Comprehensive Clinical Nephrology

SIXTH EDITION

John Feehally, DM, FRCP
Professor of Renal Medicine
The John Walls Renal Unit
Leicester General Hospital
Leicester, United Kingdom

Jürgen Floege, MD, FERA
Professor of Medicine
Director
Division of Nephrology and Clinical Immunology
RWTH University of Aachen
Aachen, Germany

Marcello Tonelli, MD, SM, MSc, FRCPC
Associate Vice President (Research)
Department of Medicine
University of Calgary
Calgary, Alberta, Canada

Richard J. Johnson, MD
Professor of Medicine
Division Chief
Tomas Berl Professor of Nephrology
University of Colorado–Denver
Denver, Colorado, USA

CONTENTS

SECTION XV Drug Therapy in Kidney Disease

SECTION XVI Chronic Kidney Disease and the Uremic Syndrome

SECTION XVII Geriatric and Palliative Nephrology

SECTION XVIII Dialytic Therapies

SECTION XIX Transplantation

SECTION XX Palliative Nephrology

PREFACE

In the sixth edition of *Comprehensive Clinical Nephrology,* we continue to offer a text for fellows, practicing nephrologists, and internists that covers all aspects of the clinical work of the nephrologist, including fluids and electrolytes, hypertension, diabetes, dialysis, and transplantation. We recognize that this single volume does not compete with multivolume or highly referenced online texts, and it remains our goal to provide "comprehensive" coverage of clinical nephrology yet also ensure that inquiring nephrologists can find the key scientific issues and pathophysiology that underlie their clinical work.

All chapters have been extensively revised and updated in response to the advice and comments that we have received from many readers and colleagues. These revisions include latest developments, such as new insights into complement mediated glomerular diseases, and the latest data on epidemiology and consequences of acute kidney injury and renal replacement therapy. Also included is a chapter on the emerging problem of endemic nephropathies in low and middle income countries. This edition retains the consistent design of the algorithms, which are a popular feature of the book, to emphasize different aspects of the information provided: yellow boxes for general information, blue boxes for necessary investigations, and green boxes for therapeutic interventions. By popular demand we continue to offer readers access to the images from the book. We are pleased to see them used in lectures and seminars in many parts of the world.

This is the third edition that features access to a companion Expert Consult website, with fully searchable text, a downloadable image library, and links to PubMed. New to this edition is an online question bank with more than 400 multiple-choice questions.

And finally, we welcome a new co-editor, Marcello Tonelli, who will bring great epidemiological expertise (and significantly lower the average age of the editors).

John Feehally
Jürgen Floege
Marcello Tonelli
Richard J. Johnson

LIST OF CONTRIBUTORS

The editor(s) would like to acknowledge and offer grateful thanks for the input of all previous editions' contributors, without whom this new edition would not have been possible.

Emaad Abdel-Rahman, MBBS
Professor of Clinical Internal Medicine
Division of Nephrology
University of Virginia Health System
Charlottesville, VA, USA

Horacio J. Adrogué, MD
Professor of Medicine
Baylor College of Medicine
Chief, Clinical Nephrology and Hypertension
Houston Methodist Hospital
Houston, TX, USA

Ala Abudayyeh, MD
University of Texas MD Anderson Cancer Center
Houston, TX;
Section of Nephrology
Department of Medicine
Yale University School of Medicine
New Haven, CT, USA

Sharon Adler, MD
Professor of Medicine
Chief and Program Director
Division of Nephrology and Hypertension
Los Angeles Biomedical Research Institute at Harbor University of California–Los Angeles
David Geffen School of Medicine
Torrance, CA, USA

Anupam Agarwal, MD
Professor and Director
Division of Nephrology
Marie S. Ingalls Endowed Chair in Nephrology
University of Alabama at Birmingham
Birmingham, AL, USA

Shikha Aggarwal, MBBS (HONS) FRACP
Consultant Nephrologist
Department of Nephrology Mater Hospital
Sydney, Australia

Venkatesh Aiyagari, MBBS, DM, FAHA
Professor
Department of Neurological Surgery and Neurology and Neurotherapeutics
University of Texas Southwestern Medical Center
Dallas, TX, USA

Kawther F. Alquadan, MD
Assistant Professor of Medicine
University of Florida
Gainesville, FL, USA

Gerald B. Appel, MD
Director
The Glomerular Kidney Center at Columbia University Medical Center;
Professor of Medicine at Columbia University
College of Physicians and Surgeons
New York, NY, USA

Fatiu A. Arogundade, MBBS, FMCP, FWACP
Associate Professor and Consultant Nephrologist
Department of Medicine
Obafemi Awolowo University and Teaching Hospitals Complex
Ile-Ife, Osun State, Nigeria

Vicente Arroyo, MD, PhD
Director of the EASL-CLIF Consortium-Efclif.
Barcelona, Spain

Stephen R. Ash, MD, FACP
Director of Dialysis, Department of Nephrology
Indiana University Health Arnett;
Chairman and Director
Research and Development
HemoCleanse, Inc. and Ash Access Technology, Inc.
Lafayette, IN, USA

Shazia Ashraf, MS
Division of Nephrology
Boston Children's Hospital
Harvard Medical School
Boston, MA, USA

Pierre Aucouturier, PhD
Professor of Immunology at Pierre et Marie Curie University
Department of Biologic Immunology
Pôle de Biologie Médicale et Pathologie Hôpitaux Universitaires de l'Est Parisien
Paris, France

Matthew A. Bailey, PhD
Reader in Renal Physiology
The Centre for Cardiovascular Science
The University of Edinburgh
Edinburgh, UK

George L. Bakris, MD
Professor of Medicine, Director
American Society of Hypertension Comprehensive Hypertension Center
Department of Medicine
University of Chicago
Chicago, IL, USA

Adam D. Barlow, MD, FRCS
Consultant Transplant Surgeon
Leeds Teaching Hospitals NHS Trust
Leeds, UK

Rashad S. Barsoum, MD, FRCP, FRCPE
Emeritus Professor of Medicine
Kasr-El-Aini Medical School
Cairo University
Cairo, Egypt

Ariela Benigni, PhD
IRCCS - Istituto di Ricerche Farmacologiche Mario Negri
Bergamo, Italy

Tomas Berl, MD
Professor of Medicine
Division of Renal Diseases and Hypertension, Department of Medicine
University of Colorado Denver
Denver, CO, USA

Gemma Bircher, MSc, BSc (hons), RD
Dietetic Manager
Renal Dietitians
Leicester General Hospital
Leicester, England

Detlef Bockenhauer, PhD
Professor of Paediatric Nephrology
UCL Centre for Nephrology;
Honorary Consultant
Great Ormond Street Hospital for Children NHS Foundation Trust
London, UK

Peter Boor, MD, PhD
Pathologist
Institute of Pathology
Uniklinik RWTH Aachen
Aachen, Germany

Josée Bouchard, MD
Associate Professor of Medicine
Hôpital du Sacré-Coeur de Montréal, Université de Montréal
Montréal, Canada

Kate Bramham
Clinical Lecturer in Renal Sciences
Department of Renal Medicine
Division of Transplantation and Mucosal Biology
King's College London
London, UK

Edwina A. Brown, DM, FRCP
Professor of Renal Medicine, Imperial College London;
Consultant Nephrologist
Imperial College Renal and Transplant Centre
Hammersmith Hospital
London, UK

Mark A. Brown, MD, MB, BS
Professor of Renal Medicine
St. George Hospital and University of New South Wales
Sydney, Australia

Emmanuel A. Burdmann, MD, PhD
Associate Professor, Division of Nephrology
University of São Paulo Medical School
São Paulo, Brazil

David A. Bushinsky, MD
John J. Kuiper Distinguished Professor of Medicine and of Pharmacology and Physiology
Department of Medicine
University of Rochester School of Medicine and Dentistry
Rochester, NY, USA

Gabriel Cara-Fuentes, MD
Clinical Lecturer
Pediatrics Nephrology
University of Michigan
Ann Arbor, MI, USA

Michael J. Casey, MD, MS
Associate Professor of Medicine
University of Florida
Gainesville, Florida, USA

Daniel C. Cattran, MD, FRCPC
Professor of Medicine
University of Toronto;
Senior Scientist
Toronto General Research Institute
Toronto, ON, Canada

Matthew J. Cervelli, BPharm
Clinical Pharmacist Specialist
Royal Adelaide Hospital
Adelaide, Australia

Steven J. Chadban, PhD, Bmed(Hons), FRACP
Clinical Professor
Nephrologist, and Transplant Physician
Royal Prince Alfred Hospital and University of Sydney
Sydney, Australia

Christopher Chan, MD
Director of Nephrology – UHN
R Fraser Elliott Chair in Home Dialysis
Professor of Medicine
Deputy Physician in Chief of Economics
Toronto, ON, Canada

Melanie M. Y. Chan, MA, MRCP
Clinical Lecturer in Renal Medicine and Transplantation
University College London Centre for Nephrology
Royal Free London National Health Service Foundation Trust
London, UK

Jeremy R. Chapman, MD, FRACP, FRCP
Director of Renal Medicine
Centre for Transplant and Renal Research
Sydney University, Westmead Hospital
Westmead, Australia

Karen E. Charlton, PhD, Adv APD, RPHNutr
Associate Professor
School of Medicine, Faculty of Science, Medicine and Health
University of Wollongong
New South Wales, Australia

Wei Chen, MD
Assistant Professor
Department of Medicine
University of Rochester School of Medicine and Dentistry
Rochester, NY, USA

Yipu Chen, MD
Professor of Medicine
Division of Nephrology
Beijing Anzhen Hospital
Capital Medical University
Beijing, People's Republic of China

John O. Connolly, PhD, FRCP
Consultant Nephrologist
University College London Centre for Nephrology
Royal Free London National Health Service Foundation Trust
London, UK

H. Terence Cook, MB, BS, FRCPath
Professor of Renal Pathology
Centre for Complement and Inflammation Research
Department of Medicine
Imperial College
London, UK

James E. Cooper, MD
Associate Professor
Department of Medicine
Renal Division
University of Colorado,
Aurora, CO, USA

Vivette D. D'Agati, MD
Director of Renal Pathology at Columbia University Medical Center and Professor of Pathology at Columbia University
College of Physicians and Surgeons
New York, NY, USA

Kevin Damman, MD, PhD
Cardiologist
Department of Cardiology
University Medical Center Groningen
Groningen, The Netherlands

Gabriel M. Danovitch, MD
Distinguished Professor of Medicine
David Geffen School of Medicine at University of California-Los Angeles;
Medical Director, Kidney Transplant Program
Ronald Reagan Medical Center at University of California-Los Angeles
Los Angeles, CA, USA

Simon J. Davies, MD, BSc, FRCP
Professor of Nephrology and Dialysis Medicine
Institute for Science and Technology in Medicine
Keele University;
Consultant Nephrologist
Department of Nephrology
University Hospital of North Staffordshire
Staffordshire, UK

Wayne Derman, MBChB, PhD, FFIMS
Professor
Institute of Sport and Exercise Medicine
Division of Orthopaedic Surgery
Stellenbosch University
IOC Research Centre
Matieland, South Africa

An S. De Vriese, MD, PhD
Division of Nephrology
AZ Sint-Jan Brugge
Brugge, Belgium

James E. Dyer, MBChB, BSc Hons
Clinical Research Fellow
Department of Urology
Leicester General Hospital
Leicester, UK

Kai-Uwe Eckardt, MD
Professor of Medicine
Department of Nephrology and Medical Intensive Care
Charité-Universitätsmedizin Berlin
Berlin, Germany

David H. Ellison, MD
Professor of Medicine and Physiology and Pharmacology
Department of Medicine
Oregon Health and Science University and VA Portland Health Care System
Portland, OR, USA

Marlies Elger, PhD
Department of Neuroanatomy
Medical Faculty Mannheim
University of Heidelberg
Mannheim, Germany

William J. Elliott, MD, PhD
Professor of Preventive Medicine
Internal Medicine and Pharmacology;
Chief, Division of Pharmacology;
Chair, Department of Biomedical Sciences
Pacific Northwest University of Health Sciences
Yakima, WA, USA

Pieter Evenepoel, MD, PhD
Professor, Nephrology and Renal Transplantation
University Hospital Leuven
Leuven, Belgium

Ronald J. Falk, MD
Nan and Hugh Cullman Eminent Professor and Chair of Medicine
Department of Medicine
University of North Carolina at Chapel Hill
Chapel Hill, NC, USA

Tarek S. Fayad, MD
Professor of Medicine
Kasr El-Aini Medical School
Cairo University
Cairo, Egypt

John Feehally, DM, FRCP
Professor of Renal Medicine
The John Walls Renal Unit
Leicester General Hospital
Leicester, UK

Javier Fernández, MD, PhD
Head of the Liver ICU
Hospital Clinic Barcelona
University of Barcelona
Barcelona, Spain

Fernando C. Fervenza, MD, PhD
Division of Nephrology and Hypertension
Mayo Clinic
Rochester, MN, USA

Evelyne A. Fischer, MD

Renal Anatomy

Wilhelm Kriz, Marlies Elger

The complex structure of the mammalian kidney is best understood in the unipapillary form that is common to all small species. Fig. 1.1 is a schematic coronal section through a unipapillary kidney, with a cortex enclosing a pyramid-shaped medulla, the tip (papilla) of which protrudes into the renal pelvis. The medulla is divided into an outer and an inner medulla; the outer medulla is further subdivided into an outer and an inner stripe.

STRUCTURE OF THE KIDNEY

The specific components of the kidney are the nephrons, the collecting ducts (CDs), and a unique microvasculature.[1] The multipapillary kidney of humans contains approximately 1 million nephrons, although this number varies considerably. The number of nephrons is already established during prenatal development; after birth, new nephrons cannot be developed and a lost nephron cannot be replaced.

Nephrons

A nephron consists of a renal corpuscle *(glomerulus)* connected to a complicated and twisted tubule that finally drains into a CD (Fig. 1.2 and Table 1.1). Three types of nephron can be distinguished by the location of renal corpuscles within the cortex: superficial, midcortical, and juxtamedullary nephrons. The tubular part of the nephron consists of a proximal tubule and a distal tubule connected by a loop of Henle[2] (see later discussion). There are two types of nephrons: those with long loops of Henle and those with short loops. Short loops turn back in the outer medulla or even in the cortex (cortical loops). Long loops turn back at successive levels of the inner medulla.

Collecting Ducts

A CD is formed in the renal cortex when several nephrons join. A connecting tubule (CNT) is interposed between a nephron and a cortical CD. Cortical CDs descend within the medullary rays of the cortex. Then they traverse the outer medulla as unbranched tubes. On entering the inner medulla, they fuse successively and open finally as papillary ducts into the renal pelvis (see Fig. 1.2 and Table 1.1).

Microvasculature

The microvascular pattern of the kidney is similarly organized in mammalian species[1,3] (Fig. 1.3; see also Fig. 1.1). The renal artery, after entering the renal sinus, finally divides into the interlobar arteries, which extend toward the cortex in the space between the wall of the pelvis (or calyx) and the adjacent cortical tissue. At the junction between cortex and medulla, the interlobar arteries divide and pass over into the arcuate arteries, which also branch. The arcuate arteries give rise to the cortical radial arteries (interlobular arteries), which ascend radially through the cortex. No arteries penetrate the medulla.

Afferent arterioles supply the glomerular tufts and generally arise from cortical radial arteries. As a result, the blood supply of the peritubular capillaries of the cortex and the medulla is exclusively *postglomerular.*

Glomeruli are drained by efferent arterioles. Two basic types of efferent arterioles can be distinguished: cortical and juxtamedullary. *Cortical* efferent arterioles, which derive from superficial and midcortical glomeruli, supply the capillary plexus of the cortex. The efferent arterioles of *juxtamedullary* glomeruli represent the supplying vessels of the renal medulla. Within the outer stripe of the medulla, these vessels divide into the *descending* vasa recta and then penetrate the inner stripe in cone-shaped vascular bundles. At intervals, individual vessels leave the bundles to supply the capillary plexus at the adjacent medullary level.

Ascending vasa recta drain the renal medulla. In the inner medulla, the vasa recta arise at every level, ascending as unbranched vessels, and traverse the inner stripe within the vascular bundles. The ascending vasa recta that drain the inner stripe may join the vascular bundles or may ascend directly to the outer stripe between the bundles. All the ascending vasa recta traverse the outer stripe as individual wavy vessels with wide lumina interspersed among the tubules. Because true capillaries derived from direct branches of efferent arterioles are relatively scarce, the ascending vasa recta form the capillary plexus of the outer stripe. The ascending vasa recta empty into arcuate veins.

The vascular bundles represent a countercurrent exchanger between the blood entering and that leaving the medulla. In addition, the organization of the vascular bundles results in a separation of the blood flow to the inner stripe from that to the inner medulla. Descending vasa recta supplying the inner medulla traverse the inner stripe within the vascular bundles. Therefore blood flowing to the inner medulla has not been exposed previously to tubules of the inner or outer stripe. All ascending vasa recta originating from the inner medulla traverse the inner stripe within the vascular bundles. Thus blood that has perfused tubules of the inner medulla does not subsequently perfuse tubules of

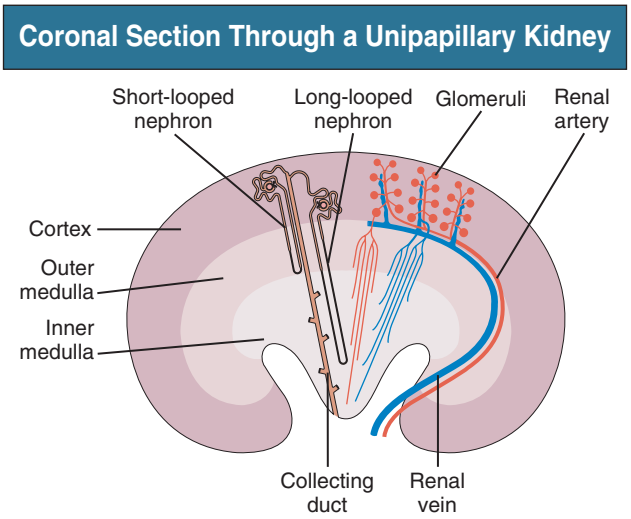

Fig. 1.1 Coronal section through a unipapillary kidney.

TABLE 1.1 Subdivisions of the Nephron and Collecting Duct System

Section	Subsections
Nephron	
Renal corpuscle	*Glomerulus:* term used most frequently to refer to entire renal corpuscle
	Bowman capsule
Proximal tubule	Convoluted part
	Straight part (pars recta), or thick descending limb of Henle loop
Intermediate tubule	Descending part, or thin descending limb of Henle loop
	Ascending part, or thin ascending limb of Henle loop
Distal tubule	Straight part, or thick ascending limb of Henle loop: subdivided into medullary and cortical parts; the cortical part contains the macula densa in its terminal portion
	Convoluted part
Collecting Duct System	
Connecting tubule	Includes the arcades in most species
Collecting duct	Cortical collecting duct
	Outer medullary collecting duct: subdivided into an outer stripe and an inner stripe portion
	Inner medullary collecting duct: subdivided into basal, middle, and papillary portions

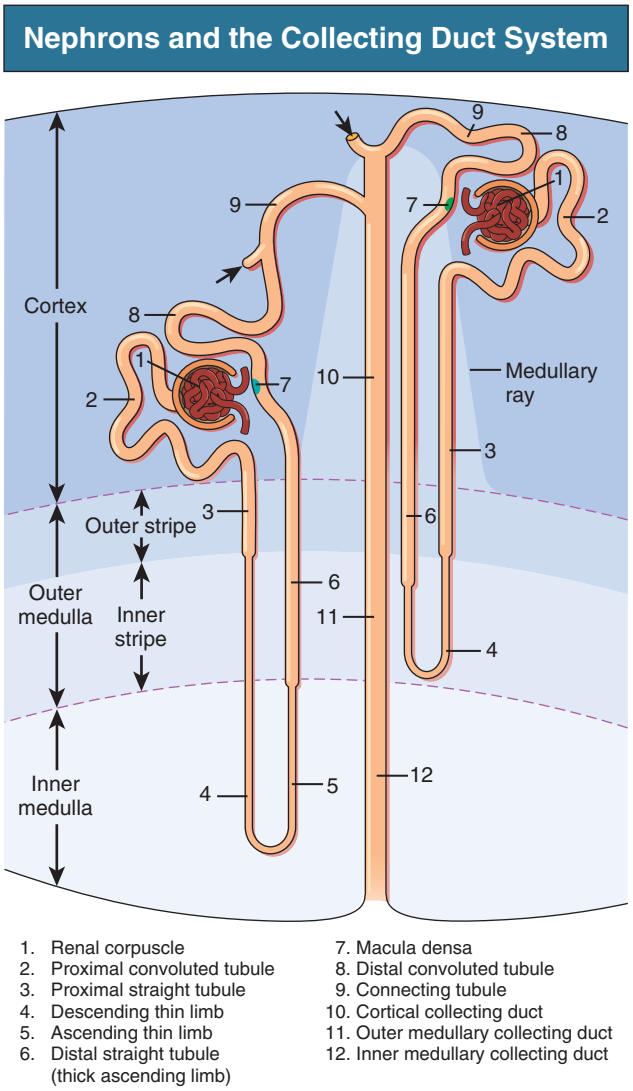

Fig. 1.2 Nephrons and the collecting duct system. Shown are short-looped and long-looped nephrons, together with a collecting duct (not drawn to scale). *Arrows* denote confluence of further nephrons.

the inner stripe. However, the blood returning from either the inner medulla or the inner stripe afterward does perfuse the tubules of the outer stripe.

The intrarenal veins accompany the arteries. Central to the renal drainage of the kidney are the arcuate veins, which, in contrast to arcuate arteries, do form real anastomosing arches at the corticomedullary border.

The intrarenal arteries and the afferent and efferent glomerular arterioles are accompanied by sympathetic nerve fibers and terminal axons representing the efferent nerves of the kidney.[1] Tubules have direct contact to terminal axons only when the tubules are located around the arteries or the arterioles. Tubular innervation consists of "occasional fibers adjacent to perivascular tubules."[4] The density of nerve contacts to convoluted proximal tubules is low; contacts to straight proximal tubules, thick ascending limbs of Henle loops, and CDs have never been encountered. Afferent nerves of the kidney are believed to be sparse.[5]

Glomerulus (Renal Corpuscle)

The glomerulus comprises a tuft of specialized capillaries attached to the mesangium, both of which are enclosed in a pouch-like extension of the tubule that represents the Bowman capsule (Figs. 1.4 and 1.5). The capillaries together with the mesangium are covered by epithelial cells (podocytes) forming the visceral epithelium of the Bowman capsule. At the vascular pole, this is reflected to become the parietal epithelium of the Bowman capsule. At the interface between the glomerular capillaries and the mesangium on one side and the podocyte layer on the

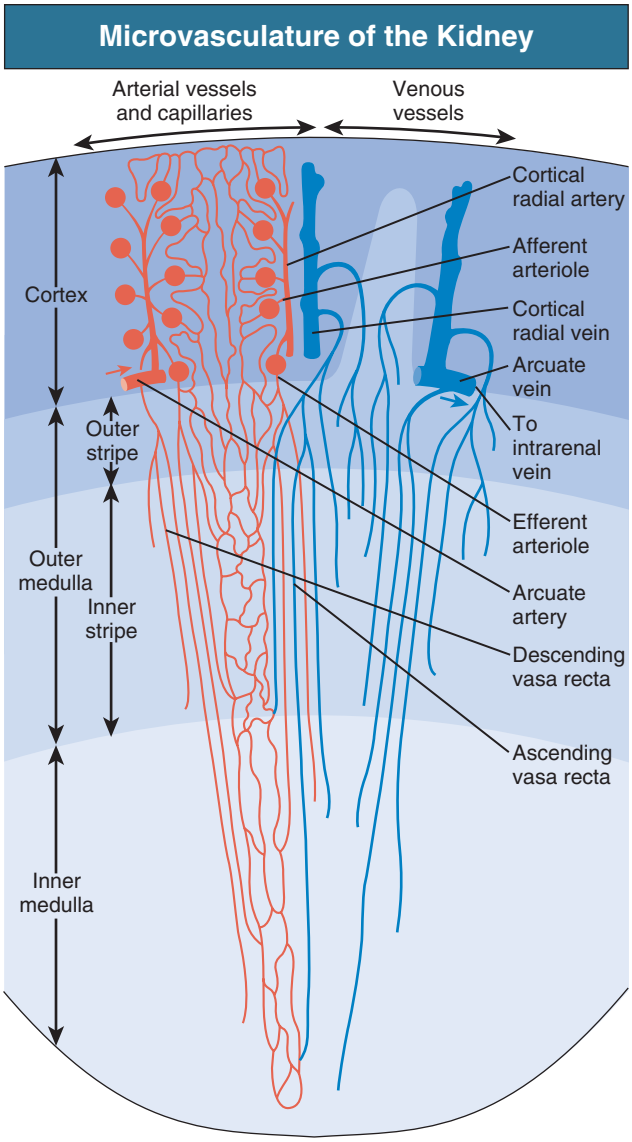

Fig. 1.3 Microvasculature of the Kidney. Afferent arterioles supply the glomeruli, and efferent arterioles leave the glomeruli and divide into the descending vasa recta, which together with the ascending vasa recta form the vascular bundles of the renal medulla. The vasa recta ascending from the inner medulla all traverse the inner stripe within the vascular bundles, whereas most of the vasa recta from the inner stripe of the outer medulla ascend outside the bundles. Both types traverse the outer stripe as wide, tortuous channels.

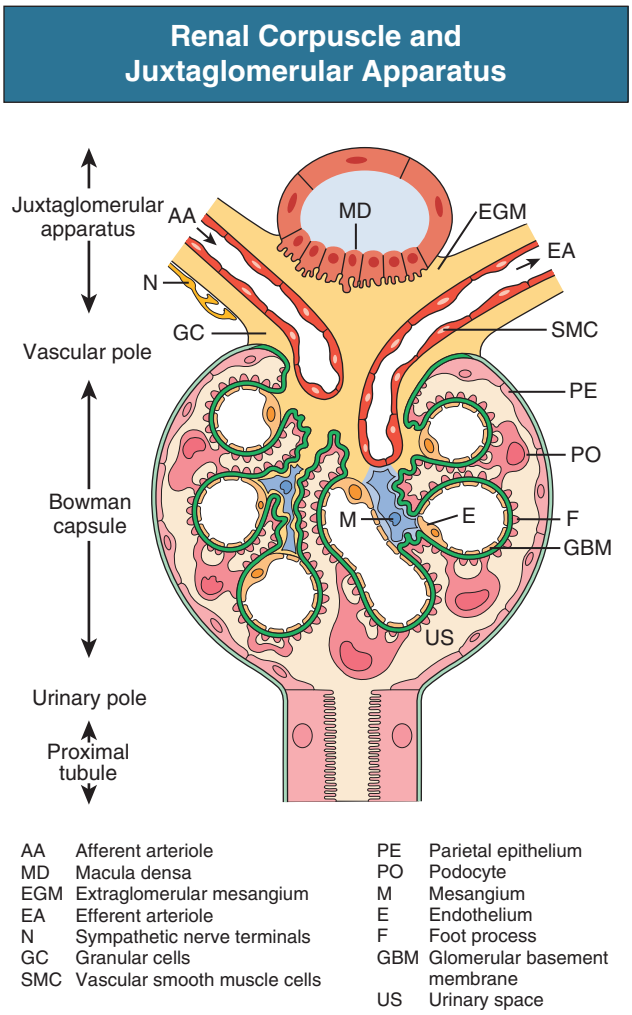

Fig. 1.4 Glomerulus and juxtaglomerular apparatus. (Modified with permission from reference 1.)

other side, the glomerular basement membrane (GBM) is developed. The space between both layers of the Bowman capsule represents the urinary space, which at the urinary pole continues as the tubule lumen.

On entering the tuft, the afferent arteriole immediately divides into several primary capillary branches, each of which gives rise to an anastomosing capillary network representing a glomerular lobule. In contrast, the efferent arteriole is already established inside the tuft by confluence of capillaries from each lobule.[6] Thus the efferent arteriole has a significant intraglomerular segment located within the glomerular stalk.

Glomerular capillaries are a unique type of blood vessel composed of nothing but an endothelial tube (Figs. 1.6 and 1.7). A small stripe of the outer aspect of this tube directly abuts the mesangium; the major part bulges toward the urinary space and is covered by the GBM and the podocyte layer. This peripheral portion of the capillary wall represents the filtration area.

Glomerular Basement Membrane

The GBM serves as the skeleton of the glomerular tuft. This membrane is a complexly folded sack with an opening at the glomerular hilum (see Fig. 1.4). The outer aspect of this GBM sack is completely covered with podocytes. The interior of the sack is filled with the capillaries and the mesangium. As a result, on its inner aspect, the GBM is in contact with either capillaries or the mesangium. At any transition between these two locations, the GBM changes from a convex pericapillary to a concave perimesangial course; the turning points are called *mesangial angles*. In electron micrographs of traditionally fixed tissue, the GBM appears as a trilaminar structure, with a lamina densa bounded by two less dense layers, the lamina rara interna and lamina rara externa (see Fig. 1.7). Studies with freeze techniques reveal only one thick, dense layer directly attached to the bases of the epithelium and endothelium.[7]

The major components of the GBM include type IV collagen, laminin, and heparan sulfate proteoglycans, as in basement membranes at other sites. However, the GBM has several unique properties, notably a distinct spectrum of type IV collagen and laminin isoforms. The mature GBM consists of type IV collagen made of α3, α4, and α5 chains and laminin 11, made of α5, β2, and γ1 chains.[8] Type IV collagen is the antigenic target in Goodpasture disease (see Chapter 16), and mutations in the

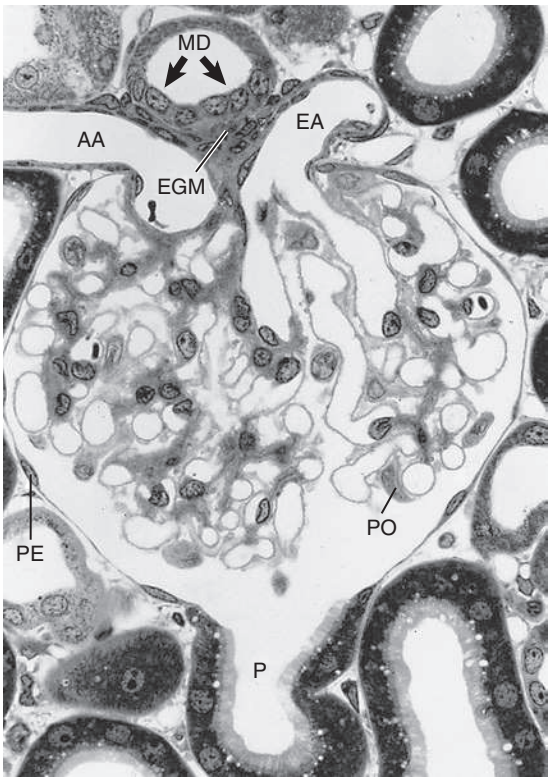

Fig. 1.5 Longitudinal section through a glomerulus (rat). At the vascular pole, the afferent arteriole *(AA),* the efferent arteriole *(EA),* the extraglomerular mesangium *(EGM),* and the macula densa *(MD)* are seen; *PO,* podocyte. At the urinary pole, the parietal epithelium *(PE)* transforms into the proximal tubule *(P).* (Light microscopy; magnification ×390.)

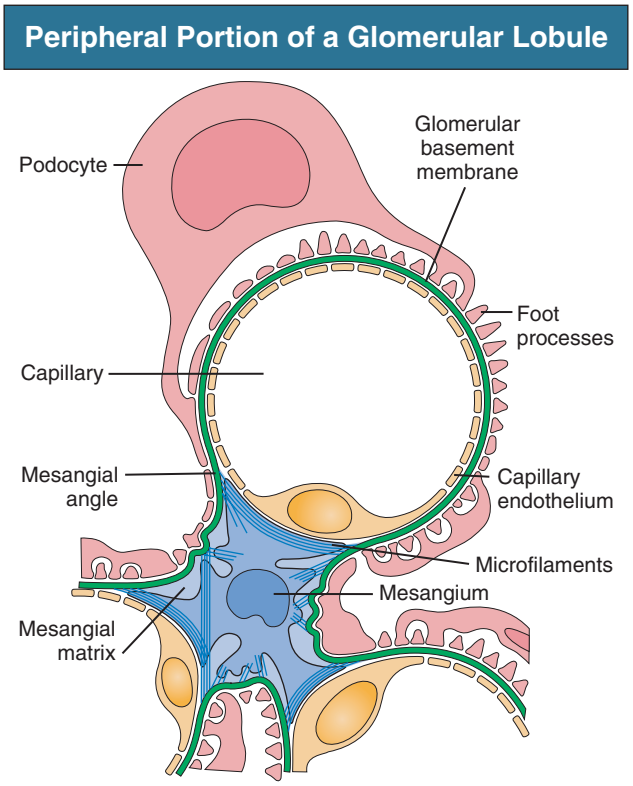

Fig. 1.6 Peripheral portion of a glomerular lobule. This part shows a capillary, the axial position of the mesangium, and the visceral epithelium (podocytes). At the capillary-mesangial interface, the capillary endothelium directly abuts the mesangium.

genes of the α3, α4, and α5 chains are responsible for Alport syndrome (see Chapter 46).

Current models depict the basic structure of the GBM as a three-dimensional network of type IV collagen.[7] The type IV collagen monomer consists of a triple helix that is 400 nm in length, with a large, noncollagenous globular domain at its C-terminal end called NC1. At the N terminus, the helix possesses a triple helical rod 60 nm long: the 7S domain. Interactions between the 7S domains of two triple helices or the NC1 domains of four triple helices allow type IV collagen monomers to form dimers and tetramers. In addition, triple helical strands interconnect by lateral associations through binding of NC1 domains to sites along the collagenous region. This network is complemented by an interconnected network of laminin 11, resulting in a flexible, nonfibrillar polygonal assembly that provides mechanical strength and elasticity to the basement membrane and serves as a scaffold for alignment of other matrix components.[9,10]

The electronegative charge of the GBM mainly results from the presence of polyanionic proteoglycans. The major proteoglycans of the GBM are heparan sulfate proteoglycans, including perlecan and agrin. Proteoglycan molecules aggregate to form a meshwork that is kept well hydrated by water molecules trapped in the interstices of the matrix.

Mesangium

Three major cell types occur within the glomerular tuft, all of which are in close contact with the GBM: mesangial cells, endothelial cells, and podocytes. The mesangial/endothelial/podocyte cell ratio is 2:3:1 in the rat. The mesangial cells and mesangial matrix establish the glomerular mesangium.

Mesangial cells. Mesangial cells are irregular in shape, with many processes extending from the cell body toward the GBM (see Figs. 1.6 and 1.7). In these processes, dense assemblies of microfilaments are found, containing α-smooth muscle actin, myosin, and α-actinin.[11]

The processes are attached to the GBM directly or through the interposition of microfibrils The GBM represents the effector structure of mesangial contractility. Mesangial cell–GBM connections are found throughout the mesangium-GBM interface but are especially prominent at the turning points of the GBM infoldings (mesangial angles). The folding pattern of the GBM is permanently challenged by the expansile forces of the high intraglomerular perfusion pressure. Centripetal mesangial cell contraction balances the expansile forces. Thus the folding pattern of the GBM, including the complex convolutions of glomerular capillaries, are maintained by mesangial cells.

Mesangial cells possess a great variety of receptors, including those for angiotensin II (Ang II), vasopressin, atrial natriuretic factor, prostaglandins, transforming growth factor β (TGF-β), and other growth factors (platelet-derived growth factor [PDGF], epidermal growth factor [EGF], connective tissue growth factor [CTGF]).[12]

Mesangial matrix. The mesangial matrix fills the highly irregular spaces between the mesangial cells and the perimesangial GBM, anchoring the mesangial cells to the GBM.[6] Many common extracellular matrix proteins have been demonstrated within the mesangial matrix, including collagen types IV, V, and VI and microfibrillar protein components such as fibrillin and the 31-kilodalton microfibril-associated glycoprotein. The matrix also contains several glycoproteins, most abundantly fibronectin.

Endothelium

Glomerular endothelial cells consist of cell bodies and peripherally located, attenuated, and highly fenestrated cytoplasmic sheets (see Figs.

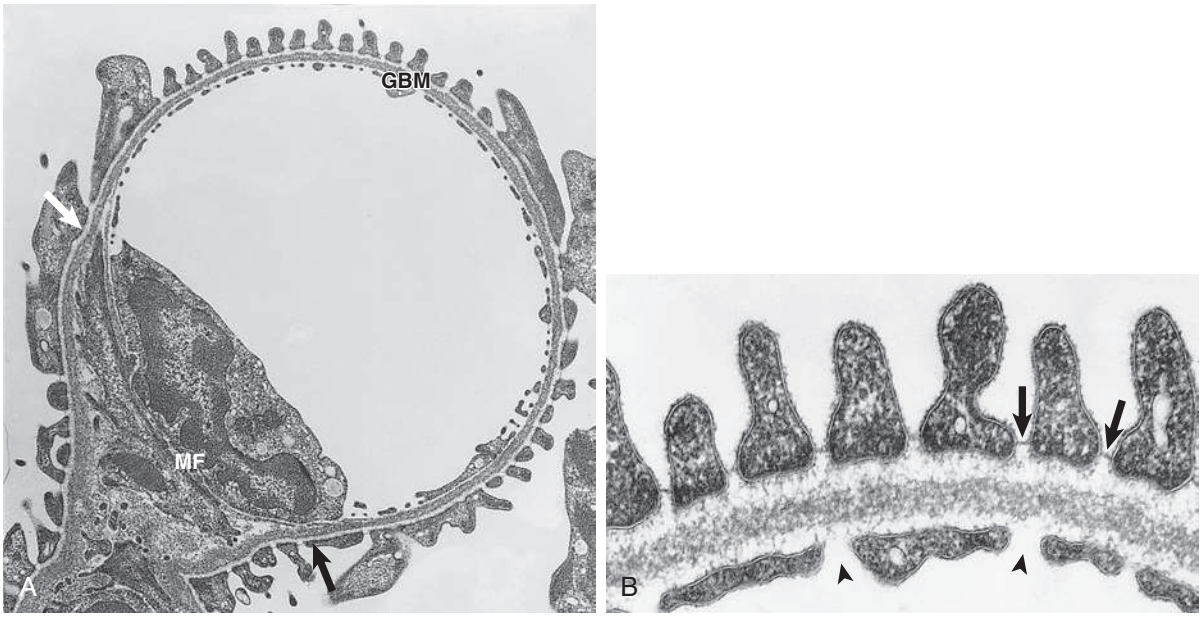

Fig. 1.7 Glomerular capillary. (A)The layer of interdigitating podocyte processes and the glomerular basement membrane *(GBM)* do not completely encircle the capillary. At the mesangial angles *(arrows),* both deviate from a pericapillary course and cover the mesangium. Mesangial cell processes containing dense bundles of microfilaments *(MF),* interconnect the GBM, and bridge the distance between the two mesangial angles. (B) Filtration barrier. The peripheral part of the glomerular capillary wall comprises the endothelium with open pores *(arrowheads),* the GBM, and the interdigitating foot processes (FPs). The GBM shows a lamina densa bounded by the lamina rara interna and externa. The FPs are separated by filtration slits bridged by thin diaphragms *(arrows).* (Transmission electron microscopy [TEM]; magnification: **A,** [×8770]; **B,** [×50,440].)

1.6 and 1.7). Glomerular endothelial pores lack diaphragms, which are encountered only in the endothelium of the final tributaries to the efferent arteriole.[6] The round to oval pores have a diameter of 50 to 100 nm. A negatively charged layer of membrane-bound and loosely attached molecules (glycocalyx) covers the entire luminal surface, including, as sieve plugs, the endothelial pores.[13] Endothelial cells are active participants in processes controlling coagulation and inflammation. Endothelial cells have receptors for vascular endothelial growth factor (VEGF), angiopoietins, and TGFβ-1, among others. They synthesize and release PDGF-B, endothelin-1, and endothelium-derived relaxing factor (EDRF), among others.[14]

Visceral Epithelium (Podocytes)

The visceral epithelium of the Bowman capsule comprises highly differentiated cells, the podocytes (Fig. 1.8; see also Fig. 1.6). Differentiated podocytes are unable to replicate; therefore lost podocytes cannot be replaced in the adult. All efforts of the last decade to find progenitor cells that might migrate into the tuft and replace lost podocytes have failed.

Podocytes have a voluminous cell body that floats within the urinary space, separated from the GBM by a subpodocyte space.[15] The cell bodies give rise to primary processes that fall apart into foot processes (FPs) that fix the cells to the capillaries, i.e. to the GBM. Sporadic FPs also may arise directly from the cell body. The FPs of neighboring podocytes regularly interdigitate with each other, leaving meandering slits (filtration slits) between them that are bridged by a complex extracellular structure, the *slit diaphragm* (SD) that may be seen as a modified adherens junction (Fig. 1.9; see also Figs. 1.6 to 1.8). Traditional scanning electron micrograph (SEM) pictures (see Fig.1.8A) do not convey the correct pattern of how FPs interdigitate and adhere to the GBM. As seen by block-face SEM (see Fig. 1.8B), individual FPs may terminate with a final branching and primary processes fall off into basal ridges that actually are also FPs.[16] Thus the interdigitating FP pattern as it adheres to the GBM is completely homogeneous, forming a uniform cover of interdigitating filopodia.

In contrast to the cell body, which harbors a prominent endoplasmic reticulum and Golgi system and has well-developed endocytotic and autophagic machinery, the cell processes apart from endocytotic elements contain only a few organelles. A sophisticated cytoskeleton accounts for the complex shape of the cells. In the cell body and the primary processes, microtubules and intermediate filaments (vimentin, desmin) dominate. Within the FPs, microfilaments (β-actin) form prominent U-shaped bundles arranged in the longitudinal axis of two successive FPs in an overlapping pattern. Above, the bends of these bundles are linked to the microtubules of the primary processes; peripherally, these bundles terminate in the dense cytoplasm associated with the sole plates, being part of the anchoring system of the FPs to the GBM (see later discussion). In addition, FPs have well developed sub-plasmalemmal actin network that has intimate contact to the anchor line of the SD and diffusely to the actin bundles. Multiple actin-associated proteins, including α-actinin-4 and synaptopodin myosin (myo-1e), among many others, establish the specific cytoskeleton in podocytes.[19]

The luminal membrane contains a great variety of receptors (see later discussion), and together with the luminal surface of the SD it is covered by a thick surface coat that is rich in sialoglycoproteins, including podocalyxin and podoendin, accounting for the high negative surface charge of the podocytes.

The abluminal cell membrane comprises a narrow band of lateral cell membrane extending from the SD to the GBM and, most important, the soles of the FPs abutting to the GBM. A complex anchoring system connects the cytoskeleton of the FPs to the GBM. Two systems are known: (1) α3β1 integrin dimers interconnect the cytoplasmic focal adhesion proteins vinculin, paxillin, and talin with the α3, α4, and α5

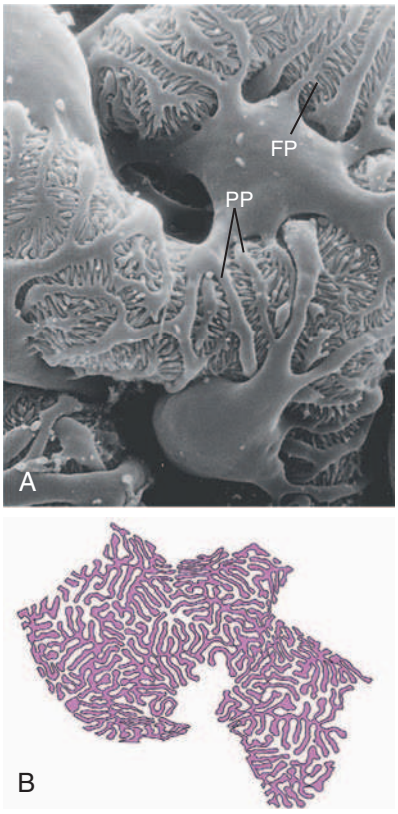

Fig. 1.8 Branching pattern of podocyte foot processes (rat). (A) Scanning electron micrograph (SEM) showing the urinary side of the podocyte cover of a glomerular capillary consisting of cell bodies, large primary processes *(PP)* and interdigitating foot processes *(FP)* separated by the filtration slits. (B) Drawing of the basal aspect of the FP-branching pattern as seen by block-face SEM. A fully homogeneous branching pattern of FPs attaches to the glomerular basement membrane (GBM) that may be compared with a pattern of interdigitating filopodia connected by adherens junctions. The high degree of branching (not seen from the luminal aspect) provides a high degree of adaptability to area changes of the underlying GBM. (**B,** From reference 45, with permission.)

chains of type IV collagen and laminin 521; and (2) β-α-dystroglycans interconnect the cytoplasmic adapter protein utrophin with agrin and laminin α5 chains in the GBM.[9]

The junctional connection of podocyte FPs by the SD bridging the filtration slits is complex and unique. The filtration slits have a constant width of approximately 30 to 40 nm: thus the SD has to connect the FPs over a considerable distance. By transmission electron microscopy (TEM), in routinely glutaraldehyde-fixed material, the SD shows up as a single dark line in cross sections and in an en-face view as a homogenous network of fibrillar structures interconnecting both membranes. Combined tannic acid and glutaraldehyde–fixed tissue reveals, in en-face view, a zipper-like structure with a row of pores approximately 14 × 2 nm on either side of a central bar. The transmembrane proteins that establish the slit diaphragm (SD) and its connection to the actin cytoskeleton of the FPs include nephrin, P-cadherin, FAT1, NEPH 1-3, podocin, and CD2AP, among others[20] (see Fig. 1.9).

Podocytes contain a great variety of surface receptors and ion channels, many of which accumulate close to the SD; the schematic in Fig. 1.9 shows some of them. They include receptors for cyclic guanosine monophosphate (cGMP) signaling, stimulated by natriuretic peptides (atrial natriuretic peptide [ANP], brain natriuretic peptide [BNP], and C-type natriuretic peptide [CNP]) and nitric oxide; receptors for cyclic adenosine monophosphate (cAMP) signaling stimulated by prostaglandin E_2 (PGE_2), dopamine, VEGF, isoproterenol, parathyroid hormone (PTH), PTH-related peptide; and receptors for Ca^{2+} signaling stimulated by numerous ligands, including angiotensin II, acetylcholine, PGF2, arginine vasopressin (AVP), adenosine triphosphate (ATP), endothelin, and histamine.[20] Among the transient receptor potential (TRP) cation channels, TRPC5 and TRPC6 have received much attention.[21-23] The major target of this signaling orchestra is the cytoskeleton (see later discussion). Other receptors, such as for TGF-β, fibroblast growth factor (FGF-2), and other cytokines/chemokines, have been shown to be involved in synthesis functions (GBM components) or in development of podocyte diseases.[20] Megalin is a multiligand endocytotic receptor and the major antigen of Heymann nephritis in the rat,[24] but is not present in humans.[12] On the other hand, podocytes, by paracrine and autocrine signaling, regulate the interplay with endothelial and mesangial cells; during development they are responsible for building a glomerulus. VEGF, angiopoietins, and PDGF, among others, are of crucial importance for the homeostatic maintenance of the tuft.[25]

Function and Maintenance of the Filtration Barrier

Most glomerular diseases start in the glomerulus, beginning with the breakdown of the filtration barrier. It is commonly accepted that the physical forces associated with filtration represent crucial challenges that account for the break down; they comprise filtration pressure and filtrate flow.

Filtration pressure and expansion. Traditionally, the high transmural hydrostatic pressure gradients necessary for filtration have been considered the main challenge to the filtration barrier. Podocyte FPs were considered a kind of pericyte process counteracting variations and derailments in perfusion pressures. This view has been challenged since we learned that the major way podocytes are lost (under any circumstances) is by detachment from the GBM as viable cells. It seems self-contradictory that FPs, which need their cytoskeleton to continually adapt their pattern of attachment to the GBM (see later discussion), would simultaneously function as contractile pericyte-like processes, counteracting the expansion of the GBM by increasing their tone. Consequently, it may be concluded that the principal burden for counteracting transmural pressure gradients (i.e., for developing wall tension) falls instead on the GBM.[26]

As described earlier, the GBM is an elastic membrane that expands or shrinks in surface area with increasing or decreasing transmural hydrostatic pressure, respectively. Its expansion decreases with increasing pressure and is limited.

Expansion of the GBM affords the immediate coordinated increase in the cover by interdigitated FPs; thus the FPs and the SD have to increase correspondingly (and vice versa when pressure decreases). The ability for such acute adaptions has been previously shown in the isolated perfused kidney. It is suggested that the changes in FP length occur by actin polymerization/depolymerization and the changes in SD length by coordinated exocytotic and endocytotic processes of SD components.[26,27]

An orchestrated connection between the mobility of the actin cytoskeleton and the dynamics of the SD has been uncovered in great depth by innumerable studies during the past two decades.[28,29]

Filtrate flow and shear stress. The flow of the filtrate through the filtration barrier represents by far the highest extravascular fluid flow in the body. It consists of the outflow from glomerular capillaries, through the GBM, and into the Bowman space. This latter step creates a problem: in contrast to the exit of filtrate from capillaries, where flow presses the endothelium against the basement membrane, its entry into the Bowman space tends to separate the podocytes from

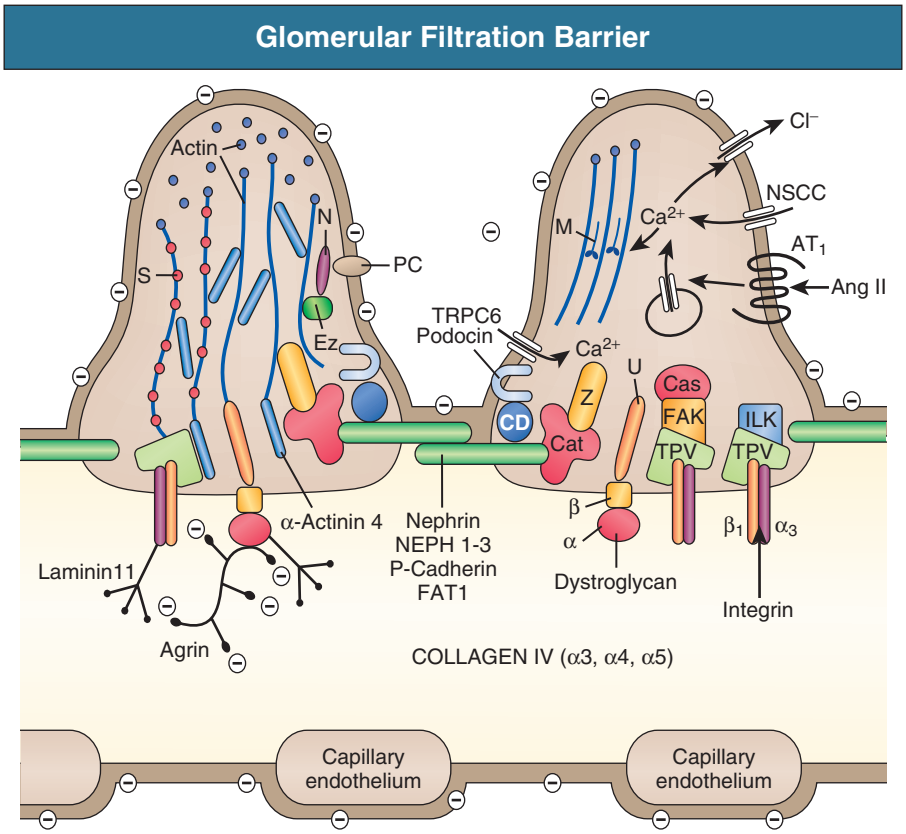

Fig. 1.9 Glomerular filtration barrier. Two podocyte foot processes (FPs) bridged by the slit membrane (SM), the glomerular basement membrane (GBM) and the porous capillary endothelium, are shown. The surfaces of podocytes and of the endothelium are covered by a negatively charged glycocalyx containing the sialoprotein podocalyxin *(PC)*. The GBM is mainly composed of type IV collagen (α3, α4, and α5), laminin 11 (α5, β2, and γ1 chains), and the heparan sulfate proteoglycan agrin. The SM represents a porous proteinaceous membrane composed of (as far as is known) nephrin, NEPH 1-3, P-cadherin, and FAT1. The actin-based cytoskeleton of the FPs connects to both the GBM and the SM. Regarding the connections to the GBM, β1α3 integrin dimers specifically interconnect the talin, paxillin, vinculin *(TPV)* complex to laminin 11; the β- and α-dystroglycans interconnect utrophin to agrin. The SM proteins are joined to the cytoskeleton by various adapter proteins, including podocin, Zonula Occludens protein 1 (ZO-1; Z), CD2-associated protein *(CD)*, and catenins *(Cat)*. Among the nonselective cation channels *(NSCC)*, TRPC6 associates with podocin (and nephrin, not shown) at the SM. Only the angiotensin II *(Ang II)* type 1 receptor *(AT_1)* is shown as an example of the many surface receptors. *Cas*, p130Cas; *Ez*, ezrin; *FAK*, focal adhesion kinase; *ILK*, integrin-linked kinase; *M*, myosin; *N*, Na^+-H^+ exchanger regulatory factor (NHERF2); *S*, synaptopodin. (Modified from reference 17.)

the GBM. The insight that the major way of losing podocytes in disease is by detachment has brought the shear stress created by the filtrate flow into discussion.

The strength of the shear stress depends on the flow rate and the geometry of the channel; the narrower the channel or the higher the flow velocity, the higher is the shear stress. In rats the filtrate flow amounts to 30 nl/min, creating a shear stress to the FPs within the filtration slit as high as 8 Pa.[30] Much lower values of shear stress to the podocyte cell bodies may lead to detachment when podocytes come to lie within the urinary orifice.[27] Moreover, a high sensitivity of podocytes to shear stress has been shown in cell culture studies.

This led to a new view of the relevance of the SM (in addition to its barrier function; see later discussion). Shear stress tends to lead to deformations of the lateral walls of FPs, and thus widens the slit. The interconnection of both opposite FPs by the SD at the narrowest site of the slit is ideally positioned to counteract these destabilizing forces. The SD uses the shear stress against one side of the slit to balance the shear stress against the opposite side. This means that during filtrate flow the SD is permanently under tension that counteracts the shear stress to both sides of the slit.[27]

Barrier function. Filtrate flow through the barrier occurs along an extracellular route, including the endothelial pores, GBM, and SD (see Figs. 1.7 and 1.9). The barrier shows a high permeability for water, small solutes, and ions, whereas the barrier is fairly tight for macromolecules, selective for size, shape, and charge.[20] The charge selectivity of the barrier results from the dense accumulation of negatively charged molecules throughout the entire depth of the filtration barrier, most importantly the surface coat of endothelial cells, and from the high content of negatively charged heparan sulfate proteoglycans in the GBM. Most plasma proteins, including albumin, are negatively charged, and thus their repulsion is dominantly charge dependent.

The size/shape selectivity seems to be established by the SD.[13] Uncharged macromolecules up to an effective radius of 1.8 nm pass freely through the filter. Larger components are increasingly restricted (indicated by their fractional clearances, which progressively decrease) and are totally restricted at effective radii of more than 4 nm. Plasma

albumin has an effective radius of 3.6 nm; without the repulsion from the negative charge, plasma albumin would pass through the filter in considerable amounts.

Studies by the group of Marcus Moeller proposed an electrophoretic mechanism for the repulsion and exclusion of plasma proteins from the glomerular filter.[31,32] According to their hypothesis, the flow of the filtrate through the charged filter creates a streaming potential. This electrical field is negatively charged on the urinary side of the glomerular filter compared with the capillary side by approximately –0.05 mV/10 mm Hg filtration pressure. Thus the negatively charged molecules (albumin) that approach the filter will be exposed to an electrophoretic force that drives them back toward the capillary lumen. The charm of this hypothesis consists of being independent of any structural pore preventing their passage. The barrier actually consists of a strictly filtration-dependent potential difference; without sufficient convective flow of filtrate, the barrier will become permeable.[31,32]

Pathology. The hypothesis that the mechanical interconnection of the FPs by the SD is the most vulnerable structure to the physical challenges of filtration is supported by the pathologic changes. The loss of the SD connection between adjacent FPs represents the earliest failure that starts the detachment of podocytes.[27]

This can be interpreted as the loss of local control of filtrate flow. Unchanneled filtrate flow through such leaks will exert unbalanced shear stress to the FPs, initiating locally the detachment of FPs. Repair of such leaks seems impossible in the face of ongoing filtrate flow, accounting for the observation that the damage will proceed.

Taken together, the layer of interdigitating FPs interconnected by the SD regulates the entry of the filtrate flow into the Bowman space by channeling the flow through the filtration slits. The geometry of the slits is maintained against the shear forces to both opposite FPs through the interconnection of opposing FPs by the SD. Loss of the junctional connection is detrimental because it opens leaks for uncontrolled filtrate flow with the tendency to increase the leaks.[33]

Parietal Epithelium

The parietal epithelium of the Bowman capsule consists of squamous epithelial cells resting on a basement membrane (see Figs. 1.4 and 1.5). The flat cells are filled with bundles of actin filaments running in all directions. In contrast to the GBM, the parietal basement membrane comprises several proteoglycan-dense layers that, in addition to type IV, contain type XIV collagen. The predominant proteoglycan of the parietal basement membrane is a chondroitin sulfate proteoglycan.[34]

Renal Tubule

The renal tubule is subdivided into several distinct segments: a proximal tubule (convoluted and straight portions), an intermediate tubule, a distal tubule (straight and convoluted portion), a CNT, and the CD (see Figs. 1.1 and 1.3).[1,2,34] The loop of Henle comprises the straight part of the proximal tubule (representing the thick descending limb), the thin descending and the thin ascending limbs (both thin limbs together represent the intermediate tubule), and the thick ascending limb (representing the straight portion of the distal tubule), which includes the macula densa. The CNT connects the nephron to the CD system.

The renal tubules are outlined by an epithelium that comprises a single layer of cells anchored to a basement membrane. The epithelial cells have multiple transport functions and show numerous structural adaptations to their special roles. They are connected apically by a junctional complex consisting of a tight junction (zonula occludens), an adherens junction, and, at some sites, a desmosome. As a result of this organization, two different pathways through the epithelium exist (Fig. 1.10): a transcellular pathway, including the transport across the luminal and basolateral cell membrane and through the cytoplasm and a paracellular pathway through the junctional complex and the lateral intercellular spaces. The functional characteristics of paracellular transport are determined by the tight junction, which differs markedly in its elaboration in the various tubular segments. The transcellular transport is determined by the specific channels, carriers, and transporters included in the apical and basolateral cell membranes. The various nephron segments differ markedly in function, distribution of transport proteins, and responsiveness to hormones and drugs such as diuretics. The cell surface area of the plasmalemmal compartments carrying the transport systems is extensively enlarged in many tubule cells, that is, by microvilli at the luminal membrane domain, by lamellar folds of the basolateral membrane interdigitating with those of the neighboring cells (interdigitations), or by lamellar folds of the basal cell membrane invaginating into its own cells (invaginations).

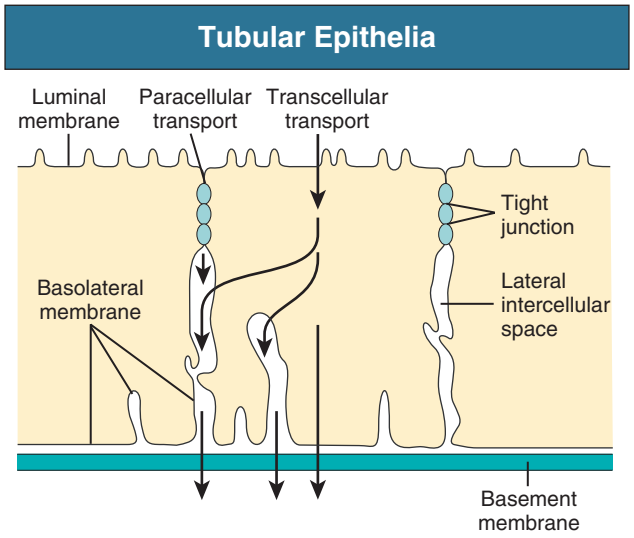

Fig. 1.10 Tubular epithelia. Transport across the epithelium may follow two routes: transcellular, across luminal and basolateral membranes, and paracellular, through the tight junction and intercellular spaces.

Proximal Tubule

The proximal tubule reabsorbs the bulk of filtered water and solutes (Fig. 1.11). The proximal tubule is generally subdivided into three segments (known as S_1, S_2, and S_3) that differ considerably in cellular organization and, consequently, also in function.[35] Generally, the proximal tubule has a prominent brush border and e xtensive interdigitation by basolateral cell processes. This lateral cell interdigitation extends up to the leaky tight junction, thus increasing the tight junctional belt in length and providing a greatly increased passage for the passive transport of ions. Proximal tubule cells have large prominent mitochondria intimately associated with the basolateral cell membrane where the Na^+,K^+–adenosine triphosphatase (Na^+,K^+-ATPase) is located; this machinery is the molecular mechanism initiating numerous secondary transcellular transport processes. The luminal transporter for Na^+ reabsorption specific for the proximal tubule is the Na^+-H^+ exchanger (NHE3) located in the plasma membrane of the apical microvilli and accounts for reabsorption of most of the filtered sodium. Further, sodium-coupled transporters in the microvillous membrane are the sodium-glucose cotransporters SGLT2 and SGLT1 and several sodium-phosphate cotransporters. The abundance of channel protein aquaporin 1 in the apical microvillous membrane and the basolateral cell membrane accounts for the high hydraulic permeability for water of this epithelium. An apical tubulovesicular compartment is part of the prominent

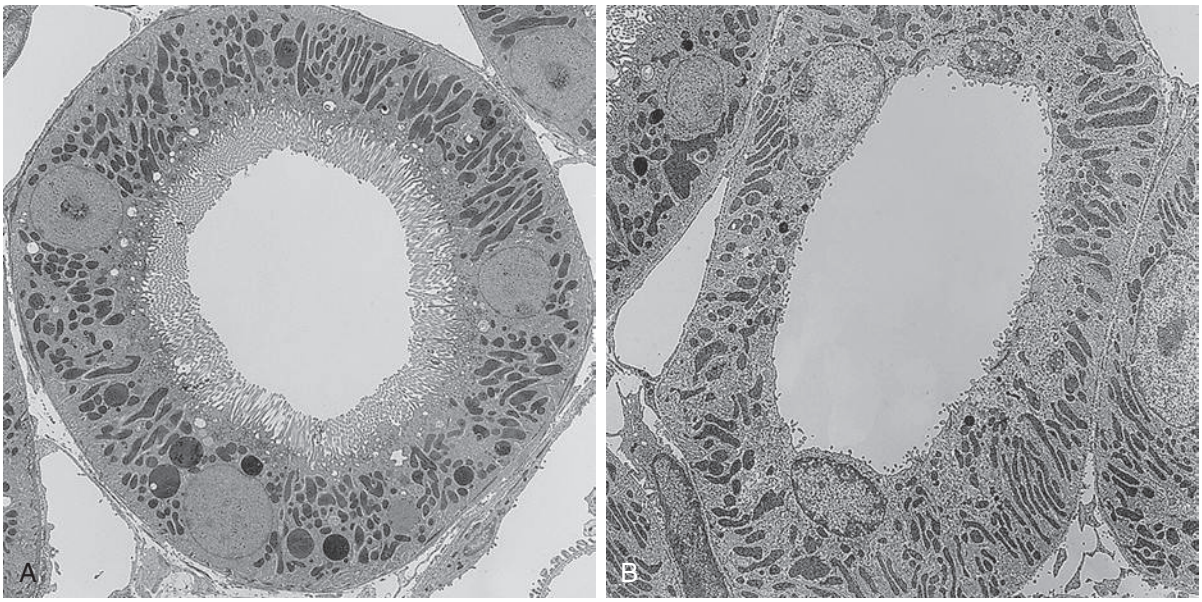

Fig. 1.11 Tubules of the renal cortex. (A) Proximal convoluted tubule is equipped with a brush border and a prominent vacuolar apparatus in the apical cytoplasm. The rest of the cytoplasm is occupied by a basal labyrinth consisting of large mitochondria associated with basolateral cell membranes. (B) Distal convoluted tubule also has interdigitated basolateral cell membranes intimately associated with large mitochondria. In contrast to the proximal tubule, however, the apical surface is amplified only by some stubby microvilli. (TEM; **A,** ×1530; **B,** ×1830.)

endosomal-lysosomal system and is responsible for the reabsorption of macromolecules (polypeptides and proteins such as albumin) that have passed the glomerular filter. The proximal tubule segment S_3, including portions of S_2, in addition, are engaged in many secretory processes of toxic substances and drugs via organic anion transporters and anorganic cation transporters. Proximal tubule cells are electrically coupled by gap junctions.

Intermediate Tubule

The intermediate tubule comprises the thin portion of the loop of Henle displaying a flat epithelium and consists of a thin descending and (only in long loops) a thin ascending limb (Fig. 1.12; see also Fig. 1.2). The thin descending limb, like the proximal tubule, is highly permeable for water (the channels are of aquaporin 1), whereas, beginning at the turning point, the thin ascending limb is impermeable to water. The latter has a highly interdigitated epithelium also along the tight junction, which is highly permeable to ions.

Distal Straight Tubule (Thick Ascending Limb of the Loop of Henle)

The thick ascending limb of the loop of Henle is often called the diluting segment. It is water impermeable but reabsorbs considerable amounts of sodium and chloride, resulting in the separation of salt from water. The salt is trapped in the medulla (see Fig. 1.12), whereas the water is carried away into the cortex, where it may return into the systemic circulation. The specific transporter for Na^+ reabsorption in this segment is the $Na^{2+}K^{2+}2Cl^-$ symporter (NKCC2), which is specifically inhibited by loop diuretics such as furosemide. This transporter is inserted in the luminal membrane, which is amplified by only solitary microvilli. The tight junctions of the thick ascending limb are elongated by lateral interdigitation of the cells. They have a comparatively low overall permeability; however, they contain the protein Claudin 16 for paracellular reabsorption of divalent ions, notably of magnesium. The cells are heavily interdigitated by basolateral cell processes, associated with large mitochondria supplying the energy for the transepithelial transport. The cells synthesize a specific protein, the Tamm-Horsfall protein, and release it into the tubular lumen. This protein is thought to be important for preventing the formation of kidney stones. A short distance before the transition to the distal convoluted tubule, the thick ascending limb contains the macula densa, which adheres to the glomerulus of the same nephron (see Juxtaglomerular Apparatus).

Distal Convoluted Tubule

The epithelium exhibits the most extensive basolateral interdigitation of the cells and the greatest numerical density of mitochondria compared with all other nephron portions (see Fig. 1.11). Apically, the cells are equipped with numerous solitary microvilli. The specific Na^+ transporter of the distal convoluted tubule is the luminal $Na^{2+}Cl^-$ cotransport system (NCC), which can be inhibited by the thiazide diuretics. Magnesium is reabsorbed via the transient receptor potential channel melastatin subtype 6 (TRPM6) in the luminal membrane and, along the paracellular route, through the tight junctional proteins Claudin 16 and 19.

COLLECTING DUCT SYSTEM

The CD system (see Fig. 1.2) includes the CNT and the cortical and medullary CDs. The embryologic origin of the CNT, which is interposed between the distal convoluted tubule and the CD, is unclear in whether it derives from the nephron anlage or the ureteral bud. Two nephrons may join at the level of the CNT, forming an arcade. Two types of cell establish the CNT: the CNT cell, which is specific to the CNT, and the intercalated (IC) cell, which is also present in varying amounts in the distal convoluted tubule and in the CD. The CNT cells are similar to the CD cells in cellular organization. Both cell types share sensitivity

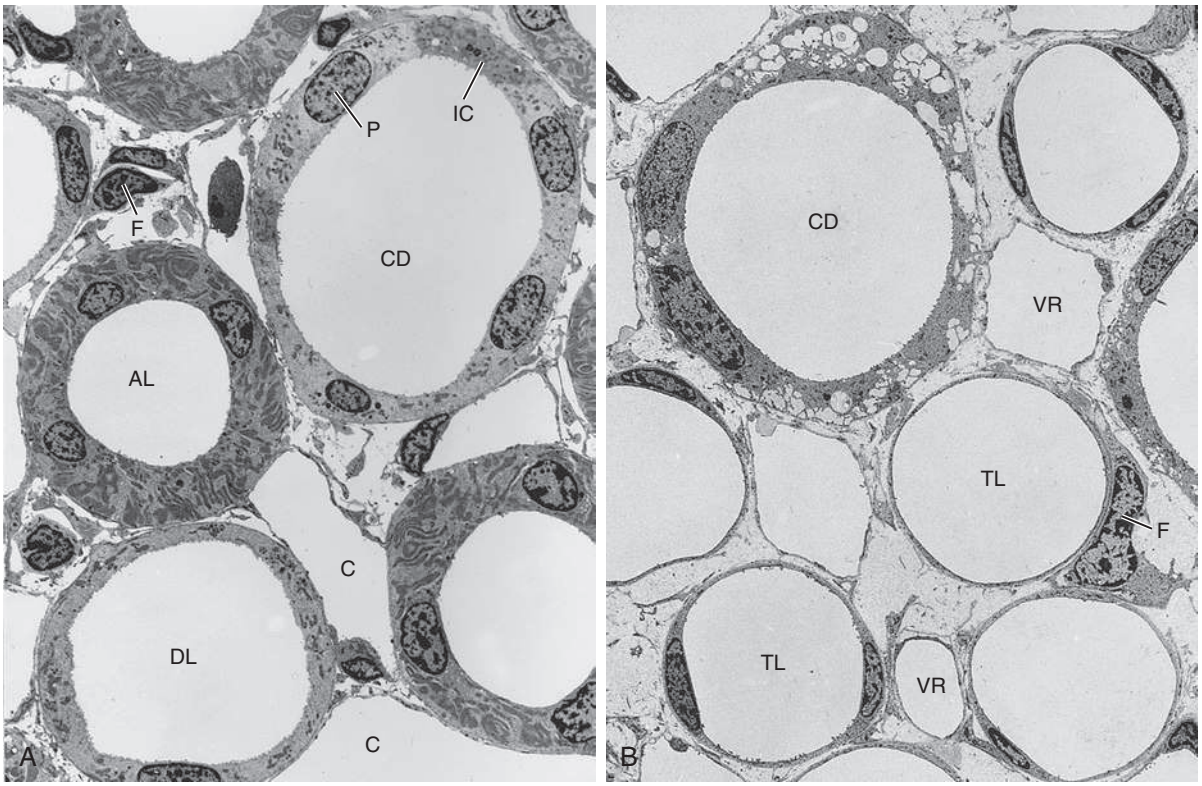

Fig. 1.12 Tubules in the medulla. (A) Cross section through the inner stripe of the outer medulla shows a descending thin limb of a long Henle loop *(DL),* the medullary thick ascending limbs of Henle *(AL),* and a collecting duct *(CD)* with principal *(P)* cells and intercalated *(IC)* cells. *C,* Peritubular capillaries; *F,* fibroblast. to vasopressin (antidiuretic hormone [ADH]; see later discussion). The amiloride-sensitive epithelial sodium channel (ENaC) and the epithelial calcium channel (TRPV5) are located in the apical membrane beginning in the distal convoluted tubule and extending into the CNT.

Collecting Ducts

The CDs (see Fig. 1.12) may be subdivided into cortical and medullary ducts, and the medullary ducts into an outer and inner portion; the transitions are gradual. Like the CNT, the CDs are lined by two types of cell: CD cells (principal cells) and IC cells. The IC cells decrease in number as the CD descends into the medulla and are absent from the inner medullary CDs.

The CD cells (Fig. 1.13A) increase in size toward the tip of the papilla. The basal cell membrane amplifies by lamellar invaginations into the cell (basal infoldings). The tight junctions have a large apicobasal depth, and the apical cell surface has a prominent glycocalyx. Along the entire CD, these cells contain an apical shuttle system for aquaporin 2 under the control of vasopressin, providing the potential to switch the water permeability of the CDs from zero to very low levels to permeable.[36] A luminal amiloride-sensitive Na^+ channel is involved in the responsiveness of cortical CDs to aldosterone. The terminal portions of the CD in the inner medulla express the urea transport system UTB1, which, in an antidiuretic hormone (ADH)-dependent fashion, accounts for the recycling of urea, a process that is crucial in the urine-concentrating mechanism.[37,38]

The second cell type, the IC cell (see Fig. 1.13B), is present in both the CNT and the CD. There are at least two types of IC cells, designated A and B cells, distinguished on the basis of structural, immunocytochemical, and functional characteristics. Type A cells have been defined as expressing an H^+-ATPase at their luminal membrane; they secrete protons. Type B cells express H^+-ATPase at their basolateral membrane; they secrete bicarbonate ions and reabsorb protons.[38]

With these different cell types, the CDs are the final regulators of fluid and electrolyte balance, playing important roles in the handling of Na^+, Cl^-, and K^+ and in acid-base homeostasis. The responsiveness of the CDs to vasopressin enables an organism to live in arid conditions, allowing production of concentrated urine and, if necessary, dilute urine.

JUXTAGLOMERULAR APPARATUS

The juxtaglomerular apparatus comprises the macula densa, the extraglomerular mesangium, the terminal portion of the afferent arteriole with its renin-producing granular cells (also often termed *juxtaglomerular cells*), and the beginning portions of the efferent arteriole (see Fig. 1.4).

The macula densa is a plaque of specialized cells in the wall of the thick ascending limb of Henle at the site where the limb attaches to the extraglomerular mesangium of the parent glomerulus (Fig. 1.14A; see also Fig. 1.5). The most obvious structural feature is the narrowly packed cells with large nuclei, which account for the name macula *densa.* The cells are anchored to a basement membrane, which blends with the matrix of the extraglomerular mesangium. The cells are joined by tight junctions with very low permeability and have prominent lateral

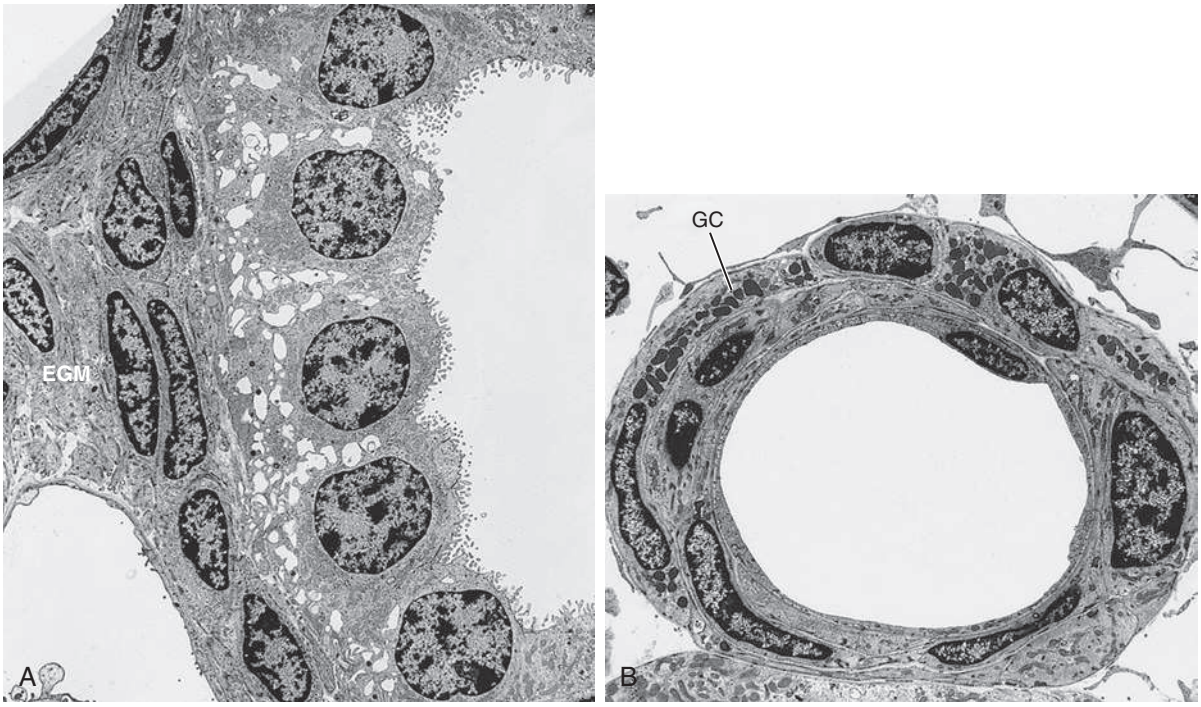

Fig. 1.14 Juxtaglomerular apparatus. (A) Macula densa of a thick ascending limb of Henle. The cells have prominent nuclei and lateral intercellular spaces. Basally, they attach to the extraglomerular mesangium *(EGM).* (B) Afferent arteriole near the vascular pole. Several smooth muscle cells are replaced by granular cells *(GC)* containing accumulations of renin granules. (TEM; **A,** ×1730; **B,** ×1310.)

intercellular spaces. The width of these spaces varies under different functional conditions.[1] The most conspicuous immunocytochemical difference between macula densa cells and other epithelial cells of the nephron is the high content of neuronal nitric oxide synthase and cyclooxygenase-2 in macula densa cells.[39,40]

The basal aspect of the macula densa is firmly attached to the extraglomerular mesangium, a solid complex of cells and matrix penetrated by neither blood vessels nor lymphatic capillaries. As with the mesangial cells proper, extraglomerular mesangial cells are heavily branched. Their processes are interconnected by gap junctions, contain prominent bundles of microfilaments, and are connected to the basement membrane of the Bowman capsule and the walls of both glomerular arterioles. As a whole, the extraglomerular mesangium interconnects all structures of the glomerular entrance.[6]

The granular cells are assembled in clusters within the terminal portion of the afferent glomerular arteriole (see Fig. 1.14B), replacing ordinary smooth muscle cells. *Granular* refers to the specific cytoplasmic granules in which renin, the major secretion product of these cells, is stored. Granular cells are the main site of the body where renin is secreted. Renin release occurs by exocytosis into the surrounding interstitium. Granular cells are connected to extraglomerular mesangial cells, adjacent smooth muscle cells, and endothelial cells by gap junctions

and are densely innervated by sympathetic nerve terminals. Granular cells are modified smooth muscle cells; under conditions requiring enhanced renin synthesis (e.g., volume depletion, renal artery stenosis), additional smooth muscle cells of the afferent arteriole may transform into granular cells.

RENAL INTERSTITIUM

The interstitium of the kidney is comparatively sparse. Its fractional volume in the cortex ranges from 5% to 7%, with a tendency to increase with age. Renal interstitium increases across the medulla from cortex to papilla. In the outer stripe, it is 3% to 4%, the lowest value of all kidney zones; this is interpreted as forming a barrier to prevent loss of solutes from a hyperosmolar medulla into the cortex. Renal interstitium is 10% in the inner stripe and up to about 30% in the inner medulla. The cellular constituents of the interstitium include resident fibroblasts, which establish the scaffold frame for renal corpuscles, tubules, and blood vessels, as well as varying numbers of migrating cells of the immune system, especially dendritic cells. The space between the cells is filled with extracellular matrix, that is, ground substance (proteoglycans, glycoproteins), fibrils, and interstitial fluid.[41]

Morphologically, fibroblasts are the central cells in the renal interstitium. Fibroblasts are interconnected by specialized contacts and adhere by specific attachments to the basement membranes surrounding the tubules, renal corpuscles, capillaries, and lymphatics.

Renal fibroblasts are difficult to distinguish from interstitial dendritic cells on a morphologic basis, because both may show a stellate cellular shape and both display substantial amounts of mitochondria and endoplasmic reticulum. However, renal fibroblasts may be easily distinguished by immunocytochemical techniques. Dendritic cells constitutively express the major histocompatibility complex class II antigen and may express antigens such as CD11c. Dendritic cells may have an important role in maintaining peripheral tolerance in the kidney (Fig. 1.15).[42] In contrast, fibroblasts in the renal cortex (not in the medulla) contain the enzyme ecto-5′-nucleotidase (5′-NT). A subset of 5′-NT–positive fibroblasts of the renal cortex synthesizes epoetin.[43] Under normal conditions, these fibroblasts are exclusively found within the juxtamedullary portions of the cortical labyrinth. When there is an increasing demand for epoetin, the synthesizing cells extend to more superficial portions of the cortical labyrinth.[44]

Fibroblasts within the medulla, especially within the inner medulla, have a particular phenotype known as *lipid-laden interstitial cells.* The cells are oriented strictly perpendicularly toward the longitudinal axis of the tubules and vessels (running all in parallel) and contain conspicuous lipid droplets. These fibroblasts of the inner medulla produce large amounts of glycosaminoglycans and, possibly related to the lipid droplets, vasoactive lipids, in particular PGE_2.[42]

SELF-ASSESSMENT QUESTIONS

1. Podocytes:
   - **A.** Are unable to replicate
   - **B.** Are connected by gap junctions
   - **C.** Have a positively charged glycocalyx
   - **D.** Are connected to the GBM by hemidesmosomes
   - **E.** Are in direct contact with mesangial cells
2. The glomerular basement membrane:
   - **A.** Consists of α1 and α2 chains of type IV collagen
   - **B.** Is produced mainly by the endothelium of glomerular capillaries
   - **C.** Transforms at the urinary pole of a glomerulus into the basement membrane of the parietal epithelium
   - **D.** Has a thickness of roughly 300 μm in humans
   - **E.** Serves as the effector structure of mesangial cell contraction
3. The slit membrane has a width of roughly:
   - **A.** 30 nm
   - **B.** 100 nm
   - **C.** 300 nm
   - **D.** 1 μm
   - **E.** 3 μm
4. Macula densa cells:
   - **A.** Are a cell plaque within the distal convoluted tubule
   - **B.** Are connected to the extraglomerular mesangial cells by gap junctions
   - **C.** Are densely innervated by sympathetic nerve terminals
   - **D.** Contain nitric oxide synthase
   - **E.** Produce renin

Renal Physiology

Matthew A. Bailey, Robert J. Unwin

GLOMERULAR STRUCTURE AND ULTRASTRUCTURE

Urine formation begins with the production of an ultrafiltrate of plasma. Chapter 1 describes glomerular anatomy and ultrastructure in detail, and the present discussion provides only the essentials for an understanding how the ultrafiltrate is formed. The pathway for ultrafiltration of plasma from the glomerulus to the Bowman space consists of the fenestrated capillary endothelium, the capillary basement membrane, and the visceral epithelial cell layer (podocytes) of the Bowman capsule; the podocytes have large cell bodies and make contact with the basement membrane only by cytoplasmic foot processes. Mesangial cells, which fill the spaces between capillaries, have contractile properties and can alter the capillary surface area available for filtration.

Filtration is determined principally by the molecular size and shape of the filtered solute and to a lesser extent by its charge. The size cut-off is not absolute, with resistance to filtration beginning at an effective molecular radius of just under 2 nm, whereas substances with an effective radius of around 4 nm or greater are not filtered at all. The fenestrations between capillary endothelial cells have a diameter of 50 to 100 nm. The podocyte foot processes have gaps—filtration slits—with a diameter of 30 to 40 nm. The filtration slits are bridged by the slit diaphragms (SDs), which are themselves penetrated by small pores. The SDs likely constitute the main filtration barrier, although the endothelium (by preventing the passage of blood cells) and the basement membrane also contribute.[1] Furthermore, the podocytes and endothelial cells are covered by a glycocalyx composed of negatively charged glycoproteins, glycosaminoglycans, and proteoglycans, and the basement membrane is rich in heparan sulfate proteoglycans. This accumulation of fixed negative charges restricts filtration of large negatively charged ions, mainly proteins (Fig. 2.1). Thus, with an effective radius of 3.6 nm (35 Å), albumin is normally almost completely excluded from filtration. If these fixed negative charges are lost, as in some forms of early or mild glomerular disease (e.g., minimal change disease), albumin filterability increases and proteinuria results. However, it has been proposed that albumin is normally filtered and then almost completely reabsorbed along the proximal tubule; this remains controversial. Proximal tubular cells can take up albumin, and genetic engineering experiments in mice have identified two proteins in the apical membrane—megalin and cubilin—as essential components of this uptake pathway.[2] However, deletion of this tubular transport system increases albumin excretion only approximately sixfold, suggesting that glomerular filtration is normally low and is still the major determinant of urinary albumin excretion. Nonetheless, recent studies suggest that the filtration-to-reabsorption relationship is dynamic and physiologically regulated.[3] The relationship is changed in diseases such as diabetic nephropathy, contributing to overall albuminuria.[4]

The glomerular barrier is usually considered to be a passive unidirectional filter, but this is not the case. Filtration pressure generates a potential difference across the filtration barrier, and although its magnitude is small, this potential difference may help in clearing the filter continuously by driving negatively charged proteins such as albumin out of the SD and back into the blood.[5]

GLOMERULAR FILTRATION RATE

At the level of the single glomerulus, the driving force for glomerular filtration (the *net ultrafiltration pressure*) is determined by the sum of the hydrostatic and oncotic (colloid osmotic) pressure gradients from plasma to the Bowman space. The single-nephron glomerular filtration rate (SNGFR) is determined by the product of the net ultrafiltration pressure and the *ultrafiltration coefficient;* the latter being a composite of the surface area available for filtration and the hydraulic conductivity of the glomerular membranes. Thus the SNGFR is calculated as:

$$K_f[(P_{gc} - P_{bs}) - (\pi_{gc} - \pi_{bs})]$$

where K_f is the ultrafiltration coefficient, P_{gc} is the glomerular capillary hydrostatic pressure (~45 mm Hg), P_{bs} is the Bowman space hydrostatic pressure (~10 mm Hg), π_{gc} is the glomerular capillary oncotic pressure (~25 mm Hg), and π_{bs} is the Bowman space oncotic pressure (0 mm Hg).

Net ultrafiltration pressure is approximately 10 mm Hg at the afferent end of the capillary tuft. As filtration of plasma from blood proceeds along the glomerular capillaries, proteins are concentrated and the glomerular capillary oncotic pressure (π_{gc}) increases. Theoretically, toward the efferent end of a glomerular capillary, π_{gc} may equal the net hydrostatic pressure gradient, at which point ultrafiltration pressure would fall to zero: *filtration equilibrium* in the human kidney is approached, but rarely (if ever) achieved (Fig. 2.2).

The (total) glomerular filtration rate (GFR) is the sum of the SNGFRs of the functioning nephrons in each kidney. The normal range for GFR is wide, but is typically cited at about 120 ml/min per 1.73 m^2 surface area. GFR can be measured with renal clearance techniques. The renal clearance of any substance not metabolized by the kidneys is the volume of plasma required to provide that amount of the substance excreted in the urine per unit time. This is a virtual volume that can be expressed mathematically as follows:

$$C_y = U_y / P_y \times V$$

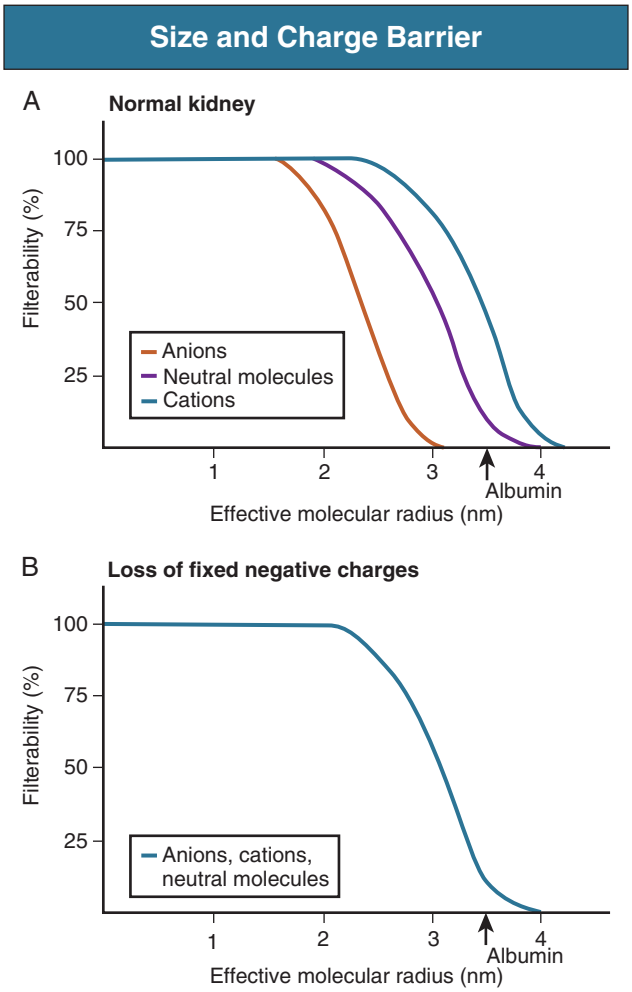

Fig. 2.1 Effects of size and electrical charge on filterability. (A) Normal kidney. (B) Loss of fixed negative charges. Filterability of 100% indicates the substance is freely filtered; that is, its concentration in the Bowman space equals that in glomerular capillary plasma. For molecules and small ions (e.g., Na^+, Cl^-), charge has no effect on filterability; but for ions whose effective molecular radius exceeds 1.6 nm, anions are filtered less easily than neutral molecules or cations. Thus insignificant amounts of albumin (anion) are normally filtered. If the fixed negative charges of the glomerular basement membranes are lost, as in early minimal change nephropathy, charge no longer influences filterability; consequently, significant albumin filtration occurs.

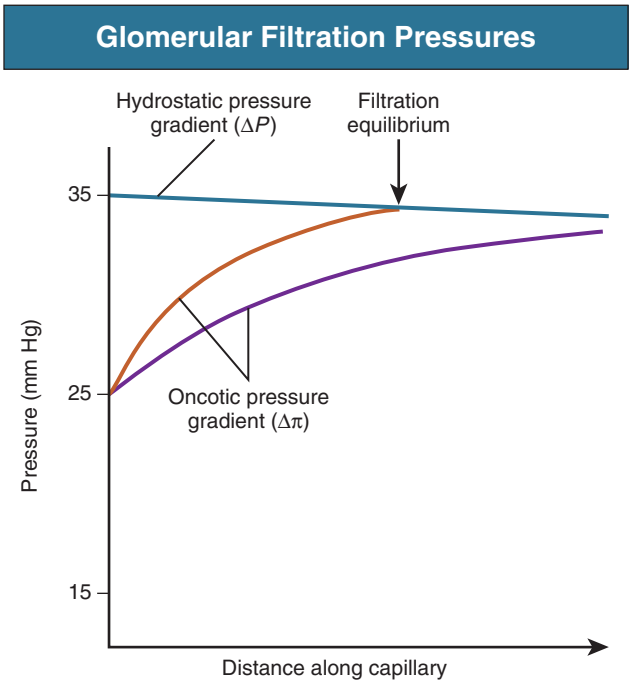

Fig. 2.2 Glomerular filtration pressures along a glomerular capillary. The hydrostatic pressure gradient ($\Delta P = P_{gc} - P_{bs}$) is relatively constant along the length of a capillary, whereas the opposing oncotic pressure gradient ($\Delta\pi = \pi_{gc}$) increases as protein-free fluid is filtered, thereby reducing net ultrafiltration pressure. Two curves are shown: one in which filtration equilibrium is reached and one in which it is merely approached.

where C_y is the renal clearance of y; U_y and P_y are the concentrations of y in the urine and plasma, respectively, and V is the urine flow rate. If a substance is freely filtered by the glomerulus and is not reabsorbed or secreted by the tubule, its renal clearance equals the GFR; that is, renal clearance measures the volume of plasma filtered through the glomeruli per unit time. The various methods for measuring GFR and their pitfalls are discussed in Chapter 3.

MEASUREMENT OF RENAL PLASMA FLOW

The use of the clearance technique and the availability of substances that undergo both glomerular filtration and almost complete (or *effective*) tubular secretion have made it possible to measure renal plasma flow (RPF; typically ~650 ml/min). Para-aminohippuric acid (PAH, hippurate) is an organic acid filtered by the glomerulus and actively secreted by the proximal tubule through organic anion transporters in the cell membranes. The amount of PAH found in the urine is the sum of that filtered plus that secreted. PAH clearance is measured using intravenous (IV) infusion to achieve a steady-state plasma concentration of PAH. When the plasma concentration is less than 10 mg/dl, PAH clearance is a robust marker of *effective* RPF, because under this concentration threshold most of the PAH reaching the peritubular capillaries is cleared by tubular secretion. Little PAH appears in renal venous plasma, and the amount found in the final urine approximates that delivered to the kidneys in the plasma. Therefore:

$$RPF \times P_{PAH} = U_{PAH} \times V$$
$$\text{or } RPF = (U_{PAH} \times V)/P_{PAH} = \text{PAH clearance}$$

where U_{PAH} and P_{PAH} are the concentrations of PAH in the urine and plasma, respectively, and V is the urine flow rate. Renal blood flow (RBF) can be calculated as follows:

$$RBF = [RPF/(100 - \text{Hematocrit})] \times 100$$

Typically, RBF is approximately 1200 ml/min.

The most important limitation of this method is the renal extraction of PAH, which is always less than 100%. At high plasma concentrations, greater than 10 mg/dl, the organic anion transport (OAT) proteins that mediate PAH secretion become saturated, the fractional tubular secretion of PAH declines, and considerable amounts of PAH appear in the renal veins. When this occurs, PAH clearance significantly underestimates RPF. In patients with liver or renal failure, the production of toxins and weak organic acids can interfere with PAH secretion or cause tubular damage, leading to inhibition of PAH transport. Certain drugs, such as probenecid, are organic acids and compete with PAH for tubular

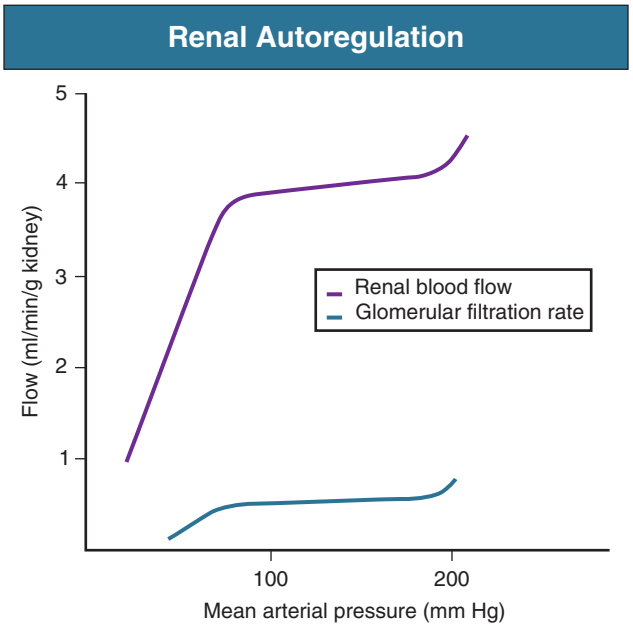

Fig. 2.3 Renal autoregulation of renal blood flow and glomerular filtration rate. If mean arterial blood pressure is in the range of 80 to 180 mm Hg, fluctuations in blood pressure have only marginal effects on renal blood flow and glomerular filtration rate. This is an intrinsic mechanism and can be modulated or overridden by extrinsic factors.

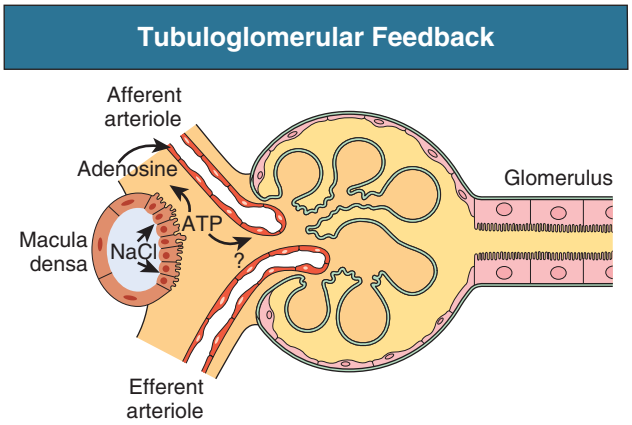

Fig. 2.4 Tubuloglomerular feedback. Changes in the delivery of NaCl to the macula densa region of the thick ascending limb of the Henle loop cause changes in the afferent arteriolar caliber. The response is mediated by adenosine triphosphate (ATP), either directly or after metabolism to adenosine, and modulated by other locally produced agents such as angiotensin II and nitric oxide. Increased macula densa NaCl delivery results in afferent arteriolar constriction, thereby reducing GFR.

secretion, thereby reducing PAH clearance. Moreover, the expression of the OAT proteins is hormonally regulated, influencing the extraction efficiency of PAH.

In a variety of patient settings, the secretion of PAH can be influenced by the abundance/pharmacokinetics of the OAT pathway, and PAH clearance can be independent of true RPF. Given that PAH clearance is invasive (requiring intravenous infusion) and expensive and has the potential to be nonquantitative, alternative nonoptical imaging approaches, such as Doppler ultrasound and arterial spin labeling magnetic resonance imaging, are being refined to measure RBF.[6]

AUTOREGULATION OF RENAL BLOOD FLOW AND GLOMERULAR FILTRATION RATE

Although acute physiologic variations in arterial blood pressure cause corresponding changes in RBF and GFR, these are usually short-lived, because compensatory (autoregulation) mechanisms return both RBF and GFR toward normal within seconds[7] (Fig. 2.3). Autoregulation is achieved primarily at the level of the afferent arterioles and is believed to result from a combination of the following two mechanisms:

- *Myogenic reflex.* Increased renal perfusion pressure stretches arteries and afferent arterioles, depolarizing smooth muscle cells to promote constriction of the vessel wall.
- *Tubuloglomerular feedback* (TGF). Increased renal perfusion pressure will increase delivery of sodium chloride (NaCl) to the nephron's macula densa region, a specialized plaque of cells at the distal end of the ascending limb of Henle. Increased delivery is sensed by the macula densa, promoting vasoconstriction of the afferent arteriole supplying the same nephron's glomerulus.

These mechanisms are tonically active and dynamic. In combination, they act to restore both RBF and P_{gc} toward normal, reversing the initial change in GFR. The TGF system is possible because of the juxtaglomerular apparatus (see Chapter 1), which consists of the macula densa region of each nephron, the adjacent glomerulus, and afferent and efferent arterioles (Fig. 2.4). Both myogenic and TGF mechanisms are dependent on extracellular adenosine triphosphate (ATP) signaling. ATP is released from cells during vascular stretch and can promote vasoconstriction via P2Y6 purinoceptors.[8] ATP is also the primary mediator of TGF. Increased NaCl delivery to the macula densa leads to increased NaCl uptake by these cells through a furosemide-sensitive $Na^+,K^+,2Cl^-$ cotransporter, triggering ATP release into the surrounding extracellular space.[9] ATP can have a direct vasoconstrictor effect on the afferent arteriole, activating $P2X_1$ purinoceptors to depolarize the smooth muscle cells. However, because the macula densa is anatomically separated from the afferent arteriole by the extraglomerular mesangium, the final signal for TGF is likely to be adenosine, rather than ATP, acting on afferent arteriolar A_1 receptors to cause vasoconstriction.[9] The sensitivity of TGF is modulated by locally produced angiotensin II (Ang II), nitric oxide (NO), and certain eicosanoids (see later discussion).

The TGF regulation of GFR may be more complex than usually described, with evidence for regulatory cross-talk between the distal nephron and vasculature sites beyond the macula densa,[10] as well as for synchronization of blood flow across networks of nephrons in response to changes in sodium delivery.[11]

Despite renal autoregulation, several extrinsic factors (neural and humoral) can alter renal hemodynamics. Independent or unequal changes in the resistance of afferent and efferent glomerular arterioles, together with alterations in K_f (thought to result largely from mesangial cell contraction/relaxation), can result in disproportionate, or even contrasting, changes in RBF and GFR. In addition, changes in regional vascular resistance can alter the distribution of blood flow within the kidney. For example, medullary vasoconstriction may affect whole-kidney blood flow, because blood can be diverted through the cortex; nevertheless, this renders the medulla hypoxic and vulnerable to ischemic injury.[12] Fig. 2.5 indicates how changes in afferent and efferent arteriolar resistance can affect net ultrafiltration. Table 2.1 lists some of the vasoactive factors that can alter renal hemodynamics (see Integrated Control of Renal Function). In addition, damage to the renal afferent arteriole, as in patients with hypertension and progressive kidney disease, also may interfere with renal autoregulatory mechanisms.

