents. Class IV diffuse proliferative lupus nephritis involves the same lesions as in class III, but with greater than 50% of all glomeruli affected with active, chronic, or both (acute and chronic) findings (Figure 26.3). Additionally, class IV is subdivided into global (G), involving the entire affected glomerulus, or segmental (S), affecting less than half of the affected glomerulus (Figure 26.4). Class V lupus nephritis
Figure 26.3 Lupus nephritis class III (A). Light micrograph showing a glomerulus with segmental endocapillary hypercellularity, mesangial hypercellularity, capillary wall thickening, and early segmental capillary necrosis (methenamine silver). (From Weening JJ, D'Agati VD, Schwartz MM, et al. The classification of glomerulonephritis in systemic lupus erythematosus revisited. Kidney Int. 2004;65:521–30.)
Figure 26.4 Class IV lesions involve greater than 50% of the total sampled glomeruli. (a) Class IV-G (A) (ISN/RPS 2003) diffuse proliferative lupus glomerulonephritis. The endocapillary hypercellularity involves more than half the individual tuft in greater than 50% of glomeruli sampled. The active or chronic tubulointerstitial injury and vascular findings are reported separately. (b) Class IV-S (A) (ISN/RPS 2003) diffuse proliferative glomerulonephritis. Glomeruli have segmental (less than 50% of the individual glomerulus) tuft injury but lesions are present in greater than 50% of the total sampled glomeruli. In this example with necrosis at the 1 o'clock position. Both images (a) and (b) are active lesions ("A") with no chronic glomerular capillary tuft injury (e.g. "C").
Figure 26.5 Class V (ISN/RPS 2003) membranous lupus glomerulonephritis. Light microscopy, immunofluorescence microscopy, and electron microscopy reveal subepithelial deposits that are global, segmental, or diffusely distributed. Associated mesangial alterations are frequently present. When a class V lesion has additional tuft abnormalities, then a designation of combine class V and III or IV is warranted, depending on the distribution of the additional lesions.

is membranous lupus nephritis and is characterized by subepithelial deposits in the majority of capillary loops (Figure 26.5). Class V lupus nephritis may be coincident with class III and class IV lesions. Class VI sclerosing lupus nephritis is the end result (chronic lesions) of renal lupus involvement, with more than 90% globally sclerotic glomeruli (Figure 26.6). In the Glomerular Disease Collaborative Network patient registry (Table 26.6), the diffuse proliferative lesion (class IV) was the most commonly observed pathologic feature (54%).
Figure 26.6 Class VI (ISN/RPS 2003) advanced sclerosis lupus glomerulonephritis. Glomerular sclerosis was present in greater than 90% of glomeruli, without any residual acuity of lesions.

Table 26.6 Distribution of classification of lupus nephritis lesions in children and adolescents from the Glomerular Disease Collaborative Network patient registry.

Classification	Lesion	N = 80	Percentage (%)
I	Mesangial immune complex	3	4
II	Mesangioproliferative	12	15
III	Focal proliferative	14	17
IV	Diffuse proliferative	43	54
V	Membranous	8	10
VI	Sclerosis	0	0

Solution: Data from Clinical Coordinating Center, University of North Carolina, Division of Nephrology and Hypertension, Chapel Hill, NC.

Immunofluorescence in SLE nephritis is associated with granular deposition of IgA, IgG, IgM and complements C3, C4, and C1q in the capillary walls and the mesangium. This pattern of extensive glomerular immune deposition is sometimes referred to as a "full house" immune localization and is characteristic of lupus nephritis. Although IgA nephropathy and Henoch-Schönlein purpura (HSP) nephritis also have IgA glomerular deposition, "full house" immune deposition is not characteristically observed in either of these clinical disorders.

KEY POINTS

- Polyclonal (kappa and lambda) IgG and complement components (C3, C1q) are characteristic of lupus nephritis glomerular deposits.
- When all three immunoglobulin isotypes, IgG, IgM and IgA are present, the pattern is often referred to as "full house" staining.