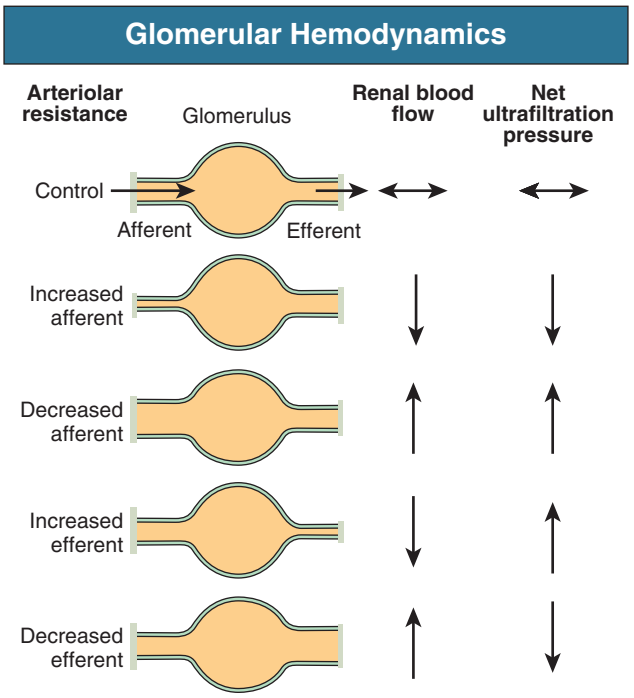

Fig. 2.5 Glomerular hemodynamics. Changes in afferent or efferent arteriolar resistance will alter renal blood flow and (usually) net ultrafiltration pressure. However, the effect on ultrafiltration pressure depends on the relative changes in afferent and efferent arteriolar resistance. The overall effect on glomerular filtration rate will depend not only on renal blood flow and net ultrafiltration pressure but also on the ultrafiltration coefficient (K_f; see Table 2.1).

TUBULAR TRANSPORT

Vectorial transport is net movement of substances from tubular fluid to blood (reabsorption) or vice versa (secretion). The cell membrane facing the tubular fluid (*luminal* or *apical*) must have different properties than the membrane facing the blood (*peritubular* or *basolateral*). Such epithelia are said to be "polarized," thus allowing the net movement of substances across the cell (transcellular route). The *tight junction,* which is a contact point close to the apical side of adjacent cells, limits water and solute movement between cells (paracellular route).

Solute transport across cell membranes uses either passive or active mechanisms.

Passive Transport

Simple diffusion always occurs down an electrochemical gradient, which is a composite of the concentration and electrical gradients (electrochemical gradient). With an undissociated molecule, only the concentration gradient is relevant; for a charged ion the electrical gradient also must be considered. Simple diffusion does not require a direct energy source, although active transport is usually necessary to establish the initial concentration and electrical gradients.

Facilitated diffusion (coupled or carrier-mediated diffusion) depends on an interaction of the molecule or ion with a specific membrane carrier protein that facilitates its passage across the cell membrane's lipid bilayer. In almost all cases of carrier-mediated transport in the kidney, two or more ions or molecules share the carrier: one moiety moves down its electrochemical gradient, and the other(s) moves against the gradient and is transported "uphill."

Diffusion through a membrane channel (or pore) formed by specific integral membrane proteins is also a form of facilitated diffusion, because it allows charged, polar, and lipophobic molecules to pass through the membrane at a high rate.

TABLE 2.1 Physiologic and Pharmacologic Influences on Glomerular Hemodynamics

	ARTERIOLAR RESISTANCE		Renal Blood Flow	Net Ultrafiltration Pressure	K^f	GFR
	Afferent	Efferent				
Renal sympathetic nerves	↑↑	↑	↓	↓	↓	↓
Epinephrine	↑	↑	↓	→	?	↓
Adenosine	↑	→	↓	↓	?	↓
Cyclosporine	↑	→	↓	↓	?	↓
NSAIDs	↑↑	↑	↓	↓	?	↓
Angiotensin II	↑	↑↑	↓	↑	↓	↓→
Endothelin-1	↑	↑↑	↓	↑	↓	↓
High-protein diet	↓	→	↑	↑	→	↑
Nitric oxide	↓	↓	↑	?	↑	↑ (?)
ANP (high dose)	↓	→	↑	↑	↑	↑
PGE_2/PGI_2	↓	↓ (?)	↑	↑	?	↑
Calcium channel blockers	↓	→	↑	↑	?	↑
ACE inhibitors, ARBs	↓	↓↓	↑	↓	↑	?*

NOTE: The overall effect on glomerular filtration rate (GFR) will depend on renal blood flow, net ultrafiltration pressure, and the ultrafiltration coefficient (K_f), which is controlled by mesangial cell contraction and relaxation. The effects shown are those seen when the agents are applied (or inhibited) in isolation; the actual changes that occur are dose dependent and are modulated by other agents.

*In clinical practice, GFR is usually either decreased or unaffected.

ACE, Angiotensin-converting enzyme; *ARBs,* angiotensin receptor blockers; *ANP,* atrial natriuretic peptide; *NSAIDs,* nonsteroidal antiinflammatory drugs; *PGE_2/PGI_2,* prostaglandins E_2 and I_2.

Active Transport

Ion movement directly against an electrochemical gradient (uphill) requires a source of energy and is known as active transport. In cells, this energy is derived from ATP production and its hydrolysis. The most important active cell transport mechanism is the sodium pump, which extrudes sodium ions (Na^+) from inside the cell in exchange for potassium ions (K^+) from outside the cell. In the kidney, this process is confined to the basolateral membrane. The "Na pump" derives energy from the enzymatic hydrolysis of ATP and is more correctly named Na^+,K^+-ATPase. It exchanges $3Na^+$ for $2K^+$ and is electrogenic, because it extrudes a net positive charge from the cell; Na^+,K^+-ATPase is an example of a *primary* active transport mechanism. Other well-defined primary active transport processes in the kidney are the proton-secreting H^+-ATPase, important in hydrogen ion secretion in the distal nephron, and the Ca^{2+}-ATPase, partly responsible for calcium reabsorption.

Activity of the basolateral Na^+,K^+-ATPase underpins the operation of all the passive transport processes outlined earlier. It ensures that the intracellular Na^+ concentration is kept low (10 to 20 mmol/l) and the K^+ concentration high (~150 mmol/l), compared with their extracellular concentrations (~140 and 4 mmol/l, respectively). The *pump-leak* model of sodium transport uses the electrochemical gradient established and maintained by the Na pump to allow "leak" of Na^+ into the cell through a variety of membrane transport proteins. These can be Na^+ channels (in the distal nephron) or specific membrane carrier proteins that couple Na^+ entry to the influx (*symport* or *cotransport*) or efflux (*antiport* or *counter-transport*) of other molecules or ions. In various parts of the nephron, glucose, phosphate, amino acids, K^+, and chloride ions (Cl^-) can all be cotransported with Na^+; moreover, H^{2+} and Ca^{2+} can be counter-transported against Na^+ entry. In each case, the non-Na molecule or ion is transported against its electrochemical gradient, using energy derived from the "downhill" movement of Na^+. Their ultimate dependence on the Na^+,K^+-ATPase makes them *secondary* active transporters.

TRANSPORT IN SPECIFIC NEPHRON SEGMENTS

Among people with normal GFR, approximately 180 liters of plasma (largely protein-free) is filtered each day, necessitating massive reabsorption by the whole nephron. Fig. 2.6 shows the major transport mechanisms operating along the nephron (except the loop of Henle, which is dealt with separately).

Proximal Tubule

The proximal tubule is adapted for bulk reabsorption of the glomerular filtrate. The epithelial cells have microvilli (brush border) on their apical surface that provide a large absorptive area, and the basolateral membrane has folds, also increasing its surface area. The cells are rich in mitochondria, and these are concentrated at the basolateral membrane to supply the Na^+,K^+-ATPase with ATP. Proximal tubule transport is heavily reliant on oxidative phosphorylation (aerobic metabolism) and is susceptible to hypoxia and mitochondrial dysfunction. Drugs that are toxic to mitochondria (e.g., tenofovir) can cause Fanconi syndrome. Future mitochondrial protection strategies may be useful in the management of patients with some forms of acute kidney injury.[13]

The proximal convoluted tubule (PCT, *pars convoluta*) makes up the first two thirds of the proximal tubule, and the final third is the proximal straight tubule *(pars recta)*. The proximal tubular epithelium is subdivided into three segments based on subtle structural and functional differences: S_1 is the initial short segment of the PCT; S_2, the remainder of the PCT and the cortical segment of the pars recta; and S_3, the medullary segment of the pars recta.

The NHE3 isoform of the Na^+-H^+ exchanger (antiporter) is the main route of Na^+ entry into proximal tubular cells. A battery of specialized transporters is also expressed in the apical membrane coupling Na^+ entry to other solutes. Thus the proximal tubule accounts for the bulk of Na^+, K^+, Cl^-, and bicarbonate (HCO_3^-) reabsorption and the almost complete reabsorption of amino acids and low-molecular-weight proteins (e.g., retinol binding protein, α- and β-microglobulin) that have passed the filtration barrier. The proximal tubule reabsorbs almost all the filtered glucose via the SGLT2 isoform of the sodium-glucose cotransporter. In contrast to SGLT1, which is also expressed in the small intestine, SGLT2 is exclusive to the kidney and is expressed predominantly in the brush border of S_1 and S_2. SGLT2 inhibitors (gliflozins) induce glycosuria and polyuria and can lower blood glucose levels and blood pressure in diabetes; in animal models they have been shown to reduce diabetes-associated glomerular hyperfiltration by inhibiting TGF and can reduce albuminuria in diabetic kidney disease. These compounds are now an important new class of antidiabetic drug mainly used to treat type 2 diabetes.

Most other filtered solutes are also reabsorbed to some extent in the proximal tubule (e.g., ~60% of calcium, 80% of phosphate, 50% of urea). Constitutive expression of aquaporin 1 (AQP1) water channels in both membranes confers a large hydraulic permeability to cells. Furthermore, the protein junctional complexes (such as Claudin 1 and Zonula Occludens 1) that connect proximal tubular cells are "leaky," facilitating the reabsorption of large amounts of sodium, potassium, and water. Overall, the substantial hydraulic permeability requires only a very small osmotic driving force (<5 mOsm/kg/H_2O) and the osmolality of the tubular fluid changes little along the proximal tubule—"isosmotic" reabsorption.

In the final section of the proximal tubule (late S_2 and S_3), there is efficient secretion of weak organic acids and bases, including most diuretics, PAH (see Measurement of Renal Blood Flow), nonsteroidal antiinflammatory drugs (NSAIDs), antiretroviral drugs, and some antibiotics. The molecular machinery for secretion is complex, mediated by 13 members of the SLC22 family of transport proteins. This comprises OATs and organic cation transporters (OCTs) that operate as facilitated transporters or exchangers.[14]

Loop of Henle

The loop of Henle is defined anatomically as comprising the pars recta of the proximal tubule (thick descending limb), the thin descending and ascending limbs (thin ascending limbs are present only in long-looped nephrons), the thick ascending limb, and the macula densa. In addition to its role in further reabsorption of solutes (Na^+, Cl^-, K^+, Ca^{2+}, Mg^{2+}), the loop of Henle is responsible for the kidney's ability to generate a concentrated or dilute urine, which is described in detail later. The thick limb of Henle also produces the Tamm-Horsfall protein, also known as *uromodulin,* normally the most abundant protein in urine. Mutations in the encoding gene, *UMOD,* cause rare autosomal dominant renal diseases with medullary cyst formation, hyperuricemia, and progressive loss of renal function. Common gain-of-function polymorphisms are associated with an increased risk for hypertension and chronic kidney disease. The physiologic role of uromodulin is not fully understood, but studies in mice suggest that it activates Na^+,K^+,$2Cl^-$ cotransport to promote sodium reabsorption in the thick limb of Henle. Uromodulin also may be a constitutive inhibitor of calcium stone formation and protect the kidney from ascending urinary infections.[15]

Distal Nephron

The distal tubule comprises three segments: the distal convoluted tubule (DCT), in which thiazide-sensitive NaCl reabsorption via an apical NaCl cotransporter (NCC)[16] occurs; the connecting tubule (CNT),

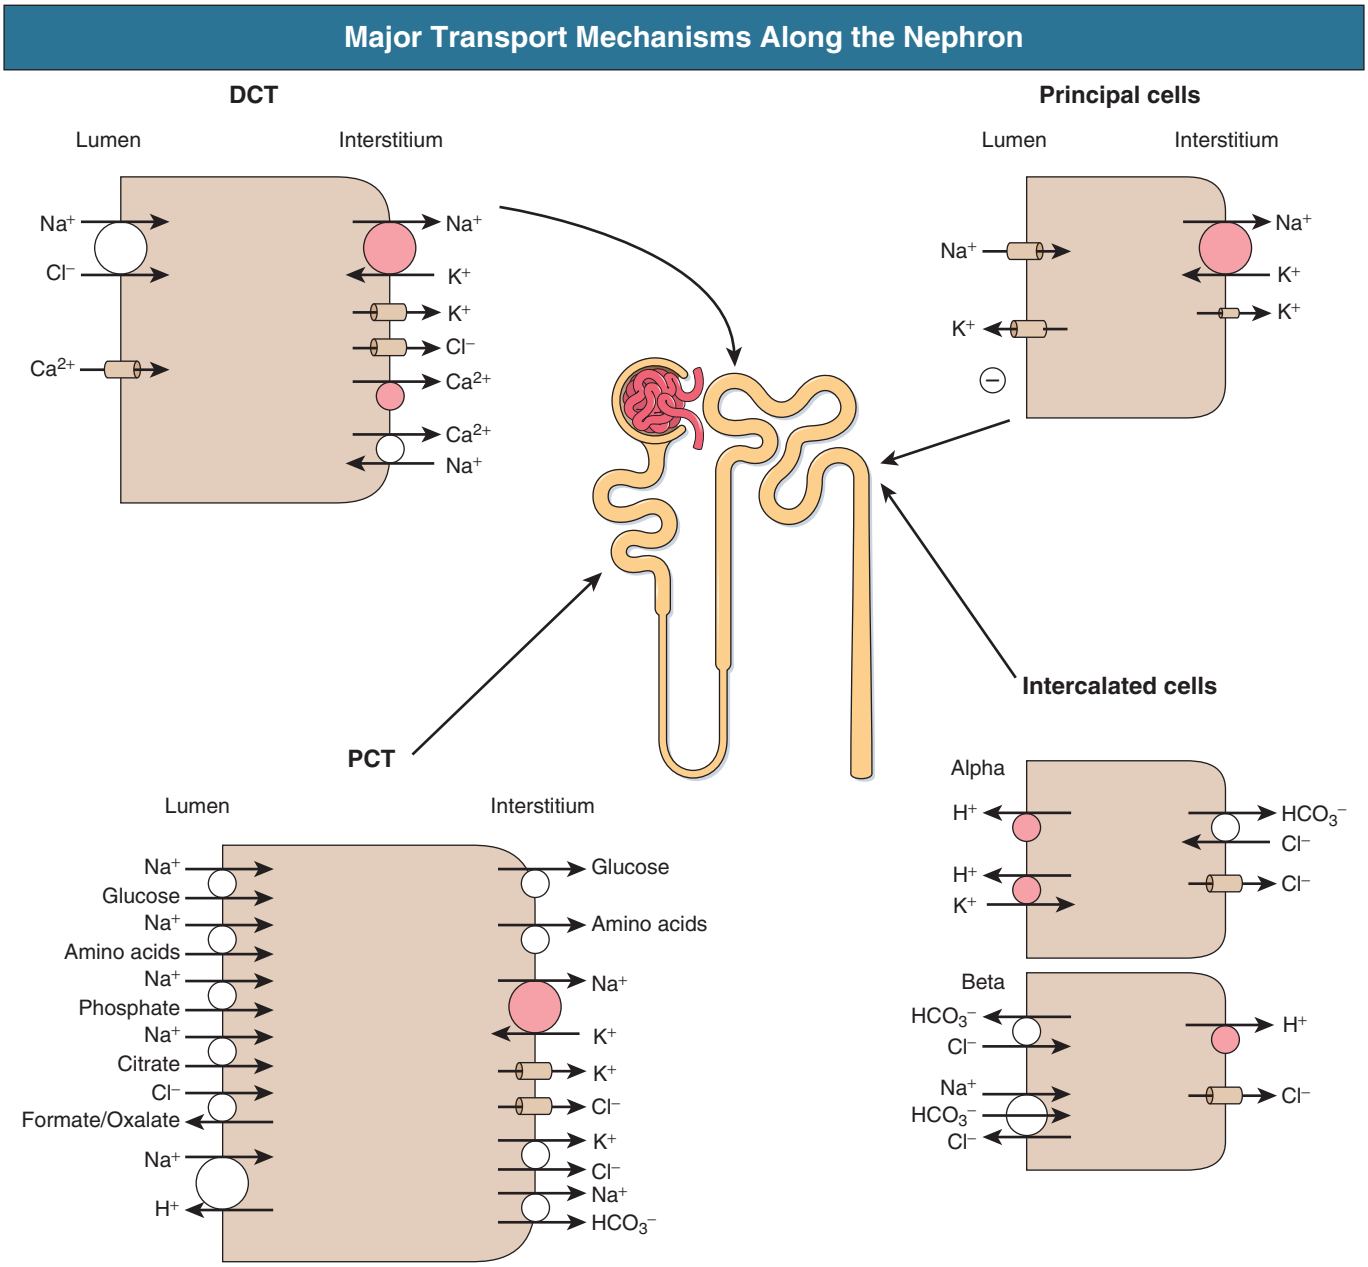

Fig. 2.6 Major transport mechanisms along the nephron. Major transport proteins for solutes in the apical and basolateral membranes of tubular cells in specific regions of the nephron. Stoichiometry is not indicated; it is not 1:1 in all cases. *Red circles* represent primary active transport; *white circles* represent carrier-mediated transport (secondary active); *cylinders* represent ion channels. In the proximal convoluted tubule *(PCT),* Na^+ enters the cell through an Na^+-H^+ exchanger and a series of cotransporters. In the distal convoluted tubule *(DCT),* Na^+ enters the cell through the thiazide-sensitive Na^+-Cl^- cotransporter. In the principal cells of the cortical collecting duct, Na^+ enters through the epithelial sodium channel (ENaC). In all cases, Na^+ is extruded from the cells through the basolateral Na^+,K^+-ATPase. Transporters in the thick ascending limb of Henle are dealt with separately (see Fig. 2.10).

whose function is essentially intermediate between that of the DCT and the next segment, the initial collecting duct (CD) that is made up of the same epithelial cell type as the cortical CD (see Fig. 2.6). Two cell types make up the cortical CD: the predominant cell, the *principal* cell (or CD cell), is responsible for Na^+ reabsorption and K^+ secretion[17] (as well as regulated water reabsorption; see later discussion). Na^+ enters the principal cell from the lumen through apical epithelial sodium channels (ENaC) and exits by the basolateral Na^+,K^+-ATPase. This process is electrogenic and sets up a lumen-negative transepithelial potential difference. K^+ enters the principal cell by the same basolateral Na^+,K^+-ATPase and leaves by K^+ transport pathways in both membranes; however, the relative depolarization of the apical membrane (caused by Na^+ entry through ENaC) favors K^+ secretion into the lumen, the major route for which is through renal outer medullary potassium (ROMK) channels. The other cell type in the late distal tubule and cortical CD is the *intercalated* (IC) cell. Type A (or α) IC cells secrete H^+ into the tubular

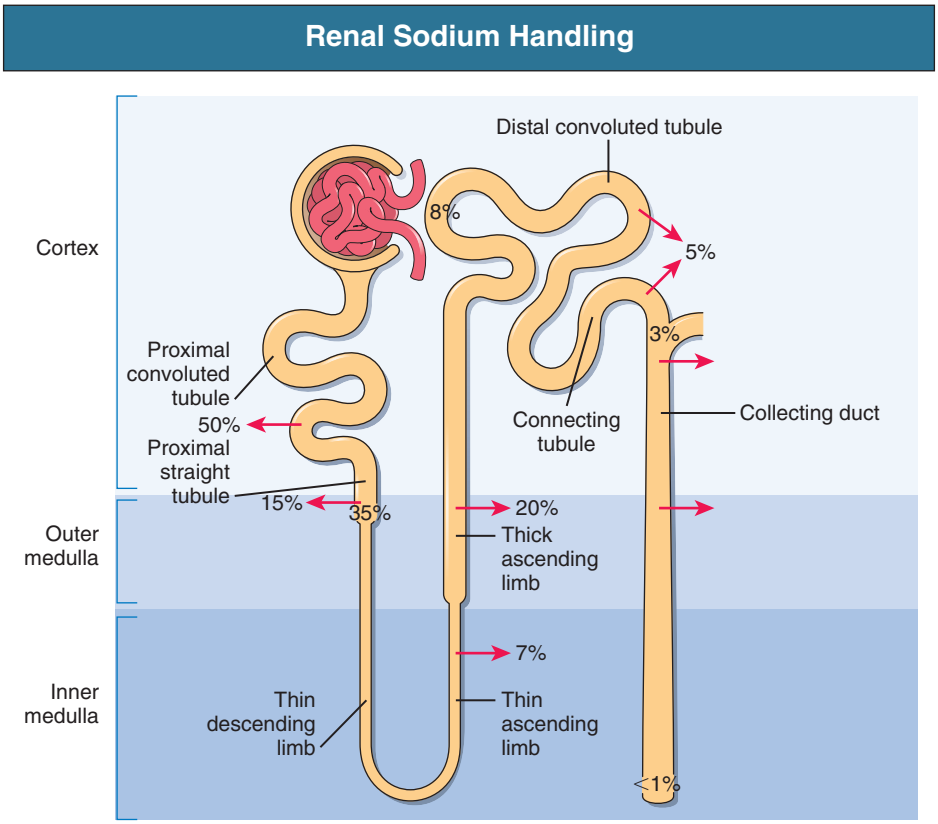

Fig. 2.7 Renal sodium handling along the nephron. Figures outside the nephron represent the approximate percentage of the filtered load reabsorbed in each region. Figures within the nephron represent the percentages remaining. Most filtered sodium is reabsorbed in the proximal tubule and loop of Henle; normal day-to-day control of sodium excretion is exerted in the distal nephron.

fluid via H^+-ATPase and H^+,K^+-ATPase. Type B (or β) IC cells mediate HCO_3^- secretion into the final urine, in exchange for Cl^-. An exchanger called pendrin, encoded by *SLC26A4*, mediates this process. Type B IC cells also express a Na^+-dependent chloride-bicarbonate exchanger (NDCBE; *SLC4A8*). Functionally coupled with pendrin, NDCBE achieves electroneutral sodium transport across the type B cell (see Fig. 2.6).[18]

In the medullary CD there is a gradual transition in the epithelium. There are increasingly fewer IC cells, whereas the principal-like cells are modified such that they reabsorb Na^+ but, lacking apical K^+ channels, do not secrete K^+.

Figs. 2.7 and 2.8 show the sites of Na^+ and K^+ reabsorption and secretion along the nephron. Table 2.2 outlines the pathophysiologic consequences of known genetic defects in some of the major transporters in the nephron (see Chapter 47 for details).

GLOMERULOTUBULAR BALANCE

Because the proportion of filtered Na^+ excreted in the urine is so small (normally <1%), it follows that without a compensatory change in reabsorption, even small changes in the filtered load would cause major changes in the amount excreted in the final urine. For example, if GFR were to increase by 10%, and the rate of reabsorption remained unchanged, Na^+ excretion would increase more than 10-fold. However, an intrinsic feature of tubular function is that the extent of Na^+ reabsorption in a given nephron segment is proportional to the Na^+ delivery to that segment. This process is called *glomerulotubular balance*. In perfect balance, both the reabsorption and the excretion of Na^+ would change in exactly the same proportion as the change in GFR, but glomerulotubular balance is usually less than perfect. Most studies have focused on the proximal tubule, because glomerulotubular balance in this segment stabilizes delivery of Na^+ and fluid to the distal nephron, permitting efficient secretion of K^+ and H^+. However, Na^+ reabsorption in the thick limb of Henle and distal tubule is also delivery-dependent. This partly explains why diuretics acting on the proximal tubule are less effective compared with those acting more distally. With distal-acting diuretics, there is less scope further downstream for compensatory Na^+ reabsorption. This also explains why combining two diuretics (acting at different nephron sites) can cause a more striking diuresis and natriuresis.

The mechanism of glomerulotubular balance is not fully understood. In the proximal tubule, physical factors (Starling forces) operating across peritubular capillary walls may be involved. Glomerular filtration of an essentially protein-free fluid means the plasma leaving the glomeruli in efferent arterioles and supplying the peritubular capillaries has a relatively high oncotic pressure, favoring reabsorption of fluid from the proximal tubules. If GFR were reduced in the absence of a change in RPF, the *filtration fraction* (GFR/RPF ratio) would fall. Peritubular capillary oncotic pressure would also be reduced, and the tendency of the peritubular vasculature to take up fluid reabsorbed from the proximal tubule would be diminished. Backflux of this fluid is thought to occur through the leaky tight junctions, reducing net reabsorption (Fig. 2.9). However, this mechanism could work only if GFR changed in the absence of a corresponding change in RPF; if the two changed in parallel, filtration fraction would stay constant, with no change in oncotic pressure.

A second contributory factor to glomerulotubular balance in the proximal tubule could be the filtered loads of glucose and amino acids:

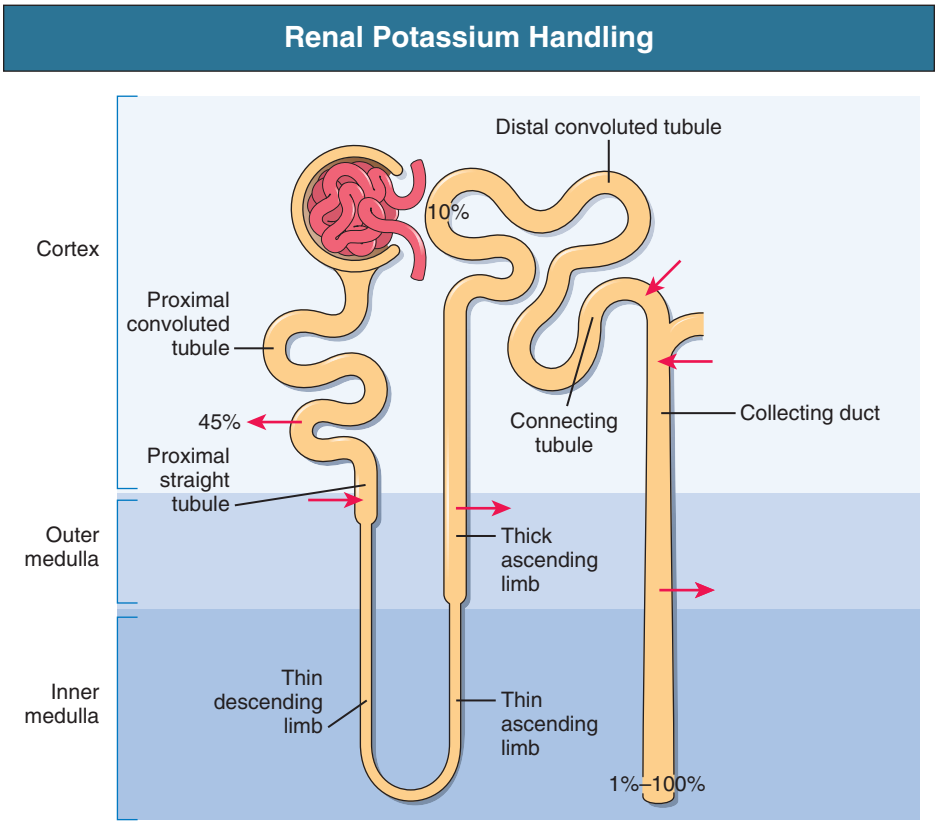

Fig. 2.8 Renal potassium handling along the nephron. Figures are not given for percentages reabsorbed or remaining in every region because quantitative information is incomplete, but most filtered potassium is reabsorbed in the proximal convoluted tubule and thick ascending limb of Henle; approximately 10% of the filtered load reaches the early distal tubule. Secretion by connecting tubule cells and principal cells in the late distal tubule–cortical collecting duct is variable and is the major determinant of potassium excretion.

if their loads increase, because of increased GFR, the rates of Na^+-coupled glucose and amino acid reabsorption in the proximal tubule will also increase. It has been proposed that the brush border microvilli of the proximal tubule serve a "mechanosensing" function, transmitting changes in torque (caused by altered tubular flow rates) to the tubular cells' actin cytoskeleton and thereby modulating transporter activity.[19] The mechanisms are unknown, but the release of paracrine mediators such as ATP, dopamine, or Ang II into the lumen fluid may contribute.[20]

Although the renal sympathetic nerves and certain hormones can influence reabsorption in the proximal tubule and loop of Henle, under normal conditions the combined effects of autoregulation and glomerulotubular balance ensure a relatively constant load of glomerular filtrate is delivered to the distal tubule. It is the final segments of the nephron that exert normal day-to-day control of Na^+ excretion. Evidence indicates important roles for the late DCT[16] and the CNT,[21] in addition to the CD.[17] Aldosterone secreted from the adrenal cortex stimulates mineralocorticoid receptors within CNT cells and in principal cells. This leads to the generation and activation by phosphorylation of the regulatory protein serum- and glucocorticoid-inducible kinase 1 (SGK1), which promotes sodium transport by increasing the density of Na^+ channels (ENaC) in the apical membrane (see Fig. 2.6), and by activating the basolateral Na^+,K^+-ATPase. Na^+ transport across the principal cell is further enhanced and the apical membrane thereby maximally depolarized, thus facilitating K^+ secretion into the tubular fluid. The electrophysiologic coupling of Na^+ reabsorption to K^+ secretion explains why aldosterone promotes antinatriuresis and kaliuresis. However, under conditions of volume depletion, aldosterone promotes sodium retention *without* promoting urinary potassium excretion. The mechanism underlying this difference is now better understood. During hypovolemia, aldosterone and Ang II engage the WNK4 kinase network to differentially activate NCC in the DCT, promoting potassium-sparing sodium reabsorption, while also inhibiting ROMK channels to limit potassium secretion.[16] Recent studies have shown direct effects of small changes in plasma potassium concentration on the WNK kinase pathway and NCC activity that explains the natriuretic and blood pressure–lowering effects of increases in dietary potassium intake.[22] Ang II also activates NDBCE and pendrin in the type B IC cell to promote potassium-sparing sodium reabsorption.

The mineralocorticoid receptors have equal affinity in vitro for aldosterone and other adrenal corticosteroids, such as cortisol. The circulating concentrations of cortisol vastly exceed those of aldosterone, but in vivo the mineralocorticoid receptors show specificity for aldosterone because of the presence along the distal nephron of the enzyme 11β-hydroxysteroid dehydrogenase 2, which inactivates cortisol in the vicinity of the receptor.[23] Mutations in the gene that encodes 11β-hydroxysteroid dehydrogenase 2, or inhibition of the enzyme by derivatives of glycyrrhetinic acid (found in licorice), can cause hypertension from excessive and unregulated stimulation of Na^+ transport[24] and salt appetite[25] by cortisol (see also Chapter 38).

TABLE 2.2 Genetic Defects in Transport Proteins Resulting in Renal Disease*

Transporter	Consequence of Mutation
Proximal Tubule	
Apical Na^+-cystine cotransporter	Cystinuria
Apical Na^+-glucose cotransporter (SGLT2)	Renal glycosuria
Basolateral Na^+-HCO_3^- cotransporter	Proximal renal tubular acidosis
Intracellular H^+-Cl^- exchanger (ClC5)	Dent disease
Thick Ascending Limb	
Apical Na^+-K^+-$2Cl^-$ cotransporter	Bartter syndrome type 1
Apical K^+ channel	Bartter syndrome type 2
Basolateral Cl^- channel	Bartter syndrome type 3
Basolateral Cl^- channel accessory protein	Bartter syndrome type 4
Distal Convoluted Tubule	
Apical Na^+-Cl^- cotransporter	Gitelman syndrome
Collecting Duct	
Apical Na^+ channel (principal cells)	Overexpression: Liddle syndrome Underexpression: Pseudohypoaldosteronism type 1b
Aquaporin 2 channel (principal cells)	Nephrogenic diabetes insipidus
Basolateral Cl^-/HCO_3^- exchanger (intercalated cells)	Distal renal tubular acidosis
Apical H^+-ATPase (intercalated cells)	Distal renal tubular acidosis (with or without deafness)

*For more detailed coverage of these clinical conditions, see Chapter 47.

Peritubular Capillaries Modulate Fluid Reabsorption

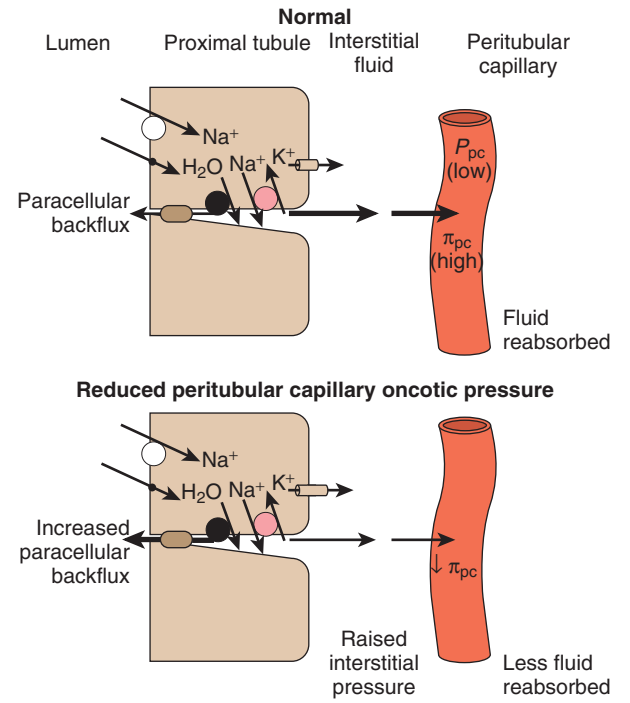

Fig. 2.9 Physical factors and proximal tubular reabsorption. Influence of peritubular capillary oncotic pressure on net reabsorption in proximal tubules. Uptake of reabsorbate into peritubular capillaries is determined by the balance of hydrostatic and oncotic pressures across the capillary wall. Compared with those in systemic capillaries, the peritubular capillary hydrostatic (P_{pc}) and oncotic (π_{pc}) pressures are low and high, respectively, so that uptake of proximal tubular reabsorbate into the capillaries is favored. If peritubular capillary oncotic pressure decreases (or hydrostatic pressure increases), less fluid is taken up, interstitial pressure increases, and more fluid may leak back into the lumen paracellularly; net reabsorption in proximal tubules would therefore be reduced.

COUNTERCURRENT SYSTEM

A major function of the loop of Henle is the generation and maintenance of the interstitial osmotic gradient that increases from the renal cortex (~290 mOsm/kg) to the tip of the medulla (~1200 mOsm/kg). As indicated in Chapter 1, the loops of Henle of superficial nephrons turn at the junction between outer and inner medulla, whereas those of deep nephrons (long-looped nephrons) penetrate the inner medulla to varying degrees. The anatomic loops of Henle reabsorb approximately 40% of filtered Na^+, mostly in the pars recta and the thick ascending limb, and approximately 25% of filtered water in the pars recta and the thin descending limbs of deep nephrons. Evidence suggests that the thin descending limb of superficial nephrons is relatively impermeable to water.[26] Both the thin ascending limb (found only in deep nephrons) and the thick ascending limb are essentially impermeable to water, although Na^+ is reabsorbed; passively in the thin ascending limb but actively in the thick ascending limb. The thick ascending limb also operates as a pump-leak system: the basolateral Na^+,K^+-ATPase maintains the electrochemical driving force for passive Na^+ entry from the lumen through the Na^+,K^+,$2Cl^-$ cotransporter (NKCC2) and to a smaller extent the NHE3 (Fig. 2.10). The apical NKCC2 is the site of action of loop diuretics such as furosemide and bumetanide. Na^+ exits the cell through the Na^+,K^+-ATPase, and Cl^- and K^+ exit via basolateral ion channels and a K^+-Cl^- cotransporter. K^+ also reenters the lumen through apical membrane channels. This "recycling" of K^+ into the tubular lumen is necessary for normal operation of the Na^+,K^+,$2Cl^-$ cotransporter, because the availability of K^+ is a limiting factor for the transporter (K^+ concentration in tubular fluid is much lower than Na^+ and Cl^-). Potassium recycling is also partly responsible for generating the lumen-positive transepithelial potential difference found in the thick ascending limb, which drives additional Na^+ reabsorption through the paracellular pathway; for each Na^+ reabsorbed by the transcellular route, another is reabsorbed paracellularly (see Fig. 2.10). Other cations (K^+, Ca^{2+}, Mg^{2+}) are also reabsorbed by this route. The reabsorption of NaCl along the thick ascending limb in the absence of significant water reabsorption means that the tubular fluid leaving this segment is hypotonic; the thick ascending limb is also called the *diluting segment.*

The reabsorption in the thick ascending limb of solute without water generates a "horizontal" osmotic gradient of about 200 mOsm/kg between the tubular fluid and interstitium. This separation is the *single osmotic effect.* The U-shaped arrangement of the loop of Henle, in which flow in the descending limb is opposite to that in the ascending limb, multiplies the single effect to generate a much larger vertical (corticomedullary) osmotic gradient by a process known as *countercurrent multiplication* (Fig. 2.11). Fluid entering the descending limb from the proximal tubule is isosmotic (~290 mOsm/kg). On encountering the hypertonicity of the medullary interstitial fluid (caused by NaCl reabsorption in the water-impermeable ascending limb), the fluid in the descending limb comes into osmotic equilibrium with its surroundings,

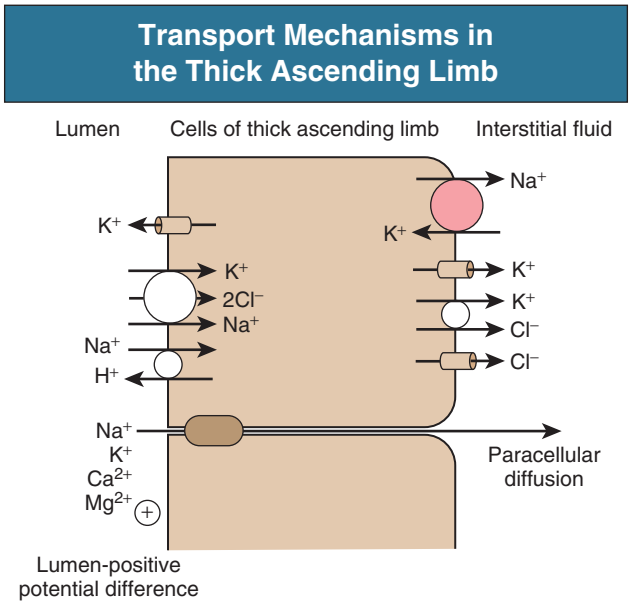

Fig. 2.10 Transport mechanisms in the thick ascending limb of Henle. The major cellular entry mechanism is the Na^+-K^+-$2Cl^-$ cotransporter. The transepithelial potential difference drives paracellular transport of Na^+, K^+, Ca^{2+}, and Mg^{2+}.

either by solute entry into the descending limb (superficial nephrons) or by water exit by osmosis (deep nephrons). These events, combined with continuing NaCl reabsorption in the ascending limb, result in a progressive increase in medullary osmolality from the corticomedullary junction to the papillary tip. A similar osmotic gradient exists in the thin descending limb, and at any level in the ascending limb the osmolality is less than in the surrounding tissue. Thus hypotonic fluid (~100 mOsm/kg) is delivered to the distal tubule. Ultimately, the energy source for countercurrent multiplication is active Na^+ reabsorption in the thick ascending limb. As stated earlier, Na^+ reabsorption in the thin ascending limb is passive, although the mechanism is not yet understood.

Role of Urea

The thin limbs of the loop of Henle are relatively permeable to urea (ascending more permeable than descending), but the thick ascending limb and beyond are urea-impermeable up to the final section of the inner medullary CD. During antidiuresis, vasopressin-induced water reabsorption from the CDs concentrates urea, such that in the terminal inner medullary CD there is a large concentration gradient between the luminal fluid and interstitium. This section of the inner medullary CD expresses urea transporters (UT-A1 and UT-A3), allowing passive reabsorption of urea into the inner medullary interstitium. This process is also under the control of vasopressin (AVP, also known as antidiuretic hormone).[27] The interstitial urea exchanges with vasa recta capillaries

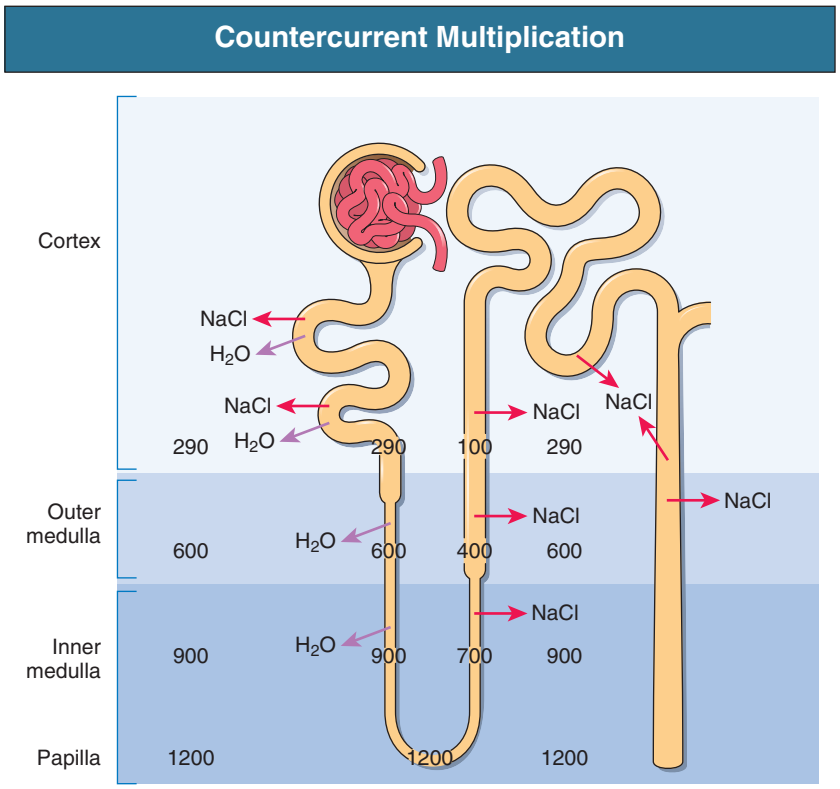

Fig. 2.11 Countercurrent multiplication by the loop of Henle. The nephron drawn represents a deep (long-looped) nephron. Figures represent approximate osmolalities (mOsm/kg). Osmotic equilibration occurs in the thin descending limb of Henle, whereas NaCl is reabsorbed in the water-impermeable ascending limb; hypotonic fluid is delivered to the distal tubule. In the absence of vasopressin, this fluid remains hypotonic during its passage through the distal tubule and collecting duct, despite the large osmotic gradient favoring water reabsorption. A large volume of dilute urine is therefore formed. During maximal vasopressin secretion, water is reabsorbed down the osmotic gradient, so that tubular fluid becomes isotonic in the cortical collecting duct and hypertonic in the medullary collecting duct. A small volume of concentrated urine is formed.

(see next section) and some urea enters the S_3 segment of the pars recta and the descending and ascending thin limbs; it is then returned to the inner medullary CDs to be reabsorbed. The net result of this urea recycling process is to add urea to the inner medullary interstitium, thereby increasing interstitial osmolality. The fact that the high urea concentration within the medullary CD is balanced by a similarly high urea concentration in the medullary interstitium allows large quantities of urea to be excreted without incurring the penalty of osmotic diuresis, because the urea in the CD is rendered osmotically inactive. Moreover, the high urea concentration in the medullary interstitium should also increase osmotic water abstraction from the thin descending limbs of deep nephrons, thus raising the intraluminal Na^+ concentration within the thin descending limbs.

Although until recently this process was thought to prepare for passive Na^+ reabsorption along the thin ascending limbs, mice with genetic deletion of the urea transporters UT-A1 and UT-A3 have a greatly reduced urea concentration in the inner medullary interstitium, but a normal interstitial NaCl gradient.[27] Therefore the mechanisms responsible for the inner medullary electrolyte gradients are still unclear. However, it is worth emphasizing that the ultimate driving force for countercurrent multiplication is active Na^+ reabsorption in the thick ascending limb. For this reason, loop diuretics disrupt the osmotic gradient and genetic mutations in the pathways contributing to efficient Na^+ reabsorption in the thick ascending limb cause salt-wasting Bartter syndrome (see Chapter 47).

Vasa Recta

If the capillaries that supply the renal medulla had a more conventional anatomic arrangement, these vessels would soon dissipate the medullary osmotic gradient because of equilibration of the hypertonic interstitium with the isotonic capillary blood. This does not happen to any appreciable extent, because the U-shaped arrangement ensures that solute entry and water loss in the descending vasa recta are offset by solute loss and water entry in the ascending vasa recta. This is the process of *countercurrent exchange* and is entirely passive (Fig. 2.12).

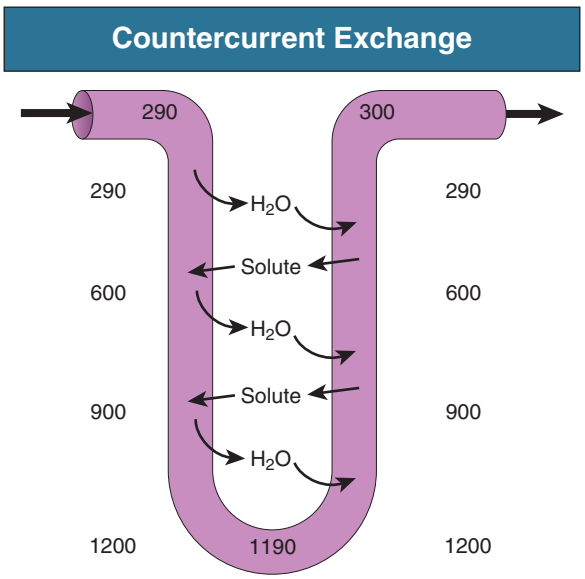

Fig. 2.12 Countercurrent exchange by the vasa recta. Figures represent approximate osmolalities (mOsm/kg). The vasa recta capillary walls are highly permeable, but the U-shaped arrangement of the vessels minimizes the dissipation of the medullary osmotic gradient. Nevertheless, because equilibration across the capillary walls is not instantaneous, a certain amount of solute is removed from the interstitium.

Renal Medullary Hypoxia

Countercurrent exchange by the medullary capillaries applies also to oxygen, which diffuses from descending to ascending vasa recta, bypassing the deeper regions. This phenomenon, combined with ongoing energy-dependent Na^+ transport in the (outer medullary) thick ascending limb, renders medullary tissue relatively hypoxic. Thus the partial pressure of oxygen normally decreases from about 50 mm Hg in the cortex to 10 mm Hg in the inner medulla.[28] Indeed, administration of furosemide, which inhibits oxygen consumption in the thick ascending limb, increases medullary oxygenation. As part of the adaptation to this relatively hypoxic environment, medullary cells have a higher capacity for glycolysis than cortical cells. Moreover, a number of *heat shock proteins* are expressed in the medulla, which assist cell survival by restoring damaged proteins and by inhibiting apoptosis.[28]

The degree of medullary hypoxia depends on the balance between medullary blood flow (influenced by contractile cells called *pericytes*) and oxygen consumption in the thick ascending limb. In health, this balance is modulated by a variety of autocrine/paracrine agents (e.g., NO, eicosanoids, ATP, adenosine; see later discussion), several of which can increase medullary oxygenation by simultaneously reducing pericyte contraction and thick ascending limb transport. Some cases of radiocontrast-induced nephropathy result from a disturbance in the balance between oxygen supply and demand, with consequent hypoxic medullary injury in which the normal cellular adaptations are overwhelmed, with subsequent apoptotic and necrotic cell death.

VASOPRESSIN (ANTIDIURETIC HORMONE) AND WATER REABSORPTION

Vasopressin, or antidiuretic hormone (AVP), is a nonapeptide synthesized in specialized neurons of the supraoptic and paraventricular nuclei. Vasopressin is transported from these nuclei to the posterior pituitary and released in response to increases in plasma osmolality and decreases in blood pressure. Osmoreceptors are found in the hypothalamus, and there is also input to this region from arterial baroreceptors and atrial stretch receptors. The actions of vasopressin are mediated by three receptor subtypes: V_{1a}, V_{1b}, and V_2. The V_{1a} receptors are found in vascular smooth muscle and are coupled to the phosphoinositol pathway; they cause an increase in intracellular Ca^{2+} resulting in contraction. V_{1a} receptors also have been identified in the apical membrane of several nephron segments; activation by luminal vasopressin can influence Na^+ transport in these segments. V_{1b} receptors are found in the anterior pituitary, where vasopressin modulates adrenocorticotropic hormone release. V_2 receptors are found in the basolateral membrane of principal cells in the late distal tubule and the whole length of the CD; they are coupled by a G_s protein to cyclic adenosine monophosphate generation, which ultimately leads to the insertion of aquaporin 2 (AQP2) water channels into the apical membrane of this otherwise water-impermeable segment (Fig. 2.13). In the X-linked form of nephrogenic diabetes insipidus, the most common inherited form, the V_2 receptor is defective.[29]

Several aquaporins have been identified in the kidney.[30] AQP1 is found in apical and basolateral membranes of all proximal tubules and of thin descending limbs of long-looped nephrons; it is largely responsible for the permanently high water permeability of these segments. AQP3 is constitutively expressed in the basolateral membrane of CNT cells and cortical and outer medullary principal cells. AQP4 is constitutively expressed in the basolateral membrane of outer medullary principal cells and inner medullary CD cells; however, AQP2 is responsible for the variable water permeability of the late distal tubule and CD. Acute vasopressin release causes shuttling of AQP2 from intracellular vesicles

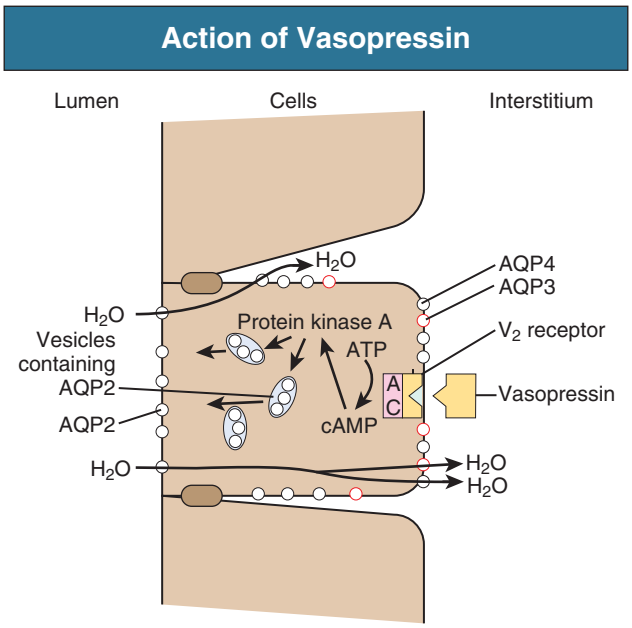

Fig. 2.13 Mechanism of action of vasopressin (antidiuretic hormone). Vasopressin binds to V_2 receptors on the basolateral membrane of collecting duct principal cells and increases intracellular cyclic adenosine monophosphate *(cAMP)* production, causing insertion of preformed aquaporin 2 *(AQP2)* water channels into the apical membrane through intermediate reactions involving protein kinase A. The water permeability of the basolateral membrane, which contains aquaporins 3 and 4, is permanently high. Therefore vasopressin secretion allows transcellular movement of water from lumen to interstitium. *AC,* Adenylate cyclase; *ATP,* adenosine triphosphate.

to the apical membrane, whereas chronically raised vasopressin levels increase transcription and translation of the gene encoding AQP2. The apical insertion of AQP2 allows reabsorption of water, driven by the high interstitial osmolality achieved and maintained by the countercurrent system. Vasopressin also contributes to the effectiveness of this system by stimulating Na^+ reabsorption in the thick ascending limb and urea reabsorption through the UT-A1 and UT-A3 transporters in the inner medullary CD. In the (rare) autosomal recessive and (even rarer) autosomal dominant forms of nephrogenic diabetes insipidus, AQP2 is abnormal and/or fails to translocate to the apical membrane.[29]

More frequently, defects in AQP2 shuttling contribute to the urine-concentrating defects associated with both hypokalemia and hypercalcemia. With chronic hypokalemia, AQP2 expression in the CD is reduced, possibly reflecting the generalized suppression of proteins central to urine concentration[31] and reduction in the medullary osmotic gradient. With hypercalcemia, increased intraluminal Ca^{2+} concentrations preventing insertion of AQP2 in the apical membrane. In addition, stimulation of the calcium receptor in the basolateral membrane of the thick ascending limb (a receptor similar to that in the parathyroid glands) reduces transcellular solute flux by inhibiting NKCC2 and ROMK channels and also by direct inhibition of paracellular permeability.[32] Overall this reduces the medullary osmotic gradient for water reabsorption.

INTEGRATED CONTROL OF RENAL FUNCTION

One of the major functions of the kidneys is the regulation of blood volume, through the regulation of *effective circulating volume,* a conceptual volume reflecting the degree of fullness of the vasculature. This is achieved largely by controlling the sodium content of the body. Chapter 7 describes the mechanisms involved in the regulation of effective circulating volume. This discussion introduces some of the more important mediator systems.

Renal Interstitial Hydrostatic Pressure and Nitric Oxide

Acute increases in arterial blood pressure lead to *pressure natriuresis.*[20] Because autoregulation is not perfect, part of this response is mediated by increases in RBF and GFR (see Fig. 2.3), but the main cause is reduced tubular reabsorption resulting from an increase in *renal interstitial hydrostatic pressure* (RIHP). An elevated RIHP reduces net reabsorption in the proximal tubule by increasing paracellular backflux through the tight junctions of the tubular wall (see Fig. 2.9). The increase in RIHP is thought to depend on intrarenally produced nitric oxide (NO) and modulated by reactive oxygen species.[20] Moreover, increased NO production in macula densa cells, which contain the neuronal (type I) isoform of nitric oxide synthase (nNOS), blunts the sensitivity of TGF, thereby allowing increased NaCl delivery to the distal nephron without incurring a TGF-mediated decrease in GFR.[20]

Another renal action of NO results from the presence of inducible (type II) nitric oxide synthase (iNOS) in glomerular mesangial cells. Local NO production counteracts the mesangial contractile response to agonists such as Ang II and endothelin (see later discussion). Furthermore, NO may contribute to the regulation of medullary blood flow. Locally synthesized NO offsets the vasoconstrictor effects of other agents on the pericytes of the descending vasa recta, and it reduces Na^+ reabsorption in the thick ascending limb; both actions help protect the renal medulla from hypoxia. NO also may promote natriuresis and diuresis through direct actions on the renal tubule. Thus, in addition to its effect on the thick ascending limb, locally produced NO inhibits Na^+ and water reabsorption in the CD.[33]

Renal Sympathetic Nerves

Reductions in arterial pressure and/or central venous pressure result in reduced afferent signaling from arterial baroreceptors and atrial volume receptors, which elicits a reflex increase in renal sympathetic nervous discharge. This reduces urinary Na^+ excretion in at least three ways: (1) constriction of afferent and efferent glomerular arterioles (predominantly afferent), thereby directly reducing RBF and GFR, and indirectly reducing RIHP; (2) direct stimulation of Na^+ reabsorption in the proximal tubule and the thick ascending limb of the Henle loop; and (3) stimulation of renin secretion by afferent arteriolar cells (see later discussion). Renal sympathetic overactivity has long been associated with Na^+ retention and experimental hypertension. The Symplicity-HTN trials initially indicated that bilateral sympathetic efferent denervation causes long-lasting reductions in blood pressure in patients with resistant hypertension.[34] This early promise from small studies was not supported in a larger single-blind, sham-controlled trial,[35] and on present evidence renal denervation is not advocated for treatment of resistant hypertension.

Renin-Angiotensin-Aldosterone System

The renin-angiotensin-aldosterone system (RAAS) is central to the control of extracellular fluid volume (ECFV) and blood pressure. Renin is synthesized and stored in specialized afferent arteriolar cells that form part of the juxtaglomerular apparatus and is released into the circulation in response to (1) increased renal sympathetic nervous discharge, (2) reduced stretch of the afferent arteriole after a reduction in renal perfusion pressure, and (3) reduced delivery of NaCl to the macula densa region of the nephron (see Fig. 2.4).

Renin catalyzes the production of the decapeptide Ang I from circulating angiotensinogen (synthesized in the liver). Ang I is converted

by the ubiquitous angiotensin-converting enzyme (ACE) to the octapeptide Ang II, which influences the control of ECFV and blood pressure as follows:

- Causes general arteriolar vasoconstriction, including renal afferent and (particularly) efferent arterioles, thereby increasing arterial pressure, but reducing RBF. The tendency of P_{gc} to increase is offset by Ang II–induced mesangial cell contraction, and reduced K_f and the overall effect on the GFR is unpredictable.
- Directly stimulates sodium reabsorption in the proximal tubule.
- Directly stimulates thiazide-sensitive NaCl cotransport.[36]
- Stimulates aldosterone secretion from the zona glomerulosa of adrenal cortex. As described earlier, aldosterone stimulates sodium reabsorption in the distal tubule and CD.

Eicosanoids

Eicosanoids are a family of metabolites of arachidonic acid (AA) produced enzymatically by three systems: *cyclooxygenase,* with two isoforms, COX-1 and COX-2, both expressed in the kidney; *cytochrome P-450* (CYP-450); and *lipoxygenase.* The major renal eicosanoids produced by the COX system are the prostaglandins E_2 (PGE_2) and I_2 (PGI_2), both of which are renal vasodilators and buffer the effects of renal vasoconstrictor agents (e.g., Ang II, norepinephrine) and the vasoconstrictor thromboxane A_2. Under normal circumstances, PGE_2 and PGI_2 have minimal effects on renal hemodynamics, but during stressful situations such as hypovolemia, they help protect the kidney from excessive functional changes. Consequently, NSAIDs, which are COX inhibitors, can cause significant falls in GFR. PGE_2 also has tubular effects, inhibiting Na^+ reabsorption in the thick ascending limb of the Henle loop, as well as both Na^+ and water reabsorption in the CD.[37] The action of PGE_2 in the thick ascending limb, together with a dilator effect on vasa recta pericytes, is another paracrine regulatory mechanism that helps protect the renal medulla from hypoxia. This may explain why inhibition of COX-2 can reduce medullary blood flow and cause apoptosis of medullary interstitial cells.

The metabolism of AA by renal CYP-450 enzymes yields epoxyeicosatrienoic acids (EETs), 20-hydroxyeicosatetraenoic acid (20-HETE), and dihydroxyeicosatrienoic acids (DHETs). These compounds appear to have multiple autocrine/paracrine/second messenger effects on the renal vasculature and tubules still to be fully unraveled. As with prostaglandins, EETs are vasodilator agents, whereas 20-HETE is a potent renal arteriolar constrictor and may be involved in the vasoconstrictor effect of Ang II, as well as the TGF mechanism. 20-HETE also constricts vasa recta pericytes and may be involved in the control of medullary blood flow. Some evidence suggests that locally produced 20-HETE and EETs can inhibit sodium reabsorption in the proximal tubule and thick ascending limb. Indeed, CYP-450 metabolites of AA may contribute to the reduced proximal tubular reabsorption seen in pressure natriuresis.[38]

The third enzyme system that metabolizes AA, the lipoxygenase system, is activated (in leukocytes, mast cells, and macrophages) during inflammation and injury and is not considered here.

COX-2 is present in macula densa cells and has a critical role in the release of renin from juxtaglomerular cells (granular cells) in response to reduced NaCl delivery to the macula densa.[38] A low-sodium diet increases COX-2 expression in the macula densa and simultaneously increases renin secretion; the renin response is virtually abolished in COX-2 knockout mice or during pharmacologic inhibition of COX-2. Therefore it is likely that the low renin observed during administration of NSAIDs is largely a consequence of COX-2 inhibition. In addition to COX-2, the enzyme PGE synthase is expressed in macula densa cells, and the principal COX-2 product responsible for enhancing renin secretion is PGE_2, acting on specific receptors identified in juxtaglomerular cells. It is not clear whether PGI_2 is also synthesized in macula densa cells. As previously discussed, nNOS (type I isomer) is also present in macula densa cells and produces NO that blunts TGF. NO also has a permissive role in renin secretion, although the mechanism is not understood. The increase in macula densa COX-2 expression induced by a low-sodium diet is attenuated during administration of selective nNOS inhibitors, which has led to speculation that NO is responsible for the increase in COX-2 activity and the resulting increase in juxtaglomerular renin secretion. Fig. 2.14 shows the established and proposed roles of COX-2 and nNOS in the macula densa.

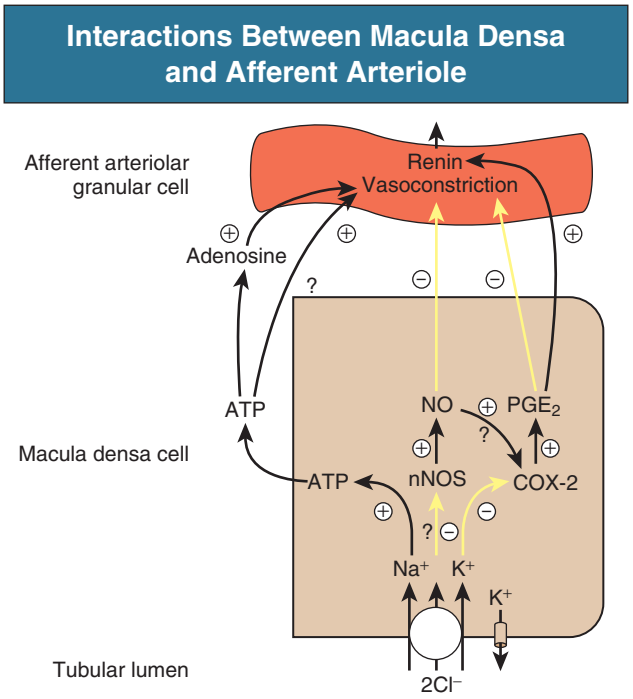

Fig. 2.14 Interactions between macula densa and afferent arteriole: proposed mediators of renin secretion and tubuloglomerular feedback. Both cyclooxygenase-2 *(COX-2)* and neuronal nitric oxide synthase *(nNOS)* enzyme systems are present in macula densa cells. Increased NaCl delivery to the macula densa stimulates NaCl entry into the cells through the Na^+-K^+-$2Cl^-$ cotransporter. This causes afferent arteriolar constriction through adenosine or adenosine triphosphate *(ATP)* and also inhibits COX-2 activity; the latter effect might be mediated partly through inhibition of (nNOS-mediated) nitric oxide *(NO)* production. Generation of prostaglandin E_2 (*PGE_2*) by COX-2 stimulates renin release. PGE_2 also modulates vasoconstriction, as does NO.

Atrial Natriuretic Peptide

If blood volume increases significantly, the resulting atrial stretch stimulates the release of atrial natriuretic peptide (ANP) from atrial myocytes. This hormone increases sodium excretion by suppressing renin and aldosterone release and through a direct inhibitory effect on sodium reabsorption in the medullary CD. ANP may also increase GFR, because high doses cause afferent arteriolar vasodilation and mesangial cell relaxation (thus increasing K_f; see Table 2.1).

Endothelins

Endothelins are potent vasoconstrictor peptides to which the renal vasculature is exquisitely sensitive.[39] Endothelins function primarily as autocrine or paracrine agents. The kidney is a rich source of endothelins, the predominant isoform being endothelin-1 (ET-1). ET-1 is generated throughout the renal vasculature, including afferent and efferent

arterioles, where it causes vasoconstriction, possibly mediated by 20-HETE, and mesangial cells, where it causes contraction (i.e., decreases K_f). Consequently, renal ET-1 can cause profound reductions in RBF and GFR (see Table 2.1).

In contrast to its effect on GFR, ET-1 can act on the renal tubule to increase urinary Na^+ and water excretion. ET-1 levels are highest in the renal medulla—in the thick ascending limb, and, more prominently, the inner medullary CD. The distribution of renal endothelin receptors (ET_A and ET_B) reflects the sites of production; the predominant receptor in the inner medulla is ET_B.[39] Mice with CD-specific deletions of either ET-1 or ET_B receptors exhibit salt-sensitive hypertension, whereas duct-specific ET_A deletion results in no obvious renal phenotype. ET-1 knockout mice also show a greater sensitivity to vasopressin than do wild-type mice. There is mounting evidence that NO mediates the natriuretic and diuretic effects of medullary ET_B stimulation.[39] Taken together with evidence that ET-1 can inhibit Na^+ reabsorption in the medullary thick ascending limb (also likely mediated by NO), these findings highlight the potential importance of ET-1/NO interactions in the control of Na^+ and water excretion.

Purines

Increasing evidence indicates that extracellular purines such as ATP, adenosine diphosphate (ADP), adenosine, and uric acid can act as autocrine or paracrine agents within the kidneys by activating specific cell surface receptors.[9] *Purinoceptors* are subdivided into P1 and P2 receptors. P1 receptors are responsive to adenosine and are more usually known as *adenosine receptors* (A_1, A_{2a}, A_{2b}, and A_3). P2 receptors are responsive to nucleotides (e.g., ATP, ADP) and are further subdivided into P2X (ligand-gated ion channel) and P2Y (metabotropic) receptors, each category having a number of subtypes.[40] As indicated earlier, A_1 and $P2X_1$ receptors are found in afferent arterioles and mediate vasoconstriction. Purinoceptors are also found in the apical and basolateral membranes of renal tubular cells. Stimulation of A_1 receptors enhances proximal tubular reabsorption and inhibits CD Na^+ reabsorption, whereas stimulation of P2 receptors generally has an inhibitory effect on tubular transport.[40] Thus luminally applied nucleotides, acting on a variety of P2 receptor subtypes, can inhibit Na^+ reabsorption in the proximal tubule, distal tubule, and CD, and stimulation of $P2Y_2$ receptors in the CD inhibits vasopressin-sensitive water reabsorption.

Exosomes, Other Extracellular Vesicles and Luminal Factors

Extracellular vesicles are released into the urine from all cells of the nephron. Exosomes are a subtype of vesicles that are approximately 100 nm. They contain proteins, mRNA, and microRNA specific to their cell of origin and have generated much interest as a reservoir for kidney disease biomarker discovery. Recent studies also show that exosomes can signal between cells along the urinary tract. Studies in renal cells lines and in mice find that these vesicles are shuttled to a recipient cell, taken up under hormonal control, and then can influence recipient cell function.[41] Finally, recent studies have also shown the importance and potential clinical relevance of enzymes (serine proteases) in urine that can activate ENaC and thereby affect Na^+ reabsorption, particularly in proteinuric diseases such as the nephrotic syndrome.[42]

SELF-ASSESSMENT QUESTIONS

1. Filtration at the glomerulus is a passive process. Which of the following statements is true?
   - **A.** Albumin is too large to be filtered.
   - **B.** Albumin is not filtered because the glomerular barrier is positively charged.
   - **C.** Hydrostatic pressure in the glomerular capillaries is the only force for filtration.
   - **D.** Dilation of the afferent arteriole, but not the efferent arteriole, can increase filtration rate.
   - **E.** Mesangial cells do not influence filtration rate.
2. Fanconi syndrome is a disorder of the proximal tubule. Patients can present with glycosuria, polyuria, hypercalciuria, hyperphosphaturia, and low-molecular-weight proteinuria. These features can be explained because the proximal tubule normally:
   - **A.** Reabsorbs about 100% of the filtered glucose
   - **B.** Reabsorbs approximately 65% of the filtered water, because of a large transepithelial osmotic gradient
   - **C.** Actively reabsorbs calcium through Ca^{2+}-ATPase in the apical membrane
   - **D.** Secretes phosphate through the organic anion transporter system
   - **E.** Is a tight epithelium, impermeable to paracellular movement of proteins
3. The corticomedullary osmotic gradient is required for urine concentration. Which of the following would diminish this gradient?
   - **A.** Increased circulating vasopressin
   - **B.** Increased blood flow through the renal medulla
   - **C.** Activation of the sympathetic nervous system
   - **D.** Activation of the renin-angiotensin-aldosterone system
   - **E.** Increased urea recycling through the collecting duct system

Assessment of Glomerular Filtration Rate

Lesley A. Inker, Andrew S. Levey

The level of glomerular filtration rate (GFR) is widely accepted as the best overall index of kidney function in health and disease. GFR decline is correlated with decline in other excretory functions of the kidney, such as tubular reabsorption and secretion, as well as with decline in endocrine and metabolic functions of the kidney. Decreased GFR is strongly associated with complications of acute and chronic kidney disease (CKD), and decreased GFR is one criterion in the definition and staging of acute and CKD. GFR estimating equations are now recommended for routine use in clinical practice, and estimated GFR is routinely reported when serum creatinine is measured.

GLOMERULAR FILTRATION RATE

GFR is the product of the average filtration rate of each nephron, the filtering unit of the kidneys, multiplied by the number of nephrons in both kidneys. The normal level for GFR is approximately 130 ml/min/1.73 m^2 for men and 120 ml/min/1.73 m^2 for women, with considerable variation among individuals according to age, gender, body size, physical activity, diet, pharmacotherapy, hyperglycemia, and physiologic states such as pregnancy. To standardize GFR for differences in kidney size, which is proportional to body size, GFR is indexed for body surface area (BSA), computed from height and weight, and is expressed per 1.73 m^2 BSA, the mean BSA of young men and women when indexing was proposed. Even after adjustment for BSA, GFR is approximately 8% higher in young men than in women and declines with age; the mean rate of decline is approximately 0.75 ml/min/yr after 40 years of age, but the variation is wide and the sources of variation are poorly understood. During pregnancy, GFR increases by about 50% in the first trimester and returns to normal immediately after delivery. GFR has a diurnal variation and is 10% lower at midnight compared with the afternoon. In an individual, GFR is relatively constant over short intervals of time but varies considerably among people, even after adjustment for the known variables.

Reductions in GFR may result from a decline in the nephron number or in the single-nephron (SN) GFR from physiologic or hemodynamic alterations. An increase in SNGFR caused by increased glomerular capillary pressure or glomerular hypertrophy can compensate for a decrease in nephron number; therefore the level of GFR may not reflect the loss of nephrons. As a result, there may be substantial kidney damage before GFR decreases.

MEASUREMENT AND ESTIMATION OF THE GLOMERULAR FILTRATION RATE

The GFR cannot be measured directly in humans. Instead, it is assessed from clearance measurements or serum levels of filtration markers, exogenous or endogenous solutes that are mainly eliminated by glomerular filtration. Both measured GFR (mGFR) and estimated GFR (eGFR) are associated with systematic and random error (bias and imprecision, respectively) in their determination and thus may differ from the "true GFR."

The classic method for GFR measurement described by Homer Smith is the urinary clearance of inulin and remains the reference (gold standard) against which other clearance methods and filtration markers are evaluated.[1] However, this technique is cumbersome in practice. Therefore many alternative clearance methods and filtration markers are used in clinical centers and as a research tool (Table 3.1). Recently, methods to estimate the GFR from serum levels of endogenous filtration markers have been developed to simplify GFR assessment without requiring administration of exogenous filtration markers and without performing clearance measurements. The principles of GFR estimation are similar in adults and children, but we discuss only GFR estimating equations developed in adults.

CLEARANCE MEASUREMENTS

Concept of Clearance

Clearance of a substance is defined as the volume of plasma cleared of a marker per unit of time. The clearance of substance x (C_x) can be calculated as $C_x = A_x/P_x$, where A_x is the amount of x eliminated from the plasma, P_x is the average plasma concentration, and C_x is expressed in units of volume per time. Clearance does not represent an actual volume; rather, it is a virtual volume of plasma that is completely cleared of the substance per unit of time. The value for clearance is related to the efficiency of elimination: the greater the efficiency of elimination, the higher the clearance. Clearance of substance x is the sum of the urinary and extrarenal clearance; for substances that are eliminated by renal and extrarenal routes, plasma clearance exceeds urinary clearance. By convention we refer to concentration in plasma when discussing physiologic principles and serum when discussing clinical measures. In practice, laboratory measurements of markers of glomerular

TABLE 3.1 Exogenous Filtration Markers for Estimation of Glomerular Filtration Rate

Marker	Method of Administration	Comments
Inulin	Continuous IV infusion	Gold standard.
Iothalamate	Bolus IV injection or subcutaneous injection	Can be administered as radioactive compound with iodine 125 (^{125}I) as the tracer or in nonradioactive form, with assay using HPLC or MS methods in plasma and whole blood. In radioactive form, potential problem of thyroid uptake of ^{125}I. Iothalamate is secreted, leading to overestimation of GFR.
^{99m}Tc-DTPA	Bolus IV injection	Dissociation of ^{99m}Tc leads to plasma protein binding and underestimation of GFR.
^{51}Cr-EDTA	Bolus IV injection	10% lower clearance than inulin.
Iohexol	Bolus IV injection	Low incidence of adverse effects; assay using HPLC or MS methods in plasma and whole blood. Lower urinary clearance than iothalamate.

^{51}*Cr-EDTA,* Chromium 51–labeled ethylenediaminetetraacetic acid; *GFR,* glomerular filtration rate; *HPLC,* high-performance liquid chromatography; *IV,* intravenous; *MS,* mass spectrophotometric; ^{99m}*Tc-DTPA,* technetium 99m–labeled diethylenetriaminepentaacetic acid.

filtration are similar in plasma and serum and are generally referred to as serum concentrations.

Urinary Clearance

The amount of substance *x* excreted in the urine can be calculated as the product of the urinary flow rate *(V)* and the urinary concentration (U_x). Therefore urinary clearance is defined as follows:

$$C_x = (U_x \times V)/P_x$$

Urinary excretion of a substance depends on filtration, tubular secretion, and tubular reabsorption. Substances that are filtered but not secreted or reabsorbed by the tubules are ideal filtration markers because their urinary clearance can be used as a measure of GFR. For substances that are filtered and secreted, urinary clearance exceeds GFR, and for substances that are filtered and reabsorbed, urinary clearance is less than GFR.

Measurement of urinary clearance requires a timed urine collection for measurement of urine volume, as well as urine and plasma concentrations of the filtration marker. The classic protocol of Smith[1] used a continuous intravenous infusion to achieve a steady state and bladder catheterization with multiple timed urine collections. Alternative protocols to assess urinary clearance have been validated, including bolus intravenous or subcutaneous administration rather than continuous intravenous infusion and spontaneous bladder emptying rather than bladder catheterization. Bolus administration of the marker results in declining plasma levels of the filtration markers during the clearance measurement, which may cause errors in determining the average plasma concentration during the clearance measurement.

Plasma Clearance

Measurement of plasma clearance avoids the need for a timed urine collection. GFR is calculated from plasma clearance (C_x) after bolus intravenous administration of an exogenous filtration marker, with

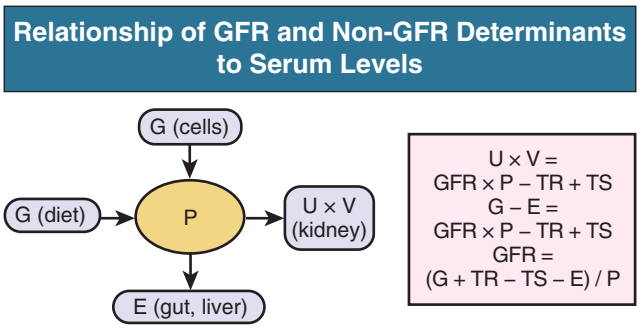

Fig. 3.1 Relationship of GFR and non-GFR determinants to serum levels. *G,* Generation; *GFR,* glomerular filtration rate; *E,* extrarenal elimination; *P,* plasma; *TR,* tubular reabsorption; *TS,* tubular secretion. (Modified from reference 50.)

the clearance (C_x) computed from the amount of the marker administered (A_x) divided by the average plasma concentration (P_x), which can be computed from the area under the curve of plasma concentration versus time.

$$C_x = A_x/P_x$$

The decline in plasma levels is secondary to the immediate disappearance of the marker from the plasma into its volume of distribution (fast component) and to renal excretion (slow component). Plasma clearance is best estimated by use of a two-compartment model that requires blood sampling early (usually two or three time points until 60 minutes) and late (one to three time points from 120 minutes onward).[2] Novel methods are under investigation to shorten the time required for clearance measurements.[3] As with urinary clearance, plasma clearance of a substance depends on filtration, tubular secretion, and tubular reabsorption, but, in addition, extrarenal elimination and the time course for equilibration of the filtration marker between plasma and its volume of distribution. Edematous conditions prolong the distribution from plasma to extracellular fluid and may cause error in GFR. Extrarenal elimination has been demonstrated for several filtration markers.

ESTIMATION OF THE GLOMERULAR FILTRATION RATE

Fig. 3.1 shows the relationship of plasma concentration of substance *x* to its generation (G_x) by cells and dietary intake, urinary excretion ($U_x \times V$), and extrarenal elimination (E_x) by gut and liver. The plasma level is related to the reciprocal of the level of GFR, but it is also influenced by generation, tubular secretion and reabsorption, and extrarenal elimination, collectively termed *non-GFR determinants* of the plasma level.[4]

In the steady state, a constant plasma level of substance *x* is maintained because generation is equal to urinary excretion and extrarenal elimination. Estimating equations incorporate demographic and clinical variables as surrogates for the non-GFR determinants and provide a more accurate estimate of GFR than the reciprocal of the plasma level alone. eGFR may differ from mGFR if a discrepancy exists between the true and average values for the relationship of the surrogate to the non-GFR determinants of the filtration marker. Other sources of errors include measurement error in the filtration marker (e.g., failure to calibrate assay for filtration marker to assay used in development of equation), measurement error in GFR in development of the equation, and regression to the mean. In principle, all these errors are likely to be greater at higher values for GFR, although such errors may be more clinically significant at lower measured GFR.

Filtration Markers

Solutes with molecular weight less than approximately 20,000 daltons and not bound to plasma proteins are freely filtered by the glomeruli and are candidate filtration markers.

Exogenous Filtration Markers

Iothalamate, iohexol, ethylenediaminetetraacetic acid, and diethylenetriaminepentaacetic acid, often chelated to radioisotopes for ease of detection, are commonly used alternatives to inulin (see Table 3.1). Deviations from ideal behavior can be inferred from differences from inulin clearance during simultaneous clearance measurements.

Endogenous Filtration Markers

Endogenous filtration markers are substances generated in the body at a relatively constant rate and eliminated largely by glomerular filtration. Therefore the plasma level correlates highly with measured GFR after accounting for the non-GFR determinants. Currently identified endogenous filtration markers include low-molecular-weight metabolites (such as creatinine and urea) and plasma proteins (such as cystatin C) (Table 3.2). Filtered metabolites may undergo reabsorption or secretion, which may be assessed by comparing their urinary clearance to urinary clearance of exogenous filtration markers. By contrast, filtered plasma proteins are reabsorbed and degraded within the tubule with minimal appearance in the urine. For metabolites excreted in the urine, urinary clearance can be computed from a timed urine collection and a single measurement of serum concentration. If the plasma level is not constant during the urine collection, as in acute kidney disease or when residual kidney function is assessed in patients undergoing intermittent dialysis, it is necessary to obtain additional blood samples during the urine collection to estimate the average plasma concentration.

CREATININE

Metabolism and Excretion

Creatinine is a 113-d end product of muscle catabolism. Advantages of creatinine include its ease of measurement and the low cost and widespread availability of assays (see Table 3.2). Disadvantages include the large number of conditions affecting its non-GFR determinants, leading to a wide range of GFR for a given serum creatinine level (Table 3.3). For example, a serum creatinine level of 1.5 mg/dl (132 µmol/l) may correspond to a GFR from approximately 20 to 90 ml/min/1.73 m^2.

Creatinine is derived by the metabolism of phosphocreatine in muscle, as well as from dietary meat intake or creatine supplements. Creatinine generation is proportional to muscle mass, which can be estimated from age, gender, race, and body size, but many other factors can affect

TABLE 3.2 Creatinine, Cystatin C, and Urea as Endogenous Filtration Markers

Variable	Creatinine	Cystatin C	Urea
Molecular Properties			
Weight (daltons)	113	13,000	60
Structure	Amino acid derivative	Nonglycosylated basic protein	Organic molecular product of protein metabolism
Physiologic Determinants of Serum Level			
Generation	Varies, according to muscle mass and dietary protein; lower in elderly persons, women, and whites	Thought to be mostly constant by all nucleated cells; increases in hyperthyroid state and with steroid use; lower in elderly persons and women	Varies, according to dietary protein intake and catabolism
Handling by kidney	Filtered, secreted, and excreted in urine	Filtered, reabsorbed, and catabolized	Filtered, reabsorbed, and excreted in urine
Extrarenal elimination	Yes; increases at reduced GFR	Preliminary evidence of increases at reduced GFR	Yes; increases at reduced GFR
Use in Estimating Equations for GFR			
Demographic and clinical variables as surrogates for physiologic determinants	Age, gender, and race; related to muscle mass	Age, sex	Not applicable
Accuracy	Accurate for GFR <60 ml/min/1.73 m^2	Unknown	Not applicable
Assay			
Method	Colorimetric or enzymatic	PENIA, PETIA, or ELISA	Direct measurement, enzymatic colorimetric, and electrochemical
Assay precision	Very good except at low range	Precise throughout range, but difficult to standardize	Precise throughout range
Clinical laboratory practice	Multiple assays; widely used nonstandard calibration	Not on most autoanalyzers; not standardized	Multiple assays; enzymatic and colorimetric more common
Standardized recommendation materials (SRMs)	SRM 967	ERM-DA471/IFCC	SRM 912a
Reference assay	IDMS	PENIA, PETIA, or ELISA	IDMS

ELISA, Enzyme-linked immunosorbent assay; *GFR,* glomerular filtration rate; *IDMS,* isotope-dilution–mass spectroscopy; *PENIA,* particle-enhanced nephelometric immunoassay; *PETIA,* particle-enhanced turbidimetric immunoassay.

TABLE 3.3 Factors Affecting Serum Creatinine and Cystatin C Concentrations Independent From Glomerular Filtration Rate

Factors	Effect on Creatinine (Direction/*Mechanism*)	Effect on Cystatin C (Direction/*Mechanism*)
Age	Decrease *Lower creatinine generation caused by age-related decline in muscle mass*	Decrease *Presumed lower cystatin C generation caused by age-related decreased cellular mass, smaller impact than creatinine*
Female sex	Decrease *Lower creatinine generation caused by lower muscle mass*	Decrease *Presumed lower cystatin C generation caused by lower cellular mass, smaller impact than creatinine*
Race		
African American	Increase *Higher creatinine generation caused by higher average muscle mass in African Americans; not known how muscle mass in other races compares with that of African Americans or Caucasians*	No effect
Diet		
Vegetarian	Decrease *Lower creatinine generation*	No effect
Ingestion of cooked meats and creatinine supplements	Increase *Transient increase in creatinine generation, although this may be blunted by transient increase in GFR*	No effect
Body Habitus		
Larger muscle mass	Increase *Higher muscle generation caused by increased muscle mass and/or increased protein intake*	No effect
Smaller muscle mass (e.g., amputation, anorexia)	Decrease *Lower creatinine generation caused by reduced muscle mass and/or reduced protein intake*	No effect
Malnutrition, muscle wasting, in context of chronic illness	Decrease *Lower creatinine generation caused by reduced muscle mass and/or reduced protein intake*	Possible increase *Presumed higher cystatin C generation in conditions associated with inflammation*
Obesity	No change *Excess fat mass, not muscle mass, which does not contribute to creatinine generation*	Increase *Presumed higher cystatin C generation by excess fat mass*
Medications		
Trimethoprim, cimetidine, fibric acid derivatives other than gemfibrozil	Increase *Reduced tubular secretion of creatinine*	No known effects, not studied
Ketoacids, some cephalosporins	Interference with alkaline picrate assay for creatinine	No known effects, not studied

creatinine generation. Creatinine is distributed in total body water, not protein bound, and freely filtered across the glomerulus and secreted by the tubules. Several medications, such as cimetidine, trimethoprim, and possibly fenofibrate, competitively inhibit creatinine secretion, leading to a rise in the serum creatinine concentration without an effect on GFR.

In addition, creatinine is contained in intestinal secretions and can be degraded by bacteria; gastrointestinal elimination of creatinine is increased at higher levels of serum creatinine but can be reduced by changes in gut flora due to antibiotic use. Clinically, it can be difficult to distinguish a rise in serum creatinine concentration caused by inhibition of creatinine secretion or extrarenal elimination from a decline in GFR.

Creatinine clearance (Clcr) is usually computed from the creatinine excretion in a 24-hour urine collection and single measurement of serum creatinine in the steady state. Creatinine excretion rates vary with age, gender, and race, with mean levels of approximately 20 to 25 mg/kg/day and 15 to 20 mg/kg/day in a complete collection in healthy young men and women, respectively. Deviations from estimated creatinine excretion (based on age, gender, weight, and other variables)[5] can indicate errors in timing or completeness of urine collection, but cannot be relied on because of wide variability in creatinine generation.

Creatinine Assay

Historically, the most common assay for measurement of serum creatinine was the alkaline picrate (Jaffe) assay that generates a color reaction. Chromogens other than creatinine can interfere with the assay, causing errors of up to 20% in normal individuals. Reference materials traceable to an isotope-dilution–mass spectrometry (IDMS) reference are now available to standardize creatinine measurements, and most

manufacturers have now calibrated their instruments using these reference materials.[6,7] Standardization has reduced, but not eliminated the error in estimating GFR at higher levels.

Estimated Glomerular Filtration Rate From Serum Creatinine

GFR can be estimated from serum creatinine ($eGFR_{cr}$) by equations that use age, gender, race, and body size as surrogates for creatinine generation. Despite ongoing refinements in recent years, GFR estimates remain imprecise; none of the equations is expected to work as well in patients with extreme levels for creatinine generation, such as amputees, large or small individuals, patients with muscle-wasting conditions, or people with atypical pattern of meat consumption (see Table 3.3). Also, equations developed in one racial or ethnic group are unlikely to be accurate in multiethnic populations. As discussed later, further improvements will probably require additional filtration markers.

Equation Currently Recommended for Use

The Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) 2009 creatinine equation was developed from a large database of people, including those with and without kidney disease, diabetes, and a history of organ transplantation.[8] The equation includes age, race, and sex and standardized serum creatinine. It uses a two-slope "spline" to model the relationship between GFR and serum creatinine and is accurate across the full range of GFR. It is accurate across a wide range of patient characteristics, including age, gender, race, body mass index (BMI), and presence or absence of diabetes or history of organ transplantation. The 2012 Kidney Disease: Improving Global Outcomes (KDIGO) guidelines recommend that clinical laboratories use CKD-EPI creatinine equations to report eGFR in all adults whenever serum creatinine is measured or use other equations if shown to be superior to CKD-EPI equation in that population (Box 3.1).[9]

Equations Previously Recommended for Use

The Cockcroft-Gault equation, developed in 1977, estimates Clcr from age, gender, and body weight, in addition to serum creatinine.[10] Comparison to normal values for Clcr requires computation of BSA and adjustment to 1.73 m^2. The Cockcroft-Gault formula has several limitations. First, it is not precise, in particular in the GFR range above 60 ml/min. Second, it estimates Clcr rather than GFR and thus is expected to overestimate GFR. Third, the formula was derived by older assay methods for serum creatinine, which cannot be calibrated to newer assay methods and would be expected to lead to a systematic bias in estimating Clcr. Fourth, it systematically overestimates Clcr in edematous or obese patients. Fifth, the large age term means that all older adults will have lower levels of estimated GFR.

The Modification of Diet in Renal Disease (MDRD) study equation[11] is similar to the CKD-EPI equation and more accurate than the Cockcroft-Gault equation. However, it was derived from a study population with CKD, so it underestimates the measured GFR in populations with higher levels of GFR, and numeric values cannot be reported for GFR levels greater than 60 ml/min/1.73 m^2.[12]

Other Equations That Could Be Considered for Use in Selected Populations

Several equations developed in Europe and North America and using standardized creatinine appear to be as accurate as the CKD-EPI equation for whites, but are not applicable for African American or other races.[13-15] Other equations have been developed in Asian and African populations that improve the accuracy of GFR estimates in the study population; however, these equation modifications do not generalize well to other populations.[16-21]

CYSTATIN C

Metabolism and Excretion

Cystatin C is a 122–amino acid protein with molecular weight of 13 kd (see Table 3.2).[22] Cystatin C is produced in all nucleated cells and is distributed in extracellular fluid. Approximately 99% of the filtered cystatin C is reabsorbed by the proximal tubular cells, where it is almost completely catabolized, with the remainder eliminated in the urine largely intact.[23] Some evidence suggests the existence of tubular secretion as well as extrarenal elimination, the latter estimated at 15% to 21% of renal clearance. Smoking, inflammation, adiposity, thyroid diseases, certain malignant neoplasms, and use of glucocorticoids appear to be associated with higher cystatin C levels independent of mGFR.[24,25] Therefore factors other than GFR must be considered in interpreting cystatin C levels.

Cystatin C Assay

Several assays are available (all more expensive than those for creatinine). The International Federation of Clinical Chemists (IFCC) has developed reference material for standardization of cystatin C, but international standardization of the assay is still in process and important differences remain.[26-28]

Estimated Glomerular Filtration Rate From Serum Cystatin C

Cystatin C is less affected by muscle than creatinine, but eGFR based on serum cystatin C ($eGFR_{cys}$) is not more accurate than $eGFR_{cr}$, because of variation in conditions affecting non-GFR determinants of serum cystatin C. However, equations combining both these filtration markers ($eGFR_{cr\text{-}cys}$) appear to be more precise than equations using either marker alone. The 2012 CKD-EPI cystatin C and creatinine–cystatin C equations are expressed for use with standardized serum creatinine and cystatin C and are recommended by the 2012 KDIGO guidelines (see Box 3.1).[9,29] The equation using cystatin C without creatinine includes age and sex, but does not require specification of race. In patients with reduced muscle mass (e.g., neuromuscular or liver disease, low BMI) or in patients with diabetes, $eGFR_{cys}$ may be more accurate than $eGFR_{cr}$. Other recent equations using cystatin C have been developed;

regional modifications appear to be less important for $eGFR_{cys}$ than for $eGFR_{cr}$.[14,30,31]

Some studies show that a lower $eGFR_{cys}$ is a better predictor of the risk for cardiovascular disease and total mortality than is a lower $eGFR_{cr}$.[32] In our view, this is likely due to confounding by non-GFR determinants of cystatin C and creatinine. Because of better accuracy and risk prediction, $eGFR_{cr\text{-}cys}$ is recommended as a confirmatory test for CKD, but full implementation will require standardization, greater availability, and cost reductions of cystatin C assays, as well as better understanding of non-GFR determinants of serum cystatin C (see Box 3.1).[9,29]

UREA AND OTHER METABOLITES

The serum urea level has limited value as an index of GFR, in view of widely variable non-GFR determinants, primarily urea generation and tubular reabsorption (see Table 3.2).

Urea is a 60-d end product of protein catabolism by the liver. Factors associated with the increased generation of urea include protein loading from hyperalimentation and absorption of blood after a gastrointestinal hemorrhage. Catabolic states caused by infection, corticosteroid administration, or chemotherapy also increase urea generation. Decreased urea generation is seen in patients with severe malnutrition and liver disease.

Urea is freely filtered by the glomerulus and then passively reabsorbed in both proximal and distal nephrons. As a result of tubular reabsorption, urinary clearance of urea underestimates GFR. Reduced kidney perfusion in the patient with volume depletion and states of antidiuresis are associated with increased urea reabsorption. This leads to a greater decrease in urea clearance than the concomitant decrease in GFR. At GFR of less than about 20 ml/min/1.73 m^2, the overestimation of GFR by Clcr resulting from creatinine secretion approximates the underestimation of GFR by urea clearance from urea reabsorption; thus the average of creatinine and urea clearance approximates the measured GFR.

Recent advances in assays for metabolites have revealed a number of compounds, such as pseudouridine and acetylthreonine, that are highly correlated with GFR and may have promise for GFR estimation.[33,34]

OTHER LOW-MOLECULAR-WEIGHT SERUM PROTEINS

β_2-Microglobulin (β_2M) and β-trace protein (βTP) are low-molecular-weight serum proteins being evaluated as filtration markers for estimating GFR and for their role in prognosis. As with cystatin C, β_2M and βTP are freely filtered by the glomerulus and extensively reabsorbed and degraded by the proximal tubule, with only small amounts excreted in the urine under normal conditions.

Serum β_2M and βTP levels are more strongly correlated with measured GFR than serum creatinine and are similar to cystatin C. Like cystatin C, serum β_2M and βTP are less influenced by age, sex, and race than creatinine, but GFR estimating equations using these markers are not more accurate than equations using creatinine and cystatin C.[24,35] In addition, studies have shown that β_2M and βTP are better predictors of adverse health outcomes than creatinine and are potentially as accurate as cystatin C in the general population and in patients with CKD.[36]

A recent study shows that serum β_2M and βTP can be used to estimate residual kidney function in patients on dialysis.[37] The likely explanation is that they are too large to be filtered by conventional dialysis membranes, so their serum concentrations reflect residual kidney function rather than the dialysis dose.

CLINICAL APPLICATION OF ESTIMATED GLOMERULAR FILTRATION RATE

Chronic Kidney Disease

Estimation of GFR is necessary for the detection, evaluation, and management of patients with CKD. GFR less than 60 ml/min/1.73 m^2 for 3 months or longer is one of the criteria for the definition of CKD (see Box 3.1).[9] Current guidelines recommend testing of patients at increased risk for CKD for decreased GFR as well as albuminuria, as a marker of kidney damage, and recommend staging of kidney disease severity and estimating prognosis using levels of albuminuria and GFR (see Box 3.1).[9] The Kidney Failure Risk Equation, a recently developed and validated prediction instrument uses age, sex, GFR, and urine albumin-to-creatinine ratio to predict the risk for onset of kidney failure within 2 or 5 years.[38]

Use of serum creatinine alone as an index of GFR is not recommended and can lead to delays in detection of CKD and misclassification of the severity of CKD. Use of estimating equations allows direct reporting of eGFR by clinical laboratories whenever serum creatinine is measured. Current estimating equations are less accurate in people with factors affecting serum creatinine concentration other than GFR (see Table 3.3). In these patients, more accurate GFR estimates require additional testing, such as measurement with an endogenous filtration marker (e.g., cystatin C, β_2M, βTP), a timed urine Clcr measurement, or clearance measurement using an exogenous marker. The KDIGO CKD guidelines recommend use of $eGFR_{cr}$ as an initial test followed by $eGFR_{cr\text{-}cys}$ or a clearance measurement for confirmation in conditions in which eGFR may be inaccurate (Fig. 3.2). Examination of consistency of the results in GFR estimates and clearance measurements is recommended. If the results are inconsistent, clinicians should consider possible reasons for the inconsistency, such as differences in expected creatinine excretion and non-GFR determinants of creatinine and cystatin C, and eliminate the inconsistent value from consideration, repeating the measurement, or performing a measured GFR using an exogenous marker.

Change in serum creatinine is routinely used to assess the progression of kidney disease, and quantitative associations with risk for end-stage renal disease (ESRD) are now available. For those with GFR less than 60 ml/min/1.73 m^2, a decline in eGFR within 2 years of 30%, 40%, and 57% (corresponding to a 1.3-, 1.5-, and 2.0-fold increase in serum creatinine), corresponded to a 5.4, 10.2, and 32.1 times higher risk for developing ESRD in the subsequent 2 to 4 years compared with a stable eGFR.[39] Similar results were observed for those with a GFR greater than 60 ml/min/1.73 m^2. The current level of eGFR was more strongly associated with ESRD risk than the rate of decline.[40] Similar results were observed for associations with mortality.

Acute Kidney Disease

Change in GFR induces a non-steady state in the serum levels of endogenous filtration markers (Fig. 3.3). After a decline in GFR, there is a lag before the rise in serum level because of the time required for retention of an endogenous filtration marker. Conversely, after recovery of GFR, there is a lag before the excretion of the retained marker. During the non-steady state, neither the serum level nor the GFR estimated from the serum level accurately reflects the measured GFR. Nonetheless, a change in the eGFR in the non-steady state can be a useful indication of the magnitude and direction of the change in measured GFR. If the eGFR is decreasing, the decline in eGFR is less than the decline in mGFR. Conversely, if the eGFR is increasing, the rise in eGFR is greater than the rise in mGFR. The more rapid the change in eGFR, the greater is the change in measured GFR. When eGFR reaches a new steady state, it more accurately reflects measured GFR. A GFR estimating equation

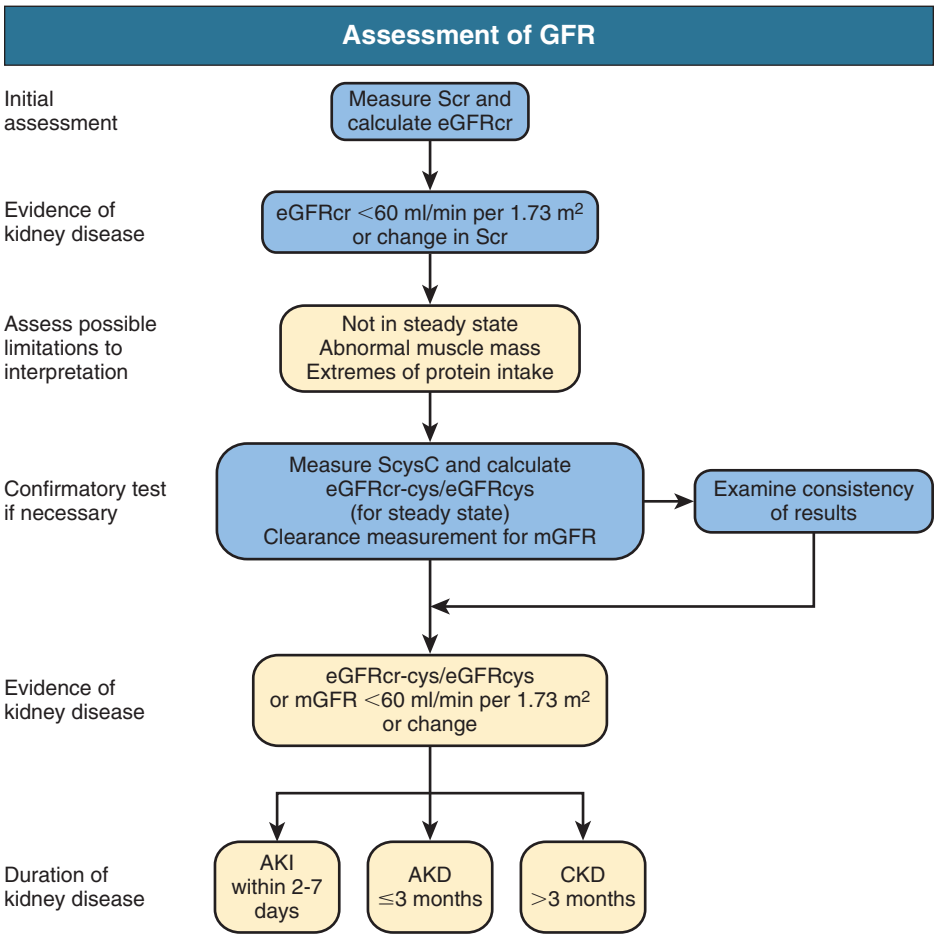

Fig. 3.2 Algorithm for GFR assessment in acute and chronic kidney diseases. *AKD,* Acute kidney disease; *AKI,* acute kidney injury; *CKD,* chronic kidney disease; *eGFR,* estimated glomerular filtration rate; $eGFR_{cr}$, eGFR from serum creatinine; $eGFR_{cr\text{-}cys}$, eGFR from creatinine and cystatin C; $eGFR_{cys}$, eGFR from cystatin C; *mGFR,* measured glomerular filtration rate; *Scr,* serum creatinine; *ScysC,* cystatin C.

for use in the non-steady state has been proposed, but has not yet been validated.[41]

An increase in serum creatinine by 0.3 mg/dl over 48 hours or by 50% over 7 days are criteria for the definition of acute kidney injury (AKI) (see Box 3.1).[42] The absolute and proportionate increase in serum creatinine are influenced by the baseline GFR as well as the magnitude of decline in GFR (Fig. 3.4).[43] In patients with AKI, serum cystatin C appears to increase more rapidly than serum creatinine.[44] More data are required to establish whether changes in serum cystatin C are a more sensitive indicator of rapidly changing kidney function than changes in serum creatinine. In addition, similar to CKD, $eGFR_{cr}$ might be inappropriate in patients with differences in muscle mass or dietary protein intake, and in such patients it would be possible to confirm the change in $eGFR_{cr}$ with changes in $eGFR_{cys}$ or clearance measures (see Fig. 3.2).

LIVING KIDNEY DONOR CANDIDATES

Despite the larger imprecision of GFR estimates at higher levels of GFR, recent KDIGO guidelines on evaluation of the living kidney donor state that eGFR could be used in the evaluation of living kidney donor candidates (see Box 3.1).[45] In the United States, where evaluation of living kidney donor candidates requires a measured clearance, eGFR could be used as a first test with measured clearance as a confirmatory test.[46,47] Performance of multiple tests and assessment of the consistency of their results is helpful to identify possible sources of error. Elsewhere, eGFR could be used to accept or decline donor candidates if the probability is very high that mGFR is above or below, respectively, the thresholds for decision making.[48]

DRUG DOSING

Pharmacokinetic properties of many drugs are affected by acute and chronic kidney disease. Drug dosing must be adjusted in patients with alterations in GFR to ensure therapeutic levels. The Cockcroft-Gault formula was widely used to assess pharmacokinetic properties of drugs in patients with impaired kidney function, but, because of the limitations described previously, the KDIGO Controversies Conference Report recommends that GFR, as it is best evaluated in an individual patient, be used to assess kidney function for drug dosing, rather than a specific equation (see Box 3.1).[49] For drug dosing, GFR should be expressed without indexing for BSA. To convert from ml/min/1.73 m^2 to ml/min, multiply by BSA/1.73 m^2.

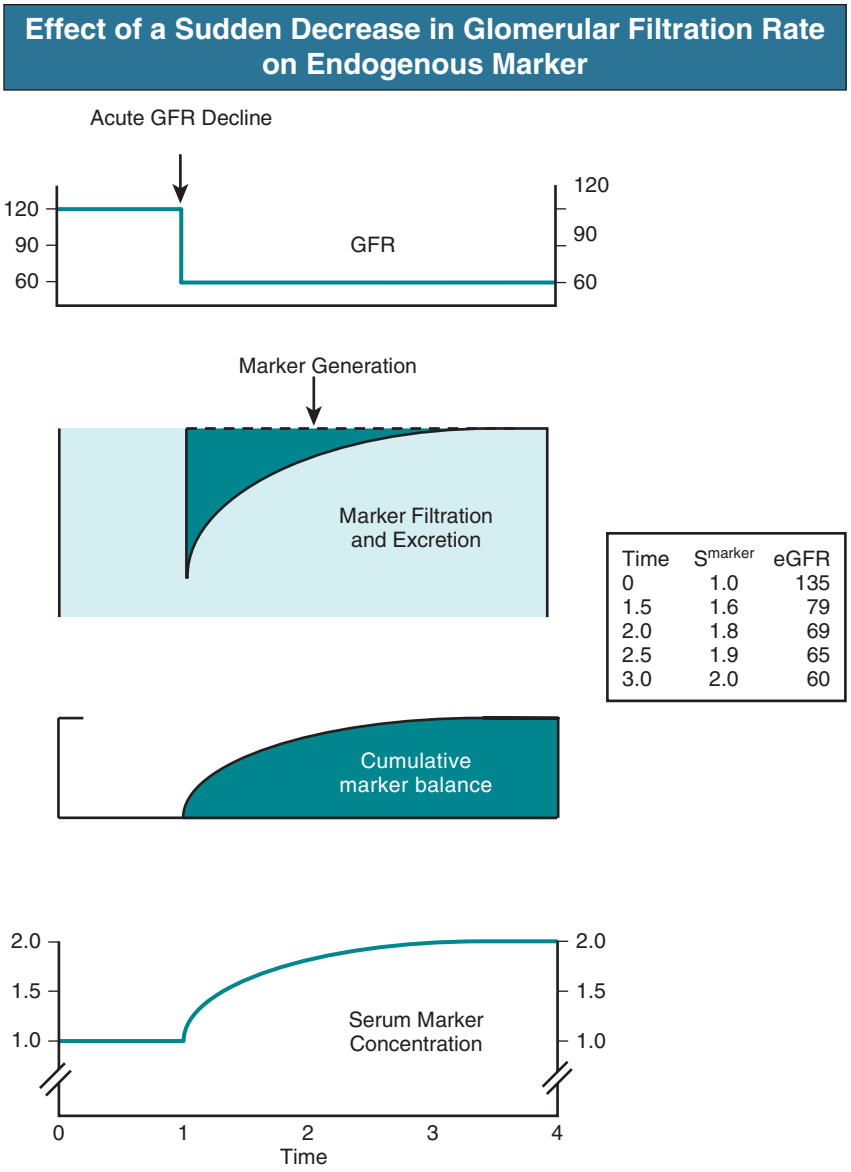

Fig. 3.3 Change in serum ceatinine and eGFR after a sudden decrease in GFR. Graphs show the effect of acute GFR decline *(top)* on generation, filtration and excretion, balance of endogenous marker *(middle),* and concentration of serum marker (S^{marker}) *(bottom).*

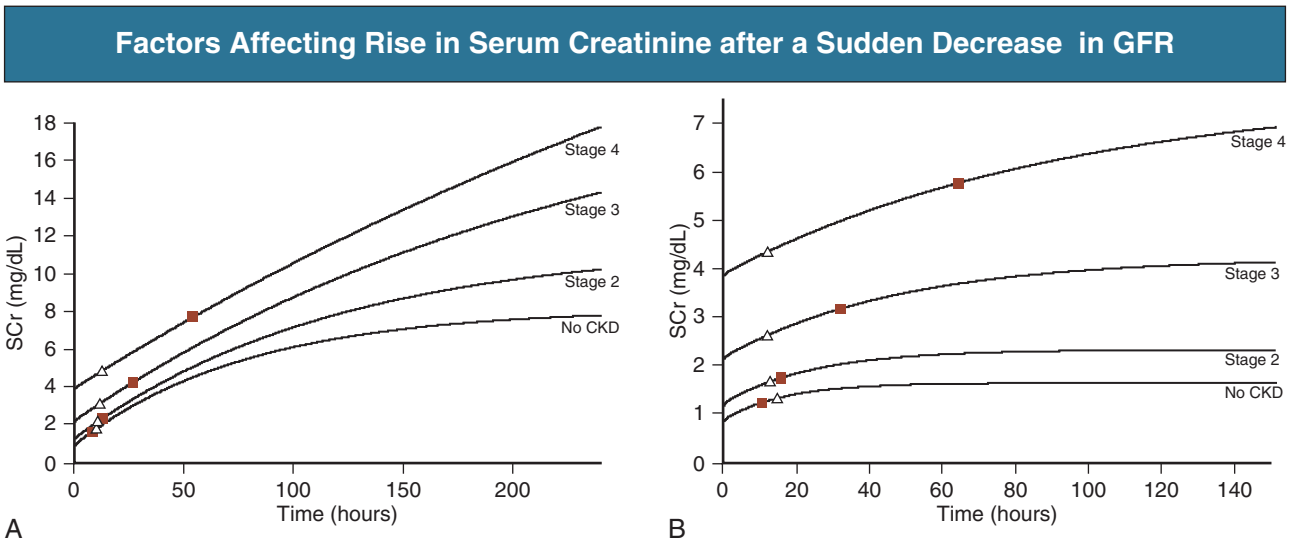

Fig. 3.4 Factors affecting rise in serum creatinine after a sudden decrease in GFR. (A) Serum creatinine concentrations after an abrupt 90% reduction in GFR, superimposed on four different levels of baseline kidney function (no CKD and stages 2 through 4 CKD). *Solid squares* show the point at which a 100% increase in serum creatinine has occurred; *open triangles* show the point at which a 1.0-mg/dl increase in serum creatinine has occurred. (B) Serum creatinine concentrations after an abrupt 50% reduction in GFR, superimposed on four different levels of baseline kidney function (no CKD and CKD stages 2 through 4). *Solid squares* show the point at which a 100% increase in serum creatinine has occurred; *open triangles* show the point at which a 1.0-mg/dl increase in serum creatinine has occurred. (Modified from reference 43.)

SELF-ASSESSMENT QUESTIONS

1. A 59-year-old, 100-kg, 193-cm-tall white man has a serum creatinine concentration of 1.5 mg/dl. Estimated glomerular filtration rate (GFR) using the chronic kidney disease Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) creatinine equation and standardized serum creatinine is 50 ml/min/1.73 m^2, but measured GFR is 90 ml/min/1.73 m^2. What factor most likely explains the underestimation of measured GFR?
   A. Non-steady state of serum creatinine
   B. Drug-induced inhibition of tubular secretion of creatinine
   C. Decreased extrarenal elimination of creatinine
   D. Increased creatinine generation from large muscle mass or diet
2. An 80-year-old white woman has a serum creatinine concentration of 1.0 mg/dl for 3 months. Her estimated GFR using the CKD-EPI creatinine equation and standardized serum creatinine is 53 ml/min/1.73 m^2. She has no chronic kidney disease risk factors. What laboratory tests could be performed to confirm the diagnosis of chronic kidney disease?
   A. Measure urine albumin-to-creatinine ratio.
   B. Measure GFR using an exogenous filtration marker.
   C. Measure serum cystatin C and calculate $eGFR_{cys}$.
   D. Image the kidneys and urinary tract.
   E. Examine the urine sediment.
   F. Any of the above.
3. A 40-year-old man with type 1 diabetes mellitus and urine albumin-to-creatinine ratio of 450 mg/g begins angiotensin-converting enzyme (ACE) inhibitor therapy to slow the progression of kidney disease. Within 2 weeks, $eGFR_{cr}$ declines from 75 to 65 ml/min/1.73 m^2. What is the most likely cause for decline in eGFR?
   A. Effect of ACE inhibitor on serum creatinine assay
   B. Effect of ACE inhibitor on GFR
   C. Effect of ACE inhibitor on tubular secretion of creatinine
   D. Effect of ACE inhibitor on muscle mass

Urinalysis

Giovanni B. Fogazzi, Giuseppe Garigali

DEFINITION

Urinalysis is one of the key tests to evaluate kidney and urinary tract disease. When a patient is first seen by a nephrologist, urinalysis must always be performed. Reagent strips are still the most widely used method for urinalysis to supply physicochemical information. However, the nephrologist should be aware of their limitations and ask for more sensitive and specific measurements by other methods in the case of reagent strip abnormalities (e.g., the accurate measurement of proteinuria in case of reagent strip positivity for albumin).[1]

As well as physiochemical findings, urine sediment examination is an integral part of urinalysis[2,3] and ideally should be performed by nephrologists, who may be able to identify particles of clinical relevance that escape laboratory personnel.[4]

THE URINE SAMPLE

The use of an early morning urine sample is suggested by the Kidney Disease: Improving Global Outcomes (KDIGO) guideline,[1] especially for the measurement of albumin (see later discussion).

However, the 24-hour urine collection is still widely used for the measurement of multiple parameters, even though errors caused by improper timing and missed samples can lead to overcollection or undercollection of urine. Errors can be minimized by giving the patient clear written instructions (e.g., at 7:00 AM discard the first urine of the morning; then collect in a capacious—of at least 2.5 L—and graduated container *all* the urine produced, including that passed at 7:00 AM of the day after; measure the volume of urine carefully and record it). Written instructions should also be provided for other types of urine samples—for example, when testing for orthostatic proteinuria, one sample produced while the patient has been recumbent for some hours, and another sample produced while the patient has been standing.

Strenuous physical exercise (e.g., running, soccer) should be avoided for at least 24 hours before the urine sample delivery to avoid exercise-induced proteinuria and hematuria or urinary casts. In women, urinalysis must be avoided during menstruation because of the high probability of blood contamination.

For urine microscopy, a midstream sample of the first morning urine is recommended by some international guidelines because this urine is the most concentrated and acidic and theoretically the best for the preservation of particles.[5] On the other hand, the prolonged persistence in the bladder may favor the lysis of cells and casts, which may lead to false-negative urine sediment examination. For this reason, we use a combined dipstick and urine microscopy on the second morning urine.[6]

For a urine sediment sample, after the washing of hands, women should spread the labia of the vagina and men withdraw the foreskin of the glans. The external genitalia are washed and wiped dry with a paper towel, and the midstream urine is collected after the first portion is discarded. The same procedures can be used for children. For small infants, bags for urine are often used, even though these carry a high probability of contamination. A suprapubic bladder puncture may occasionally be necessary. In special situations, urine can also be collected through a bladder catheter, although this procedure may cause hematuria. Permanent indwelling catheters are almost invariably associated with bacteriuria, leukocyturia, hematuria, and candiduria.

The container for urine should be clean, have a capacity of at least 50 ml, and have a diameter opening of at least 4 cm to allow easy collection. It should have a wide base to avoid accidental spillage and should be capped. The label should identify the patient and the hour of urine collection.[5]

Several elements (but especially leukocytes) can lyse rapidly after collection; thus ideally the sample should be handled and examined as soon as possible. We recommend analysis within 3 hours from collection. If this is not possible, refrigeration of specimens at +4° to +8° C assists preservation but may cause precipitation of phosphates or urates, which can hamper examination. Alternatively, chemical preservatives such as formaldehyde or glutaraldehyde can be used.

PHYSICAL CHARACTERISTICS

Color

The color of normal urine ranges from pale yellow to amber, depending on the concentration of the urochrome. Abnormal changes in color can be caused by pathologic conditions, drugs, or foods.

The most frequent color changes are caused by hematuria, hemoglobinuria, or myoglobinuria (pink, red, brown, or black urine); bilirubinuria (dark-yellow to brown urine); and massive uric acid crystalluria (pink urine). Less frequent causes are urinary infection, mainly from *Klebsiella* spp., *Proteus mirabilis, Escherichia coli, Providencia stuartii,* or *Enterococcus* spp. in patients with a permanent bladder catheter (purple urine, known as "purple urine bag syndrome")[7]; chyluria (white milky urine); porphyrinuria (associated with the excretion in the urine of porphobilinogen); and alkaptonuria (red urine turning black on standing).

The main drugs responsible for abnormal urine color are rifampin; phenazopyridine (yellow-orange to red urine); desferrioxamine (pinkish urine); phenytoin (red urine); chloroquine and nitrofurantoin (brown urine); triamterene, propofol, and blue dyes of enteral feeds (green urine); methylene blue (blue urine); and metronidazole, methyldopa, and imipenem-cilastatin (darkening on standing).

Among foods are beetroot (red urine), senna and rhubarb (yellow to brown or red urine), and carotene (brown urine).

Turbidity

Normal urine is transparent. Urine can be turbid because of a high concentration of any urine particle, especially cells, crystals, and bacteria. The most frequent causes of turbidity are urinary tract infection (UTI), heavy hematuria, and genital secretions. The absence of turbidity is not a reliable criterion by which to judge a urine sample because pathologic urine can be transparent.

Odor

A change in urine odor may be caused by the ingestion of some foods, such as asparagus. A pungent odor, caused by the production of ammonia, is typical of most bacterial UTIs, whereas there is often a sweet or fruity odor with ketones in the urine. Some rare conditions confer a characteristic odor to the urine. These include maple syrup urine disease (maple syrup odor), phenylketonuria (musty odor), isovaleric acidemia (sweaty feet odor), and hypermethioninemia (rancid butter or fishy odor).

Relative Density

Relative density can be measured by specific gravity or osmolality. *Specific gravity* (SG) refers to the weight of a volume of urine compared with the weight of the same volume of distilled water and depends on the mass and number of the dissolved particles. SG is most frequently evaluated by reagent strip (see discussion of chemical characteristics), which measures the ionic concentration of urine. In the presence of ions, protons are released by a complexing agent and produce a color change in the indicator bromothymol blue from blue to blue-green to yellow. Underestimation occurs with urine of pH above 6.5, whereas overestimation is found with urine protein concentration above 7.0 g/l. Because nonionized molecules, such as glucose and urea, are not detected by dipstick, this method does not strictly correlate with the results obtained by refractometry and osmolality.

Refractometry measures SG through the refraction of light while it passes through a drop of urine on a glass plate. This measures the number of solutes per unit volume and measures all solutes rather than just ionic substances. Therefore refractometry is more accurate than reagent strip, despite being influenced by urine temperature, although temperature-compensated refractometers are available. We suggest refractometry for everyday practice, because refractometers are inexpensive, simple to use, and require only one drop of urine. SG of 1.000 to 1.003 is seen with marked urinary dilution, as observed in patients with diabetes insipidus or water intoxication. SG of 1.010 is often called *isosthenuric* urine because it is of similar SG (and osmolality) to plasma, so it is often observed in conditions in which urinary concentration is impaired, such as acute tubular necrosis (ATN) and chronic kidney disease (CKD) with renal dysfunction. SG above 1.040 almost always indicates the presence of some extrinsic osmotic agent, such as radiocontrast.

Osmolality is measured by an osmometer, which evaluates the freezing-point depression of a solution and supplies results as milliosmoles per kilogram (mOsm/kg) of water. Osmolality depends only on the number of particles present and is not influenced by urine temperature or protein concentrations. However, high glucose concentrations significantly increase osmolality (10 g/l of glucose = 55.5 mOsm/l). Measurement of osmolality is more reliable than SG by either reagent strip or refractometry.

CHEMICAL CHARACTERISTICS

Chemical characteristics of urine are most frequently evaluated by reagent strips. These plastic strips bear several pads (the most used are SG, pH, glucose, hemoglobin, albumin, leukocyte esterase, nitrites, bile pigments, and ketones), each pad being impregnated with chemical reagents meant to detect a specific urine feature. In wealthy countries, the reagent strip reading is performed by automated reader devices, using reflectance spectrometry. Alternatively, the reading is performed manually, which is simple and quick; however, it must be performed correctly, that is, rapid plunging of the strip in the urine; removal of the urine in excess on the pads to avoid color carryover from one pad to the close ones; adherence to the time interval between removal of the strip from urine and the reading of results as indicated by the manufacturer; matching the color developed in the pad with the color scale reported on the strip box in adequate light conditions.

Reagent strips have the advantages of simplicity and low cost and supply a full urinary profile within 2 to 3 minutes. Disadvantages include semiquantitative results only, susceptibility to interference by substances and urine discoloration. Sensitivity and specificity of reagent strips greatly differ across studies and partly depend on the brand used (there is no standardization across manufacturers). Table 4.1 summarizes the

TABLE 4.1 Urine Reagent Strip Testing

Constituent	False-Negative Results	False-Positive Results
Specific gravity (SG)	Urine pH >6.5	Urine protein >7.0 g/l
pH	Reduced values in presence of formaldehyde	—
Hemoglobin	High urine SG Ascorbic acid Formaldehyde (0.5 g/l) used to preserve samples	Myoglobin Microbial peroxidases
Glucose	Ascorbic acid Bacteria	Oxidizing detergents Very acid urine pH
Albumin	Albumin <0.25-0.30 g/l Low urine SG Tubular proteins Monoclonal heavy/light chains	Urine SG ≥1.030 Urine pH >8.0 Quaternary ammonium detergents Chlorhexidine Polyvinylpyrrolidone
Leukocyte esterase	Ascorbic acid Glucose ≥20 g/l Protein >5.0 g/l Cephalothin (+++) Tetracycline (+++) Cephalexin (++) Tobramycin (+) High urine SG	Formaldehyde (0.4 g/l) Imipenem Meropenem Clavulanate Abnormally colored urine
Nitrites	Bacteria that do not reduce nitrates to nitrites No vegetables in diet Short bladder incubation time	Abnormally colored urine
Ketones	Improper storage	Free sulfhydryl groups (e.g., captopril) Levodopa Abnormally colored urine

(Main false-negative and false-positive results of urine reagent strips. False results also may occur when time-expired strips are used.)

main false-negative and false-positive results that can occur with strip reagent testing.

pH

The pH is determined by a strip that covers the pH range of 5.0 to 8.5 or to 9.0, with intervals of only 0.5, which limits precision. Moreover, significant deviations from true pH are observed for values below 5.5 and above 7.5. In the presence of formaldehyde, the strip supplies reduced pH values; no causes of increased pH values are known. When an accurate measurement of pH is necessary, a pH meter with a glass electrode is mandatory.

Urine pH reflects the presence of hydrogen ions (H^+), but this does not necessarily reflect the overall acid load in the urine because most of the acid is excreted as ammonia. Low pH is often observed with metabolic acidosis (in which acid is secreted), high-protein meals (which generate more acid and ammonia), and volume depletion (in which aldosterone is stimulated, resulting in an acid urine). In addition, low urine pH may help distinguish pre-renal acute kidney injury (AKI) from ATN, which is typically associated with a higher pH. High pH is often observed with renal tubular acidosis, vegetarian diets (caused by minimal nitrogen and acid generation), and infection due to urease-positive organisms (e.g., *Proteus*) that generate ammonia from urea.

Measurement of urine pH is also needed for a correct interpretation of other urine parameters (e.g., specific gravity, albumin) and several urine sediment findings.

Hemoglobin

Hemoglobin is detected by a dipstick based on the pseudoperoxidase activity of the heme moiety of hemoglobin, which catalyzes the reaction of a peroxide and a chromogen to form a colored product. The presence of hemoglobin is shown as green spots, which result from intact erythrocytes, or as a homogeneous, diffuse green pattern. The latter can result from marked hematuria because of the high number of erythrocytes that cover the whole pad surface; from lysis of erythrocytes favored by delayed examination, alkaline urine pH, or low SG; or from hemoglobinuria secondary to intravascular hemolysis.

False-negative results are most frequently caused by high SG or by ascorbic acid, a strong reducing agent, which can result in low-grade microhematuria being completely missed. Some reagent strips also include a vitamin C pad to reduce these false-negative results.[8]

The most important causes of false-positive results are myoglobinuria, resulting from rhabdomyolysis, and a high concentration of bacteria with pseudoperoxidase activity (Enterobacteriaceae, staphylococci, and streptococci).[9]

Glucose

The reagent strip uses glucose oxidase as catalyst: glucose is first oxidized to gluconic acid and hydrogen peroxide. Through the catalyzing activity of a peroxidase, hydrogen peroxide then reacts with a reduced colorless chromogen to form a colored product. This test detects concentrations of 0.5 to 20 g/l. When more precise quantification of urine glucose is needed, enzymatic methods such as hexokinase must be used.

False-negative results for glucose occur in the presence of ascorbic acid and bacteria. False-positive findings may be observed in the presence of oxidizing detergents and very acid urine pH.

Protein

Although there has been no consistent definition of proteinuria,[10] the definitions in the KDIGO guideline are increasingly used.[1] It is accepted that physiologic proteinuria does not exceed 150 mg/24 h for adults[1] and 140 mg/m^2 for children,[10] in whom, however, the normal values do vary by age.[1] Three different approaches can be used for the evaluation of proteinuria, as described next.

Albumin Reagent Strip

The albumin reagent strip test is based on the effect of albumin on a buffer (tetrabromophenol blue), which causes a change in pH proportional to the concentration of the albumin itself. The pad changes color, from pale green to green and blue, according to the pH changes induced by the albumin. The strip is sensitive to albumin but has a very low sensitivity to other proteins, such as tubular proteins and light-chain immunoglobulins; thus it will not detect tubular proteinuria or overflow proteinuria, which can occur in monoclonal gammopathies. Moreover, the detection limit is 0.25 to 0.3 g/l, so does not identify microalbuminuria and is influenced by hydration status (false-negative results may occur at low urine SG, and vice versa) and urine pH (false-positive results at strongly alkaline pH). The reagent strip supplies only a semiquantitative measurement of urine albumin, which is expressed on a scale from 0 to +++ or ++++. Some manufacturers also supply numerical results, although these represent only approximate quantitative measurements. Some reagent strips also include a creatinine pad, which supplies an albumin-to-creatinine ratio (ACR) and reduces the variability caused by changing diuresis and urine dilution.[11] Nevertheless, for accurate quantification other methods are needed.

24-Hour Protein Excretion

The 24-hour protein excretion averages the variation of proteinuria caused by the circadian rhythm and is still considered the reference method,[1] especially for monitoring proteinuria during treatment.[12-14] The measurement of proteinuria can be done by chemical assays (e.g., biuret or Folin-Lowry reaction), turbidimetric techniques (e.g., trichloroacetic acid, benzethonium chloride, ammonium chloride), or dye-binding techniques (e.g., Ponceau S, Coomassie brilliant blue G-250, pyrogallol red molybdate), which quantify total proteins rather than only albumin. However, the 24-hour urine collection can be impractical in some settings (e.g., children, outpatients, elderly patients) and is subject to error from overcollection or undercollection.

Protein-to-Creatinine Ratio and Albumin-to-Creatinine Ratio on Random Urine Sample

The protein-to-creatinine ratio (PCR) measured on an early morning urine sample represents a practical alternative to the 24-hour urine collection because the sample is easy to supply and is not influenced by variation in water intake or rate of diuresis.[1] The PCR is obtained by the ratio between urine protein excretion and creatinine excretion, expressed as milligrams per milligrams or milligrams per millimole. A close correlation between the PCR in a random urine sample and the 24-hour protein excretion has been demonstrated in a wide range of patients,[10,15] including those with different types of glomerulonephritis (GN) evaluated longitudinally during treatment.[16] However, the results may be influenced by a reduced creatinine excretion because of low muscle mass. Thus, in elderly and female patients, PCR values can be higher than in young men. Some investigators consider a normal PCR sufficient to rule out pathologic proteinuria, but an elevated PCR should be confirmed and quantified with a 24-hour collection.[12] Others have found poor correlation between PCR and 24-hour proteinuria at high levels of protein excretion[16] or that PCR is an unreliable method to monitor some patients with lupus nephritis.[17]

The KDIGO guideline suggests ACR rather than PCR as first measurement of proteinuria in adults because albuminuria is a reliable marker of the outcome of CKD, it provides a specific and sensitive measure of changes in glomerular permeability in several renal diseases, and the measurement of total proteins is problematic in several respects.[1]

However, false-negative results may occur with ACR,[18] especially in tubulointerstitial diseases and monoclonal gammopathies, in which urine proteins are mostly composed of tubular proteins and monoclonal light chains, respectively. In children, KDIGO guidelines[1] recommend the measurement of PCR rather than ACR because the latter can miss the identification of congenital disorders associated with nonalbumin proteinuria.[1]

Specific Proteins

Albuminuria. *Albuminuria* is the term that should be used now, according to the KDIGO guideline, instead of *microalbuminuria,*[1] defined as urine albumin in the range of 30 to 299 mg/24 h. In persons with diabetes it identifies increased risk for developing overt diabetic nephropathy and, in the general population, subjects at increased risk of CKD, cardiovascular morbidity, and overall mortality. Semiquantitative reagent strips are available to screen for urine albumin in this range.[19] Once the reagent strip is positive, a quantitative method on early morning urine must be used for confirmation.[1] Because of its great simplicity, immunoturbidometry is most frequently used.

Tubular proteins. When an isolated tubular lesion is suspected, specific tubular proteins such as α_1-microglobulin, retinol-binding protein, or β_2-microglobulin should be measured.[1] This can be done by qualitative analysis of urine proteins, using electrophoresis on cellulose acetate or agarose after protein concentration or using very sensitive stains such as silver and gold, or sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE).

Bence Jones proteinuria. Bence Jones proteinuria indicates the presence of free monoclonal immunoglobulin (heavy or light chains) as occurs with monoclonal gammopathies. Bence Jones proteinuria is revealed by urine electrophoresis, whereas light-chain identification requires urine immunofixation.[20]

Leukocyte Esterase

The leukocyte esterase dipstick test evaluates the presence of leukocytes based on the activity of an indoxyl esterase released from lysed neutrophil granulocytes. Leukocyte esterase may be positive but microscopy negative when leukocytes are lysed because of low SG, alkaline pH, or a delay in sample handling and examination.

False-negative results derive from vitamin C,[8] high glucose (≥20 g/l) or high protein (≥5 g/l) concentration or from the presence of antibiotics such as cephalothin and tetracycline (strong inhibition), cephalexin (moderate inhibition), or tobramycin (mild inhibition). The sensitivity is also reduced by high SG, because this prevents leukocyte lysis. False-positive results may occur when formaldehyde is used as a urine preservative, from the presence in the urine of imipenem, meropenem, or clavulanate,[21] and with all discolored urine.

Nitrites

The dipstick nitrites test detects bacteria that reduce nitrates to nitrites by nitrate reductase activity. This includes most gram-negative uropathogenic bacteria, but not *Pseudomonas, Staphylococcus albus,* or *Enterococcus*. False-negative results also may occur on a diet with low content of nitrate (vegetables), which form the substrate for nitrite production and short bladder incubation time. Thus the sensitivity of the dipstick nitrites test is low, whereas specificity is high.[22] False-positive results may occur in the presence of abnormally colored urine.

Ketones

The ketone dipstick tests for acetoacetate and acetone (but not β-hydroxybutyrate), which are excreted into urine during diabetic acidosis or during fasting, vomiting, or strenuous exercise. It is based on the reaction of the ketones with nitroprusside.

URINE MICROSCOPY

Methods

We instruct the patient to deliver the second urine specimen of the morning because it avoids the lysis of particles that can occur in the bladder overnight (Box 4.1). We centrifuge an aliquot of urine within 3 hours from collection and concentrate it by removal of a fixed aliquot of supernatant urine. After this, the sediment is resuspended with a Pasteur pipette, and a fixed aliquot is transferred to the slide and prepared using a coverslip with a fixed surface. Some suggest the use of noncentrifuged urine, because centrifugation may cause the damage and/or lysis of particles during the procedure. On the other hand, with this approach, clinically important particles (e.g., erythrocyte casts), when in small numbers, can easily be missed.

Phase contrast microscopy is recommended because it improves the identification of almost all particles, especially cells and casts, whereas polarized light is mandatory for the correct identification of lipids and crystals, especially when they have uncommon morphologies.[6]

At least 20 microscopic fields, in different areas of the sample, should be examined at both low magnification (e.g., ×100 or ×200) and high magnification (e.g., ×400). More extensive examination may be required in certain clinical settings, such as isolated microhematuria of unknown origin, for which we suggest examination of 50 low-power fields (lpfs) to look for erythrocyte casts.[23]

For correct examination, both pH and SG of the sample must be known. Both alkaline pH (≥7.0) and low SG (especially ≤1.010) favor the lysis of erythrocytes and leukocytes, which can cause discrepancies between dipstick readings and the microscopic examination (see earlier discussion). Alkaline pH also impairs the formation of casts and favors the precipitation of amorphous phosphates. On the contrary, high SG (≥1.030) may reduce the sensitivity of reagent strips for hemoglobin and leukocyte esterase.

We quantify the particles seen as number per microscopic field, whereas if counting chambers are used, the elements are quantified as number per volume. Counting chambers allow a precise quantitation but are not frequently used in everyday practice.

BOX 4.1 Procedures for Preparation and Examination of Urine Sediment*

- Written instructions for the patient to deliver a correct urine sample (i.e., the second urine of the morning after discarding the first few milliliters of urine [midstream urine] collected in a proper container).
- Sample handling and examination within 3 hours of collection.
- Centrifugation of a 10-ml aliquot of urine at 400 g for 10 minutes.
- Removal by suction of 9.5 ml of supernatant urine.
- Gentle but thorough resuspension with a Pasteur pipette of sediment in remaining 0.5 ml of urine.
- Transfer by a precision pipette of 50 µl of resuspended urine to a slide.
- Covering of sample with a 24- × 32-mm coverslip.
- Examination of the urine sediment with a phase contrast microscope at ×160 and ×400.
- Use of polarized light to identify doubtful lipids and crystals.
- Matching of the microscopic findings with reagent strip for pH, specific gravity, hemoglobin, leukocyte esterase, nitrites, and albumin.
- Cells expressed as lowest/highest number seen per high-power field (hpf), casts as number per low-power field (lpf), and all other elements (e.g., bacteria, crystals) on scale from 0 to ++++.

*Procedures used in the authors' laboratory.

Cells

Erythrocytes

Urinary erythrocytes have a mean diameter of approximately 6 µm. In the urine, there are two main types of erythrocytes: *isomorphic*, with regular shapes and contours, derived from the urinary excretory system; and *dysmorphic*, with irregular shapes and contours, which are of glomerular origin (see Fig. 4.1A and B).[24] Erythrocyte dysmorphism is thought to result from deformation of the erythrocytes as they pass through gaps in the glomerular basement membrane, followed by physicochemical insults while the erythrocytes pass through the tubular system.[25]

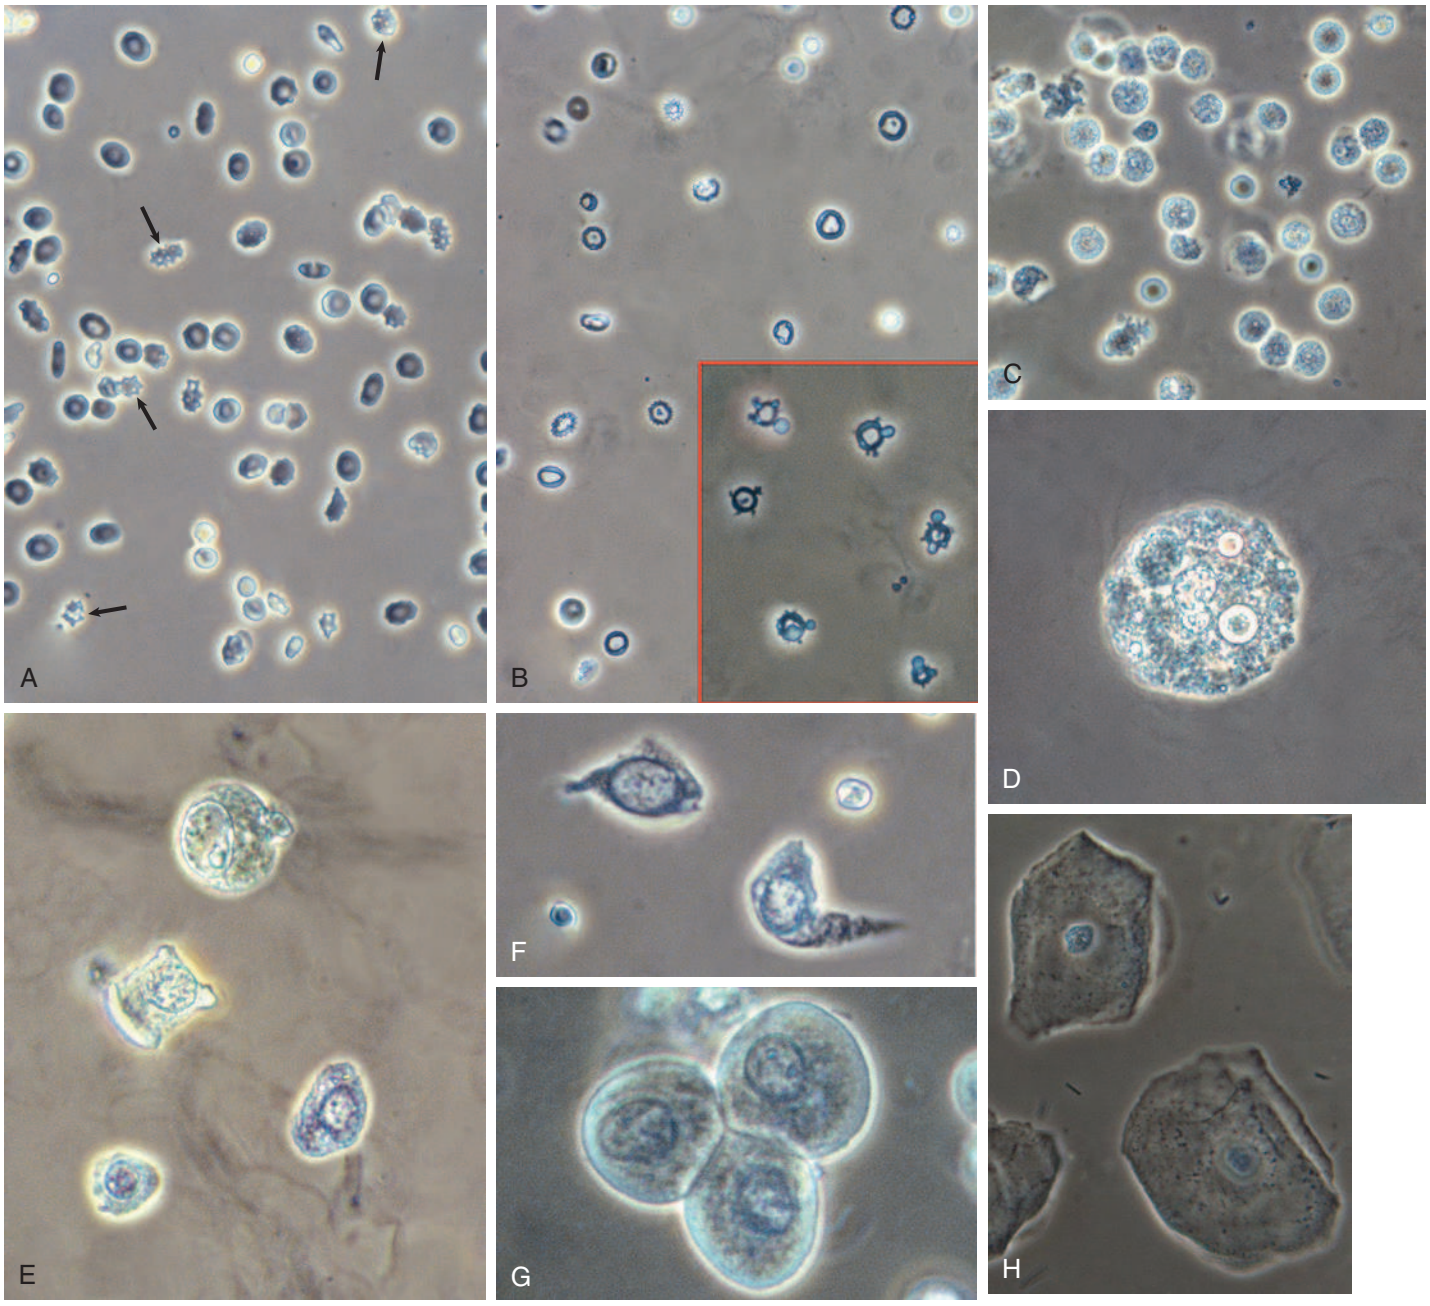

Fig. 4.1 Urinary sediment cells. (A) Isomorphic nonglomerular erythrocytes (diameter ~6 µm). The *arrows* indicate the so-called crenated erythrocytes, which are a finding in nonglomerular hematuria. (B) Dysmorphic glomerular erythrocytes (diameter ~6 µm). The dysmorphism consists mainly of irregularities of the cell membrane. *Inset,* Acanthocytes, with their typical ring-formed cell bodies with one or more blebs of different sizes and shapes. (C) Neutrophils (diameter ~10 µm). Note their typical lobulated nucleus and granular cytoplasm. (D) Granular phagocytic macrophage (diameter ~60 µm). (E) Different types of renal tubular epithelial cells (diameter ~14 µm). (F) Two cells from deep layers of uroepithelium (diameter ~18 µm). (G) Three cells from superficial layers of uroepithelium (diameter ~25 µm). Note the difference in shape, size, and ratio of nucleus to cytoplasm between the two types of uroepithelial cells. (H) Squamous epithelial cells (diameter ~50 µm). (All images by phase contrast microscopy; original magnification ×400.)

Unfortunately, there is no agreement on the criteria to classify hematuria as glomerular or nonglomerular. Some define glomerular hematuria as more than 80% of erythrocytes being dysmorphic; others define the discriminating cut-off as low as 10% or 15%.[6] Still, others define hematuria as glomerular when at least 5% of erythrocytes examined are *acanthocytes,*[26] a subtype of dysmorphic erythrocytes with a distinguishing appearance easily identifiable by the presence of one or more blebs of different size and shape protruding from a ring-shaped body (see Fig. 4.1B, *inset*).

In our laboratory, glomerular hematuria is diagnosed when there are 40% or more dysmorphic erythrocytes and/or 5% or more acanthocytes and/or one or more red blood cell casts/50 lpf (×160). With this criterion, a good correlation was found between urinary sediment and renal biopsy findings in 16 patients with long-standing isolated microhematuria.[23]

The distinction between glomerular and nonglomerular hematuria is of special value in the evaluation of patients with isolated microhematuria, in whom it is important to decide whether nephrologic or urologic investigation is needed.

Rare types of erythrocytes found in the urine include sickle cells, elliptocytes, spherocytes, dacryocytes, etc. The finding in the urine of such cells reflects their presence in the circulation.[27]

Leukocytes

Urinary *neutrophils* have an average diameter of approximately10 µm and are the most frequently found leukocytes in the urine. Neutrophils are identified by their granular cytoplasm and lobulated nucleus (see Fig. 4.1C). In most patients, neutrophils indicate UTI, but they may also result from urine contamination caused by genital secretions, especially in fertile women. Variable numbers of neutrophils are often, but not always, found in acute interstitial nephritis. Neutrophils can be found in low numbers in chronic interstitial nephritis and in proliferative GN, intermingled with high numbers of erythrocytes.[28]

Eosinophils, which can be identified only by the use of stains (e.g., Hansel), were once considered a marker of acute allergic interstitial nephritis. However this is not specific,[29] because eosinophils may be present in various types of GN, prostatitis, chronic pyelonephritis, urinary schistosomiasis, and cholesterol embolism.

Lymphocytes, whose identification also requires staining, may indicate acute cellular rejection in renal allograft recipients, although this is not sufficiently reliable to avoid renal biopsy. Lymphocytes are also a typical finding in patients with chyluria.

Macrophages are mononucleated or multinucleated cells of variable size (13 to 95 µm in diameter) and variable appearance: some are granular (see Fig. 4.1D). In patients with nephrotic syndrome, macrophages may be engorged with lipid droplets, appearing as "oval fat bodies." Macrophages have been found in the urine of patients with active GN. In our experience, macrophages are frequently seen in the urine of kidney transplant recipients with BK virus infection (see later discussion). However, urinary macrophages are not yet diagnostic of any specific condition.

Renal Tubular Epithelial Cells

The renal tubular epithelial cells (RTECs) derive from the exfoliation of the tubular epithelium. In the urine, RTECs can differ in size (diameter ~9 to 25 µm, average 14 µm) and shape, from roundish to rectangular or columnar, with a central or peripheral large nucleus (see Fig. 4.1E). RTECs are not found in the normal individual but can be found when there is acute tubular damage, including ATN,[30] acute interstitial nephritis, and acute cellular rejection. In smaller numbers, RTECs also can be found in glomerular diseases.[28] In ATN, these cells are frequently damaged and necrotic and may be present in casts (so-called epithelial casts).

Transitional Epithelial Cells

The transitional epithelial cells derive from the exfoliation of the uroepithelium, which lines the urinary tract from the calyces to the bladder in women and to the proximal urethra in men. This multilayered epithelium has small cells in the deep layers and larger cells in the superficial layers. When cells of the deep epithelial layers (average diameter 18 µm, see Fig. 4.1F) are present in large numbers (e.g., ≥1/high-power field [hpf]), this suggests severe uroepithelial damage, such as caused by neoplasia, stones, obstruction, or long-standing bladder catheters or ureteral stents.[6] Transitional cells of the superficial layers (average diameter ~25 µm; see Fig. 4.1G) are a common finding associated with mild uroepithelial damage, as may occur in cystitis.

Squamous Epithelial Cells

Squamous epithelial cells (SECs) (average diameter 50 µm; see Fig. 4.1H) derive from the urethra or from the external genitalia. In small numbers, SECs are a normal finding, but in large numbers, they indicate urine contamination from genital secretions.

Lipids

Lipids are found in the urine as *drops,* which are spherical, translucent, yellowish particles of different size that can be isolated or in clusters (see Fig. 4.2A); as *oval fat bodies,* which are RTECs or macrophages gorged with lipid droplets; as *fatty casts,* cylindrical structures containing variable amounts of fatty droplets or even oval fat bodies; and *cholesterol crystals* (see Crystals). All these particles contain mainly cholesterol esters and free cholesterol. Under polarized light, drops, oval fat bodies, and casts give the appearance of Maltese crosses with symmetric arms (see Fig. 4.2B), whereas cholesterol crystals are nonbirefringent.

These lipids are typical of glomerular diseases associated with marked proteinuria, usually but not invariably in the nephrotic range.

In Fabry disease, urine sediment may contain fatty particles even in the absence of proteinuria. These particles contain glycosphingolipids (especially globotriaosylceramide-3) and have irregular shape and size, variable protrusions or an internal lamellar structure, and irregular or truncated Maltese crosses under polarized light (see Fig. 4.2C).[31]

Casts

Casts are cylindrical structures that form in the lumen of distal renal tubules and collecting ducts. Their matrix is made of Tamm-Horsfall glycoprotein, today known as uromodulin, which is secreted by the cells of the thick ascending limb of Henle loop. Trapping of particles within the cast matrix results in casts with different appearances, each of which may have specific clinical significance (Table 4.2). Because casts form in the renal tubules, whatever particle is contained in a cast derives from the kidneys. Specific casts include the following:

- *Hyaline casts* are colorless with a low refractive index (see Fig. 4.3A). They are easily seen with phase contrast microscopy but can be overlooked when bright-field microscopy is used. Hyaline casts may occur in normal urine, especially when it is concentrated and acidic (both conditions favor precipitation of uromodulin). In patients with renal disease, hyaline casts are usually associated with other types of casts.
- *Hyaline-granular casts* contain variable amounts of granules within the hyaline matrix (see Fig. 4.3B) and are the most common mixed casts (see later discussion). Hyaline-granular casts are rare in normal individuals but are common in patients with renal diseases such as GN[28] and acute interstitial nephritis.[32]
- *Granular casts* can be finely granular (see Fig. 4.3C) or coarsely granular. Both types indicate renal disease. In patients with AKI, granular casts together with RTECs[30] or with epithelial casts[33] are a sensitive marker of ATN.

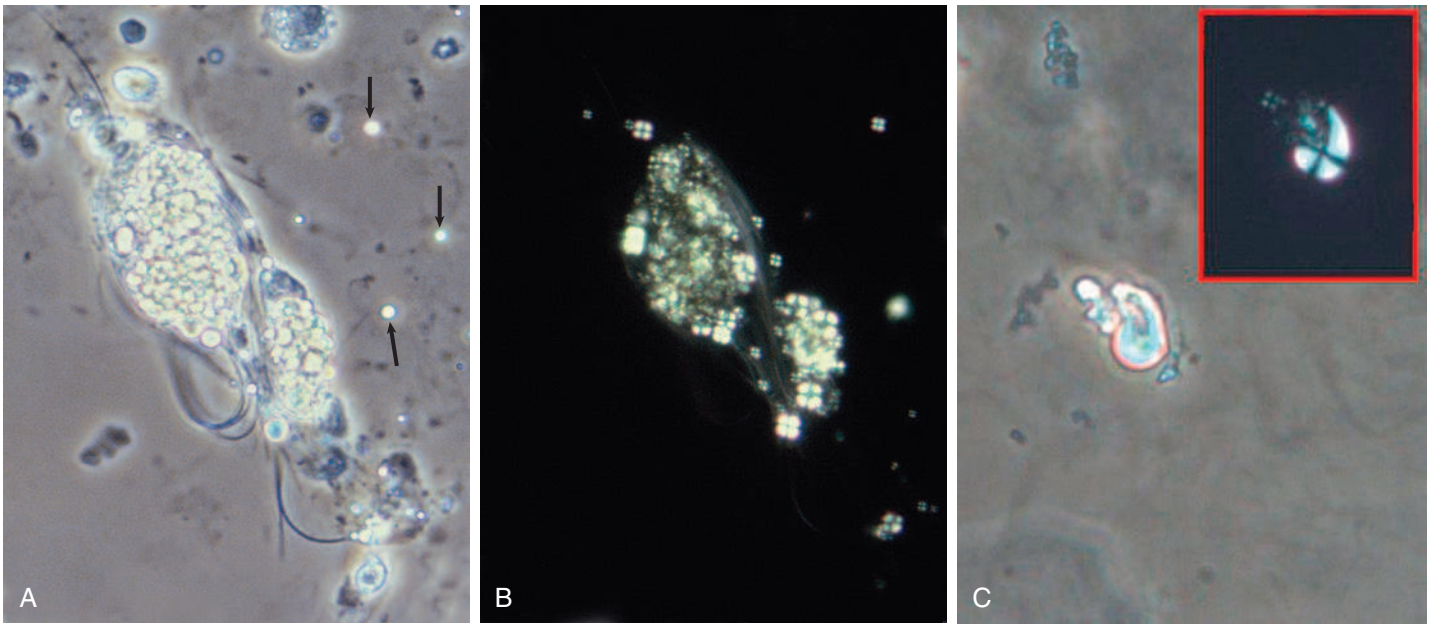

Fig. 4.2 Fatty particles. (A) Lipid droplets, both aggregated and isolated *(arrows)*, and filaments also made up of cholesterol by phase contrast microscopy. (B) Same lipid droplets in *A* under polarized light, showing typical Maltese crosses with symmetric arms. (C) Fatty particle with protrusions, as found in Fabry disease (phase contrast microscopy). *Inset*, Same particle under polarized light. Note the truncated and asymmetric Maltese cross. (Original magnification ×400.)

TABLE 4.2 Types of Casts and Their Main Clinical Associations

Cast	Main Clinical Associations
Hyaline	Normal individual; renal disease
Hyaline-granular	Normal individual; renal disease
Granular	Renal disease; acute tubular necrosis
Waxy	Renal disease with possible functional impairment
Fatty	Proteinuria; nephrotic syndrome
Erythrocyte	Glomerular hematuria; proliferative/necrotizing GN; acute interstitial nephritis
Leukocyte	Acute interstitial nephritis; acute pyelonephritis; proliferative GN
Renal tubular epithelial cell (so-called epithelial casts)	Acute tubular necrosis; acute interstitial nephritis; proliferative GN; nephrotic syndrome
Hemoglobin	Same as for erythrocyte cast; hemoglobinuria caused by intravascular hemolysis
Myoglobin	Rhabdomyolysis
Bilirubin	Jaundice caused by increased direct bilirubin
Bacterial, fungal	Bacterial or fungal infection in the kidney
Containing crystals	Renal stone disease; crystalline nephropathies
Mixed	According to components present in the cast

AKI, Acute kidney injury; *GN,* glomerulonephritis.

- *Waxy casts* derive their name from their appearance, which is similar to that of melted wax (see Fig. 4.3D). They are typically found in patients with renal disease associated with impaired renal function, whether acute, rapidly progressive, or chronic.[34]
- *Fatty casts* contain variable amounts of lipid droplets, isolated, in clumps, or packed or even oval fat bodies or cholesterol crystals. Fatty casts are typical of glomerular diseases associated with marked proteinuria or the nephrotic syndrome.
- *Erythrocyte casts* may contain a few erythrocytes (see Fig. 4.3E) or so many that the matrix of the cast cannot be identified. Erythrocyte casts are usually considered a marker of glomerular bleeding, although a recent report found them in 28% of patients with acute interstitial nephritis.[32]
- *Hemoglobin casts* generally have a brownish hue and a coarsely granular appearance, which derives from the degradation of erythrocytes entrapped within the cast matrix (see Fig. 4.3F). In such cases, hemoglobin casts have the same clinical significance as erythrocyte casts. However, hemoglobin casts also may derive from hemoglobinuria, as may occur in intravascular hemolysis. In these patients, hemoglobin casts have a smooth surface.
- *Leukocyte casts* contain variable amounts of polymorphonuclear leukocytes (see Fig. 4.3G). They can be found in patients with acute pyelonephritis and acute interstitial nephritis, as well as in active proliferative GN.[28]
- *Renal tubular epithelial cell casts* (so-called epithelial casts) contain variable numbers of RTECs, which can be identified by their prominent nucleus (see Fig. 4.3H). Epithelial casts indicate damage of the renal tubular epithelium and can therefore be found in the urine of patients with ATN,[30] acute interstitial nephritis, and glomerular disease.[28]
- *Myoglobin casts* are pigmented cylinders, with the myoglobin providing their color. They may be similar to hemoglobin casts

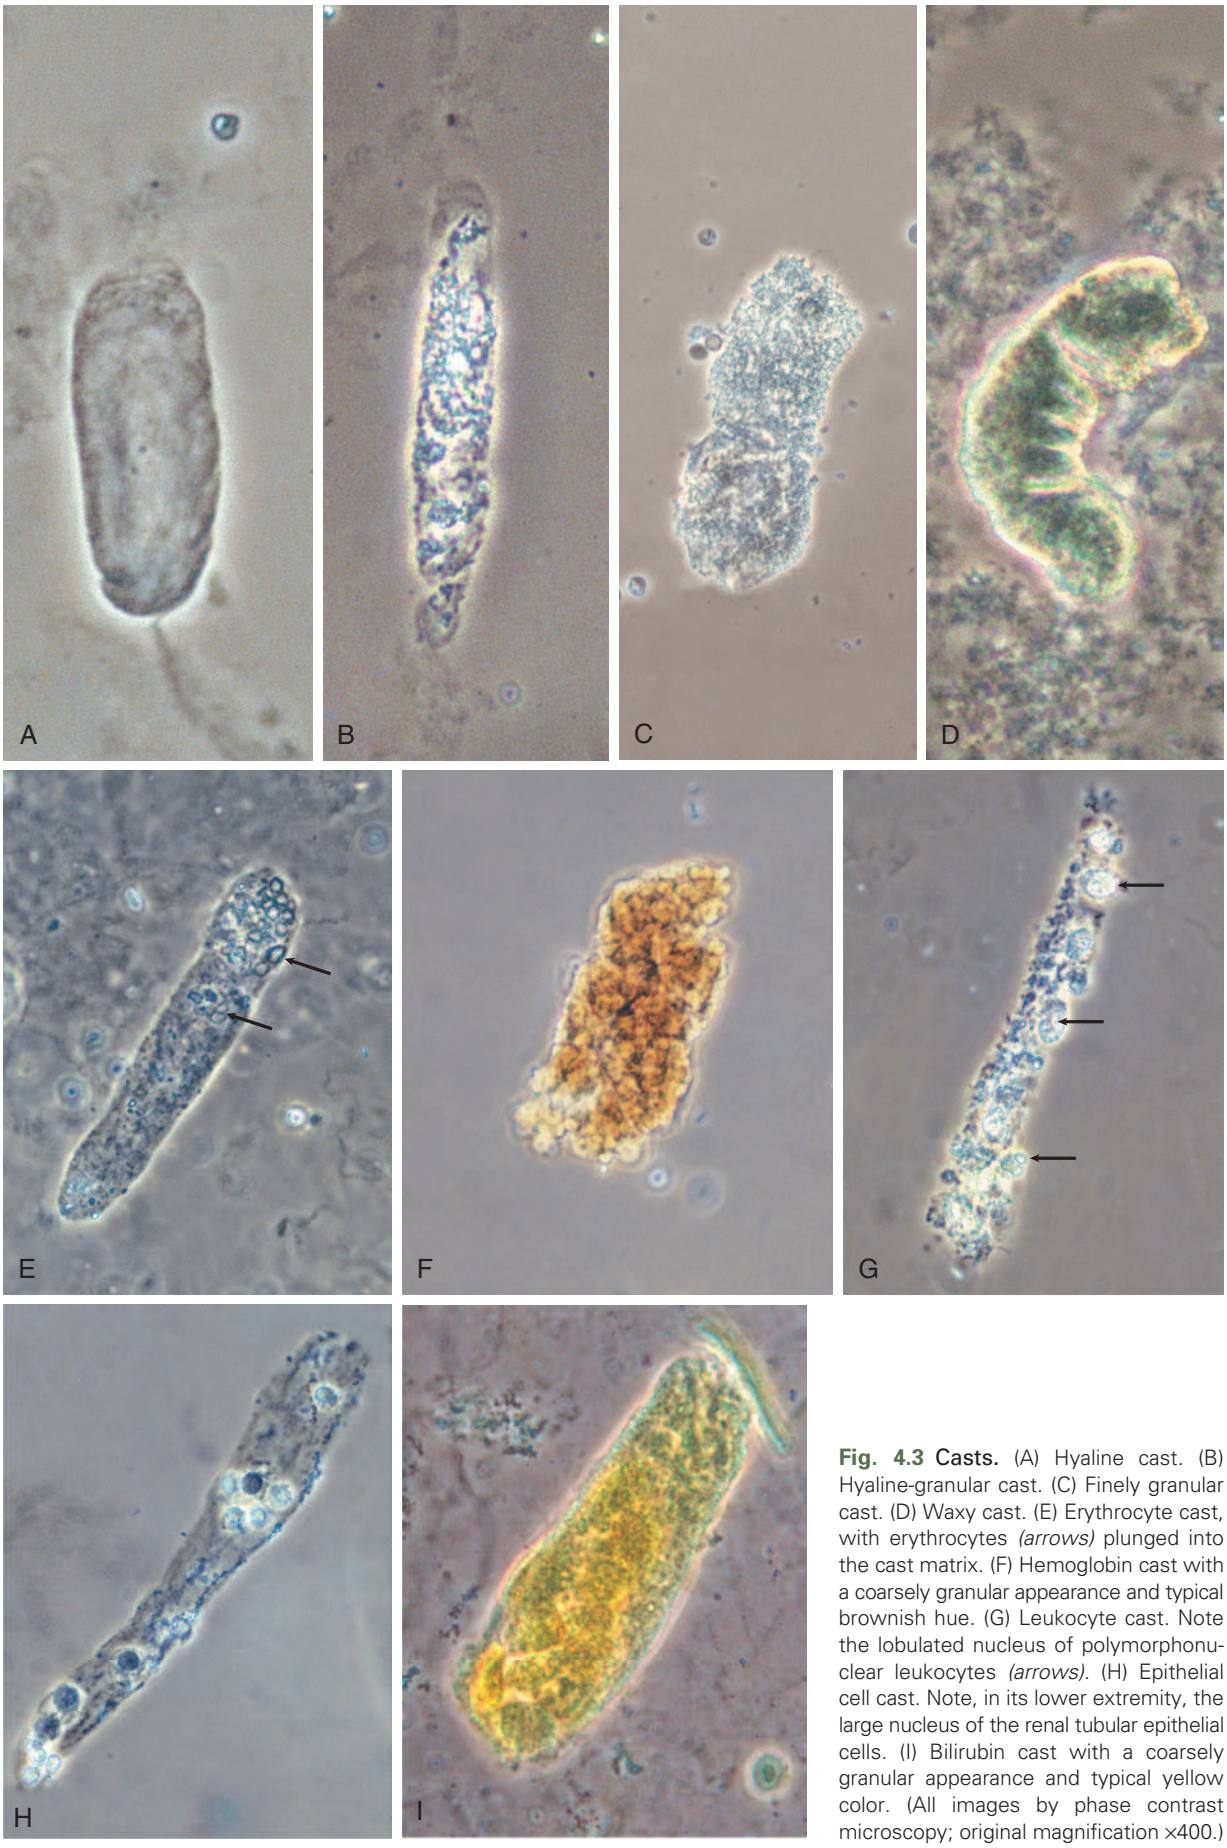

Fig. 4.3 Casts. (A) Hyaline cast. (B) Hyaline-granular cast. (C) Finely granular cast. (D) Waxy cast. (E) Erythrocyte cast, with erythrocytes *(arrows)* plunged into the cast matrix. (F) Hemoglobin cast with a coarsely granular appearance and typical brownish hue. (G) Leukocyte cast. Note the lobulated nucleus of polymorphonuclear leukocytes *(arrows)*. (H) Epithelial cell cast. Note, in its lower extremity, the large nucleus of the renal tubular epithelial cells. (I) Bilirubin cast with a coarsely granular appearance and typical yellow color. (All images by phase contrast microscopy; original magnification ×400.)

(see Fig. 4.3F), from which they can be distinguished by the clinical setting. Myoglobin casts are observed in the urine of patients with AKI associated with rhabdomyolysis.

- *Bilirubin casts* are cylinders pigmented with bilirubin, which can stain any particle contained in the cast (see Fig. 4.3I). They are observed in the urine of patients with jaundice associated with increased direct (conjugated) bilirubin.
- *Casts containing microorganisms* (bacteria and yeasts) indicate renal infection.
- *Casts containing crystals* indicate that crystals derive from the renal tubules. Crystal casts are an important diagnostic element in crystalline-induced nephropathies, such as acute urate nephropathy.[35]
- *Mixed casts* contain components of different nature, such as granules, cells, and lipids. This causes the appearance of pleomorphic cylinders, whose clinical significance is the same as that for the pure types of casts, of which mixed casts contain some components.

Crystals

Correct identification of urine crystals requires knowledge of crystal morphology, their appearance under polarized light, and urine pH. However, for unusual crystals, additional investigation may be needed, such as infrared spectroscopy, which is available only in specialized laboratories.[36] Examination of the urine for crystals is a key test in the assessment of patients with stone disease, with some rare inherited metabolic disorders (e.g., cystinuria, hyperoxaluria, phosphoribosyltransferase deficiency), and with suspected drug nephrotoxicity.[6] Crystals can be classified in four categories: common, pathologic, caused by drugs, and other crystals.

Common Crystals

Uric acid crystals and amorphous urates. Uric acid crystals have an amber color and a wide spectrum of appearances, most frequently rhomboids or barrels (see Fig. 4.4A) and, rarely, needle-like structures. Under polarized light they are strongly birefringent and polychromatic. They are found in acidic urine (pH 5.0 to 5.8).

Amorphous urates are tiny granules of irregular shape that polarize light and precipitate in acidic urine. They are identical to amorphous phosphates, which, however, precipitate in alkaline urine and do not polarize light.

Calcium oxalate crystals. There are two types of calcium oxalate crystals: bihydrated (or weddellite) crystals, which most often have a bipyramidal appearance (see Fig. 4.4B), and monohydrated (or whewellite) crystals, which are ovoid, dumbbell-shaped, or biconcave disks (see Fig. 4.4C). Monohydrated crystals always polarize light, whereas bihydrated crystals usually do not. Both types of calcium oxalate crystals precipitate at pH 5.4 to 6.7.

Calcium phosphate crystals (brushite) and amorphous phosphates. Calcium phosphate crystals are pleomorphic, appearing as prisms, star-like particles, or needles of various sizes and shapes (see Fig. 4.4D) that polarize light intensely. They also can appear as plates with a granular surface and do not polarize light. Both types of crystals precipitate in alkaline urine (pH ≥7.0).

Amorphous phosphates are tiny particles identical to amorphous urates, but they do not polarize light and precipitate at a pH of 7.0 or higher.

Triple phosphate (struvite) crystals. Triple phosphate crystals contain magnesium ammonium phosphate, and most frequently have the appearance of "coffin lids" (see Fig. 4.4E), although variants such as "flower-like, scissors-like" structures, etc., can be found. These crystals usually polarize light strongly and are found in alkaline urine (pH ≥7.0).

Pathologic Crystals

Cholesterol crystals. Cholesterol crystals are thin, transparent plates, often clumped together, with sharp edges (see Fig. 4.4F), which do not polarize light. They can be found in a wide spectrum of urine pH.

Cystine crystals. Cystine crystals occur in cystinuria and are hexagonal plates with irregular sides that are often heaped on one another (see Fig. 4.4G). They either do not polarize light or show a whitish biferingence. They are insoluble in a urine pH up to 7.4. Their persistence in urine and their number is significantly associated with the formation of cystine stones.[37]

2,8-dihydroxyadenine(2,8-DHA) crystals. 2,8-DHA crystal are spherical, brownish structures with a central umbilicus and a birefringent cross-like appearance under polarized light (see Fig. 4.4H). They are a marker of homozygous deficiency of the enzyme adenine phosphoribosyltransferase. Crystalluria is absent in heterozygotes and so allows specific identification of homozygotes in 100% of cases. The search for crystalluria is best performed on the first voided morning urine samples, which are the most concentrated.[38]

Other rare pathologic crystals are tyrosine, found in patients with acute liver disease and the rare hereditary disease tyrosinemia, and leucine, found in acute liver disease.

Crystals Caused by Drugs

Many drugs can cause crystalluria, especially in a setting of drug overdose, dehydration, or hypoalbuminemia in the presence of a urinary pH favoring drug crystallization. Examples include the antibiotics sulfadiazine, amoxicillin (see Fig. 4.4I), ciprofloxacin[6] (see Fig. 4.4J), and sulfamethoxazole[39]; the antiviral agents acyclovir, indinavir (see Fig. 4.4K),[6] atazanavir, and darunavir[40]; the vasodilators pyridoxylate and naftidrofuryl oxalate; the barbiturate primidone; the antiepileptic felbamate; the inhibitor of gastroenteric lipase orlistat; and intravenous vitamin C.[6] Most of these drugs cause crystals made of the drug, with unusual morphologies that differ from those of the crystals previously described. However, naftidrofuryl oxalate, orlistat, and vitamin C cause calcium oxalate crystals, which are indistinguishable from calcium oxalate crystals resulting from other causes.[6]

Other Crystals

Hippuric acid crystals, calcium carbonate crystals, and ammonium biurate crystals are rare and devoid of clinical significance.

Clinical Significance of Crystals

Uric acid, calcium oxalate, and calcium phosphate crystals may have no clinical significance because they can reflect transient supersaturation of the urine caused by ingestion of some foods (e.g., meat for uric acid, spinach or chocolate for calcium oxalate, milk or cheese for calcium phosphate) or mild dehydration. However, the persistence of calcium oxalate or uric acid crystalluria may reflect hypercalciuria, hyperoxaluria, or hyperuricosuria. In calcium stone formers, the evaluation of crystalluria is an important tool to assess calcium stone disease activity.[41]

Large numbers of uric acid crystals may be associated with AKI caused by acute urate nephropathy, whereas large numbers of monohydrated calcium oxalate crystals, especially with a spindle shape, may be associated with AKI from ethylene glycol intoxication. Triple phosphate crystals are usually associated with UTI caused by urea-splitting microorganisms such as *Proteus* sp., *Ureaplasma urealyticum,* and *Corynebacterium urealyticum.*

Cholesterol crystals are found in association with other fatty particles in patients with marked proteinuria. Cystine crystals are a marker of cystinuria, and 2,8-dihydroxyadenine crystals are associated with phosphoribosyltransferase enzyme deficiency. Crystalluria resulting from

drugs must be suspected whenever crystals with unusual morphology are seen. In this setting, crystalluria may be isolated and asymptomatic or associated with hematuria, obstructive uropathy, or AKI caused by the precipitation of crystals within the renal tubules.[6,35]

Organisms

Bacteria are a frequent finding because urine is usually collected and handled under nonsterile conditions and examination is often delayed. UTI should be suspected if bacteria are found in freshly voided midstream urine in association with leukocytes (in the absence of large amounts of SECs, which indicate likely contamination from genital secretions). *Candida* (yeasts), *Trichomonas vaginalis* (protozoon), and *Enterobius vermicularis* (parasite) are usually present as contaminants derived from genital secretions.

Examination of the urinary sediment is the most widely used, simplest, and fastest method for diagnosis of schistosomiasis because it shows the eggs of the *Schistosoma haematobium* parasite, with their typical terminal spike (see Fig. 4.5). The eggs are especially found in the urine collected between 10 AM and 2 PM, when the parasite female lays the eggs, and after physical exercise such as running, which favors the detachment of the eggs from the bladder mucosa.

Contaminants

A large number of particles can contaminate urine. These particles may come from the patient (e.g., spermatozoa; erythrocytes from menstruation; leukocytes from vaginitis, cloth or synthetic fibers, creams, or talcum), the laboratory (e.g., starch particles, glass fragments from coverslips), or the environment (e.g., pollens, plant cells, fungal spores).[6]

INTERPRETATION OF URINE SEDIMENT FINDINGS

Examination of the urine sediment, coupled with the quantity of proteinuria and other urine and blood findings, results in urine sediment profiles that aid in diagnosis of urinary tract diseases (Table 4.3).

Nephrotic Syndrome

The typical nephrotic sediment contains lipids, casts, and RTECs. Fatty, epithelial, granular, hyaline, and hyaline-granular casts are frequent, whereas erythrocyte or hemoglobin casts, leukocyte casts, and waxy casts are few or absent. Erythrocytes may be totally absent, especially in minimal change disease or may be in low to moderate numbers (e.g., 3-5/hpf to 20-30/hpf), which is seen especially in membranous nephropathy and focal segmental glomerulosclerosis. Leukocytes are usually not found.

Nephritic Syndrome

Erythrocytes with erythrocyte and hemoglobin casts are the hallmark of the nephritic sediment. Usually, the number of erythrocytes ranges from 30 to 40 cells/hpf to more than 100 cells/hpf, with the higher figure found especially in patients with extracapillary or necrotizing glomerular lesions. Leukocyturia is also common and is mild (e.g., 3-5/hpf) in most patients, but in those with acute postinfectious GN or active proliferative lupus nephritis, we have seen samples with up to 30 to 40 leukocytes/hpf. Leukocyte casts and waxy casts[34] also may be observed.

Acute Kidney Injury

In patients with AKI, the finding in the urine sediment of RTECs in association with granular casts and/or epithelial casts is the hallmark of ATN,[30,33] whereas these elements are rarely found in functional prerenal AKI.[30] A score based on the number of RTECs and granular casts significantly correlates with the severity of AKI, with new AKI urine biomarkers (NGAL, KIM-1, IL 18), with the progression of AKI, and with the need for dialysis and death.[30] Depending on the cause of the

TABLE 4.3 Main Urinary Profiles

Renal Disease	Hallmark	Associated Findings
Nephrotic syndrome (proteinuria: ++++)	Fatty particles	Renal tubular epithelial cells (RTECs) RTEC casts Erythrocytes (absent to moderate number)
Nephritic syndrome (proteinuria: + → ++++)	Erythrocytes (moderate to high number) Erythrocyte/hemoglobin casts	Leukocytes (low to moderate number) RTECs (low number) RTEC casts Waxy casts
AKI with ATN (proteinuria: absent to +)	RTECs RTEC casts Granular casts	Variable according to cause of ATN (e.g., myoglobin casts in rhabdomyolysis, uric acid crystals in acute urate nephropathy, erythrocytes in proliferative/active glomerulonephritis)
Urinary tract infection (proteinuria: absent)	Bacteria Leukocytes	Isomorphic erythrocytes Superficial transitional epithelial cells Struvite crystals (for infections caused by urease-producing bacteria) Leukocyte casts (in renal infection)
Polyomavirus BK infection (proteinuria: absent)	Decoy cells	Decoy cell casts (in BK virus nephropathy)
Urologic diseases (proteinuria: absent)	Isomorphic erythrocytes (low to high number) Leukocytes	Transitional cells (deep, superficial, atypical)

tubular damage, other elements can be seen. These include myoglobin-pigmented casts in rhabdomyolysis, uric acid crystals (usually in massive amounts) in acute uric acid nephropathy (tumor lysis syndrome), and erythrocytes (high numbers) and erythrocyte casts in proliferative glomerular diseases.

Urinary Tract Infection

Bacteria and leukocytes are the hallmarks of UTI, with or without superficial transitional epithelial cells and/or isomorphic erythrocytes. Struvite crystals also can be present when the infection is caused by urease-producing bacteria, such as *Proteus* sp., *U. urealyticum,* and *C. urealyticum.* In patients with renal infection, leukocyte casts and casts containing microorganisms may be found.

The correlation between the urine sediment findings and the urine culture is usually good. False-positive results may be caused by urine contamination from genital secretions (in which case large amounts of SECs are usually found, especially in women) or bacterial overgrowth on standing. False-negative results may be caused by the lysis of leukocytes or misinterpretation of cocci with other tiny particles, such as amorphous urates or phosphates.

BK Virus Infection

The KDIGO clinical practice guideline in kidney transplant recipients recommends that the monitoring of BK polyomavirus (BKV) reactivation, which may lead to BKV nephropathy (BKVN) and graft loss, is carried out by the periodical measurement of viral nucleic acid in the blood (i.e., viremia).[42] This approach, however, is expensive and not always available.[43] As an alternative, the search of "decoy cells" on either smeared or cytocentrifuged alcohol-fixed and Papanicolaou-stained urine specimens, also provides satisfactory diagnostic accuracy.[43,44] However, decoy cells can be easily seen by phase contrast microscopy in routine unstained samples.[45] Four decoy cell phenotypes are recognized: (1) nuclear ground-glass or gelatinous appearance (see Fig. 4.6A), (2) intranuclear inclusion surrounded by a clear halo (cytomegalovirus-like) (see Fig. 4.6B), (3) multinucleated cells (see Fig. 4.6C), and (4) vesicular nuclei with clumped chromatin and nucleoli (see Fig. 4.6D). In addition, hybrid forms, which represent transitions between the different phenotypes cells are frequently seen, as well as cells with eccentric nucleus and comet-like appearance. The presence of decoy cells may just indicate the reactivation of BKV infection; however, when they persist over time, are

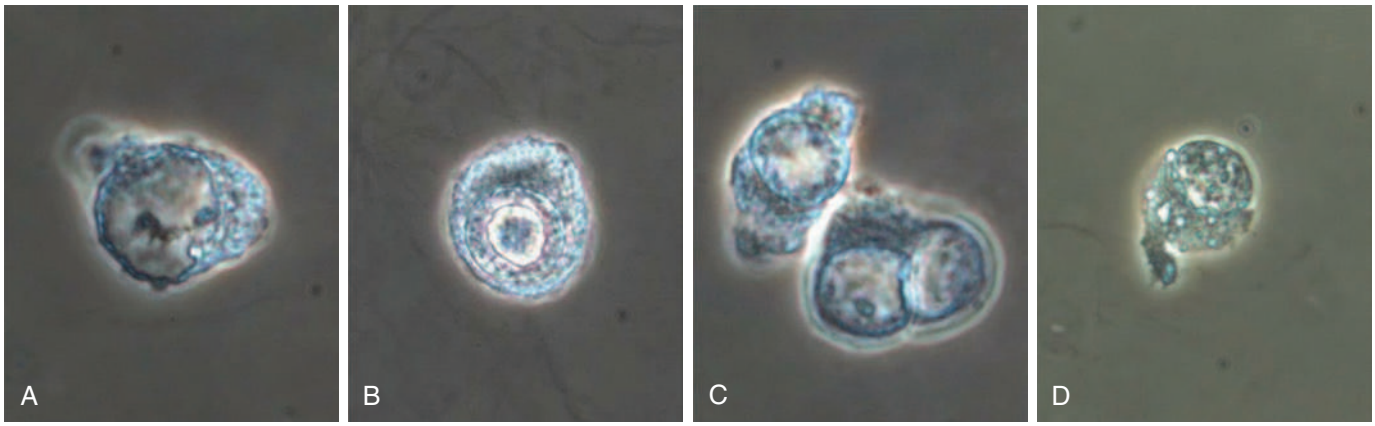

Fig. 4.6 Decoy cells. (A) Cell with nuclear ground-glass or gelatinous appearance (phenotype 1). (B) Cytomegalovirus-like cell with a large intranuclear inclusion surrounded by a clear halo (phenotype 2). (C) a binucleated cell (bottom, phenotype 3) and a cell with an enlarged ground glass nucleus (phenotype 1). (D) Cell with clumped chromatin (phenotype 4). (Phase contrast microscopy; original magnification ×400.)

in high numbers, or are found within urinary casts, they are a reliable marker of likely BKVN, which should be confirmed by measurement of BK viremia.[43,44,46]

Urologic Diseases

Urinary tract disorders such as cancer, urolithiasis, and hydronephrosis are associated with variable numbers of isomorphic urinary erythrocytes, which are often associated with leukocytes or transitional epithelial cells (from deep or superficial layers of uroepithelium). In addition, in uroepithelial cancer, malignant transitional cells can be found, which show abnormal size and shape, increased number and size of nuclei, and enlarged nucleoli. These cells also can be identified in unstained samples by phase contrast microscopy.[47]

Nonspecific Urinary Abnormalities

Some urine sediment findings are nonspecific. This occurs when variable numbers of hyaline or hyaline-granular casts are found with or without low numbers of erythrocytes (either isomorphic or dysmorphic), leukocytes, common crystals, or small numbers of superficial transitional epithelial cells.

AUTOMATED ANALYSIS OF URINE SEDIMENT

The three main types of automated instruments using different technology are flow cytometry, automated intelligent microscopy, and cuvette-based microscopy. Flow cytometry supplies quantitative results and graphics ("scattergrams"), but no images, of the identified particles. Compared with manual microscopy, the instrument shows a satisfactory correlation for red blood cells (RBCs), white blood cells (WBCs), and SECs, whereas for casts the correlation is not as good.[48]

Intelligent microscopy supplies quantitative results and images of the particles present in the sample, which are pooled and shown on the screen by categories (e.g., all SECs, all crystals found in the sample), with a good precision and accuracy for RBCs, WBCs, and SECs. For other particles, the accuracy may be improved by a trained technologist reviewing the images classified by the instrument.[49]

Cuvette-based microscopy also supplies quantitative results and black and white images of whole microscopic fields similar to those obtained with bright-field manual microscopy. This has good sensitivity for erythrocytes, leukocytes, SECs, and casts.[50]

Compared with manual microscopy, automated urine sediment analyzers offer several advantages. Small volumes of urine are required (1 to 3 ml), and high numbers of samples can be examined in a short time (up to 100/h). Drawbacks associated with centrifugation (time consumption, loss/lysis of particles) are avoided; there is acceptable accuracy for some particles, with quantitative results and small variation coefficients. Moreover, they signal to the operator the most complex samples, for which examination by manual microscopy is required. However, they also have limitations—they do not identify some clinically relevant epithelial cells (RTECs, transitional cells either deep or superficial, DCs); they underestimate casts, which they can only define as hyaline "non-hyaline" or "pathologic"; they identify only a few types of crystals; and they miss lipids completely.

Therefore automated urine sediment analyzers have their place in large clinical laboratories, in which hundreds of urine samples are tested every day, whereas they are not yet adequate for the examination of the most complex samples.

SELF-ASSESSMENT QUESTIONS

1. The reagent strip for protein:
   - **A.** Detects all types of proteins present in the urine
   - **B.** Is not adequate for the evaluation of the renal patient
   - **C.** Is not influenced by the pH of the urine
   - **D.** Is not influenced by the specific gravity of the urine
2. Phase contrast microscopy coupled with polarized light:
   - **A.** Is the correct approach for urine sediment examination
   - **B.** Does not offer any advantage over bright-field microscopy alone
   - **C.** Only phase contrast is useful
   - **D.** Only polarized light is useful
3. The automated urine sediment analyzers available today:
   - **A.** Are adequate for the evaluation of the renal patient
   - **B.** Require high volumes of urine
   - **C.** Identify renal tubular epithelial cells
   - **D.** Are not adequate for the evaluation of the renal patient

5

Imaging

David T. G. Wymer, David C. Wymer

Imaging evaluation of patients with renal disease has changed significantly in recent years. Intravenous urography (IVU) is infrequently used and has mostly been replaced by ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), and nuclear medicine scanning. Rapidly changing computer-based data manipulation has resulted in major technologic advances in each of these modalities. Three-dimensional (3D) or even 4D (time-sensitive) image analysis is now available. *Molecular imaging,* which visualizes cellular function using biomarkers, is providing functional as well as anatomic information.

The American College of Radiology (ACR) has published Appropriateness Criteria,[1] guidelines that suggest the choice of imaging modality to provide a rapid answer to the clinical question while minimizing cost and potential adverse effects to the patient, such as contrast-induced adverse events and radiation exposure. Tables 5.1, 5.2, and 5.3 list relative radiation exposures, first-choice imaging modalities in renal disease, and risk estimates, respectively. Risks of imaging and cost need to be balanced against benefits.

ULTRASOUND

Ultrasound is relatively inexpensive and provides a rapid way to assess renal location, contour, and size without radiation exposure. Nephrologists are increasingly undertaking straightforward ultrasound examination; the practical techniques as well as the appropriate interpretative skills are discussed in Chapter 92. Portable ultrasound is available and is essential in the pediatric or emergency setting. Obstructing renal calculi can be readily detected, and renal masses can be identified as cystic or solid. In cases of suspected obstruction, the progression or regression of hydronephrosis is readily evaluated. Color Doppler imaging permits assessment of renal vascularity and perfusion. Unlike the other imaging modalities, ultrasound is highly dependent on operator skills. Limitations of ultrasound include lack of an acoustic window, body habitus, and poor patient cooperation.

Kidney Size

The kidney is imaged in transverse and sagittal planes and is normally 9 to 12 cm in length in adults. Differences in kidney size can be detected with all imaging modalities. Fig. 5.1 diagrams the common causes of enlarged and shrunken kidneys.

Renal Echo Pattern

The normal renal cortex is hypoechoic compared with the fat-containing echogenic renal sinus (Fig. 5.2A). The cortical echotexture is defined as isoechoic or hypoechoic compared with the liver or spleen. In children, the renal pyramids are hypoechoic (Fig. 5.2B) and the cortex is characteristically hyperechoic compared with the liver and the spleen. In adults, an increase in cortical echogenicity is a sensitive marker for parenchymal renal disease but is nonspecific (Fig. 5.3). Decreased cortical echogenicity can be found in acute pyelonephritis and acute renal vein thrombosis.

The normal renal contour is smooth, and the cortical mantle should be uniform and slightly thicker toward the poles. Two common benign pseudomasses that can be seen with ultrasound are the dromedary hump and the column of Bertin. The column of Bertin results from bulging of cortical tissue into the medulla; it is seen as a mass with an echotexture similar to that of the cortex, but it is found within the central renal sinus (Fig. 5.4). The renal pelvis and proximal ureter are anechoic. An *extrarenal pelvis* refers to the renal pelvis location outside the renal hilum. The ureter is not identified beyond the pelvis in nonobstructed patients.

Obstruction can be identified by the presence of hydronephrosis (Fig. 5.5). Parenchymal and pelvicalyceal nonobstructing renal calculi as well as ureteral obstructing calculi can be readily detected (Fig. 5.6). The upper ureter also will be dilated if obstruction is distal to the pelviureteral junction (see Fig. 5.5C). False-negative ultrasound examination findings with no hydronephrosis occasionally occur in early obstruction. Obstruction without ureteral dilation also may occur in retroperitoneal fibrosis and in transplanted kidneys as a result of periureteral fibrosis.

Renal Cysts

Cysts can be identified as anechoic lesions and are a frequent coincidental finding during renal imaging. Ultrasound usually readily identifies renal masses as cystic or solid (Figs. 5.7 and 5.8). However, hemorrhagic cysts may be mistakenly called solid because of increased echogenicity. Differentiation of cysts as simple or complex is required to plan intervention.

Simple Cysts

A simple cyst on ultrasound is anechoic, has a thin or imperceptible wall, and demonstrates through-transmission because of the relatively rapid progression of the sound wave through fluid compared with adjacent soft tissue.

Complex Cysts

Complex cysts contain calcifications, septations, and mural nodules. Instead of being anechoic, these masses may contain internal echoes representing hemorrhage, pus, or protein. Complex cysts may be benign or malignant; cyst wall nodularity, septations, and vascularity strongly suggest malignancy. The Bosniak classification of cystic renal masses is widely used (see Table 59.5). Complex cysts identified by ultrasound require further evaluation by contrast-enhanced CT (or MRI) to identify

TABLE 5.1 Relative Radiation Doses of Imaging Examinations

Examination	Effective Dose (mSv)
Chest: PA x-ray film	0.02
Lumbar spine	1.8
KUB abdomen	0.53
CT abdomen	10
CT chest	20-40

TABLE 5.2 Suggested Imaging in Renal Disease*

Renal Pathology	First-Choice Imaging
Acute kidney injury, chronic kidney disease	Ultrasound
Hematuria	Ultrasound or CT
Proteinuria, nephrotic syndrome	Ultrasound Multiphase CT urography
Hypertension with normal renal function	Ultrasound Consider CTA or MRA
Hypertension with impaired renal function	Ultrasound with Doppler
Renal infection	Contrast-enhanced CT
Hydronephrosis identified on ultrasound	Nuclear renogram
Retroperitoneal fibrosis	Contrast-enhanced CT
Papillary or cortical necrosis	Contrast-enhanced CT
Renal vein thrombosis	Contrast-enhanced CT
Renal infarction	Contrast-enhanced CT
Nephrocalcinosis	CT

Modified from reference 1.
*These recommendations assume availability of all common imaging modalities.
CT, Computed tomography; *CTA,* computed tomographic angiography; *MRA,* magnetic resonance angiography.

TABLE 5.3 Risk Estimates in Diagnostic Imaging

Imaging Risk	Estimated Risk
Cancer from 10 mSv of radiation (1 body CT)[2]	1 in 1000
Contrast-induced nephropathy in patient with renal impairment[4]	Uncertain but higher with diabetes or hyperuricemia
Nephrogenic systemic fibrosis[4,6]	1 in 25,000 to 1 in 30,000 (depends on gadolinium agent) Higher risk if GFR >30 ml/min
Death from iodine contrast anaphylaxis[5]	1 in 130,000
Death from gadolinium contrast anaphylaxis[6]	1 in 280,000

abnormal contrast enhancement of the cyst wall, mural nodule, or septum, which may indicate malignancy.

Bladder

Real-time imaging can be used to evaluate for bladder wall tumors and bladder stones. Color flow Doppler evaluation of the bladder in well-hydrated patients can be used to identify a ureteral jet, produced when peristalsis propels urine into the bladder. The incoming urine has a higher specific gravity relative to the urine already in the bladder (Fig. 5.9). Absence of the ureteral jet can indicate total ureteral obstruction.

Renal Vasculature

Color Doppler investigation of the kidneys provides a detailed evaluation of the renal vascular anatomy. The main renal arteries can be identified in most patients (Fig. 5.10). Power Doppler imaging is a more sensitive indicator of flow, but unlike color Doppler imaging, power Doppler provides no information about flow direction and cannot be used to assess vascular waveforms. However, power Doppler imaging is exquisitely sensitive for detection of renal parenchymal flow and has been used to identify cortical infarction.

Renal Artery Duplex Scanning

The role of gray-scale and color Doppler sonography in evaluating for renal artery stenosis is controversial. The principle is that a narrowing in the artery will cause a velocity change commensurate with the degree of stenosis, as well as a change in the normal renal artery waveform downstream from the lesion. The normal renal artery waveform demonstrates a rapid systolic upstroke and an early systolic peak (Fig. 5.11A). The waveform becomes damped downstream from a stenosis. This consists of a slow systolic acceleration (tardus) and a decreased and rounded systolic peak (parvus) (see Fig. 5.11B). It also results in a decrease in the *resistive index,* defined as the end-diastolic velocity (EDV) subtracted from the peak systolic velocity (PSV) divided by PSV: (PSV – EDV)/PSV. The normal resistive index is 0.70 to 0.72.

The entire length of the renal artery should be examined for the highest velocity signal. The origins of the renal arteries are important to identify because this area is often affected by atherosclerosis, but the arteries are often difficult to visualize because of overlying bowel gas. Within the kidney, medullary branches and cortical branches in the upper, middle, and lower thirds should be included to attempt detection of stenosis in accessory or branch renal arteries.

Proximal and distal criteria exist for diagnosis of significant renal artery stenosis, usually defined as stenosis greater than 60%. The *proximal* criteria detect changes in the Doppler signal at the site of stenosis and provide sensitivities and specificities ranging from, respectively, 0% to 98% and 37% to 98%.[7,8] Technical failure rates are typically 10% to 20%.[9] Renal artery stenosis also may be missed if PSV is low because of poor cardiac output or aortic stenosis. False-positive results can occur when renal artery velocity is increased because of high-flow states, such as hyperthyroidism or vessel tortuosity. The *distal* criteria are related to detection of a tardus-parvus waveform distal to a stenosis; sensitivities and specificities of 66% to 100% and 67% to 94%, respectively, have been reported.[10,11] Technical failure with distal criteria is much lower than with proximal evaluation (<5%). False-negative results can occur from stiff poststenotic vessels, which will decrease the tardus-parvus effect. The tardus-parvus effect also may be a result of aortic stenosis, low cardiac output, or collateral vessels in complete occlusion, giving a false-positive result.

Combining the proximal and distal criteria improves detection of stenoses. Sensitivity of 97% and specificity of 98% can be achieved

when both the extrarenal and the intrarenal arteries are examined.[12] When it is technically successful, Doppler ultrasound has a negative predictive value of more than 90%.[12] However, reliable results require a skilled and experienced sonographer and a long examination time. Despite these limitations, Doppler studies also have several advantages. Noninvasive, inexpensive, and widely available, Doppler studies also allow structural and functional assessment of the renal arteries and imaging without exposure to radiation or contrast material.

Some physicians prefer computed tomography angiography (CTA) or magnetic resonance angiography (MRA) as a faster and more reliable test than ultrasound, but at present the choice should depend on local expertise and preference. For further discussion of the diagnosis and management of renovascular disease, see Chapter 41.

Contrast-Enhanced and Three-Dimensional Ultrasound

Ultrasound contrast agents, initially introduced to assess cardiac perfusion, are now being used to evaluate perfusion to other organs, such as the kidney. These intravenous agents are microbubbles 1 to 4 µm in diameter (smaller than erythrocytes) that consist of a shell surrounding the echo-producing gas core. The microbubbles oscillate in response to the ultrasound beam frequency and give a characteristic increased echo signal on the image. Preliminary studies evaluating renal perfusion in dysfunctional kidneys show reduced flow compared with normal kidneys, as well as improved lesion detection (Fig. 5.12). However, the clinical adoption of microbubble imaging in the kidney remains uncertain, particularly with the general availability and robustness of CT and MRI.

Two-dimensional ultrasound images can be reconstructed into 3D volume images by a process similar to 3D reconstructions for MRI and CT. Potential applications include vascular imaging and fusion with MRI or positron emission tomography (PET).

PLAIN RADIOGRAPHY AND INTRAVENOUS UROGRAPHY

The use of IVU has receded as cross-sectional imaging by CT and MRI has become more widely applied to the urinary tract. Although now with few primary indications in many centers, contrast urography may still be a key investigation in parts of the world where economic limitations mean that cross-sectional imaging is not available. However, plain radiography, often called KUB (kidneys, ureter, bladder) imaging, still has an important role in the identification of soft tissue masses, bowel gas pattern, calcifications, and renal location.

Renal Calcification

Most renal calculi are radiodense, although only about 60% of urinary stones detected on CT are visible on plain films.[13] CT demonstrates

nonopaque stones, which include uric acid, xanthine, and struvite stones. However, neither CT nor plain radiography may detect calculi associated with protease inhibitor therapy.[14] Oblique films are sometimes obtained to confirm whether a suspicious upper quadrant calcification is renal in origin. Calculi that are radiolucent on plain films are usually detected as filling defects on IVU. IVU has higher sensitivity than radiography but lower sensitivity than CT. If available, CT is the imaging modality of choice for detection of urinary calculi.[15]

Nephrocalcinosis may be medullary (Fig. 5.13A and B) or cortical (C) and is localized or diffuse. The causes of nephrocalcinosis are discussed in Chapter 57 (see Box 57.7).

Intravenous Contrast Urography

Before contrast material is administered, an abdominal compression device may be placed, to compress the midureters against the bony pelvis. This retains the excreted contrast material in the upper tract and distends the renal pelvis and calyces. The first film is usually performed at 30 seconds after contrast injection, when the renal parenchyma is at peak enhancement. Subtle renal masses are often detected only on these early films. The compression device is then removed, and films of the entire abdomen are obtained at 5 minutes, when there is renal excretion of the contrast agent and the ureters are best evaluated. Films with the patient prone may be required to visualize the entirety of the ureter. A filled-bladder film is obtained. A postvoid film of the bladder assesses emptying and assists in evaluation of the distal ureters, which may be obscured by a distended contrast-filled bladder. The usual contrast volume injected for IVU is similar to that for routine abdominal CT. The primary difference is timing of imaging. IVU is contraindicated in patients with a history of allergic reactions to radiographic contrast agents. When the glomerular filtration rate (GFR) is less than 60 ml/min, IVU yields increasingly poor images.

Kidneys

Evaluation of the kidneys on IVU (as well as CT and MRI) should include their number, location, axis, size, contour, and degree of

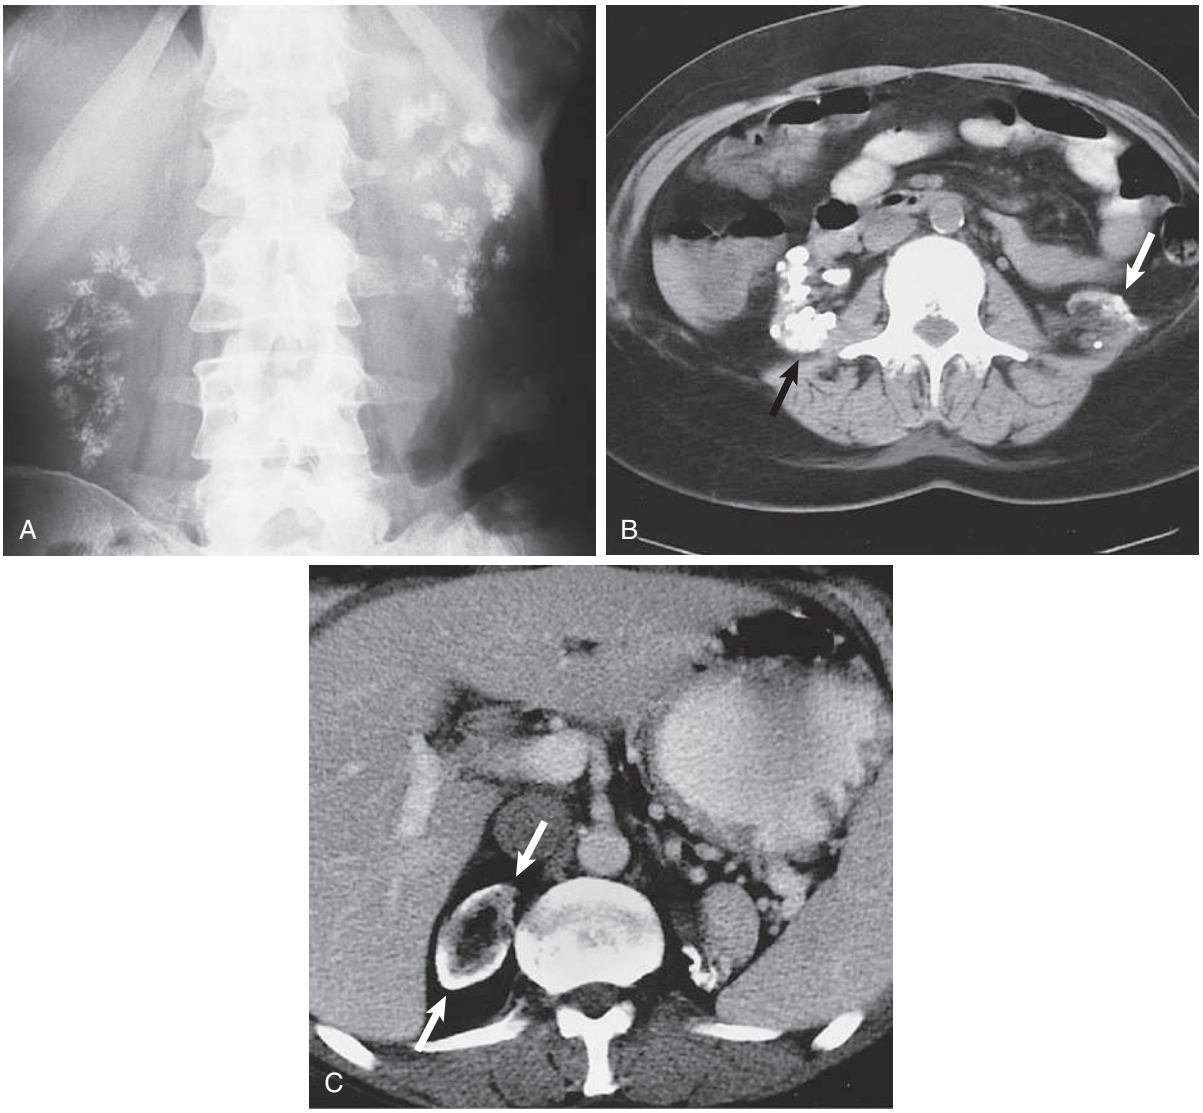

Fig. 5.13 Nephrocalcinosis. (A) Plain x-ray film shows bilateral medullary nephrocalcinosis in a patient with distal renal tubular acidosis. (B) Noncontrast CT scan in a patient with hereditary oxalosis and dense bilateral renal calcification *(arrows)*. The left kidney is atrophic. (C) Noncontrast CT scan shows cortical nephrocalcinosis in the right kidney *(arrows)* after cortical necrosis.

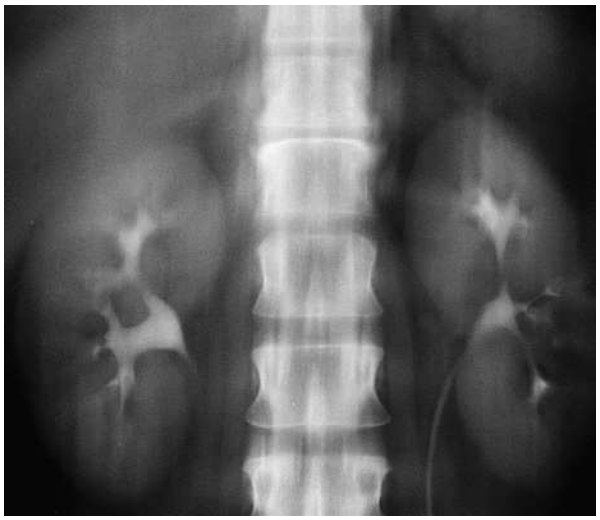

Fig. 5.14 Normal parenchymal enhancement and normal renal excretion. Early postcontrast tomogram in intravenous urography.

enhancement. Renal size is variable, but a normal kidney should be about three or four lumbar vertebral bodies in length. The renal outline should be smooth and sharply demarcated from the retroperitoneal fat. Renal enhancement after contrast administration should be symmetric and progress centrally from the cortex, with excretion evident in the ureters by 5 minutes. Asymmetry of renal enhancement may indicate renal artery disease.

Pelvicalyceal System

The pelvicalyceal system is best evaluated on the early postcontrast films. Normally, there are about 10 to 12 calyces per kidney. The calyces drain into the infundibula, which in turn empty into the renal pelvis (Fig. 5.14). The infundibulum and renal pelvis should have smooth contours without filling defects. In a common variant, vessels can cross the pelvicalyceal system or ureters, causing extrinsic compression defects that should not be mistaken for tumors or other urothelial lesions. When more than one calyx drains into an infundibulum, it is known as a *compound calyx,* most frequently seen in the poles. The normal calyx is gently cupped. Calyceal distortion occurs with papillary necrosis and reflux nephropathy.

Ureters

The ureters are often seen segmentally because of active peristalsis. The ureters should be free of filling defects and smooth. In the abdomen, the ureters lie in the retroperitoneum, passing anterior to the transverse processes of the vertebral bodies. In the pelvis, the ureters course laterally and posteriorly, eventually draining into the posteriorly located vesicoureteral junction. At the vesicoureteral junction, the ureters gently taper. Medial bowing or displacement of the ureter is often abnormal and can be seen secondary to ureter displacement from retroperitoneal masses, lymphadenopathy, and retroperitoneal fibrosis.

Bladder

The bladder should be rounded and smooth-walled. Benign indentations on the bladder include the uterus, prostate gland, and bowel. In chronic bladder outlet obstruction and neurogenic bladder, numerous trabeculations and diverticula may be seen around the bladder outline. Other incidental bladder diverticula, such as the Hutch diverticulum, can be seen and are usually of no significance unless they are large and do not empty completely on voiding.

RETROGRADE PYELOGRAPHY

Retrograde pyelography is performed when the ureters are poorly visualized on other imaging studies or when samples of urine need to be obtained from the kidney for cytology or culture. Patients who have severe allergies to contrast agents or impaired renal function can be evaluated with retrograde pyelography. The examination is performed by placing a catheter through the ureteral orifice under cystoscopic guidance and advancing it into the renal pelvis. With use of fluoroscopy, the catheter is slowly withdrawn while radiocontrast is injected (see Figs. 58.2 and 58.11). This technique provides excellent visualization of the renal pelvis and ureter and also can be used for cytologic sampling from suspect areas.

ANTEGRADE PYELOGRAPHY

Antegrade pyelography is performed through a percutaneous renal puncture and is used when retrograde pyelography is not possible. Ureteral pressures can be measured, hydronephrosis evaluated, and ureteral lesions identified (see Fig. 58.14). The examination is often performed as a prelude to nephrostomy placement. Both antegrade and retrograde pyelography are invasive and should be performed only when other studies are inadequate.

IMAGING ILEAL CONDUITS

After cystectomy or bladder failure, numerous types of continent or incontinent urinary diversions can be surgically created. One of the most common diversions is the ileal conduit; an ileal loop is isolated from the small bowel, and the ureters are implanted into the loop. This end of the loop is closed, and the other end exits through the anterior abdominal wall. This type of conduit can be evaluated by an excretory or a retrograde study. The excretory or *antegrade* study is performed and monitored in the same way as an IVU. A *retrograde* examination, also referred to as a "loop-o-gram," is obtained when the ureters and conduit are suboptimally evaluated on the excretory study. A Foley catheter is placed into the stoma and contrast slowly instilled. The ureters should fill by reflux because the ureteral anastomoses are not of the antireflux variety (Fig. 5.15).