CLINICAL MANIFESTATIONS

The initial presentation of SLE is typically recognized by the extrarenal symptoms. SLE is often more acute and more severe with onset in children before the age of 16 years.[69,70] The aggregates of immune complexes in SLE can deposit throughout the body, with resulting multiorgan systemic involvement and a broad spectrum of possible clinical presentations.[13,16,23,71] As the disease progresses, additional organ system involvement can alter the individual patient's clinical manifestations. Generalized symptoms of fever, fatigue, weight loss, and anorexia are common. Abdominal pain caused either by vasculitis or by serositis occurs frequently in children with SLE. Rash occurs in more than 50% of patients with SLE, and alopecia is also

frequent.[16,72,73] Musculoskeletal complaints, such as arthralgias, arthritis, myalgias, or myositis, occur in nearly 86% of children; both large and small joints are affected similarly.[72,73]

Pulmonary involvement occurs in more than 75% of children, and it can manifest as pleuritis, dyspnea, and restrictive lung disease. Pericarditis and endocarditis are well-known clinical indicators of cardiac involvement in pediatric SLE. Neuropsychiatric symptoms, typically attributable to central nervous system vasculitis, are frequent in pediatric SLE and include headache, chorea, cranial nerve palsies, seizures, and psychiatric and behavioral problems. Hematologic abnormalities such as normochromic, normocytic anemia, hemolytic anemia, neutropenia, lymphopenia and thrombocytopenia are common. Manifestations of "polyserositis," such synovitis, pleuritis, and pericarditis, should raise the diagnostic concern of SLE in patients with multisystem disease.

Justification for initial and serial evaluation for renal disease in SLE is supported by the observation that up to 80% of children with SLE develop nephritis over the course of their disease.[22] Clinically evident lupus nephritis may produce a combination of hematuria, proteinuria, edema, diminished glomerular filtration rate, or hypertension. Abnormal urinary sediment consisting of cellular casts and sterile pyuria secondary to renal inflammation is frequently present. Renal tubular dysfunction may be present, and this can manifest as metabolic acidosis, normoglycemic glycosuria, and electrolyte imbalance, especially hyperkalemia.

EVALUATION AND DIAGNOSIS

The diagnosis of lupus nephritis most often is made in a patient with other signs and symptoms of SLE. The clinical history and examination should prompt the screening for serum antinuclear antibodies (ANAs). In patients with SLE, these autoantibodies associate with their complementary antigen and form immune complexes that either are detected in the circulation or are found as immune deposits in tissue biopsy specimens. The immunofluorescent ANA screen allows for the detection of antibodies that bind an array of potential nuclear antigens such as DNA, RNA, and proteins. Although ANAs are present in as many as 95% of patients with SLE, as many as 30% of persons with a positive screening ANA titer of 1:40 are healthy and without lupus.[74] The false-positive rate drops to 3% if the reported titer is 1:320. Because diseases other than SLE are associated with positive ANA test results, the predictive value of a positive test result depends on the test population. In patients with other rheumatic and collagen vascular diseases, a positive ANA test result

may have only a 20% to 35% predictive value for SLE.[75] However, the negative predictive value, the probability of having SLE if the ANA test result is negative, is less than 0.14%. Consequently, if the ANA test result is positive and SLE is suspected, tests for anti–double stranded DNA (anti-dsDNA) and anti-Smith (anti-Sm) antibodies should be ordered. These autoantibodies are the most specific for SLE. Although anti-dsDNA and anti-Sm antibody specificity is much greater than screening ANA, the sensitivity is much lower, 40% to 90% and 5% to 30%, respectively.[22] Antiphospholipid antibodies may occur in 29% to 87% of children with SLE.[76–79] The increased risk of thrombotic events in children with antiphospholipid antibodies is well known.[77,79]