CYSTOGRAPHY

A cystogram is obtained when more detailed radiographic evaluation of the bladder is required. *Voiding* cystography is performed to identify ureteral reflux and assess bladder function and urethral anatomy. A urethral catheter is placed into the bladder, the urine drained, contrast infused, and the bladder filled under fluoroscopic guidance. Early frontal and oblique films with the patient supine are obtained while the bladder is filling. Ureteroceles are best identified on early films. When the bladder is full, multiple films are obtained with varying degrees of obliquity. Reflux may be seen on these films. To obtain a voiding cystogram, the catheter is removed, the patient voids, and the contrast is followed into the urethra. Occasionally, bladder diverticula are seen only on the voiding films. When the patient has completely voided, a final film is used to assess the amount of residual urine and the mucosal pattern.

Radionuclide cystography is an alternative often used in children. It is useful in the diagnosis of reflux, but it does not provide the detailed anatomy seen with contrast cystography.

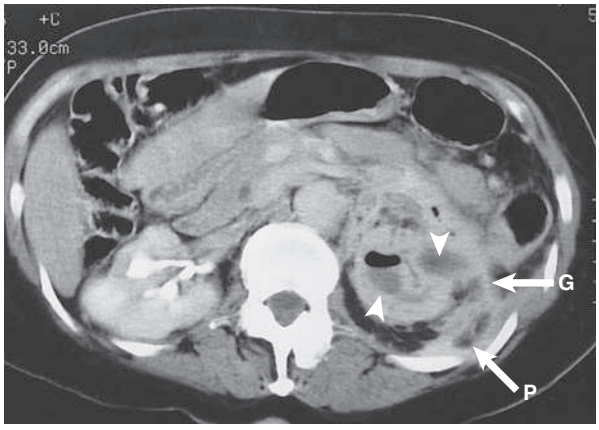

Fig. 5.18 Emphysematous pyelonephritis. Contrast-enhanced CT scan shows gas *(arrowheads)* within an enlarged left kidney and marked enhancement of the Gerota fascia *(G)* and posterior perirenal space *(P)*, indicative of inflammatory involvement.

COMPUTED TOMOGRAPHY

Computed tomography examination of the kidneys is performed to evaluate suspect renal masses, locate ectopic kidneys (Figs. 5.16 and 5.17), investigate calculi, assess retroperitoneal masses, and evaluate the extent of parenchymal involvement in patients with acute pyelonephritis (Figs. 5.18 and 5.19). Helical CT scanners allow the abdomen and pelvis to be scanned at submillimeter intervals with single breath-held acquisitions, which eliminates motion artifact. Newer multidetector row CT results in multiple slices of information (64-slice and even 320-slice machines are now common) being acquired simultaneously, allowing the entire abdomen and pelvis to be covered in very fast acquisition times of less than 30 seconds. Although the improved CT imaging usually comes at a price of increased radiation exposure to the patient, new reconstruction software with *iterative reconstruction* significantly reduces radiation exposure by as much as 30%. The CT data can be reconstructed in multiple planes and even 3D for improved anatomic visualization and localization.

Tissue Density

The Hounsfield unit (HU) scale is a measurement of relative densities determined by CT. Distilled water at standard pressure and temperature is defined as 0 HU; the radiodensity of air is defined as −1000 HU. All other tissue densities are derived from this (Table 5.4). Tissues can vary in their exact HU measurements and will also change with contrast enhancement. Water, fat, and soft tissue often can look identical on the scan, depending on the window and level settings of the image, so actual HU measurement is essential to characterize the tissues accurately.

Contrast-Enhanced and Noncontrast Computed Tomography

CT examination of the kidneys can be performed with or without intravenous administration of contrast material. Noncontrast imaging

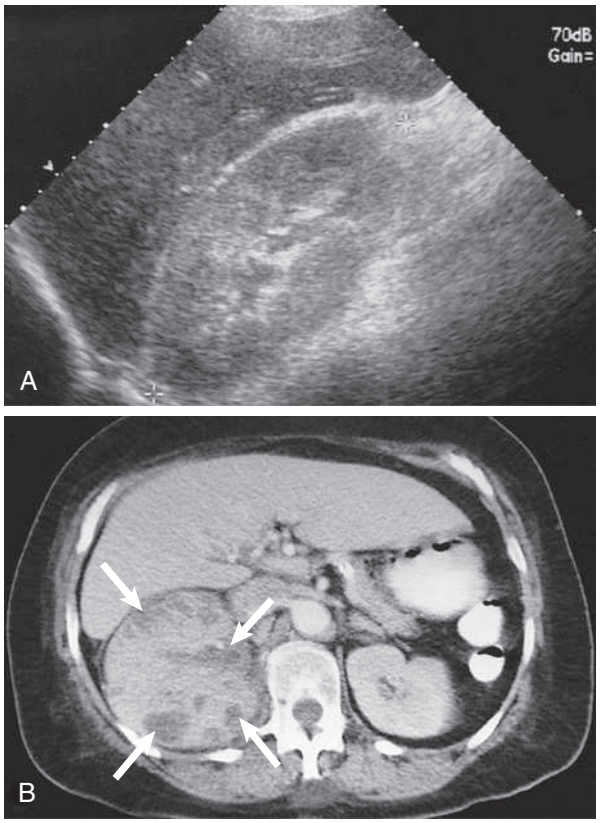

Fig. 5.19 Acute pyelonephritis. (A) Ultrasound image demonstrates an enlarged echogenic kidney. Bipolar length of kidney is 12.9 cm. (B) CT scan with contrast enhancement obtained 24 hours later demonstrates multiple nonenhancing abscesses *(arrows)*.

TABLE 5.4 Computed Tomography Determination of Density of Common Substances

Substance	Hounsfield Units*
Air	−1000
Fat	−120
Water	0
Muscle	+40
Bone	+400 or more

*Hounsfield unit (HU) scale is a measurement of relative densities compared with distilled water.

allows the kidneys to be evaluated for the presence of calcium deposition and hemorrhage, which are obscured after contrast administration.

Noncontrast CT is the examination of choice in patients with suspected nephrolithiasis and has replaced the KUB and IVU in most situations. The study consists of unenhanced images from the kidneys through the bladder for detection of calculi. CT has the advantage of being both highly sensitive (97% to 100%) and specific (94% to 96%) for diagnosis of urinary calculi.[15,16] Noncontrast CT can identify a possible obstructing calculus and the extent of parenchymal and perinephric involvement.

In cases other than stone evaluation, the kidneys are imaged after contrast administration (CT urography [CTU]). The kidneys are imaged in the corticomedullary phase for evaluation of the renal vasculature

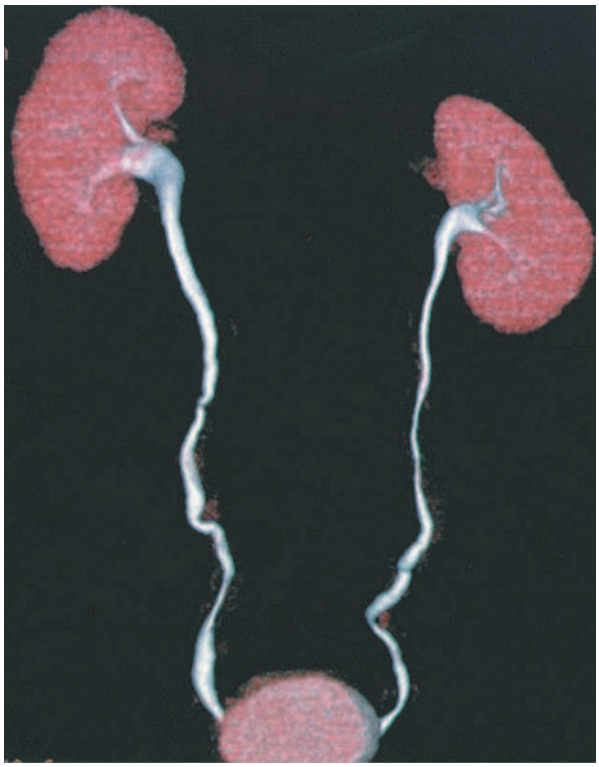

Fig. 5.20 Noncontrast CT of bladder and kidney. Computer-reformatted, volume-rendered CT urogram obtained from axial CT acquisition.

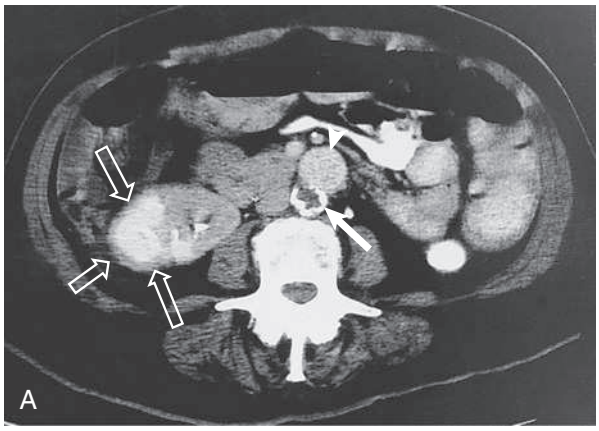
and in the nephrographic phase for evaluation of the renal parenchyma. The degree of enhancement can be assessed in both solid masses and complex cysts.

A compression device can be used as in IVU, but is very uncommonly used. Delayed images through the kidneys and bladder are performed for evaluation of the opacified and distended collecting system, ureters, and bladder.[17,18] After acquisition, the axial images can be reformatted into coronal or sagittal planes to optimize visualization of the entire collecting system (Fig. 5.20). The CT study can be tailored to the individual clinical scenario. For example, the corticomedullary phase can be eliminated to decrease the radiation dose if there is no concern about a vascular abnormality or no need for presurgical planning. A diuretic or saline bolus can be administered after contrast to better distend the collecting system and ureters during the excretory phase.

The kidneys should be similar in size and show equivalent enhancement and excretion. During the corticomedullary phase, there is brisk enhancement of the cortex. The cortical mantle should be intact. Any disruption of the cortical enhancement requires further evaluation; it may be caused by acute pyelonephritis (see Fig. 5.19), scarring, mass lesions, or infarction (Fig. 5.21). During the excretory phase, the entire kidney and renal pelvis enhance. Delayed excretion and delay in pelvicalyceal appearance of contrast material may be found in obstruction (Fig. 5.22), but also in renal parenchymal disease such as acute tubular necrosis (ATN).

Computed Tomographic Angiography

Helical scanning facilitates CTA, which can produce images similar to conventional angiograms, but is less invasive. A bolus of contrast material is administered, and the images are reconstructed at 0.5- to 3-mm



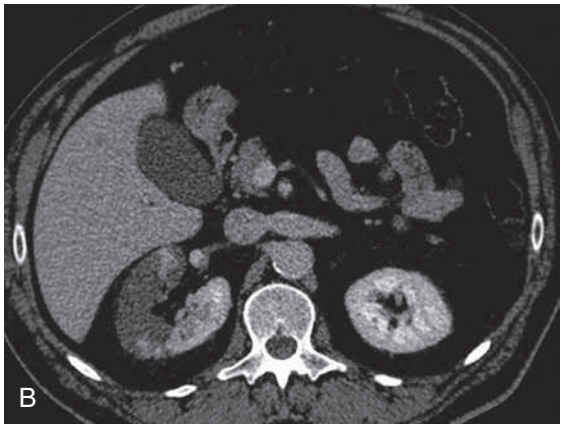


Fig. 5.21 Renal infarction. (A) CT scan showing a chronic calcified infarct *(open arrows)* involving half of the right kidney after aortic bypass surgery. The native aorta has a densely calcified wall *(arrow)*. The aortic graft is anterior to the native aorta *(arrowhead)*. (B) CT scan showing acute infarct in the right kidney with decreased parenchymal enhancement *(arrows)*.

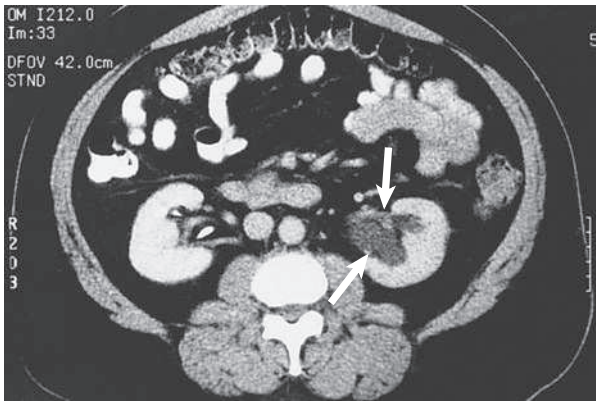

Fig. 5.22 Delayed excretion in left kidney secondary to distal calculus. Contrast-enhanced CT scan shows dilated left renal pelvis *(arrows)*.

consecutive intervals. The contrast bolus is timed for optimal enhancement of the aorta. The tightly focused and narrow CT beam allows higher resolution and better subsequent multiplanar reconstructions. The aorta and branch vessels are well demonstrated (Fig. 5.23). This technique is now widely used in living transplant donor evaluation (see Fig. 104.2), providing information not only on arterial and venous

Fig. 5.23 Normal renal arteries. 3D reformatted CT angiogram.

anatomy but also on size, number, and location of the kidneys and any ureteral anomalies of number or position.

In addition, CTA can be used to evaluate for atheromatous renal artery stenosis, with sensitivity of 96% and specificity of 99% for the detection of hemodynamically significant stenosis compared with digital subtraction angiography (DSA).[19] Furthermore, CTA allows visualization of both the arterial wall and lumen, which helps in planning renal artery revascularization procedures. Another advantage of CTA is the depiction of accessory renal arteries as well as nonrenal causes of hypertension, such as adrenal masses. CTA can be used to diagnose fibromuscular dysplasia but has a lower sensitivity (87%) than DSA.[20]

Dual-Energy Computed Tomography

In dual-energy CT (DECT), two CT datasets are acquired using different tube potentials, usually 140 and 80 kilovolts (kV), with different x-ray spectra. The density values at both acquired spectra differentiate materials on the basis of the photoelectric effect. Among other uses of DECT, using mathematical algorithms, the density values allow kidney stone differentiation (i.e., differentiation of uric acid from magnesium or calcium), allowing tailored treatment strategies.[21,22]

Limitations of Computed Tomography

CT does have some limitations. The cradle that the patient lies on usually has an upper weight limit of 100 to 200 kg (300 to 400 lb), but newer scanners can now accommodate up to 270 kg (600 lb). Obese patients often have suboptimal scans because of weight artifact and need higher radiation exposures to adjust for x-ray attenuation. Contrast-enhanced CT studies may be contraindicated in patients with an allergy to radiographic contrast and in patients with impaired renal function. If contrast is administered, subjects should be hydrated with intravenous saline and/or sodium bicarbonate. For further discussion on contrast use in patients with impaired renal function, see Radiologic Contrast Agents.

CT is very sensitive to metal artifact and patient motion. Retroperitoneal clips and intramedullary rods will cause extensive streak artifact, which severely degrades the images. Patients who are unable to remain motionless will also have suboptimal or even nondiagnostic studies, and sometimes sedation or general anesthesia may be needed to obtain diagnostic scans, particularly in children. Critically ill patients may not be stable enough for transport to the CT suite, and ultrasound can be considered as an alternative to CT in that setting.

MAGNETIC RESONANCE IMAGING

Although it only rarely should be the first examination used to evaluate the kidneys, MRI is typically an adjunct to other imaging. The major

advantage of MRI over other modalities is direct multiplanar imaging. CT is limited to slice acquisition in the axial plane of the abdomen, and coronal and sagittal planes are acquired only by reconstruction, which can lead to loss of information.

Tissues contain an abundance of hydrogen, the nuclei of which are positively charged protons. These protons spin on their axis, producing a magnetic field (magnetic moment). When a patient is placed in a strong magnetic field in an MRI scanner, some of the protons align themselves with the field. When a radiofrequency pulse is applied, some of the protons aligned with the field will absorb energy and reverse direction. This absorbed energy is given off as a radiofrequency pulse as the protons relax (return to their original alignment), producing a voltage in the receiver coil. The coil is the hardware that covers the region of interest. For renal imaging, a body coil or torso coil is used. Relaxation is a 3D event giving rise to two parameters: T1 relaxation results in the recovery of magnetization in the longitudinal (spin-lattice) plane, whereas T2 results from the loss of transverse (spin-spin) magnetization. A rapid-sequence variant of T2 in common use is fast spin echo (FSE). Hydrogen ions move at slightly different rates in the different tissues. This difference is used to select imaging parameters that can suppress or aid in the detection of fat and water. Fluid, such as urine, is dark or low in signal on T1-weighted sequences and bright or high in signal on FSE sequences. Fat is bright on T1 and not as bright on FSE sequences (Fig. 5.24). The sequences and imaging planes selected must be tailored to the individual MR study. Diffusion-weighted imaging (DWI) evaluates the freedom of water molecules to diffuse in tissues; restriction of diffusion is imaged as bright areas on the DWI image set. Using the DWI data, regional apparent diffusion coefficients of the tissue can be calculated and an image of the distribution of the coefficients of the tissue can be produced. Dark areas on what is known as an apparent diffusion coefficient map are seen in infection, neoplasia, inflammation, and ischemia (Fig. 5.25).

Standard MR images usually include T1, T2, or FSE sequences and often additional contrast-enhanced T1 images. The imaging plane varies according to the clinical concerns. Usually, at least one sequence is performed in the axial plane. Sagittal and coronal images cover the entire length of the kidney and can make some subtle renal parenchymal abnormalities more conspicuous (Fig. 5.26).

On T1-weighted sequences, the normal renal cortex is higher in signal than the medulla, producing a distinct corticomedullary differentiation, which becomes indistinct in parenchymal renal disease. It is analogous to the echogenic kidney seen on ultrasound. On FSE sequences, the corticomedullary distinction is not as sharp but should still be present.

Contrast-Enhanced Magnetic Resonance Imaging

As with CT, intravenous contrast material can be administered to allow further characterization of renal lesions. Gadolinium is a *paramagnetic* contrast agent frequently used in MRI. Nephrotoxicity to gadolinium agents appears to be very uncommon and likely insignificant.[23] Adverse reactions to gadolinium are discussed later (see Magnetic Resonance Contrast Agents). Paramagnetic contrast agents are being evaluated for measurement of glomerular function.

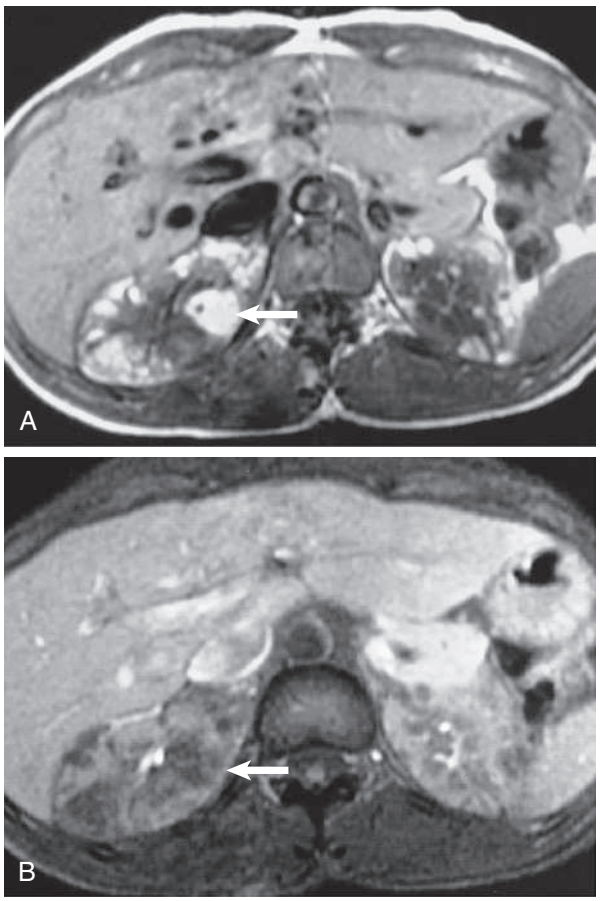

Fig. 5.24 Tuberous sclerosis on MRI. Multiple renal angiomyolipomas are seen. (A) T1-weighted MR image. The tumors are high in signal on T1 because of their fat; *arrow* shows the largest tumor. (B) T1-weighted MR image with fat suppression. The fat within the tumors is now low in signal *(arrow)*.

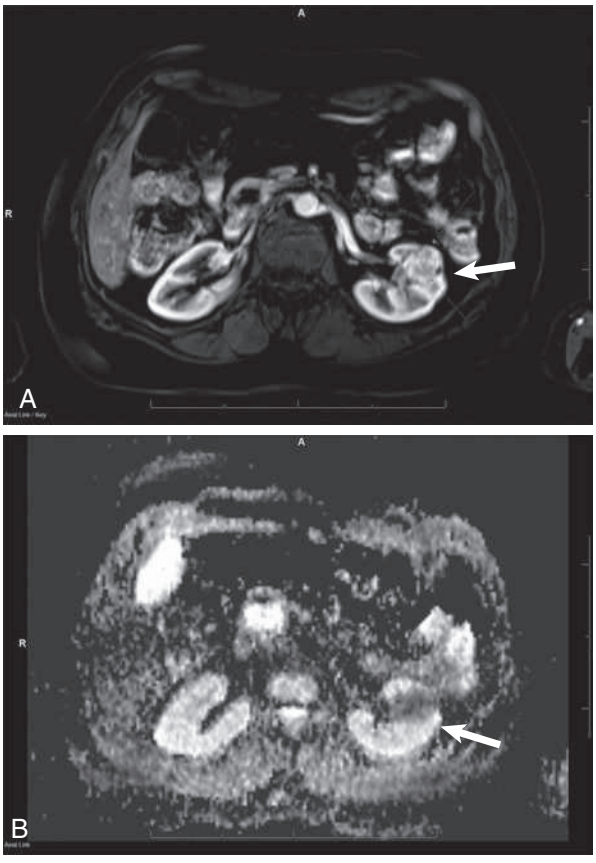

Fig. 5.25 MRI of renal tumor. T1-weighted contrast enhanced image showing enhancing left renal tumor.

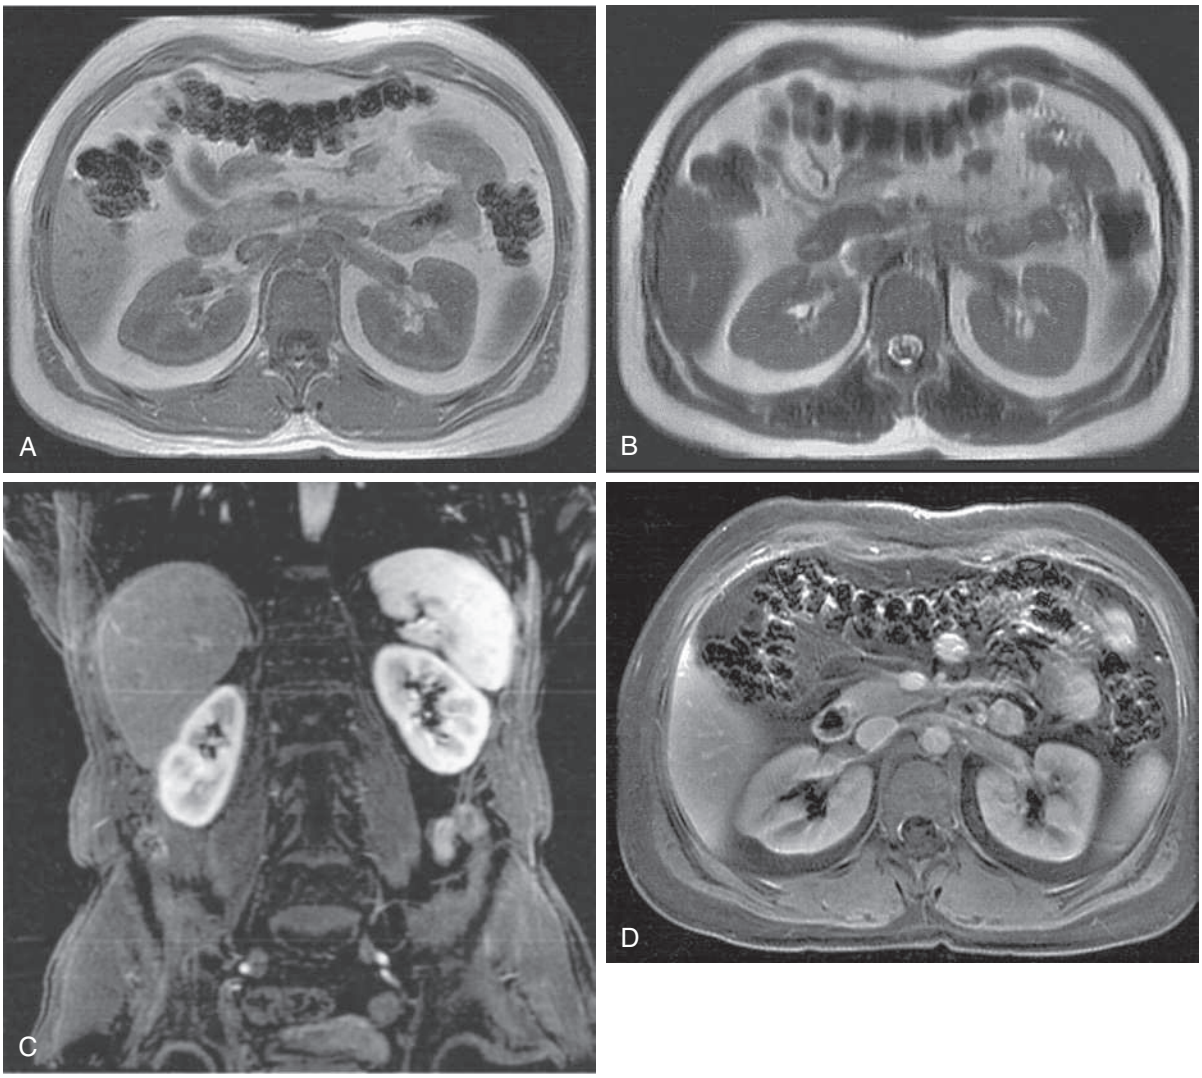

Fig. 5.26 Normal MR images through kidneys. (A) T1-weighted MR image. Note the distinct corticomedullary differentiation. (B) Fast spin echo MR image. Urine in the collecting tubules causes the high signal within the renal pelvis on this sequence. (C) Coronal T1-weighted, fat-suppressed MR image after contrast administration. (D) Axial T1-weighted, fat-suppressed image after contrast administration.

After injection of gadolinium, the vessels appear high in signal, or white, on T1-weighted sequences. Multiple images can be obtained in a single breath-held acquisition. This technique is useful for lesion characterization in patients who cannot receive iodinated contrast material. As with contrast-enhanced CT, the kidneys initially show symmetric cortical enhancement, which progresses to excretion. A delay in enhancement can be seen with renal artery stenosis.

Magnetic Resonance Urography

There are two techniques for performing magnetic resonance urography (MRU).[24] The first technique is sometimes called *static* MRU. Because urine contains abundant water, it will demonstrate high signal on a T2-weighted image. Therefore a heavily T2-weighted sequence accentuates the static fluid in the collecting system and ureters, which stands out against the darker background soft tissues. Static MRU can be performed rapidly, which is a benefit in imaging of children. A disadvantage is that any fluid in the abdomen or pelvis, such as fluid collections or fluid in the small bowel, will demonstrate a similar bright signal that can obscure superimposed structures. Also, the collecting system and ureters need to be distended for acquisition of good MR images.

The second technique, often referred to as *excretory* MRU, is similar to CTU. Intravenous administration of gadolinium is followed by T1-weighted imaging. This technique allows some assessment of renal function because the contrast is filtered by the kidney and excreted into the urine (see Fig. 58.10). The opacified collecting system and ureters are well seen, and a diuretic can be administered to further dilate the renal pelvis and ureters if necessary. MRU has limited capacity to detect calculi because calcification is poorly visualized by MRI.

Because CTU and MRU are comparable examinations in identifying the cause and anatomic location of urinary obstruction, the choice of modality is a matter of local preference. CTU is the better choice in the evaluation of urinary tract calculi. In patients with renal impairment caused by obstruction, MRU is superior to CTU in identifying noncalculous causes of obstruction, whereas CTU is superior in identifying calculi as a cause of obstruction.[25] CTU is also more widely available, faster, and less expensive than MRU. MRU is better suited in patients with allergy to iodinated contrast agents and

Fig. 5.27 Magnetic resonance angiography. Coronal 3D MR angiogram after contrast administration shows normal renal arteries.

Fig. 5.28 MR venography.

sometimes in children when radiation is an issue. MRU is also useful in depicting the anatomy in patients with urinary diversion to bowel conduits.

Magnetic Resonance Angiography

Although MRA can be performed with or without intravenous contrast, contrast provides better images. The aorta and branch vessels are beautifully demonstrated (Fig. 5.27). By adjustment of timing and type of sequences, the abdominal venous structures can be visualized (Fig. 5.28). MRA is performed to evaluate the renal arteries for stenosis and is less invasive than catheter angiography (Fig. 5.29). Technical advances, including faster sequences, now give sensitivity of 97% and specificity of 93% compared with DSA for contrast-enhanced MRA in the detection of renal artery stenosis.[26] MRA without gadolinium has a lower sensitivity (53% to 100%) and specificity (65% to 97%) for detection of renal artery stenosis.[27] MRA has limited ability to assess accessory renal arteries and therefore is not an ideal study to evaluate fibromuscular dysplasia. It has become the most commonly used modality in patients with hypertension, declining renal function, or allergy to iodinated contrast agents.[28] Where MRA is unavailable, Doppler ultrasound can be used.

Disadvantages of Magnetic Resonance Imaging

As with CT, MRI has some disadvantages. The table and gantry are confining, so claustrophobic patients may be unable to cooperate. Patients with some types of internal metallic hardware cannot undergo MRI. MRI safety guidelines have been developed with an extensive list of devices that are or are not MRI approved, and any devices in the patient need to be checked against this list. Examples of contraindications include neural stimulator devices and cerebral aneurysm clips. Many

Fig. 5.29 Dysplasia on MR angiography. Coronal 3D MR angiogram shows fibromuscular dysplasia of the proximal right renal artery.

cardiac pacemakers are now compatible with MRI, but if the patient is pacemaker-dependent, they cannot be scanned.

Determination of in-stent stenosis is impossible as metallic artifact from renal artery stents completely obscures the lumen. Even with the new, fast imaging techniques, patients need to be able to cooperate with breath-holding instructions to minimize motion-related artifacts. MRI

with gadolinium had been contraindicated in patients with GFR below 30 ml/min/1.73 m^2 in older linear contrast agents because of the risk for nephrogenic systemic fibrosis (see Magnetic Resonance Contrast Agents).

MRI can be used in the intensive care unit and in critically ill patients only if they are stable enough to be transported to the MRI suite and have no implanted metallic devices. Ventilated patients can undergo MRI; however, specific MRI-compatible, nonferromagnetic ventilators and other life support devices must be used. Because of the confined nature of the MRI gantry, visualization and monitoring of the patient during the scan are compromised.

Incidental Findings

With the growth of cross-sectional imaging, incidental renal lesions are being found with increasing frequency. Almost 70% of renal cell carcinomas are discovered incidentally on imaging studies performed for other reasons. There is an age-dependent incidence of renal cysts, from about 5% in patients younger than 30 to almost one third of those older than 60.[29] The differentiation of solid and cystic lesions is the first mandate because as many as two thirds of solid lesions are found to be malignant.[30] MRI is ideally suited for lesion evaluation and is often better than ultrasound, particularly for complex cystic lesions. Parameters being characterized include solid versus cystic, overall lesion complexity, lesion enhancement, involvement of renal vasculature and collecting system, and extension into perirenal tissues and organs. Diffusion-weighted MRI sequences are often useful as a means of further differentiating benign and malignant solid lesions.

MEASUREMENT OF GLOMERULAR FILTRATION RATE

Renal blood flow and split renal function can be evaluated by CT and MRI.[31-33] The attenuation of the accumulated contrast material within the kidney is directly proportional to the GFR. Taking into account the renal volume, the function of each kidney can be determined. Although both modalities yield similar information, MRI is used more in children and in patients with allergy to contrast agents. This technique has not yet gained full acceptance, and renal scintigraphy remains a widely used method for determination of renal function, as discussed later.

ANGIOGRAPHY

Angiography is now most often performed for therapeutic intervention, such as embolotherapy or angioplasty and stenting, preceded by diagnostic angiography to evaluate the renal arteries for possible stenosis (Fig. 5.30). With improved resolution and scanning techniques, CTA and MRA have replaced conventional angiography, even for detection of accessory renal arteries, which are often small and bilateral but a possible cause of hypertension. However, angiography remains the gold standard (reference) test for the diagnosis of renal artery stenosis and fibromuscular dysplasia. There also remains a role for diagnostic angiography in the evaluation of medium- and large-vessel vasculitis and detection of renal infarction.

The conventional angiogram is performed through arterial puncture, followed by catheter placement in the aorta. An abdominal aortogram is obtained to identify the renal arteries. Selective renal artery catheterization can be performed as necessary. Contrast is administered intra-arterially, and the images are obtained with conventional film or more often with DSA. Conventional angiography images are superior but require higher doses of contrast material and more radiation exposure. DSA uses computer reconstruction and manipulation to generate the images, with the advantage that previously administered and excreted contrast material and bones can be digitally removed to better visualize the renal vasculature. Angiography can cause contrast-induced nephropathy and cholesterol embolization (see Chapter 41). Pathologic evidence of cholesterol embolization is common, but clinically significant symptoms occur infrequently (1% to 2%).[34]

RENAL VENOGRAPHY

Catheter venography was once used for evaluation of renal vein and gonadal vein thrombosis and for renal vein sampling to measure renin, but has largely been replaced with Doppler ultrasound, followed by contrast-enhanced CT or MRI (see Fig. 5.28).

NUCLEAR SCINTIGRAPHY

Nuclear scintigraphy evaluates function and anatomy seen with other diagnostic imaging modalities. Radiotracers are designed to accumulate

TABLE 5.5 Choice of Radionuclide in Renal Imaging

Imaging Target	Radiotracer
Glomerular filtration rate	^{99m}Tc-DTPA
Glomerular filtration rate with renal impairment	^{99m}Tc-MAG3, ^{131}I-OIH
Effective renal plasma flow	^{99m}Tc-MAG3, ^{131}I-OIH
Renal scarring	^{99m}Tc-DMSA, ^{99}Tc-GH
Renal pseudotumor	^{99m}Tc-DMSA
Upper renal tract obstruction	^{99m}Tc-DTPA
Upper renal tract obstruction with renal impairment	^{99m}Tc-MAG3

^{99m}*Tc-DMSA,* Technetium 99m–labeled dimercaptosuccinate; ^{99m}*Tc-DTPA,* technetium 99m–labeled diethylenetriaminepentaacetic acid; ^{99m}*Tc GH,* technetium-99m glucoheptonate; ^{131}*I-OIH,* 131I orthoiodohippurate.

in tissues or organs on the basis of underlying functions unique to that organ. The gamma camera captures the photons from a radiotracer within the patient and generates an image. Single-photon emission computed tomography (SPECT) is a specialized type of imaging in which the emitted photons are measured at multiple angles, similar to CT, and multiplanar or even 3D images can be created. Three categories of radiotracers that differ in mode of renal clearance are used in renal imaging: glomerular filtration, tubular secretion, and tubular retention agents (Table 5.5).

Scintigraphy remains superior to the other imaging modalities in the evaluation of renal flow. It is the study of choice in the evaluation of renal transplants and functional obstruction, especially when ultrasound evidence is equivocal. Scintigraphy is also widely used to measure GFR, although CT or MRI are preferred in some centers.

Nuclear scintigraphy also provides an accurate assessment of renal function, used, for example, in estimating the reduction in renal function after nephron-sparing surgery. Although CT, MRI, and contrast-enhanced ultrasound are being assessed for the evaluation of renal function, scintigraphy remains the preferred modality. Both CTA and MRA have replaced nuclear scintigraphy in the evaluation of renal artery stenosis and benign renal masses, such as a column of Bertin. Nuclear medicine is still used to assess the functional significance of renal artery stenosis independent of anatomy.

Glomerular Filtration Agents

Glomerular filtration agents can be used to measure GFR. Technetium-99m–labeled diethylenetriaminepentaacetic acid (^{99m}Tc-DTPA) is the most common glomerular agent used for imaging and also can be used for GFR calculation. In patients with poor renal function, renal imaging with tubular secretion agents such as mercaptoacetyltriglycine (^{99m}Tc-labeled MAG3) is superior to DTPA.[35,36]

Tubular Secretion Agents

^{99m}Tc-labeled MAG3 is handled primarily by tubular secretion and can be used to estimate effective renal plasma flow. The clearance rate for ^{99m}Tc-MAG3 is 340 ml/min.[37]

Tubular Retention Agents

Tubular retention agents include ^{99m}Tc-labeled dimercaptosuccinate (DMSA) and less often ^{99m}Tc-labeled glucoheptonate (GH). These agents provide excellent cortical imaging and can be used in suspected renal scarring or infarction, in pyelonephritis, and for clarification of renal pseudotumors. These agents bind with high affinity to sulfhydryl groups on the surface of proximal tubular cells.

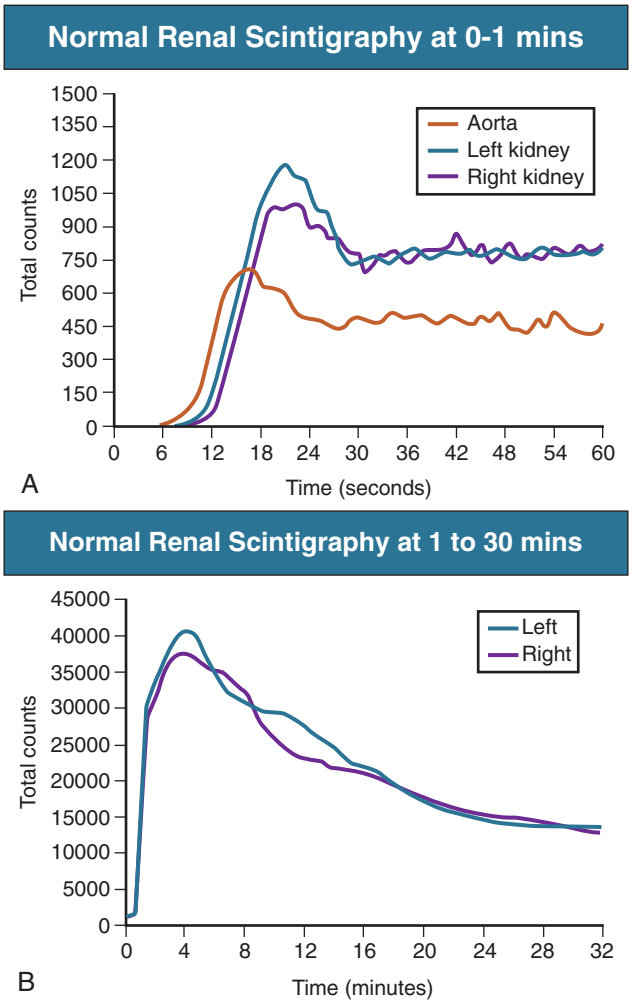

Fig. 5.31 Normal ^{99m}Tc-labeled DTPA study: time-activity curves. (A) Early (0 to 1 minute), showing renal blood flow. (B) Later (1 to 30 minutes), showing renal uptake and excretion of tracer. (Courtesy Dr. Chun Kim.)

Renogram

A renogram (or renal scintigram) is generated by scintigraphy and provides information about blood flow, renal uptake, and excretion. Time-activity graphs are produced that plot blood flow of the radiotracer into each kidney relative to the aorta. Peak cortical enhancement and pelvicalyceal clearance of the tracer are also plotted. DTPA or MAG3 can be used to generate the renogram. The relative radiotracer uptake can be measured and can provide split or differential information about renal function (Fig. 5.31).

The blood pool or flow images are obtained after bolus injection of the radiotracers. Images are obtained with the gamma camera every few seconds for the first minute. The second component of the renogram evaluates renal function by measuring radiotracer uptake and excretion by the kidney. In health, the peak renal cortical concentration occurs between 3 and 5 minutes after injection of tracer. Delayed transit of the isotope secondary to renal dysfunction (e.g., ATN or rejection) or obstructive uropathy will alter the curve of the renogram.

In cases of suspected obstructive uropathy, a diuresis renogram can be obtained. A loop diuretic is injected intravenously when radiotracer activity is present in the renal pelvis; a computer-generated washout curve is obtained. In patients with true obstruction, activity will remain

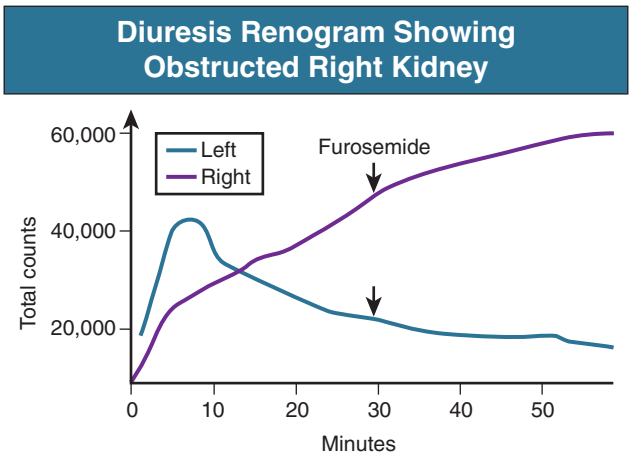

Fig. 5.32 Diuresis renogram showing obstructed right kidney. Isotope continues to accumulate in the right kidney despite intravenous furosemide (given at 30 minutes). Isotope excretion in the left kidney is normal.

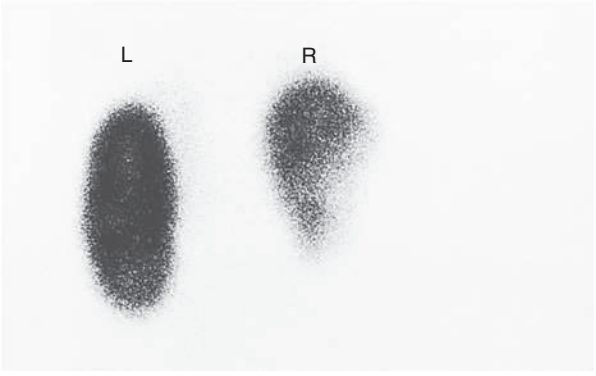

Fig. 5.33 Renal infarct. ^{99m}Tc-DMSA scan in a newborn with an infarct of the right lower pole *(R)* secondary to embolus from umbilical catheter. (Courtesy Dr. Chun Kim.)

in the renal pelvis, whereas it will quickly wash out in patients without an obstruction (Fig. 5.32; see also Fig. 58.12).

Cortical Imaging

Renal cortex imaging is performed with tubular retention agents, usually ^{99m}Tc-DMSA. Information about renal size, location, and contour can be obtained (Fig. 5.33). The cortical study is used most frequently for evaluation of renal scarring, particularly in children with reflux or chronic infections (see Chapter 61). It was formerly used for clarification of renal pseudotumors, such as a suspected column of Bertin, but this is now done with CT and MRI. Split renal function also can be determined from cortical imaging. Pinhole imaging (pinhole collimator magnifies the kidney to provide more anatomic detail than with planar imaging) and more recently SPECT have been found useful for detection of cortical defects caused by inflammation or scarring. Cortical imaging may be better than ultrasound in the evaluation of the young patient with urinary tract infection.[38] An infection, scar, or space-occupying lesion (tumor or cyst) will create a cortical defect, and correlation of the cortical defect site with other cross-sectional imaging should be performed to differentiate these entities.

Vesicoureteral Reflux

In children with suspected vesicoureteral reflux, a standard cystogram is obtained. If reflux is shown, follow-up is subsequently performed with radioisotope cystography, which exposes the child to a lower radiation dose and can be used to quantitate the bladder capacity when reflux occurs. The study is performed after instillation of technetium pertechnetate through a catheter into the bladder. Images are obtained during voiding.

Fig. 5.34 Normal PET scan. Note normal radiotracer uptake in brain, heart, intestines, and liver, with normal excretion in kidneys.

Renal Transplant

Renal transplants are easily evaluated with scintigraphy. ^{99m}Tc-MAG3 is cleared through tubular secretion, which is maintained in most kidneys to a better degree than glomerular filtration in renal failure. Because many transplant recipients have declining renal function, ^{99m}Tc-MAG3 is the first-choice nuclide.

As with the normal kidneys, information about blood flow and function can be determined. Postoperative complications involving the artery, vein, or ureter are also well delineated. Nuclear imaging can help define ATN versus rejection in transplant patients with declining renal function. Ultrasound with Doppler evaluation of resistive index is often a complementary investigation, and choice of imaging modality in part depends on local expertise and preference.

POSITRON EMISSION TOMOGRAPHY

PET scanning uses radioactive positron emitters, most often fluorine-18–labeled fluorodeoxyglucose (FDG). The FDG is intravenously injected and distributes in the body according to metabolic activity. Any process, such as a tumor or infection, that causes increased metabolic activity will result in an area of increased uptake on the scan. These areas of abnormality need to be differentiated from normally hypermetabolic tissues, such as brain, liver, bone marrow, and to some extent heart and bowel (Fig. 5.34). Because FDG is cleared through the kidneys and excreted in the urine, which can obscure renal masses or infection, PET

scanning has a limited role in renal imaging but is useful in the staging and follow-up of metastatic renal cancer.[39,40]

MOLECULAR IMAGING

With molecular imaging, radiology is moving from the identification of generic anatomy and nonspecific enhancement patterns to assessment of specific molecular differences in tissues and disease processes. Nuclear imaging presently is molecular based but still nonspecific (e.g., FDG-PET, renal DTPA). The newer focus of molecular imaging studies is dynamic processes such as metabolic activity, cell proliferation, apoptosis, receptor status, and antigen modulation. Typically, this involves imaging of biochemical and physiologic processes. Techniques are being developed with optical scanning, MRI, and ultrasound as well as with radionuclides.

Applications are established in clinical practice, particularly in oncology (e.g., CD20 imaging in lymphoma), and work is under way for renal-specific molecular imaging. For example, MR renal cell imaging may be available soon to help differentiate ATN from renal rejection and renal cell cancer from benign tumors.

RADIOLOGIC CONTRAST AGENTS

X-ray Contrast Agents

Contrast agents continue to have a role in many imaging techniques. A triiodinated benzene ring forms the chemical basis for CT intravascular contrast agents. Conventional contrast agents have high osmolality, about five times greater than plasma osmolality. Modifications to the benzene ring have led to newer contrast agents, including low-osmolar (which is still hyperosmolar compared with normal plasma) and more recently iso-osmolar nonionic agents, which are less nephrotoxic.

Intravascular iodinated contrast material rapidly passes through the capillary pores into the interstitial, extracellular space and into the renal tubules through glomerular filtration.[41] In patients with normal renal function, the kidneys eliminate almost all the contrast agent. Extrarenal routes of excretion include the liver and bowel wall and account for less than 1% of elimination, but this can increase when renal function is compromised. The half-time in patients with normal renal function is 1 to 2 hours, compared with 2 to 4 hours in dialysis patients.[42]

The overall incidence of contrast reactions for iodinated agents is 3.1% to 4.7%.[43-45] Of patients who have a contrast reaction, 20% will experience a reaction on reexposure that may be similar or worse. Contrast reactions can be anaphylactoid or chemotoxic reactions. The anaphylactoid reactions mimic an allergic response, whereas the chemotoxic reactions are believed to be mediated by direct toxic effects of the contrast material. The exact mechanism of contrast reaction is not known but is likely to be multifactorial. Formation of antigen-antibody complexes, complement activation, protein binding, and histamine release have been cited as possible mechanisms.

Reactions may be minor, intermediate, or severe. Minor reactions include heat sensation, nausea, and mild urticaria. Intermediate reactions include vasovagal reaction, bronchospasm, and generalized urticaria. Severe reactions include profound hypotension, pulmonary edema, and cardiac arrest. The use of low-osmolar or iso-osmolar contrast agents reduces the incidence of minor and intermediate contrast reactions. The reported incidence of death related to high-osmolar contrast agents is 1 in 40,000. Immediate treatment of reactions should be directed toward the symptoms. In patients with a history of contrast allergy, pretreatment on reexposure is usually recommended. Various protocols are used but typically include antihistamines and corticosteroids.

Contrast-Induced Nephropathy

Although acute kidney injury (AKI) associated with the administration of contrast material has been reported as the third most common cause of in-hospital AKI, recent data indicate this risk has been markedly overestimated.[45] The original studies and reports came from cardiac catheterization, and most follow-up studies have failed to provide adequate control groups. Patients with normal renal function rarely develop contrast-induced AKI. Even in patients with GFR less than 45 ml/min, this should not preclude the use of intravenous contrast if clinically necessary. Despite the concern for long-term complications, there is evidence suggesting that intravenous contrast carries little risk for dialysis dependence or mortality.[46] Although low risk, some caution should be taken in patients with preexisting renal impairment, and possible risk factors include preexisting renal impairment, diabetes, cardiovascular disease, use of diuretics, advanced age (>75 years), multiple myeloma in dehydrated patients, hypertension, uricosuria, and high-dose contrast. In end-stage renal disease, contrast administration may result in fluid overload because of thirst induced by the osmotic load.

Historically, there have been several theories for the pathogenesis of contrast-induced nephropathy, including renal vasoconstriction, perhaps mediated by alterations in nitric oxide, direct nephrotoxicity of the contrast agent, and possibly the effects of uricosuria (induced by the contrast agent). Most underlying cellular events were thought to occur within the first 60 minutes after administration of the contrast agent, with the greatest risk in the first 10 minutes.

There is some evidence that suggests that patients with diabetes and heart failure have altered nitric oxide metabolism, which may account for their reported increased risk for nephrotoxicity. Tubular injury produces oxygen free radicals, possibly from the vasoconstriction. In animal studies, reduction in antioxidant enzymes associated with hypovolemia contributes to the injury.[47] Hydration with normal saline or sodium bicarbonate is the mainstay of prevention; there is no substantial evidence that sodium bicarbonate offers any advantage over saline.[48] Oral *N*-acetylcysteine, a thiol-containing antioxidant, is often given in conjunction with hydration but has not proved consistently to be protective.[49]

An important differential diagnosis for contrast-induced nephropathy in patients with vascular disease undergoing catheter angiography is cholesterol embolization (see Chapter 41).

In patients with estimated GFR less than 60 ml/min/1.73 m^2, low-osmolar or iso-osmolar contrast agents can be used and the doses reduced. Repetitive, closely performed contrast studies should be avoided. In high-risk patients, alternative imaging studies—ultrasound, MRI, or noncontrast CT— always should be considered. Issues related to contrast-induced nephropathy is further discussed in Chapter 70.

Magnetic Resonance Contrast Agents

The two classes of MRI contrast agents are diffusion and nondiffusion agents. Diffusion agents, with appropriate timing of imaging sequences, can delineate vessels as well as parenchymal tissues. Nondiffusion agents remain in the bloodstream and are primarily useful for MRA. All the contrast agents are based on the paramagnetic properties of gadolinium. Gadolinium itself is highly toxic and is given only when it is tightly chelated (e.g., Gd-tetraazacyclododecane-1,4,7,10-tetraacetic acid [Gd-DOTA], Gd-diethylenetriamine penta-acetic acid [Gd-DTPA]).

Minor reactions such as headache and nausea occur in 3% to 5% of patients; but life-threatening reactions and nephrotoxic reactions are rare. In patients with renal impairment, a rare severe reaction, nephrogenic systemic fibrosis (NSF), has been described (see Chapter 87). The most recent guidelines confirm that MRI using high-risk

gadolinium-containing contrast agents is contraindicated in patients with AKI and in those with chronic kidney disease stages 4 and 5 (i.e., GFR <30 ml/min/1.73 m^2),[27] because use of some agents has been linked to NSF. Cases of NSF are particularly associated with the linear structure chelates (such as gadodiamide, gadopentetate, and gadoversetamide). However, some linear chelates have a higher dissociation constant and to date have not been associated with NSF (such as gadobenate).[50] The newer macrocyclic gadolinium–containing contrast agents (e.g., gadoterate and gadoteridol) also have not been associated with NSF, even in patients with significantly impaired renal function (GFR <30 ml/min/1.73 m^2). Recently, studies have shown gadolinium deposition and retention in tissues, especially the brain, and especially after multiple injections of the contrast material. To date there are no documented adverse events associated with this retention. The choice of gadolinium agent in each case should be determined by discussion between the nephrologist and radiologist.

SELF-ASSESSMENT QUESTIONS

1. On ultrasound, compared with the liver, the normal adult renal cortex is:
   A. Isoechoic
   B. Hyperechoic
   C. Hypoechoic
   D. Anechoic
2. Which of the following imaging modalities has the *least* chance of inducing contrast nephropathy?
   A. CO_2 angiography
   B. Contrast-enhanced CT
   C. Contrast-enhanced MRI
   D. Intravenous urography
3. The imaging modality that exposes the patient to the *least* radiation risk is:
   A. CT urography
   B. Dual-energy CT with virtual noncontrast imaging
   C. Intravenous urography
   D. Diffusion-weighted MRI
4. Which of the following is a mandatory reason that a renal MRI *cannot* be performed?
   A. Cardiac pacemaker in a patient who is not pacemaker-dependent
   B. Titanium total hip replacement less than 6 weeks old
   C. When eGFR is 35 ml/min
   D. History of cerebral aneurysm clip

Renal Biopsy

Peter S. Topham, Yipu Chen

Percutaneous renal biopsy was first described in the early 1950s by Iversen and Brun[1] and Alwall.[2] These early biopsies were performed with the patient in the sitting position by use of a suction needle and intravenous urography for guidance. An adequate tissue diagnosis was achieved in less than 40% of these early cases. In 1954, Kark and Muehrcke[3] described a modified technique using the Franklin-modified Vim-Silverman needle, with the patient in a prone position and an exploring needle used to localize the kidney before insertion of the biopsy needle. These modifications yielded a tissue diagnosis in 96% of cases, and no major complications were reported. Since then, the renal biopsy procedure has remained largely unchanged, although the use of real-time ultrasound and refinement of biopsy needle design have offered significant improvements. Renal biopsy now provides a tissue diagnosis in more than 95% of patients, with a life-threatening complication rate of less than 0.1%.

INDICATIONS FOR RENAL BIOPSY

Ideally, analysis of a renal biopsy sample should identify a specific diagnosis, reflect the level of disease activity, and provide information to allow informed decisions about treatment. Although not always able to fulfill these criteria, the renal biopsy remains a valuable clinical tool and is particularly beneficial in the clinical situations discussed in Box 6.1.

Nephrotic Syndrome

Routine clinical and serologic examination of patients with nephrotic syndrome usually allows the clinician to determine whether a systemic disorder is present. In adults and in adolescents beyond puberty without systemic disease, the glomerular pathologic process cannot be predicted with confidence by noninvasive criteria alone; therefore a renal biopsy should be performed. In children age 1 year up to puberty, a presumptive diagnosis of minimal change disease (MCD) usually can be made. Renal biopsy is reserved for nephrotic children with atypical features, including microhematuria, reduced serum complement levels, renal impairment, and failure to respond to corticosteroids.

Acute Kidney Injury

In most patients with acute kidney injury (AKI) on a background of chronic kidney disease (CKD), the cause can be determined without a renal biopsy. Obstruction, reduced renal perfusion, and acute tubular necrosis (ATN) usually can be identified from other lines of investigation. In a minority of patients, however, a confident diagnosis cannot be made, and a renal biopsy should be urgently performed so appropriate treatment can be started before irreversible renal injury develops. This is particularly true in patients with AKI accompanied by an active urine sediment or with suspected drug-induced or infection-induced acute interstitial nephritis.

Systemic Disease Associated With Renal Dysfunction

Patients with diabetes mellitus and renal dysfunction do not usually require biopsy if the clinical setting is associated with diabetic nephropathy, as in isolated proteinuria, diabetes of long duration, or evidence of other microvascular complications. However, renal biopsy should be performed if the presentation is atypical, such as proteinuria associated with glomerular hematuria (acanthocytes), absence of retinopathy or neuropathy (in patients with type 1 diabetes), onset of proteinuria less than 5 years from documented onset of diabetes, uncharacteristically rapid change in renal function or renal disease of acute onset, or immunologic abnormalities.

Serologic testing for antineutrophil cytoplasmic antibody (ANCA) and for anti–glomerular basement membrane (anti-GBM) antibodies has allowed a confident diagnosis of renal small-vessel vasculitis or Goodpasture disease without invasive measures in most patients. Nonetheless, a renal biopsy still should be performed to confirm the diagnosis and clarify the extent of active inflammation versus chronic fibrosis and thus the potential for recovery. This information may be important in helping decide whether to initiate or continue immunosuppressive therapy, particularly when complications of immunosuppression are observed or expected.

Lupus nephritis usually can be diagnosed by noninvasive criteria such as autoantibodies, urine protein excretion, renal function, and urine sediment abnormalities. Some argue that this information can be used to gauge the severity of renal involvement and inform decisions about initial immunosuppressive treatment. However, a renal biopsy will clarify the underlying pathologic lesion, level of active inflammation, and extent of chronic fibrosis, thereby providing robust guidance for therapy.

The diagnosis of viral infection–related nephropathy (e.g., hepatitis B virus–associated membranous nephropathy) is suggested by the presence of the expected glomerular lesion in association with evidence of active viral infection. However, the identification of virus-specific protein or DNA or RNA in the renal biopsy tissue by immunopathologic and molecular pathologic techniques (e.g., in situ hybridization) can ensure the diagnosis.

Other systemic diseases, such as amyloidosis, sarcoidosis, and myeloma, can be diagnosed with renal biopsy. However, because these diagnoses often can be made by other investigative approaches, a renal biopsy is indicated only if the diagnosis remains uncertain or if knowledge of renal involvement would change management.

BOX 6.1 Indications for Renal Biopsy

Nephrotic Syndrome
- Routinely indicated in adults
- In prepubertal children, indicated only if clinical features atypical of minimal change disease present

Acute Kidney Injury
- Indicated if obstruction, reduced renal perfusion, and acute tubular necrosis have been ruled out

Systemic Disease With Renal Dysfunction
- Indicated in patients with small-vessel vasculitis, anti–glomerular basement membrane disease, and systemic lupus
- Indicated in patients with diabetes only if atypical features present

Non-Nephrotic Proteinuria
- May be indicated if proteinuria is greater than 1 g/24 h

Isolated Microscopic Hematuria
- Indicated only in unusual circumstances

Unexplained Chronic Kidney Disease
- May be diagnostic (e.g., identify immunoglobulin A nephropathy even in "end-stage kidney")

Familial Renal Disease
- Biopsy of one affected member may give diagnosis and minimize further investigation of family members

Renal Transplant Dysfunction
- Indicated if ureteral obstruction, urinary sepsis, renal artery stenosis, and toxic calcineurin inhibitor levels are not present

Renal Transplant Dysfunction

Renal allograft dysfunction in the absence of ureteral obstruction, urinary sepsis, renal artery stenosis, or toxic levels of calcineurin inhibitors requires a renal biopsy to determine the cause. In the early post-transplantation period, this is most useful in differentiating acute rejection from ATN and the increasingly prevalent BK virus nephropathy. Later, renal biopsy can differentiate acute rejection from chronic allograft nephropathy, recurrent or de novo glomerulonephritis (GN), and calcineurin inhibitor toxicity. The accessible location of the renal transplant in the iliac fossa facilitates biopsy of the allograft and allows repeated biopsies when indicated. This has encouraged many units to adopt a policy of *protocol* (surveillance) biopsies to detect subclinical acute rejection and renal scarring and to guide the choice of immunosuppressive therapy (see Chapter 104).

Non-Nephrotic Proteinuria

The value of renal biopsy in patients with non-nephrotic proteinuria is debatable. All conditions that result in nephrotic syndrome can cause non-nephrotic proteinuria, except for MCD. However, the benefit of specific treatment with corticosteroids and other immunosuppressive agents in these patients probably does not justify the risk for significant drug-related side effects. In patients with proteinuria of more than 1 g/day, generic treatment with strict blood pressure control and angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) reduces proteinuria and reduces the risk for development of progressive renal dysfunction (see Chapter 79). Nonetheless, although the renal biopsy may not lead to an immediate change in management, it can be justified in these circumstances if it will provide prognostic information, identify a disease for which a different therapeutic approach is indicated, or provide clinically important information about the future risk for disease recurrence after renal transplantation.

Isolated Microhematuria

Patients with microhematuria initially should be evaluated to identify structural lesions such as renal stones or renal and urothelial malignant neoplasms if they are older than 40 years. The absence of a structural lesion suggests that the hematuria may have a glomerular source. Biopsy studies have identified glomerular lesions in up to 75% of biopsies.[4] In all series, immunoglobulin A (IgA) nephropathy is the most common lesion, followed by thin basement membrane nephropathy and normal kidney morphology. In the absence of nephrotic proteinuria, renal impairment, or hypertension, the prognosis for patients with these conditions is excellent, and because specific therapies are not available, renal biopsy is not necessary and patients require only follow-up. Biopsy should be performed only if the result would reassure the patient, avoid repeated urologic investigations, or provide specific information, as in the evaluation of potential living kidney donors, in familial hematuria, or for life insurance and employment purposes.

Unexplained Chronic Kidney Disease

Renal biopsy can be informative in the patient with unexplained chronic renal impairment and normal-sized kidneys, because in contrast to AKI, it is often difficult to determine the underlying cause with clinical criteria alone. Studies have shown that in these patients, the biopsy will demonstrate disease that was not predicted in almost half.[5] However, if both kidneys are small (<9 cm on ultrasound), the risks of biopsy are increased and the diagnostic information may be limited by extensive glomerulosclerosis and tubulointerstitial fibrosis. In this setting, however, immunofluorescence studies still may be informative. For example, glomerular IgA deposition may be identified despite advanced structural damage.

Familial Renal Disease

A renal biopsy can be helpful in the investigation of patients with a family history of renal disease. A biopsy performed in one affected family member may secure the diagnosis for the whole family and avoid the need for repeat investigation. Conversely, a renal biopsy may unexpectedly identify inherited disease, thereby stimulating evaluation of other family members.

Role of Repeat Renal Biopsy

In some patients, a repeat biopsy may be indicated. For example, the pathologic changes in lupus nephritis may evolve, necessitating treatment adjustment. In addition, corticosteroid-resistant, corticosteroid-dependent, or frequently relapsing MCD may represent a missed diagnosis of focal segmental glomerulosclerosis (FSGS), which may be detected on repeat biopsy. Some nephrologists think repeat biopsy in patients who have had aggressive immunosuppressive therapy of crescentic GN can help determine the most appropriate next line of therapy.

VALUE OF RENAL BIOPSY

Biopsy Adequacy

In the assessment of a renal biopsy, the number of glomeruli in the sample is the major determinant of whether the biopsy will be diagnostically informative.

For a focal entity such as FSGS, the diagnosis could be made on a biopsy specimen containing a single glomerulus that contains a typical sclerosing lesion. However, the probability that FSGS is not present in

a patient with nephrotic syndrome and minimal changes on the biopsy specimen depends on the actual proportion of abnormal glomeruli in the kidney and the number of glomeruli obtained in the biopsy specimen. For example, if 20% of glomeruli in the kidney have sclerosing lesions and five glomeruli are sampled, there is a 35% chance that all the glomeruli in the biopsy specimen will be normal and the biopsy will miss the diagnosis. By contrast, in the same kidney, if 10 or 20 glomeruli are sampled, the chance of obtaining all normal glomeruli is reduced to 10% and less than 1%, respectively, and the biopsy is more discriminating. This argument assumes that any segmental lesions present in the biopsy specimen are actually identified; this requires the biopsy specimen to be sectioned at multiple levels.

Unless all glomeruli are affected equally, the probability that the observed involvement in the biopsy specimen accurately reflects true involvement in the kidney depends not only on the number of glomeruli sampled but also on the proportion of affected glomeruli (Fig. 6.1). For example, in a biopsy specimen containing 10 glomeruli, of which 3 are abnormal (30%), there is a 95% probability that the actual glomerular involvement is between 7% and 65%. In the same kidney, if the biopsy specimen contained 30 glomeruli with 30% being abnormal, the 95% confidence intervals are narrowed to 15% and 50%.

Therefore the interpretation of the biopsy needs to take into account the number of glomeruli obtained. A typical biopsy sample will contain 10 to 15 glomeruli and will be diagnostically useful. Nonetheless, it must be appreciated that because of the sampling issue, a biopsy sample of this size will occasionally be unable to diagnose focal diseases and at best will provide imprecise guidance on the extent of glomerular involvement.

An adequate biopsy also should provide samples for immunohistologic examination and electron microscopy (EM). Immunohistologic examination is performed by either immunofluorescence on frozen material or immunoperoxidase on fixed tissue, according to local protocols and expertise. It is helpful for the biopsy cores to be viewed under an operating microscope immediately after being taken to ensure that they contain cortex and that when the cores are divided, the immunohistologic and EM samples both contain glomeruli.

If the material obtained for a complete pathologic evaluation is insufficient, a discussion with the pathologist should address how best to proceed before the tissue is placed in fixative, so the material can be processed in a way that will provide maximum information for the specific clinical scenario. For example, if the patient has heavy proteinuria, most information will be gained from EM because it can demonstrate podocyte foot process effacement, focal sclerosis, electron-dense deposits of immune complexes, and the organized deposits of amyloid.

If a sample is supplied for immunofluorescence microscopy but contains no glomeruli, it may be possible to reprocess the paraffin-embedded sample to identify immune deposits by immunoperoxidase or immunofluorescence techniques.

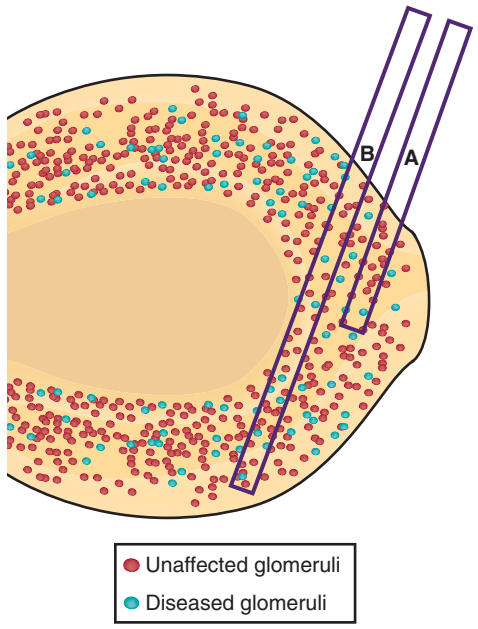

Fig. 6.1 Effect of sampling on renal biopsy interpretation. Red dots represent unaffected glomeruli. Blue dots represent diseased glomeruli. The size of the biopsy core affects the probability that the observed glomerular involvement is a true reflection of involvement in the whole kidney. In a biopsy specimen containing 10 glomeruli (core A), of which three are abnormal (30%), there is a 95% probability that the actual glomerular involvement is between 7% and 65%. In the same kidney, if the biopsy specimen contained 30 glomeruli with 30% being abnormal *(core B),* the 95% confidence intervals are narrowed to 15% and 50%.

Is Renal Biopsy a Necessary Investigation?

The role of the renal biopsy has been much debated. Early studies suggested that renal biopsy provided diagnostic clarity in most patients, but that this information did not alter management, except for those with heavy proteinuria or systemic disease. More recent prospective studies have suggested that the renal biopsy identifies a diagnosis different from that predicted on clinical grounds in 50% to 60% of patients and leads to a treatment change in 20% to 50%.[6] This is particularly apparent in patients with heavy proteinuria or AKI, more than 80% of whom have biopsy findings that alter their management.[7]

PREBIOPSY EVALUATION

The prebiopsy evaluation identifies issues that may compromise the safety and success of the procedure (Fig. 6.2). It will determine whether the patient has two normal-sized unobstructed kidneys, sterile urine, controlled blood pressure, and no bleeding diathesis. A thorough history should be taken to identify evidence of a bleeding diathesis, such as previous prolonged surgical bleeding, spontaneous bleeding, family history of bleeding, and ingestion of medication that increases bleeding risk, including antiplatelet agents and warfarin.

An ultrasound scan should be performed to assess kidney size and identify significant anatomic abnormalities, such as solitary kidney, polycystic or simple cystic kidneys, malpositioned kidneys, horseshoe kidneys, small kidneys, and hydronephrosis.

The value of the *bleeding time* in patients undergoing renal biopsy is controversial. The predictive value of the bleeding time for postrenal biopsy bleeding has never been prospectively tested. Retrospective studies, however, demonstrated a threefold to fivefold increase in bleeding complications after renal biopsy in patients with prolonged bleeding time. Prospective studies of percutaneous liver biopsy patients showed a fivefold increase in bleeding complications in those with uncorrected bleeding times.[8] A consensus document concluded that the bleeding time is a poor predictor of postsurgical bleeding, but it does correlate with clinical bleeding episodes in uremic patients.[9]

Several approaches to the management of bleeding risk have been adopted. First, all subjects undergoing biopsy should discontinue any agent that can prolong bleeding, including aspirin (7 days before biopsy), clopidogrel (7 days), warfarin (7 days), nonsteroidal antiinflammatory drugs (NSAIDs; 24 hours), and subcutaneous heparin (24 hours). Many centers measure the prebiopsy bleeding time and administer 1-desamino-8-D-arginine vasopressin (desmopressin, DDAVP; 0.4 μg/kg intravenously 2 to 3 hours before biopsy) if the bleeding time is prolonged

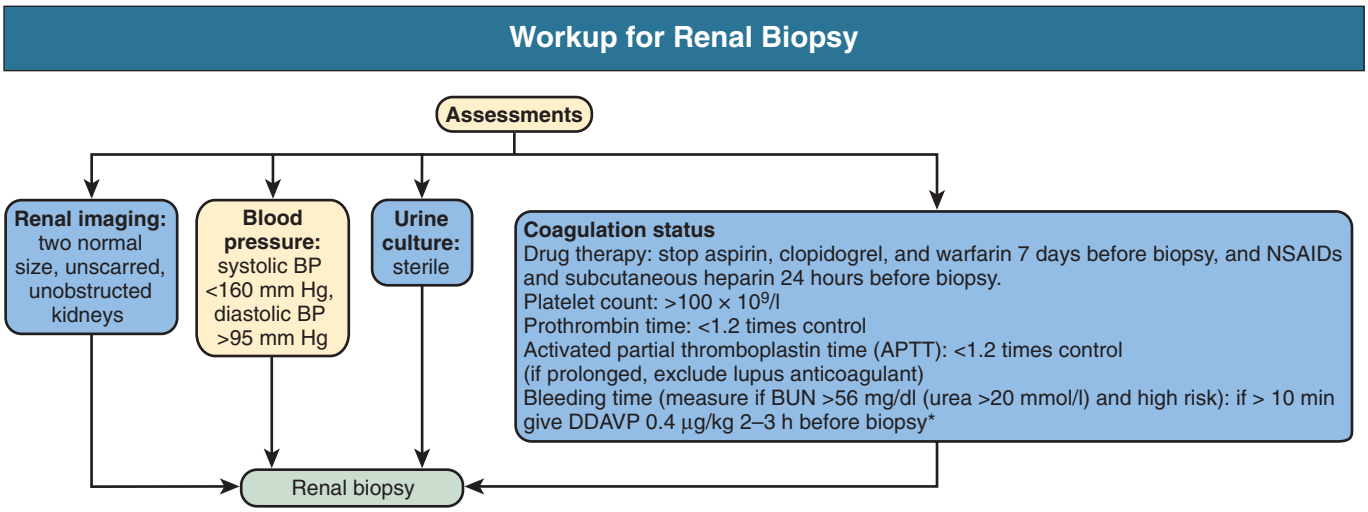

Fig. 6.2 Workup for renal biopsy. *BUN,* Blood urea nitrogen; *DDAVP,* desmopressin; *NSAID,* nonsteroidal antiinflammatory drug. *Some centers administer DDAVP in high risk cases without measuring bleeding time (see text).

beyond 10 minutes. Another approach is not to measure the bleeding time but routinely administer DDAVP to patients with significant renal impairment (blood urea nitrogen level >56 mg/dl [urea >20 mmol/l] or serum creatinine >3 mg/dl [250 µmol/l]). Platelet transfusion also can be used to reverse clopidogrel-induced platelet dysfunction when the renal biopsy is urgent.

The routine use of desmopressin in low-risk patients (estimated GFR >60 ml/min; blood pressure <140/90 mm Hg; normal coagulation parameters) has been shown to reduce the risk for hematoma formation after biopsy compared with placebo (13.7% vs. 30.5%, respectively).[10] The hematomas were clinically silent, however, and no patient in either group had macrohematuria or required a transfusion. The study was also unable to determine the risks related to DDAVP (thrombosis or hyponatremia). Therefore use of DDAVP prophylaxis in all patients undergoing renal biopsy cannot be recommended.

The use of thromboelastography (TEG) has been described in the patient undergoing renal transplant biopsy.[11] TEG provides an overall measure of the coagulation, platelet, and fibrinolytic systems in one assay and thus may be more predictive of clinical bleeding. In this study, most bleeding episodes were associated with normal clotting test results, but TEG was the only assay associated with an increased risk for post-biopsy bleeding. The role of TEG in the patient undergoing native kidney biopsy requires further evaluation.

Contraindications to Renal Biopsy

The contraindications to percutaneous renal biopsy are listed in Table 6.1. The major contraindication is a bleeding diathesis. If the disorder cannot be corrected and the biopsy is deemed indispensable, alternative approaches can be used, such as open biopsy, laparoscopic biopsy, or transvenous (usually transjugular) biopsy. Inability of the patient to comply with instructions during renal biopsy is another major contraindication. Sedation or, in extreme cases, general anesthesia may be necessary.

Hypertension (>160/95 mm Hg), hypotension, perinephric abscess, pyelonephritis, hydronephrosis, severe anemia, large renal tumors, and cysts are relative contraindications to renal biopsy. When possible, these should be corrected before the biopsy is undertaken.

The presence of a solitary functioning kidney has been considered a contraindication to percutaneous biopsy, and some argue that the risk of biopsy is reduced by direct visualization at open biopsy. However, the postbiopsy nephrectomy rate of 1/2000 to 1/5000 is comparable to the mortality rate associated with the general anesthetic required for an open procedure. Therefore, in the absence of risk factors for bleeding, percutaneous biopsy of a solitary functioning kidney can be justified.

TABLE 6.1 Contraindications to Renal Biopsy

Kidney Status	Patient Status
Multiple cysts	Uncontrolled bleeding diathesis
Solitary kidney	Uncontrolled blood pressure
Acute pyelonephritis	Uremia
Perinephric abscess	Obesity
Renal neoplasm	Uncooperative patient

Most contraindications are relative rather than absolute. Clinical circumstances that necessitate urgent renal biopsy may be overridden, except for uncontrolled bleeding diathesis.

RENAL BIOPSY TECHNIQUE

Percutaneous Renal Biopsy

Native Renal Biopsy

At our centers, the kidney biopsy is performed by nephrologists with continuous (real-time) ultrasound guidance and disposable automated biopsy needles. We use 16-gauge needles as a compromise between the greater tissue yield of larger needles and the trend toward fewer bleeding complications of smaller needles. For most patients, premedication or sedation is not required. The patient is prone, and a pillow is placed under the abdomen at the level of the umbilicus to straighten the lumbar spine and splint the kidneys. Fig. 6.3 shows the anatomic relationships of the left kidney. Ultrasound is used to localize the lower pole of the kidney where the biopsy will be performed (usually the left kidney). An indelible pen mark is used to indicate the point of entry of the biopsy needle. The skin is sterilized with povidone-iodine (Betadine) or chlorhexidine solution. A sterile fenestrated sheet is placed over the area to maintain a sterile field. Local anesthetic (2% lidocaine [lignocaine]) is infiltrated into the skin at the point previously marked.

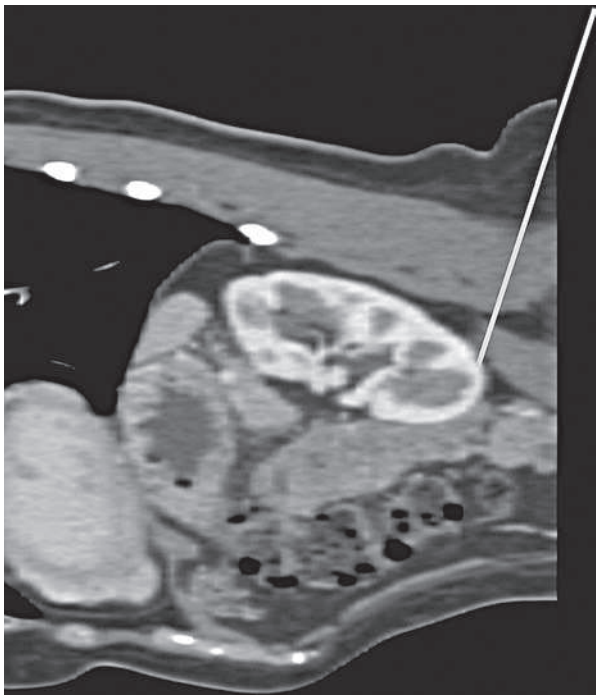

Fig. 6.3 Computed tomography through the left kidney. The angle of approach of the needle is demonstrated. Note the relative adjacency of the lower pole of the kidney to other structures, particularly the large bowel.

Fig. 6.4 Renal biopsy procedure. The biopsy needle is introduced at an angle of approximately 70 degrees to the skin and is guided by continuous ultrasound. The operator is shown wearing a surgical gown. This is not strictly necessary; sterile gloves and maintenance of a sterile field are sufficient.

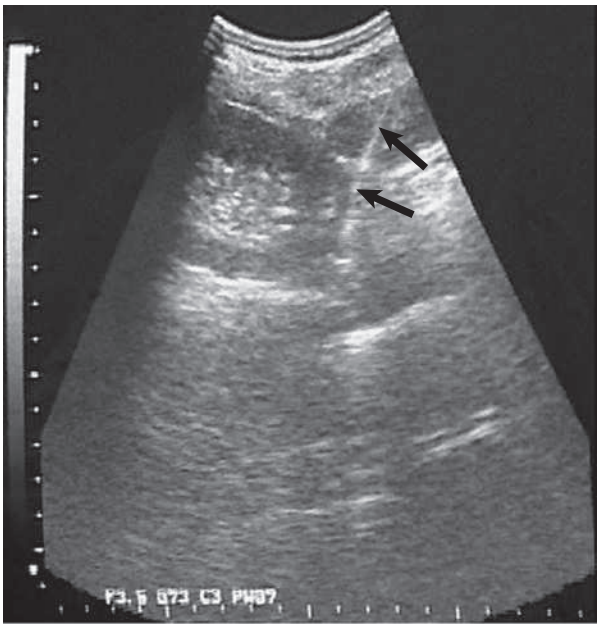

Fig. 6.5 Renal biopsy imaging. Ultrasound scan shows the needle entering the lower pole of the left kidney. *Arrows* indicate the needle track, which appears as a fuzzy white line.

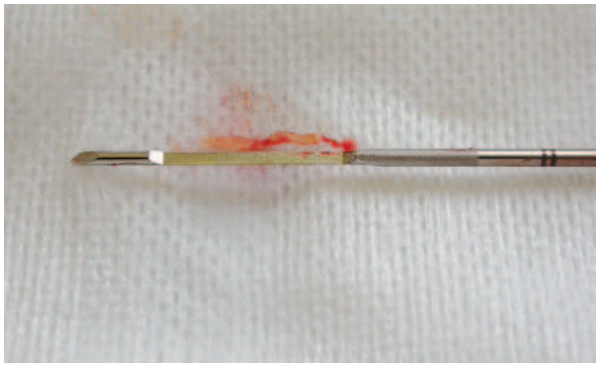

Fig. 6.6 Renal biopsy sample. A core of renal tissue is demonstrated in the sampling notch of the biopsy needle.

While the anesthetic takes effect, the ultrasound probe is covered in a sterile sheath. Sterile ultrasound jelly is applied to the skin, and, under ultrasound guidance, a 10-cm, 21-gauge needle is guided to the renal capsule and further local anesthetic infiltrated into the perirenal tissues, then along the track of the needle on withdrawal. A stab incision is made through the dermis to ease passage of the biopsy needle. This is passed under ultrasound guidance to the kidney capsule (Fig. 6.4). As the needle approaches the capsule, the patient is instructed to take a breath until the kidney is moved to a position such that the lower pole rests just under the biopsy needle, and then to stop breathing. The biopsy needle tip is advanced to the renal capsule, and the trigger mechanism is released, firing the needle into the kidney (Fig. 6.5). The needle is immediately withdrawn, the patient is asked to resume breathing, and the contents of the needle are examined (Fig. 6.6). We examined the tissue core under an operating microscope to ensure that renal cortex has been obtained (Fig. 6.7). A second pass of the needle is usually necessary to obtain additional tissue for immunohistologic examination and EM. If insufficient tissue is obtained, further passes of the needle are made. In our experience, however, passing the needle more than four times is associated with a modest increase in the post-biopsy complication rate.

Once sufficient renal tissue has been obtained, the skin incision is dressed and the patient rolled directly into bed for observation.

No single fixative has been developed that allows good-quality light microscopy, immunofluorescence, and EM to be performed on the same sample. Therefore the renal tissue is often divided into three samples and placed in formalin for light microscopy, normal saline for subsequent snap-freezing in liquid nitrogen for immunofluorescence, and glutaraldehyde for EM. Some centers can produce satisfactory light

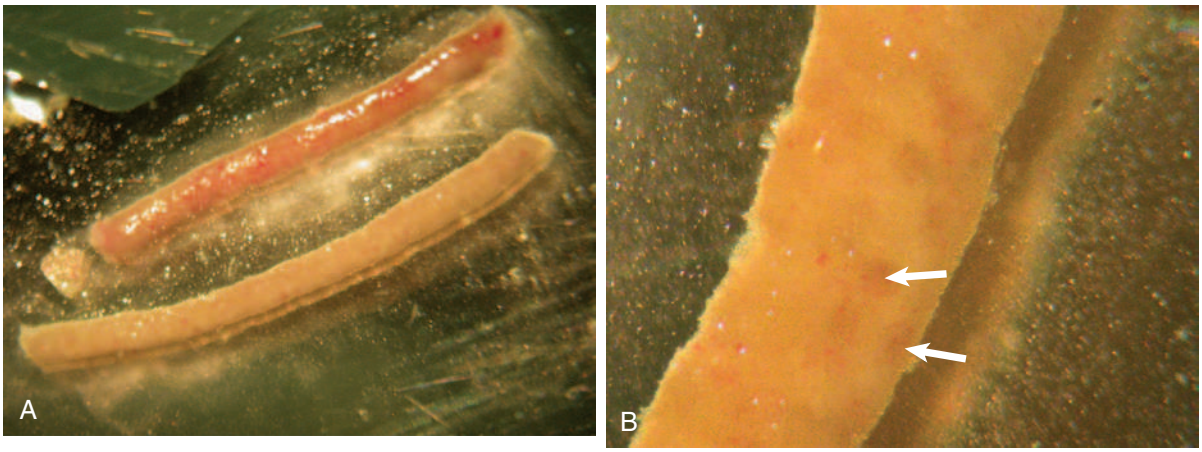

Fig. 6.7 Renal biopsy micrographs. Appearance of renal biopsy material under the operating microscope. (A) Low-power view shows two good-sized cores. (B) Higher magnification view shows the typical appearance of glomeruli *(arrows)*.

microscopy, immunohistochemistry, and EM on formalin-fixed biopsy material, although this depends on the expertise of individual laboratories.

The percutaneous renal biopsy technique has several variations. Whereas most biopsies are guided by ultrasound, some operators use ultrasound only to localize the kidney and determine the depth and angle of approach of the needle and perform the biopsy without further ultrasound guidance. The success and complication rates appear to be no different from those seen with continuous ultrasound guidance. For technically challenging biopsies, computed tomography (CT) can be used to guide the biopsy needle.

For obese patients and patients with respiratory conditions who find the prone position difficult, the supine anterolateral approach recently has been described.[12] Patients lie supine with the flank on the side to be sampled elevated by 30 degrees with towels under the shoulder and buttocks. The biopsy needle is inserted through the inferior lumbar triangle, bounded by the latissimus dorsi muscle, 12th rib, and iliac crest. This technique provides good access to the lower pole of the kidney, is better tolerated than the prone position by these patients, and has a diagnostic yield and safety profile comparable to that of the standard technique for native renal biopsy.

Renal Transplant Biopsy

Biopsy of the transplant kidney is facilitated by the proximity of the kidney to the anterior abdominal wall and the lack of movement on respiration. It is performed under real-time ultrasound guidance with use of an automated biopsy needle. It is important to confirm that the transplanted kidney is in the normal extraperitoneal position—occasionally it will be intraperitoneal (simultaneous pancreas and kidney transplants in particular), and bowel injury becomes a potential hazard. In most patients, the renal transplant biopsy is performed to identify the cause of acute allograft dysfunction. In these circumstances, the goal is to identify acute rejection, and therefore the diagnosis can be made on a formalin-fixed sample alone for light microscopy. If vascular rejection is suspected, a snap-frozen sample for C4d immunostaining also should be obtained (although some laboratories can detect C4d on formalin-fixed material). If recurrent or de novo GN is suspected in patients with chronic allograft dysfunction, additional samples for EM and immunohistologic examination should be collected.

Postbiopsy Monitoring

After the biopsy, the patient is placed supine and subjected to strict bed rest for 6 to 8 hours. The blood pressure is monitored frequently, the urine examined for visible hematuria, and the skin puncture site examined for excessive bleeding. If there is no evidence of bleeding after 6 hours, the patient is sat up in bed and subsequently allowed to ambulate. If visible hematuria develops, bed rest is continued until the bleeding settles. We advise minimal activity for 48 hours after biopsy and avoidance of contact sports and activities requiring straining for a total of 2 weeks.

Conventionally, patients have been observed for complications in the hospital for 24 hours after biopsy. However, outpatient (day-case) renal biopsy with same-day discharge after 6 to 8 hours of observation has become increasingly popular for both native and renal transplant biopsies. Largely driven by financial and resource implications of overnight hospital admission, this has been justified by the perception that the significant complications of renal biopsy will become apparent during this shortened period of observation. This view has been challenged by a study of 750 native renal biopsies, which showed that only 67% of major complications, defined as those that required either a blood transfusion or an invasive procedure or resulted in urinary tract obstruction, septicemia, or death, were apparent by 8 hours after biopsy.[13] These authors concluded that the widespread application of an early discharge policy after renal biopsy is not in the patient's best interest and that a 24-hour observation period is preferable.

In the author's UK center, approximately half of renal biopsies are outpatient procedures. The patient population is selected to avoid those with the highest risk for complications, including impaired renal function (estimated GFR <30 ml/min), small kidneys, and uncontrolled hypertension. In addition, we require that the patient not be alone at home for at least one night after the biopsy. This selection policy has proved to be safe. Of 429 outpatient biopsies performed in our unit, 6% developed a self-limited postbiopsy complication within 6 hours that required a short hospital admission. Five patients returned after same-day discharge with biopsy-related complications, one with visible hematuria at 24 hours and four with loin pain between 3 and 5 days after biopsy. All patients recovered with conservative management. We believe that outpatient renal biopsy is acceptably safe when a low-risk patient group is selected.

A study investigated whether ultrasound 1 hour after biopsy is able to predict bleeding complications.[14] The absence of hematoma was predictive of an uncomplicated course, but the identification of hematoma was not reliably predictive of a significant biopsy complication; identification of hematoma at 1 hour had a 95% negative predictive value and 43% positive predictive value. The role of this imaging in

the wider clinical setting remains to be determined given the additional expense of routine postbiopsy ultrasound.

Alternatives to the Percutaneous Approach

When the percutaneous approach is contraindicated, other approaches to renal biopsy have been described. The choice of technique depends on the safety, morbidity, recovery period, and adequacy of the technique, but mainly on the local expertise available.

Transvenous (Transjugular or Transfemoral) Renal Biopsy

Transvenous sampling of the kidney is theoretically safer than the percutaneous approach because the needle passes from the venous system into the renal parenchyma and is directed away from large blood vessels. Any bleeding that occurs should be directed back into the venous system, and if capsular perforation develops, significant bleeding points can be immediately identified and controlled by coil embolization. Others argue that coil embolization of the punctured vein is unhelpful because significant bleeding into a perirenal hematoma or the urine indicates an arterial breach that requires selective angiography and arterial embolization.

Transvenous renal biopsy cannot be regarded as routine because it involves specialist skills and additional time and expense compared with the percutaneous approach. The main indication for this approach is an uncontrollable bleeding diathesis. It also has been advocated for patients receiving artificial ventilation in the intensive care unit; the need to obtain tissue from more than one organ, including the kidney, liver, or heart; large-volume ascites that precludes the prone position; uncontrolled hypertension; morbid obesity; severe respiratory insufficiency; solitary kidney; failed percutaneous approach; and coma.

The patient lies supine, and the right internal jugular vein is cannulated. A guidewire is passed into the inferior vena cava (IVC), and a catheter is passed over the guidewire and selectively into the right renal vein, which is shorter and enters the IVC at a more favorable angle than the left renal vein. A sheath is passed over the catheter to a suitable peripheral location in the kidney with the aid of contrast enhancement. Finally, the biopsy device (usually a side-cut biopsy needle system) is passed through the sheath and samples are taken. Contrast is then injected into the biopsy track to identify capsular perforation, and embolization coils are inserted if brisk bleeding is identified.

The quality of renal tissue obtained by transjugular biopsy is variable, although studies report diagnostic yields of more than 90%.[15] The complication rate appears comparable to that seen with percutaneous renal biopsy, which is reassuring given that these are high-risk patients.

Open Renal Biopsy

Open renal biopsy has been established as a safe alternative to percutaneous biopsy when uncorrectable contraindications exist. In a series of 934 patients, tissue adequacy was 100% with no major complications.[16] This is an effective approach with minimal postprocedure complications, but the risk of general anesthesia and the delayed recovery time have prevented its widespread adoption. Open biopsy still may be performed, however, when a renal biopsy is required in patients who are otherwise undergoing abdominal surgery.

Laparoscopic Renal Biopsy

Laparoscopic renal biopsy requires general anesthesia and two laparoscopic ports in the posterior and anterior axillary lines to gain access to the retroperitoneal space. Laparoscopic biopsy forceps are used to obtain cortical biopsy samples, and the biopsy sites are coagulated with laser and packed to prevent hemorrhage. In the largest study of laparoscopic renal biopsy, adequate tissue was obtained in 96% of 74 patients.[17] Significant bleeding occurred in three patients, the colon was injured in one, and a biopsy was performed inadvertently on the spleen and liver, respectively, in two others. Inadvertent biopsy was subsequently averted using intraoperative ultrasound to define the anatomy in difficult cases.

COMPLICATIONS OF RENAL BIOPSY

The complication rates compiled from large series of renal biopsies are shown in Table 6.2.[18]

Pain

Patients should be informed about the inevitable dull ache around the needle entry site when the local anesthetic wears off after renal biopsy. Simple analgesia with acetaminophen (paracetamol) or acetaminophen-codeine combinations usually suffices. More severe pain in the loin or abdomen on the side of the biopsy suggests significant perirenal hemorrhage. Opiates may be necessary for pain relief, with appropriate investigation to clarify the severity of the bleed. Patients with visible hematuria may develop clot colic and describe the typical severe pain associated with ureteral obstruction.

Hemorrhage

A degree of perirenal bleeding accompanies every renal biopsy. The mean decrease in hemoglobin after a biopsy is approximately 1 g/dl.[19] Significant perirenal hematomas are almost invariably associated with severe loin pain. Both visible hematuria and painful hematoma are seen in 3% to 4% of patients after biopsy. The initial management is strict bed rest and maintenance of normal coagulation indices. If bleeding is brisk and associated with hypotension or prolonged and fails to settle with bed rest, renal angiography should be performed to identify the source of bleeding. Coil embolization can be performed during the same procedure, and this has largely eliminated the need for open surgical intervention and nephrectomy.

Arteriovenous Fistula

Most postbiopsy arteriovenous fistulas are detected by Doppler ultrasound or contrast-enhanced CT and, when looked for specifically, can be found in as many as 18% of patients. Because most are clinically silent and more than 95% resolve spontaneously within 2 years, fistulas should not be routinely sought. In a small minority of patients, arteriovenous fistulas can lead to visible hematuria (typically recurrent, dark red, and often with blood clots), hypertension, and renal impairment, which requires embolization.

Other Complications

A variety of rare complications have been reported, including biopsy performed on other organs (liver, spleen, pancreas, bowel, gallbladder), pneumothorax, hemothorax, calyceal-peritoneal fistula, dispersion of carcinoma, and Page kidney (compression of kidney by perirenal hematoma leading to renin-mediated hypertension).

TABLE 6.2 Complications in 9474 Native Kidney Biopsies

Complication	Percentage
Visible hematuria	3.5
Need for blood transfusion	0.9
Need for intervention to control bleeding	0.7 (0.6 angiographic; 0.1 surgical)
Death	0.02

Data from reference 18.

Death

Death resulting directly from renal biopsy is much less common in recent biopsy series compared with earlier reports. Most deaths are the result of uncontrolled hemorrhage in high-risk patients, particularly those with severe renal impairment.

SELF-ASSESSMENT QUESTIONS

1. A 68-year-old woman with non-nephrotic proteinuria of unknown cause attended the outpatient unit for a renal biopsy. She had a background of hypertension, chronic alcohol abuse, and osteoarthritis. Which of the following would be a contraindication to renal biopsy for this patient?
   - **A.** Ingestion of naproxen 24 hours earlier
   - **B.** Blood pressure of 162/94 mm Hg
   - **C.** Dipstick urinalysis positive for nitrites and leukocytes
   - **D.** Presence of simple cysts in both kidneys (four in left, three in right)
   - **E.** Body mass index (BMI) of 36 kg/m^2
2. A 32-year-old woman was referred to the renal-obstetric clinic for evaluation of kidney disease. Which is a recognized indication for renal biopsy during pregnancy?
   - **A.** Isolated proteinuria, ratio of protein to creatinine of 320 mg/mmol
   - **B.** Asymptomatic proteinuria with nonvisible hematuria
   - **C.** Episodic visible hematuria
   - **D.** Symptomatic nephrotic syndrome after 32 weeks of gestation
   - **E.** Unexplained deterioration in renal function before 32 weeks of gestation
3. A 75-year-old man was admitted as an emergency with acute kidney injury (AKI). He had been unwell for 4 months with myalgia, arthralgia, and generalized fatigue. More recently, he had developed epistaxis and a nonblanching leg rash. Six months earlier, he had a myocardial infarction, followed by right coronary artery angioplasty and stenting. He was taking aspirin (75 mg), clopidogrel (75 mg), bisoprolol (5 mg), ramipril (5 mg), and atorvastatin (40 mg). On examination, his blood pressure was 148/86 mm Hg, and he was euvolemic. A purpuric rash was present on both lower legs. Investigations were as follows:
   - Serum creatinine: 523 µmol/l (60-110)
   - Serum C-reactive protein: 25 mg/l (<10)
   - Urine dipstick: 3+ blood, 2+ protein, 0 nitrites, 0 leukocytes
   - Antinuclear antibodies: Negative
   - Anti–neutrophil cytoplasmic antibodies: Negative
   - Anti–glomerular basement membrane antibodies: Negative

   An urgent renal biopsy is requested to determine the cause of AKI. What should be done to minimize the risk for postbiopsy bleeding?
   - **A.** Undertake a transjugular renal biopsy
   - **B.** Transfuse platelets before the biopsy
   - **C.** Administer DDAVP
   - **D.** Stop aspirin and clopidogrel and wait 24 hours before performing the biopsy
   - **E.** Administer vitamin K and proceed if international normalized ratio and activated partial thromboplastin time ratio APTTR are normal
4. A 32-year-old man was seen in the nephrology clinic with proteinuria. He has a background of type 1 diabetes mellitus and hypertension. He was treated with lisinopril (10 mg), amlodipine (5 mg), aspirin (75 mg), simvastatin (40 mg), and insulin. On examination, he was overweight (body mass index [BMI]: 30 kg/m^2), blood pressure was 146/84 mm Hg, and edema was present to midcalf level bilaterally. Investigations were as follows:
   - Serum creatinine: 123 µmol/l (60-110)
   - Serum albumin: 28 g/l (37-49)
   - Serum creatinine: 123 µmol/l (60-110)
   - Serum albumin: 28 g/l (37-49)
   - Urinary protein/creatinine ratio: 460 mg/mmol (<15)

   Which additional feature would provide justification for undertaking a renal biopsy?
   - **A.** Presence of diabetic retinopathy
   - **B.** Duration of diabetes of 12 years
   - **C.** Presence of nonselective proteinuria
   - **D.** Negative dipstick urinalysis 4 months earlier
   - **E.** HbA_{1c} of 7.2%

7

Disorders of Extracellular Volume

David H. Ellison, Robert W. Schrier

EXTRACELLULAR FLUID COMPARTMENT

Water comprises 60% of a typical healthy man's body weight and 50% of a woman's body weight. Total body water (TBW) is distributed in two compartments: the intracellular fluid (ICF) compartment (55% to 65% of TBW) and extracellular fluid (ECF) compartment (35% to 45% of TBW). The ECF is further subdivided into two spaces: the *interstitial* space accounts for about 75% of the ECF, and the *intravascular* space represents the remaining 25% (Fig. 7.1).

Water diffuses freely between the intracellular space and the extracellular spaces in response to gradients in effective osmolality, where effective osmolality (tonicity) is the product of the solute concentration and its reflection coefficient (similar to the inverse of permeability). Therefore the amount of water in different compartments depends on the quantity of effective osmoles in that compartment. The major solute in the ECF is sodium ion (Na^+), and the major intracellular solute is potassium ion (K^+); the number of cations always equals the number of anions in fluid. The maintenance of this uneven ion distribution is fulfilled by active transport through the Na^+-K^+–adenosine triphosphate (ATP)–dependent pumps on the cell membrane, and this determines the relative volume of different compartments. Because sodium (with anions) is the predominant extracellular solute, the ECF volume is determined primarily by the sodium content of the body. The sodium content largely depends on salt intake and renal excretion, which is tightly regulated.

Fluid movement between the intravascular and interstitial spaces of the ECF occurs across the capillary wall and is governed by Starling forces, namely, the capillary hydrostatic pressure and colloid osmotic pressure. Unlike cell membranes, capillary membranes are traditionally believed to be highly permeable to small solutes, such as Na^+, rendering small molecules incapable of generating transcapillary water movement. In this case, plasma proteins, especially albumin, play special roles in retaining fluid within capillaries, because proteins are poorly permeable across capillary membranes. The outward transcapillary hydrostatic pressure gradient exceeds the corresponding inward oncotic pressure gradient, thereby favoring movement of plasma ultrafiltrate into the interstitial space.

Titze and colleagues[1] proposed revisions to this model. They emphasize that not all fluid compartments are in osmotic equilibrium and not all extracellular sodium is osmotically active. Accordingly, sodium can be stored in compartments such as the skin (whether osmotically silent[2] or osmotically active[3] is not clear) and then released in a rhythmic manner that is independent of ECF volume.[4] One of the contributors to the skin sodium storage is immune cells, and this process may help determine the ability of skin to resist microbial pathogens. Both the traditional and the alternative model of sodium homeostasis rely on the crucial role of the lymphatics in returning sodium to the circulation. Despite these important revisions to the traditional model, treating edema removes fluid primarily from an "interstitial" (nonplasma) compartment, indicating that most extravascular fluid is in osmotic equilibrium with plasma.[5]

The ECF volume determines the adequacy of the circulation and in turn the adequacy of delivery of oxygen, nutrients, and other substances needed for organ functions; it is also necessary for removal of waste products. This is achieved despite day-to-day variations in the intake of sodium and water, with the ECF volume varying by only 1% to 2%.

REGULATION OF EXTRACELLULAR FLUID HOMEOSTASIS

Circulatory stability depends on homeostatic mechanisms that include an *afferent* sensing limb, comprising several volume and stretch detectors distributed throughout the vascular bed, and an *efferent* effector limb (Table 7.1). Adjustments in the effector mechanisms occur in response to afferent stimuli by sensing-limb detectors, to modify circulatory parameters. Disorders of either sensing mechanisms or effector mechanisms can lead to failure of adjustment of sodium handling by the kidney, with resultant hypertension or edema formation in the patient with positive sodium balance or hypotension and hypovolemia in the patient with negative sodium balance.

Afferent (Sensor) Limb

Afferent limb (sensing) sites include low-pressure cardiopulmonary receptors (atrial, ventricular, and pulmonary stretch receptors), high-pressure arterial baroreceptors (carotid, aortic arch, and renal sensors), central nervous system (CNS) receptors, and hepatic receptors. The cardiac atria possess the distensibility and compliance needed to monitor changes in intrathoracic venous volume. Atrial distention and a sodium load cause release of atrial natriuretic peptide (ANP), a polypeptide normally stored in secretory granules within atrial myocytes. The closely related brain natriuretic peptide (BNP) is stored primarily in ventricular

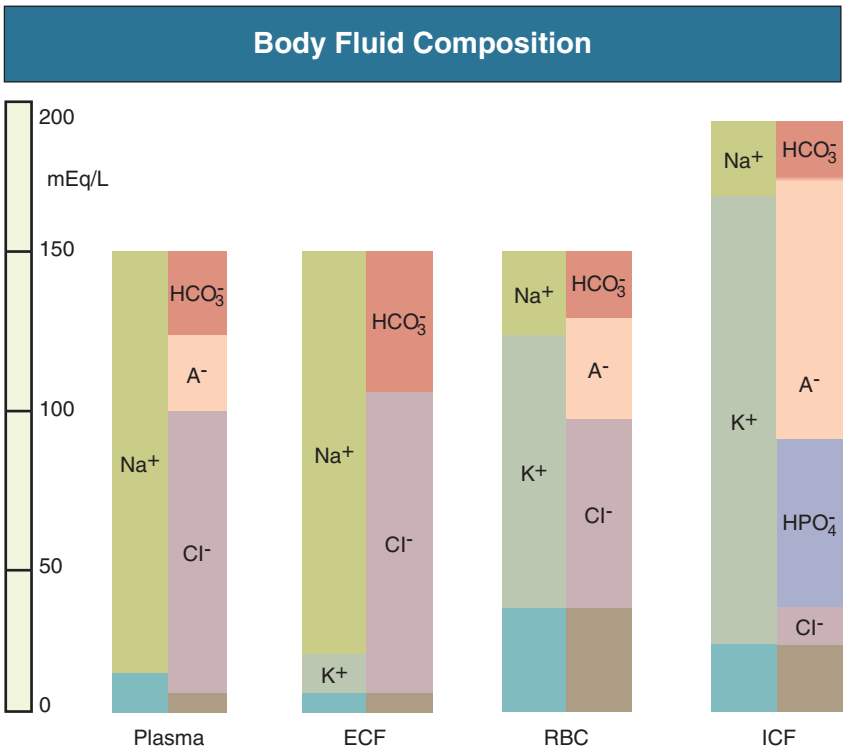

Fig. 7.1 Gamblegram of body composition. A 70-kg man has 42 liters (60%) of water, whereas a 60-kg woman has 36 liters (50%) of water. Of water, two thirds is intracellular *(ICF)* and one third is extracellular (ECF). The osmolality in compartments is similar, even though solute concentrations differ, owing to valence of ions. *RBC,* Red blood cell.

TABLE 7.1 Homeostatic Mechanisms in Extracellular Fluid Volume

Afferent (Sensing)	Efferent (Effector)
Cardiopulmonary receptors	Renal-angiotensin-aldosterone system (RAAS)
Atrial	Prostaglandins
Ventricular	Arginine vasopressin (AVP)
Pulmonary	Natriuretic peptides
High-pressure baroreceptors	Atrial (ANP)
Carotid	Brain (BNP)
Aortic	C-type (CNP)
Renal	Other hormones
Pressure sensors*	Nitric oxide (NO)
Glomerular afferent	Endothelin
Juxtaglomerular apparatus	Kallikrein-kinin system
Central nervous system receptors	
Hepatic receptors	

*Pressure sensors are unspecified receptors contributing to pressure natriuresis.

myocardium and is released when ventricular diastolic pressure rises. An increase in left atrial pressure also sends signals to the hypothalamus that can suppress the release of antidiuretic hormone (ADH), also called arginine vasopressin (AVP). These atrial-renal and atrial-hypothalamic reflexes enhance renal sodium and water excretion on sensing of a distended left atrium.

The sensitive arterial stretch receptors in the carotid artery, aortic arch, and glomerular afferent arteriole respond to a decrease in arterial pressure. Information from these nerve endings is carried by the vagal and glossopharyngeal nerves to vasomotor centers in the medulla and brainstem. In the normal situation, these receptors exert a tonic restraining effect on the heart and circulation by inhibiting the sympathetic outflow and augmenting parasympathetic activity. In addition, changes in transmural pressure across the arterial vessels and the atria also influence the secretion of AVP and renin and the release of ANP. Activation of the arterial receptors signals the kidney to retain sodium and water by increases in sympathetic activity and vasopressin release. Stimulation of the sympathetic nervous system (SNS) also enhances the renin-angiotensin-aldosterone system (RAAS). A rise in arterial pressure elicits the opposite response, resulting in decreased catecholamine release and natriuresis.

Renal sensing mechanisms include the juxtaglomerular apparatus (JGA), which is involved in the generation and release of renin from the kidney and in tubuloglomerular feedback (THF) (see later discussion). Renin secretion is inversely related to perfusion pressure and directly related to intrarenal tissue pressure. Solute delivery to the macula densa is also an important determinant of renin release; an increase in sodium chloride entry into macula densa cells inhibits renin release, whereas a decrease in entry stimulates it. Renal nerve stimulation through activation of β-adrenergic receptors of the JGA directly enhances renin release. Other receptors reside in the CNS and hepatic circulation but have been less well defined.

Glomerulotubular Balance

Increases or decreases in glomerular filtration rate (GFR) lead to parallel changes in NaCl reabsorption (Fig. 7.2), the phenomenon of glomerulotubular balance (GTB), so that GFR is not a major determinant of net solute excretion. A second process, TGF, senses NaCl at the macula densa

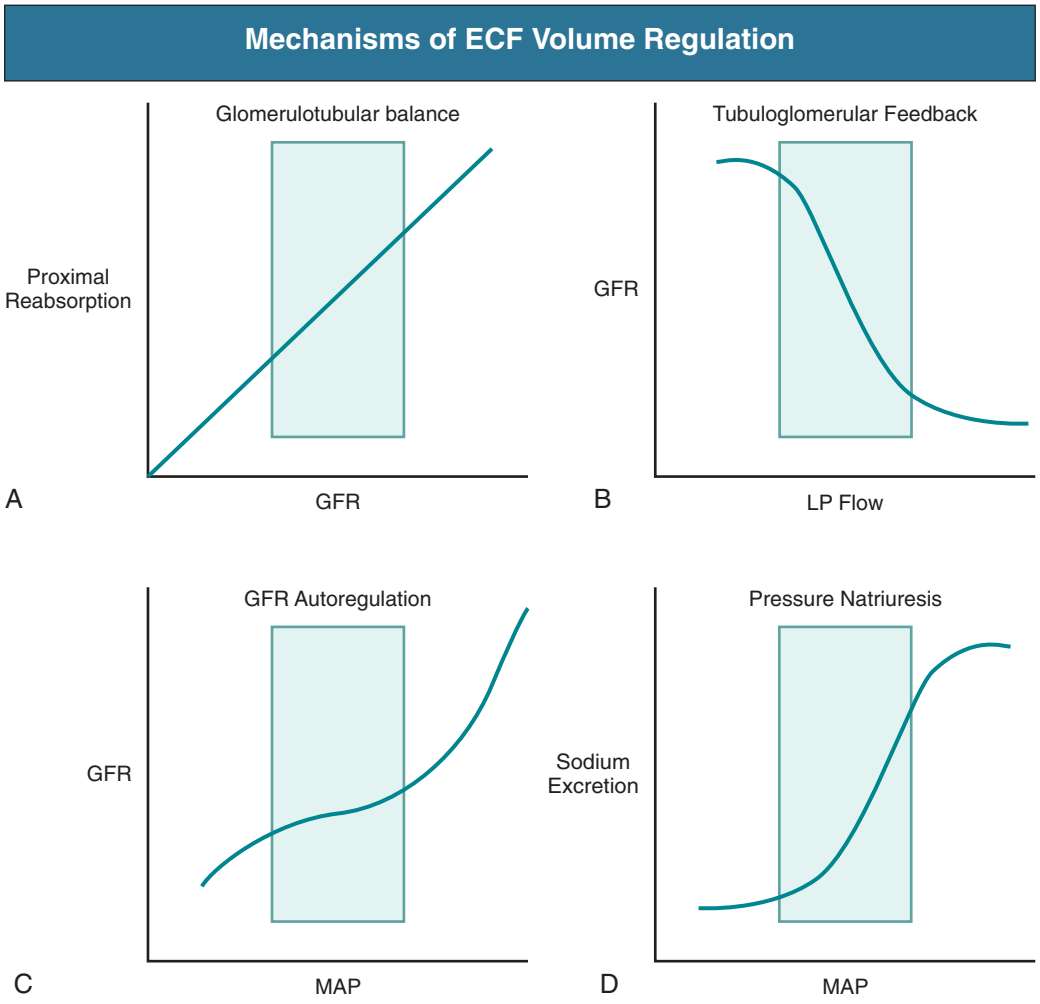

Fig. 7.2 Overall mechanisms of ECF volume regulation. (A) Proximal reabsorption rises with increased glomerular filtration rate (GFR) (glomerulotubular balance). (B) Relationship between late proximal (LP) flow and GFR (tubuloglomerular feedback). (C) GFR is autoregulated across mean arterial pressure (MAP). (D) Sodium excretion increases, as MAP increases, the pressure natriuresis. *Boxes* indicate typical operating ranges.

to adjust GFR. High luminal NaCl concentration at the macula densa, as occurs during high loop segment flow rates and volume expansion, leads to constriction of the nearby afferent arteriole and reduction of GFR (see Fig. 7.2). This process reduces GFR (see Fig. 7.2) and therefore proximal flow, tending to keep solute excretion rates constant. Although functionally independent of GTB, the sequential arrangement of GTB and TGB means they work in concert and are remarkably effective in maintaining NaCl excretion rates in the face of changing GFR.[6]

Pressure Natriuresis

Both renal blood flow and GFR are autoregulated (see Fig. 7.2), meaning they are relatively insensitive to variations in arterial pressure, within a range of typical pressure values. In contrast, urinary Na^+ excretion is strongly affected by even modest variations in pressure, with a rise in pressure increasing renal Na^+ excretion (see Fig. 7.2). This process appears to be intrinsic to the kidney, but the shape of the relationship is strikingly altered by actions of the RAAS. The phenomenon, termed *pressure natriuresis*, likely results from the adjustment of Na^+ reabsorption by several segments of the nephron, via pathways that remain incompletely defined. The dominant importance of pressure natriuresis, at least under sodium retentive conditions, is clear from experimental models. Natriuretic sensitivity to natriuretic peptides can be restored[7] by a rise in renal perfusion pressure (RPP). Conversely, escape from the sodium retentive effects of aldosterone[8] or angiotensin II (Ang II)[9] also requires a rise in RPP.

Efferent (Effector) Limb

The stimulation of the effector limb of the ECF volume homeostasis leads to activation of effector mechanisms (see Table 7.1). These effector mechanisms aim predominantly at modulation of renal sodium and water excretion to preserve circulatory stability.

Renin-Angiotensin-Aldosterone System

Renin secretion from the JGA increases in response to depletion of the ECF volume, as a result of the processes described previously. Renin converts angiotensinogen to Ang I, which is then converted to Ang II by the action of the angiotensin-converting enzyme (ACE); Ang II can subsequently affect circulatory stability and volume homeostasis. It is a vasoconstrictor, it stimulates sodium retention, and it stimulates aldosterone release, all effects that maintain arterial pressure, when ECF volume is low. Ang II has complex effects on GFR and renal plasma flow (RPF), but when the ECF volume is low, it preferentially increases

renal efferent arteriolar tone, thus tending to preserve GFR; this is one reason that the RAAS contributes importantly to autoregulation of GFR. Ang II also increases the filtration fraction by altering Starling forces across the glomerulus, which leads to enhanced proximal sodium and water retention.[10]

Ang II also augments sympathetic neurotransmission and enhances the TGF mechanism. In addition to these indirect mechanisms, Ang II directly enhances proximal tubular volume reabsorption by activating apical membrane sodium-hydrogen (Na^+-H^+) exchangers. Ang II also enhances sodium absorption by stimulating secretion of aldosterone, which in turn increases sodium reabsorption in the cortical collecting tubule.

Sympathetic Nervous System

Sympathetic nerves that originate in the prevertebral celiac and paravertebral ganglia innervate cells of the afferent and efferent arterioles, JGA, and renal tubule. Sympathetic nerves alter renal sodium and water handling by direct and indirect mechanisms.[11] Increased nerve stimulation indirectly stimulates proximal tubular sodium reabsorption by altering preglomerular and postglomerular arteriolar tone, thereby influencing filtration fraction. Renal nerves directly stimulate proximal tubular fluid reabsorption through receptors on the basolateral membrane of the proximal convoluted tubule cells. These effects on sodium handling are further amplified by the ability of the sympathetic nerves to stimulate renin release, which leads to the formation of Ang II and aldosterone.

Natriuretic Peptides

Secretion of ANP and BNP was discussed earlier. These peptides augment sodium and water excretion by increasing the GFR, possibly by dilating the afferent arteriole and constricting the efferent arteriole. Furthermore, they inhibit sodium reabsorption in the cortical collecting tubule and inner medullary collecting duct, reduce renin and aldosterone secretion, and oppose the vasoconstrictive effects of Ang I.[12] Circulating levels of ANP and BNP are elevated in congestive heart failure (CHF) and in cirrhosis with ascites, but these levels are not sufficient to overcome the sodium-retaining effects of low RPP.

Prostaglandins

Prostaglandins are derived from arachidonic acid and modulate renal blood flow and sodium handling. Important renal prostaglandins include prostaglandin I_2, which mediates baroreceptor (but not β-adrenergic) stimulation of renin release. Prostaglandin E_2 is stimulated by Ang II and has vasodilatory properties. Increased levels of Ang II, AVP, and catecholamines stimulate synthesis of prostaglandins, which in turn act to dilate the renal vasculature, inhibit sodium and water reabsorption, and stimulate renin release. In situations of ECF volume depletion or depletion of the effective arterial blood volume (EABV), the combination of prostaglandin-mediated afferent arteriolar dilation and Ang II–mediated efferent arteriolar constriction plays a central role in autoregulatory maintenance of GFR. Often, in these situations, interference with efferent vasoconstriction (e.g., ACE inhibition), and with afferent vasodilation (e.g., nonsteroidal antiinflammatory drugs [NSAIDs]) leads to a precipitous decline in GFR, manifested as acute kidney injury (AKI).

Arginine Vasopressin

The polypeptide AVP is synthesized in supraoptic and paraventricular nuclei of the hypothalamus and is secreted by the posterior pituitary gland. The predominant stimulus for AVP release under typical conditions is hypertonicity. Substantial reductions in EABV, however, act as a second, nonosmotic regulatory pathway.[13] AVP release is suppressed in response to ECF volume overload sensed by increased afferent impulses from arterial baroreceptors and atrial receptors, whereas decreased ECF volume has the opposite effect. AVP release leads to antidiuresis and, at higher concentrations, to systemic vasoconstriction through the V_1 receptors.[14] The antidiuretic action of AVP results from the effect on the principal cell of the collecting duct through activation of the V_2 receptor. AVP increases the synthesis and provokes the insertion of aquaporin 2 (AQP2) water channels into the luminal membrane, thereby allowing water to be reabsorbed down the favorable osmotic gradient. AVP also may lead to enhanced Na^+ reabsorption and K^+ secretion. AVP appears to have synergistic effects with aldosterone on sodium transport in the cortical collecting duct.[15] AVP stimulates potassium secretion by the distal nephron, and this preserves potassium balance during ECF depletion, when circulating levels of vasopressin are high and tubular delivery of sodium and fluid is reduced.

Other Hormones

Other hormones that contribute to renal sodium handling and ECF volume homeostasis include nitric oxide (NO), endothelin, and the kallikrein-kinin system. NO is an endothelium-derived mediator that participates in the natriuretic responses to increases in blood pressure or ECF volume expansion. Endothelins, in addition to their potent actions to constrict vascular smooth muscle, are natriuretic factors. Endothelin 1, via the endothelin B (ET_B) receptor, increases NO production, which tends to increase urinary salt excretion. Kinins are potent vasodilator peptides, but their physiologic roles are not yet fully defined.

Terms Useful for Disorders of Extracellular Fluid Volume

In clinical practice it is helpful to view disorders of ECF volume as distinct from disorders of water. The latter reflect gain or loss of electrolyte-free water, typically resulting in changes in plasma osmolality (hyponatremia or hypernatremia); when losses or gains are substantial, detectable changes in ECF volume can occur. But changes in ECF volume, often termed simply *volume contraction* or *volume expansion,* reflect gain or loss of NaCl. Water is often retained or lost secondarily.

Loss of salt and water produces true depletion of ECF volume, but there are many pathologic conditions (e.g., heart failure [HF]; cirrhosis) in which ECF volume is expanded but the kidneys behave as if contracted. To account for this discrepancy, the term *EABV* is used to describe the blood volume detected by the sensitive arterial baroreceptors. The EABV can change independently of the total ECF volume. The state of the EABV is often inferred from the behavior of the kidneys.

EXTRACELLULAR FLUID VOLUME CONTRACTION

Contraction of ECF volume typically results from sodium losses that exceed intake. Losses may be renal or extrarenal through the gastrointestinal tract, skin, and lungs or by sequestration in potential spaces in the body (e.g., abdomen, muscle) that are not in hemodynamic equilibrium with the ECF (Table 7.2). The reduction in ECF volume occurs from both the interstitial and intravascular compartments. The loss of solute-free water (e.g., diabetes insipidus [DI]) has a lesser effect on intravascular volume because water is lost from all aqueous spaces in the body, and the body's solute content remains unchanged. Thus, in this case of disordered water balance, hypertonicity—rather than ECF volume contraction—predominates.

Extrarenal Causes

Gastrointestinal Losses

Approximately 3 to 6 liters of fluids and digestive juices are secreted daily throughout the gastrointestinal tract, and most of this fluid is

TABLE 7.2 Major Causes of Extracellular Fluid Volume Depletion

Renal	Extrarenal
Diuretic use	Gastrointestinal losses
Tubular disorders	Vomiting
Genetic	Gastrointestinal suctioning
Bartter and Gitelman syndromes	Diarrhea
Pseudohypoaldosteronism type 1	Ileostomy and colostomy secretions
Acquired tubular disorders	Dermal losses
Acute kidney injury	Sweat
Recovery phase of oliguric kidney injury	Exudative skin disease
Release of urinary tract obstruction	Third-space sequestration
Hormonal and metabolic disturbances	Ascites
Mineralocorticoid deficiency or resistance	Pleural effusion, hydrothorax
Primary adrenal insufficiency	Intestinal obstruction
Hyporeninemic hypoaldosteronism	Retroperitoneal collection
Diabetes mellitus	Hemorrhage
Chronic interstitial renal diseases	Internal
Solute diuresis	External
Renal water loss	
Diabetes insipidus	

reabsorbed. Vomiting or nasogastric suction may cause volume loss that is usually accompanied by metabolic alkalosis, whereas diarrhea may result in volume depletion that is accompanied by metabolic acidosis.

Dermal Losses

Sweat is typically hypotonic, leading to more water loss than salt loss. Sweat production can be excessive in high ambient temperature or with prolonged exercise in hot, humid climates and may lead to volume depletion. Loss of the skin barrier with superficial burns and exudative skin lesions may lead to significant ECF volume depletion.

Third-Space Sequestration

Body fluid accumulation in potential spaces that are not in hemodynamic equilibrium with the ECF compartment can cause volume depletion. This pathologic accumulation, often called third-space sequestration, includes ascites, hydrothorax, and intestinal obstruction, with fluid collecting in the peritoneal cavity, pleural space, and intestines, respectively, and leading to significant ECF volume loss. Severe pancreatitis may result in retroperitoneal fluid collections.

Hemorrhage

Hemorrhage occurring internally (e.g., from bleeding esophageal varices) or externally (e.g., trauma) may lead to significant volume loss.

Renal Losses

In health, approximately 25,000 mmol of sodium is filtered every day. The small quantities of sodium excreted in urine relative to the filtered load depend on intact tubular reabsorptive mechanisms to adjust urinary sodium excretion to maintain ECF homeostasis. Impairment in the integrity of these mechanisms can result in significant volume depletion.

Diuretic Use

Most of the widely used diuretic medications inhibit sodium transport pathways along the nephron (see later discussion). Diuretics may cause renal sodium wasting, volume contraction, and metabolic acid-base disturbances.

Genetic and Acquired Tubular Disorders

Tubular sodium reabsorption may be disrupted in several genetic disorders that include Bartter syndrome and Gitelman syndrome. These autosomal recessive disorders are caused by mutations of sodium transporters and result in sodium wasting, volume contraction, and hypokalemic metabolic alkalosis. They are discussed in more detail in Chapter 47. Pseudohypoaldosteronism type 1 (PHA1) is another rare inherited disorder, characterized by sodium wasting and hyperkalemic metabolic acidosis and is caused by mutations in the epithelial sodium channel, ENaC.

Acquired tubular disorders that may be accompanied by salt wasting include AKI, during the recovery phase of oliguric AKI or urinary obstruction (see Chapters 58 and 70).

Hormonal and Metabolic Disturbances

Mineralocorticoid deficiency and resistance states often lead to sodium wasting. This may occur in the setting of primary adrenal insufficiency (Addison disease) and PHA1. Salt wasting also can be seen in chronic tubular and interstitial renal diseases. Severe hyperglycemia or high levels of blood urea during release of urinary tract obstruction can lead to obligatory renal sodium and water loss secondary to glycosuria or urea diuresis, respectively.

Renal Water Loss

DI represents a spectrum of diseases resulting from AVP deficiency, (*central* DI), or tubular resistance to AVP (*nephrogenic* DI). The most common causes of polyuria from nephrogenic DI in adults are chronic lithium ingestion, hypercalcemia, and less frequently, hypokalemia (see Chapter 8). In these disorders the tubular reabsorption of solute-free water is impaired. This generally results in a lesser effect on ECF volume because, in contrast to sodium, there is a relatively smaller amount of the TBW in the ECF compartment compared with the ICF compartment.

Clinical Manifestations of Extracellular Fluid Volume Contraction

The spectrum of the clinical manifestations of volume contraction (Box 7.1) depends on the amount and rate of ECF volume loss, as well as on the vascular and renal responses to that loss. An adequate history and physical examination are crucial to elucidate the cause of hypovolemia. Symptoms are usually nonspecific and can range from mild postural symptoms, thirst, muscle cramps, and weakness to drowsiness and disturbed mentation with profound volume loss. Physical examination may reveal tachycardia, cold clammy skin, postural or recumbent hypotension, and reduced urine output, depending on the degree of volume loss. Low jugular venous pressure (JVP; ≤5 cm H_2O) is consistent with volume depletion. However, the JVP may be elevated in patients with pulmonary hypertension or when the EABV is low. The lack of symptoms or discernible physical findings does not preclude volume depletion, and hemodynamic monitoring and administration of a fluid challenge may be necessary.

Laboratory Tests

Hemoconcentration and increased serum albumin concentration may be seen early with hypovolemia, but anemia or hypoalbuminemia caused by a concomitant disease may confound interpretation of these laboratory values. In healthy individuals, the ratio of blood urea nitrogen (BUN) to serum creatinine is approximately 10 to 20:1 (measured in milligrams per deciliter). In volume-contracted states, this ratio may increase because of an associated differential increase in urea reabsorption

BOX 7.1 Clinical Evaluation of Extracellular Fluid Volume Depletion

Mild to Moderate Volume Loss

- Thirst
- Delay in capillary refill
- Postural dizziness, weakness
- Dry mucous membranes and axillae
- Cool, clammy extremities and collapsed peripheral veins
- Tachypnea
- Tachycardia with pulse rate >100 beats/min, or postural pulse increment of 30 beats/min or more
- Postural hypotension (systolic blood pressure decrease >20 mm Hg on standing)
- Low jugular venous pulse
- Oliguria

Severe Volume Loss and Hypovolemic Shock

- Depressed mental status (or loss of consciousness)
- Peripheral cyanosis
- Reduced skin turgor (in young patients)
- Marked tachycardia, low pulse volume
- Supine hypotension (systolic blood pressure <100 mm Hg)

in the collecting duct. Several clinical conditions affect this ratio. Upper gastrointestinal tract hemorrhage and administration of corticosteroids increase urea production, and hence the ratio of BUN to creatinine increases. Malnutrition and liver disease diminish urea production, making the ratio less helpful.

Urine osmolality and specific gravity may be elevated in hypovolemic states, but may be altered by an underlying renal disease that leads to renal sodium wasting, concomitant intake of diuretics, or a solute diuresis. Hypovolemia normally promotes avid renal sodium reabsorption, resulting in low urine sodium concentration and low fractional excretion of sodium. Urine chloride follows a similar pattern because sodium and chloride are generally reabsorbed together. Volume depletion with metabolic alkalosis (e.g., with vomiting) is an exception because of the need to excrete the excess bicarbonate in conjunction with sodium to maintain electroneutrality; in this case, urine chloride concentration is a better index of ECF volume contraction. The fractional excretion of sodium (FE_{Na}) is calculated by the following formula:

$$FE_{Na} = [U_{Na} \times P_{creat} / U_{creat} \times P_{Na}] \times 100$$

where U_{Na} and U_{creat} are urinary sodium and creatinine concentrations, respectively, and P_{Na} and P_{creat} are serum sodium and creatinine concentrations, respectively. In an oliguric patient with AKI, FE_{Na} less than 1% is consistent with volume depletion; FE_{Na} greater than 1% is more consistent with acute tubular necrosis.

Therapy of Extracellular Fluid Volume Contraction

The goal of treatment is to replace the fluid deficit and ongoing losses with a fluid that resembles the lost fluid. The first step is to determine the urgency of the hypovolemic condition. In severe hypovolemia or hypovolemic shock, immediate treatment should be initiated, typically with 1 to 2 liters of isotonic crystalloid. The adequacy of repletion can then be monitored clinically, with central venous pressure monitoring or, in the intensive care unit (ICU), respiratory variation in the arterial pressure tracing. Estimating the magnitude of volume deficit is imprecise; thus a key component of successful treatment is frequent monitoring and adjustment of therapy.

Mild volume contraction usually can be corrected orally. It is important to note, however, that unlike oral rehydration solutions used for childhood diarrhea (50 to 90 mmol/L sodium), sports drinks typically contain very little NaCl (7 to 20 mmol/L) and do not replace ongoing losses, although normal kidneys can typically adjust for the discrepancy when losses are mild.

Crystalloid solutions (isotonic or slightly hypotonic) with sodium as the principal cation are effective because they distribute primarily in the ECF. One third of an infusate of isotonic saline (0.9% NaCl) remains in the intravascular compartment, whereas two thirds distributes into the interstitial compartment. Colloid-containing solutions include human albumin (5% and 25%) and hetastarch (6% hydroxyethyl starch [HES]), which remain within the vascular compartment (provided the transcapillary barrier is intact and not disrupted by capillary leak states such as often occurs with multiorgan failure). The solutions augment the plasma oncotic pressure and thus expand the plasma volume by counteracting the capillary hydraulic pressure.

Colloid-containing solutions have not shown an advantage in the treatment of hypovolemic states. A large, multicenter trial that randomized medical and surgical critical patients to receive fluid resuscitation with 4% albumin or normal saline showed similar mortality, morbidity, and hospitalization rates in the two groups.[16] A recent study randomly assigned ICU patients with severe sepsis to fluid resuscitation with either 6% HES or Ringer acetate solution.[17] Patients who received HES had increased mortality and were more likely to receive renal replacement therapy. Consequently, artificial colloids should be avoided in patients with severe sepsis or at risk for developing AKI.[18]

Isotonic saline or a balanced salt solution (e.g., lactated Ringer solution) is usually the preferred initial choice in volume-depleted patients with normal serum [Na^+] and most of those with low serum [Na^+]. Furthermore, isotonic saline is the preferred fluid to restore ECF volume in hypovolemic patients with hypernatremia. Once euvolemia is established, hypotonic (0.45% NaCl) saline should be delivered to gradually correct tonicity. Administration of large volumes of isotonic saline may result in the development of hyperchloremic metabolic acidosis or AKI. Although a number of smaller studies suggest benefit from buffered crystalloid solutions, such as lactated Ringer solution, a randomized trial could not detect a difference.[19] Any hypokalemia should be corrected by adding potassium chloride to replacement solutions.

Hypovolemic shock may be accompanied by lactic acidosis resulting from tissue hypoperfusion. Fluid resuscitation restores tissue oxygenation and will decrease the production of lactate, but lactated Ringer solution is inappropriate because the infused lactate will not be converted to bicarbonate. Correction of acidosis with sodium bicarbonate ($NaHCO_3$) has the potential for increasing tonicity, expanding volume, worsening intracellular acidosis from increased carbon dioxide production, and not improving hemodynamics compared with isotonic saline. Whether $NaHCO_3$ effectively corrects the impaired cardiac contractility associated with lactic acidosis has not been well documented by clinical studies. Therefore $NaHCO_3$ to manage lactic acidosis in the setting of volume depletion is not recommended (unless arterial pH is <7.1).

EXTRACELLULAR FLUID VOLUME EXPANSION

Expansion of ECF volume usually results from renal sodium and water retention. Generalized edema results from an apparent increase in the interstitial fluid volume, most often in response to HF, cirrhosis with ascites, and nephrotic syndrome. Weight gain of several kilograms usually precedes clinically apparent edema. Localized excess fluid may accumulate in the peritoneal and pleural cavities, leading to ascites and pleural effusion, respectively.

Pathogenesis

Renal sodium and water retention secondary to arterial underfilling leads to an alteration in capillary hemodynamics that favors fluid movement from the intravascular compartment into the interstitium. In general, these two processes account for edema formation.

Capillary Hemodynamic Disturbances

According to the Starling equation, the exchange of fluid between the plasma and the interstitium is determined by the hydrostatic and oncotic pressures in each compartment. Interstitial fluid excess results from a decrease in plasma oncotic pressure or an increase in capillary hydrostatic pressure. In other words, edema is a result of an increase in fluid movement from the intravascular compartment to the interstitial space or a decrease in fluid movement from the interstitial space to the intravascular compartment, or both. Thus the degree of interstitial fluid accumulation as determined by rate of fluid removal by the lymphatic vessels is a determinant of edema.

The capillary hydrostatic pressure is relatively insensitive to alterations in arterial pressure. The stability of the capillary pressure is a result of variations in the precapillary sphincter, which governs how much arterial pressure is transmitted to the capillary, a locally controlled response called *autoregulation*. In contrast, the venous end is not similarly well regulated. Therefore, when the blood volume expands, as in HF and renal disease, capillary hydrostatic pressure increases and edema ensues. Venous obstruction works by the same mechanism to cause edema, as exemplified by ascites formation in liver cirrhosis and by acute pulmonary edema after sudden impairment in cardiac function (e.g., myocardial infarction). In hepatic cirrhosis and nephrotic syndrome, another factor in edema formation is reduction in plasma oncotic pressure, with fluid transudation into the interstitial space. Even normal conditions favor net filtration into the interstitium because capillary hydrostatic pressure exceeds the plasma colloid pressure in several tissues throughout the length of the capillary. In these tissues, a substantial amount of filtered fluid is returned to the circulation through lymphatic channels, which minimizes edema formation.

Renal Sodium Retention

The mechanism for maintenance of ECF volume expansion and edema formation is renal sodium retention, which can be primary or secondary in response to reduction in EABV (Table 7.3).

Primary renal sodium retention. A primary defect in renal sodium excretion can occur with AKI, chronic kidney disease (CKD), or glomerular disease. Patients with AKI have limited ability to excrete sodium and water. Advanced CKD may lead to sodium and water retention by GFR reduction. Primary renal sodium retention characterizes some forms of glomerulonephritis and occurs through incompletely understood mechanisms in the presence of a relatively suppressed renin-angiotensin-aldosterone system (RAAS), but frequently with decreased GFR.

Mineralocorticoid excess or enhanced mineralocorticoid activity are associated with sodium retention. However, because of mineralocorticoid escape (discussed previously) the clinical manifestation is generally hypertension rather than hypervolemia. In normal individuals, administration of a high-dose mineralocorticoid initially increases renal sodium retention so that ECF volume is increased. However, renal sodium retention then ceases, spontaneous diuresis ensues, sodium balance is reestablished, and there is no detectable edema. This escape from mineralocorticoid-mediated sodium retention explains why edema is not a characteristic feature of primary hyperaldosteronism. The pathophysiologic mechanism of mineralocorticoid escape involves an increase in GFR and reduction of proximal tubular sodium and water reabsorption. This leads to an increase in sodium and water delivery to the distal nephron site of aldosterone action, which overrides the sodium reabsorption of aldosterone. Other contributing mechanisms include decreased expression of distal tubular thiazide-sensitive NaCl cotransporters,[20] increased secretion of ANP induced by hypervolemia,[21] and pressure natriuresis. Regardless of the mechanisms involved, RPP must rise to enable the escape process[8]; because this can occur during primary renal salt retention, these states are typically characterized by hypertension and not edema.

Secondary renal sodium retention. An estimated 85% of blood circulates on the low-pressure venous side of the circulation, and 15% in the high-pressure arterial circulation. Thus an increase in total blood volume could occur, even when there is underfilling of the arterial circulation, if the increase in total blood volume is primarily caused by expansion of the venous compartment. Underfilling of the arterial circulation could result from a decrease in cardiac output, as occurs in low-output cardiac failure, or from systemic arterial vasodilation, which occurs early in cirrhosis as a result of decreased systemic vascular resistance (SVR) in the splanchnic circulation.[22] As arterial pressure is determined by the product of cardiac output and SVR, both states would be characterized by a decline in arterial pressure below the kidney's set point. This model proposes that renal sodium retention triggered by arterial underfilling (arterial pressure less than pressure set point) is a compensatory response necessary to restore arterial circulatory integrity.

If there is arterial underfilling from decreased cardiac output or systemic arterial vasodilation, the hypotension is sensed by the arterial stretch receptors. This leads to activation of the efferent limb of body fluid volume homeostasis. Specifically, a decrease in glossopharyngeal and vagal tone from the carotid and aortic receptors to the CNS leads to a rapid increase in sympathetic activity with associated activation of the RAAS axis and nonosmotic release of vasopressin. Additionally, a decrease in pressure at the renal baroreceptors and decreased NaCl delivery to the macula densa increase renin secretion and thereby Ang II and aldosterone. The resultant increase in SVR and renal sodium and water retention attenuates the arterial underfilling, through the Frank-Starling mechanism, and tends to restore arterial perfusion. Together, these actions maintain the arterial circulatory integrity and restore perfusion to vital organs at the expense of expanded ECF volume and edema.

Sodium and Water Retention in Heart Failure

HF can occur with reduced or preserved ejection fraction (HF_REF and HF_PEF, respectively), but the mechanisms involved in renal sodium and water retention appear to involve similar mediators.[23] Decreased cardiac output with arterial underfilling leads to reduced stretch of arterial baroreceptors and reduced perfusion pressure in the kidney. In the case

TABLE 7.3 Major Causes of Extracellular Fluid Volume Expansion

Primary Renal Sodium Retention	Secondary Renal Sodium Retention*
Acute kidney injury	Cardiac failure
Advanced chronic kidney disease	Cirrhosis
Glomerular diseases	Nephrotic syndrome
	Idiopathic edema
	Drug-induced edema
	Pregnancy

*Secondary to reduced effective arterial blood volume depletion (arterial underfilling).

of HF_PEF, this often involves a decrease below a hypertensive baseline or below a baseline raised by CKD. This results in increased sympathetic discharge from the CNS and activation of the RAAS. Adrenergic stimulation and increased Ang II activate receptors on the proximal tubular epithelium that enhance sodium reabsorption. The renal vasoconstriction of the glomerular efferent arteriole by Ang II in CHF also alters net Starling forces in the peritubular capillary in a direction to enhance sodium reabsorption.[24] Thus Ang and α-adrenergic stimulation increase sodium reabsorption in the proximal tubule by a direct effect on the proximal tubule epithelium and secondarily by renal vasoconstriction. This subsequently leads to decreased sodium delivery to the collecting duct, which impairs escape from both aldosterone and natriuretic peptides.[7,25] This failure of escape explains why sodium retention and ECF volume expansion occur in HF (Fig. 7.3). Accordingly, patients with HF may have substantial natriuresis when spironolactone, a competitive mineralocorticoid receptor antagonist (MRA), is given in adequate doses to compete with increased endogenous aldosterone levels.[26]

The atrial-renal reflexes, which normally enhance renal sodium excretion, are also impaired because plasma levels of ANP do not increase further when patients with dilated cardiomyopathy and mild HF receive a saline load, and the natriuretic response is also blunted. Autonomic dysfunction and blunted arterial baroreceptor sensitivity in HF are associated with increased circulating catecholamines and increased renal sympathetic activity. There is also evidence for parasympathetic withdrawal in HF, in addition to the increase in sympathetic drive.

Another outcome of the neurohumoral activation that occurs in HF is the baroreceptor-mediated nonosmotic release of AVP.[27] This nonosmotic AVP stimulation overrides the osmotic regulation of AVP and is the major factor leading to the hyponatremia associated with end-stage HF.[28] AVP causes antidiuresis by activating V_2 receptors on the basolateral surface of the principal cells in the collecting duct.[29] Activation of these receptors initiates a cascade of intracellular signaling events by means of the adenylyl cyclase–cyclic adenosine monophosphate (cAMP) pathway, leading to an increase in AQP2 water channel protein expression and its trafficking to the apical membrane of the collecting duct. This sequence of events leads to increased water reabsorption and can cause hyponatremia, which is an ominous prognostic indicator in patients with HF.[30] Concurrently, increased nonosmotic AVP release stimulates V_1 receptors on vascular smooth muscle cells and thereby may increase SVR. This adaptive vasoconstrictive response may become maladaptive and contribute to cardiac dysfunction in patients with severe HF.

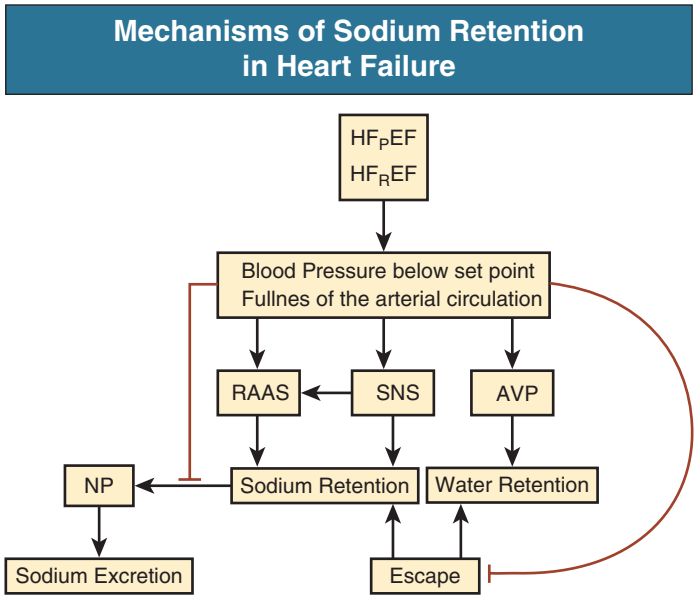

Fig. 7.3 Mechanisms of sodium retention in heart failure. Heart failure, from reduced ejection fraction *(HF_REF)* or preserved ejection fraction *(HF_PEF),* activates neurohormonal systems, which lead to sodium and water retention, including the renin-angiotensin-aldosterone system *(RAAS),* the sympathetic nervous system *(SNS),* and arginine vasopressin *(AVP).* Ensuing ECF volume expansion increases natriuretic peptide *(NP)* secretion. Low renal perfusion pressure (blood pressure below set point) causes resistance to NP and prevents escape from sodium and water retention from aldosterone, angiotensin II, and AVP.

Sodium and Water Retention in Cirrhosis

Many pathogenetic aspects of sodium and water retention are similar in cirrhosis and HF (Fig. 7.4). However, arterial underfilling in cirrhosis occurs secondary to splanchnic arterial vasodilation, with resultant water and sodium retention. Ascites formation in cirrhosis is likely initiated by sinusoidal and portal hypertension[31] from distortion of hepatic architecture, increased hepatic vascular tone, or increased splenohepatic flow. Decreased intrahepatic bioavailability of NO and increased production of vasoconstrictors (Ang, endothelin) also are responsible for increased resistance in the hepatic vasculature.[32] Portal hypertension caused by increased sinusoidal pressure activates vasodilatory mechanisms in the splanchnic circulation.[33] These mechanisms, mediated at least partly by NO and carbon monoxide (CO) overproduction, lead to splanchnic and peripheral arteriolar vasodilation. In advanced stages of cirrhosis, arteriolar vasodilation causes underfilling of the systemic arterial vascular space. This event, through a decrease in EABV, leads to a fall in arterial pressure. Consequently, baroreceptor-mediated activation of the RAAS, SNS stimulation, and nonosmotic release of ADH occur to restore the blood volume homeostasis.[34] This involves compensatory vasoconstriction as well as renal sodium and water retention. However, splanchnic vasodilation also increases splanchnic lymph production, which exceeds the lymph transporting capacity, and thus lymph leakage into the peritoneal cavity occurs with ascites development.[35] Persistent renal sodium and water retention (along with lymph leakage into the peritoneal cavity from increased splanchnic vascular permeability) play the major role in sustained ascites formation.

Sodium and Water Retention in Nephrotic Syndrome

Unlike HF and liver cirrhosis, in which the kidneys are structurally normal, the nephrotic syndrome is characterized by diseased kidneys. Many nephrotic patients have a higher arterial blood pressure, higher GFR, and less impairment of sodium and water excretion than patients with HF and cirrhosis. Two mechanisms, underfill and overfill, may account for nephrotic edema; components of each mechanism may exist in different edematous conditions (Fig. 7.5). The underfill theory suggests that reduced plasma oncotic pressure from proteinuria increases fluid movement from the vascular to interstitial compartment. The resultant arterial underfilling culminates in activation of homeostatic mechanisms involving the SNS and the RAAS. The overfill theory implicates primary renal sodium and water retention that translates into elevated total plasma volume, hypertension, and suppressed RAAS. Distinguishing between the two mechanisms is important because it influences the approach to diuretic use in nephrotic patients.

The following observations support the underfill theory for edema formation. Plasma volume, systemic arterial blood pressure, and cardiac output are diminished in some nephrotic patients, especially in children with minimal change disease (MCD) (see Chapter 17). The Starling forces governing the fluid movement across the capillary wall equal the difference of the hydrostatic pressure and the oncotic pressure gradients. The gradual decrease in the plasma albumin concentration and the plasma oncotic pressure is mitigated by the reduced entry of albumin

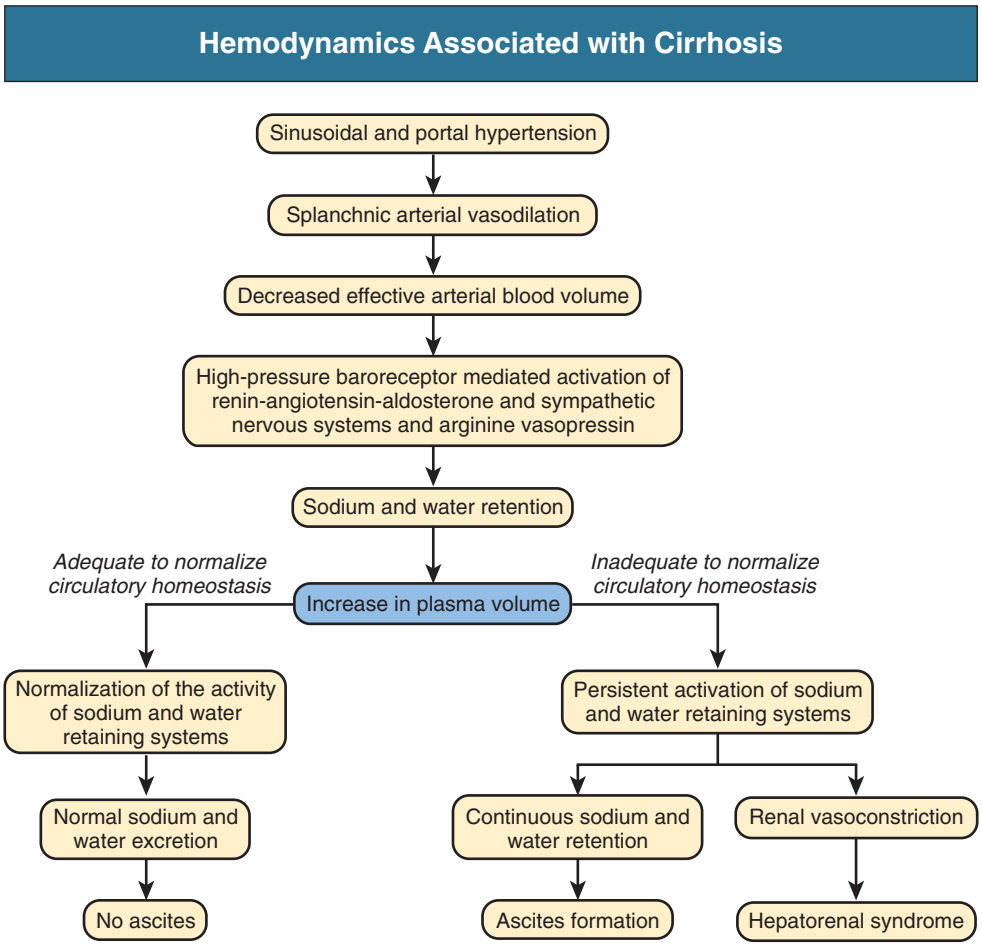

Fig. 7.4 Pathogenesis of functional renal abnormalities and ascites formation in cirrhosis. (Modified from reference 61.)

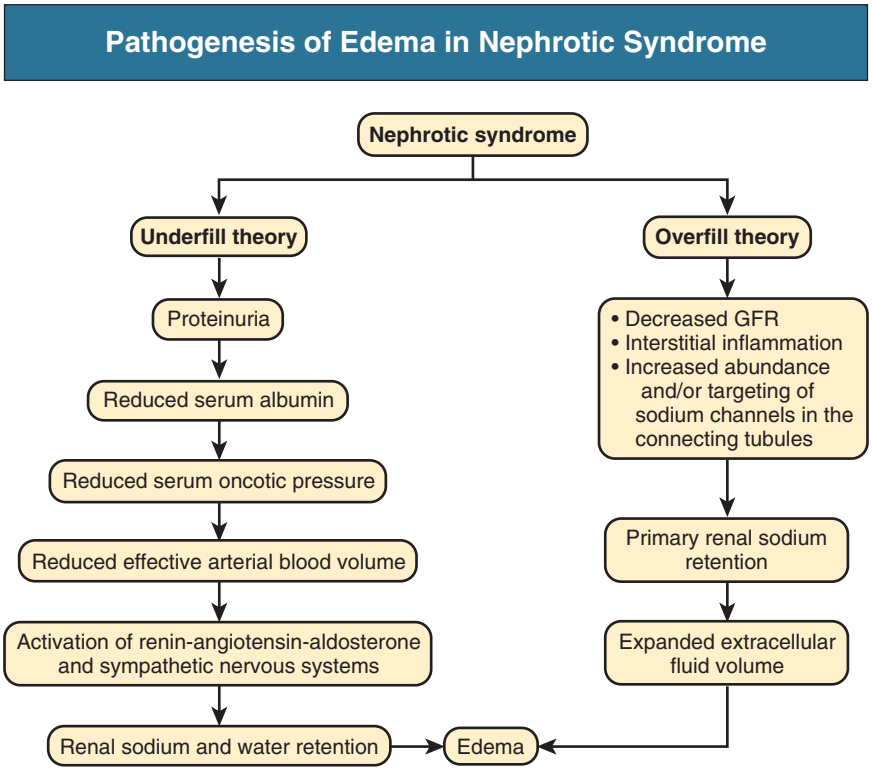

Fig. 7.5 Underfill and overfill mechanisms in pathogenesis of edema in nephrotic syndrome. The ratio of underfill and overflow likely varies, depending on the cause of the nephrotic syndrome. *GFR,* Glomerular filtration rate.

into the interstitial space and a concurrent decline in interstitial oncotic pressure. Consequently, less ECF volume expansion and edema formation is noted unless hypoalbuminemia is severe.[36] Thus nephrotic patients who are underfilled and are predisposed to AKI despite generalized edema generally have serum albumin concentration of less than 2 g/dl (20 g/l). However, serum albumin concentration may not be the primary driver of ECF volume expansion, because either spontaneous or steroid-induced remission of minimal change leads to natriuresis before albumin rises[37]; this suggests other mechanisms, in addition to low oncotic pressure, must be involved.

Observations supporting the overfill theory include studies of adults with MCD who have increased blood volume and blood pressure. After remission induced by corticosteroids, plasma volume and blood pressure decline, with an increase in plasma renin activity. However, evaluation of intravascular volume is somewhat unreliable because the afferent stimulus for edema formation appears to be a dynamic process, with different results at different phases of edema formation.[36] Also supporting primary renal sodium retention, experimental studies in animals with unilateral nephrotic syndrome demonstrate that sodium retention occurs secondary to increased reabsorption in the collecting tubules.[38] Increased abundance and apical targeting of ENaC subunits may be mediated, in part, by proteolytic cleavage of the channel by filtered proteases.[39-41]

In summary, nephrotic patients with arterial underfilling are more likely to have MCD with severe hypoalbuminemia, preserved GFR, and low blood pressure or postural hypotension. Other glomerular diseases, especially those involving renal inflammation, are more often associated with an overfill picture with volume expansion, raised blood pressure, and a decline in GFR. It has been postulated that interstitial inflammatory cells, a feature of some glomerular diseases other than MCD, may facilitate an increase in sodium retention and hypertension by releasing mediators that cause vasoconstriction.[42]

Drug-Induced Edema

Systemic vasodilators such as minoxidil and diazoxide induce arterial underfilling and subsequent retention of sodium with water (causing edema) through mechanisms similar to those in HF or cirrhosis. Dihydropyridine calcium channel blockers may cause peripheral edema, which is related to redistribution of fluid from the vascular space into the interstitium, possibly induced by preferential dilation of resistance arterioles in the absence of an appropriate microcirculatory myogenic reflex. This facilitates transmission of the systemic pressure to the capillary circulation.[43] Fluid retention and HF exacerbation may be seen with thiazolidinedione therapy in patients with type 2 diabetes mellitus, involving activation of peroxisome proliferator–activated receptor γ (PPARγ). Although this leads to stimulation of sodium reabsorption by the sodium channels in collecting tubule cells,[44] primary renal sodium retention alone should cause hypertension, not edema (see earlier discussion). Thus the effects of PPARγ agonists on vascular smooth muscle, which reduce arterial pressure,[45] likely play a central role. NSAIDs can exacerbate volume expansion in HF and cirrhotic patients by decreasing vasodilatory prostaglandins in the afferent arteriole of the glomerulus.[46]

Idiopathic Edema

This poorly defined syndrome occurs most often in premenopausal women and is characterized by intermittent edema secondary to sodium and water retention. Patients often complain of face and hand edema, leg swelling, and variable weight gain[47] and often misuse diuretics or laxatives, which may chronically stimulate the RAAS. The diagnosis of idiopathic edema is usually made by exclusion of other causes after history, physical examination, and sometimes diuretic screening.

Sodium and Water Retention in Pregnancy

In the first trimester of normal pregnancy, systemic arterial vasodilation and a decrease in blood pressure occur in association with a compensatory increase in cardiac output.[48] The lower arterial pressure activates the RAAS, contributing to the renal sodium and water retention and expanding the plasma volume (10%-30%).[49] Decreased plasma osmolality, stimulated thirst, and persistent nonosmotic vasopressin release are other features of normal pregnancy. In contrast to diseases such as HF and cirrhosis, pregnancy is associated with an increase in GFR and renal blood flow. The increased GFR leads to higher filtered load and increased distal sodium delivery in pregnancy, which contributes to the better escape from the sodium-retaining effect of aldosterone and attenuates edema formation. See Chapter 42 for more details.

Clinical Manifestations of Extracellular Fluid Volume Expansion

A history of an underlying disease, such as coronary artery disease, hypertension, or liver cirrhosis, can pinpoint the underlying mechanism of edema formation. Patients with left HF may present with exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea. Patients with right-sided HF or biventricular failure may exhibit weight gain and lower limb swelling. Physical examination reveals increased JVP, pulmonary crackles, a third heart sound, or dependent peripheral edema that may be elicited in the ankles or sacrum.

Nephrotic patients classically present with periorbital edema because of their ability to lie flat during sleep. However, those with severe disease may exhibit marked generalized edema with anasarca. Patients with cirrhosis present with ascites and lower limb edema caused by portal hypertension and hypoalbuminemia. Physical examination may reveal stigmata of chronic liver disease and splenomegaly.

Diagnostic and Therapeutic Approach to Extracellular Volume Expansion

Management of ECF volume expansion consists of recognizing and treating the underlying cause and attempting to achieve negative sodium balance by dietary sodium restriction and administration of diuretics. Before embarking on diuretic therapy, it is imperative to appreciate that ECF volume expansion may have occurred to compensate for arterial underfilling, as in HF and cirrhosis. A judicious approach is therefore necessary to avoid a precipitous fall in cardiac output and tissue perfusion. Rapid removal of excess fluid is generally necessary only in life-threatening situations, such as pulmonary edema and hypervolemia-induced hypertension.

Moderate dietary sodium restriction (2 to 3 g Na^+/day; 86 to 130 mmol/day) should be encouraged. Salt substitutes contain potassium chloride and should not be used in patients with advanced renal impairment or those taking potassium-sparing diuretics. Restriction of total fluid intake is usually necessary only for patients with hyponatremia. Medications that promote sodium retention (e.g., NSAIDs) should be discontinued. Diuretics are the cornerstone of therapy to remove excess volume. Other measures can be used in patients with inadequate response or lack of response to diuretics. In those with liver cirrhosis, large-volume paracentesis with albumin infusion provide symptomatic relief. Although extracorporeal fluid removal by ultrafiltration can be used in patients with acute decompensated HF accompanied by renal impairment or diuretic resistance, a randomized controlled trial did not indicate benefit.[50] ACE inhibitors and angiotensin receptor blockers (ARBs) are effective treatments for HF or nephrotic syndrome. Additional therapies for HF include antiarrhythmic agents, positive inotropes, and left ventricular assist devices.

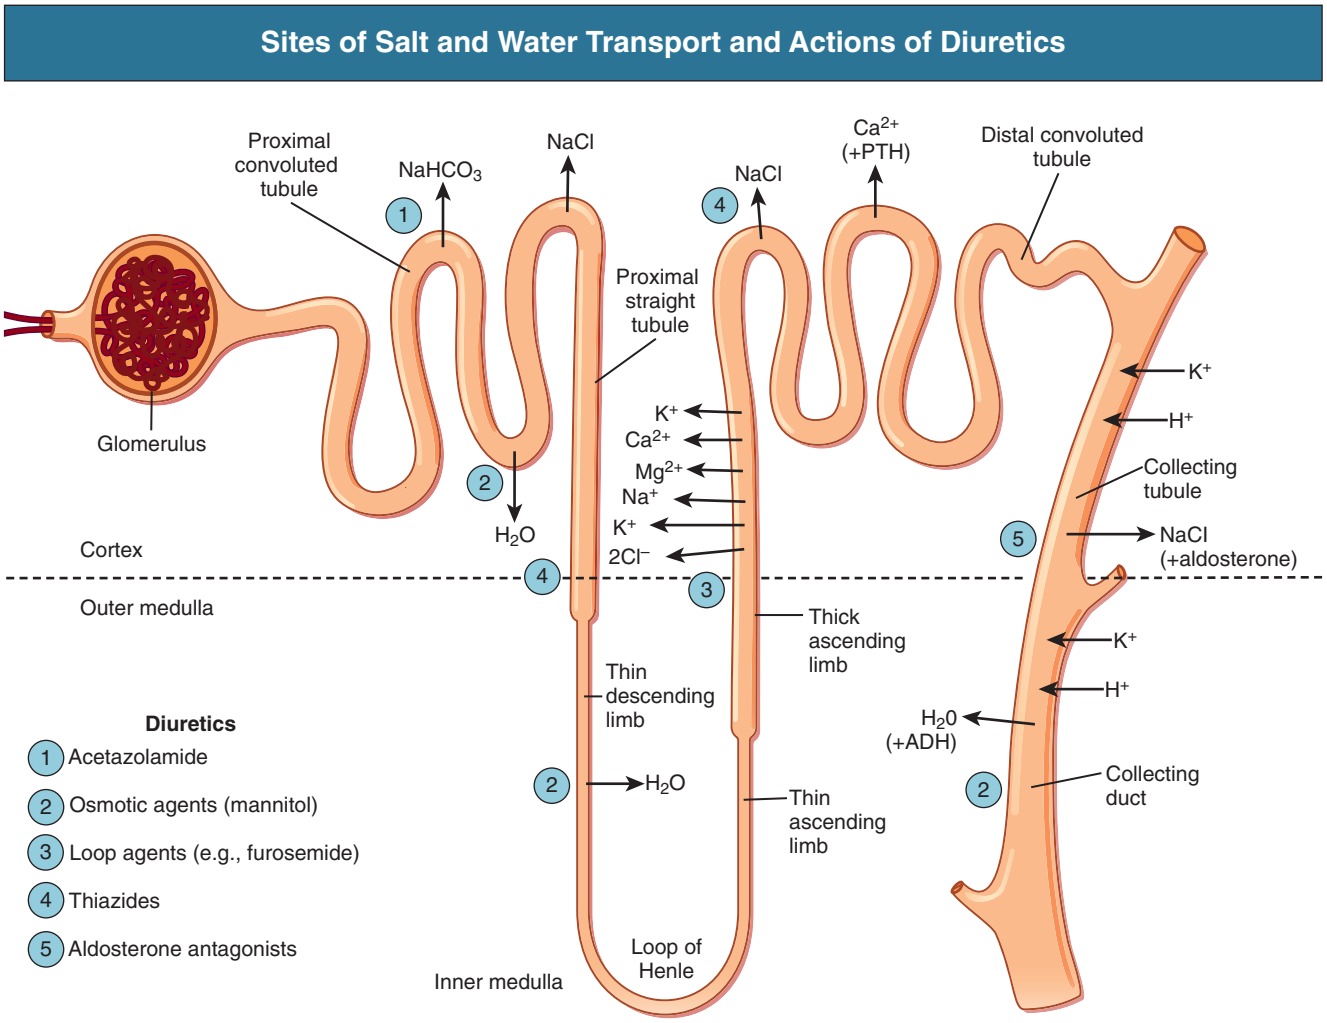

Fig. 7.6 Sites of salt and water transport and actions of diuretics. Specific sites are indicated by numbers. (Modified from reference 62.)

Diuretics

Principles of Action

Diuretics are the mainstay of therapy for edematous states, with five classes based on the predominant sites of diuretic action along the nephron (Fig. 7.6). Most diuretics reach their luminal transport sites by secretion across the proximal tubule epithelium. All diuretics except osmotic agents have a high degree of protein binding, which limits glomerular filtration, traps the drug in the vascular spaces, and allows it to be delivered to the proximal convoluted tubule for secretion.[51] Diuretics act by inhibiting sodium reabsorption with an accompanying anion, usually chloride. The resultant natriuresis decreases the ECF volume. At least two types of adaptation to diuretics are recognized. Loop diuretics have relatively short half-lives, and each dose is followed by a phase of natriuresis and a phase of antinatriuresis (often referred to as postdiuretic Na^+ retention). A low-salt diet can ensure that postdiuretic Na^+ retention does not overcome effective diuresis. A second type of adaptation occurs during chronic treatment. During continued administration of a diuretic, the magnitude of each natriuretic response declines, so daily salt excretion once again equals daily salt intake. This is known as the *braking phenomenon;* mechanisms include activation of the SNS and RAAS, decreased systemic and renal arterial blood pressure, hypertrophy of the distal nephron cells with increased expression of epithelial transporters, and perhaps alterations in natriuretic hormones (e.g., ANP).[51]

Classes of Diuretics

Loop diuretics. Loop diuretics such as furosemide, bumetanide, and torsemide act by blocking the Na^+-K^+-Cl^- cotransporters at the apical surface of the thick ascending limb (TAL) cells, thereby diminishing net reabsorption.[52] These agents are the most potent of all diuretics, inhibiting the reabsorption of 25% of filtered sodium, which normally occurs along the TAL. Moreover, the nephron segments past the TAL typically do not possess the capacity to reabsorb completely the volume of fluid exiting the TAL. Thus a substantial percentage of the solute rejected from the TAL is excreted.

The oral bioavailability of furosemide averages 50%, but varies between 10% and 100%; that of bumetanide and torsemide are higher (~80%). Loop diuretics have a short elimination half-life, so the dosing interval needs to be short to maintain adequate levels in the lumen. Excessive prolongation of dosing interval provides more time for postdiuretic sodium retention to overcome natriuresis. This is the reason that loop diuretics are typically given twice daily.

The intrinsic potency of a diuretic is defined by its dose-response curve, which is generally sigmoidal. The steep dose-response is the reason that loop diuretics are often referred to as "threshold drugs." This is exemplified by furosemide, which can initiate diuresis in a person with normal renal function with an intravenous dose of 10 mg, and a maximal effect is seen with 40 mg. A larger dose provides minimal or no extra benefit, and side effects may increase. However, the effective diuretic dose is higher in patients with HF, advanced cirrhosis, and renal failure. Patients who respond poorly to intermittent doses of a loop diuretic may receive continuous intravenous infusion, which might enhance the response by virtue of maintaining an effective amount of drug at the site of action.[53] A Cochrane review suggested that continuous infusions led to greater diuresis and a better safety profile, but the quality of the evidence was poor.[54] A randomized trial in acute decompensated HF found no difference in the primary end points—the global assessment of symptoms over the course of 72 hours and the change in serum creatinine from baseline to 72 hours—for continuous versus bolus infusion of furosemide. A higher dose of diuretic was more effective without clinically important negative effects on renal function.[55] This study did not include diuretic-resistant patients or those with significant renal dysfunction, in whom there may be a benefit of continuous infusion.

Although pharmacologically similar to other loop diuretics, ethacrynic acid has greater ototoxic potential and therefore is reserved for patients allergic to other agents.

Distal convoluted tubule diuretics. Thiazide and thiazide-like diuretics (chlorothiazide, hydrochlorothiazide, chlorthalidone, metolazone, and indapamide) inhibit NaCl absorption in the distal tubule, where up to 5% of filtered sodium and chloride is reabsorbed, and are therefore less potent than loop diuretics. Thiazides have a relatively longer half-life and can be administered once or twice daily. Metolazone has pharmacologic characteristics similar to those of thiazide diuretics and is more often used in conjunction with other classes of diuretics.

Thiazides are used commonly to treat hypertension (see Chapter 36). For edema, they are occasionally used alone in patients with mild HF, but more often are used in combination to synergize the effect of loop diuretics by blocking multiple nephron segment sites. Because thiazide diuretics must reach the lumen to be effective, higher doses are required in patients with impaired renal function. Thiazides as sole agents (possibly excluding the thiazide-like diuretics metolazone and indapamide) lose effectiveness at GFR less than 30 ml/min, but can still enhance the diuretic effect of loop diuretics when coadministered in sufficient doses to attain effective nephron lumen concentration. If used, such combination therapy should be closely monitored because of a pronounced risk for hypokalemia and excessive ECF depletion.

Collecting duct diuretics. Amiloride, triamterene, and the aldosterone antagonists spironolactone and eplerenone, act on the collecting duct. Amiloride and triamterene act primarily in the connecting tubule and cortical collecting duct (the aldosterone-sensitive distal nephron) by interfering with sodium reabsorption through the apical ENaC and inhibit potassium secretion by dissipating the electronegative gradient (normally created by sodium reabsorption) that favors potassium secretion. Spironolactone and eplerenone are competitive antagonists of aldosterone and cause natriuresis and potassium retention. Potassium-sparing diuretics are considered weak diuretics because they block only about 3% of the filtered sodium load reaching their site of action and thus are most often used with other diuretics to augment diuresis or preserve potassium. If combination therapy is used, careful monitoring is essential to prevent dangerous hyperkalemia. Vulnerable patients include those with underlying renal dysfunction, those with HF, patients with diabetes, and those concurrently taking ACE inhibitors, ARBs, NSAIDs, or β-blockers. Finerenone is the first of a group of new nonsteroidal MRAs. It is currently in clinical trials and has been suggested to improve albuminuria in the setting of diabetes, perhaps with a lower rate of side effects.[56] A goal is to find a product that will confer the beneficial effects of mineralocorticoid blockade, without the complicating effects on plasma potassium and GFR.

Collecting duct diuretics are considered first-line agents in certain conditions. For example, spironolactone is used in patients with liver cirrhosis with ascites, and amiloride in the treatment of Liddle syndrome, a rare autosomal dominant condition characterized by a primary increase in ENaC function (see Chapter 47).

Proximal tubule diuretics. Acetazolamide indirectly inhibits Na^+-H^+ exchange by reducing the elimination of secreted protons in the proximal tubule lumen, thus increasing sodium bicarbonate excretion. Acetazolamide is a weak diuretic because distal segments reabsorb much of the inhibited Na^+ and proximal inhibition activates the TGF to reduce Na^+ filtration.[6] Acetazolamide generates hyperchloremic metabolic acidosis, particularly with prolonged use. It also may cause hypokalemia because of increased distal sodium delivery; it may cause hypophosphatemia, but the mechanism of this is not well understood. Rarely used as a single agent, acetazolamide is most frequently used with other diuretics, in treatment of metabolic alkalosis accompanied by edematous states, and in chronic obstructive pulmonary disease. It is also used in acute and chronic high altitude sickness because of its ability to stimulate ventilation as a compensatory response to the metabolic acidosis, although unpleasant paresthesias may occur.

Osmotic diuretics. Osmotic diuretics such as mannitol are freely filtered at the glomerulus but are poorly reabsorbed. Mannitol is used intravenously and produces diuresis by increasing the osmotic pressure within the lumen of the proximal tubule and loop of Henle. This causes enhanced water diuresis and to a lesser extent sodium and potassium excretion. Mannitol is not used for edematous states but rather to treat cerebral edema induced by trauma or neoplasms and to reduce intraocular pressure. Mannitol is also used in the treatment of dialysis disequilibrium syndrome, preventing the brisk decline in serum osmolality that would otherwise occur with dialysis. This helps prevent a shift of fluid into the brain that may occur with rapid rate of solute removal by dialysis, which is thought to be responsible for the symptoms.

Adverse Effects

Many common diuretics are derived from sulfanilamide and may therefore induce allergy in susceptible patients, manifested as hypersensitivity reactions, usually as a rash or, rarely, acute interstitial nephritis. The most serious and common adverse effects of diuretics, however, are electrolyte disturbances.

Loop diuretics impair tubular reabsorption by abolishing the transepithelial potential gradient and thus increase excretion of magnesium and calcium. Thiazide diuretics exert the same effect on magnesium. In a recent study of community-dwelling subjects, the use of a thiazide was associated with prevalent hypomagnesemia, whereas loop diuretic use was not.[57] Unlike loop diuretics, thiazide diuretics decrease urinary calcium losses and are therefore preferred in the treatment of hypercalciuric states and in patients with osteoporosis. Thiazide diuretics interfere with urine-diluting mechanisms by blocking sodium reabsorption at the distal convoluted tubule, an effect that may contribute to hyponatremia.[58] Acutely, loop and thiazide diuretics increase the excretion of uric acid, whereas chronic administration results in reduced uric acid excretion. The chronic effect is likely caused by enhanced absorption in the proximal convoluted tubule secondary to volume depletion. Other adverse effects with large doses may include ototoxicity with loop diuretics, particularly with aminoglycoside coadministration, and gynecomastia, which may develop with spironolactone.

Approach to Diuretic Treatment of Extracellular Fluid Volume Expansion

Although the mechanisms underlying expansion of the ECF volume are similar in the different clinical syndromes, some evidence-based differences in diuretic approach are recommended. For HF, either HF_rEF or HF_pEF, initial treatment involves loop diuretics. A starting dose of 20 to 40 mg furosemide, or an equivalent, is typical, and may be effective, but it may be necessary to increase, or double, subsequent doses if the initial dose does not elicit a diuresis. Such a diuresis should occur promptly after drug administration and be notable to the patient. This approach is based on the threshold nature of the loop diuretic dose response curve. It is often necessary to use loop diuretics twice daily, but it is always important to ensure that each dose is above the threshold. The pharmacokinetic profile of torsemide is more favorable than that of furosemide; some clinicians prefer this drug, but solid evidence to support this choice is lacking.

For cirrhotic ascites, patients should be started on a combination of spironolactone and furosemide, at a fixed ratio (100 mg spironolactone to 40 mg furosemide).[59] Single-agent spironolactone was used previously, but was shown to cause more potassium imbalance. Doses can be titrated retaining the same ratio of spironolactone and furosemide.

For nephrotic syndrome and CKD, loop diuretics are indicated, but higher doses than used for HF are typically required, because both CKD and nephrotic syndrome are diuretic-resistant conditions.

Diuretic Resistance

Diuretic *resistance* typically refers to edema that has become refractory to maximal doses of loop diuretics. Apparent resistance may be the result of drug interactions. NSAIDs block prostaglandin-mediated increases in renal blood flow and natriuresis and can precipitate HF exacerbations.[46] Arterial underfilling in cirrhosis and HF increases proximal tubular sodium reabsorption, which reduces delivery of sodium to the distal nephron segment sites of diuretic action. Yet, in HF, resistance most commonly results from activation of distal nephron transport.[60] This problem can be addressed by combining loop and thiazide diuretics, because the latter block the distal nephron sites responsible. As loop diuretics stimulate renin secretion at the macula densa, leading to Ang II production and aldosterone secretion, it may be reasonable to initiate aldosterone antagonist therapy before addition of a thiazide diuretic in patients with low or low-normal serum potassium level. In nephrotic syndrome, the filtered protein in tubular fluid may contain serine proteases, which cleave and activate ENaC, thereby promoting excess sodium reabsorption.[41]

SELF-ASSESSMENT QUESTIONS

1. A 58-year-old woman with a history of alcohol dependence and known chronic liver disease presents to the emergency department with increasing breathlessness and distended abdomen. Vital signs reveal temperature of 36.9° C (98.5° F), respiratory rate of 17 breaths/min, oxygen saturation of 93% on room air, pulse rate of 76/min, and blood pressure of 93/58 mm Hg without significant orthostatic change. Physical examination reveals scleral icterus, and jugular venous pressure (JVP) is flat. Cardiac auscultation is normal; breath sounds are decreased at the bases. Her abdomen is distended with a fluid wave and a positive shifting dullness. The patient has bilateral pitting edema to the midcalves and intact peripheral pulses. The primary mechanism responsible for *maintaining* volume excess in this patient is:
   - **A.** Reduction in plasma oncotic pressure resulting from synthetic hypoalbuminemia causing an increase in fluid movement from the vascular to the interstitial compartment
   - **B.** Underfilling of the arterial circulation resulting from splanchnic venous dilation causing neurally and hormonally mediated renal sodium retention
   - **C.** Primary renal sodium and water retention that results in elevated total plasma volume
   - **D.** Decrease in plasma osmolality with stimulation of thirst and persistent release of antidiuretic hormone
2. Laboratory investigations of the patient described in question 1 reveal serum sodium of 128 mmol/L, potassium 3.7 mmol/L, chloride 101 mmol/L, bicarbonate 23 mg/dL, blood urea nitrogen (BUN) 56 mg/dL, and creatinine 1.0 mg/dL. Albumin is 3.0 g/dL. Reasonable initial approaches to remove excess volume in this patient include all the following *except:*
   - **A.** Prescribe a diet restricted to 2.3 g (100 mmol) of sodium daily to mitigate renal retention of sodium and prevent diuretic resistance
   - **B.** Perform a large-volume paracentesis with albumin infusion to rapidly decompress the abdomen
   - **C.** Administer spironolactone up to 400 mg/day, with a loop diuretic to increase sodium excretion
   - **D.** Administer intravenous mannitol to increase osmotic pressure within the tubule and thus sodium and water reabsorption
3. Over the next 3 days, the patient previously described becomes febrile, temperature 37.8° C (100° F), and confused. Her pulse rate is 120 beats/min with blood pressure of 88/52 mm Hg. The JVP is now near the angle of the jaw when the patient is sitting at 45 degrees. Hemoglobin is 7.6 g/dL, total WBC count 15,000 (85% polymorphonuclear leukocytes [PMNs]), and platelet count 81,000 × 10^9 cells/l. Analysis of the ascitic fluid reveals 100 RBCs/μl and 450 WBCs/μl, but no organisms on Gram stain. BUN is 48 mg/dL, serum creatinine 1.7 mg/dL, and urine sodium 65 mEq/l, with a fractional sodium excretion of 1.4%. Appropriate immediate measures for the patient at this time would include which of the following?
   - **A.** Administer 50 g of albumin, with the goal of improving her hemodynamic profile
   - **B.** Administer fluid resuscitation with 6% HES to expand extracellular fluid compartment rapidly and restore blood pressure
   - **C.** Treat for presumptive bacterial peritonitis
   - **D.** Insert jugular venous dialysis access for urgent initiation of dialysis

8

Disorders of Water Metabolism

Tomas Berl, Jeff M. Sands

PHYSIOLOGY OF WATER BALANCE

The maintenance of the tonicity of body fluids within a narrow physiologic range is made possible by homeostatic mechanisms that control the intake and excretion of water. Vasopressin, known as arginine vasopressin (AVP) or antidiuretic hormone (ADH), governs the excretion of water by its effect on the renal collecting system. Osmoreceptors located in the hypothalamus control the secretion of AVP in response to changes in tonicity.

In the steady state, water intake matches water loss. Water intake is regulated by the need to maintain a physiologic serum osmolality of 285 to 290 mOsm/kg H_2O. Despite major fluctuations of solute and water intake, the total solute concentration (i.e., the tonicity) of body fluids is maintained virtually constant. The ability to dilute and to concentrate the urine allows wide flexibility in urine flow (see Chapter 2). During water loading, the diluting mechanisms permit excretion of 20 to 25 liters of urine daily, and during water deprivation the urine volume may be as low as 0.5 l/day.[1-3]

VASOPRESSIN

AVP plays a critical role in determining the concentration of urine: it is a 9–amino acid cyclic peptide, synthesized and secreted by the supraoptic and paraventricular magnocellular nuclei in the hypothalamus. AVP has a half-life of 15 to 20 minutes and is rapidly metabolized in the liver and the kidney.

Osmotic Stimuli for Vasopressin Release

Substances restricted to the extracellular fluid (ECF), such as hypertonic saline and mannitol, decrease cell volume by acting as effective osmoles and enhancing osmotic water movement from the cell. This stimulates AVP release; in contrast, urea and glucose readily cross cell membranes and thus do not cause changes in cell volume. The "osmoreceptor" cells, located close to the supraoptic nuclei in the anterior hypothalamus, are sensitive to changes in serum osmolality as small as 1% and bring about the release of AVP by a pathway that involves the activation of transient receptor potential (TRPV4) channels.[4] In humans, the osmotic threshold for AVP release is 280 to 290 mOsm/kg H_2O[2,5] (Fig. 8.1). This system is so efficient that serum osmolality usually does not vary by more than 1% to 2% despite wide fluctuations in water intake.

Nonosmotic Stimuli for Vasopressin Release

Decreased effective circulating volume (e.g., heart failure, cirrhosis, vomiting) causes discharge from parasympathetic afferent nerves in the carotid sinus baroreceptors and increases AVP secretion. Much higher AVP levels can be achieved with hypovolemia than with hyperosmolality, although a large (7%) decrease in blood volume is required before this response is elicited. Other nonosmotic stimuli include nausea, pain, pregnancy, and fructose. AVP levels (as reflected by elevation of serum copeptin, a surrogate marker) are also elevated in patients with metabolic syndrome and in patients with chronic kidney disease (CKD) compared to healthy individuals.

Mechanism of Vasopressin Action

AVP binds three types of receptors coupled to G proteins: the V_{1a} (vascular and hepatic), V_{1b} (anterior pituitary and pancreatic islet), and V_2 (renal) receptors. The V_2 receptor is primarily localized in the collecting duct and leads to an increase in water permeability through aquaporin 2 (AQP2), a member of a family of cellular water transporters (Fig. 8.2). AQP1 is localized in the apical and basolateral region of the proximal tubule epithelial cells and the descending limb of the loop of Henle and accounts for the high water permeability of these nephron segments. AQP1 is constitutively expressed and not subject to regulation by AVP.[6] AQP2 is localized primarily in apical plasma membranes and intracellular vesicles in the collecting duct principal cells. AVP affects both the short-term and the long-term regulation of AQP2. The short-term regulation, also described as the "shuttle hypothesis," explains the rapid and reversible increase (within minutes) in collecting duct water permeability after AVP administration. This involves the insertion of water channels from subapical vesicles into the luminal membrane. Long-term regulation relates to AVP-mediated increases in the transcription of genes involved in AQP2 production and occurs if AVP levels are elevated for 24 hours or more. An increased number of AQP2 channels per cell elevates the maximal water permeability of the collecting duct epithelium.[6]

AQPs 3 and 4 are located on the basolateral membranes of the collecting duct (see Fig. 8.2) and are involved in water exit from the cell. AQP3 is expressed along the entire collecting duct, and AQP4 is found in the inner medullary collecting duct. AQP4 is also found in the hypothalamus and is a candidate osmoreceptor for the control of AVP release.[6]

AVP also stimulates urea transporters in the inner medullary collecting duct. UT-A1 is found primarily in apical plasma membranes and intracellularly in inner medullary collecting ducts. UT-A3 is found predominantly in the basolateral plasma membrane in inner medullary collecting ducts. Urea reabsorption into the inner medullary interstitium is important for increasing inner medullary tonicity and the driving force for water reabsorption.[7]

Thirst and Water Balance

Hypertonicity is the most potent stimulus for thirst, with a change of only 2% to 3% in serum osmolality producing a strong desire to drink. The osmotic threshold for thirst usually occurs at 290 to 295 mOsm/

kg H_2O and is above the threshold for AVP release (see Fig. 8.1). This osmolality closely approximates the level at which maximal concentration of urine is achieved. Hypovolemia, hypotension, and angiotensin II (Ang II) are also stimuli for thirst. Between the limits imposed by the osmotic thresholds for thirst and AVP release, serum osmolality may be regulated more precisely by small, osmoregulated adjustments in urine flow and water intake. The exact level at which balance occurs depends on insensible losses, water intake, and water generated from metabolism.

QUANTITATION OF RENAL WATER EXCRETION

Urine volume can be considered as having two components. The osmolar clearance (C_{osm}) is the volume needed to excrete solutes at the concentration of solutes in serum. The free water clearance (C_{water}) is the volume of water that has been added to (positive C_{water}) or subtracted from (negative C_{water}) isotonic urine (C_{osm}) to create either hypotonic or hypertonic urine.

Urine volume flow (V) comprises the isotonic portion of urine (C_{osm}) plus the free water clearance (C_{water}).

$$V = C_{osm} + C_{water}$$

Therefore:

$$C_{water} = V - C_{osm}$$

The C_{osm}, solute clearance is determined by urine flow, urine osmolality, and serum osmolality P_{osm} as follows:

$$C_{osm} = \left(\frac{U_{osm} \times V}{P_{osm}}\right)$$

Therefore:

$$C_{water} = V - \left(\frac{U_{osm} \times V}{P_{osm}}\right)$$

$$= V\left(1 - \frac{U_{osm}}{P_{osm}}\right)$$

This relationship reflects the following:

1. In hypotonic urine ($U_{osm} < P_{osm}$), C_{water} is positive.
2. In isotonic urine ($U_{osm} = P_{osm}$), C_{water} is zero.
3. In hypertonic urine ($U_{osm} > P_{osm}$), C_{water} is negative (i.e., water is retained).

If excretion of free water in a polyuric patient is unaccompanied by water intake, the patient becomes hypernatremic. Conversely, failure to excrete free water with increased water intake can cause hyponatremia.

A limitation of the previous equation is that it fails to predict clinically important alterations in serum tonicity and serum sodium concentration (serum $[Na^+]$) because urea is included in the calculation of urine osmolality. Urea is an important component of urinary osmolality; however, because it crosses cell membranes readily, urea does not establish a transcellular osmotic gradient and does not cause water movement between fluid compartments. Therefore urea does not influence serum Na^+ concentration or the release of AVP and changes in serum $[Na^+]$ are better predicted by electrolyte free water clearance

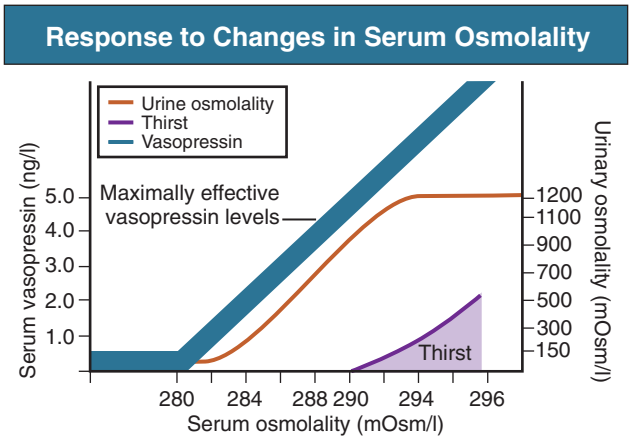

Fig. 8.1 Mechanisms maintaining serum osmolality. Thirst, vasopressin levels, and urinary osmolality in response to changes in serum osmolality. (Modified from reference 2.)

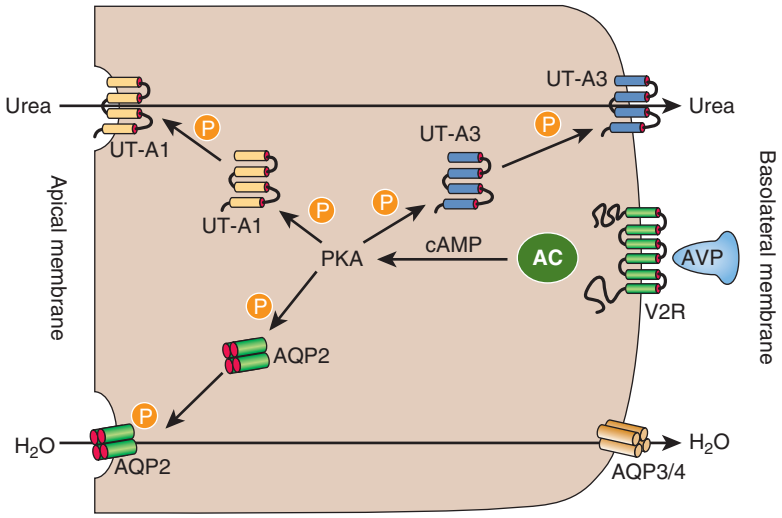

Fig. 8.2 Cellular mechanism of vasopressin action. Vasopressin *(AVP)* binds to V_2 receptors *(V2R)* on the basolateral membrane and activates G proteins that initiate a cascade *(cAMP, PKA)* resulting in aquaporin 2 *(AQP2)* and urea transporter A1 *(UT-A1)* phosphorylation and accumulation in the apical membrane. Water exits the cell through *AQP3* and *AQP4* in the basolateral membrane. Urea exits the cell through *UT-A3* in the basolateral membrane. *AVP,* Arginine vasopressin; *cAMP,* cyclic adenosine monophosphate; *PKA,* protein kinase A.

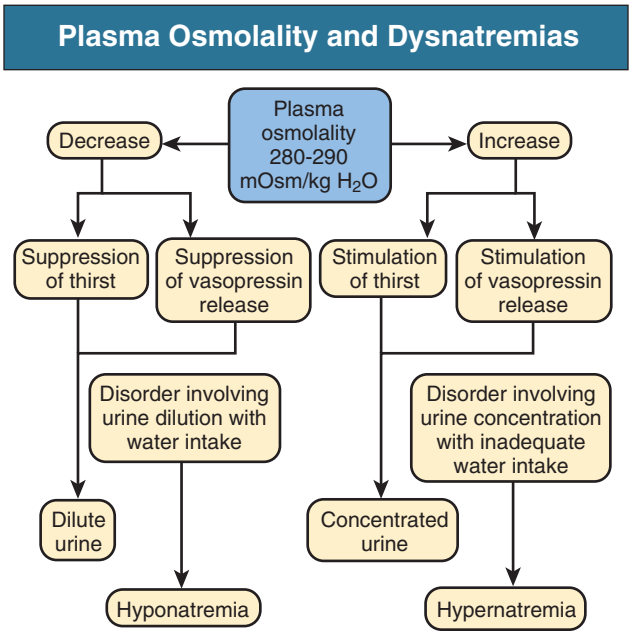

Fig. 8.3 Maintenance of serum osmolality and pathogenesis of dysnatremias. (Modified from reference 8.)

$[C_{water}(e)]$. The equation can be modified, replacing P_{osm} by serum $[Na^+]$ (P_{Na}) and the urine osmolality by urine $[Na^+]$ and urine $[K^+]$, potassium concentration, ($U_{Na} + U_K$):

$$C_{water}(e) = V\left(1 - \frac{U_{Na} + U_K}{P_{Na}}\right)$$

If $U_{Na} + U_K$ is less than P_{Na}, then $C_{water}(e)$ is positive and serum $[Na^+]$ increases. If $U_{Na} + U_K$ is greater than P_{Na}, then $C_{water}(e)$ is negative and serum $[Na^+]$ decreases. In the clinical setting, it is more appropriate to use the equation for electrolyte-free clearance to predict if a patient's serum $[Na^+]$ will increase or decrease in the face of the prevailing water excretion. For example, in a patient with high urea excretion, the original equation would predict negative water excretion and a decrease in serum $[Na^+]$; but in fact, $[Na^+]$ increases, which is accurately predicted by the latter equation.

SERUM SODIUM CONCENTRATION, OSMOLALITY, AND TONICITY

The kidney's countercurrent mechanism, which allows urinary concentration and dilution, acts in concert with the hypothalamic osmoreceptors through AVP secretion to maintain serum $[Na^+]$ and tonicity within a very narrow range[8] (Fig. 8.3). A defect in the urine-diluting capacity coupled with excess water intake leads to hyponatremia. A defect in urine-concentrating ability with inadequate water intake leads to hypernatremia.

Serum $[Na^+]$, along with its accompanying anions, accounts for nearly all the osmotic activity of the serum. Calculated serum osmolality is given by 2[Na^+] + blood urea nitrogen (BUN) (mg/dl)/2.8 + glucose (mg/dl)/18. The addition of other solutes to ECF results in an increase in measured osmolality (Table 8.1). Solutes that are permeable across cell membranes do not cause water movement and cause hypertonicity without cellular dehydration, as in uremia or ethanol intoxication. By contrast, in diabetic ketoacidosis, when glucose cannot freely cross cell membranes in the absence of insulin, water moves from the cells to the ECF, leading to cellular dehydration and lowering serum $[Na^+]$. This

TABLE 8.1 Effects of Osmotically Active Substances on Serum Sodium (Na^+) Levels

Substances That Increase Osmolality Without Changing Serum Na^+	Substances That Increase Osmolality and Decrease Serum Na^+ (Translocational Hyponatremia)
Urea	Hyperglycemia
Ethanol	Mannitol
Ethylene glycol	Glycine
Isopropyl alcohol	Maltose
Methanol	

can be viewed as *translocational* because the decrease in serum $[Na^+]$ does not reflect a change in total body water but rather the movement of water from intracellular to extracellular space. Therefore serum $[Na^+]$ can be corrected by 1.6 mmol/l for every 100 mg/dl (5.6 mmol/l) increase in serum glucose, although this may somewhat underestimate the impact of glucose to decrease serum $[Na^+]$.

Pseudohyponatremia occurs when the solid phase of serum (usually 6% to 8%) is increased by large increments in either lipids or proteins (e.g., in hypertriglyceridemia and paraproteinemias). Serum osmolality is normal in pseudohyponatremia. This false result occurs because the usual method that measures the concentration of sodium uses whole serum and not just the liquid phase, in which the concentration of sodium is 150 mmol/l. Many laboratories are now moving to direct ion-selective potentiometry, which gives the true aqueous sodium activity. In the absence of a direct-reading potentiometer, an estimate of serum water may be obtained from the following formula[9]:

$$\text{Serum water content (\%)} = 99.1 - (0.1 \times L) - (0.07 \times P)$$

where L and P refer to the total lipid and protein concentration (in grams per liter), respectively. For example, if the formula reveals that serum water is 90% of the serum sample rather than the normal 93% (which yields a serum sodium concentration of 140 mmol/l as 150 × 0.93 = 140), the concentration of measured sodium would be expected to decrease to 135 mmol/l (150 × 0.90).

ESTIMATION OF TOTAL BODY WATER

In normal individuals, total body water is approximately 60% of body weight (50% in women and obese individuals). With hyponatremia or hypernatremia, the change in total body water can be calculated from the serum $[Na^+]$ by the following formula:

$$\text{Water excess} = 0.6W \times \left(1 - \frac{[Na^+]_{obs}}{140}\right)$$

$$\text{Water deficit} = 0.6W \times \left(\frac{[Na^+]_{obs}}{140} - 1\right)$$

where $[Na^+]_{obs}$ is observed sodium concentration (in millimoles per liter) and W is body weight (in kilograms). By use of this formula, a change of 10 mmol/l in the serum $[Na^+]$ in a 70-kg individual is equivalent to a change of 3 liters in free water.

HYPONATREMIC DISORDERS

Hyponatremia is defined as serum $[Na^+]$ of less than 135 mmol/l. If translocational and pseudohyponatremia are not responsible for the

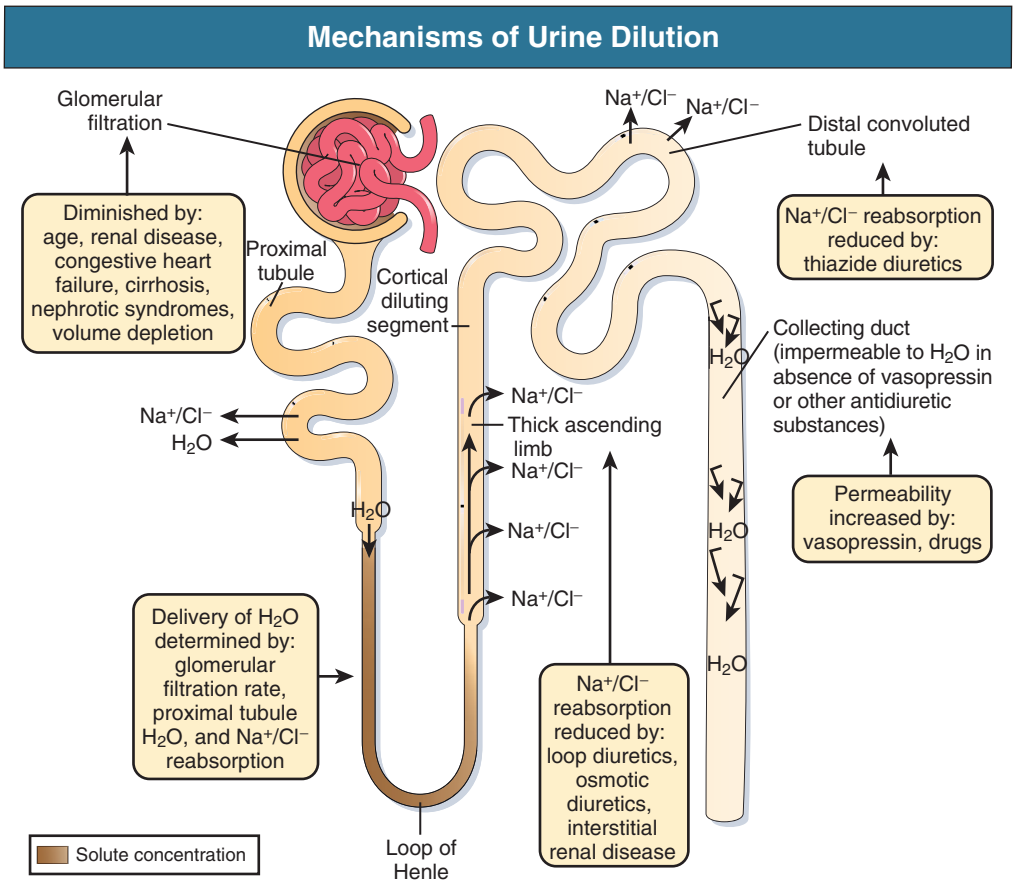

Fig. 8.4 Mechanisms of urine dilution. Normal determinants of urinary dilution and disorders causing hyponatremia. (Modified from reference 10.)

hyponatremia, the decrease in serum sodium concentration reflects a low serum osmolarity, also designated as hypotonicity. The underlying cause of hypotonic hyponatremia is a disturbance in the urinary diluting mechanism.[10] Fig. 8.4 depicts the normal diluting process and the sites at which it can be disrupted so as to impair water excretion, causing its retention and culminating in hyponatremia. A diminished glomerular filtration rate (GFR) and/or an increase in proximal tubular fluid reabsorption decrease distal delivery of filtrate to the diluting segments of the nephron, quantitatively limiting maximal water excretion. In addition, hyponatremia may result from a decrement in Na^+-Cl^- transport from the thick ascending limb of the loop of Henle or distal convoluted tubule, critical processes in the generation of a dilute tubular fluid. Most frequently, hyponatremia results from nonosmotic AVP secretion despite the presence of serum hypo-osmolality. This renders the collecting duct water permeable, thereby not allowing for the excretion of a maximally dilute urine.

Etiology and Classification of Hyponatremia

Once the patient is ascertained as being hypo-osmolar, the next step is to determine whether the individual is hypovolemic, euvolemic, or hypervolemic (Fig. 8.5).

Hypovolemia: Hyponatremia Associated With Decreased Total Body Sodium

A patient with hypovolemic hyponatremia has both a total body Na^+ and a water deficit, with the Na^+ deficit exceeding the water deficit. This occurs in patients with high gastrointestinal and renal losses of water and solute accompanied by free water or hypotonic fluid intake. The underlying mechanism is the nonosmotic release of AVP stimulated by volume contraction, which maintains AVP secretion despite the hypotonic state. Measurement of urine $[Na^+]$ is a useful tool to help diagnose these conditions (see Fig. 8.5).

Gastrointestinal and third-space sequestered losses. The kidney responds to volume contraction by conserving Na^+ and Cl^-. A similar response is observed in burn victims and patients with sequestration of fluids in third spaces, as in the peritoneal cavity with peritonitis or pancreatitis or in the bowel lumen with ileus. In all these, urine $[Na^+]$ is usually less than 10 mmol/l and the urine is hyperosmolar. An exception occurs in patients with vomiting and metabolic alkalosis. Here, increased bicarbonate ion (HCO_3^-) excretion obligates simultaneous cation excretion resulting in a urine $[Na^+]$ that may exceed 20 mmol/l despite severe volume depletion, however the urine $[Cl^-]$ remains less than 10 mmol/l. Sodium conservation is also impaired in CKD that may also result in high urine $[Na^+]$ despite volume depletion.

Diuretics. Diuretic use is one of the most common causes of hypovolemic hyponatremia associated with a high urine $[Na^+]$. Loop diuretics inhibit Na^+-Cl^- reabsorption in the TAL impairing the generation of a hypertonic medullary interstitium. Therefore, despite increased AVP secretion, responsiveness to AVP is diminished and free water is excreted. In contrast, thiazide diuretics act in the distal tubule, where they interfere with urine dilution, limiting free water excretion. Hyponatremia usually occurs within 14 days of initiation of therapy, with manifestation in approximately one third of patients within 5 days. Underweight women and elderly patients are most susceptible. Postulated mechanisms for diuretic-induced hyponatremia include the following:

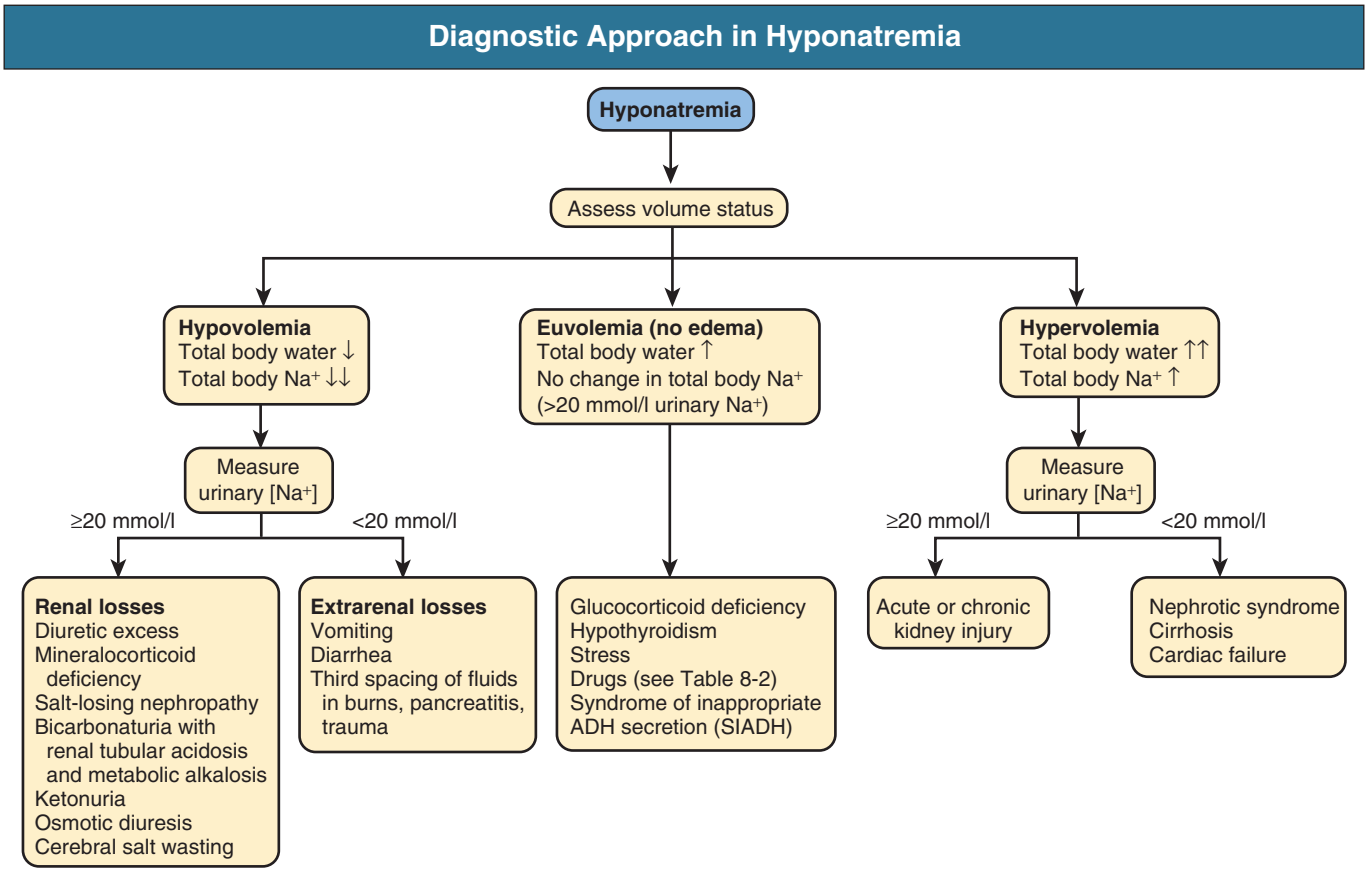

Fig. 8.5 Algorithm for diagnostic assessment of the patient with hyponatremia. (Modified from reference 8.)

- Hypovolemia-stimulated AVP release and decreased fluid delivery to the diluting segment
- Impaired water excretion through interference with maximal urinary dilution in the cortical diluting segment
- K^+ depletion, directly stimulating water intake by alterations in osmoreceptor sensitivity and increasing thirst

Water retention can mask the physical findings of hypovolemia, making the patients with diuretic-induced hyponatremia appear euvolemic.

Salt-losing nephropathy. A salt-losing state may occur in patients with advanced CKD (GFR <15 ml/min), particularly from interstitial disease. It is characterized by hyponatremia and hypovolemia. In proximal (type 2) renal tubular acidosis, there is renal Na^+ and K^+ wasting despite only moderately reduced GFR, and bicarbonaturia further obligates urine Na^+ excretion.

Mineralocorticoid deficiency. Mineralocorticoid deficiency is characterized by hyponatremia with ECF volume contraction, urine [Na^+] above 20 mmol/l, and high serum K^+, urea, and creatinine. Decreased ECF volume provides the nonosmotic stimulus for AVP release.

Osmotic diuresis. An osmotically active, nonreabsorbable solute obligates the renal excretion of Na^+ and results in volume depletion. In the face of continuing water intake, the diabetic patient with severe glycosuria, the patient with a urea diuresis after relief of urinary tract obstruction, and the patient with mannitol diuresis all undergo urinary losses of Na^+ and water, leading to hypovolemia and hyponatremia. Urine [Na^+] is typically above 20 mmol/l. The ketone bodies β-hydroxybutyrate and acetoacetate also obligate urinary electrolyte losses and aggravate the renal Na^+ wasting seen in diabetic ketoacidosis, starvation, and alcoholic ketoacidosis.

Cerebral salt wasting. Cerebral salt wasting is a syndrome described primarily in patients with subarachnoid hemorrhage. The primary defect is salt wasting from the kidneys with subsequent volume contraction, which stimulates AVP release. The exact mechanism is not understood, but it is postulated that brain natriuretic peptide increases urine volume and Na^+ excretion. Serum uric acid is often low, similar to that observed in syndrome of inappropriate anti-diuretic hormone (SIADH, see later). The diagnosis requires evidence of inappropriate sodium losses and reduced effective blood volume. These criteria are rarely fulfilled, suggesting that cerebral salt wasting is overdiagnosed.

Hypervolemia: Hyponatremia Associated With Increased Total Body Sodium

In hypervolemia, if the total body water is increased more than total body Na^+ hyponatremia occurs, as in congestive heart failure (CHF), nephrotic syndrome, and cirrhosis (see Fig. 8.5 and Chapter 7).

Congestive heart failure. Edematous patients with CHF have reduced effective intravascular volume as a result of decreased systemic mean arterial pressure and cardiac output. This reduction is sensed by aortic and carotid baroreceptors activating nonosmotic pathways, resulting in AVP release. In addition, the relative "hypovolemic" state stimulates the renin-angiotensin axis and increases norepinephrine production, which in turn decreases GFR. This causes an increase in proximal tubular reabsorption and a decrease in water delivery to the distal tubule.

The neurohumorally mediated decrease in delivery of tubular fluid to the distal nephron and an increase in AVP secretion mediate hyponatremia by limiting Na^+-Cl^- and water excretion. In addition, low cardiac output and high Ang II levels are potent stimuli of thirst.

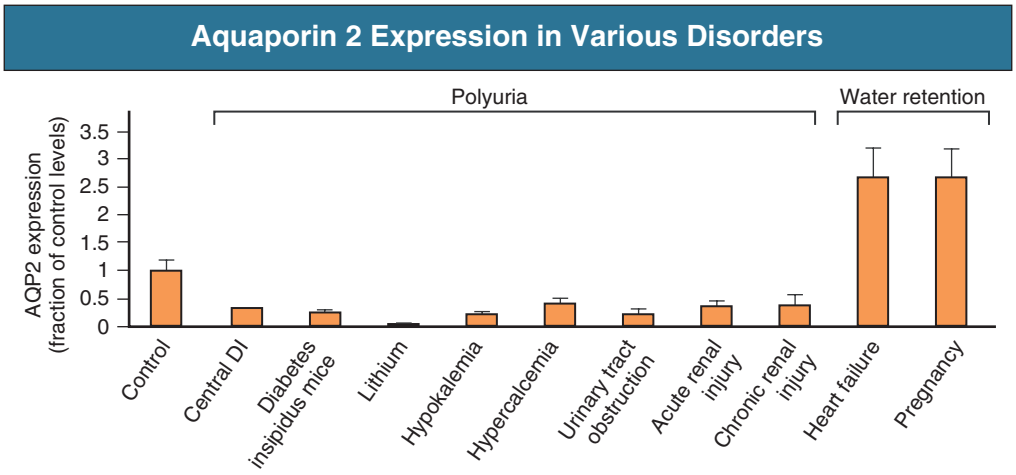

Fig. 8.6 Changes in aquaporin 2 (AQP2) expression seen in association with different water balance disorders. Levels are expressed as a fraction (percentage) of control levels. AQP2 expression is reduced, sometimes dramatically, in a wide range of hereditary and acquired forms of diabetes insipidus *(DI)* characterized by different degrees of polyuria. Conversely, congestive heart failure and pregnancy are conditions associated with increased expression of AQP2 levels and excessive water retention. (Modified from reference 3.)

There is also excessive intracellular targeting of AQP2 to the apical cell membrane of the collecting duct, most likely from high AVP levels (Fig. 8.6).[11]

As cardiac function improves with afterload reduction, plasma AVP decreases, with concomitant improvement in water excretion. The degree of hyponatremia also has been correlated with the severity of cardiac disease and patient survival; serum [Na^+] of less than 125 mmol/l reflects severe CHF.

Hepatic failure. Patients with cirrhosis and hepatic insufficiency also have increased ECF volume (ascites, edema). Because of splanchnic venous dilation, they have increased plasma volume. Cirrhotic patients have an increased cardiac output because of multiple arteriovenous fistulas in their alimentary tract, lungs, and skin. Vasodilation and arteriovenous fistulas cause a decrease in mean arterial blood pressure. As the severity of cirrhosis increases, there are progressive increases in plasma renin, norepinephrine, AVP, and endothelin and an associated decline in mean arterial pressure and serum [Na^+]. In experimental models, expression of AQP2 is upregulated in collecting ducts.[6]

Nephrotic syndrome. In some patients with nephrotic syndrome, especially those with minimal change disease, low plasma oncotic pressure from hypoalbuminemia alters Starling forces, leading to intravascular volume contraction and stimulation of AVP with hyponatremia. In contrast, most nephrotic patients have a renal defect in sodium excretion resulting in increased effective circulating volume. Hyponatremia may still occur in these latter conditions. In experimental models of nephrotic syndrome, expression of AQP2, AQP3, and UT-A1 are downregulated in the collecting duct (which would have countering effects), but so are the sodium transporters, NKCC2, NHE3, and Na^+,K^+-ATPase, in the TAL, resulting in hyponatremia.[6]

Advanced chronic kidney disease. Patients with severely reduced GFR, either acute or chronic, have a profound increase in fractional excretion of Na^+ to maintain normal salt balance given the overall decreased number of functioning nephrons. Edema usually develops when the Na^+ ingested exceeds the capacity of the kidneys to excrete this load. Likewise, if water intake exceeds threshold, there is positive water balance and hyponatremia. At a GFR of 5 ml/min, only 7.2 liters of filtrate is formed daily. Approximately 30%, or 2.2 liters, of this filtered fluid will reach the diluting segment of the nephron, which is therefore the maximum solute-free water that can be excreted daily. As GFR progressively declines, a defect in renal concentration precedes a disorder in urinary dilution. The excretion of free water as a function of remaining glomeruli is well maintained until renal failure is very advanced.[12]

Aging results in 20% reduction in maximum urine osmolality in people over 60 years of age. The concentrating defect is not related to a decrease in GFR or an abnormality in AVP secretion.

Euvolemia: Hyponatremia Associated With Normal Total Body Sodium

Euvolemic hyponatremia is the most common dysnatremia in hospitalized patients. These patients have no physical signs of increased or decreased total body Na^+.

Glucocorticoid deficiency. Glucocorticoid deficiency causes impaired water excretion in patients with primary and secondary adrenal insufficiency. Elevation of AVP accompanies the water excretion defect resulting from anterior pituitary and adrenocorticotropic hormone (ACTH, corticotropin) deficiency. This can be corrected by physiologic doses of corticosteroids, but not by volume expansion. Hyponatremia may be enhanced by reduced renal blood flow and decreased distal fluid delivery to the diluting segments of the nephron.

Hypothyroidism. Hyponatremia occurs in patients with severe hypothyroidism, who usually meet the clinical criteria for myxedema coma. A decrease in cardiac output leads to nonosmotic release of AVP. A reduction in GFR leads to diminished free water excretion through decreased distal delivery to the distal nephron. The exact mechanisms are unclear. In patients with untreated hypothyroidism who have moderately severe disease, an AVP-independent mechanism is suggested by normal suppression of AVP after water loading. However, in patients with more advanced hypothyroidism, elevated AVP levels are reported in the basal state and after a water load. Hyponatremia is readily reversed by hormonal replacement treatment.

Psychosis. Patients with acute psychosis may develop hyponatremia. Psychogenic drugs, particularly selective serotonin reuptake inhibitors (SSRIs), are associated with hyponatremia, but psychosis can cause hyponatremia independently.[13] The pathophysiologic process involves an increased thirst perception, a mild defect in osmoregulation that

causes AVP to be secreted at lower osmolality, and an enhanced renal response to AVP. Individuals with self-induced water intoxication also may be more prone to the development of rhabdomyolysis.

Postoperative hyponatremia. Postoperative hyponatremia mainly is a result of excessive infusion of electrolyte-free water (hypotonic saline or 5% dextrose in water) and the presence of AVP, which prevents water excretion. Hyponatremia also can occur despite infusion with near-isotonic (normal) saline within 24 hours of induction of anesthesia.[14] Young premenstrual women are at higher risk for developing acute postoperative hyponatremia accompanied by cerebral edema. The mechanism has not been fully elucidated, and the patients at highest risk cannot be prospectively identified. Nevertheless, hypotonic fluids should be avoided after surgery, isotonic fluids minimized, and serum [Na^+] checked if hyponatremia is suspected (e.g., symptoms of headache or nausea).

Exercise-induced hyponatremia. Hyponatremia is seen in long-distance runners. A study at a marathon race associated increased risk of hyponatremia with body mass index less than 20 kg/m^2, running time exceeding 4 hours, and greatest weight gain.[15] A study in ultramarathon runners showed elevated AVP despite normal or low serum [Na^+]. The mechanism may be due to an exuberant AVP response in relation to exercise-induced dehydration.

Drugs causing hyponatremia. Drug-induced hyponatremia is becoming the most common cause of hyponatremia.[13] Thiazide diuretics and SSRIs are the most commonly implicated medications. Hyponatremia can be mediated by AVP analogues such as desmopressin (DDAVP, 1-desamino-D-arginine AVP) that enhance AVP release, and agents potentiating the action of AVP. In other cases, the mechanism is unknown (Table 8.2). Desmopressin for nocturia in elderly patients and enuresis in young persons has caused hyponatremia in some of these subjects, so it is not routinely used to treat these conditions. Desmopressin for nocturia should be used only when the number of voidings is not tolerable and is debilitating (>2/night). On awakening the drug is likely to be still active for several more hours, requiring great attention to water restriction. Hyponatremia also may result from use of intravenous immune globulin (IVIG).[16] The mechanism of IVIG-associated hyponatremia is multifactorial, involving pseudohyponatremia (secondary to increases in serum protein concentration), translocation (as a result of sucrose in the solution), and true dilutional hyponatremia (secondary to the retention of water, particularly when associated with acute kidney injury [AKI]).[16]

TABLE 8.2 Drugs Associated With Hyponatremia*

Vasopressin Analogues	Drugs That Potentiate Renal Action of Vasopressin
Desmopressin (DDAVP)	Chlorpropamide
Oxytocin	Cyclophosphamide
	Nonsteroidal antiinflammatory drugs (NSAIDs)
	Acetaminophen
Drugs That Enhance Vasopressin Release	**Drugs That Cause Hyponatremia by Unknown Mechanisms**
Chlorpropamide	*Haloperidol*
Clofibrate	Fluphenazine
Carbamazepine-oxcarbazepine	Amitriptyline
Vincristine	Thioridazine
Nicotine	Fluoxetine
Narcotics	*Methamphetamine* (MDMA, "ecstasy")
Antipsychotics/antidepressants (SSRIs)	Intravenous immune globulin (IVIG)
Ifosfamide

*Not including diuretics.
MDMA, 3,4-Methylenedioxymethamphetamine; *SSRIs,* selective serotonin reuptake inhibitors.

Syndrome of inappropriate antidiuretic hormone secretion. Despite being the most common cause of hyponatremia in hospitalized patients, SIADH is a diagnosis of exclusion. A defect in osmoregulation causes AVP to be inappropriately stimulated, leading to urine concentration (Table 8.3). A few causes deserve special mention. Central nervous system (CNS) disturbances such as hemorrhage, tumors, infections, and trauma cause SIADH by excess AVP secretion. Small cell lung cancer, cancer of the duodenum and pancreas, and olfactory neuroblastoma cause ectopic production of AVP. Idiopathic cases of SIADH are unusual except in elderly patients, in whom hyponatremia is frequently multifactorial,[17] but in whom as many as 10% have abnormal AVP secretion without known cause.

Several patterns of abnormal AVP release have emerged from studies of patients with clinical SIADH,[18] and have now been reproduced employing the simpler, more reliable and stable copeptin assay.[19] In one third of patients with SIADH, AVP release varies appropriately with serum [Na^+] but begins at a lower threshold of serum osmolality, implying a "resetting of the osmostat." Ingestion of free water then leads to water retention to maintain the serum [Na^+] at a new lower level, usually 125 to 130 mmol/l. In two thirds of patients, AVP release does not correlate with serum [Na^+], but a solute-free urine cannot be excreted. Therefore ingested water is retained, giving rise to moderate nonedematous volume expansion and dilutional hyponatremia. In about 10% of patients, AVP levels are not measurable, suggesting that the syndrome of inappropriate antidiuresis (SIAD) is a more accurate term.[18] It was suggested that such patients may have a nephrogenic syndrome of antidiuresis, and a gain-of-function mutation in the AVP receptor. However, none of the six patients who had unmeasurable copeptin (a surrogate marker for AVP) levels had an identifiable gain of function mutation.[19]

The diagnostic criteria for SIADH are summarized in Box 8.1.[1] Plasma AVP may be in the "normal" range (up to 10 ng/l), but this is inappropriate given the hypo-osmolar state. The measurement of plasma AVP is rarely needed because the urinary osmolality provides an excellent surrogate bioassay. Thus a hypertonic urine (>300 mOsm/kg H_2O) provides strong evidence for the presence of AVP in the circulation because such urinary tonicities are unattainable in its absence. Likewise, a urinary osmolality lower than 100 mOsm/kg H_2O reflects the virtual absence of the hormone. Urinary osmolalities in the range of 100 to 300 mOsm/kg H_2O can occur in the presence or absence of AVP. A decrease in serum uric acid concentration associated with a high fractional excretion (>10%) is frequently encountered in the patient with SIADH.

Clinical Manifestations of Hyponatremia

Most patients with a serum [Na^+] above 125 mmol/l are asymptomatic. Below 125 mmol/l, headache, yawning, lethargy, nausea, reversible ataxia, psychosis, seizures, and coma may occur as a result of cerebral edema. Rarely, hypotonicity leads to cerebral edema so severe that there is increased intracerebral pressure, tentorial herniation, respiratory depression, and death. These events occur with rapid development of hyponatremia, typically in hospitalized postoperative patients receiving diuretics

TABLE 8.3 Causes of Syndrome of Inappropriate Antidiuretic Hormone Secretion

Carcinomas	Pulmonary Disorders	Nervous System Disorders	Other
Bronchogenic carcinoma	*Viral pneumonia*	*Encephalitis (viral, bacterial)*	*Human immunodeficiency virus (HIV) infection; acquired immunodeficiency syndrome (AIDS)*

BOX 8.1 Diagnostic Criteria for Syndrome of Inappropriate Antidiuretic Hormone Secretion

Essential Diagnostic Criteria

- Decreased extracellular fluid effective osmolality (270 mOsm/kg H_2O)
- Inappropriate urine concentration (>100 mOsm/kg H_2O)
- Clinical euvolemia
- Elevated urine Na^+ concentration under conditions of normal salt and water intake
- Absence of adrenal, thyroid, pituitary, or renal insufficiency or diuretic use

Supplemental Criteria

- Abnormal water-load test result (inability to excrete at least 90% of a 20-ml/kg water load in 4 hours and/or failure to dilute urine osmolality to <100 mOsm/kg)
- Serum vasopressin level inappropriately elevated relative to the serum osmolality
- No significant correction of serum Na^+ level with volume expansion, but improvement after fluid restriction
- Hypouricemia and elevated fractional excretion of uric acid

Modified from reference 1.

or hypotonic fluids. Untreated severe hyponatremia has a mortality rate as high as 50%. Neurologic symptoms in a hyponatremic patient call for immediate attention and treatment.

Cerebral Edema

The development of cerebral edema largely depends on the cerebral adaptation to hypotonicity. Decreases in extracellular osmolality cause movement of water into cells, increasing intracellular volume and causing tissue edema. The water channel AQP4 appears to play a key role in the movement of water across the blood-brain barrier. AQP4 knockout mice are protected from hyponatremic brain swelling, whereas animals overexpressing AQP4 have exaggerated brain swelling.[20] Cellular edema within the fixed confines of the cranium increases intracranial pressure, leading to the neurologic syndrome. In most hyponatremic patients, mechanisms of volume regulation prevent cerebral edema.

Within 1 to 3 hours after hyponatremia develops a decrease in cerebral extracellular volume occurs by movement of fluid into the cerebrospinal fluid, which is then shunted back into the systemic circulation. Loss of extracellular solutes Na^+ and Cl^- occurs as early as 30 minutes after the onset of hyponatremia (Fig. 8.7). If hyponatremia persists for longer than 3 hours, the brain adapts by losing cellular osmolytes, including K^+ and organic solutes, which tends to lower the osmolality of the brain, resulting in water losses. Thereafter, if hyponatremia persists, other organic osmolytes, such as phosphocreatine, myoinositol, and amino acids (e.g., glutamine, taurine), are lost, greatly decreasing cerebral swelling. As a result of these adaptations, some patients may have minimal symptoms despite severe hyponatremia ($[Na^+]$ <125 mmol/l).

Certain patients are at increased risk for development of acute cerebral edema in the course of hyponatremia[21] (Table 8.4). Hospitalized premenstrual women with hyponatremia are more symptomatic and more likely to have complications of therapy than postmenopausal women or men. This increased risk for cerebral edema is independent of the rate of development or the magnitude of hyponatremia. The best management of these patients is to avoid the administration of hypotonic fluids in the postoperative setting. Children are particularly vulnerable to the development of acute cerebral edema, perhaps because of a relatively high ratio of brain to skull volume.

Osmotic Demyelination

Another neurologic syndrome can occur in hyponatremic patients as a complication of correction of hyponatremia. Osmotic demyelination most often affects the central pons and is therefore also termed *central pontine myelinolysis* (CPM). It occurs at all ages; Table 8.4 lists patients most at risk. Osmotic demyelination syndrome is especially common after liver transplantation, with a reported incidence of 13% to 29% at autopsy. The risk for CPM is related to the severity and chronicity of

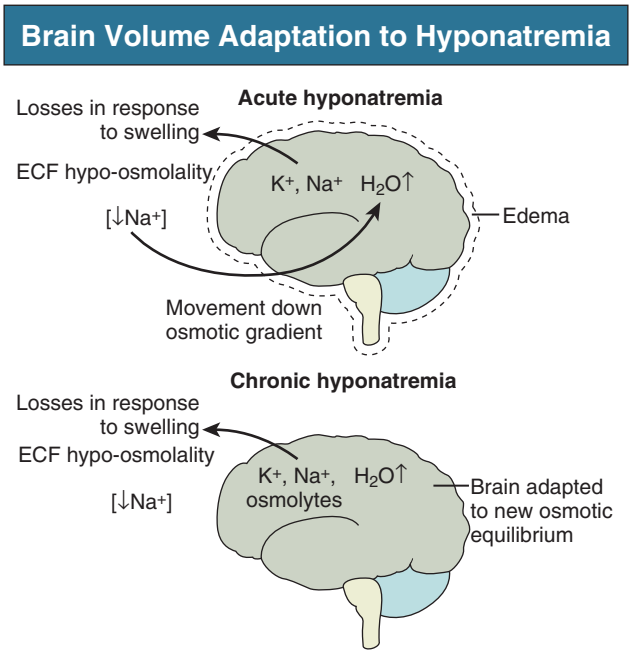

Fig. 8.7 Brain volume adaptation to hyponatremia. During acute hyponatremia, water enters the brain to establish osmotic equilibrium with the ECF. As an acute adaptive change, NaCl exits from the brain interstitial space, followed by loss of potassium from cells several hours later. In chronic hyponatremia, the brain loses osmolytes, which lead to further water losses from the brain and an almost full restoration of brain water to levels marginally greater than baseline. (Modified from reference 1.)

TABLE 8.4 Subjects at Risk for Neurological Complications with Hyponatremia

Acute Cerebral Edema	Osmotic Demyelination Syndrome (Central Pontine Myelinolysis)
Postoperative menstruating women	Liver transplant recipients
Elderly women taking thiazides	Alcoholic patients
Children	Malnourished patients
Patients with polydipsia secondary to psychiatric disorders	Hypokalemic patients
Hypoxemic patients	Burn victims
Marathon runners	Elderly women taking thiazides
	Hypoxemic patients
	Severe hyponatremia ([Na+] <105 mmol/l)

Patient groups at risk for acute cerebral edema and central pontine myelinolysis (osmotic demyelination)
From reference 21.

the hyponatremia. It rarely occurs with serum [Na+] above 120 mmol/l or a short duration of hyponatremia (<48 hours). The symptoms are biphasic. Initially, there is a generalized encephalopathy associated with rapid correction of serum [Na+]. At 2 to 3 days after correction, the patient displays behavioral changes, cranial nerve palsies, and progressive weakness, culminating in quadriplegia and a "locked-in" syndrome. T2-weighted magnetic resonance imaging shows nonenhancing and hyperintense pontine and extrapontine lesions. These lesions may not appear until 2 weeks after development, so a diagnosis of myelinolysis should not be excluded if the imaging is initially normal.

The pathogenesis of osmotic demyelination syndrome is uncertain; one suggestion is that sodium-coupled amino acid transporters (e.g., SNAT2) are downregulated by hypotonicity, thereby delaying the return of osmolytes to the brain, rendering it more sensitive to the correction of hyponatremia.[22] Although [Na+] and [K+] return to normal in a few hours, osmotically active solutes require several days to return to normal levels. This temporary imbalance causes cerebral dehydration and can lead to a potential breakdown of the blood-brain barrier. Astrocytes appear to be an early target of the disease, activating microglial cells resulting in the expression of proinflammatory cytokines.[23]

Whereas CPM was originally considered to be uniformly fatal, a substantial number of patients can have some neurologic recovery, even with severe symptoms at onset, suggesting there are reversible forms of osmotic demyelination.

Treatment of Hyponatremia

Symptoms and duration of hyponatremia determine treatment. Acutely hyponatremic patients (developing within 48 hours) are at great risk for permanent neurologic sequelae from cerebral edema if the hyponatremia remains uncorrected. Patients with chronic hyponatremia are at risk for osmotic demyelination if the hyponatremia is corrected too rapidly.

Acute Symptomatic Hyponatremia

Acute symptomatic hyponatremia with seizures or other neurologic manifestations almost always develops in hospitalized patients receiving hypotonic fluids (Fig. 8.8). Treatment should be prompt because the risk for acute cerebral edema far exceeds the risk for osmotic demyelination. The cell volume adaptive response whereby the brain decreases its water content in acute hyponatremia may be inhibited by female hormones, possibly explaining the large female predominance. A contribution of hypoxia also may be important, because when hypoxia is combined with hyponatremia in experimental animals; the volume adaptive response is abrogated, resulting in brain edema and increased mortality.[24] Because the neurologic complications associated with acute symptomatic hyponatremia are devastating, patients require prompt treatment with 3% NaCl.[21,25,26] A rapid increment of 4 to 6 mmol/l appears to be sufficient to reverse cerebral edema; correction to normal levels is unnecessary.[27] Initial treatment should entail an infusion of 1 to 2 ml/kg of 3% NaCl over 60 minutes. Administration of a loop diuretic enhances free water excretion and hastens the normalization of serum [Na+]. If the patient presents with severe neurologic symptoms, such as seizures, obtundation, or coma, 3% NaCl may be infused at higher rates (4 to 6 ml/kg/hr). Patients should be monitored carefully for changes in neurologic and pulmonary status, and serum electrolytes should be checked every 2 hours.

Chronic Symptomatic Hyponatremia

If the hyponatremia has taken more than 48 hours to evolve or if the duration is not known, correction should be undertaken with caution (see Fig. 8.8). Controversy exists as to whether it is the rate of correction or the magnitude of correction of hyponatremia that predisposes to neurologic complications. It is difficult to dissociate these two variables because a rapid correction rate is usually accompanied by a greater absolute magnitude of correction during a given time. The following three important principles guide treatment:

1. Because cerebral water is increased by approximately 10% in severe chronic hyponatremia, the goal is to increase the serum Na+ level by 10%, or about 10 mmol/l in the first 24 hours.

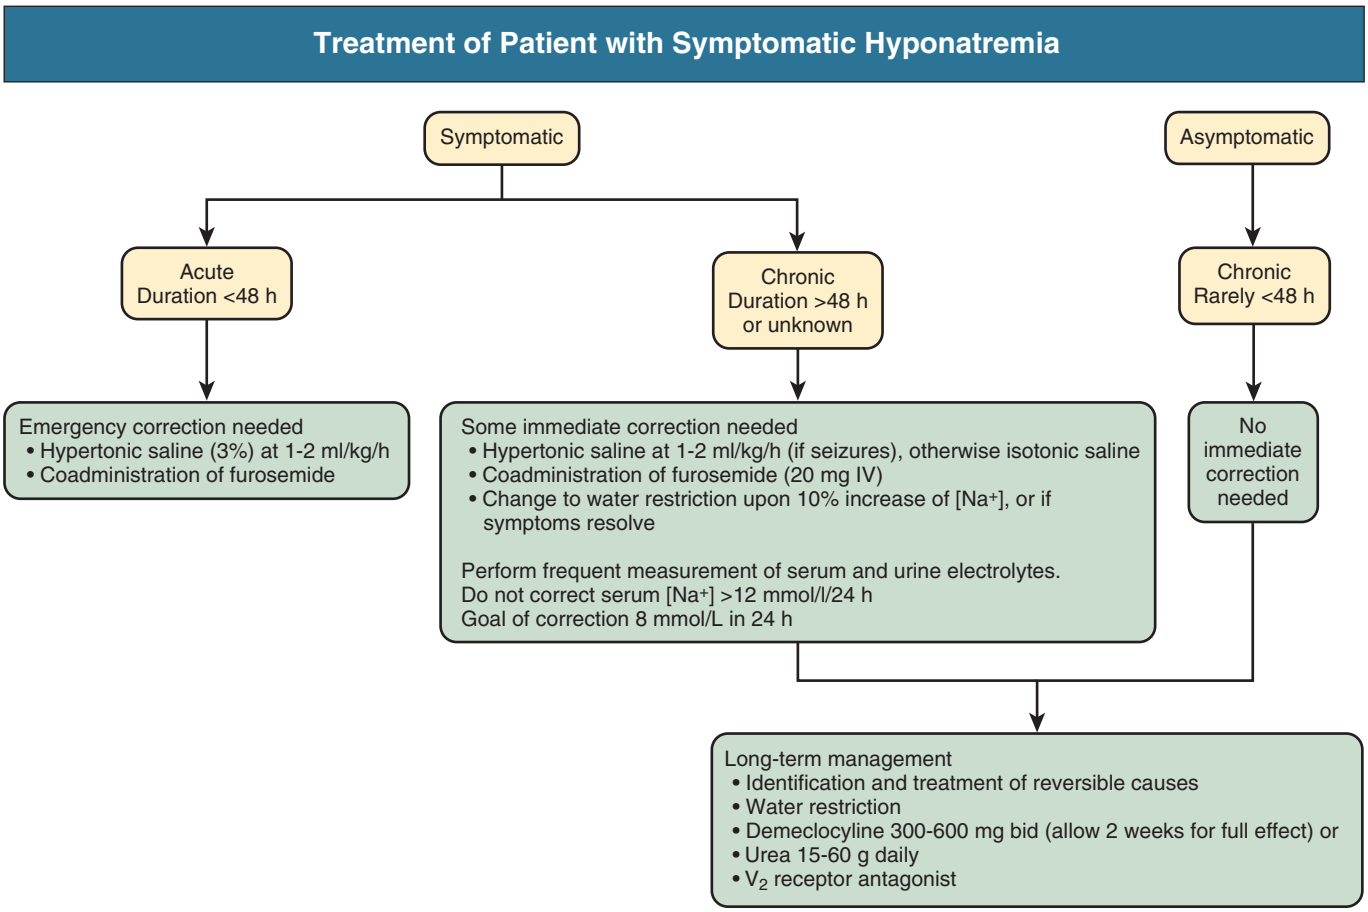

Fig. 8.8 Algorithm for management of the patient with symptomatic (and "asymptomatic") hyponatremia. (Modified from reference 21.)

2. A correction rate of 1.0 to 1.5 mmol/l in any given hour should not be exceeded.
3. The goal of treatment is an increase of 6 to 10 mmol/l/24 h, but do not increase by more than 12 mmol/l/24 h and 18 mmol/l/48 h.

Numerous formulas have been used to assess the expected changes in serum sodium with various infusions[18] but the one proposed by Adrogue and Madias[28] is the most widely employed. Although helpful in the initial treatment phase, it does not take into account ongoing renal and extrarenal losses, thus commonly resulting in correction larger than those predicted by the formula.[29] The risk for overcorrection can be mitigated by the coadministration of DDAVP, thus preventing the excretion of hypotonic urine.[30] If the previously noted limits are exceeded, relowering of serum sodium can be achieved by the infusion of dextrose and water and the administration of DDAVP.[30]

Chronic "Asymptomatic" Hyponatremia

Patients with chronic hyponatremia are often asymptomatic. However epidemiologic data consistently show higher mortality rates than matched controls with normal serum sodium levels.[31] Formal neurologic testing frequently reveals subtle impairments, including gait disturbances that reverse with correction of the hyponatremia. This results in an increased risk for falls and fractures.[32] Therefore, even "asymptomatic" patients should be treated in an attempt to restore serum sodium to near-normal levels, particularly if they display gait instability or have sustained a fall. These patients should also be evaluated for hypothyroidism, adrenal insufficiency, and SIADH and should have their medications reviewed.

Fluid restriction. Stopping any medication associated with hyponatremia and fluid restriction is the cornerstone of therapy in patients with chronic asymptomatic hyponatremia (Table 8.5). Intake of all fluids should be restricted, and fructose-containing fluids should be avoided because fructose stimulates AVP release independently of osmolarity. This approach is usually successful if patients are compliant. It involves a calculation of the fluid restriction that will maintain a specific serum $[Na^+]$. The daily osmolar load and the minimal urinary osmolality $(U_{osm})_{min}$ determine a patient's maximal urine volume (V_{max}), as follows:

$$V_{max} = \frac{OL}{(U_{osm})_{min}}$$

The value of $(U_{osm})_{min}$ is a function of the severity of the diluting disorder. In the absence of circulating AVP, it can be as low as 50 mOsm/kg H_2O. In a normal North American diet, the daily osmolar load is approximately 10 mOsm/kg (700 mOsm for 70-kg person). Assuming that a patient with SIADH has U_{osm} that cannot be lowered to less than 500 mOsm/kg H_2O, the same osmolar load of 700 mOsm allows only 1.4 liters of urine to be excreted daily. Therefore, if the intake exceeds 1.4 l/day, the serum Na^+ concentration will decrease. Measurement of urine $[Na^+]$ and $[K^+]$ can guide the required degree of water restriction.[33] Unless the ratio of urine $[Na^+]$ plus $[K^+]$ over serum [Na] is 0.5 or less, compliance with the needed water restriction is not likely to occur. Likewise a urinary osmolality greater than 500 mOSm/kg also predicts poor response to water restriction.[1] In a report from a hyponatremia registry, the increment in serum sodium observed in patients

TABLE 8.5 Treatment of Patients With Chronic Asymptomatic Hyponatremia

Treatment	Mechanism of Action	Dose	Advantages	Limitations
Fluid restriction	Decreases availability of free water	Variable	Effective and inexpensive; not complicated	Noncompliance
Pharmacologic Inhibition of Vasopressin Action				
Lithium	Inhibits kidney's response to vasopressin	900-1200 mg/day	Unrestricted water intake	Polyuria, narrow therapeutic range, neurotoxicity
Demeclocycline	Inhibits kidney's response to vasopressin	300-600 mg twice daily	Effective; unrestricted water intake	Neurotoxicity, polyuria, photosensitivity, nephrotoxicity
V_2 receptor antagonist	Antagonizes vasopressin action	—	Addresses underlying mechanisms	Limited clinical experience
Increased Solute (Salt) Intake				
With furosemide	Increases free water clearance	Titrate to optimal dose; coadminister 2-3 g NaCl	Effective	Ototoxicity, K^+ depletion
With urea	Osmotic diuresis	30-60 g/day	Effective; unrestricted water intake	Polyuria, unpalatable, gastrointestinal symptoms

placed on water restriction did not achieve statistical significance when compared to their baseline admission serum sodium.[34] If the diluting defect is so severe that fluid restriction to less than 1 liter is necessary or if the serum Na^+ concentration remains low (<130 mmol/l), an alternative approach to treatment should be considered, such as increasing solute excretion or pharmacologic inhibition of AVP.

Increase solute excretion. If the patient remains unresponsive to fluid restriction, solute intake can be increased to facilitate an obligatory increase in excretion of solute and free water.[35] This can be achieved by increasing oral salt and protein intake in the diet to increase the C_{osm} of the urine. Loop diuretics combined with high sodium intake (2 to 3 g of additional salt) are effective in the management of hyponatremia. A single dose of diuretic (40 mg furosemide) is usually sufficient but should be doubled if the diuresis induced in the first 8 hours is less than 60% of the total daily urine output.

The administration of urea increases urine flow by causing an osmotic diuresis. This permits a more liberal water intake without worsening the hyponatremia and altering urine concentration. The dose of urea is usually 30 to 60 g/day. The limitations are gastrointestinal distress and unpalatability.

Pharmacologic inhibition of vasopressin. *Vaptans* are novel oral V_2 receptor antagonists that block AVP binding to the collecting duct tubular epithelial cells and increase free water excretion without significantly altering electrolyte excretion.[36-38] Vaptans are effective in the treatment of hyponatremia in euvolemic and hypervolemic patients, as reported in two meta-analyses.[39,40] Conivaptan, a V_2 and V_{1a} antagonist, is the only vaptan available for intravenous use,[38] but treatment should be limited to 4 days because it is a potent cytochrome P-450 3A4 (CYP3A4) inhibitor. Tolvaptan, an oral V_2 antagonist, is now available at doses of 15 to 60 mg/day. In the Tolvaptan trials in patients with polycystic kidney disease (TEMPO), higher doses were used and some cases of hepatic toxicity, as well as rhabdomyolysis, were encountered. This has led to a U.S. Food and Drug Administration warning requiring careful monitoring of liver function tests and creatine kinase (CK, CPK) levels.

An alternative pharmacologic treatment is demeclocycline 600 to 1200 mg/day given 1 to 2 hours after meals; calcium-, aluminum-, and magnesium-containing antacids should be avoided. Onset of action is usually 3 to 6 days after initiation of treatment. Dose should be titrated to the minimum that keeps serum $[Na^+]$ within the desired range with unrestricted water intake. Photosensitivity may develop, and tooth or bone abnormalities may occur in children. Polyuria leads to noncompliance, and nephrotoxicity may occur, especially in patients with underlying liver disease. Lithium was previously used to antagonize AVP action but has been superseded by the vaptans and demeclocycline.

Hypovolemic Hyponatremia

When thiazides are prescribed, especially in elderly women, serum $[Na^+]$ should be monitored and water intake restricted. If hyponatremia develops, the thiazide should be discontinued.

Neurologic syndromes directly related to hyponatremia are unusual in hypovolemic hyponatremia because both Na^+ and water loss limits any osmotic shifts in the brain. Restoration of ECF volume with crystalloids or colloids interrupts the nonosmotic release of AVP. AVP antagonists should not be used in these patients.[41]

Hypervolemic Hyponatremia

Congestive heart failure. In patients with CHF, sodium and water restriction is critical. Treatment with a combination of angiotensin-converting enzyme (ACE) inhibitors and loop diuretics increase cardiac output thereby decreasing the neurohumoral mediators that impair water excretion. Loop diuretics also diminish the action of AVP on the collecting tubules. Thiazides should be avoided because they impair urinary dilution and may worsen hyponatremia. V_2 antagonists increase serum $[Na^+]$ in patients with heart failure[36] and correction of serum $[Na^+]$ is associated with better long-term outcomes.[42] However, in the much larger randomized controlled EVEREST trial in patients with decompensated heart failure, tolvaptan did not affect long-term clinical outcomes. In principle, a vaptan with V_1 antagonist activity could have additional benefit in the CHF patient, but this remains unproven.

Cirrhosis. In patients with cirrhosis, water and sodium restriction is the mainstay of therapy. Loop diuretics increase C_{water}. V_2 antagonists increase water excretion and increase serum $[Na^+]$.[41] The response to vaptans in cirrhosis is more attenuated than in patients with SIADH or CHF, which suggests that AVP-independent mechanisms also may contribute to the hyponatremia. The administration of V_2 antagonists to patients with liver failure is not associated with decrements in blood pressure. Combined V_1 and V_2 antagonists (e.g., conivaptan) should not be used in these patients, and in view of the potential liver toxicity the use of tolvaptan should probably be limited to management of serum hyponatremia before liver transplant.[41]

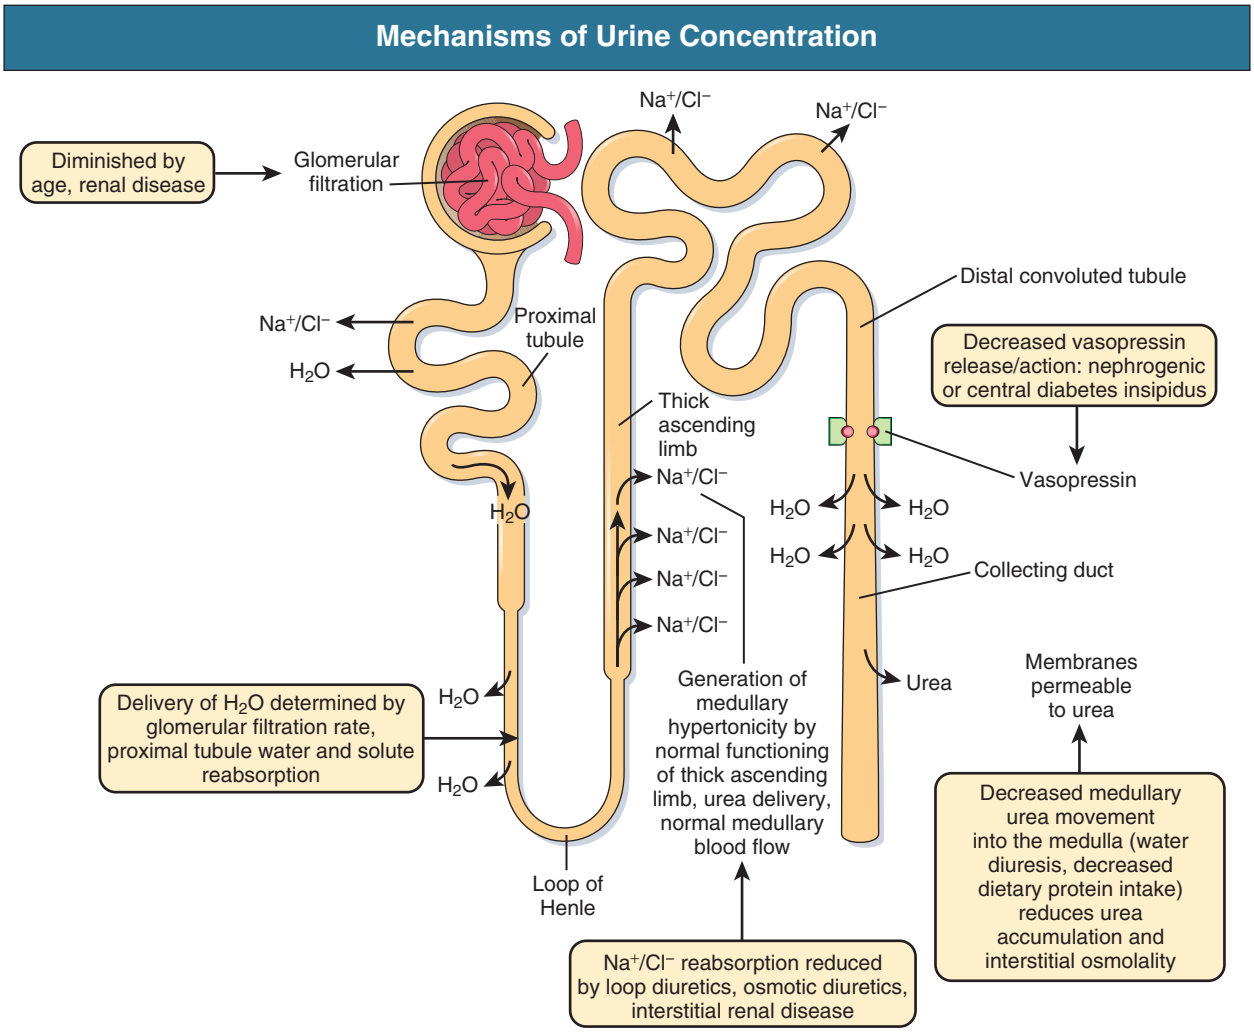

Fig. 8.9 Urine-concentrating mechanisms. Determinants of normal urine concentration and disorders causing hypernatremia. (Modified from reference (10).)

HYPERNATREMIC DISORDERS

Hypernatremia is defined as serum [Na^+] above 145 mmol/l and reflects serum hyperosmolarity. The renal concentrating mechanism provides the first defense mechanism against water depletion and hyperosmolarity. The components of the normal concentrating mechanism are shown in Fig. 8.9. Disorders of urine concentration may result from decreased delivery of solute (with decreasing GFR) or the inability to generate interstitial hypertonicity because of decreased Na^+ and Cl^- reabsorption in the ascending limb of Henle's loop (loop diuretics), decreased medullary urea accumulation (poor dietary intake), or alterations in medullary blood flow. Hypernatremia also may result from failure to release or respond to AVP. Thirst is the first and most important defense mechanism in preventing hypernatremia.

Etiology and Classification of Hypernatremia

Patients with hypernatremia fall into three broad categories based on volume status.[43] A diagnostic algorithm is helpful in the evaluation of these patients (Fig. 8.10).

Hypovolemia: Hypernatremia Associated With Low Total Body Sodium

Patients with hypovolemic hypernatremia sustain losses of both Na^+ and water, but with a relatively greater loss of water. On physical examination, there are signs of hypovolemia, including orthostatic hypotension, tachycardia, flat neck veins, poor skin turgor, and altered mental status. Patients generally have hypotonic water loss from the kidneys or the gastrointestinal (GI) tract; in the GI tract, the urine [Na^+] will be low.

Hypervolemia: Hypernatremia Associated With Increased Total Body Sodium

Hypernatremia with increased total body Na^+ is the least common form of hypernatremia. It results from the administration of hypertonic solutions such as 3% NaCl and $NaHCO_3$ for the treatment of metabolic acidosis, hyperkalemia, and cardiorespiratory arrest. It also may result from inadvertent dialysis against a dialysate with a high Na^+ concentration or from consumption of salt tablets. Therapeutic hypernatremia is also becoming common as hypertonic saline solutions have emerged as an alternative to mannitol for treatment of increased intracranial pressure.[27] Hypernatremia is also increasingly recognized in hypoalbuminemic hospitalized patients with renal failure who are edematous and unable to concentrate their urine.

Euvolemia: Hypernatremia Associated With Normal Body Sodium

Most patients with hypernatremia secondary to water loss appear euvolemic with normal total body Na^+ because loss of water without Na^+ does not lead to overt volume contraction unless severe. Water

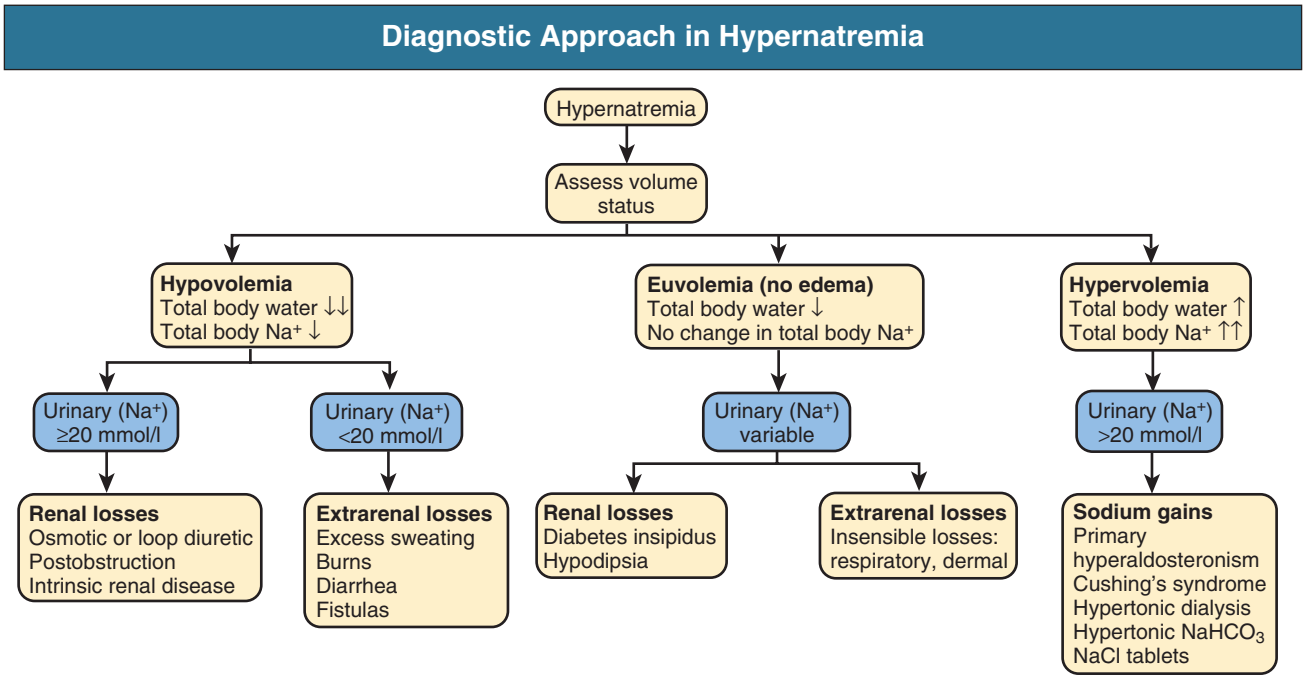

Fig. 8.10 Algorithm for diagnostic assessment of the patient with hypernatremia. (Modified from reference 8.)

loss need not result in hypernatremia unless unaccompanied by water intake. Because hypodipsia is uncommon, hypernatremia usually develops only in those who have no access to water and in very young children and old persons, who may have an altered perception of thirst. Extrarenal water loss occurs from the skin and respiratory tract in febrile or other hypermetabolic states and is associated with high urine osmolality because the osmoreceptor-AVP-renal response is intact. The urine Na^+ concentration varies with intake. Renal water loss leading to euvolemic hypernatremia results either from a defect in AVP production or release (central diabetes insipidus [DI]) or from a failure of the collecting duct to respond to the hormone (nephrogenic DI). Defense against the development of hyperosmolality requires the appropriate stimulation of thirst and the patient's ability to respond by drinking water.

Polyuric disorders can result from either an increase in C_{osm} or an increase in C_{water}. An increase in C_{osm} occurs with loop diuretic use, renal salt wasting, excess salt ingestion, vomiting (bicarbonaturia), alkali administration, and administration of mannitol (as a diuretic, for bladder lavage, or for the treatment of cerebral edema). An increase in C_{water} occurs with excess ingestion of water (psychogenic polydipsia) or in abnormalities of the renal concentrating mechanism (DI).

Diabetes Insipidus

DI is characterized by polyuria and polydipsia and is caused by defects in AVP action. Patients with central and nephrogenic DI and primary polydipsia present with polyuria and polydipsia. These entities can be differentiated by clinical evaluation, with measurements of AVP levels and response to a water deprivation test, followed by AVP administration (Table 8.6).[44]

Central diabetes insipidus

Clinical features. Central DI usually has an abrupt onset. Patients have a constant need to drink, have a predilection for cold water, and typically have nocturia. By contrast, the compulsive water drinker may give a vague history of the onset and has large variations in water intake and urine output. Nocturia is unusual in compulsive water drinkers. A

WATER DEPRIVATION TEST

Test procedure: water intake is restricted until the patient loses 3% to 5% of body weight or until three consecutive hourly determinations of urinary osmolality are within 10% of each other. (Caution must be exercised to ensure patient does not become excessively dehydrated.) Aqueous vasopressin is given, 5 units subcutaneously, and urinary osmolality is measured after 60 minutes. Expected responses are outlined in the Table.

TABLE 8.6 Interpretation of Water Deprivation Test

Condition	Urinary Osmolality with Water Deprivation (mOsm/kg H_2O)	Serum Vasopressin After Dehydration (pg/ml)	Increase in Urinary Osmolality with Exogenous Vasopressin or Desmopressin
Normal	>800	>2	Little or no increase
Complete central diabetes insipidus	<300	Undetectable	Substantially increased
Partial central diabetes insipidus	300-800	<1.5	Increase of >10% of urinary osmolality after water deprivation
Nephrogenic diabetes insipidus	<300-500	>5	Little or no increase
Primary polydipsia	>500	<5	Little or no increase

From reference 44.

BOX 8.2 Causes of Central Diabetes Insipidus

Congenital Causes
- Autosomal dominant
- Autosomal recessive

Acquired Causes
- Post-traumatic
- Iatrogenic (postsurgical)
- Tumors (metastatic from breast, craniopharyngioma, pinealoma)
- Histiocytosis
- Granuloma (tuberculosis, sarcoid)
- Aneurysm
- Meningitis
- Encephalitis
- Guillain-Barré syndrome
- Drugs
- Idiopathic

Entries in italics are the most common causes.

TABLE 8.7 Treatment of Central Diabetes Insipidus

Disease	Drug	Dose	Interval (hours)
Complete central diabetes insipidus	Desmopressin (DDAVP)	10-20 mcg intranasally	12-24
	Desmopressin (DDAVP)	0.1-0.8 mg orally	Every 12
Partial central diabetes insipidus	Desmopressin (DDAVP)	10-20 mcg intranasally	12-24
	Aqueous vasopressin	5-10 units subcutaneously	4-6
	Chlorpropamide	250-500 mg	24
	Clofibrate	500 mg	6 or 8
	Carbamazepine	400-600 mg	24

serum osmolality of more than 295 mOsm/kg H_2O suggests central DI, and less than 270 mOsm/kg H_2O suggests compulsive water drinking.

Causes. Central DI is caused by infection, tumors, granuloma, and trauma affecting the CNS in 50% of patients; in the other 50% it is idiopathic (Box 8.2). In a survey of 79 children and young adults, central DI was idiopathic in half the patients. The other half had tumors or Langerhans cell histiocytosis; these patients had an 80% risk for development of anterior pituitary hormone deficiency compared with the patients with idiopathic disease.[5]

Autosomal dominant DI is caused by point mutations in a precursor gene for AVP that cause "misfolding" of the provasopressin peptide, preventing its release from the hypothalamic and posterior pituitary neurons.[5] Patients present with a mild polyuria and polydipsia in the first year of life. These children have normal physical and mental development. There is a rare autosomal recessive central DI associated with diabetes mellitus, optic atrophy, and deafness (Wolfram syndrome).[45] DI is usually partial and gradual in onset in Wolfram syndrome. It is linked to chromosome 4 and involves abnormalities in mitochondrial DNA.

A rare clinical entity involving the combination of central DI and deficient thirst has been reported in approximately 100 patients. When AVP secretion and thirst are both impaired, affected patients are vulnerable to recurrent episodes of hypernatremia. Formerly called *essential hypernatremia,* the disorder is now called central DI with deficient thirst, or *adipsic* DI.[46]

Differential diagnosis. Measurement of circulating AVP by radioimmunoassay, or more recently, measurement of copeptin levels, is preferred to the tedious water deprivation test. Under basal conditions, AVP levels are unhelpful because there is a significant overlap among the polyuric disorders. Measurement after a water deprivation test is more useful (see Table 8.6).

Treatment. Central DI is treated with hormone replacement or pharmacologic agents (Table 8.7). In acute settings, when renal water losses are extensive, desmopressin has replaced aqueous AVP (Pitressin) as the treatment of choice. For chronic central DI, desmopressin acetate is the agent of choice. It has a long half-life and none of the significant vasoconstrictive effects of aqueous AVP. Desmopressin is administered at the dose of 10 to 20 mcg intranasally every 12 to 24 hours. It is tolerated well, safe to use in pregnancy, and resistant to degradation by circulating AVPase. Oral desmopressin (0.1 to 0.8 mg every 12 hours) is available as second-line therapy. In patients with partial DI, in addition to desmopressin itself, agents that potentiate the release of AVP may be used, including chlorpropamide, clofibrate, and carbamazepine.

Congenital nephrogenic diabetes insipidus. Inherited forms of DI are caused by mutations in genes for AVP V2-receptors or AQP2.[5] These entities are discussed further in Chapter 47. Urine volumes are typically very high, and there is a risk for severe hypernatremia if patients do not have free access to water. Thus patients must drink enough water to match urine output and prevent dehydration. Therapy for congenital nephrogenic DI is only partially effective and includes a thiazide diuretic, a very-low-salt diet, and indomethacin. Sildenafil improved urine concentration in a patient with congenital nephrogenic DI.[47] Simvastatin induces an increase in urine AQP2 and osmolality in hypercholesterolemic patients, suggesting that it may be useful in congenital nephrogenic DI.[47] Metformin results in a sustained increase in urine osmolality in rodent models of nephrogenic DI, but it has not been tested in patients.[47]

Acquired nephrogenic diabetes insipidus. Acquired nephrogenic DI is more common than congenital nephrogenic DI but rarely as severe. In patients with acquired nephrogenic DI, the ability to elaborate a maximal concentration of urine is impaired, but urine-concentrating mechanisms are partially preserved. For this reason, urine volumes are less than 3 to 4 l/day, which contrasts with the much higher volumes seen in patients with congenital or central DI or compulsive water drinking. Table 8.8 outlines the causes and mechanisms of acquired nephrogenic DI.

Chronic kidney disease. A defect in urine-concentrating ability may develop in patients with CKD of any cause, but this defect is most prominent in tubulointerstitial diseases, particularly medullary cystic disease. (A complete discussion on the mechanisms of abnormalities in urine concentration and dilution in CKD can be found in reference 12). Disruption of inner medullary structures and diminished medullary concentration are thought to play a role; alterations in V_2 receptor and AQP2 expression also contribute (see Fig. 8.6). To achieve daily osmolar clearance, patients should be advised to maintain a fluid intake that matches their urine volume.

Electrolyte disorders. Hypokalemia causes a reversible abnormality in urine-concentrating ability. Hypokalemia stimulates water intake and reduces interstitial tonicity, which relates to the decreased Na^+-Cl^- reabsorption in the TAL. Hypokalemia resulting from diarrhea, chronic diuretic use, and primary aldosteronism also decreases

TABLE 8.8 Acquired Nephrogenic Diabetes Insipidus: Causes and Mechanisms

Disease State	Defect in Medullary Interstitial Tonicity	Defect in cAMP Generation	Downregulation of Aquaporin 2	Other
Chronic kidney disease	Yes	Yes	Yes	Downregulation of V_2 receptor message
Hypokalemia	Yes	Yes	Yes	—
Hypercalcemia	Yes	Yes	—	—
Sickle cell disease	Yes	—	—	—
Protein malnutrition	Yes	—	Yes	—
Demeclocycline therapy	—	Yes	—	—
Lithium therapy	—	Yes	Yes	—
Pregnancy	—	—	—	Placental secretion of vasopressinase

cAMP, Cyclic adenosine monophosphate.

intracellular cyclic adenosine monophosphate accumulation and causes a reduction in AVP-sensitive AQP2 expression (see Fig. 8.6).

Hypercalcemia also impairs urine-concentrating ability, resulting in mild polydipsia. The pathophysiologic mechanism is multifactorial and includes a reduction in medullary interstitial tonicity caused by decreased AVP-stimulated adenylyl cyclase in the TAL and a defect in adenylyl cyclase activity with decreased AQP2 expression in the collecting duct, mediated by the calcium-sensing receptor.[6]

Pharmacologic agents. Lithium is the most common cause of nephrogenic DI, occurring in up to 50% of patients receiving long-term lithium therapy. Lithium causes downregulation of AQP2 in the collecting duct; experimentally, it also increases cyclooxygenase-2 (COX-2) expression and urinary prostaglandins, which may contribute to the polyuria.[6] The concentrating defect of lithium may persist even when the drug is discontinued. The epithelial sodium channel (ENaC) is the entrance pathway for lithium into collecting duct principal cells. Amiloride inhibits lithium uptake through ENaC and has been used clinically to treat nephrogenic DI caused by lithium. Aldosterone administration dramatically increased urine production in experimental nephrogenic DI caused by lithium (an effect associated with decreased expression of AQP2 on luminal membranes of collecting duct), whereas administration of the mineralocorticoid receptor blocker spironolactone decreased urine output and increased AQP2 expression.[6] Clopidogrel, P2Y12-R purinergic receptor antagonist, ameliorates lithium-induced nephrogenic DI in mice by increasing water and sodium reabsorption in the collecting duct.[47] It is not yet known if spironolactone or clopidogrel will be a useful treatment for lithium-induced nephrogenic DI in patients.

Other drugs impairing urine-concentrating ability include amphotericin, foscarnet, and demeclocycline, which reduce renal medullary adenylyl cyclase activity, thereby decreasing the effect of AVP on the collecting ducts.

Sickle cell anemia. Patients with sickle cell disease and trait often have a urine-concentrating defect. In the hypertonic medullary interstitium, the "sickled" red cells cause occlusion of the vasa recta and papillary damage. Although initially reversible, medullary infarcts occur with sickle cell disease in the second to third decades of life, and even with sickle cell trait by the fourth to fifth decade, and the concentrating defects become irreversible.

Dietary abnormalities. Extensive water intake or a marked decrease in salt and protein intake leads to impairment of maximal urine-concentrating ability through a reduction in medullary interstitial tonicity. On a low-protein diet with excessive water intake, there is a decrease in AVP-stimulated osmotic water permeability that is reversed with feeding.

BOX 8.3 Patient Groups at Risk for Development of Severe Hypernatremia

- Elderly patients
- Infants
- Hospitalized patients
  - Hypertonic infusions
  - Tube feedings
  - Osmotic diuretics
  - Lactulose
  - Mechanical ventilation
- High-risk patient groups
  - Altered mental status
  - Uncontrolled diabetes mellitus
  - Underlying polyuric disorders

From reference 21.

Gestational diabetes insipidus. In gestational DI, there is an increase in circulating AVPase, which is produced by the placenta. Patients are typically unresponsive to AVP but respond to desmopressin, which is resistant to vasopressinase.

Clinical Manifestations of Hypernatremia

Certain patients are at increased risk for development of severe hypernatremia (Box 8.3). Signs and symptoms mostly relate to the CNS and include altered mental status, lethargy, irritability, restlessness, seizures (usually in children), muscle twitching, hyperreflexia, and spasticity. Fever, nausea or vomiting, labored breathing, and intense thirst also can occur. In children, mortality of acute hypernatremia ranges from 10% to 70%; as many as two thirds of survivors have neurologic sequelae. In contrast, mortality in patients with chronic hypernatremia is 10%.

In adults, serum $[Na^+]$ above 160 mmol/l is associated with 75% mortality, although this may reflect associated comorbidities rather than hypernatremia. Chronic hypernatremia is independently associated with higher mortality in patients with CKD.[48] Patients presenting to the intensive care unit with a serum $[Na^+]$ above 155 mmol/l have a significantly increased risk for mortality, with an odds ratio of 3.64.[49] Thus both acute and chronic hypernatremia are associated with an increased risk for mortality.

Treatment of Hypernatremia

Hypernatremia occurs in predictable clinical settings, allowing opportunities for prevention. Elderly and hospitalized patients are at high

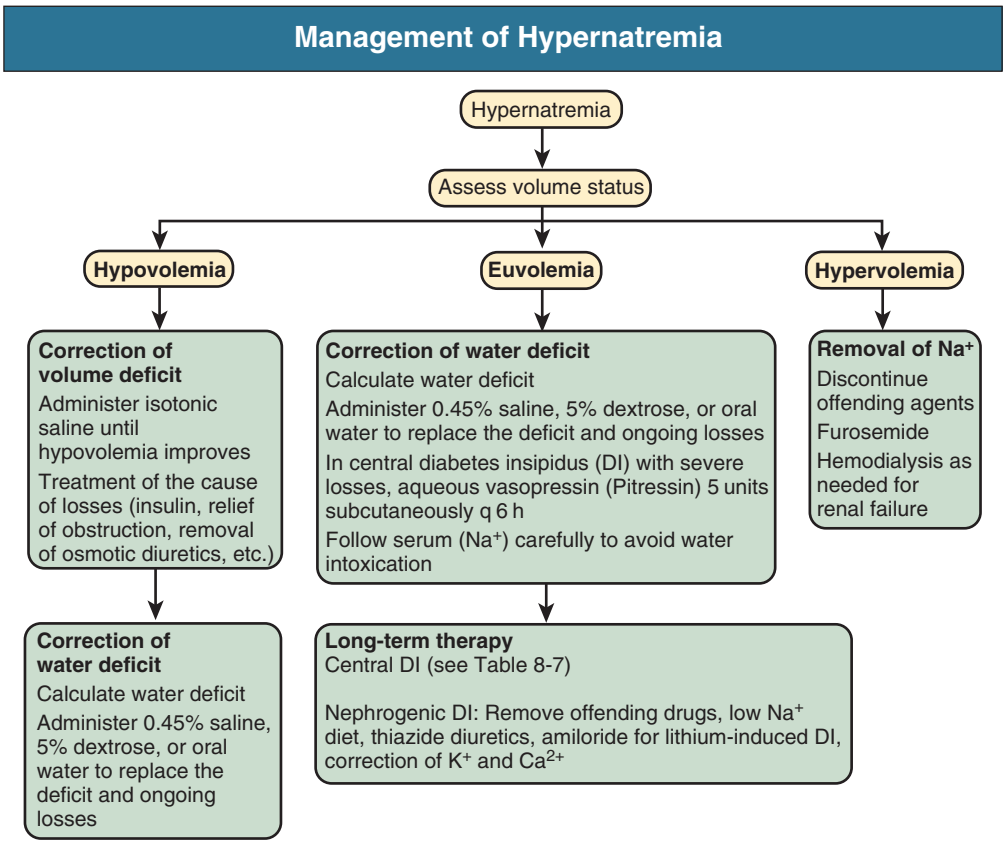

Fig. 8.11 Algorithm for management of the patient with hypernatremia. (From reference 21.)

risk because of impaired thirst and inability to access free water independently.[50] Certain clinical situations, such as recovery from acute kidney injury, catabolic states, therapy with hypertonic solutions, uncontrolled diabetes, and burns, should prompt close attention to serum sodium concentration and increased administration of free water.

Hypernatremia always reflects a hyperosmolar state. The primary goal in the treatment of these patients is the restoration of serum tonicity. Fig. 8.11 outlines specific management options.[21] Restoration of volume takes precedence over restoration of tonicity; thus, in hypovolemic hypernatremic patients, sodium-containing solutions should be used until euvolemia is achieved. Thereafter, dextrose in water or oral water intake should be given to decrease serum sodium concentration.

The rapidity with which hypernatremia should be corrected is controversial. Some animal studies and case series in pediatric patients suggest that a correction rate of more than 0.5 mmol/l/h in [Na^+] can cause seizures. Cerebral edema also can be caused by rapid correction of hypernatremia by the net movement of water into the brain. Most clinicians believe that even in adults, correction should be achieved during 48 hours at a rate no greater than 2 mmol/l/h.

SELF-ASSESSMENT QUESTIONS

1. A 78-year-old woman sustained a stroke and is receiving enteral nutrition by nasoduodenal tube at a nursing home. She is transferred to the hospital with altered mental status. Nursing home staff reported that she had plentiful urine output 2 days before transfer. Laboratory data on hospital arrival reveal serum sodium of 165 mmol/l, blood urea nitrogen (BUN) 60 mg/dl, and creatinine 1.6 mg/dl; all were normal 6 weeks earlier. Additional laboratory data include serum osmolality of 341 mOsm/kg and urine osmolality 690 mOsm/kg, urine sodium 7 mmol/l, and urine potassium 32 mmol/l.
   The most likely explanation for this patient's polyuria and hypernatremia and the most appropriate confirmatory test are:
   A. Nephrogenic diabetes insipidus and measurement of ADH
   B. Central diabetes insipidus and measurement of ADH
   C. Lithium toxicity and measurement of serum lithium level
   D. Increased solute load and measurement of electrolyte-free water clearance
2. A 71-year-old woman with a history of coronary artery disease and mild hypertension is seen in the clinic. She is free of complaints. Her medications include lisinopril (20 mg/day), occasional zolpidem tartrate (Ambien), and multivitamins. Her blood pressure is 140/95 mm Hg, weight 62 kg, and skin turgor normal. Examination reveals no evidence of edema or ascites. Laboratory results are as follows:
   - Serum creatinine: 0.9 mg/dl
   - Sodium: 120 mmol/l
   - Potassium: 3.9 mmol/l
   - Chloride: 95 mmol/l
   - HCO_3^-: 22 mmol/l
   - U_{osm}: 686 mOsm/kg
   - U_{Na}: 127 mmol/l
   - Normal thyroid and adrenal function
   - Chest x-ray film unremarkable

   Which of the following statements explains this patient's status?
   A. Patient is unlikely to have improved water excretion because she is not taking a thiazide diuretic
   B. Patient probably has idiopathic SIADH
   C. The hyponatremia is probably a consequence of poor solute intake
   D. Patient's hyponatremia is caused by age-related decrements in vasopressin metabolism
3. A 74-year-old man with a history of heart failure is admitted with increasing shortness of breath. He is treated with lisinopril 20 mg/day, HCTZ 50 mg/day, and digoxin 0.25 mg/day. Examination reveals blood pressure of 145/90 mm Hg, pulse rate 88/min, respiratory rate 24/min, O_2 saturation 90% on 2 liters. His electrolytes are normal. The patient is prescribed a low-sodium restricted diet, furosemide 40 mg bid, and fluid restriction. In the next 24 hours, he excretes 2.5 liters of urine. Laboratory results are as follows:
   - Serum creatinine: 1.8 mg/dl
   - BUN: 25 mg/dl
   - Sodium: 147 mmol/l
   - Potassium: 3.7 mmol/l
   - HCO_3^-: 26 mmol/l
   - Chloride: 120 mmol/l
   - U_{osm}: 392 mOsm/kg
   - U_{Na}: 59 mmol/l
   - U_K: 32 mmol/l

   Which of the following treatment regimens is most likely to prevent worsening of this patient's hypernatremia?
   A. 1 ml of half-normal per milliliter of urine
   B. 0.5 ml of 5% dextrose in water per milliliter of urine
   C. 0.5 ml of normal saline per milliliter of urine
   D. 0.5 ml of normal saline per milliliter of urine

Disorders of Potassium Metabolism

I. David Weiner, Stuart L. Linas, Charles S. Wingo

Potassium disorders are some of the most frequently encountered fluid and electrolyte abnormalities in clinical medicine. Patients with disorders of potassium metabolism may be asymptomatic or they may have symptoms ranging from mild weakness to sudden death. An abnormal serum potassium level once verified should be promptly addressed, but inappropriate treatment can worsen symptoms and even lead to death.

NORMAL PHYSIOLOGY OF POTASSIUM METABOLISM

Potassium Intake

Potassium is essential for many cellular functions, is present in most foods, and is excreted primarily by the kidney. The typical Western diet provides about 70 mmol of potassium daily, even though the recommended intake for people with normal renal function is closer to 120 mmol per day.[1] The gastrointestinal (GI) tract efficiently absorbs potassium, and total dietary potassium intake depends on the composition of the diet. Table 9.1 shows the potassium content of several foods high in potassium.

Potassium Distribution

After absorption from the GI tract, potassium distributes rapidly into the extracellular fluid (ECF) and intracellular fluid (ICF) compartments. Cellular potassium uptake is rapid and limits the magnitude of changes in serum potassium concentration. Conversely, during states of potassium loss, shift of potassium from intracellular to extracellular compartments limits the change in extracellular potassium concentration.

Unlike many other ions in the ECF, the majority of total body potassium is intracellular. Potassium is the major intracellular cation, with cytosolic K^+ concentrations about 100 to 120 mmol/l. Total intracellular K^+ content is 3000 to 3500 mmol in healthy adults and is found primarily in muscle (70%), with a lesser amount in bone, red blood cells, liver, and skin (Table 9.2). Only 1% to 2% of total body potassium is present in the ECF. The electrogenic sodium pump, Na^+,K^+-ATPase, is the primary effector of this asymmetric potassium distribution; it transports two potassium ions into cells in exchange for extrusion of three sodium ions, which results in high intracellular potassium concentration (high $[K^+_i]$) and low intracellular sodium concentration (low $[Na^+_i]$). Potassium-selective ion channels are the predominant determinant of the resting membrane potential. Therefore the intracellular-to-extracellular $[K^+]$ ratio largely determines the resting cell membrane potential and the intracellular electronegativity. Normal maintenance of this ratio and membrane potential is critical for normal nerve conduction and muscular contraction.

Under some conditions, the normal distribution of potassium between the extracellular and intracellular pools is altered (Fig. 9.1). Causes of these potassium shifts include acid-base disorders, several hormones, plasma osmolality, and exercise. Because the amount of extracellular K^+, relative to intracellular K^+, is low, modest movements of K^+ into or out of the extracellular pool can result in substantial changes in extracellular K^+ concentration.

Metabolic acidosis is frequently associated with abnormal serum potassium. Acidosis caused by inorganic anions (e.g., NH_4Cl, HCl) can cause hyperkalemia, but the mechanism is not fully understood, and changes in renal potassium excretion are often not observed. In contrast, organic acids (e.g., lactic acid) generally do not cause transcellular potassium shifts. Although hyperkalemia may be seen with lactic acidosis, it is more likely related to tissue ischemia leading to cellular death and subsequent release of cytoplasmic K^+ into extracellular fluid compartments. In type 4 (hyperkalemic) renal tubular acidosis (RTA), hyperkalemia may contribute to the metabolic acidosis by inhibiting net acid excretion in the form of ammonia.[2]

Several hormones, most prominently catecholamines, insulin, and aldosterone, have important roles in regulating serum K^+. The effect of catecholamines differs depending on which adrenergic receptor subtype they activate. Activation of β_2-adrenergic receptors stimulates Na^+,K^+-ATPase, inducing cellular potassium uptake and decreasing serum K^+, whereas α_1-adrenergic receptor activation has the opposite effect. Thus drugs that block the β_2-adrenoreceptor tend to increase serum K^+ and those that block the α_1-adrenoreceptor tend to lower serum K^+.

Insulin has important effects on serum K^+. It activates Na^+,K^+-ATPase, directly increasing cellular K^+ uptake and decreasing serum K^+. This effect is rapid and enables insulin administration to be a component of the acute therapy of hyperkalemia. Importantly, insulin stimulates Na^+,K^+-ATPase through a mechanism that is distinct from its stimulation of glucose entry and does not involve effects on either α- or β-adrenoreceptors. Thus the effects of insulin and β_2-adrenoceptor activation are synergistic. In diabetic ketoacidosis, the lack of insulin-induced cellular K^+ uptake contributes to the hyperkalemia that is often observed in this condition.

Aldosterone regulates serum potassium at least in part by altering the distribution of potassium between ECF and ICF. It does so predominantly by enhancing cellular potassium uptake through stimulation of Na^+,K^+-ATPase.[3] Indeed, aldosterone administration can cause hypokalemia in the absence of altered renal potassium excretion through mechanisms involving altered cellular K^+ distribution.[3,4]

Serum osmolality is another important factor that alters cellular potassium distribution. Hyperosmolality can cause hyperkalemia when the result of "effective osmoles," such as mannitol, or hyperglycemia. The likely mechanism is that increased serum osmolality induces water movement out of the cells, decreasing cell volume and increasing intracellular $[K^+]$. This in turn causes stimulation of K^+-permeable cation

TABLE 9.1 Amount of Potassium (K^+) in Select Foods With High K^+ Content

Food	Portion Size	K^+ (mmol)
Artichoke, boiled	1, medium	27
Avocado	1, medium	38
Sirloin steak	8 oz	23
Hamburger, lean	8 oz	18
Cantaloupe, cut up	1 cup	13
Grapefruit juice	8 oz	10
Milk	8 oz	10
Orange juice	8 oz	12
Potato, baked	7 oz	22
Prunes	10	16
Raisins	2/3 cup	19
Squash	1 cup	15-20
Tomato paste	½ cup	31
Tomato juice	6 oz	10
Banana	Medium size	12

Data from reference 43. 1 oz = 28.4 gram.

TABLE 9.2 Distribution of Total Body Potassium in Organs and Body Compartments

Organ/Fluid	Total K^+ Amount	Body Compartment	K^+ Concentration
Muscle	2650 mmol	Intracellular fluid (ICF)	100-120 mmol/l
Liver	250 mmol	Extracellular fluid (ECF)	~4 mmol/l
Interstitial fluid	35 mmol	—	—
Red blood cells	350 mmol	—	—
Plasma	15 mmol	—	—

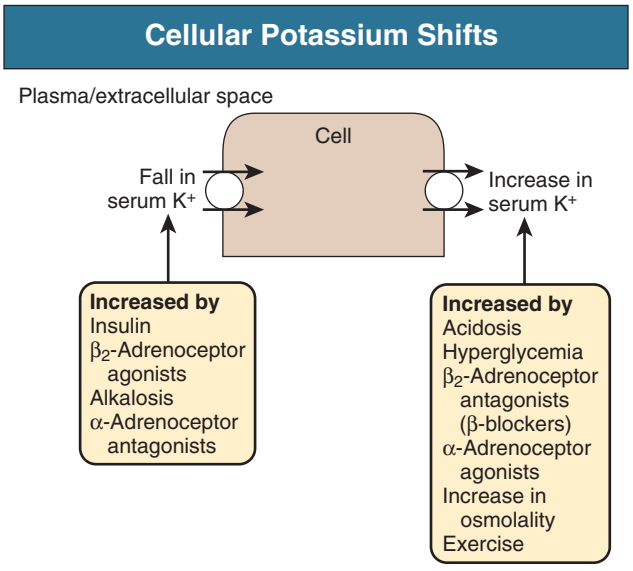

Fig. 9.1 Regulation of extracellular/intracellular potassium shifts.

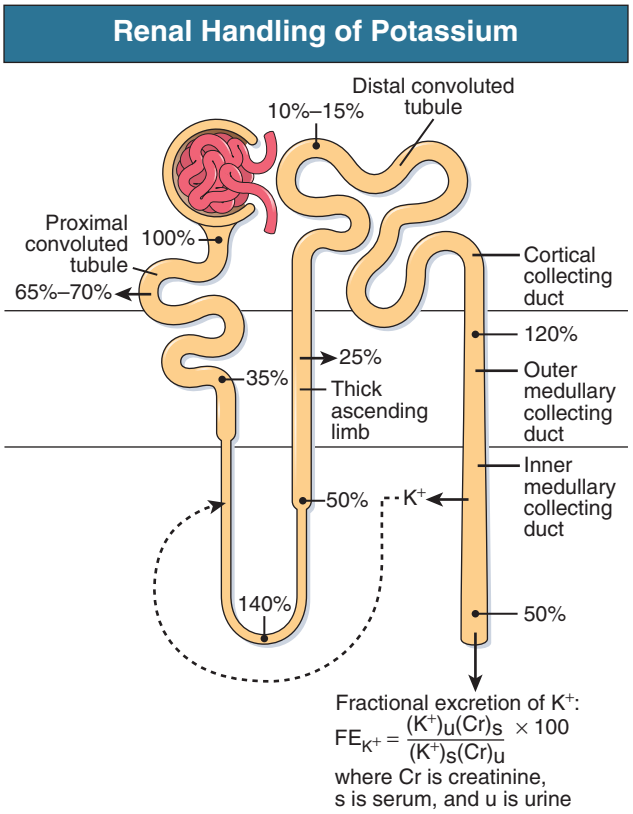

Fig. 9.2 Renal handling of potassium.

channels, increasing transport of K^+ out of cells and normalizing intracellular $[K^+]$. Both glucose in patients with intact insulin secretion and urea in patients with high blood urea nitrogen levels are "ineffective osmoles" because they rapidly cross plasma membranes, do not alter cell volume, and do not alter transcellular K^+ shifts. Administering a glucose load to a nondiabetic patient, because it stimulates insulin secretion, can stimulate insulin-induced cellular potassium uptake and decrease serum K^+.

Exercise has multiple effects on K^+. Cellular K^+ release is a critical component of repolarization of contracting skeletal muscle cells and can cause mild hyperkalemia during strenuous physical exercise. Catecholamines released during exercise can contribute to this hyperkalemia because α_1-adrenergic receptor activation shifts potassium out of cells. The local increase in extracellular potassium induces arterial dilation in normal blood vessels, which increases skeletal muscle blood flow and acts as an adaptive mechanism during exercise. Catecholamines released during exercise also activate β_2-adrenoceptors, which stimulates skeletal muscle cellular potassium uptake and minimizes the severity of exercise-induced hyperkalemia, but can also lead to hypokalemia after cessation of exercise. With preexisting potassium depletion, postexercise hypokalemia may be severe and can cause rhabdomyolysis.[5]

Renal Potassium Handling With Normal Renal Function

Long-term potassium homeostasis occurs primarily through changes in renal potassium excretion. Serum potassium is almost completely ionized, is not bound to plasma proteins, and is filtered efficiently by the glomerulus (Fig. 9.2). The proximal tubule reabsorbs the majority (~65% to 70%) of filtered potassium, but there is relatively little variation in proximal tubule potassium reabsorption in response to hypokalemia or hyperkalemia. In the loop of Henle, potassium is secreted in the descending loop, at least in deep nephrons, particularly with

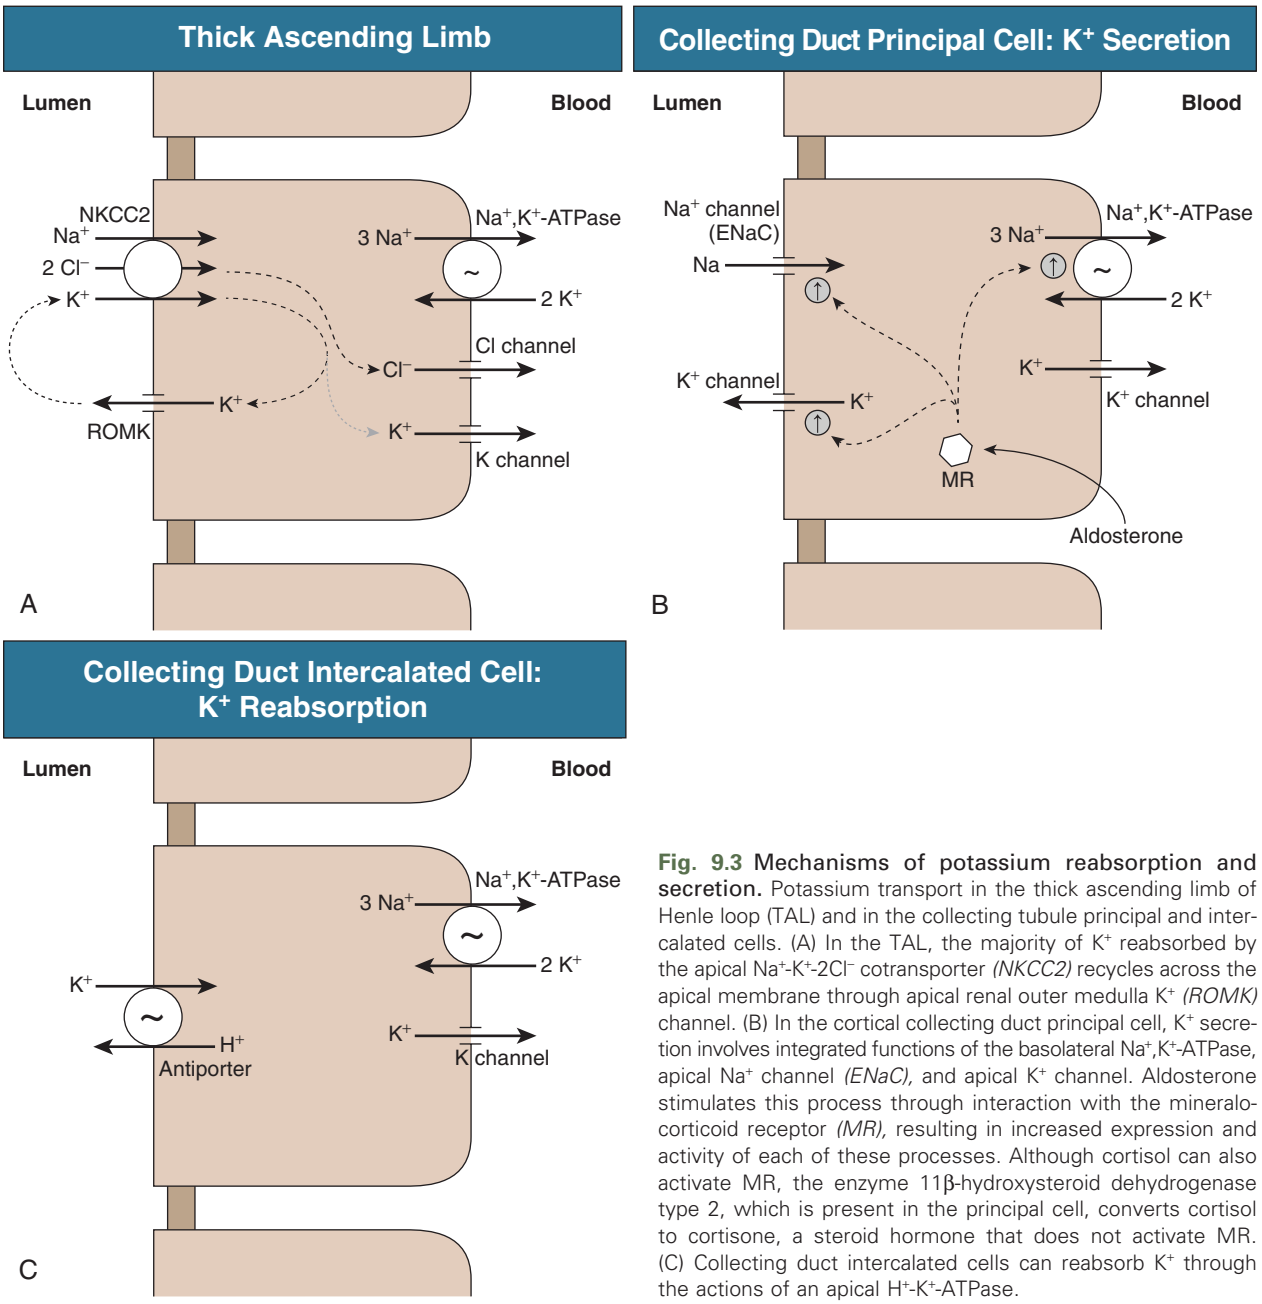

Fig. 9.3 Mechanisms of potassium reabsorption and secretion. Potassium transport in the thick ascending limb of Henle loop (TAL) and in the collecting tubule principal and intercalated cells. (A) In the TAL, the majority of K^+ reabsorbed by the apical Na^+-K^+-$2Cl^-$ cotransporter *(NKCC2)* recycles across the apical membrane through apical renal outer medulla K^+ *(ROMK)* channel. (B) In the cortical collecting duct principal cell, K^+ secretion involves integrated functions of the basolateral Na^+,K^+-ATPase, apical Na^+ channel *(ENaC),* and apical K^+ channel. Aldosterone stimulates this process through interaction with the mineralocorticoid receptor *(MR),* resulting in increased expression and activity of each of these processes. Although cortisol can also activate MR, the enzyme 11β-hydroxysteroid dehydrogenase type 2, which is present in the principal cell, converts cortisol to cortisone, a steroid hormone that does not activate MR. (C) Collecting duct intercalated cells can reabsorb K^+ through the actions of an apical H^+-K^+-ATPase.

adaptation to a large K^+ intake, and is reabsorbed in the ascending loop through the action of the Na^+-K^+-$2Cl^-$ cotransporter (Fig. 9.3A). However, the majority of K^+ transported by this protein is recycled back into the tubular lumen through an apical K^+ channel. As a result, there is only modest net potassium reabsorption in the loop of Henle. This absorption can be reversed to secretion, however, by administration of a loop diuretic or substantial potassium loading. Nonetheless, the magnitude of the change in Henle loop potassium transport in various physiologic conditions is relatively small.

The collecting duct is the primary site at which the kidney regulates urinary K^+ excretion. The collecting duct has the ability both to secrete K^+, enabling adaptation to K^+ excess states, and to actively reabsorb K^+, enabling adaptation to K^+ depletion states. The principal cell, particularly in the cortical collecting duct, secretes potassium, whereas intercalated cells throughout the entire collecting duct reabsorb potassium. In the principal cell, sodium is reabsorbed through the apical epithelial sodium channel (ENaC), which stimulates basolateral Na^+,K^+-ATPase (Fig. 9.3B); active potassium uptake by this protein maintains a high intracellular K^+. Subsequent to basolateral potassium uptake, K^+ is secreted across the apical plasma membrane of principal cells into the luminal fluid by apical potassium channels and KCl cotransporters. Intercalated cells, in contrast, actively reabsorb potassium through an apical H^+-K^+-ATPase[6] (Fig. 9.3C); this protein actively secretes H^+ into the luminal fluid in exchange for reabsorption of luminal potassium. The presence of two separate potassium transport processes, secretion by principal cells and reabsorption by intercalated cells, contributes to rapid and effective regulation of renal potassium excretion.

Several factors influence principal cell potassium secretion. In relative order of importance these include luminal flow rate, distal sodium delivery, aldosterone, extracellular potassium intake, and extracellular

pH. Under conditions in which Na^+ delivery or luminal [Na^+] is drastically reduced, K^+ excretion falls precipitously due to decreased K^+ secretion. However, whether Na^+ delivery is normally rate limiting to K excretion in euvolemic subjects is an important area of investigation. An increase in luminal flow rate reduces changes in luminal [K^+] that would otherwise result from K^+ secretion, thereby minimizing changes in the concentration gradient across the apical membrane and facilitating continued K^+ transport. In addition, flow rate directly influences cellular potassium secretion by modulating the activity of potassium channels. Consequently, reduced luminal flow, such as occurs in pre-renal azotemia and obstruction, may contribute to the hyperkalemia that is often seen in these conditions. Decreased sodium reabsorption, whether from reduced luminal sodium delivery or treatment with sodium channel inhibitors, i.e., potassium-sparing diuretics, decreases K^+ secretion by altering electrochemical forces for K^+ secretion. Conversely, increased sodium delivery to the collecting duct, as may occur with either a high-salt diet or administration of either loop or thiazide diuretics, increases principal cell sodium reabsorption and causes a secondary increase in potassium secretion. Aldosterone has many effects that increase principal cell potassium secretion, including increased Na^+,K^+-ATPase, increased apical expression of ENaC, and increased apical K^+ channels. The net effect is increased principal cell-mediated K^+ secretion. Changes in extracellular potassium directly alter Na^+,K^+-ATPase activity, thereby altering increased K^+ secretion. Metabolic acidosis decreases K^+ secretion, both through direct effects on potassium channels and through changes in interstitial ammonia concentration, both of which decrease K^+ secretion.[7] Respiratory acidosis has minimal effect on K^+ secretion, whereas acute respiratory alkalosis can cause marked increases in K^+ excretion associated with increases in urinary bicarbonate excretion.

Intercalated cell-mediated potassium reabsorption occurs in parallel with principal cell-mediated potassium secretion. Active potassium reabsorption occurs through the action of the potassium-reabsorbing protein, H^+-K^+-ATPase. The major factors regulating H^+-K^+-ATPase expression and activity include potassium balance, aldosterone, and acid-base status. Potassium depletion increases H^+-K^+-ATPase expression, resulting in increased active potassium reabsorption and decreased net potassium excretion. Aldosterone increases H^+-K^+-ATPase expression and activity and, by decreasing net potassium excretion, may minimize changes in urinary potassium excretion during aldosterone excess that otherwise would lead to more severe hypokalemia. Metabolic acidosis has both direct and indirect effects, mediated through alterations in ammonia metabolism, that increase H^+-K^+-ATPase potassium reabsorption.[2]

Fundamental regulators of renal K^+ transport in the distal nephron include the "with no lysine" or "WNK" kinases.[8,9] WNK kinases activate Na^+ reabsorption in the distal convoluted tubule as well as inhibiting the renal outer medulla potassium (ROMK) channel. This combination of effects, increased DCT Na^+ reabsorption, which decreases collecting duct Na^+ delivery, in conjunction with decreased ROMK expression, promotes decreased K^+ secretion. Extracellular K alters intracellular Cl^- through direct effects on membrane voltage; the former appears to directly regulates WNK activity.[8,9] This results in hypokalemia activating and hyperkalemia inhibiting WNK activity. Medications targeting WNK inhibition are in development and may in the future enable entirely new treatments of hypertension and K^+ disorders.[10]

Finally, in the intestinal tract, gut or portal potassium sensors can elicit a rapid increase in renal potassium excretion through mechanisms independent of serum potassium and aldosterone.[3,11] This reflex system, which is still not understood fully, provides a mechanism to "sense" dietary potassium intake and alter renal potassium excretion before changes in serum potassium and without involving aldosterone concentration.

Renal Potassium Handling in Chronic Kidney Disease

Because the kidneys are the major route for elimination of potassium, as renal function declines the balance among dietary potassium intake, renal potassium excretion, and baseline serum potassium changes. In general, most patients with chronic kidney disease (CKD) are able to maintain their serum potassium in the normal range, although there is a graded increase in mean serum K^+ as the glomerular filtration rate (GFR) declines. The risk for developing hyperkalemia is increased in patients with stage IV CKD; patients with stage III CKD who have diabetes mellitus, tubulointerstitial disease, or receive certain drugs also are at increased risk.

Many of the medications used in the treatment of patients with CKD have important effects on potassium homeostasis. Common medications that predispose to hyperkalemia (Table 9.3) include agents that inhibit

TABLE 9.3 Classes of Drugs Associated With Hyperkalemia

Class	Mechanism	Representative Example(s)
Potassium-containing drugs	Increased potassium intake	KCl, PCN G, K citrate
β-Adrenergic receptor blockers (β-blockers)	Inhibit renin release	Propranolol, metoprolol, atenolol
Angiotensin-converting enzyme (ACE) inhibitors	Inhibit conversion of angiotensin I (Ang I) to Ang II	Captopril, lisinopril
Angiotensin receptor blockers (ARBs)	Inhibit activation of AT_1 receptor by Ang II	Losartan, valsartan, irbesartan
Direct renin inhibitors	Inhibit renin activity, leading to decreased Ang II production	Aliskiren
Heparin	Inhibit aldosterone synthase, rate-limiting enzyme for aldosterone synthesis	Heparin sodium
Aldosterone receptor antagonists	Block aldosterone receptor activation	Spironolactone, eplerenone
Potassium-sparing diuretics	Block collecting duct apical ENaC Na channel, decreasing gradient for K^+ secretion	Amiloride, triamterene; certain antibiotics, specifically trimethoprim and pentamidine
NSAIDs and COX-2 inhibitors	Inhibit prostaglandin stimulation of collecting duct K^+ secretion; inhibit renin release	Ibuprofen
Digitalis glycosides	Inhibit Na^+,K^+-ATPase necessary for collecting duct K^+ secretion and regulation of K^+ distribution into cells	Digoxin
Calcineurin inhibitors	Inhibit Na^+,K^+-ATPase necessary for collecting duct K^+ secretion	Cyclosporine, tacrolimus

COX-2, Cyclooxygenase; *ENaC,* amiloride-sensitive epithelial sodium channel; *NSAIDs,* nonsteroidal antiinflammatory drugs; *PCN G,* penicillin G.

the ENaC or renin-angiotensin-aldosterone system (RAAS), nonsteroidal antiinflammatory drugs (NSAIDs), and calcineurin inhibitors. Medications that can directly inhibit ENaC, such as amiloride, triamterene, trimethoprim, and pentamidine, may acutely reduce the rate of renal K^+ excretion and cause hyperkalemia. Drugs that inhibit the RAAS, such as mineralocorticoid receptor (MR) blockers, angiotensin receptor blockers (ARBs), angiotensin-converting enzyme (ACE) inhibitors, direct renin inhibitors, and heparin, have the potential to inhibit the action of aldosterone, which reduces renal clearance of K^+. Mineralocorticoid blockers are increasingly used in patients with congestive heart failure and refractory hypertension and have potential benefit to slow the progression of CKD. NSAIDs that inhibit prostaglandin synthesis and β-blockers that inhibit renin release and catecholamine action also can increase the risk for hyperkalemia. In contrast, both loop and thiazide diuretics increase renal K^+ excretion and predispose to hypokalemia.

Patients with CKD generally tolerate hyperkalemia with fewer cardiac and electrocardiographic (ECG) abnormalities than do patients with normal renal function. The mechanism of this adaptation is incompletely understood. In particular, patients with CKD appear to tolerate serum $[K^+]$ of 5.0 to 5.5 mmol/l with no significant adverse effect, and levels of 5.5 to 6.0 mmol/l are associated with lower mortality than $[K^+]$ of 3.5 to 3.9 mmol/l.[12] Nevertheless, severe hyperkalemia (>6.0 mmol/l or presence of ECG changes) can have lethal effects and should be treated aggressively.

HYPOKALEMIA

Epidemiology

The incidence of potassium disorders depends greatly on the patient population. Less than 1% of adults with normal renal function who are not receiving medications develop hypokalemia or hyperkalemia; however, diets with high sodium and low potassium content may lead to potassium depletion. Thus identification of hypokalemia or hyperkalemia suggests either that an underlying disease is present or that the individual is taking drugs that alter potassium handling. For example, hypokalemia may be present in as many as half of patients taking diuretics[13] and is present in many patients with primary or secondary hyperaldosteronism.

Clinical Manifestations

Potassium deficiency, because it alters the ratio of extracellular to intracellular potassium, alters the resting membrane potential, which can impair normal functioning of almost every cell in the body. Several studies have shown that hypokalemia, even when mild, is associated with increased long-term mortality. Overall, children and young adults tolerate hypokalemia better than elderly persons. Prompt correction is warranted in patients with coronary heart disease or in patients receiving digitalis glycosides, because hypokalemia increases the risk for lethal cardiac arrhythmias.

Cardiovascular

Potassium deficiency affects blood pressure and increases sensitivity to cardiac arrhythmias. Epidemiologic studies link hypokalemia and a low-potassium diet with an increased prevalence of hypertension, and experimental studies show that hypokalemia increases blood pressure by 5 to 10 mm Hg and that potassium supplementation can lower blood pressure by a similar amount.[14] Potassium deficiency also increases the magnitude of salt-dependent changes in blood pressure. Potassium deficiency increases blood pressure through multiple mechanisms, including stimulating sodium retention and increasing intravascular volume, and by sensitizing the vasculature to endogenous vasoconstrictors.[14] In part, sodium retention is related to decreased expression of the kidney-specific isoform of WNK1, which leads to increased NaCl cotransporter (NCC)–mediated and ENaC-mediated sodium reabsorption in the distal convoluted tubule and cortical collecting duct, respectively.[15]

Hypokalemia also predisposes to arrhythmia, including ventricular tachycardia and ventricular fibrillation[16] and the risk for sudden cardiac death. Diuretic-induced hypokalemia is of particular concern, because sudden cardiac death may occur more frequently in those treated with thiazide diuretics.[16] Ventricular arrhythmias are also more common in patients receiving digoxin who develop hypokalemia.

Hormonal

Hypokalemia impairs insulin release and induces insulin resistance, resulting in worsened glucose control in patients with diabetes.[17] The insulin resistance that usually occurs with thiazide diuretic therapy is caused by endothelial dysfunction mediated by thiazide-induced hypokalemia and hyperuricemia.[18]

Muscular

Hypokalemia can lead to skeletal muscle weakness and increased sensitivity to developing exertion-related rhabdomyolysis. Hypokalemia hyperpolarizes skeletal muscle cells, thereby impairing the ability to generate the action potential needed for muscle contraction. Hypokalemia also reduces skeletal muscle blood flow, possibly by impairing local nitric oxide release; this effect can predispose patients to rhabdomyolysis during vigorous exercise.[19]

Renal

Hypokalemia leads to several important disturbances of renal function. Reduced medullary blood flow and increased renal vascular resistance may predispose to hypertension, tubulointerstitial and cystic changes, alterations in acid-base balance, and impairment of renal concentrating mechanisms.

Potassium depletion causes tubulointerstitial fibrosis that is generally greatest in the outer medulla. The degree of reversibility is related to the duration of hypokalemia, and, if prolonged, hypokalemia may result in renal failure. Experimental studies suggest an increased risk for irreversible renal injury when hypokalemia is present during the neonatal period.[20]

Long-standing potassium depletion also causes renal hypertrophy and predisposes to renal cyst formation, particularly when there is increased mineralocorticoid activity.

Metabolic alkalosis is a common acid-base consequence of potassium depletion and results primarily from increased renal net acid excretion caused by increased renal ammonia excretion.[21] Conversely, metabolic alkalosis may increase renal potassium excretion and cause potassium depletion. Severe hypokalemia can lead to respiratory muscle weakness and development of respiratory acidosis, and, if severe, respiratory failure.

Severe hypokalemia can cause mild polyuria, typically 2 to 3 l/day. Both increased thirst and mild nephrogenic diabetes insipidus contribute to the polyuria.[22] The nephrogenic diabetes insipidus is caused by decreased expression of several proteins, such as the water transporter aquaporin 2 (AQP2) and the urea transporters UT-A1, UT-A3, and UT-B, which are involved in urine concentration and water reabsorption.

Hypokalemia substantially increases renal ammonia production. Some ammonia is excreted in the urine, increasing net acid excretion and leading to development of metabolic alkalosis. In addition, approximately half of this increase returns to the systemic circulation via the renal veins. In patients with acute or chronic liver disease, this increased ammonia delivery may exceed hepatic ammonia clearance capacity,

increase plasma ammonia levels, and either precipitate or worsen hepatic encephalopathy.[2]

Etiology

Hypokalemia results typically from one of four causes: pseudohypokalemia, redistribution, extrarenal potassium loss, or renal potassium loss. However, multiple causes may coexist in a specific patient.

Pseudohypokalemia

Pseudohypokalemia refers to the condition in which serum potassium decreases, artifactually, after phlebotomy. The most common cause is acute leukemia; the large numbers of abnormal leukocytes take up potassium when the blood is stored in a collection vial for prolonged periods at room temperature. Rapid separation of plasma and storage at 4° C is used to confirm this diagnosis and should be used for subsequent testing once pseudohypokalemia is diagnosed, to avoid this artifact leading to inappropriate treatment.

Redistribution

Because less than 2% of total body potassium is in the ECF compartment, quantitatively small potassium shifts from the ECF to the ICF compartment can cause substantial hypokalemia. A chronic increase in aldosterone secretion increases the pump-leak kinetics and reduces plasma K^+ in the absence of perceptible increases in urinary K^+ excretion if intake is constant.

A rare, but important, cause of redistribution-induced hypokalemia is hypokalemic periodic paralysis. In this condition, attacks characterized by flaccid paralysis or severe muscular weakness occur typically during the night or the early morning or after a carbohydrate-rich meal, and persist for 6 to 24 hours. A genetic defect in a dihydropyridine-sensitive calcium channel has been identified in some patients, whereas other cases are associated with hyperthyroidism.

Nonrenal Potassium Loss

The skin and the GI tract excrete small amounts of potassium under normal circumstances. Occasionally, excessive sweating or chronic diarrhea results in substantial potassium loss and leads to hypokalemia.[23] Vomiting or nasogastric suction also may result in loss of potassium, although gastric fluids typically contain only 5 to 8 mmol/l of potassium. The concomitant metabolic alkalosis, however, can increase urinary potassium loss and contribute to development of hypokalemia.[24]

Renal Potassium Loss

The most common cause of hypokalemia is renal potassium loss, which typically results from drugs, endogenous hormone production, or, more rarely, intrinsic renal defects.

Drugs. Both thiazide and loop diuretics increase urinary potassium excretion, and the incidence of diuretic-induced hypokalemia is related to both dose and treatment duration. When loop and thiazide diuretics are dosed to produce similar effects on sodium excretion, thiazide diuretics have greater effects on urinary potassium and are more likely to lead to hypokalemia. Some penicillin analogues, such as piperacillin/tazobactam, increase distal tubular delivery of a nonreabsorbable anion, which obligates the presence of a cation such as potassium, and increases urinary potassium excretion.[25] The antifungal agent amphotericin B directly increases collecting duct potassium secretion. Aminoglycosides may cause hypokalemia either with or without simultaneous nephrotoxicity. The mechanism is incompletely understood but may relate to magnesium depletion (see later discussion). Cisplatin is an antineoplastic agent that can induce hypokalemia from renal potassium wasting; the increased potassium excretion may persist after discontinuation of the medication. Toluene exposure, from sniffing certain glues, also can cause RTA with renal potassium wasting, leading to hypokalemia.[26] In addition, certain herbal products, including herbal cough mixtures, licorice tea, licorice root, and *gan cao,* contain glycyrrhizic and glycyrrhetinic acids, which have mineralocorticoid-like effects.[27]

Endogenous hormones. Aldosterone is an important hormone regulating total body potassium homeostasis. Aldosterone predominantly causes hypokalemia by stimulating cellular potassium uptake.[3] Aldosterone also has direct effects to increase both collecting duct potassium secretion and reabsorption. During states of chronic aldosterone excess, urinary potassium excretion may not appropriately decrease despite the presence of low serum potassium, thus contributing to the maintenance of hypokalemia (see Chapter 38).

Genetic causes. Genetic defects leading to excessive aldosterone production are occasionally seen that result in hypokalemia (see Chapter 47). These include glucocorticoid-remediable aldosteronism, congenital adrenal hyperplasia, *and* apparent mineralocorticoid excess. These conditions are discussed in detail in Chapter 47.

Magnesium depletion. Magnesium deficiency can cause inappropriately high renal potassium excretion despite hypokalemia.[28] This appears to occur because intracellular magnesium inhibits the apical ROMK channels critical for distal nephron K^+ secretion. In magnesium deficiency, decreased intracellular magnesium reduces the magnesium-mediated inhibition of ROMK channels, leading to increased ROMK-mediated K^+ secretion and thereby to increased net K^+ secretion.[29] Magnesium deficiency occurs most frequently as a complication of prolonged diuretic use and also can result from proton pump inhibitor drugs or aminoglycoside- or cisplatin-induced renal toxicity. Magnesium deficiency should be suspected when potassium replacement does not correct hypokalemia; treatment with magnesium replacement generally reverses the potassium wasting. Proton pump inhibitors should be discontinued.

Primary renal defect. Intrinsic renal potassium transport defects leading to hypokalemia are rare. They include Bartter and Gitelman syndromes, which have clinical phenotypes similar to those that follow use of loop and thiazide diuretics, respectively, and Liddle syndrome. These are discussed in Chapter 47.

Bicarbonaturia. Bicarbonaturia can result from metabolic alkalosis, distal RTA, or treatment of proximal RTA. In each case, the increased distal tubular bicarbonate delivery increases potassium secretion.

Diagnostic Evaluation

The evaluation of hypokalemia is summarized in Fig. 9.4. The clinician should first exclude pseudohypokalemia or potassium redistribution from the extracellular to the intracellular space. Insulin, aldosterone, fludrocortisone, and sympathomimetic agents such as theophylline and β_2-adrenoceptor agonists, are common causes of potassium redistribution. In the hypertensive patient, frank hypokalemia in the absence of diuretic use suggests primary aldosteronism.

If neither pseudohypokalemia nor potassium redistribution is present, hypokalemia represents total body potassium depletion caused by renal, GI, or skin losses. Renal potassium loss is caused most frequently by diuretics. Hypomagnesemia can also cause renal potassium wasting and is frequently a complication of diuretic use. Less common causes of renal potassium loss include proximal and distal RTA, diabetic ketoacidosis, and ureterosigmoidostomy. Primary aldosteronism, surreptitious diuretic use or vomiting, laxative abuse, concomitant magnesium depletion, and Bartter or Gitelman syndrome should be considered when the cause of the hypokalemia is not obvious. Excessive potassium loss also may result from skin losses from excessive sweating or from the GI tract from diarrhea, vomiting, nasogastric suction, or GI fistula. Occasionally, patients are reluctant to admit to self-induced diarrhea, and the diagnosis may need to be confirmed by direct testing of the stool for cathartic agents.

Treatment

Primary short-term risks of hypokalemia are cardiovascular arrhythmias and neuromuscular weakness. Overly rapid therapy can cause acute hyperkalemia, which can cause ventricular fibrillation and sudden death.

Conditions requiring urgent therapy are rare. The clearest indications include hypokalemic periodic paralysis, severe hypokalemia in a patient requiring urgent surgery, and the patient with an acute myocardial infarction and life-threatening ventricular ectopy. In these patients, potassium chloride (KCl) can be administered intravenously at a dose of 5 to 10 mmol over 15 to 20 minutes. This dose can be repeated as needed. Close and continuous monitoring of the serum [K^+] and the electrocardiogram are necessary to reduce the risk for potentially lethal acute hyperkalemia.

In the great majority of hypokalemic patients, emergency therapy is not necessary. The body responds to potassium losses by shifting potassium from ICF to ECF, thereby minimizing the change in extracellular [K^+]. During potassium replacement, there is shift of potassium back into ICF. Consequently, the amount of potassium replacement needed is much greater than predicted by the change in extracellular [K^+] and the ECF volume (Fig. 9.5).

Oral or enteral potassium administration is preferred if the patient can take oral medication and has normal GI tract function. Acute hyperkalemia is highly unusual when potassium is given orally. This reflects several factors, most prominently gut sensors that minimize changes in serum potassium levels. When potassium is given intravenously, acute hyperkalemia can occur if the administration rate is too rapid and can cause sudden cardiac death. Intravenous replacement can generally be given safely at a rate of 10 mmol KCl/h. If more rapid replacement is necessary, 20 or 40 mmol/h can be administered through a central venous catheter, but continuous ECG monitoring should be used under these circumstances.

The choice of the parenteral fluid, used to administer the potassium can affect the response. In patients without diabetes mellitus, dextrose leads to a reflex increase in serum insulin levels, which causes redistribution of potassium from ECF to ICF. As a result, administering KCl in dextrose-containing solutions, such as dextrose 5% in water (D5W), can stimulate cellular potassium uptake to an extent that it exceeds the

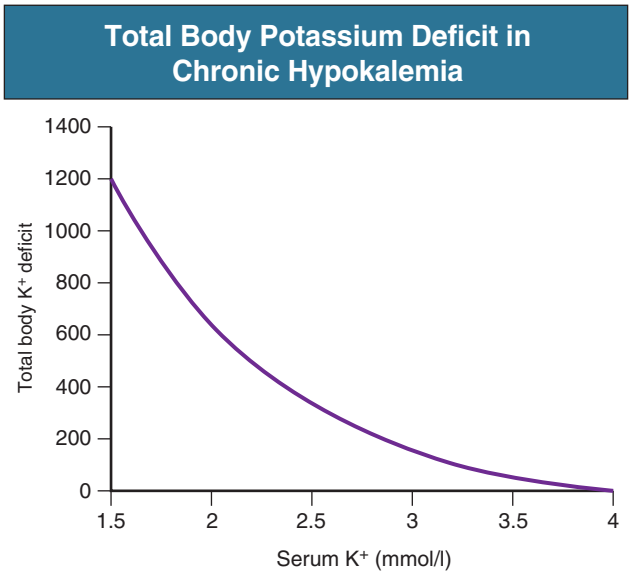

Fig. 9.5 Total body potassium deficit in hypokalemia. Because of shift of potassium from the intracellular fluid (ICF) to the extracellular fluid (ECF) compartment during chronic potassium depletion, the magnitude of deficiency can be masked and is generally much larger than would be calculated solely from the ECF volume and the change in serum potassium.

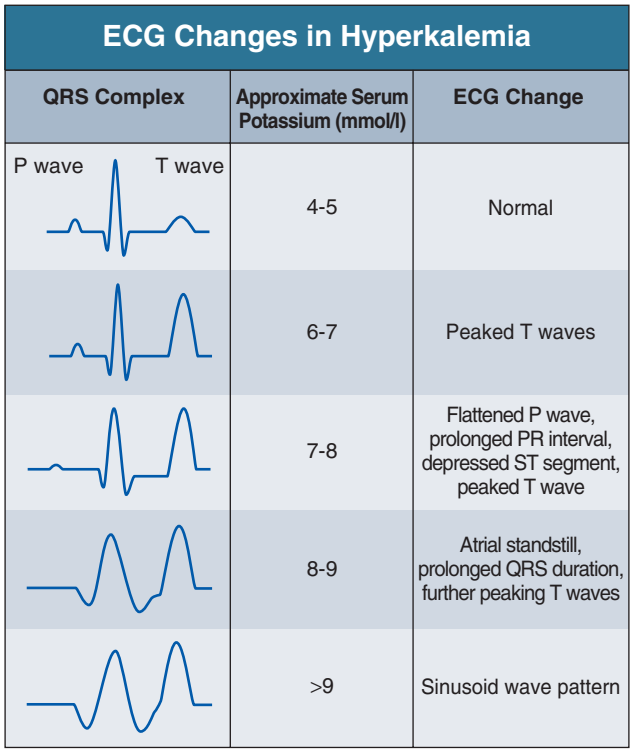

Fig. 9.6 Electrocardiographic (ECG) changes in hyperkalemia. Progressive hyperkalemia results in identifiable changes in the electrocardiogram. These include peaking of the T wave, flattening of the P wave, prolongation of the PR interval, depression of the ST segment, prolongation of the QRS complex, and eventually, progression to a sine wave pattern. Ventricular fibrillation may occur at any time during this ECG progression.

KCl replacement rate, resulting in paradoxical worsening of the hypokalemia.[30] Consequently, in the presence of hypokalemia, parenteral KCl should be administered in dextrose-free solutions.

The underlying condition should be treated whenever possible. If patients with diuretic-induced hypokalemia require ongoing diuretic administration, addition of potassium-sparing diuretics may be considered. When oral replacement therapy is required, KCl is the preferred drug in all patients, except those with metabolic acidosis, in whom potassium citrate may be considered a concomitant alkali source. If clinically indicated for other reasons, the use of β-blockers, ACE inhibitors, or ARBs can assist in maintaining serum potassium levels.

Hypomagnesemia can lead to refractoriness to potassium replacement because of inability of the kidneys to decrease potassium excretion.[28] Correction of the hypokalemia may not occur until the hypomagnesemia is corrected. Patients with unexplained hypokalemia or with diuretic-induced hypokalemia should have serum magnesium checked and, if indicated, magnesium replacement therapy instituted.

HYPERKALEMIA

Epidemiology

Hyperkalemia is distinctly unusual in healthy individuals with normal renal function not being treated with drugs that alter renal K^+ handling, with less than 1% of normal healthy adults developing hyperkalemia. This low frequency is a testament to the potent renal mechanisms for potassium excretion. Accordingly, the presence of chronic hyperkalemia, if not due to pseudohyperkalemia or redistribution, should strongly suggest impaired renal potassium excretion, whether from decreased nephron/collecting duct number, medications that decrease renal potassium excretion, or adrenal insufficiency.

Clinical Manifestations

Hyperkalemia can be asymptomatic, cause mild symptoms, or be life threatening. Importantly, the mortality risk of hyperkalemia is independent of the patient's clinical symptoms and reflects acute effects of hyperkalemia on cardiac conduction and repolarization. This is demonstrable on the electrocardiogram (Fig. 9.6). The initial effect of hyperkalemia is a generalized increase in the height of the T waves, most evident in the precordial leads, but typically present in all leads, which is known as "tenting." More severe hyperkalemia is associated with delayed electrical conduction, resulting in an increased PR interval and a widened QRS complex. This is followed by progressive flattening and eventual absence of the P waves. Under extreme conditions, the QRS complex widens sufficiently that it merges with the T wave, resulting in a sine-wave pattern. Finally, ventricular fibrillation develops. Although the ECG findings correlate generally with the degree of hyperkalemia, the rate of progression from mild to severe cardiac effects may be unpredictable and may not correlate well with changes in the serum potassium concentration. Chronic hyperkalemia is also associated with increased long-term mortality. This could reflect an increased predisposition to severe hyperkalemia with subsequent cardiac rhythm disturbances, other direct effects of chronic hyperkalemia, or a marker of more severe underlying disease that leads to the chronic hyperkalemia.

Hyperkalemia also has effects on noncardiac tissues. Skeletal muscle cells are particularly sensitive to hyperkalemia, causing generalized weakness. In patients with severe hyperkalemia, diaphragmatic muscle weakness may lead to respiratory failure.

Etiology

Hyperkalemia can result from pseudohyperkalemia, potassium redistribution from intracellular to extracellular space, or imbalances between

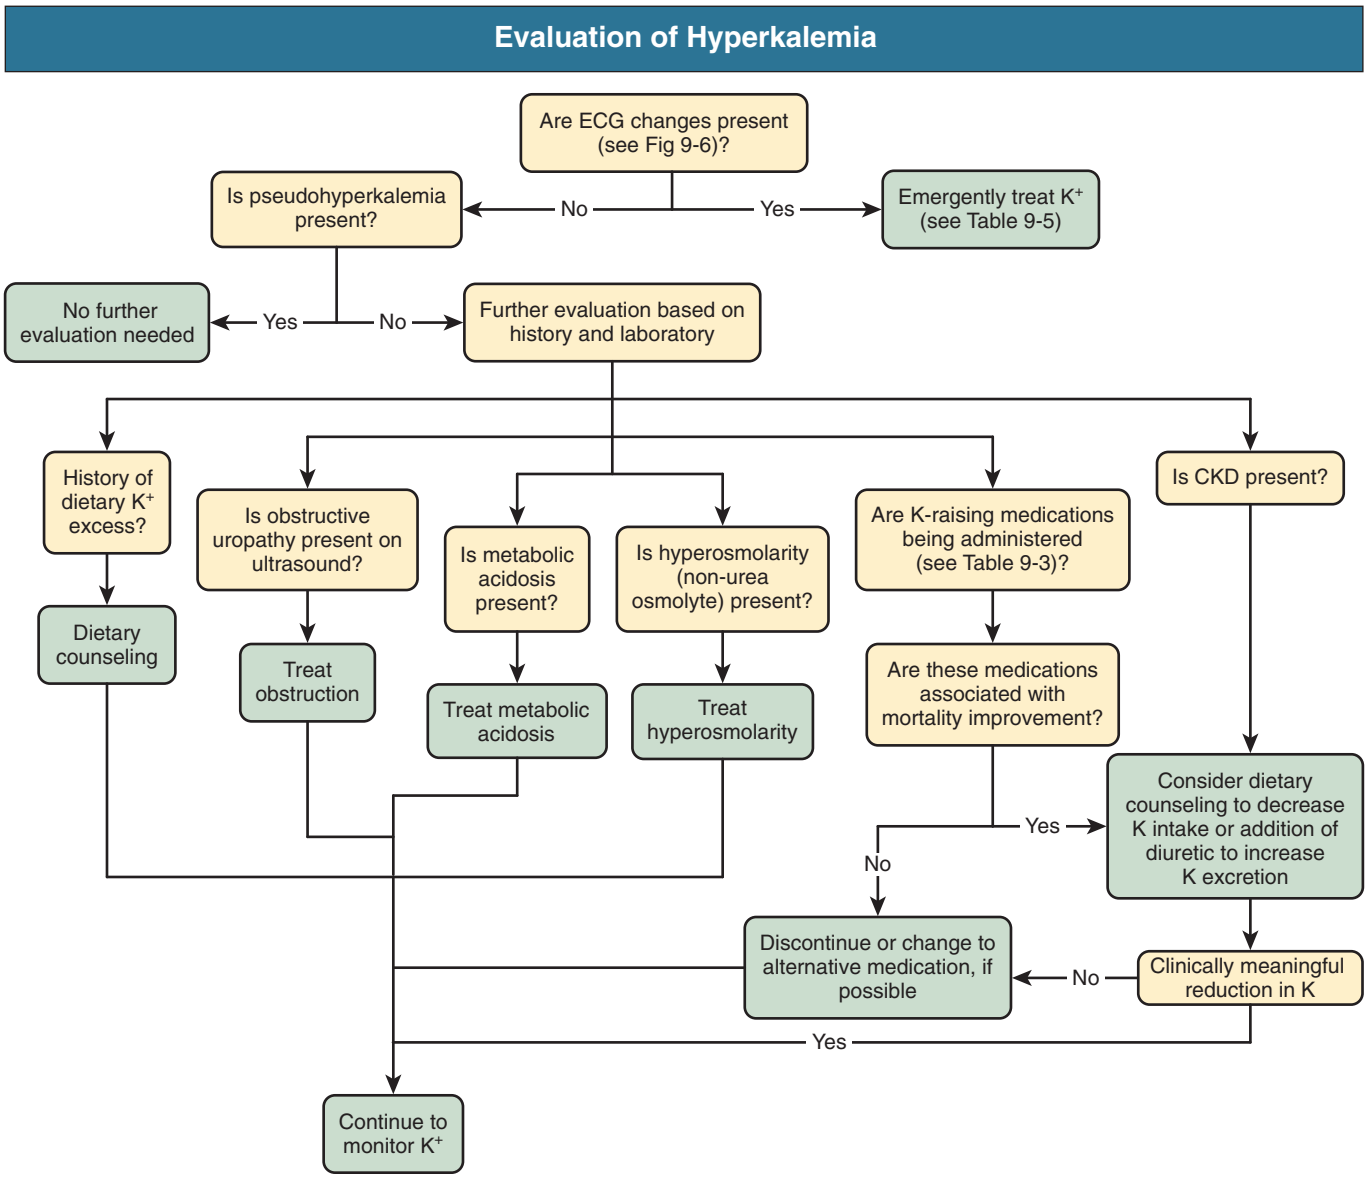

Fig. 9.7 Workup of hyperkalemia. *CKD,* Chronic kidney disease.

potassium intake and renal potassium excretion. A diagnostic approach is shown in Fig. 9.7.

Pseudohyperkalemia

Pseudohyperkalemia refers to the condition in which potassium release from blood cells occurs after the phlebotomy procedure. This most commonly results from damaged erythrocytes and is identified clinically by the presence of free hemoglobin in the plasma, reported as "hemolysis" by most clinical laboratories. If hemolysis is present, the reported serum $[K^+]$ measurement does not accurately reflect the actual serum $[K^+]$. Treatment should not be prescribed based on this value, and repeat measurement is necessary. Ischemia from prolonged tourniquet time or from exercise of the limb in the presence of a tourniquet also can lead to abnormally increased potassium values. Potassium can be released from the other cellular elements present in blood during clotting. This can occur in patients with severe leukocytosis (>70,000/cm^3) or thrombocytosis. About one third of patients with platelet counts of 500 to 1000 $\times$ 10^9/l exhibit pseudohyperkalemia.

Pseudohyperkalemia is diagnosed by showing that the serum $[K^+]$ is more than 0.3 mmol/l higher than in a simultaneous plasma sample. If not caused by hemolysis, future potassium levels may need to be measured in plasma samples to allow accurate measurement of extracellular $[K^+]$.

Redistribution

Redistribution of potassium from ICF to ECF may occur with severe hyperglycemia (from development of hyperosmolarity), during insulin deficiency, and with administration of drugs that alter cellular K^+ uptake, such as β_2-adrenoceptor blockers, ACE inhibitors, ARBs, and MR blockers. During diabetic ketoacidosis, both the hyperosmolarity that results from the hyperglycemia and the insulin deficiency contribute to transcellular K^+ shifts that are the primary cause of the often observed hyperkalemia. During treatment with insulin, resolution of both the hyperglycemia and resultant hyperosmolarity, and of the insulin deficiency, can lead to rapid stimulation of cellular potassium uptake, and a subsequent decrease in the serum potassium. In the patient with

diabetic ketoacidosis who presents with a normal serum potassium, potassium redistribution from the insulin deficiency and hyperglycemia-induced hyperosmolarity may be masking substantial total body potassium deficiency resulting from hyperglycemia-induced polyuria. In this case, severe hypokalemia may develop during insulin treatment. Close and careful management of serum potassium may be needed. Patients who have received mannitol also may develop hyperosmolarity-induced hyperkalemia. Digoxin overdose can block cellular potassium uptake and lead to hyperkalemia that requires rapid treatment.

Excess Intake

Excessive potassium ingestion generally does not lead to chronic hyperkalemia unless other contributing factors are present. Under normal conditions, the kidney has the capacity to excrete several multiples of the mean daily potassium intake. However, if renal potassium excretion is impaired, as from drugs, acute kidney injury (AKI), or CKD, excessive potassium intake can contribute to the development of hyperkalemia.

Common sources of excess potassium intake are potassium supplements, salt substitutes, enteral nutrition products, and several common foods. As many as 4% of patients receiving potassium supplements develop hyperkalemia. Salt substitutes contain an average of 10 to 13 mmol K/g. Many enteral nutrition products contain at least 40 mmol/l KCl; administration of 100 ml/h of such products can result in a potassium intake of about 100 mmol/day. Also, many food products are particularly high in potassium (see Table 9.1). In some countries, pharmacies routinely label medication bottles containing diuretics with recommendations to increase intake of high-potassium dietary sources such as bananas.

Impaired Renal Potassium Excretion

Chronic hyperkalemia typically involves a component of impaired renal potassium excretion. As discussed previously, renal potassium excretion is determined primarily by potassium secretion in the collecting duct. Typically, the number of collecting duct segments parallels GFR, and therefore most patients have impaired capacity to excrete potassium when GFR is decreased. In CKD, adaptive increases in the ability of each collecting duct segment to secrete potassium may allow renal potassium excretion to remain moderately well preserved until the GFR is reduced to 10 to 20 ml/min. Multiple drugs affect renal potassium secretion (see Table 9.3); these drugs are sometimes used in combination, which further exacerbates the risk for hyperkalemia in this patient population.

Obstructive uropathy leads frequently to hyperkalemia, at least in part from decreased Na^+,K^+-ATPase expression and activity. In many patients, hyperkalemia may persist for months or even years after relief of the obstruction.[31] This impairment appears to be related to a persistent defect in collecting duct K^+ secretion and not to aldosterone deficiency.[31]

Mineralocorticoid hormones are necessary for the normal response to hyperkalemia. Lack of these hormones both causes potassium redistribution from ICF to ECF and reduces the maximal ability of the kidneys to secrete potassium. Primary adrenal insufficiency should be strongly considered in the patient with chronic hyperkalemia and other clinical factors suggestive of adrenal insufficiency, particularly spontaneous hypotension and hyponatremia.

The colon can excrete potassium, but adaptive changes in enteric potassium excretion are quantitatively small and generally are not sufficient to maintain normal potassium homeostasis.

A rare genetic disorder, pseudohypoaldosteronism type 2 (PHA2; also known as Gordon syndrome) is characterized by hypertension, hyperkalemia, non–anion gap metabolic acidosis, and normal GFR[32]; it is discussed in Chapter 47.

Determining the Role of Excessive Potassium Intake in Chronic Hyperkalemia

In most patients, a careful history and measurement of K^+ in a 24-hour urine collection will identify the role of excessive dietary potassium intake in the development of chronic hyperkalemia. In selected patients, specifically those not using diuretics and either unable to be compliant with or preferring not to perform a 24-hour urine collection, assessment of the urine potassium-to-creatinine ratio in a random urine specimen may be used, with potassium excretion greater than 60 mmol K^+/g creatinine suggesting that excessive dietary K^+ intake contributes to the persistent hyperkalemia. However, urinary K^+ measurements may be difficult to interpret, because K^+ excretion depends on multiple factors, including GFR, tubule lumen flow, time of day, and water reabsorption in the distal tubule and collecting duct. If there is a clinical concern about possible hypoaldosteronism as a primary cause of the hyperkalemia, such as in a patient with concomitant normal or low blood pressure and hyponatremia, the transtubular K^+ gradient (TTKG), when considered in context with assessment of K^+ intake, can be helpful (Table 9.4).

Treatment

Acute Therapy

Acute therapies for hyperkalemia are divided into those that minimize the cardiac effects of hyperkalemia, those that induce potassium uptake by cells resulting in a decrease in serum potassium, and those that remove potassium from the body (Table 9.5). Treatment of hyperkalemia should not include sodium bicarbonate ($NaHCO_3$) therapy unless the

TABLE 9.4 Transtubular Potassium Gradient

Transtubular potassium gradient (TTKG) is a measurement of net K^+ secretion by the collecting duct after correcting for changes in urinary osmolality and is often used to determine whether hyperkalemia is caused by aldosterone deficiency/resistance or whether the hyperkalemia is secondary to nonrenal causes. As with all diagnostic aids, clinical correlation is indicated, and potassium intake should be assessed.

$$TTKG = \frac{[K^+]_U / [K^+]_S}{Osmo_U / Osmo_S}$$

Where $[K^+]_U$ and $[K^+]_S$ are the concentration of K^+ in urine and serum, respectively, and $Osmo_U$ $Osmo_S$ are the osmolality of urine and serum, respectively.

TTKG Value	Indication
6-12	Normal.
>10	Suggests normal aldosterone action and extrarenal cause of hyperkalemia.
<5-7	Suggests aldosterone deficiency or resistance.

PHA, Pseudohypoaldosteronism.
If TTKG remains >10 after 0.05 mg of 9α-fludroxortisone, hypoaldosteronism is likely. Suggests a renal tubule defect from either K^+-sparing diuretics (amiloride, triamterene, spironolactone), aldosterone resistance (interstitial renal disease, sickle cell disease, urinary tract. obstruction, PHA1), or increased distal K^+ reabsorption (PHA2, urinary tract obstruction).

TABLE 9.5 Acute Treatment of Hyperkalemia

Mechanism	Therapy	Dose	Onset	Duration
Antagonize membrane effects	Calcium	Calcium gluconate, 10% solution, 10 ml IV over 10 min	1-3 min	30-60 min
Cellular potassium uptake	Insulin	Regular insulin, 10 U IV, with dextrose 50%, 50 ml, if plasma glucose <250 mg/dl	30 min	4-6 hr
	β_2-Adrenergic agonist	Nebulized albuterol, 10 mg	30 min	2-4 hr
Potassium removal	Sodium polystyrene sulfonate or calcium polystyrene sulfonate (calcium resonium)*	30-60 g PO in 20% sorbitol *or* 30-60 g in water, per retention enema	1-2 hr	4-6 hr
	Hemodialysis	—	Immediate	Until dialysis completed

*A newer K-binding resin, patiromer, should not be used as an emergency treatment for life-threatening hyperkalemia because of its delayed onset of action.

patient is frankly acidotic (pH <7.2) or unless there is substantial endogenous renal function. Administering hypertonic $NaHCO_3$ (e.g., 50 mmol in 50 ml of sterile water) can worsen intravascular volume overload, as frequently seen in the patient with oliguric AKI, can cause acute hypernatremia, and can acutely increase serum potassium in the anephric patient.[33]

Blocking cardiac effects. Intravenous calcium administration does not produce changes in extracellular potassium but rapidly antagonizes the effects of hyperkalemia on the myocardial conduction system and on myocardial repolarization. Calcium should be given intravenously as the initial therapy if unambiguous ECG changes of hyperkalemia are present. If the electrocardiogram is ambiguous, comparison to a previous electrocardiogram may be helpful. Patients with a prolonged PR interval, a widened QRS complex, or the absence of P waves should receive intravenous calcium in the form of either calcium chloride or calcium gluconate without delay. Responses can occur within 1 to 3 minutes, but typically last for only 20 to 60 minutes. Doses may be repeated as needed if ECG changes persist or they recur. If a delay in more definitive therapy, such as institution of dialysis, is anticipated, a continuous calcium infusion can be used.

Intravenous calcium is relatively safe if certain precautions are taken. Intravenous calcium should not be administered in $NaHCO_3$-containing solutions because calcium carbonate ($CaCO_3$) precipitation can occur. Hypercalcemia, which occurs during rapid calcium infusion, can potentiate the myocardial toxicity of digoxin. Patients taking digoxin, particularly if they have evidence of digoxin toxicity as a contributing cause of hyperkalemia, should be given calcium as a slow infusion over 20 to 30 minutes.

Cellular potassium uptake. The second most rapid way to treat hyperkalemia is to stimulate cellular potassium uptake using either insulin or β_2-adrenergic agonist administration. Insulin rapidly stimulates cellular potassium uptake and should be administered intravenously to ensure rapid and predictable bioavailability. The effect of insulin on serum $[K^+]$ is seen generally within 10 to 20 minutes and can last for 4 to 6 hours. Glucose is generally coadministered to avoid hypoglycemia but may not be needed if hyperglycemia coexists. This is particularly important because extracellular glucose in patients with diabetes mellitus can function as an "ineffective osmole" and can increase serum potassium. Conversely, in patients with impaired renal function, there is delayed insulin clearance, and hypoglycemia can result from intravenous insulin administration, even if glucose is coadministered, because glucose uptake may occur more rapidly than insulin clearance. Accordingly, patients given intravenous insulin for treatment of hyperkalemia should be closely monitored for the development of hypoglycemia. If dialysis is indicated and a delay in its initiation is anticipated, administering a continuous infusion of insulin, 4 to 10 U/h (with 10% dextrose in water, D10W), may be beneficial; periodic monitoring of serum glucose and potassium is required.

β_2-Adrenoceptor agonists directly stimulate cellular potassium uptake and can be administered intravenously, subcutaneously, or by inhalation. However, β_2-agonist therapy frequently induces substantial tachycardia, and as many as 25% of patients do not respond to β_2-agonist therapy given by nebulizer.[34] A frequent mistake when administering nebulized β_2-adrenoceptor agonists is underdosage; the dose required is two to eight times that usually given for bronchodilation and is 50 to 100 times greater than the dose administered by metered dose inhalers.

Potassium removal. Most patients with persistent, severe hyperkalemia will benefit from K^+ removal from the ECF. Definitive treatment of these patients requires potassium elimination, through the kidneys, GI tract, or dialysis. Patients with chronic hyperkalemia may benefit from drugs that stimulate renal or stool K^+ excretion.

With chronic or mild hyperkalemia, loop or thiazide diuretics increase renal potassium excretion; this is particularly important for patients with hyperkalemic RTA (type 4 RTA), in whom the hyperkalemia is an important causative factor in the development of the metabolic acidosis.[35] With life-threatening hyperkalemia, diuretics are usually not effective because the rate of renal potassium excretion is usually inadequate and most patients will have renal impairment, which decreases the response to diuretic therapy. If a rapidly reversible cause of renal failure is identified (e.g., obstructive uropathy, or pre-renal azotemia and renal failure from volume depletion), treating the underlying condition may be sufficient therapy, along with close observation of serum potassium and continuous ECG monitoring.

A second mode of potassium elimination is with cation exchange resins such as sodium polystyrene sulfonate (Kayexalate) or calcium polystyrene sulfonate (calcium resonium). These resins exchange sodium or calcium, respectively, for potassium in the GI tract, enabling potassium elimination. They can be administered orally or as a retention enema. The rate of potassium removal is relatively slow, requiring about 4 hours for full effect, although administering the resin as a retention enema results in more rapid onset of action. When given orally, cation exchange resins are generally administered with 20% sorbitol to avoid constipation. If given as an enema, sorbitol should be avoided, because rectal administration of cation exchange resins with sorbitol may increase the risk for colonic perforation.[36] Questions have been raised recently as to the efficacy of these compounds and whether the risk for colonic perforation exceeds their benefits.[37] Two new enteric potassium-binding medications, patiromer and sodium zirconium silicate (ZS-9),[38,39] have

been developed. All testing of these was against placebo and not against the previously mentioned established agents. Moreover, their effectiveness in acute hyperkalemia associated with cardiac effects is currently unknown, and we are hesitant to recommend their use for this indication at present.

Acute hemodialysis is the primary method of potassium removal in AKI or advanced CKD, when hyperkalemia is life-threatening. Serum potassium can decrease as much as 1.2 to 1.5 mmol/h with a low-potassium (2 mmol/l) dialysate. In general, the more severe the hyperkalemia, the more rapid should be the reduction in serum potassium until K^+ is less than 6.0 mEq/L. However, care should be taken to avoid reducing the serum potassium too rapidly in patients with coronary heart disease or severe cardiac arrhythmias. In these patients, longer dialysis with dialysate potassium of 3 mmol/l allows serum potassium to equilibrate to that level. Continuous dialysis modalities, such as peritoneal dialysis and continuous venovenous hemodialysis, generally do not remove potassium sufficiently quickly for use in patients with life-threatening hyperkalemia, but may be justified under unusual circumstances in which hemodialysis is not available.

If dialysis is delayed, as when access to equipment or nursing support is not immediate, or while vascular access is established, other therapies should be instituted and continued until hemodialysis is begun.

Specific therapies are available for certain causes of hyperkalemia. For example, digoxin-specific Fab fragments are beneficial in patients with severe digitalis glycoside toxicity.[40] Hyperkalemia in patients with acute urinary tract obstruction may be treated by relieving the obstruction, but the rate of potassium excretion afterward is variable and frequent measurement of serum potassium is necessary.

Chronic Treatment

Management of chronic hyperkalemia is a common and often challenging problem, particularly in the patient with CKD. Patients with CKD have impaired capacity to excrete a potassium load rapidly and are often treated with many drugs, including ACE inhibitors, ARBs, β-blockers, and MR antagonists—all of which can cause hyperkalemia.

The optimal serum potassium level for patients with CKD and the serum potassium level that requires management may differ from the laboratory's report of the normal range of serum potassium. As noted previously, patients with CKD tolerate hyperkalemia with fewer cardiac side effects than do most patients with normal renal function. Recent studies have suggested that serum potassium levels of up to 5.5 mmol/l may be associated with optimal reduction of cardiovascular risk and that levels between 5.5 and 6.0 mmol/l are associated with only a minimal increase in risk.[12]

Although the majority of patients with chronic hyperkalemia are receiving medicines associated with the development of hyperkalemia, discontinuing all drugs that can cause hyperkalemia may not be the correct approach. Many medicines, such as ACE inhibitors, ARBs, β-blockers, and MR blockers, have significant benefits. Discontinuing these drugs simply because of mild hyperkalemia is therefore not recommended in first-line management. However, if the patient is receiving combined therapy with an ACE inhibitor and ARB, discontinuing one of these drugs may decrease the risk for further hyperkalemia, and this does not appear to be associated with adverse renal effects. Similarly, if a patient is receiving combination therapy of either an ACE inhibitor or an ARB with a direct renin inhibitor, such as aliskiren, the direct renin inhibitor may be discontinued.

Instead of immediately discontinuing such beneficial drugs without review, a careful assessment should be made for medicines that cause hyperkalemia but are not necessary for renoprotective or cardioprotective benefits and therefore can be discontinued, such as NSAIDs, cyclooxygenase-2 (COX-2) inhibitors, potassium-sparing diuretics (e.g., amiloride, triamterene), and oral KCl or potassium citrate supplementation. If hyperkalemia persists, addition of diuretics to increase renal potassium excretion can be considered. Thiazide diuretics may be preferred, because when adjusted for their effect on sodium excretion, thiazide diuretics are associated with a greater increase in renal potassium excretion than loop diuretics. In the patient with CKD, the thiazide diuretic metolazone may be effective.[41] Combination of thiazide and loop diuretics is more effective than either alone. Finally, screening for and treating metabolic acidosis may facilitate correction of the hyperkalemia. Alkali therapy also may increase K^+ clearance.

A dietary history should be obtained, and if the patient is ingesting a diet with potassium-rich foods, instruction on avoidance of these foods should be provided. However, routine instruction in a low-potassium diet for patients with CKD is not recommended. Recent studies have suggested that a diet higher in potassium-rich foods may be associated with slower progression of CKD.[42]

Finally, chronic therapy with drugs that increase enteric K^+ excretion can be considered. Intermittent administration of exchange resins, sodium polystyrene sulfonate (Kayexalate), or calcium polystyrene sulfonate (calcium resonium) may be helpful for selected patients with persistent hyperkalemia. This should be limited to intermittent use because of the risk for bowel infarction.

Two new drugs that increase enteric K^+ excretion have been developed: patiromer and sodium zirconium cyclosilicate (ZS-9).[38,39] Both appear to decrease serum K^+ within the first 24 hours of use, with few side-effects, with the exception of an increased risk for peripheral edema with high-dose ZS-9 and, if used long-term, can reduce the recurrence of hyperkalemia. Whether these drugs, if used on a chronic basis, will alter the long-term mortality associated with hyperkalemia is as yet undetermined. These drugs also may allow greater use of drugs that improve mortality in selected patient populations but whose use is otherwise limited because of development of hyperkalemia, for example, ACE inhibitors and ARB. Additional studies are required to examine long-term effects of these new drugs on mortality and other firm clinical end-points beyond changes in serum $[K^+]$.

Synthetic mineralocorticoid therapy, such as fludrocortisone, has been used for the treatment of chronic hyperkalemia. This approach may be helpful in patients with chronic hypotension secondary to adrenal insufficiency who have normal renal function. In patients with CKD, the accompanying renal sodium retention, intravascular volume expansion, and increased blood pressure are relative contraindications to synthetic mineralocorticoids. Furthermore, selective blockade of the MRs appears to decrease renal injury in several experimental models of renal injury, suggesting administration of synthetic mineralocorticoids may be injurious. As a result, their adverse effects may exceed their benefits in patients with CKD.

SELF-ASSESSMENT QUESTIONS

1. Deficiency of which of the following ions can result in renal potassium wasting?
   A. Phosphate
   B. Calcium
   C. Sulfate
   D. Magnesium
2. Which of the following drugs is *not* associated with development of hyperkalemia?
   A. Terazosin
   B. Propranolol
   C. Spironolactone
   D. Cyclosporine
3. Hypokalemia is associated with which of the following conditions?
   A. Decreased insulin sensitivity
   B. Increased renal interstitial fibrosis
   C. Increased risk for hepatic encephalopathy
   D. Polyuria
   E. All of the above

10

Disorders of Calcium, Phosphate, and Magnesium Metabolism

Bryan Kestenbaum, Pascal Houillier

CALCIUM HOMEOSTASIS AND DISORDERS OF CALCIUM METABOLISM

Distribution of Calcium in the Organism

Most (>99%) calcium is bound and associated with bony structures. Free calcium, either in diffusible (ultrafilterable) nonionized form or in ionized form (Ca^{2+}), is found in the intracellular fluid (ICF) and extracellular fluid (ECF) compartments. Similar to potassium, there is a steep concentration gradient between Ca^{2+} in the intracellular and extracellular compartments (Fig. 10.1).

The serum concentration of Ca^{2+} is tightly regulated within a narrow range by the actions of parathyroid hormone (PTH, parathormone) and calcitriol (1,25-dihydroxycholecalciferol). The physiologic role of other regulatory hormones, such as calcitonin, estrogens, and prolactin, in calcium homeostasis is less clear. Fig. 10.2 demonstrates the physiologic defense mechanisms used to counter changes in serum Ca^{2+} levels.[1] Circulating Ca^{2+} levels are also influenced by acid-base status, with acute alkalosis causing a decrease in serum Ca^{2+} and acute acidosis an increase in Ca^{2+}. Long-term maintenance of calcium homeostasis depends on (1) the adaptation of intestinal Ca^{2+} absorption to the needs of the organism, (2) the balance between bone accretion and resorption, and (3) urinary excretion of calcium (Fig. 10.3).

Intestinal, Skeletal, and Renal Handling of Calcium

Gastrointestinal (GI) calcium absorption is a selective process; only about 25% of total dietary calcium is absorbed under normal conditions. The proportion of calcium absorbed in the GI tract can fall precipitously in the setting of chronic kidney disease (CKD) due to decline in 1,25-dihydroxycholecalciferol synthesis. Ca^{2+} transport across the intestinal wall occurs in two directions: absorption and secretion. Absorption can be subdivided into transcellular and paracellular flow (Fig. 10.4). Transcellular calcium flux takes place through the apical transient receptor potential TRPV6 calcium channel.[2] Calcitriol is the most important hormonal regulatory factor for calcium absorption. After binding to and activating the vitamin D receptor (VDR), calcitriol increases active transport by inducing the expression of transient receptor potential channel vanilloid subtype 6 (TRPV6), calbindin-D_{9k}, and Ca^{2+}-ATPase (PMCA1b).[3] Other hormones, including estrogens, prolactin, growth hormone, and PTH, also stimulate Ca^{2+} absorption, either directly or indirectly. The amount of dietary calcium intake regulates the proportion of GI calcium absorption (Fig. 10.5).[5]

Cutaneous synthesis on exposure to ultraviolet (UV) light converts 7-dehydrocholesterol into cholecalciferol, which is also obtained through supplementation and diet; however, the cholecalciferol content of most foods is low. Cholecalciferol and ergocalciferol (which contains an additional methyl group) have minimal inherent biologic activity and require two hydroxylation steps for full hormonal activity. 25-Hydroxylation occurs in the liver and is thought to be non–rate limiting. Circulating 25-hydroxyvitamin D concentrations are widely accepted as a measure of vitamin D stores. Further hydroxylation to 1,25-dihydroxyvitamin D (calcitriol) occurs predominantly in the kidney, but can also occur in macrophages, parathyroid glands, and other tissues.

Increased calcium absorption is required in puberty and pregnancy, whereas in lactation, calcium is mostly obtained from maternal bone,[4] In puberty and pregnancy, calcitriol synthesis is increased to enhance GI calcium absorption. Intestinal Ca^{2+} absorption is also increased in states of vitamin D excess and acromegaly. Rarely, ingestion of calcium and alkali in large quantities can overwhelm GI checks on calcium absorption, resulting in hypercalcemia (milk-alkali syndrome). A decrease in intestinal Ca^{2+} transport occurs in advanced age, CKD, gastrectomy, intestinal malabsorption syndromes, diabetes mellitus, corticosteroid treatment, and estrogen deficiency and with dietary factors such as high vegetable fiber and fat content, low Ca^{2+}-to-phosphate ratio in food, and fructose ingestion. The decrease in Ca^{2+} absorption in older adults probably results from multiple factors in addition to lower serum calcitriol and intestinal VDR levels.[6]

The net balance between Ca^{2+} entry and exit is positive during skeletal growth in children, zero in young adults, and negative in the elderly. Exchangeable skeletal Ca^{2+} contributes to maintaining extracellular Ca^{2+} homeostasis. Several growth factors, hormones, and genetic factors participate in the differentiation from the mesenchymal precursor cell to the osteoblast and the maturation of the osteoclast from its granulocyte-macrophage precursor cell (Fig. 10.6). The regulation of bone formation and resorption involves many hormones, growth factors, and mechanical factors[7,8] (Fig. 10.7).

The kidneys play a major role in the minute-by-minute regulation of calcium, and the intestine, kidney, and skeleton ensure homeostasis in the mid and long term (Fig. 10.8).[9] Moreover, the kidney controls conversion of substrate 25-hydroxyvitamin D to calcitriol, which then regulates GI calcium absorption through the TRPV6 channel. Renal calcitriol production is stimulated by PTH and inhibited by fibroblast growth factor 23 (FGF-23) and perhaps hyperphosphatemia. The adjustment of blood Ca^{2+} is mainly achieved by modulation of tubular Ca^{2+} reabsorption, perfectly compensating minor increases or decreases in the filtered load of calcium, which is normally approximately 220 mmol (8800 mg) in 24 hours (see Fig. 10.3). In the proximal tubule, Ca^{2+} reabsorption follows the convective flow of salt and water, whereas the transport mechanisms are more complex in the distal segments.

States of excess volume delivery to the kidney, such as a high-sodium diet, diminish the concentration gradient between proximal tubule and

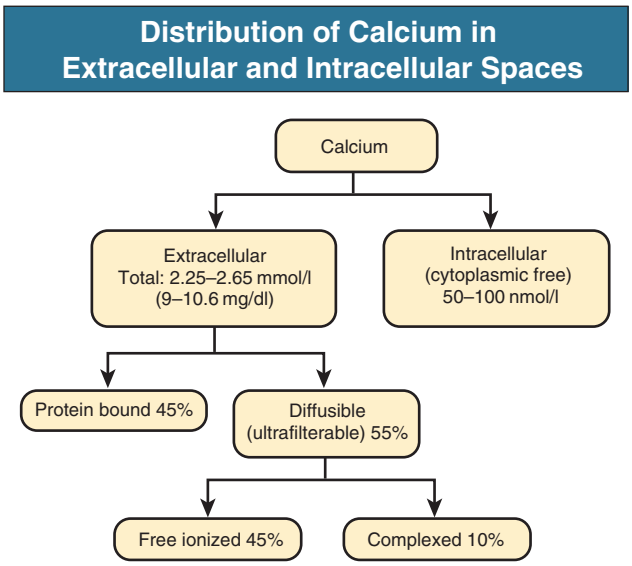

Fig.10.1 Calcium distribution in extracellular and intracellular spaces.

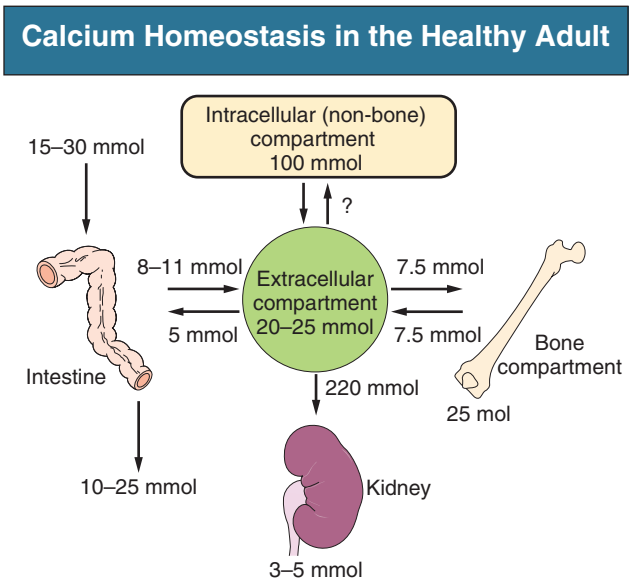

Fig.10.3 Calcium homeostasis in healthy adults. Net zero Ca^{2+} balance is the result of net intestinal absorption (absorption minus secretion) and urinary excretion, which by definition are the same. After its passage into the extracellular fluid, Ca^{2+} enters the extracellular space, is deposited in bone, or is eliminated via the kidneys. Entry and exit fluxes between the extracellular and intracellular spaces (skeletal and nonskeletal compartments) are also of identical magnitude under steady-state conditions.

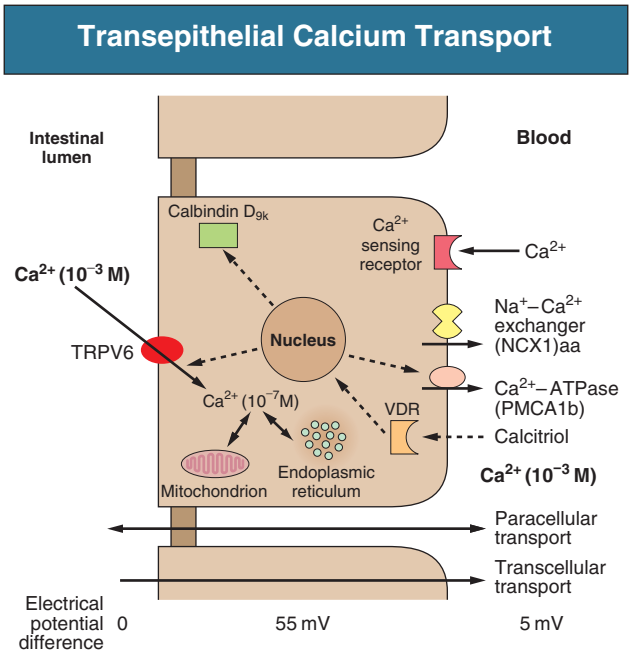

Fig.10.4 Transepithelial calcium transport in small intestine. Calcium penetrates into the enterocyte channels via a transient receptor potential calcium channel *(TRPV6)* through the brush border membrane along a favorable electrochemical gradient. Under physiologic conditions, the cation is pumped out of the cell at the basolateral side against a steep electrochemical gradient by the adenosine triphosphate–consuming pump Ca^{2+}-ATPase. When there is a major elevation of intracytoplasmic Ca^{2+}, the cation leaves the cell using the Na^+-Ca^{2+} exchanger. Passive Ca^{2+} influx as well as efflux is sensitive to calcitriol, which binds the vitamin D receptor *(VDR)*.

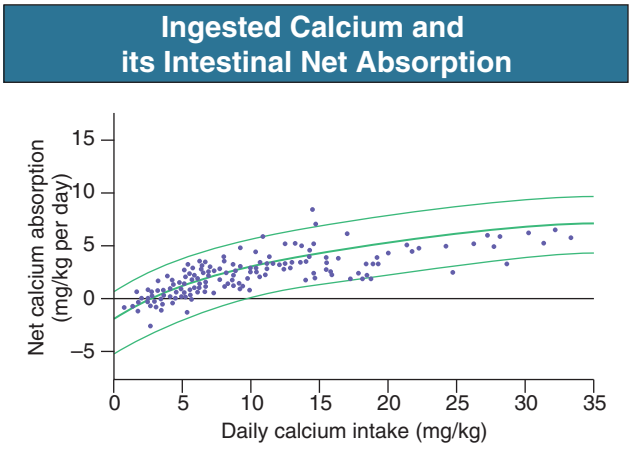

Fig.10.5 Calcium ingestion and absorption. Relationship between ingested calcium and its absorption in the intestinal tract (net) in healthy young adults. (From reference 5.)

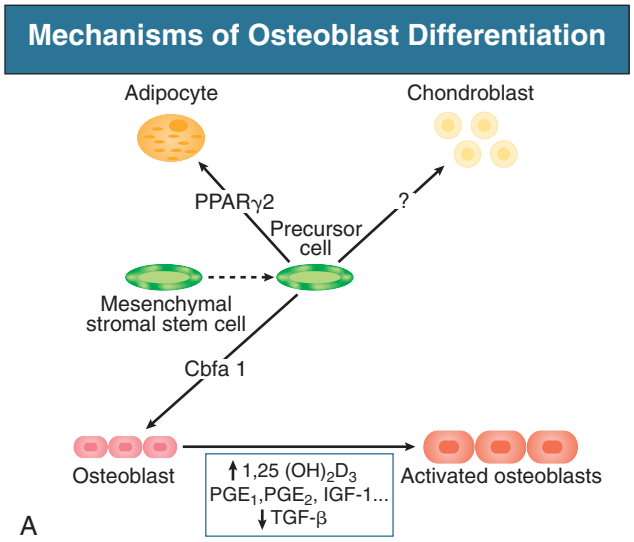

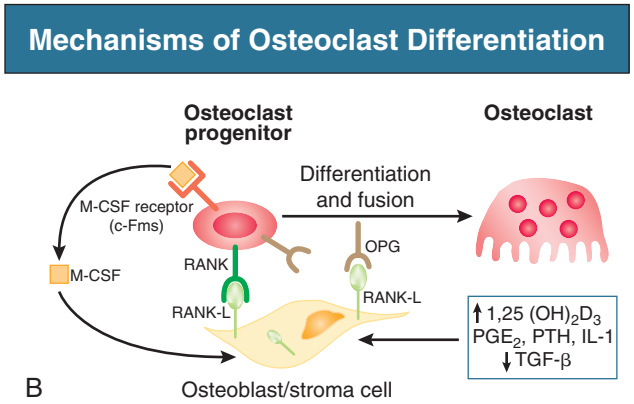

Fig.10.6 Mechanisms of osteoblast differentiation. (A) Major growth factors and hormones controlling the differentiation from the mesenchymal precursor cell to the osteoblast. (B) The major growth factors, cytokines, and hormones controlling osteoblast and osteoclast activity. *IGF,* Insulin-like growth factor; *IL,* interleukin; *M-CSF,* macrophage colony-stimulating factor; *OPG,* osteoprotegerin; *PGE_2,* prostaglandin E_2; *PPAR,* peroxisome proliferator–activated receptor; *PTH,* parathyroid hormone; *RANKL,* receptor activator of nuclear factor-κβ ligand; *TGF,* transforming growth factor.

peritubular capillary, reducing calcium absorption and increasing calcium in the urine. This mechanism likely plays a role in the pathogenesis of calcium-based kidney stones. On the other hand, volume depletion increases salt, water, and (by convection) calcium reabsorption in the proximal tubule, exacerbating states of hypercalcemia. For this reason, intravascular volume repletion is an essential component of the treatment for hypercalcemia. In the thick ascending limb (TAL) of the Henle loop, Ca^{2+} transport is linked with activity of the Na^+-K^+-$2Cl^-$ transporter. Stimulation of the Ca^{2+}-sensing receptor (CaSR) on the basolateral membrane decreases the permeability of the paracellular pathway to Ca^{2+}.[9] The result is decreased calcium reabsorption through Claudin-16 and -19 in the tight junction. In contrast, understimulation of CaSR because of lower serum calcium levels results in greater calcium reabsorption. In the distal tubule, active Ca^{2+} transport occurs via the transcellular route through the calcium transient receptor potential channel V5 (TRPV5) located in the apical membrane and coupled with a specific basolateral calcium-ATPase (PMCa1b) and a Na^+-Ca^{2+} exchanger (NCX1). Both PTH and calcitriol regulate distal tubular Ca^{2+} transport. The expression and role of CaSR in tubular segments other than TAL has recently been questioned.[10]

Numerous factors influence glomerular filtration and tubular Ca^{2+} reabsorption.[2,9,11,12] Elevated renal blood flow and glomerular filtration pressure (during ECF volume expansion) lead to an increase in the filtered calcium load, as do changes in the ultrafiltration coefficient K_f and an increase in glomerular surface. True (nonfactitious) hypercalcemia (see later discussion) also increases ultrafilterable calcium, whereas true hypocalcemia decreases it. PTH decreases glomerular K_f and thus reduces the ultrafiltered calcium load; PTH increases Ca^{2+} reabsorption

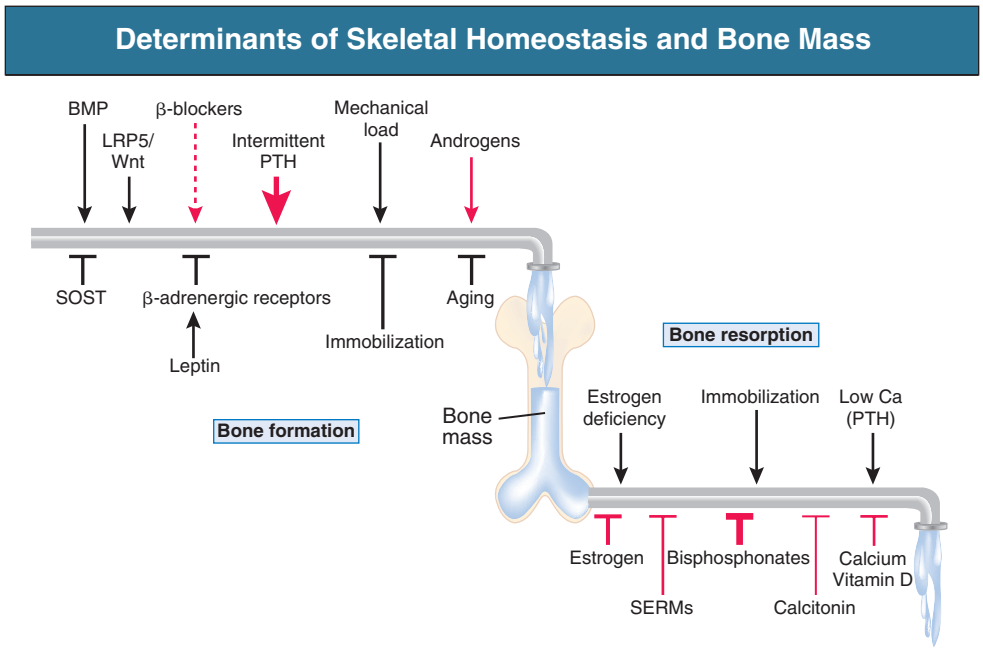

Fig.10.7 Determinants of skeletal homeostasis and bone mass. Physiologic *(black)* and pharmacologic *(red)* stimulators and inhibitors of bone formation and resorption are listed with the relative impact (represented by thickness of *arrows*). *BMP,* Bone morphogenetic protein; *LRP5,* low-density lipoprotein receptor–related protein 5; *PTH,* parathyroid protein; *SERMs,* selective estrogen receptor modulators; *SOST,* sclerostin. (From reference 7.)

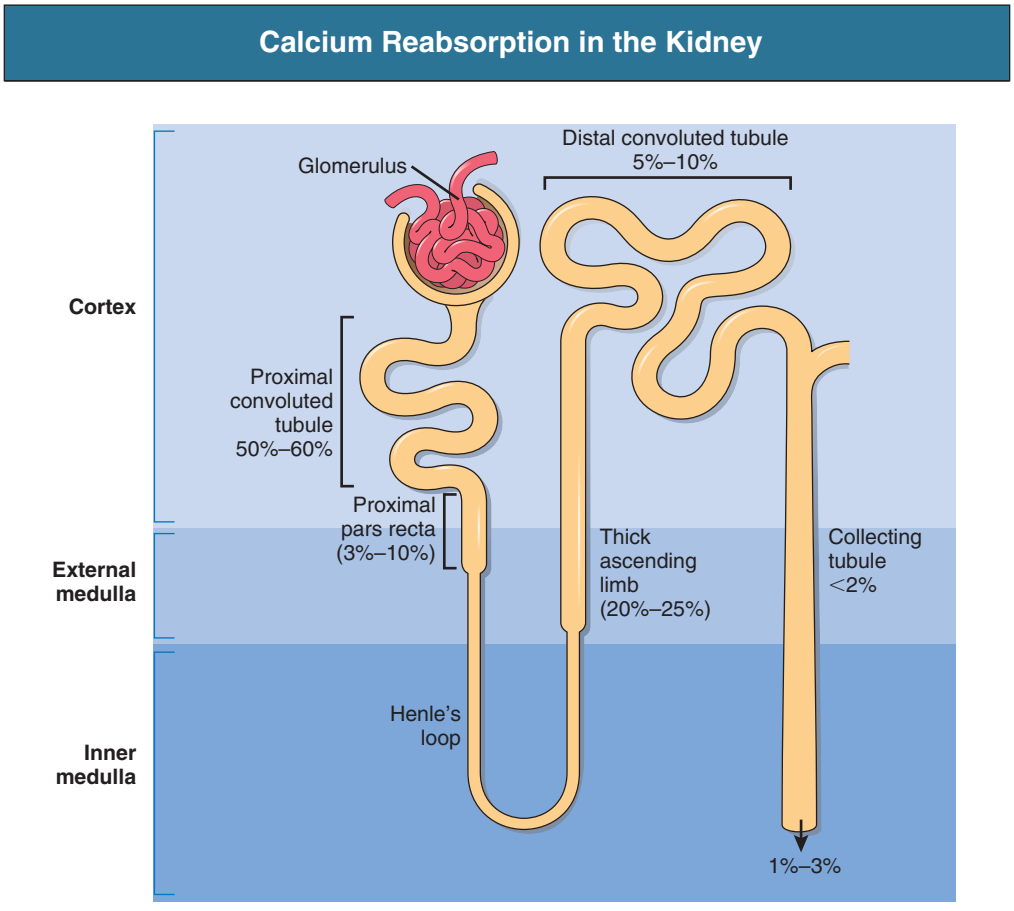

Fig.10.8 Sites of calcium reabsorption. Percentage of Ca^{2+} absorbed in various segments of the renal tubule after glomerular ultrafiltration. (Redrawn from reference 9.)

in the distal nephron. However, PTH and PTH-related peptide (PTHrp) also induce hypercalcemia via bone demineralization, and, because of the increase in serum calcium, the excretion of filtered calcium is elevated overall. An excess of both extracellular Ca^{2+} and intracellular Ca^{2+} reduce tubular calcium reabsorption by activating CaSR, and the effect of extracellular Ca^{2+} is enhanced by treatment with calcimimetics (see later discussion). Both respiratory and metabolic acidosis lead to hypercalciuria through an inhibitory effect on tubular Ca^{2+} reabsorption. Conversely, alkali ingestion reduces renal excretion of calcium. The enhancing effect of phosphate depletion on urinary calcium elimination can partly occur through changes in PTH and calcitriol secretion. Dietary factors modify urinary excretion of calcium mostly by their effects on intestinal Ca^{2+} absorption. Several classes of diuretics act directly on the tubules. Loop diuretics increase urinary calcium excretion via inhibition of the Na^+-K^+-$2Cl^-$ channel in the TAL, whereas thiazide diuretics and amiloride increase tubular calcium absorption.

HYPERCALCEMIA

Increased total serum calcium concentration (S_{Ca}) can result from increase in serum proteins (false hypercalcemia) or serum ionized Ca^{2+} (true hypercalcemia). Only increased Ca^{2+} leads to clinically relevant hypercalcemia. Usually only the value for the total S_{Ca} is available rather than the free ion level. Serum [Ca^{2+}] can then be estimated by taking into account serum albumin; an increase in albumin of 1.0 g/dl reflects a concomitant increase of 0.20 to 0.25 mmol/l (0.8 to 1.0 1.0 mg/dl) S_{Ca}. However, simple correction of S_{Ca} for serum albumin may not be valid in patients with CKD stages 3 to 5.[13] Moreover, the two most common assays used to measure serum albumin yield discordant results in patients with CKD stages 3 to 5, the bromocresol purple method providing lower albumin values than the bromocresol green method.

CaSR has been identified in numerous tissues.[14] Mutations of the gene for CaSR result in various clinical syndromes characterized by hypercalcemia or hypocalcemia (see later discussion). Other Ca^{2+} receptors subsequently cloned include GPRC6A, which is expressed in osteoblasts and is clearly distinct from CaSR.[15] The role of GPRC6A in regulation of osteoblast function and in human disease is still unknown.

Causes of Hypercalcemia

True hypercalcemia results from an increase in intestinal Ca^{2+} absorption, a stimulation of bone resorption, an increase in renal reabsorption of Ca^{2+}, or a combination of these processes. Enhanced bone resorption is the predominant mechanism in most cases of hypercalcemia, and secondary volume depletion commonly prolongs the condition by interfering with urinary calcium excretion (Fig. 10.9).

Malignant Neoplasias

The main cause of hypercalcemia is excessive bone resorption induced by neoplastic processes, usually solid tumors. Tumors of the neck, breast, lung, and kidney are the most common, followed by hematopoietic neoplasias, particularly myeloma. Most hypercalcemic tumors act on the skeleton by direct invasion (metastases) or by producing factors that stimulate osteoclastic activity, including most frequently PTHrp, as well as other factors activating osteoclasts, transforming growth factors (TGFs), prostaglandin E (PGE), and, rarely, calcitriol, and tumor necrosis factor-α (TNF-α) and even more rarely PTH, as produced by parathyroid cancer. Most PTHrp found in the body is synthesized by solid tumors.

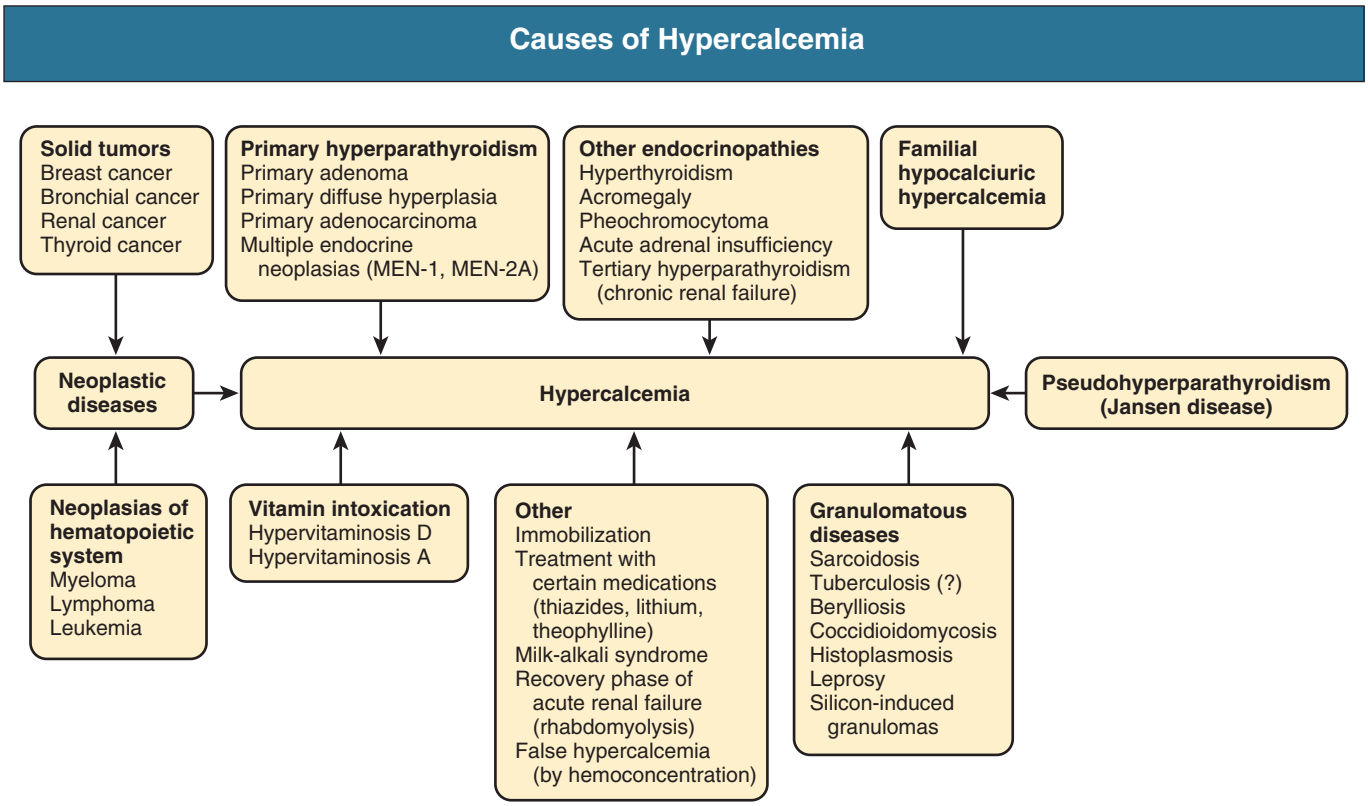

Fig.10.9 Causes of hypercalcemia. Neoplastic diseases and primary hyperparathyroidism are the most common causes of hypercalcemia. (From reference 8.)

Only 8 of the 13 first amino acids of PTHrp are identical with those of the N-terminal fragment of PTH, but the effects of both hormones on target cells are mostly the same because they share a common receptor, the PTH/PTHrp receptor, PTH1R.

Osteoclast-activating factors secreted by myeloma plasmocytes and the lymphoblasts of malignant lymphomas include interleukins (IL-1α, IL-1β, IL-6) and TNF-α. Other osteoclast-activating factors include PGE_1 and PGE_2, which can be secreted in large amounts by some tumors, especially renal masses. Some lymphoid tumors synthesize excess quantities of calcitriol, including Hodgkin disease, T-cell lymphoma, and leiomyoblastoma.

Primary Hyperparathyroidism

The second most common cause of hypercalcemia is primary hyperparathyroidism. In more than 80% of patients, the disease is caused by adenoma of a single parathyroid gland; 10% to 15% have diffuse hyperplasia of all glands, and less than 5% have a parathyroid cancer. Primary hyperparathyroidism is most often idiopathic, but can be inherited either as diffuse hyperplasia of the parathyroid glands alone or as a component in multiple glandular hereditary endocrine disorders. Patients with multiple endocrine neoplasia type 1 (MEN-1) have various combinations of parathyroid, anterior pituitary, enteropancreatic, and other endocrine tumors, resulting in hypersecretion of prolactin and gastrin in addition to parathormone. MEN-1 is caused by inactivating germline mutations of a tumor suppressor gene *(MEN-1)* that is inherited as an autosomal dominant trait. In MEN-2A, the thyroid medulla and the adrenal medulla are involved with the parathyroid, resulting in hypersecretion of calcitonin and catecholamines. MEN-2A is caused by activating mutations of the *RET* proto-oncogene. It is also inherited as an autosomal dominant trait. Not all patients with mildly elevated plasma PTH levels develop hypercalcemia, which may require concomitant elevation of plasma calcitriol.

Jansen Disease

Jansen disease is a rare hereditary form of short-limbed dwarfism characterized by severe hypercalcemia, hypophosphatemia, and metaphyseal chondrodysplasia. It is the result of activating mutations of the gene coding for the PTH1R receptor, a particular form of pseudohyperparathyroidism.

Familial Hypocalciuric Hypercalcemia

Familial hypocalciuric hypercalcemia (FHH) is a rare hereditary disease, most often caused by inactivating mutations in the gene for CaSR with autosomal dominant transmission.[16] The key clinical finding in FHH is an inappropriately low urinary calcium excretion in the setting of high-normal S_{Ca}. Plasma PTH concentration is normal or moderately elevated, and the fractional excretion of calcium (FE_{Ca}) is commonly lower than that observed in primary hyperparathyroidism. FE_{Ca} is best assessed by calculating the calcium-to-creatinine clearance ratio from a 24-hour urine collection, as follows:

$$\text{Calcium-creatinine clearance ratio} = \frac{(\text{24-hour urine calcium}) \times (\text{serum creatinine})}{(\text{24-hour urine calcium}) \times (\text{serum creatinine})}$$

In FHH, FE_{Ca} is usually less than 0.01. The ratio of urine Ca to creatinine concentration is most often less than 0.07 mg/mg (0.2 mmol/mmol), but the values significantly overlap with those in patients with primary hyperparathyroidism.[17] In patients with FHH, hypercalcemia never leads to severe clinical signs, except in the neonatal period, when life-threatening hypercalcemia can be observed in the child with severe hyperparathyroidism.

Other Endocrine Causes

Other endocrine disorders associated with moderate hypercalcemia include hyperthyroidism, acromegaly, and pheochromocytoma. In addition, acute adrenal insufficiency should be considered in the differential diagnosis, although in these patients, hypercalcemia is usually false and results from hemoconcentration. Hypercalcemia also can occur in severe forms of the secondary hyperparathyroidism of CKD, which have been called tertiary hyperparathyroidism. However, this has become relatively uncommon because low circulating calcitriol concentrations in patients with CKD limit GI calcium absorption and overfunctioning parathyroid glands can be controlled more easily. Nonetheless, hypercalcemia in the setting of chronic dialysis does occur and is typically caused by overtreatment of secondary hyperparathyroidism by large dosages of calcium-based phosphate binders plus activated vitamin analogs.

Other Causes

Several other disorders sometimes induce hypercalcemia. Among the granulomatoses, sarcoidosis results in increased serum Ca^{2+}, particularly in patients exposed to sunlight. The cause is uncontrolled production of calcitriol by macrophages, a result of 1α-hydroxylase in the macrophages within the granulomas. Tuberculosis, leprosy, berylliosis, and many other granulomatous diseases are rare causes of hypercalcemia, probably through the same mechanism.

Hypercalcemia also may result from prolonged bed rest, especially in patients with preexisting high bone turnover rates, such as children, adolescents, and patients with Paget disease. Recovery from acute kidney injury (AKI) secondary to rhabdomyolysis has been associated with hypercalcemia in 25% of cases and likely results from mobilization of soft tissue calcium deposits and through increases in PTH and calcitriol. Other causes include intoxication by vitamin D or its derivatives, vitamin A overload, and thiazide diuretics. Large doses of calcium (5 to 10 g/day), especially when ingested with alkali (antacids), also can lead to hypercalcemia and nephrocalcinosis (milk-alkali syndrome).

Clinical Manifestations

The severity of clinical symptoms and signs caused by hypercalcemia depends on not only the degree but also the rapidity of its development. Severe hypercalcemia that progresses slowly can be accompanied by few manifestations in some patients, whereas much less severe hypercalcemia can lead to major disorders if it develops rapidly.

In general, the first symptoms are increasing fatigue, muscle weakness, inability to concentrate, nervousness, increased sleepiness, and depression. Subsequently, GI signs may occur, such as constipation, nausea and vomiting, and, rarely, peptic ulcer disease or pancreatitis. Renal-related signs include polyuria (secondary to nephrogenic diabetes insipidus), renal salt wasting, urinary tract stones and their complications, and, occasionally, tubulointerstitial disease with medullary and to a lesser extent cortical nephrocalcinosis. Patients with chronic hypercalcemia often present with a modest elevation in serum creatinine concentrations, indicating reduced GFR. Neuropsychiatric manifestations include headache, loss of memory, somnolence, stupor, and, rarely, coma. Ocular symptoms include conjunctivitis from crystal deposition and rarely band keratopathy. Osteoarticular pain in primary hyperparathyroidism has become rare in Western countries because of earlier diagnosis of hypercalcemia. High blood pressure can be induced by hypercalcemia, but it is more frequently a chance association. Soft tissue calcifications can occur with long-standing hypercalcemia. The electrocardiogram (ECG) may show shortening of the QT interval and coving of the ST wave. Hypercalcemia may increase cardiac contractility and can amplify digitalis toxicity.

Diagnosis

When the history, clinical examination, and review of medications are unhelpful, primary hyperparathyroidism should be investigated first. Although this is only the second most frequent cause, its laboratory diagnosis is easier than that of tumoral involvement. The initial step should be to measure plasma PTH and total or ionized [Ca^{2+}], as available. When the PTH value is high-normal or high in the presence of high-normal or high [Ca^{2+}], the diagnosis of primary hyperparathyroidism is likely (although FHH is not excluded). Other helpful laboratory tests may include phosphate, creatinine, total alkaline phosphatase, and urinary calcium and creatinine. Neck ultrasound and/or sestamibi isotope scanning and/or computed tomography may be performed to locate a parathyroid adenoma, although some surgeons still consider these examinations unnecessary before an initial neck exploration. However, imaging is indispensable in patients with recurrent hyperparathyroidism and having unilateral neck surgery under local anesthesia. If the plasma PTH level is low-normal or low, the possibility of a neoplastic disorder should be seriously considered. In addition to the usual examinations, such as serum protein electrophoresis, measurement of the plasma PTHrp level can be done in specialized laboratories. Exogenous vitamin D overload is associated with increased serum 25-hydroxyvitamin D levels, and granulomatous diseases such as sarcoidosis are associated with elevated calcitriol levels and increased serum angiotensin-converting enzyme (ACE) activity.

Treatment

Treatment of hypercalcemia is aimed at the underlying cause, although severe (>3.25 mmol/L) and symptomatic hypercalcemia always requires rapid correction. Initially, the patient must be volume expanded with isotonic saline to correct the commonly marked volume depletion, to reduce proximal tubule calcium reabsorption and enhance calcium excretion. Only when euvolemia is established could loop diuretics be used when necessary (e.g., intravenous furosemide 100 to 200 mg every other hour) to facilitate urinary excretion of calcium; however, intravenous saline should be continued to prevent hypovolemia. Oral intake and intravenous administration of fluids and electrolytes should be carefully monitored, and urinary excretions measured if excessive, especially potassium, magnesium, and phosphate. Acid-base balance also should be carefully monitored. Severe cardiac failure and CKD are contraindications to massive ECF volume expansion along with diuretics.

Bisphosphonates are the treatment of first choice, especially in patients with hypercalcemia associated with cancer.[18] These agents inhibit bone resorption as well as calcitriol synthesis. Bisphosphonates can be administered orally in less severe disease or intravenously in severe hypercalcemia. Common bisphosphonates include pamidronate 15 to 90 mg IV over 1 to 3 days, once a month and zoledronate 4 mg IV once; intravenous doses should be infused in 500 ml of isotonic saline or dextrose over at least 2 hours (pamidronate) or 15 minutes (zoledronate). Although package warnings state that bisphosphonates should be used with caution in patients with CKD, this warning pertains to the theoretical possibility of inducing hypocalcemia and does not apply to the treatment of elevated serum calcium levels. Bisphosphonates have been safely used in patients with CKD for the correction of hypercalcemia. A reasonable strategy is first to attempt correcting AKI by volume repletion before administering a bisphosphonate, and to avoid repetitive dosing; a single 60-mg dose of pamidronate can maintain normal [Ca^{2+}] for weeks. Calcitonin acts within hours, especially after intravenous administration. Human, porcine, or salmon calcitonin can be given. However, calcitonin often has no effect, or only a short-term effect, because of the rapid development of tachyphylaxis.

Mithramycin is a cytostatic drug with remarkable power to inhibit bone resorption, which is almost no longer used because of the high toxicity. Denosumab, a monoclonal antibody to the receptor activator of nuclear factor κ-B ligand (RANKL), is a potent inhibitor of bone resorption that can be useful in bisphosphonate-refractory hypercalcemia. Denosumab is not removed by the kidney. The typical dose is 120 mg subcutaneously and can be repeated no earlier than 1 week after the first administration.[19]

Corticosteroids such as prednisone (or prednisolone), 0.5 to 1.0 mg/kg daily, are mainly indicated in hypervitaminosis D of endogenous origin, as in patients with sarcoidosis or tuberculosis, to decrease macrophage synthesis of calcitriol. Corticosteroids also can be used in patients with hypercalcemia associated with some hematopoietic tumors (e.g., myeloma, lymphoma) and even for some solid tumors such as breast cancer. Ketoconazole, an antifungal agent that can inhibit renal and extrarenal calcitriol synthesis, can also be used to treat hypervitaminosis D.

In rare cases of malignant hypercalcemia, treatment with prostaglandin antagonists such as indomethacin or aspirin can be successful. Hyperkalemia and impaired renal function may occur with indomethacin. Hypercalcemia caused by thyrotoxicosis can rapidly resolve with intravenous administration of propranolol or less rapidly with oral administration.

In moderate and nonsymptomatic hypercalcemia secondary to primary hyperparathyroidism, treatment with estrogens has been tried, at least in female patients. In patients with primary hyperparathyroidism, the CaSR agonist cinacalcet (a *calcimimetic*), can reduce serum PTH concentrations and achieve normalization of serum Ca^{2+} in most cases, together with a reduction in serum PTH.[20] However, surgical removal of benign parathyroid adenomas remains the first option in patients with no overt contraindications because this allows definitive cure in most patients at lower cost. Surgical parathyroidectomy remains an important consideration in patients on dialysis who are unresponsive to vitamin D analogues and calcimimetics.[21] Of note, cinacalcet may be effective in patients with parathyroid carcinoma.

HYPOCALCEMIA

As with hypercalcemia, hypocalcemia can be secondary to either reduced plasma albumin (false hypocalcemia) or a change in ionized [Ca^{2+}] (true hypocalcemia). False hypocalcemia can be excluded by directly measuring serum [Ca^{2+}], by determining plasma total protein or albumin levels, by the clinical context, or by other laboratory results (Fig. 10.10). An acute decrease in ionized [Ca^{2+}] is often observed during acute hyperventilation and the respiratory alkalosis that follows, regardless of the cause of hyperventilation. Hyperventilation can result from cardiopulmonary or cerebral diseases. After excluding false hypocalcemia linked to hypoalbuminemia, hypocalcemia can be divided into that associated with elevated plasma phosphate concentration and that associated with low plasma phosphate concentration.

Hypocalcemia Associated With Hyperphosphatemia

CKD leads to diminished calcitriol production and subsequently a low-normal S_{Ca}. In parallel, declining glomerular filtration of phosphate leads to a progressive rise in serum phosphate once the glomerular filtration rate (GFR) falls below approximately 35 ml/min/1.73 m^2. AKI may cause hypocalcemia and hyperphosphatemia through the same mechanisms, as well as specific mechanisms in rhabdomyolysis or pancreatitis.

Hypoparathyroidism may be caused by surgical removal of the parathyroid glands (post-thyroidectomy or parathyroidectomy), radiation, autoimmune destruction of parathyroid tissue, or infiltrative diseases.

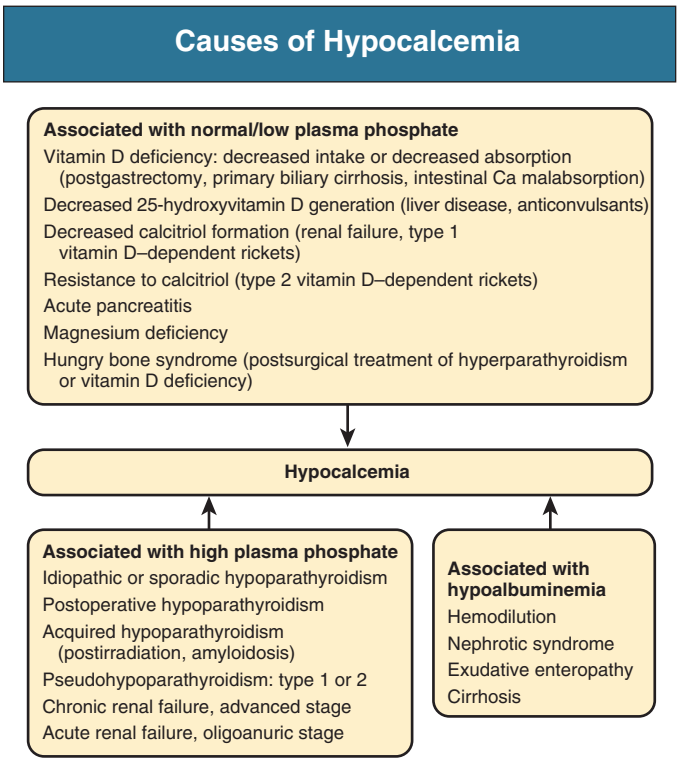

Fig.10.10 Causes of hypocalcemia.

Sporadic cases of hypoparathyroidism are occasionally seen in patients with pernicious anemia or adrenal insufficiency. Pseudohypoparathyroidism (Albright hereditary osteodystrophy) has a characteristic phenotype including short neck, round face, and short metacarpals, with end-organ resistance to PTH.

In addition, massive oral phosphate administration, such as that used in bowel preparations, also can lead to hypocalcemia with hyperphosphatemia, often with AKI.[22]

Hypocalcemia Associated With Hypophosphatemia

Hypocalcemia with hypophosphatemia may occur in vitamin D–deficient states. This may result from insufficient daylight exposure, dietary deficiency of vitamin D, decreased absorption after GI surgery, intestinal malabsorption syndromes (steatorrhea), or hepatobiliary disease (primary biliary cirrhosis). Hyperuricemia or gout may be associated with low calcitriol levels. Hypocalcemia also may be caused by magnesium deficiency, often in conjunction with hypokalemia, which may be caused by inappropriate kaliuresis or diarrhea. The mechanism for hypocalcemia in this setting appears to be decreased PTH release and end-organ resistance. AKI in the polyuric phase, especially after rhabdomyolysis, also may be associated with hypocalcemia and hypophosphatemia.

Clinical Manifestations

As with hypercalcemia, the symptoms of hypocalcemia depend on the rate of development and severity. The most common manifestations, in addition to fatigue and muscular weakness, are increased irritability, loss of memory, a state of confusion, hallucination, paranoia, and depression. The best known clinical signs are the Chvostek sign (tapping of facial nerve branches leading to twitching of facial muscle) and the Trousseau sign (carpal spasm in response to forearm ischemia caused by inflation of a sphygmomanometer cuff). Patients with acute hypocalcemia may have paresthesias of the lips and the extremities, muscle cramps, and occasionally frank tetany, laryngeal stridor, or seizures. Chronic hypocalcemia may be associated with cataracts, brittle nails with transverse grooves, dry skin, and decreased or even absent axillary and pubic hair, especially in idiopathic hypoparathyroidism.

Laboratory and Radiographic Signs

Plasma phosphate is elevated in hypoparathyroidism, pseudohypoparathyroidism, and advanced CKD, whereas it is decreased in steatorrhea, vitamin D deficiency, acute pancreatitis, persistent hyperparathyroidism after kidney transplantation, and the polyuric phase during recovery from AKI. Plasma PTH is reduced in hypoparathyroidism and during chronic magnesium deficiency, whereas it is normal or increased in pseudohypoparathyroidism and in CKD. Urinary calcium excretion is increased only in patients with hypoparathyroidism receiving calcium or vitamin D derivatives, in whom it may lead to nephrocalcinosis; excretion is low in all other patients with hypocalcemia. *Fractional* urinary calcium excretion is high in hypoparathyroidism, in the polyuric phase during recovery from AKI, and in severe CKD; it is low in all other patients with hypocalcemia. Urinary phosphate excretion increases with intestinal phosphate absorption and thus depends on phosphate intake and calcitriol. Determination of serum 25-hydroxyvitamin D and calcitriol levels may also be useful.

On the ECG the corrected QT interval is frequently prolonged, and arrhythmias may occur. The electroencephalogram shows nonspecific signs such as an increase in slow, high-voltage waves. Intracranial calcifications, notably of the basal ganglia, are observed radiographically in 20% of patients with idiopathic hypoparathyroidism, but much less frequently in patients with postsurgical hypoparathyroidism or pseudohypoparathyroidism.

Treatment

Therapy of hypocalcemia is directed toward the underlying cause. Severe and symptomatic (tetany) hypocalcemia requires rapid treatment. Acute respiratory alkalosis, if present, should be corrected if possible. When the cause is functional, simple carbon dioxide retention, as by breathing into a paper bag, may suffice. In other patients, and to obtain a prolonged effect, intravenous infusion of calcium salts is most often required. In the patient with seizures or tetany, calcium gluconate should be administered as an intravenous bolus (e.g., 10 ml 10% weight/volume [2.2 mmol of calcium], diluted in 50 ml of 5% dextrose in water [D5W] or isotonic saline), followed by 12 to 24 g over 24 hours (in D5W or isotonic saline). Calcium gluconate is preferred to calcium chloride, which can lead to extensive skin necrosis in accidental extravasation.

Treatment of chronic hypocalcemia includes oral administration of calcium salts, thiazide diuretics, or vitamin D. Several oral presentations of calcium are available, each with advantages and disadvantages. It should be remembered that the amount of elemental calcium of the various salts differs greatly. For example, the calcium content is 40% in carbonate, 36% in chloride, 12% in lactate, and only 8% in gluconate salts. The daily amount prescribed can be 1 to 4 g elemental Ca. Concurrent magnesium deficiency (serum $[Mg^{2+}]$ <0.70 mmol/l) should be treated with oral magnesium oxide or carbonate 100 to 300 mg elemental magnesium/day or with magnesium sulfate 4 to 8 mmol/day intramuscularly or 20 to 40 mmol/day in D5W IV.

Treatment of hypocalcemia secondary to hypoparathyroidism is difficult because urinary calcium excretion increases markedly with calcium and active vitamin D supplementation and can lead to nephrocalcinosis and loss of renal function. To reduce urinary calcium concentration, thiazide diuretics can be used in association with restricted salt intake; high fluid intake is advised.

Therapy with active forms of vitamin D—calcitriol 0.25 to 1.5 μg/day or its analogue 1α-hydroxycholecalciferol (alfacalcidol) 0.25 to 3.0 μg/day—is the treatment of choice for idiopathic or acquired

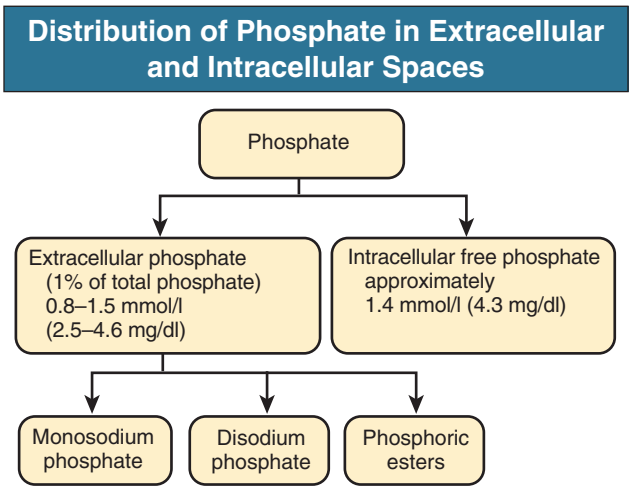

Fig.10.11 Phosphate distribution in extracellular and intracellular spaces.

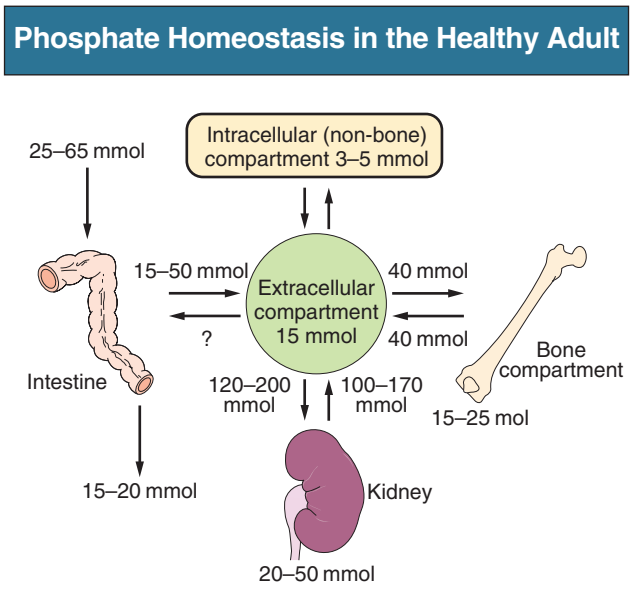

Fig.10.12 Phosphate homeostasis in healthy young adults. At net zero balance, identical net intestinal uptake (absorption minus secretion) and urinary loss occur. After its passage into the extracellular fluid, phosphate enters the intracellular space, is deposited in bone or soft tissue, or is eliminated via the kidneys. Entry and exit fluxes between the extracellular and intracellular spaces (skeletal and nonskeletal compartments) are also the same under steady-state conditions.

hypoparathyroidism because these compounds are better tolerated than massive doses of calcium salts. Administration of vitamin D derivatives generally leads to hypercalciuria and rarely to nephrocalcinosis. The patient requires regular monitoring to avoid hypercalcemia.

In patients with severe bone disease related to hyperparathyroidism, parathyroidectomy can be followed by severe hypocalcemia as a result of massive deposition of calcium salts in bone (hungry bone syndrome); large amounts of calcium and active forms of vitamin D may be needed for days or sometimes weeks.

PHOSPHATE HOMEOSTASIS

Distribution of Phosphate in the Organism

Phosphate plays a crucial role in cell structure, signaling, and metabolism. Phosphate is found in the organism both as mineral phosphate and organic phosphate (phosphoric esters). Most phosphate in the body resides in bone, teeth, and inside cells, with less than 1% circulating in serum. The serum phosphorus concentration is maintained within a narrow range under the direction of hormonal regulators FGF23, PTH, and calcitriol. Phosphate circulates as HPO_4^{2-} and $H_2PO_4^-$, in a 4:1 ratio at normal pH. Normal serum phosphate levels of 2.8 to 4.5 mg/dl in adults (0.9 to 1.5 mmol/l) fluctuate in a circadian rhythm, with levels approximately 0.6 mg/dl higher in the afternoon, compared with an 11 AM nadir. Fig. 10.11 shows the distribution of phosphate in the ECF and ICF compartments.

Fig. 10.12 shows the balance of ingestion, body distribution, and excretion of phosphate in a healthy human. A young adult requires approximately 0.5 mmol/kg of phosphate daily. These needs are much greater in the child during growth. Phosphate is widely found in milk products, meat, eggs, and cereals and is used extensively as a food additive. Bone permanently exchanges phosphate with the surrounding milieu. Entry and exit of phosphate amount to approximately 100 mmol daily (slowly exchangeable phosphate), for a total skeleton content of about 20,000 mmol. The net balance is positive during growth, zero in the young adult, and negative in the elderly adult.

Phosphate enters cells by active transport through a variety of sodium-phosphate (Na-Pi) cotransporters. In the small intestine, phosphate is mainly absorbed through the type 2b Na-Pi cotransporter (NPT2b). The major hormonal regulator of NPT2b is calcitriol, which increases phosphate transport into the body. In contrast, the lipid-lowering agent niacin inhibits NPT2b activity, thereby decreasing phosphate uptake.

In the proximal tubule of the kidney, most of the filtered phosphate load is reabsorbed through type 2a and type 2c Na-Pi cotransporters (NPT2a, NPT2c). A genome-wide association study of more than 16,000 normal adults found that a common genetic variant in NPT2a was associated with serum phosphate concentrations.[23] The phosphaturic hormones FGF-23 and PTH are the principal factors that downregulate NPT2a in the kidneys, increasing phosphate excretion in the urine. Now recognized as a central hormone in phosphate homeostasis, FGF-23 is produced by osteocytes and possesses weak inherent binding properties, requiring a cofactor, klotho, for optimal binding and function within the kidney.[24] Disruption of klotho or FGF-23 genes in animal models leads to a similar hyperphosphatemic phenotype. In addition to promoting phosphate excretion, FGF-23 potently suppresses calcitriol by inhibiting CYP27B1 and stimulating CYP24A1. Other hormones that may influence phosphate transport within the kidney include growth hormone, insulin-like growth factor 1 (IGF-1), insulin, thyroid hormone, secreted frizzled-related protein 4 (sFRP-4), and FGF-7.

Phosphate transport across the intestinal wall occurs via both the transepithelial and the paracellular routes (Fig. 10.13). GI absorption of phosphate is far more permissive than that of calcium. Absorption is a linear, nonsaturable function of phosphate intake that amounts to 60% to 75% of total phosphate intake (15 to 50 mmol/day) (Fig. 10.14). Cations, such as calcium, magnesium, or aluminum, bind to phosphate in the GI tract, limiting its absorption. In both animals and humans, ingestion of a high-phosphate meal results in the rapid excretion of phosphate in the urine, without detectable changes in serum phosphate levels.

The kidneys play a central role in controlling extracellular phosphate homeostasis.[25,26] Phosphate is minimally protein bound, freely filtered at the glomerulus, and reabsorbed primarily in the proximal tubule. To maintain homeostasis, the daily amount of phosphate excreted in urine must equal that absorbed in the intestine. Normally, the kidneys excrete 5% to 20% of the filtered phosphate load to maintain phosphate

Transepithelial Phosphate Transport

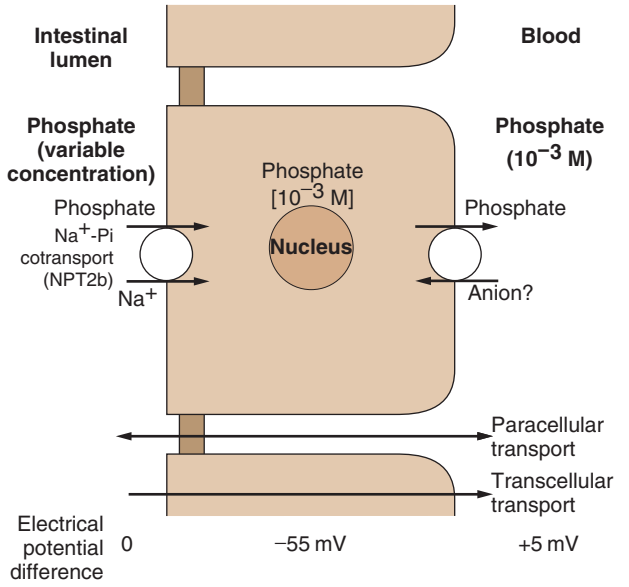

Fig.10.13 Transepithelial phosphate transport in the small intestine. Phosphate enters the enterocyte (influx) through the brush border membrane using the Na^+/Pi cotransport system, with a stoichiometry of 2:1, operating against an electrochemical gradient. Phosphate exit at the basolateral side possibly occurs by passive diffusion or more probably by anion exchange.

Ingested Phosphate and Its Intestinal Net Absorption

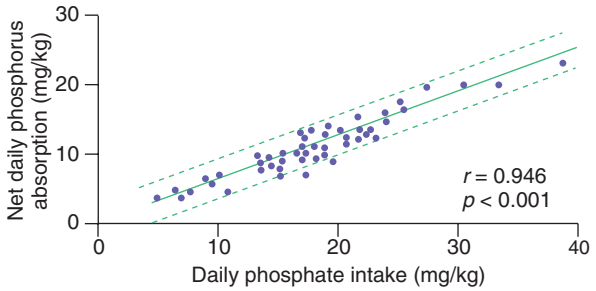

Fig.10.14 Phosphate ingestion and absorption. Relationship between ingested phosphate and phosphorus absorbed in the digestive tract (net absorption) in healthy young adults. (From reference 5.)

balance. In CKD, fewer functioning nephrons necessitate the excretion of a higher proportion of the filtered phosphate load per nephron to maintain homeostasis and the fractional excretion of phosphate may exceed 50% in late stages of CKD.

The amount of phosphate reabsorbed can be expressed in relation to the amount filtered as the urinary fractional excretion of phosphate (FE_{PO_4}), as follows:

$$FE_{PO_4} = (U_{PO_4} \times S_{Cr})/(S_{PO_4} \times U_{Cr})$$

where U_{PO_4}, S_{PO_4}, U_{Cr}, and S_{Cr} are urinary and serum phosphate and creatinine concentrations, respectively. Ideally FE_{PO_4} should be calculated from 24-hour urine samples to incorporate dietary phosphate

Nomogram for Estimation of the Renal Threshold Phosphate Concentration

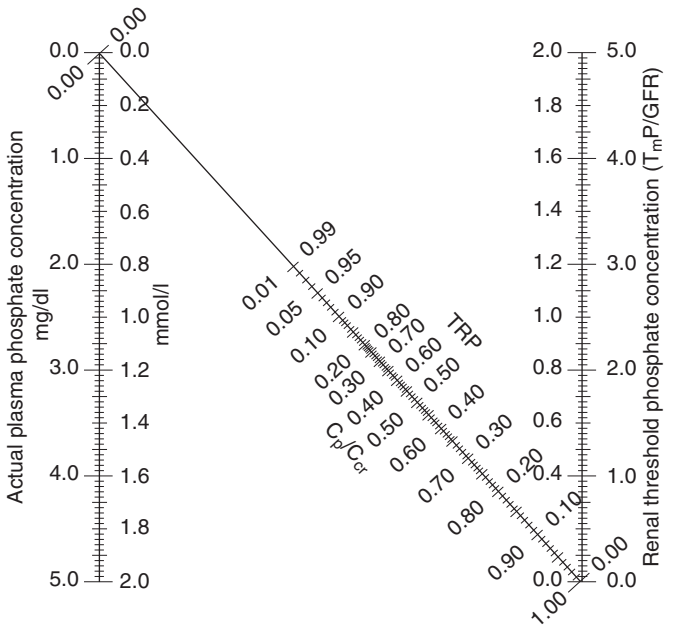

Fig.10.15 Nomogram for estimation of renal threshold phosphate concentration. A straight line through the appropriate values of phosphate concentration and *TRP* (amount of phosphate reabsorbed, or C_P/C_{cr}, where *C* is clearance for phosphate or creatinine) passes through the corresponding value of T_mP/GFR. (From reference 27.)

consumption and circadian changes in serum phosphate throughout the day. In practice, FE_{PO_4} is typically calculated using spot urine samples, which correlates only modestly with the results obtained from a 24-hour sample[27,28] (Fig. 10.15).

HYPERPHOSPHATEMIA

Causes of Hyperphosphatemia

The most common cause of increased serum phosphate levels is reduced urinary excretion caused by acute and chronic kidney diseases.[29] Less frequently, hyperphosphatemia is caused by increased exogenous or endogenous phosphate supply (Fig. 10.16).

Acute Kidney Injury

An acute reduction in GFR leads directly to a rise in the serum phosphate concentration, often in parallel with serum creatinine.

Chronic Kidney Disease

As kidney function slowly declines during CKD, increasing levels of phosphaturic hormones PTH and FGF-23 maintain phosphate balance until about 75% of normal kidney function has been lost. Once GFR falls below about 35 ml/min/1.73 m^2, inadequate nephron mass results in a steady rise in serum phosphate. Similar to acidosis and anemia, the presence of hyperphosphatemia in patients with CKD generally suggests more advanced disease.

The price paid for preservation of serum phosphate in CKD is high circulating levels of FGF-23 and PTH. FGF-23 potently suppresses calcitriol, inhibiting intestinal phosphate absorption through NPT2b and further defending against phosphate excess. However, suppression of calcitriol may have an adverse impact on cardiovascular and kidney

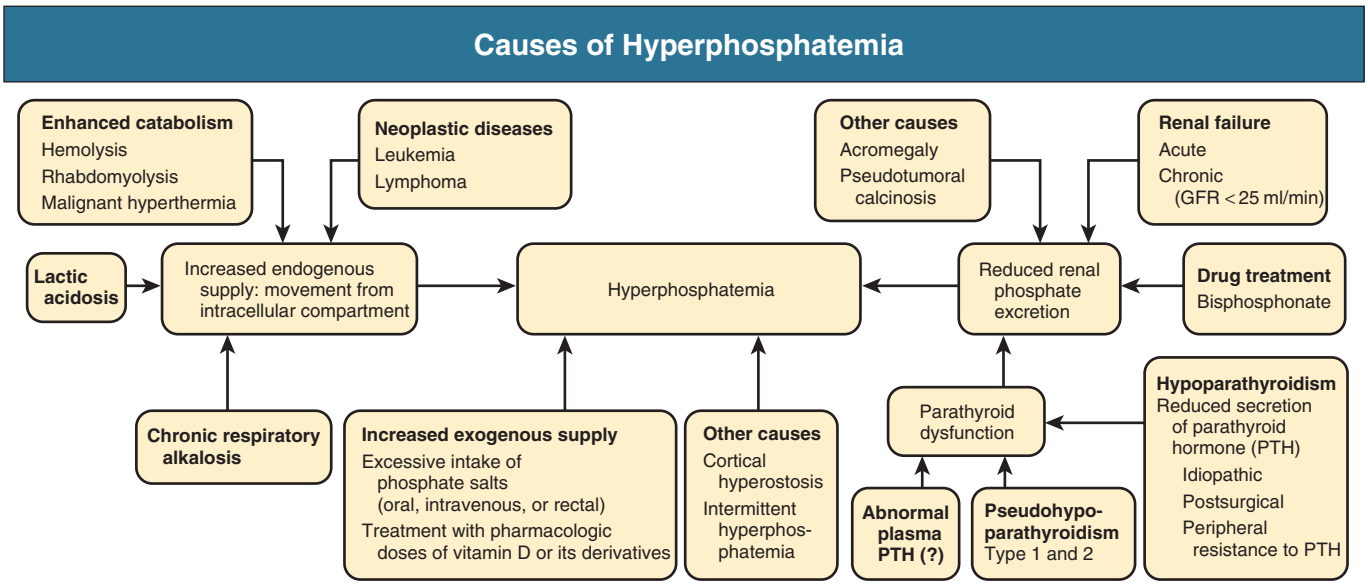

Fig.10.16 Causes of hyperphosphatemia.

health because of biologic activities of calcitriol in downregulating renin expression, reducing inflammatory cytokines, and moderating ventricular hypertrophy. FGF-23 excess may have direct cardiovascular toxicity through stimulation of cardiac hypertrophy, as seen in animal models. A randomized controlled trial of phosphate binders in nondialysis CKD patients assessed the hormonal impact of phosphate binders in the setting of normal or only modestly elevated phosphate levels.[30] Compared with placebo, intensive therapy with phosphate binders over a median 8 months of follow-up lowered serum phosphate by a mean of 0.3 mg/dl, reduced mean 24-hour urine phosphate by 22%, and prevented an increase in PTH. However, phosphate binder treatment did not have an impact on serum FGF-23 levels.

Lytic States

Exaggerated phosphate loss by tissues is seen in states of extreme cell lysis, particularly rhabdomyolysis (crush injury), and in patients with malignancies, especially lymphoma and leukemia, and with their treatment. The hyperphosphatemia of rhabdomyolysis is typically accompanied by hypocalcemia, myoglobinuria, and AKI. Severe hypercatabolic states during severe infection or in diabetic ketoacidosis also can cause hyperphosphatemia through increased cellular release of phosphate, usually accompanied by an acute reduction in GFR.

Treatment-Induced Hyperphosphatemia

A massive supply of phosphate (e.g., phosphate-based laxatives or enemas) can lead to hyperphosphatemia. Oral sodium phosphate solutions used to prepare for colonoscopy contain massive quantities of phosphate and can cause precipitation of calcium phosphate crystals within the renal tubules and AKI. Recovery from this condition is slow and often incomplete, with some cases resulting in end-stage renal disease. Patients who have CKD should therefore receive alternative bowel preparations. Bisphosphonates, in particular etidronate in Paget disease, can increase serum phosphate levels, possibly through increased liberation of tissue phosphate or an increase in renal tubular reabsorption.

Hypoparathyroidism

Parathyroid hormone is a major phosphaturic hormone. In states of reduced PTH secretion (idiopathic or postsurgical hypoparathyroidism) or resistance to its peripheral action (pseudohypoparathyroidism), tubular excretion of phosphate is diminished. The resulting increase in plasma phosphate leads to an increase in the ultrafiltered load. This results in regulation of plasma phosphate at a new steady-state level.

Chronic Hypocalcemia

Hyperphosphatemia may be observed in association with chronic hypocalcemia with normal or high plasma PTH levels. In the absence of characteristic abnormalities of pseudohypoparathyroidism, the existence of an abnormal form of plasma PTH may be responsible, perhaps caused by abnormal conversion of the prohormone to its secreted form.

Acromegaly

In acromegaly, hyperphosphatemia results from an increase in tubular reabsorption of phosphate caused by stimulation by growth hormone and IGF-1.

Familial Tumoral Calcinosis

This rare autosomal recessive disorder seen primarily in people of Middle Eastern or African ancestry is caused by an inactivating mutation in *GALNT3, FGF23,* or klotho gene. The glycosyltransferase encoded by *GALNT3* is necessary for FGF-23 activity, thus resulting in a shared phenotype.[31] The lack of functional FGF-23 results in an exaggerated tubular phosphate reabsorption and uninhibited vitamin D activation, leading to hyperphosphatemia and hypercalcemia, high circulating levels of calcitriol, and metastatic soft tissue calcifications. The most common finding is densely calcified masses surrounding major joints that recur after removal. Circulating PTH is not decreased.

Respiratory Alkalosis With Prolonged Hyperventilation

Respiratory alkalosis resulting from prolonged hyperventilation is characterized by resistance to the renal action of PTH, hyperphosphatemia, and hypocalcemia. There also may be functional pseudohypoparathyroidism because renal phosphate clearance is diminished, whereas plasma PTH is normal, despite hypocalcemia. There is no decrease in urinary calcium excretion.

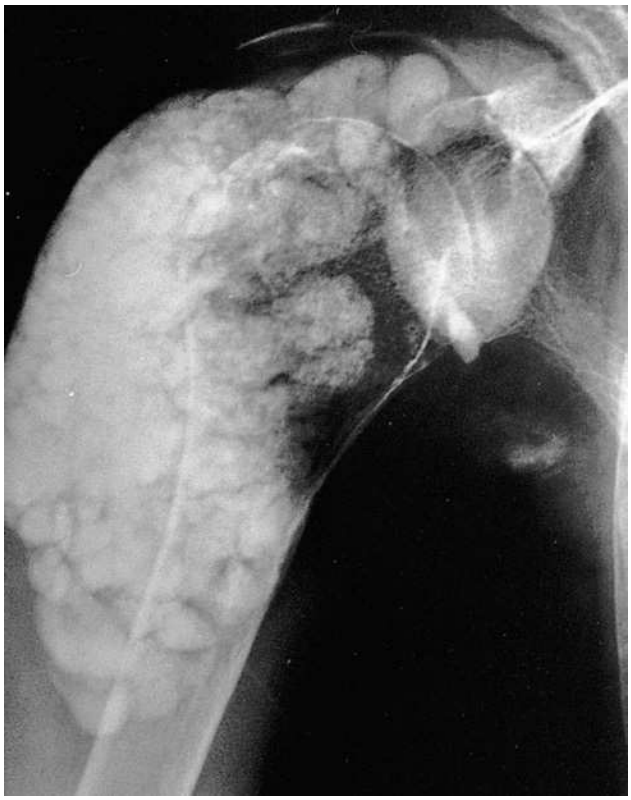

Fig.10.17 Tumor-like extraskeletal calcification in the shoulder.

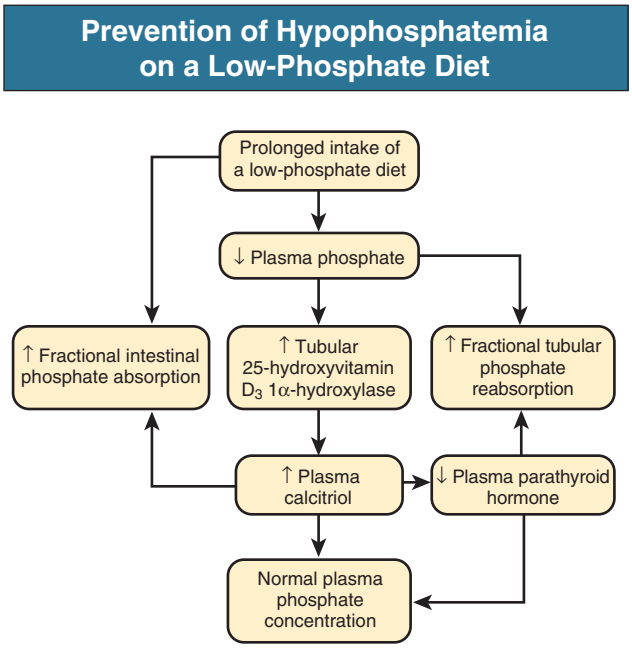

Fig.10.18 Prevention of hypophosphatemia. Compensatory mechanisms during prolonged intake of a phosphate-poor diet help to prevent hypophosphatemia.

Clinical Manifestations

The major clinical implication of profound hyperphosphatemia is deposition of phosphate and calcium in soft tissues and in the renal tubules. Chronic hyperphosphatemia may contribute to cardiovascular calcification, particularly in CKD (see Chapter 81). In extreme cases, hyperphosphatemia can induce tumor-like soft tissue calcium phosphate deposits (Fig. 10.17) or extensive vascular calcification within the arteries of the skin (calciphylaxis or calcific uremic arteriolopathy; see Chapter 87). Hyperphosphatemia also blocks the conversion of 25-hydroxyvitamin D to calcitriol, leading to concomitant hypocalcemia and the stimulation of PTH.

Treatment

Treatment of acute hyperphosphatemia is usually targeted at improving phosphate excretion by intravenous fluids or by renal replacement therapy in patients with severe AKI. Intravenous dextrose and insulin can shift phosphate into cells, similar to treatment of hyperkalemia.

Treatment of chronic hyperphosphatemia in patients with CKD and those receiving dialysis remains a major component of CKD clinical care. Higher serum phosphate concentrations are *associated* with vascular calcification, cardiovascular events, and mortality in CKD,[32] but evidence that treatment improves hard outcomes is lacking. In patients on chronic dialysis, dietary phosphate restriction and phosphate binders lower the serum phosphate concentration. (see Chapter 84). Nicotinamide is an intriguing possible alternative to phosphate binding agents due to its ease of administration (once daily) and novel mechanism of action (inhibition of NPT2b in small intestine, blocking phosphate absorption).[33] However, nicotinamide may cause significant side effects and is unproven for treating hyperphosphatemia clinically.[34]

HYPOPHOSPHATEMIA

Decreased plasma phosphate levels may reflect phosphate deficiency, which in theory could be due to a prolonged decrease in phosphate intake. However, several defense mechanisms counter a decrease in plasma phosphate resulting from low intake (Fig. 10.18). Moderately reduced plasma phosphate levels also may accompany maldistribution between the ICF and ECF compartments during acute respiratory alkalosis.

Causes of Hypophosphatemia

Moderate hypophosphatemia can be caused by genetic or acquired conditions (Fig. 10.19). The main acquired condition is malnutrition because of low food intake or anorexia during severe disease or alcoholism. Another cause is a shift of phosphate into cells, which can occur through various mechanisms, but especially with insulin administration. Although there are many genetic diseases and syndromes that can cause hypophosphatemia, overall these are rare. Severe forms of hypophosphatemia are all acquired conditions.

Inherited Forms of Hypophosphatemia

Inherited diseases associated with chronic hypophosphatemia are generally diagnosed in childhood.[35] Persistently low plasma phosphate usually leads to rickets or osteomalacia. Inherited hypophosphatemia results from primary defects, which are isolated or associated with proximal tubular disorders (Fanconi syndrome) or defects secondary to another genetically transmitted disease, mainly metabolic disorders or disturbances in vitamin D activity.

Autosomal dominant hypophosphatemic rickets. Children with this phosphate wasting disorder present with skeletal defects, including bowing of the long bones and widening of costochondral joints. Autosomal dominant hypophosphatemic rickets is linked to mutations in *FGF23,* in which an aberrant form of the molecule is resistant to proteolytic cleavage.[36] Excess FGF-23 causes phosphate wasting by downregulating NPT2a in the proximal renal tubule.

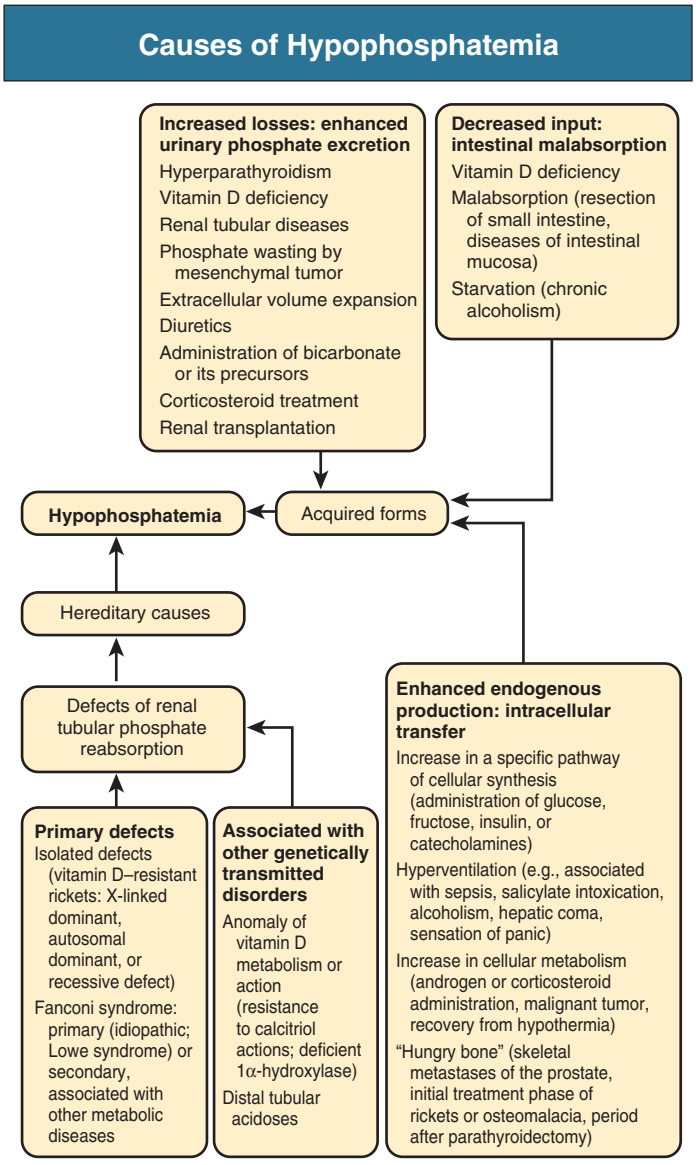

Fig.10.19 Causes of hypophosphatemia.

X-linked hypophosphatemic rickets. The rare phosphate wasting syndrome X-linked hypophosphatemic rickets is characterized by skeletal deformities, short stature, and osteomalacia. X-linked hypophosphatemic rickets has been associated with various mutations in the *PHEX* gene (phosphate-regulating endopeptidase on X chromosome). *PHEX* likely plays a role in the proteolysis of FGF-23.[37] *PHEX* mutations result in high circulating FGF-23 concentrations, renal phosphate wasting, and hypophosphatemia. Serum calcium, calcitriol, and PTH levels are normal, and alkaline phosphatase level is elevated.

Autosomal recessive hypophosphatemic rickets. Inherited autosomal recessive hypophosphatemic rickets is caused by mutations in dentin matrix protein 1 gene *(DMP1)*, which is believed to suppress FGF-23 secretion by bone.

Fanconi syndrome and proximal renal tubular acidosis. Fanconi syndrome is characterized by a complex transport defect of the proximal tubule that results in decreased reabsorption of glucose, amino acids, bicarbonate, and phosphate. Because 70% of the filtered phosphate load is typically reabsorbed in the proximal tubule, Fanconi syndrome leads to renal phosphate wasting and hypophosphatemia. A fractional urinary phosphate excretion greater than 15% in the setting of overt hypophosphatemia is helpful for suggesting renal phosphate wasting. Causes and management of Fanconi syndrome are discussed in Chapter 48.

In addition to a tubular defect causing phosphate wasting, the activity of renal 1α-25-OH-vitamin D hydroxylase may be insufficient, resulting in decreased circulating calcitriol levels and bone disease such as rickets and osteomalacia. Functional disorders associated with the Fanconi syndrome, such as polyuria and ECF volume contraction, lead to hyperaldosteronism with hypokalemia and eventually to renal failure.

Vitamin D–dependent rickets. Several rare inherited diseases are associated with hypophosphatemia and include vitamin D–dependent rickets type 1, caused by a defect of renal 25-OH-vitamin D hydroxylase, and type 2, caused by peripheral resistance to the action of calcitriol. Clinical signs are similar to those of vitamin D–deficient rickets, but alopecia also occurs in 50% of patients. In type 1, calcitriol levels are low, whereas in type 2 there is normal circulating 25-hydroxyvitamin D and high calcitriol. Treatment with low doses of calcitriol is sufficient to treat type 1, whereas extremely high doses of calcitriol, alfacalcidol, or calcidiol are required for type 2 vitamin D–dependent rickets.

Distal renal tubular acidosis (type 1). Distal renal tubular acidosis (type 1 RTA) is associated with hypercalciuria and sometimes nephrocalcinosis. Chronic acidosis enhances the reabsorption of citrate in the proximal tubule, preventing it from forming soluble calcium-citrate complexes in the urine (see Chapter 12). Chronic acidosis also causes increased calcium and phosphate release from bone. Hypophosphatemia is inconstant, possibly resulting only from concomitant vitamin D deficiency.

Acquired Forms of Hypophosphatemia

The number of acquired diseases that can be associated with hypophosphatemia is even greater than inherited diseases and includes hyperparathyroidism and vitamin D deficiency (see Fig. 10.19). True phosphate deficiency associated with total body depletion must be distinguished from enhanced influx of phosphate into cells or increased skeletal mineralization.

Alcoholism. Alcoholism is the most common cause of severe hypophosphatemia in Western countries. The multiple causes include prolonged poor food intake, excessive phosphate loss in urine secondary to hypomagnesemia, and phosphate transfer from the ECF to ICF compartment caused by hyperventilation or glucose infusion in patients with postalcoholic cirrhosis or in acute abstinence.

Hyperparathyroidism. PTH enhances urinary phosphate excretion by downregulating the NPT2a cotransporter. Patients with primary hyperparathyroidism typically present with mild hypercalcemia and hypophosphatemia.

Post-transplant hypophosphatemia. Renal phosphate wasting is exceedingly common in renal transplant recipients. At some point in their post-transplant course, most patients develop hypophosphatemia, which may be prolonged. Proposed explanations include residual hyperparathyroidism from CKD, but the best evidence implicates persistently high circulating levels of FGF-23 as the key factor.

Acute respiratory alkalosis. In intense and short-term hyperventilation, plasma phosphate can decrease to values as low as 0.1 mmol/l (0.3 mg/dl). Such a decrease is never observed in metabolic alkalosis. Hypophosphatemia after acute and intense hyperventilation is probably the result of muscle sequestration of extracellular phosphate. However, prolonged chronic hyperventilation leads to hyperphosphatemia (see previous discussion).

Diabetic ketoacidosis. During decompensated diabetes associated with acidosis provoked by accumulation of ketone bodies, glycosuria, and polyuria, plasma phosphate can be normal or high, even in the

presence of hyperphosphaturia. Correction of this complication by administering insulin and refilling the ECF compartment leads to massive transfer of phosphate into the intracellular compartment, hypophosphatemia, and subsequently less urinary loss of phosphate. In general, plasma phosphate does not decrease to less than 0.3 mmol/l (0.9 mg/dl) unless there is preexisting phosphate deficiency.

Total parenteral nutrition. Hyperalimentation can be associated with severe hypophosphatemia through the insulin-mediated shift of phosphate into cells, particularly if phosphate is omitted from the parenteral nutrition solution. Severe hypophosphatemia also can occur with acute feeding after starvation.

Oncogenic hypophosphatemic osteomalacia. Hypophosphatemia associated with tumor-induced osteomalacia results from renal phosphate wasting in patients with mesenchymal tumors (hemangiopericytoma, fibroma, angiosarcoma). The mechanism of hypophosphatemia is tumor secretion of phosphatonins (FGF-23, sFRP-4, matrix extracellular phosphoglycoprotein [MEPE], FGF-7).[38] The condition resolves after tumor resection.

Drug-induced hypophosphatemia. Imatinib mesylate, a tyrosine kinase inhibitor, has been reported to cause hypophosphatemia and elevated PTH levels. The mechanism of action likely associates dysfunction of the renal proximal tubule and increased osteoformation.[39]

Clinical Manifestations

Clinical manifestations depend more on the rate of onset of hypophosphatemia than on its severity or the total body phosphate deficit. In practice, it is not clinically evident when serum phosphate is greater than 0.65 mmol/l (2.0 mg/dl). Manifestations include metabolic encephalopathy, red and white blood cell dysfunction, sometimes hemolysis, and thrombocytopenia. Reduced muscle strength (e.g., diaphragmatic strength) and decreased myocardial contractility, with occasional rhabdomyolysis and cardiomyopathy, respectively, may occur, motivating clinical practice to replete low serum phosphate concentration in intensive care settings.

Treatment

In general, phosphate deficiency is not an emergency. First, the mechanism involved should be defined to determine the most appropriate treatment. When phosphate deficiency is diagnosed, oral treatment by milk products or phosphate salts always should be tried first whenever possible, except in the presence of nephrocalcinosis or nephrolithiasis with urinary phosphate wasting. In severe symptomatic deficiency, phosphate also can be infused intravenously, in divided doses over 24 hours. In patients undergoing parenteral nutrition, 10 to 25 mmol potassium phosphate should be given for each 1000 kcal, taking care to avoid hyperphosphatemia because of the risk for inducing soft tissue calcifications. Dipyridamole may reduce the urinary excretion of phosphate in patients with a low renal phosphate threshold.

MAGNESIUM HOMEOSTASIS AND DISORDERS OF MAGNESIUM METABOLISM

Distribution of Magnesium in the Organism

Magnesium (Mg^{2+}) is the second most abundant cation in the ICF in living organisms and the fourth most abundant cation in the body. Mg^{2+} is involved in most metabolic processes and contributes to DNA and protein synthesis. Magnesium is involved in the regulation of mitochondrial function, inflammatory processes and immune defense, allergy, growth, and stress and in the control of neuronal activity, cardiac excitability, neuromuscular transmission, vasomotor tone, and blood pressure. Fig. 10.20 shows the distribution of Mg^{2+} within the intracellular and extracellular spaces. Fig. 10.21 shows the balance of ingestion, body distribution, and excretion of Mg^{2+} in healthy humans. Cell influx and efflux are linked to carbohydrate-dependent active transport systems; stimulation of β-adrenoceptors favors Mg^{2+} exit, whereas insulin, calcitriol, and vitamin B_6 favor Mg^{2+} entry into cells.

Intestinal and Renal Handling of Magnesium

The intestinal absorption of dietary Mg^{2+} occurs by both saturable and passive transport processes, the major part being absorbed in the distal

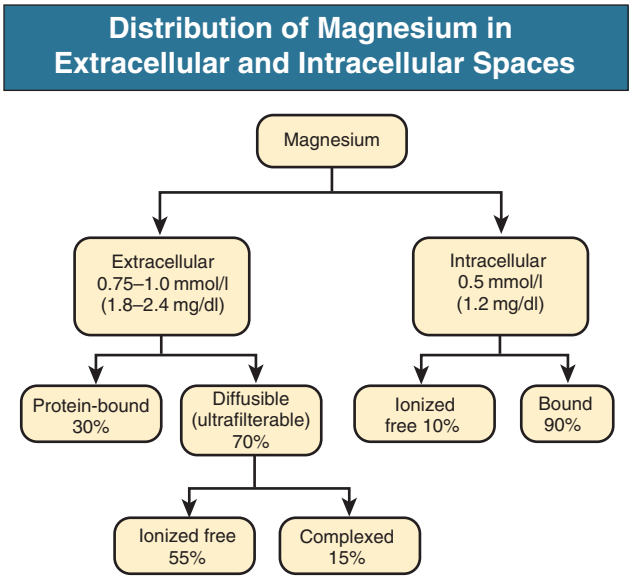

Fig.10.20 Magnesium distribution in extracellular and intracellular spaces. Intracellular magnesium concentration is that of free, not total, magnesium.

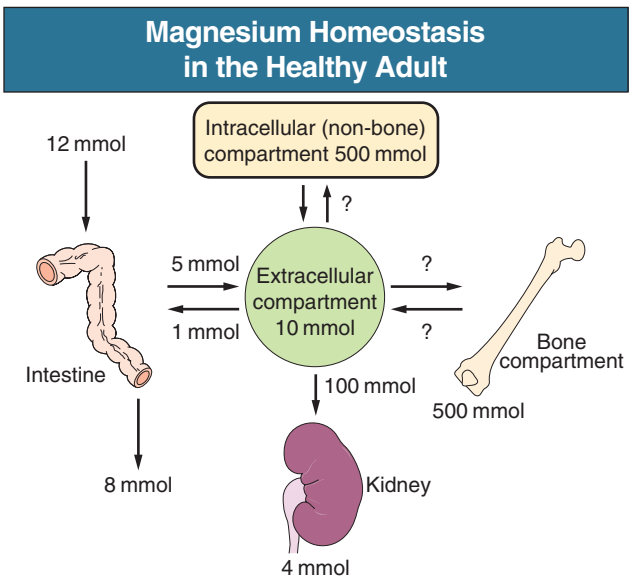

Fig.10.21 Magnesium homeostasis in healthy adults. Net zero balance results from net intestinal uptake (absorption minus secretion) equaling urinary loss. After its passage into the extracellular fluid, Mg^{2+} enters the intracellular space, is deposited in bone or soft tissue, or is eliminated via the kidneys. Entry and exit fluxes between the extracellular and intracellular spaces (skeletal and nonskeletal compartments) are also of identical magnitude; however, precise values of exchange are still debated.

small intestine and the colon. Paracellular Mg^{2+} absorption is responsible for 80% to 90% of intestinal Mg^{2+} uptake. It seems restricted primarily to areas that lack tightening claudins. Transcellular Mg^{2+} transport is mediated by transient receptor potential channel melastatin member 6 (TRPM6) and TRPM7 Mg^{2+} channels.[4] Mg^{2+} absorption can vary by as much as 25% to 60%, mainly depending on magnesium intake, with a mean absorption of approximately 30%. When magnesium intake is low, intestinal transport can rise up to 80%.[40,41]

Various factors modify intestinal Mg^{2+} absorption. In addition to high magnesium intake, high dietary phosphate intake is inhibitory, as is high phytate consumption. The effect of dietary calcium is complex, and calcitriol has an enhancing effect. Growth hormone slightly increases Mg^{2+} absorption, whereas aldosterone and calcitonin appear to reduce it. Vitamin B_6 has been reported to enhance absorption.

Magnesium is mainly eliminated by the kidney. Losses through intestinal secretion and sweat are negligible under normal conditions. With a normal plasma magnesium concentration (0.70 to 0.95 mmol/L [1.7 to 2.3 mg/dl]), of which 80% is ultrafilterable, the filtered load of magnesium amounts to approximately 104 mmol (or 2500 mg) daily. The urine output represents approximately 5% of the filtered load (4 to 5 mmol, or 100 mg daily). The major portion of filtered magnesium is reabsorbed by the renal tubules: 25% in proximal tubule, 65% in the TAL, and 5% in distal tubule (Fig. 10.22).[42,43]

Transport of Mg^{2+} in the TAL is primarily passive via the paracellular route. However, two conditions are necessary for normal Mg^{2+} reabsorption: (1) generation of an electrical, lumen-positive gradient induced by NaCl reabsorption that creates the driving force required for the reabsorption of divalent cations and (2) expression of Claudins-16 and -19, which form a cation-selective tight junction, facilitating paracellular Mg^{2+} transport. Different anomalies associated with either NaCl reabsorption or with Claudin-16 or -19 expression result in hypermagnesuria, such as Bartter syndrome, which is defined by genetic defects related to NaCl transport in the TAL.[44,45]

In the distal nephron (i.e., distal convoluted tubule and connecting tubule), Mg^{2+} is reabsorbed via the transcellular route against an uphill electrochemical gradient. The gatekeeper channel that controls Mg^{2+} entry into the tubular epithelium across the apical membrane is TRPM6.[4] Its activity is regulated by epidermal growth factor (EGF) and estrogen, but not by calcitriol or PTH.

Tubular Mg^{2+} transport is modulated by serum Mg^{2+} and Ca^{2+} and ECF volume. An increase in plasma Mg^{2+} or Ca^{2+} concentration results in impaired magnesium transport. ECF volume expansion produces a decrease in proximal tubular Mg^{2+} reabsorption, in parallel with that of Na^+ and Ca^{2+}. Dietary phosphate restriction results in marked hypercalciuria and hypermagnesuria and thus leads to overt hypomagnesemia. PTH, vasopressin, calcitonin, and glucagon increase tubular Mg^{2+} reabsorption, probably by the paracellular pathway, whereas acetylcholine, bradykinin, and atrial natriuretic peptide stimulate urinary Mg^{2+} excretion.

Several drugs have also been shown to increase renal Mg^{2+} excretion, including the loop diuretics (furosemide, bumetanide), distal diuretics (thiazides), and osmotic diuretics (mannitol, urea). Thiazide diuretics increase sodium delivery to the cortical collecting duct, dissipating the

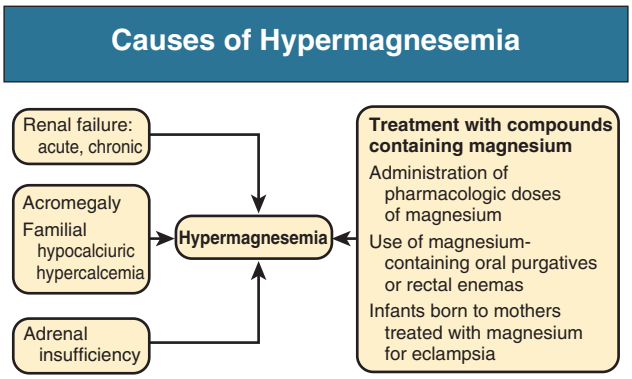

Fig.10.23 Causes of hypermagnesemia.

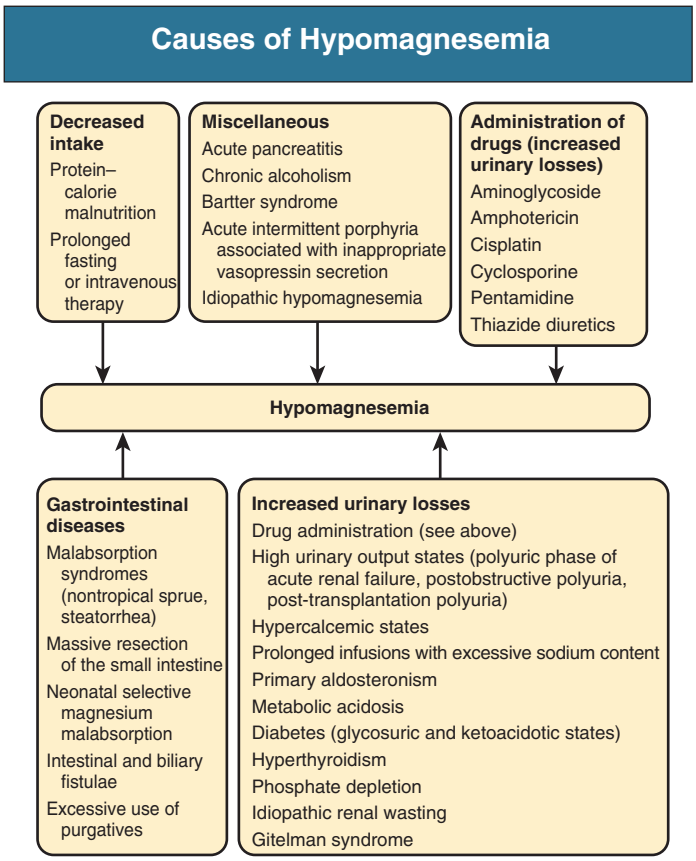

Fig.10.24 Causes of hypomagnesemia.

favorable electrochemical gradient for magnesium entry at this site. Thiazides also reduce TRPM6 expression in the distal convoluted tubule. Furthermore, renal Mg^{2+} wasting syndromes have been observed in patients treated with antibiotics such as gentamicin, antineoplastic agents such as cisplatin, and the calcineurin inhibitors cyclosporine and tacrolimus. The precise mechanisms of action of most of these agents are not well understood.

Hypermagnesemia

Elevated plasma Mg^{2+} is seen in patients with AKI and CKD, during the administration of pharmacologic doses of magnesium, in some infants born to mothers who received magnesium for eclampsia, and with the use of oral laxatives or rectal enemas containing magnesium (Fig. 10.23). Mild hypermagnesemia also may be present in patients with adrenal insufficiency, acromegaly, or FHH.

Clinical Manifestations

Symptoms and signs result from the effects of increased [Mg^{2+}] on the nervous and cardiovascular systems. At [Mg^{2+}] up to 1.5 mmol/l (3.6 mg/dl), hypermagnesemia is asymptomatic. Deep tendon reflexes are usually lost when plasma [Mg^{2+}] is greater than 3 mmol/l (7.2 mg/dl). Respiratory paralysis, hypotension, and loss of consciousness may occur as plasma levels of magnesium approach 5 mmol/l (12 mg/dl).

Treatment

Treatment consists of cessation of magnesium administration and intravenous infusion of calcium salts, which is thought to counteract Mg blockade of calcium channels at the neuromuscular junction. For the management of symptomatic hypermagnesemia, calcium gluconate may be given, 1 to 2 g in 10 to 20 ml D5W IV over 5 to 10 minutes (each gram of calcium gluconate is approximately 90 mg elemental calcium).

HYPOMAGNESEMIA AND MAGNESIUM DEFICIENCY

Magnesium deficiency is defined as a decrease in total body magnesium content. Poor dietary intake of magnesium is usually not typically associated with marked magnesium deficiency because of the ability of the intestine to increase Mg^{2+} absorption and the kidney to conserve Mg^{2+}. However, prolonged and severe dietary magnesium restriction of less than 0.5 mmol/day can produce symptomatic magnesium deficiency. Severe hypomagnesemia is usually associated with magnesium deficiency. About 10% of patients admitted to a large U.S. city hospital were hypomagnesemic. The incidence may be as high as 65% in medical intensive care units.

Underlying causes are usually GI diseases, in particular malabsorption syndromes such as nontropical sprue (celiac disease) and massive resection of the small intestine. Hypomagnesemia also can be induced by prolonged tube feeding without magnesium supplements and excessive use of non–magnesium-containing laxatives (Fig. 10.24). The widely used proton pump inhibitors can induce a selective impairment in intestinal magnesium absorption.[43]

Hypomagnesemia occurs in 25% to 35% of patients with acute pancreatitis, is frequently observed in chronic alcoholism, and can also occur in poorly controlled diabetes mellitus. Hypomagnesemia may be observed in patients with hypercalcemic disorders and primary aldosteronism, and magnesium deficiency can contribute to the metabolic syndrome.[45]

Excessive urinary loss of magnesium leads to hypomagnesemia and magnesium deficiency, even with normal dietary intake. It may result from the overzealous use of loop and thiazide diuretics, and therefore it is important to monitor plasma Mg^{2+} levels in patients with congestive heart failure who are treated with diuretic agents. Other drugs that may cause hypomagnesemia, as previously described, include gentamicin, cisplatin, cyclosporine, anti EGF receptor monoclonal antibodies and tacrolimus. A rise in blood alcohol level has been associated with renal magnesium wasting, which is one factor contributing to magnesium deficiency in chronic alcoholism.

Several familial diseases are associated with hypermagnesuria, with or without hypomagnesemia. Inactivating mutations of the genes of the Na^+-K^+-$2Cl^-$ cotransporter, rectifying K^+ channel (ROMK), or basolateral Cl^- channel in Bartter syndrome are responsible for the abolition of the driving force for Mg^{2+} reabsorption in the TAL or distal nephron. This results in hypermagnesuria, although not necessarily

hypomagnesemia. Activating mutations of the *CaSR* gene, whose protein product is a key regulator of paracellular ion reabsorption in the TAL through extracellular [Ca^{2+}], lead to hypermagnesuria and hypomagnesemia. Mutation of the CLDN16 and CLDN19 genes induces recessive diseases characterized by hypomagnesemia, hypermagnesuria, hypercalciuria, and nephrocalcinosis.

In the distal convoluted tubule, mutations in the *TRPM6* gene induce profound hypomagnesemia from impaired intestinal Mg^{2+} absorption and renal Mg^{2+} wasting, with secondary hypocalcemia.[46] Inactivating mutations of the thiazide-sensitive, electroneutral NaCl cotransporter gene *(NCC)* in Gitelman syndrome are also responsible for selective renal magnesium wasting and hypomagnesemia.

Hypomagnesemia associated with inappropriate magnesuria has been reported in an autosomal-dominant, isolated familial hypomagnesemia syndrome, apparently caused by misrouting of the Na^+,K^+-ATPase γ subunit.

Clinical Manifestations

Specific clinical manifestations of hypomagnesemia may be difficult to appreciate because of concomitant hypocalcemia and hypokalemia. The main clinical manifestations of moderate to severe magnesium depletion include general weakness and neuromuscular hyperexcitability with hyperreflexia, carpopedal spasm, seizure, tremor, and, rarely, tetany. Cardiac findings include a prolonged QT interval and ST depression. There is a predisposition to ventricular arrhythmias and potentiation of digoxin toxicity. The role of magnesium deficiency in the clinical development of seizures and cardiac arrhythmias is demonstrated by the treatment of these conditions with magnesium. In mothers with pregnancy-related hypertension, intravenous magnesium is more effective than phenytoin for preventing eclamptic seizures. In patients with acute myocardial infarction and hypomagnesemia, magnesium repletion reduces the frequency of cardiac arrhythmias.

Magnesium deficiency also can be associated with hypocalcemia (decreased PTH release and end-organ responsiveness) and hypokalemia (urinary loss). In addition, intracellular K^+ is frequently decreased. Magnesium deficit constitutes a cardiovascular risk factor and also a risk factor in pregnancy for the mother and the fetus.

The diagnosis of moderate degrees of magnesium deficiency is not easy because clinical manifestations may be absent and serum Mg^{2+} levels may not reflect the state of body magnesium. Severe magnesium deficits, however, are associated with hypomagnesemia.

Treatment

Magnesium deficiency is managed with the administration of magnesium salts. Magnesium sulfate is generally used for parenteral therapy, 2400 to 4800 mg (480–960 mg elemental Mg) daily. A variety of magnesium salts are available for oral administration, including oxide, hydroxide, sulfate, lactate, chloride, carbonate, and pidolate. Oral magnesium salts often are not well tolerated, at least at high dosage. All may induce GI intolerance, in particular diarrhea.

SELF-ASSESSMENT QUESTIONS

1. Which is the most common cause of hypercalcemia in patients with chronic kidney disease?
   A. Secondary hyperparathyroidism
   B. Cholecalciferol or ergocalciferol therapy
   C. Malignant neoplasias
   D. Familial hypocalciuric hypercalcemia
   E. Hypomagnesemia
2. Which of the following conditions are *not* associated with hypocalcemia in patients with chronic kidney disease?
   A. Primary hypoparathyroidism
   B. Secondary hyperparathyroidism
   C. Hyperphosphatemia
   D. Vitamin D overload
   E. Treatment by calcium-based phosphate binders
3. All the following factors are involved in the regulation of renal phosphate handling *except:*
   A. Parathyroid hormone
   B. Adrenocorticotropin hormone
   C. Fibroblast growth factor (FGF-23)
   D. Klotho
   E. Growth hormone
4. Based on current evidence, which of the following outcomes is *most likely* to result from untreated hyperparathyroidism in a patient with chronic kidney disease (CKD)?
   A. Premature death
   B. Heart failure
   C. Wrist fractures
   D. Progression to chronic dialysis
   E. Worsening of secondary hyperparathyroidism
5. Which of the following symptoms and signs is *not* induced by hypermagnesemia?
   A. Anemia
   B. Nausea
   C. Muscle weakness
   D. Hypotension
   E. Bradycardia

Normal Acid-Base Balance

Biff F. Palmer

DEFINITION

The acid-base status of the body is carefully regulated to maintain arterial pH between 7.35 and 7.45 and intracellular pH between 7.0 and 7.3. This regulation occurs in the setting of continuous production of acidic metabolites and is accomplished by intracellular and extracellular buffering processes with respiratory and renal regulatory mechanisms. This chapter reviews the normal physiology of acid-base homeostasis.

NET ACID PRODUCTION

Both acid and alkali are generated from diet. Lipid and carbohydrate metabolism results in production of carbon dioxide (CO_2), a volatile acid, at the rate of approximately 15,000 mmol/day. Protein metabolism yields amino acids, which can be metabolized to form nonvolatile acid and alkali. Amino acids such as lysine and arginine yield acid on metabolism, whereas the amino acids glutamate and aspartate and organic anions such as acetate and citrate generate alkali. Sulfur-containing amino acids (methionine, cysteine) are metabolized to sulfuric acid (H_2SO_4), and organophosphates are metabolized to phosphoric acid (H_3PO_4). In general, animal foods are high in proteins and organophosphates and provide a net acid diet; plant foods are higher in organic anions and provide a net alkaline load. In addition to acid and alkali generated from diet, there is a small daily production of organic acids, including acetic acid, lactic acid, and pyruvic acid. Also, a small amount of acid is generated by the excretion of alkali into the stool. Under normal circumstances, daily net nonvolatile acid production is approximately 1 millimole (mmol) of hydrogen ions (H^+) per kilogram (kg) of body weight (Fig. 11.1).

BUFFER SYSTEMS IN REGULATION OF PH

Intracellular and extracellular buffer systems minimize the change in pH during the addition of acid or base equivalents but do not remove acid or alkali from the body. The most important buffer system is bicarbonate ion and carbon dioxide (HCO_3^--CO_2). In this system, carbon dioxide concentration [CO_2] is maintained at a constant level set by respiratory control. Addition of acid (HA) leads to conversion of HCO_3^- to CO_2 according to the reaction $HA + NaHCO_3 \rightarrow NaA + H_2O + CO_2$. HCO_3^- is consumed, but [CO_2] does not change because this is maintained by respiration. The net result is that the acid load has been buffered and pH changes are minimal.

Whereas the HCO_3^--CO_2 buffer system is the most important of the buffers in extracellular fluid (ECF), other buffers such as plasma proteins and phosphate ions also participate in the maintenance of a stable pH. During metabolic acidosis, the skeleton becomes a major buffer source as acid-induced dissolution of bone apatite releases alkaline Ca^{2+} salts and HCO_3^- into the ECF. With chronic metabolic acidosis, this can result in osteomalacia and osteoporosis. The calcium released can result in hypercalciuria and an increased likelihood of renal stones. Within the intracellular fluid (ICF) compartment, pH is maintained by intracellular buffers such as hemoglobin, cellular proteins, organophosphate complexes, and HCO_3^- as well as by the H^+-HCO_3^- mechanisms that transport acid and alkali in and out of the cell.

RESPIRATORY SYSTEM IN REGULATION OF PH

Removal of acid or alkali from the body is accomplished by the lungs and kidneys. The lungs regulate CO_2 tension (P_{CO_2}), and the kidneys regulate serum bicarbonate concentration, [HCO_3^-]. Although the HCO_3^--CO_2 buffer system is not the only buffer system, all extracellular buffer systems are in equilibrium. Because serum [HCO_3^-] is much greater than that of other buffers, changes in the HCO_3^--CO_2 buffer pair easily titrate other buffer systems and thus set pH. The Henderson-Hasselbalch equation explains how the lungs and kidneys function in concert:

$$pH = 6.1 + \log \frac{HCO_3^-}{(0.03 \times Pa_{CO_2})}$$

pH is determined by the ratio of HCO_3^- to CO_2. Conditions associated with similar fractional changes in [HCO_3^-] and [CO_2], such as when both are halved, will not change blood pH.

The lungs defend pH by altering alveolar ventilation, which alters the CO_2 excretion rate and thereby controls the arterial CO_2 tension (Pa_{CO_2}) of body fluids. Systemic acidosis stimulates the respiratory center, resulting in increased respiratory drive that lowers the Pa_{CO_2}. As a result, the fall in blood pH is less than would have occurred in the absence of respiratory compensation. If the fractional change in P_{CO_2} were similar to that in serum [HCO_3^-], blood pH would not change. However, respiratory compensation rarely normalizes blood pH, and thus the fractional change in P_{CO_2} is less than the change in serum [HCO_3^-]. Quantitatively, the normal respiratory response in metabolic acidosis is a 1.2 mm Hg decrease in Pa_{CO_2} for every 1 mmol/l decrease in HCO_3^-; the increase in Pa_{CO_2} in response to metabolic alkalosis averages 0.7 mm Hg for every 1 mmol/l increase in HCO_3^- above baseline.[1]

RENAL REGULATION OF PH

Buffer systems and respiratory excretion of CO_2 help maintain normal acid-base balance, but the kidneys provide a critical role in acid-base homeostasis. The kidneys normally generate sufficient net acid excretion

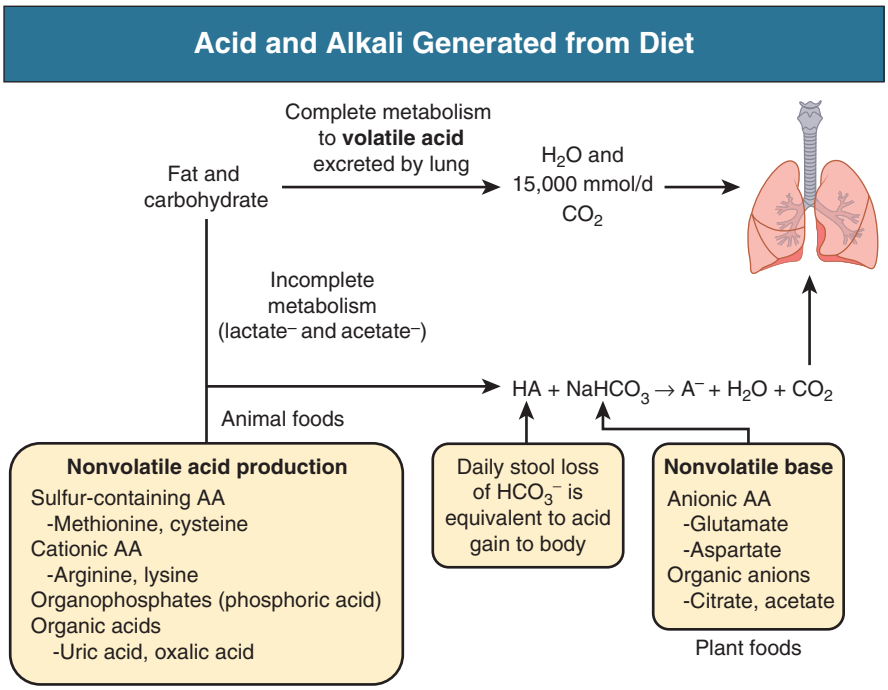

Fig. 11.1 Acid and alkali generated from the diet. A nonvolatile acid is an acid produced from sources other than CO_2 and is not excreted by the lungs. Nonvolatile acids are produced from incomplete metabolism of carbohydrates, fats, and proteins and from metabolism of animal foods. Plant foods tend to produce an alkali load. *AA,* Amino acids.

(NAE) to balance nonvolatile acid produced from normal metabolism. NAE has three components, titratable acids, ammonium (NH_4^+), and bicarbonate, and is calculated by the following formula:

$$NAE = V\,(U_{Am} + U_{TA} - U_{HCO_3^-})$$

where $U_{Am}V$ is the rate of NH_4^+ excretion, $U_{TA}V$ is the rate of titratable acid excretion, and $U_{HCO3}{}^{-}V$ is the rate of HCO_3^- excretion. Under basal conditions, approximately 40% of NAE is in the form of titratable acids and 60% is in the form of ammonia (NH_3); urinary bicarbonate concentrations and excretion are essentially zero under normal conditions.

Titratable acidity refers to weak acids filtered at the glomerulus that can act as buffers in the urine. These buffers are referred to as titratable because they are measured by determining the amount of alkali required to titrate the urine back to a pH of 7.4. To serve as a titratable buffer, a buffer must have a pK_a near the range of tubular fluid pH. The most important titratable buffer is phosphate ($HPO_4^{2-} \leftrightarrow H_2PO_4^-$) because it has a favorable pK_a of 6.80 and there is a relatively high rate of urinary excretion. However, when acid production increases, the increase in acid excretion is almost entirely caused by an increase in excretion of NH_4^+ because the ability to increase urinary phosphate is limited.

RENAL TRANSPORT MECHANISMS OF HYDROGEN AND BICARBONATE IONS

Glomerulus

The glomerulus is not normally considered as participating in acid-base regulation. However, the glomerulus filters an amount of HCO_3^- equivalent to serum [HCO_3^-] multiplied by the glomerular filtration rate (GFR). Under normal circumstances, the filtered load of HCO_3^- averages approximately 4000 mmol/day. Normal acid-base homeostasis requires both the reabsorption of this filtered bicarbonate and the generation of "new" bicarbonate; the latter replenishes bicarbonate and other alkaline buffers consumed in the process of titrating endogenous acid production. From the standpoint of prevention or correction of acidosis, GFR is not regulated by alterations in acid or base and therefore does not contribute to acid-base homeostasis.

Proximal Tubule

The proximal tubule reabsorbs approximately 80% of the filtered load of HCO_3^-. In addition, by titration of luminal pH from 7.4 down to approximately 6.7, the majority of phosphate, the major form of titratable acid, is titrated to its acid form. Finally, ammonia synthesis occurs in the proximal tubule.

Fig. 11.2 shows the acid-base transport mechanisms of the proximal tubule cell. HCO_3^- absorption from the tubular lumen is mediated by H^+ secretion across the membrane.[2] This H^+ secretion is active in that the electrochemical gradient favors H^+ movement from lumen to cell. Two mechanisms mediate active apical H^+ secretion. Approximately two thirds occurs through the apical membrane Na^+-H^+ antiporter NHE3.[3] This protein uses the inward Na^+ gradient to drive H^+ secretion. The Na^+-H^+ exchanger has a 1:1 stoichiometry and is electroneutral. In parallel with the Na^+-H^+ antiporter, there is an apical membrane H^+-ATPase that mediates approximately one third of basal proximal tubular HCO_3^- absorption.

Both these H^+ transporters generate base in the cell, which must exit across the basolateral membrane to effect transepithelial transport. This primarily occurs through a basolateral Na^+-HCO_3^--CO_3^{2-} cotransporter.[4] Because this protein transports the equivalent of two net negative charges, the negative cell voltage generated by the basolateral Na^+,K^+-ATPase provides a strong favorable driving force for base efflux. The Na^+ carried on this transporter is moved out of the cell without requiring ATP. The Na^+-$3HCO_3^-$ cotransporter NBCe1, encoded by the gene *SLC4A4,* mediates most of the exit of base from the proximal tubule.[5]

Carbonic anhydrase II is present in the proximal tubular cell cytoplasm, and carbonic anhydrase IV is on the apical and basolateral

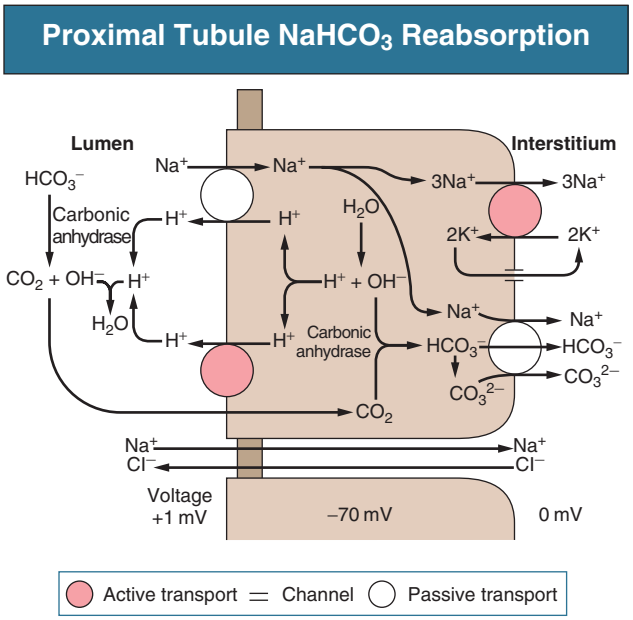

Fig. 11.2 Proximal tubule sodium bicarbonate ($NaHCO_3$) reabsorption. The secretion of H^+ into the proximal tubule lumen involves a Na^+-H^+ antiporter and an H^+-ATPase. Apical membrane H^+ secretion generates OH^-, which reacts with CO_2 to form HCO_3^- and CO_3^{2-}, and these exit with a Na^+ on the basolateral membrane Na^+-HCO_3^--CO_3^{2-} cotransporter. The Na^+ absorbed by the Na^+-H^+ antiporter exits the cell on the basolateral membrane Na^+,K^+-ATPase and the Na^+-HCO_3^--CO_3^{2-} cotransporter. The K^+ that enters the cell on the Na^+,K^+-ATPase exits on a basolateral membrane K^+ channel. Carbonic anhydrase catalyzes the conversion of HCO_3^- to CO_2 and OH^- in the lumen and the reverse reaction in the cell. Electrogenic H^+ secretion generates a small, lumen-positive voltage that generates a current flow across the paracellular pathway.

membranes. Carbonic anhydrase (carbonate dehydratase) has a number of functions in the proximal tubule. Apical membrane carbonic anhydrase allows secreted H^+ ions to react with luminal HCO_3^-, forming H_2CO_3, which rapidly dissociates to CO_2 + H_2O. This CO_2 diffuses across the apical plasma membrane into the cell. There the process is reversed, with use of cytoplasmic carbonic anhydrase, generating intracellular H^+ and HCO_3^-. This H^+ "replenishes" the H^+ secreted across the apical membrane, resulting in net movement of the HCO_3^- from the luminal solution to the cell cytoplasm. The intracellular HCO_3^- is then secreted across the basolateral plasma membrane, as described previously.

Thick Ascending Limb of the Loop of Henle

Tubular fluid arriving at the early distal tubule has a pH and serum [HCO_3^-] similar to that in the late proximal tubule. Because there is significant water extraction in the loop of Henle, maintenance of a constant serum HCO_3^- concentration requires reabsorption of HCO_3^-. The majority of this HCO_3^- absorption occurs in the thick ascending limb (TAL) through mechanisms similar to those present in the proximal tubule (Fig. 11.3). The majority of apical membrane H^+ secretion is mediated by the Na^+-H^+ antiporter NHE3. As in the proximal tubule, the low intracellular Na^+ concentration maintained by the basolateral Na^+,K^+-ATPase provides the primary driving force for the antiporter. Base efflux across the basolateral membrane is mediated by a Cl^--HCO_3^- exchanger (AE2) and K^+-HCO_3^- cotransport likely mediated by the K^+-Cl^- cotransporter KCC4.[6] These cells also possess an H^+-ATPase. The contribution of this pump to overall acidification in this segment is not clear.

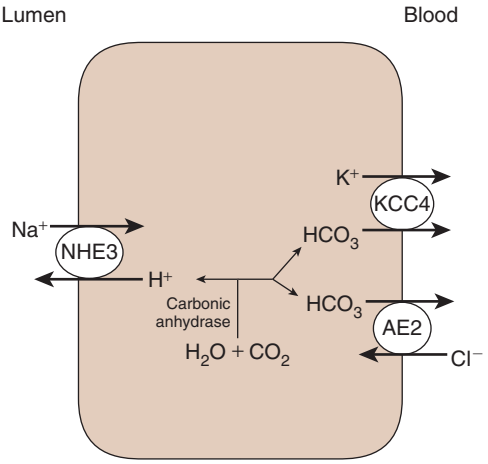

Fig. 11.3 Hydrogen (H^+) and bicarbonate (HCO_3^-) ion transport in thick ascending limb. Apical H^+ secretion is mediated by a Na^+-H^+ antiporter. The low intracellular Na^+ concentration, maintained by the basolateral Na^+,K^+-ATPase, provides the primary driving force for the antiporter. Both Cl^--HCO_3^- exchange and K^+-HCO_3^- cotransport mediate base exit across the basolateral membrane.

Distal Nephron

Approximately 80% of the filtered HCO_3^- is reabsorbed in the proximal tubule; most but not all of the remainder is absorbed in the TAL. One function of the distal nephron is to reabsorb the remaining 5% of filtered HCO_3^-. In addition, the distal nephron must secrete a quantity of H^+ equal to that generated systemically by metabolism to maintain acid-base balance.

The distal nephron is subdivided into several distinct portions that differ in their anatomy and acid secretory properties. Most of these segments transport H^+ and HCO_3^- into the luminal fluid, but the main segments appear to be in the collecting duct.[9] The segments of the collecting duct include the cortical collecting duct (CCD), the outer medullary collecting duct, and the inner medullary collecting duct. There are two distinct cell types in the CCD that can be distinguished histologically: the principal cell and the intercalated (IC) cell. The principal cell reabsorbs Na^+ and secretes K^+ and is discussed later. Depending on chronic acid-base status, the CCD is capable of either H^+ or HCO_3^- secretion. These functions are mediated by two types of IC cells: the acid-secreting α-IC cell and the base-secreting β-IC cell. Both IC cell types are rich in carbonic anhydrase II.

Reabsorption of HCO_3^- in the distal nephron is mediated by apical H^+ secretion by the α-IC cell. Two transporters secrete H^+: a vacuolar H^+-ATPase and an H^+-K^+-ATPase (Fig. 11.4). The vacuolar H^+-ATPase is an electrogenic pump related to the H^+ pump present within lysosomes, the Golgi apparatus, and endosomes. The H^+-K^+-ATPase uses the energy derived from adenosine triphosphate hydrolysis to secrete H^+ into the lumen and to reabsorb K^+ in an electroneutral fashion. The activity of the H^+-K^+-ATPase increases in K^+ depletion and thus provides a mechanism by which K^+ depletion enhances both collecting duct H^+ secretion and K^+ absorption.[7]

Active H^+ secretion by the apical membrane generates intracellular base that must exit the basolateral membrane. A basolateral Cl^--HCO_3^- exchanger (AE1) is the mechanism by which this base exit occurs. The Cl^- that enters the cell in exchange for HCO_3^- exits the cell through a basolateral membrane Cl^- conductance channel (see Fig. 11.4).

The HCO_3^--secreting β-IC cell is a mirror image of the α-IC cell (Fig. 11.5). It possesses an H^+-ATPase on the basolateral membrane, which mediates active H^+ extrusion. Alkali that is generated within the

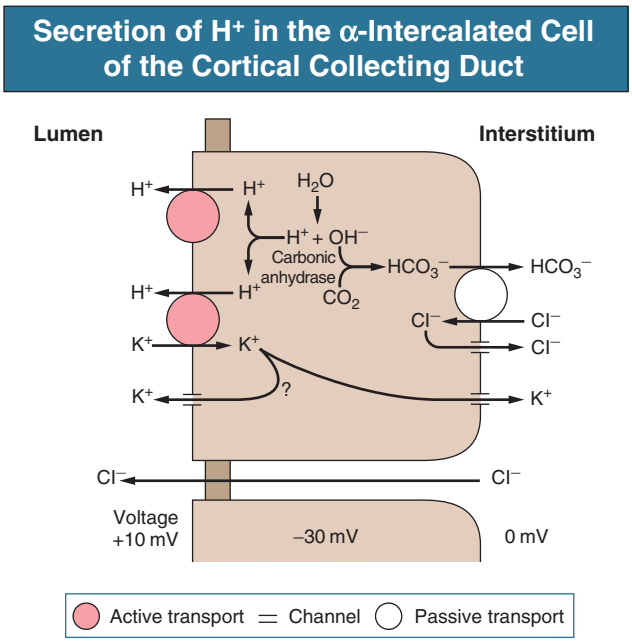

Fig. 11.4 H^+ secretion in cortical collecting duct α-intercalated cell. Secretion of hydrogen ions into the lumen by an H^+-ATPase and an H^+-K^+-ATPase. Apical membrane H^+ secretion generates OH^-, which reacts with CO_2 to form HCO_3^-. This bicarbonate exits across the basolateral membrane on a Cl^--HCO_3^- exchanger, a member of the anion exchanger-1 (AE1) family and a truncated form of the red blood cell AE1 Cl^--HCO_3^- exchanger. The Cl^- that enters the cell on the exchanger recycles across a basolateral membrane Cl^- channel. The K^+ that enters the cell on the H^+-K^+-ATPase appears to be able either to recycle across the apical membrane or exit across the basolateral membrane, depending on the potassium balance of the individual. Carbonic anhydrase catalyzes the conversion of CO_2 and OH^- to HCO_3^- in the cell. Electrogenic H^+ secretion generates a lumen-positive voltage that generates a current flow across the paracellular pathway.

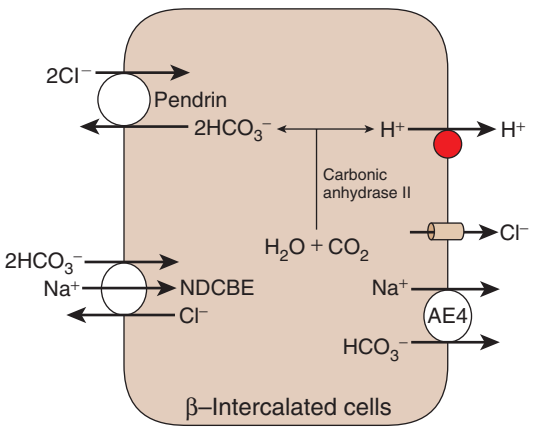

Fig. 11.5 Bicarbonate secretion by cortical collecting duct β-intercalated cell. H^+ is secreted into the interstitium by an H^+-ATPase. The OH^- generated by basolateral membrane H^+ secretion reacts with CO_2 to form HCO_3^-, which exits across the apical membrane on a Cl^--HCO_3^- exchanger (pendrin). The Cl^- that enters the cell on the exchanger exits across a basolateral membrane Cl^- channel. Carbonic anhydrase catalyzes the conversion of CO_2 and OH^- to HCO_3^- in the cell. The Na^+-driven Cl^--HCO_3^- exchanger (NDCBE) colocalizes with pendrin on the apical membrane and mediates thiazide-sensitive electroneutral NaCl reabsorption in this segment.

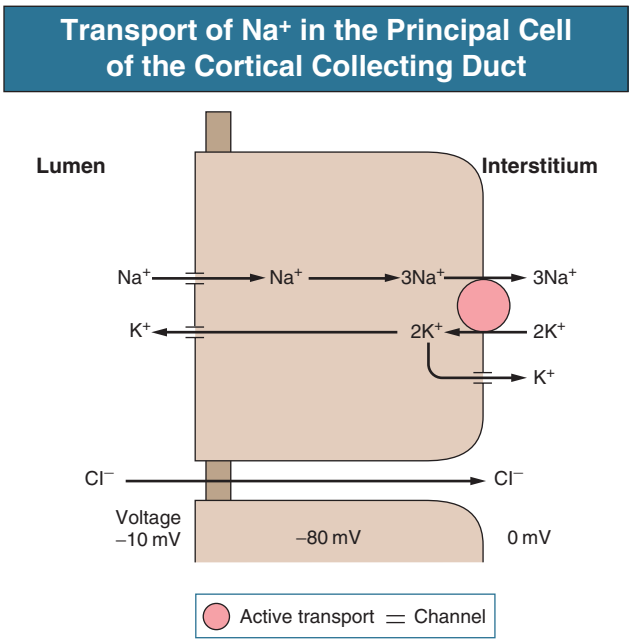

Fig. 11.6 Sodium transport in cortical collecting duct principal cell. Electrogenic Na^+ absorption is mediated by the Na^+ channel. The Na^+ enters the cell across the apical membrane channel and exits the cell on the basolateral membrane Na^+,K^+-ATPase. The K^+ that enters the cell on the basolateral Na^+,K^+-ATPase can be secreted into the luminal fluid by an apical membrane K^+ channel. Electrogenic Na^+ absorption establishes a lumen-negative voltage that drives a paracellular current.

cell then exits on an apical membrane Cl^--HCO_3^- exchanger. This Cl^--HCO_3^- exchanger is distinct from the basolateral Cl^--HCO_3^- exchanger present in the α-IC cell and functions as an anion exchanger or Cl^- channel in the luminal membrane of epithelial cells.[10] The SLC26A4 protein (pendrin) is a family member that mediates apical Cl^--HCO_3^- exchange in the β-IC cell of the kidney. The Na^+-driven Cl^--HCO_3^- exchanger (NDCBE) colocalizes with pendrin on the apical membrane and together may explain a component of electroneutral NaCl reabsorption in the collecting duct that is thiazide sensitive.[8]

The other cortical collecting tubule cell type is the principal cell, which also regulates acid-base transport, although indirectly. Principal cells mediate electrogenic Na^+ reabsorption that results in a net negative luminal charge (Fig. 11.6). The greater this negative charge, the lesser is the electrochemical gradient for electrogenic proton secretion and therefore the greater the rate of net proton secretion. Thus factors that stimulate Na^+ reabsorption indirectly regulate the H^+ secretory rate.

The medullary collecting duct possesses mechanisms only for H^+ secretion. This H^+ secretion is mediated by α-IC cells but also by cells that appear morphologically distinct from IC cells but are functionally similar.

Net Acid Excretion

For the kidney to generate NAE, it must both reabsorb filtered HCO_3^- and excrete titratable acids and ammonia. Several weak acids, such as phosphate, creatinine, and uric acid, are filtered at the glomerulus and can buffer secreted protons. Of these, phosphate is the most important because of its favorable pK_a of 6.80 and its relatively high rate of urinary excretion (~25 to 30 mmol/day). However, the capacity of phosphate to buffer protons is maximized at a urine pH of 5.8, and acid-base disturbances generally do not induce substantial changes in urinary phosphate excretion. Other titratable acids, such as creatinine and uric acid, are limited by their lower excretion rate, which is not dramatically

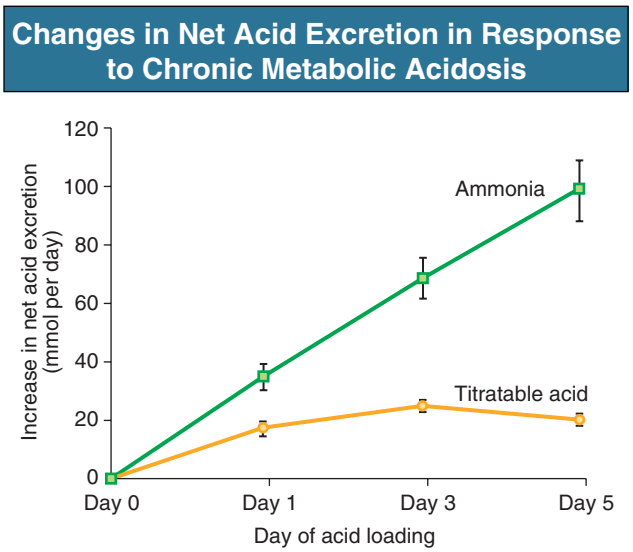

Fig. 11.7 Changes in net acid excretion. Chronic metabolic acidosis increases net acid excretion dramatically over several days; shown quantitatively are the increases in the two major components of net acid excretion, titratable acids and ammonia. Titratable acid excretion increases slightly and predominantly in the first 24 to 48 hours. In contrast, urinary ammonia excretion progressively increases over 7 days and is responsible for most of the increase in net acid excretion in chronic metabolic acidosis. (Plotted data redrawn from original data in reference 14.)

changed in response to acid-base disturbances. Titratable acid excretion is a minor component of the increase in NAE in response to metabolic acidosis (Fig. 11.7).

Ammonia Metabolism

Quantitatively, the most important component of NAE is the NH_3/NH_4^+ system.[11] Unlike for titratable acids, the rate of ammonia (NH_3) production and excretion varies according to physiologic needs. Under normal circumstances, ammonia excretion accounts for approximately 60% of total NAE, and in chronic metabolic acidosis, almost the entire increase in NAE is caused by increased NH_3 metabolism. Ammonia metabolism involves interplay among the proximal tubule, TAL, and collecting duct.

The proximal tubule is responsible for both ammonia production and luminal secretion. Ammonia is synthesized in the proximal tubule predominantly from glutamine metabolism through enzymatic processes in which phosphoenolpyruvate carboxykinase and phosphate-dependent glutaminase are the rate-limiting steps. This results in production of two ammonium (NH_4^+) and two HCO_3^- ions from each glutamine ion. Ammonia is then preferentially secreted into the lumen. The primary mechanism for this luminal secretion appears to be NH_4^+ transport by the apical Na^+-H^+ antiporter NHE3 (Fig. 11.8).

Metabolic acidosis increases the mobilization of glutamine from skeletal muscle and intestinal cells. Glutamine is preferentially taken up by the proximal tubular cell through the Na^+- and H^+-dependent glutamine transporter SNAT3. This transporter is a member of the *SCL38* gene family of Na^+-coupled neutral amino acid transporters. SNAT3 expression increases several-fold in metabolic acidosis, and it is preferentially expressed on the cell's basolateral surface, where it is poised for glutamine uptake.[12] The increase in plasma cortisol that typically accompanies metabolic acidosis plays a role in this transporter's upregulation.[13] Metabolic acidosis also causes increased expression and activity of phosphate-activated glutaminase and glutamate dehydrogenase.

Most of the ammonia that leaves the proximal tubule does not reach the distal tubule. Thus there is transport of ammonia out of the loop of Henle. This ammonia transport appears to occur predominantly in the TAL and is mediated by at least three mechanisms (Fig. 11.9). First, the lumen-positive voltage provides a driving force for passive paracellular NH_4^+ transport out of the TAL. Second, NH_4^+ can be transported out of the lumen by the furosemide-sensitive Na^+-K^+-$2Cl^-$ transporter. Third, NH_4^+ can leave the lumen across the apical membrane K^+ channel of the TAL cell. NH_4^+ exits the cell via the Na^+-H^+ exchanger NHE4, functioning in Na^+-NH_4^+ mode.

In addition, ammonia is secreted by the collecting duct. Although the traditional thought was that NH_3/NH_4^+ then enters the collecting duct by nonionic diffusion driven by the acid luminal pH, increasing evidence suggests that the nonerythroid glycoproteins Rhbg and Rhcg may be involved in collecting duct ammonia secretion.[15,16]

On the basis of the preceding discussion, it can be shown that ammonia excretion can be regulated by three mechanisms. First, ammonia synthesis in the proximal tubule can be regulated. Chronic acidosis and hypokalemia increase ammonia synthesis, whereas hyperkalemia suppresses ammonia synthesis. Second, ammonia delivery from the proximal tubule to the medullary interstitium can be regulated. In particular, chronic metabolic acidosis increases expression of both NHE3 and the loop of Henle Na^+-K^+-$2Cl^-$ cotransporter. Hyperkalemia can inhibit NH_4^+ reabsorption from the TAL. The combined effects of decreased NH_3 synthesis in the proximal tubule and interference in NH_4^+ reabsorption in the thick limb may explain the low urinary [NH_4^+] found in hyperkalemic distal renal tubular acidosis. The reduced availability of ammonia to serve as a urinary buffer leads to a reduction in distal H^+ secretion and development of metabolic acidosis. Also, any interstitial renal disease that destroys renal medullary anatomy may decrease medullary interstitial [NH_3/NH_4^+] transfer. Third, mechanisms that regulate collecting duct H^+ secretion or ammonia transporter expression can regulate ammonia entry into the collecting duct and ammonia excretion. Importantly, the primary mechanisms require synthesis of new proteins to increase both ammonia production and transport. Accordingly, changes in ammonia excretion may be delayed, and the maximal renal response to chronic metabolic acidosis requires 4 to 7 days.

REGULATION OF RENAL ACIDIFICATION

The regulation of acid-base balance requires an integrated system that precisely regulates proximal tubular H^+-HCO_3^- transport, distal nephron H^+-HCO_3^- transport, and ammonia synthesis and transport.

Blood pH

The regulation of acid-base balance requires that net H^+ excretion increase in states of acidosis and decrease in states of alkalosis. This form of regulation involves both acute and chronic mechanisms. In the proximal tubule, acute decreases in blood pH increase the rate of HCO_3^- absorption, and acute increases in blood pH inhibit HCO_3^- absorption. These alterations in the rate of HCO_3^- absorption occur whether the change in pH is the result of changes in $Paco_2$ or serum [HCO_3^-]. Similarly, in the collecting duct, acute changes in peritubular serum [HCO_3^-] and pH regulate the rate of H^+ secretion.

In addition to acute regulation, mechanisms exist for chronic regulation. Chronic acidosis or alkalosis leads to parallel changes in the activities of the proximal tubule apical membrane Na^+-H^+ antiporter and basolateral membrane Na^+-HCO_3^--CO_3^{2-} cotransporter. Metabolic acidosis acutely increases the kinetic activity of NHE3 through direct pH effects and by phosphorylation; chronic acidosis increases the number of NHE3 transporters.[17,18] In addition, chronic acidosis increases proximal

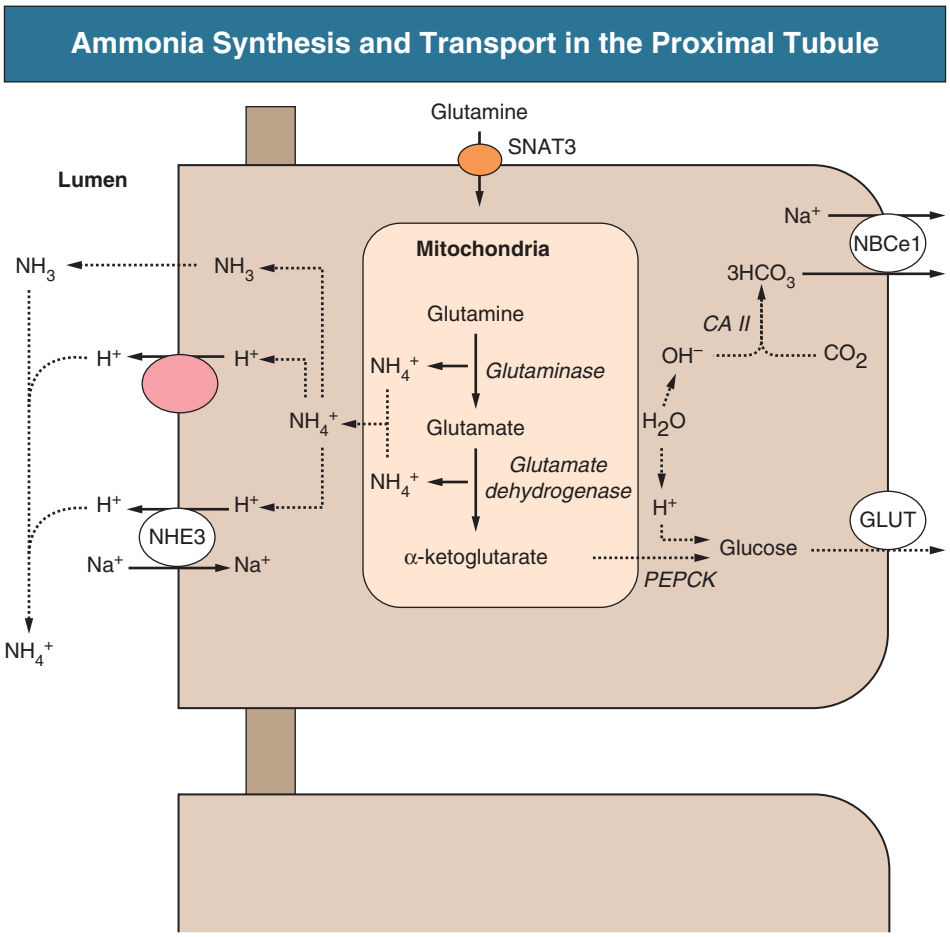

Fig. 11.8 Ammonia synthesis and transport in proximal tubule. Metabolic acidosis and hypokalemia stimulate proximal ammonia synthesis by stimulating the uptake of glutamine through SNAT3.The generation of ammonia is the result of glutamine metabolism by enzymes closely linked to gluconeogenesis.

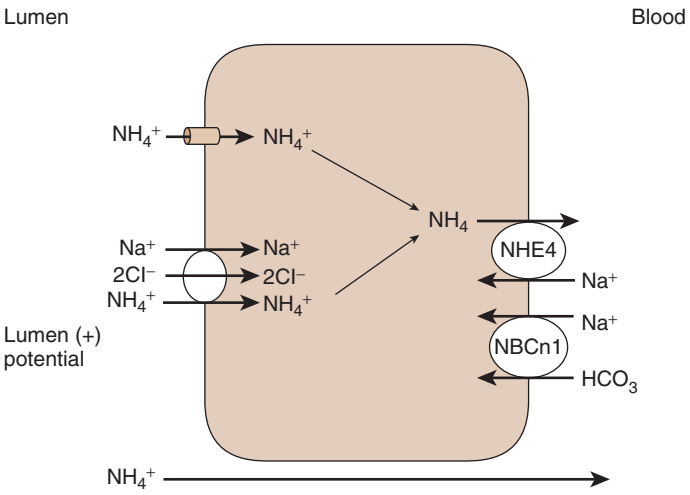

Fig. 11.9 Ammonia transport in thick ascending limb of Henle loop. In addition to reabsorption through the paracellular pathway driven by the lumen-positive potential, ammonium can substitute for K^+ on the Na^+-K^+-$2Cl^-$ transporter and the apical membrane K^+ channel (ROMK). NH_4^+ exits the cell via the Na^+-H^+ exchanger NHE4. The basolateral Na^+-HCO_3^- cotransporter (NBCn1) is thought to play a housekeeping role to maintain cell pH given the large transcellular ammonium flux.

tubular ammonia synthesis by increasing the activities of the enzymes involved in ammonia metabolism.

The CCD is also modified by chronic acid-base changes. Long-term increases in dietary acid lead to an increase in H^+ secretion, whereas long-term increases in dietary alkali lead to an increased capacity for HCO_3^- secretion.[19] This effect is mediated by changes in the relative number of α- and β-IC cells. For example, during metabolic acidosis the number of α-IC cells increases and the number of β-IC cells decreases, without a change in the total number of IC cells. Recent evidence suggests that the extracellular protein hensin may be involved in the switch between the predominant IC cell types.[20]

Mineralocorticoids, Distal Sodium Delivery, and Extracellular Fluid Volume

Mineralocorticoid hormones are key regulators of distal nephron and collecting duct H^+ secretion. Two mechanisms appear to be involved. First, mineralocorticoid hormone stimulates Na^+ absorption in principal cells of the CCD (see Fig. 11.6). This leads to a more lumen-negative voltage that then stimulates H^+ secretion. This mechanism is indirect in that it requires the presence of Na^+ and of Na^+ transport. The second mechanism is the direct activation of H^+ secretion by mineralocorticoids. This effect is chronic, requiring long exposure, and involves parallel increases in apical membrane H^+-ATPase and basolateral membrane Cl^--HCO_3^- exchanger activity.

Plasma Volume

Changes in plasma volume have important effects on acid-base homeostasis. This effect appears to be related to a number of factors. First, volume contraction is associated with a decreased GFR, which lowers the filtered load of HCO_3^- and decreases the load placed on the tubules, to maintain NAE. Volume contraction also acutely decreases the paracellular permeability of the proximal tubule. This will decrease HCO_3^- backleak around cells, thereby increasing net bicarbonate reabsorption by the proximal tubule. Third, chronic volume contraction is associated with an adaptive increase in the activity of the proximal tubule apical membrane Na^+-H^+ antiporter NHE3. Because this transporter contributes to both $NaHCO_3$ and NaCl absorption, both these capacities will be increased with chronic volume contraction. Further, volume contraction limits distal delivery of chloride. In the presence of chronic metabolic alkalosis, the CCD is poised for HCO_3^- secretion. However, collecting duct HCO_3^- secretion requires luminal Cl^- and is inhibited by Cl^- deficiency.

Potassium

Potassium deficiency is associated with an increase in renal NAE. This effect is multifactorial. First, chronic K^+ deficiency increases the proximal tubule apical membrane Na^+-H^+ antiporter and basolateral membrane Na^+-HCO_3^--CO_3^{2-} cotransporter activities. This effect is similar to that seen with chronic acidosis and may be caused by intracellular acidosis. Chronic K^+ deficiency also increases proximal tubular ammonia production. Finally, chronic K^+ deficiency leads to an increase in collecting duct H^+ secretion. This appears to be related to increased activity of the apical membrane H^+-K^+-ATPase. Such an effect increases the rate of H^+ secretion and the rate of K^+ reabsorption in the collecting duct. In addition, ammonia, whose production is stimulated by hypokalemia, has direct effects that stimulate collecting duct H^+ secretion. Counterbalancing these effects is that K^+ deficiency decreases aldosterone secretion, which can inhibit distal acidification. Thus, in normal individuals, the net effect of K^+ deficiency is typically a minor change in acid-base balance. However, in patients with nonsuppressible mineralocorticoid secretion (e.g., hyperaldosteronism, Cushing syndrome), K^+ deficiency can greatly stimulate renal acidification and cause profound metabolic alkalosis.

Hyperkalemia appears to have opposite effects on renal acidification. The most notable effect of hyperkalemia is inhibition of ammonia synthesis in the proximal tubule and ammonia absorption in the loop of Henle, resulting in inappropriately low levels of urinary ammonia excretion. This contributes to the metabolic acidosis seen in patients with hyperkalemic distal (type 4) renal tubular acidosis.

SELF-ASSESSMENT QUESTIONS

1. Which of the following is *true* in regard to the effect of chronic K^+ deficiency on renal acidification?
   - **A.** Decreases basolateral membrane Na^+-HCO_3^--CO_3^{2-} cotransporter activity
   - **B.** Increases proximal tubular ammonia production
   - **C.** Decreases collecting duct H^+ secretion
   - **D.** Increases aldosterone secretion
2. Which one of the following is *true* with regard to ammonia handling in the kidney?
   - **A.** Ammonia synthesized in the proximal tubule is primarily reabsorbed in the cortical collecting duct.
   - **B.** Ammonia is reabsorbed passively in the thick ascending limb driven by the lumen-negative voltage.
   - **C.** NH_4^+ is transported into the lumen of the thick ascending limb by the Na^+-K^+-Cl^- transporter
   - **D.** Nonthyroid glycoproteins Rhbg and Rhcg are involved in collecting duct ammonia secretion.
3. Which of the following is *true* in regard to net acid production by the kidney?
   - **A.** Sulfur-containing amino acids are metabolized to CO_2.
   - **B.** Metabolism of lysine and arginine yield base on metabolism.
   - **C.** Animal foods are high in protein and organophosphates and provide a net acid diet.
   - **D.** Daily volatile acid production is approximately 1 mmol H^+.

Metabolic Acidosis

Biff F. Palmer

DEFINITION

Metabolic acidosis is defined as a low arterial blood pH in conjunction with a reduced serum bicarbonate concentration [HCO_3^-]. Respiratory compensation results in a decrease in arterial carbon dioxide tension ($Paco_2$). A low serum [HCO_3^-] alone is not diagnostic of metabolic acidosis because it also results from the renal compensation to chronic respiratory alkalosis. Measurement of the arterial pH differentiates between these two possibilities. Box 12.1 shows the expected compensatory responses for metabolic and respiratory acid-base disorders.[1]

After the diagnosis of metabolic acidosis is confirmed, the first step in the examination of the patient is to calculate the serum anion gap. The *anion gap* equals the difference between the serum concentrations of the major cation sodium ([Na^+]) and the major measured anions chloride and bicarbonate ([Cl^-] and [HCO_3^-]) and is given by the following formula:

$$\text{Anion gap} = [Na^+] - ([Cl^-] + [HCO_3^-])$$

In healthy individuals, the normal value of the anion gap is approximately 12 ± 2 mmol/l. Because many of the unmeasured anions consist of albumin, the normal anion gap is decreased by approximately 2.5 mmol/l for each 1 g/dl decrease in the serum albumin concentration below normal. The total number of cations must equal the total number of anions, so a decrease in the serum HCO_3^- concentration must be offset by an increase in the concentration of other anions. If the anion accompanying excess H^+ is Cl^-, the decrease in serum [HCO_3^-] is matched by an equal increase in serum [Cl^-]. This acidosis is classified as a "normal anion gap" or a "non–anion gap" or a hyperchloremic metabolic acidosis. By contrast, if excess H^+ is accompanied by an anion other than Cl^-, the decreased [HCO_3^-] is balanced by an increase in the concentration of the unmeasured anion. [Cl^-] remains the same. In this setting, the acidosis is said to be a "high anion gap" or "anion gap" metabolic acidosis.

The normal value for the anion gap has tended to fall over time because of changes in how serum Na^+ and Cl^- are measured.[2] Flame photometry for Na^+ measurement and a colorimetric assay for Cl^- have been replaced by the use of ion-selective electrodes, with which the serum Na^+ values have largely remained the same, whereas the serum Cl^- values have tended to be higher. As a result, the normal value for the anion gap has decreased to as low as 6 mmol/l in some reports. Recognizing this change, some laboratories have adjusted the calibration set point for Cl^- to return the normal value for the anion gap to the 12 ± 2 mmol/l range. The clinician needs to be aware that the average anion gap and range of normal values will vary across different facilities.

Fig. 12.1 provides a recommended approach to a patient with metabolic acidosis and lists the common causes of metabolic acidosis according to the anion gap.

NON–ANION GAP (NORMAL ANION GAP) METABOLIC ACIDOSIS

A non–anion gap metabolic acidosis can result from either renal or extrarenal causes. Renal causes of metabolic acidosis occur when renal bicarbonate generation, which results from net acid excretion, does not balance the loss of bicarbonate and other alkali buffers consumed in the buffering of normal endogenous acid production. This failure of net acid excretion is termed *renal tubular acidosis* (RTA). Extrarenal causes occur when exogenous acid loads, endogenous acid production, or endogenous bicarbonate losses are elevated and exceed renal net acid excretion. The most common extrarenal cause of non–anion gap metabolic acidosis is chronic diarrhea.

Renal and extrarenal causes of metabolic acidosis can be distinguished by measuring urinary ammonia excretion.[3] The primary response of the kidney to metabolic acidosis is to increase urinary ammonia excretion, each millimole of urinary ammonia excreted resulting in the generation of 1 mmol of "new" bicarbonate. Thus renal causes of metabolic acidosis are characterized by low urinary ammonia excretion rates. In contrast, in extrarenal metabolic acidosis, urinary ammonia excretion is elevated. Because most laboratories do not measure urinary ammonia, one can indirectly assess ammonia excretion by measuring the *urinary anion gap* (UAG):

$$UAG = (U_{Na^+} + U_{K^+}) - U_{Cl^-}$$

The UAG is normally a positive value, ranging from +30 to +50 mmol/l. A negative value for the UAG suggests increased renal excretion of an unmeasured cation (i.e., cation other than Na^+ or K^+). One such cation is NH_4^+. With chronic metabolic acidosis because of extrarenal causes, urinary ammonia concentrations, in the form of NH_4Cl, can reach 200 to 300 mmol/l. As a result, the measured cation concentration will be less than the measured anion concentration, which includes the increased urinary Cl^-, and the UAG will be less than zero and frequently less than −20 mmol/l.

The UAG only indirectly reflects the urinary ammonia concentration and, if other unmeasured ions are excreted, can give misleading results. Examples include diabetic ketoacidosis, associated with substantial urinary excretion of sodium ketoacid salts, and toluene exposure (discussed later), associated with increased urinary excretion of sodium hippurate and sodium benzoate. In these settings, the UAG value may remain positive despite an appropriate increase in urinary ammonia

BOX 12.1 Expected Compensatory Responses to Acid-Base Disorders

Acute respiratory acidosis
For every 10 mm Hg rise in P_{CO_2}, HCO_3^- increases by 1 mmol/l
Chronic respiratory acidosis
For every 10 mm Hg rise in P_{CO_2}, HCO_3^- increases by 3.5 mmol/l
Acute respiratory alkalosis
For every 10 mm Hg fall in P_{CO_2}, HCO_3^- decreases by 2 mmol/l
Chronic respiratory alkalosis
For every 10 mm Hg decrease in P_{CO_2}, HCO_3^- decreases by 5 mmol/l
Metabolic acidosis
1.2 mm Hg decrease in P_{CO_2} for each 1 mmol/l fall in HCO_3^-
$P_{CO_2} = HCO_3^- + 15$
P_{CO_2} = Last digits of pH
Metabolic alkalosis
P_{CO_2} increases by 0.7 for each mmol/l HCO_3^-

excretion because of the increased urinary excretion of Na^+ acid-anion salts. A similar situation occurs when urinary NH_4^+ is excreted with an anion other than Cl^-, such as β-hydroxybutyrate, acetoacetate, bicarbonate, or hippurate. In these settings, and even when NH_4^+ is excreted with Cl^-, the urine osmolal gap (UOG) can be used as a surrogate for NH_4^+ concentration. The UOG is the difference between the measured and the calculated urine osmolality.

$$\text{UOG} = \text{Calculated urine osmolality (mOsmol/kg)}$$
$$= (2\times[Na^+ + K^+]) + [\text{Urea nitrogen in mg/dL}]/2.8 + [\text{Glucose in mg/dL}]/18$$

In SI units the formula is $2\times[Na^+ + K^+]$ mmol/L + [Urea] in mmol/L + [Glucose] in mmol/L

The normal value of the UOG is approximately 10 to 100 mOsmol/kg. $NH4^+$ salts are generally the only other major urinary solute that contributes importantly to the urine osmolality, so values appreciably greater than 100 mOsmol/kg reflect increased excretion of NH_4^+ salts.

Urine pH, in contrast to the UAG or UOG, does not reliably differentiate acidosis of renal origin from that of extrarenal origin. For example, an acid urine pH does not necessarily indicate an appropriate increase in net acid excretion. If renal ammonia metabolism is inhibited, as occurs with chronic hyperkalemia, there is decreased ammonia available in the distal nephron to serve as a buffer, and small amounts of distal H^+ secretion can lead to significant urine acidification. In this setting, the urine pH is acid, but net acid excretion is low because of the low ammonia excretion. Similarly, alkaline urine does not necessarily imply a renal acidification defect. In conditions in which ammonia metabolism is stimulated, distal H^+ secretion can be massive and yet the urine remains relatively alkaline because of the buffering effects of ammonia.

Metabolic Acidosis of Renal Origin

An overall approach to patient assessment for workup of metabolic acidosis of renal origin is shown in Fig. 12.2.

Proximal Renal Tubular Acidosis (Type 2)

Normally, 80% to 90% of the filtered load of HCO_3^- is reabsorbed in the proximal tubule. In proximal (type 2) RTA, the proximal tubule has a decreased capacity to reabsorb filtered bicarbonate. When serum bicarbonate concentration is normal or nearly normal, the amount of

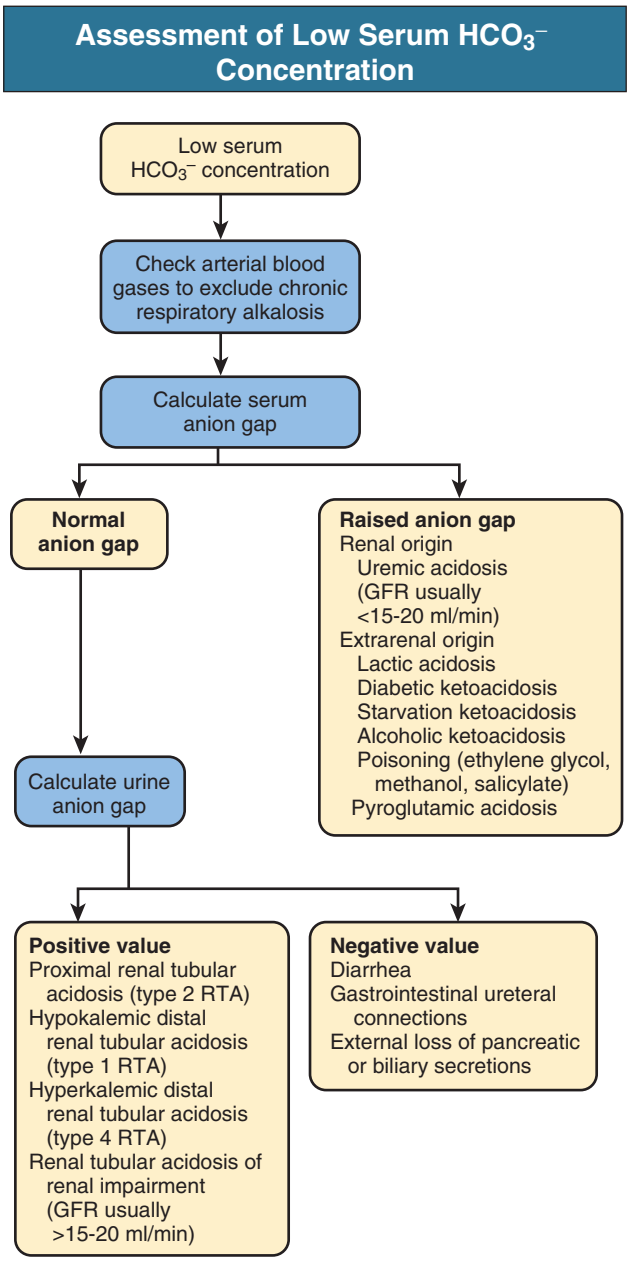

Fig. 12.1 Approach to the patient with low serum HCO_3^- concentration.

bicarbonate filtered by the glomerulus exceeds proximal tubule bicarbonate reabsorptive capacity. When this happens, there is increased bicarbonate delivery to the loop of Henle and distal nephron that exceeds their capacity to reabsorb bicarbonate. As a result, some filtered bicarbonate appears in the urine. The net effect is that serum $[HCO_3^-]$ decreases. Eventually, the filtered bicarbonate load decreases to the point at which the proximal tubule is able to reabsorb sufficient filtered bicarbonate that the bicarbonate load to the loop of Henle and the distal nephron is within their reabsorptive capacity. When this occurs, no further bicarbonate is lost in the urine, net acid excretion normalizes, and a new steady-state serum $[HCO_3^-]$ develops, although at a lower-than-normal level.

Hypokalemia is present in proximal RTA. Renal $NaHCO_3$ losses lead to intravascular volume depletion, which in turn activates the

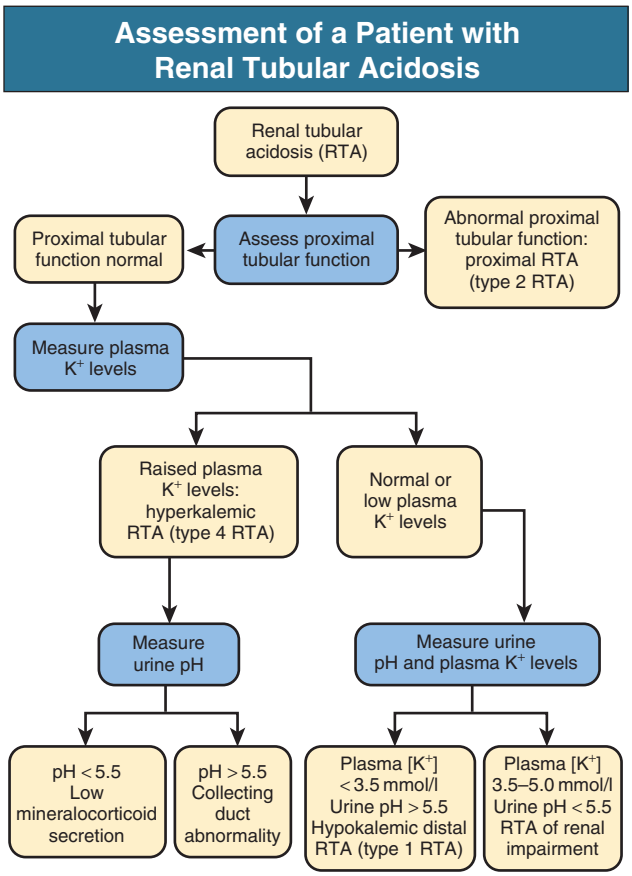

Fig. 12.2 Approach to the patient with renal tubular acidosis.

renin-angiotensin-aldosterone system. Distal Na^+ delivery is increased as a result of the impaired proximal reabsorption of $NaHCO_3$. Because of the associated hyperaldosteronism and increased distal nephron Na^+ reabsorption, there is increased K^+ secretion. The net result is renal potassium wasting and the development of hypokalemia. In the steady state, when virtually all the filtered HCO_3^- is reabsorbed in the proximal and distal nephron, renal potassium wasting is less and the degree of hypokalemia tends to be mild.

Proximal RTA may occur as an isolated defect in acidification, but type 2 typically occurs in the setting of widespread proximal tubule dysfunction (Fanconi syndrome). In addition to decreased HCO_3^- reabsorption, patients with Fanconi syndrome have impaired reabsorption of glucose, phosphate, uric acid, amino acids, and low-molecular-weight proteins. Various inherited and acquired disorders have been associated with the development of Fanconi syndrome and proximal RTA (Box 12.2). The most common inherited cause in children is cystinosis (see Chapter 48). Most adults with Fanconi syndrome have an acquired condition that is related to an underlying dysproteinemic condition, such as multiple myeloma.

Skeletal abnormalities are common in these patients. Osteomalacia can develop from chronic hypophosphatemia caused by renal phosphate wasting if Fanconi syndrome is present. These patients also may have a deficiency in the active form of vitamin D because of an inability to convert 25-hydroxyvitamin D_3 to 1,25-dihydroxyvitamin D in the proximal tubule.

In contrast to distal RTA, proximal RTA is not associated with nephrolithiasis or nephrocalcinosis. One exception is the use of topiramate,[4,5] an antiepileptic drug that is increasingly used to treat a variety of neurologic and metabolic disorders. The drug exerts an inhibitory effect on renal carbonic anhydrase activity, resulting in a proximal acidification defect similar to that observed with acetazolamide. Topiramate also is associated with hypocitraturia, hypercalciuria, and elevated urine pH, leading to an increased risk for kidney stone disease.

BOX 12.2 Causes of Proximal (Type 2) Renal Tubular Acidosis

Not Associated With Fanconi Syndrome
- Sporadic
- Familial

Disorder of Carbonic Anhydrase
- Drugs: Acetazolamide, sulfanilamide, topiramate
- Carbonic anhydrase II deficiency

Associated With Fanconi Syndrome
- Selective (no systemic disease present)
- Sporadic

Familial
- Autosomal recessive proximal RTA with ocular abnormalities: Na^+-HCO_3^- cotransporter (NBCe1) defect
- Autosomal recessive proximal RTA with osteopetrosis and cerebral calcification: Carbonic anhydrase II defect
  - Generalized (systemic disorder present)
  - Genetic disorders
    - Cystinosis
    - Wilson disease
    - Hereditary fructose intolerance
    - Lowe syndrome
    - Metachromatic leukodystrophy

Dysproteinemic States
- Myeloma kidney
- Light-chain deposition disease

Hyperparathyroidism
- Primary
- Secondary

Drugs and Toxins
- Outdated tetracycline
- Ifosfamide
- Gentamicin
- Streptozocin
- Lead
- Cadmium
- Mercury

Tubulointerstitial Disease
- Post-transplantation rejection
- Balkan nephropathy
- Medullary cystic disease

Others
- Bone fibroma
- Osteopetrosis
- Paroxysmal nocturnal hemoglobinuria

HCO_3^-, bicarbonate ions; *P_{CO_2}*, carbon dioxide tension; *RTA*, renal tubular acidosis.

Proximal RTA should be suspected in a patient with a normal anion gap acidosis and hypokalemia who has an intact ability to acidify the urine to below 5.5 while in a steady state.[6] Proximal tubular dysfunction, such as euglycemic glycosuria, hypophosphatemia, hypouricemia, and mild proteinuria, helps support this diagnosis. The UAG is greater than zero, indicating the lack of increase in net acid excretion.

Treatment of proximal RTA is difficult. Administration of alkali increases serum [HCO_3^-], which increases urinary bicarbonate losses and thereby minimizes subsequent increases in the serum [HCO_3^-]. Moreover, the increased distal sodium load, in combination with increased circulating plasma aldosterone, results in increased renal potassium wasting and worsening hypokalemia. As a result, substantial amounts of alkali, often in the form of a potassium salt, such as potassium citrate, are required to prevent worsening hypokalemia. Children with proximal RTA should be aggressively treated to normalize their serum [HCO_3^-] to minimize growth retardation. These children may require large amounts of alkali therapy, typically 5 to 15 mmol/kg/day.

Adults with proximal RTA are frequently not treated as aggressively as children are because of the lack of systemic metabolic abnormalities or bone disease. Many clinicians administer alkali therapy if serum [HCO_3^-] is less than 18 mmol/l to prevent severe acidosis. Whether more aggressive therapy to normalize serum [HCO_3^-] is beneficial remains unknown. However, the large amounts of alkali required, about 700 to 1000 mmol/day for a 70-kg individual, make this approach problematic.

Hypokalemic Distal Renal Tubular Acidosis (Type 1)

In contrast to proximal RTA, patients with distal RTA are unable to acidify their urine, either under basal conditions or in response to metabolic acidosis.[7,8] Type 1 RTA results from a reduction in net H^+ secretion in the distal nephron and prevents urinary acidification, thereby minimizing titratable acid excretion and urinary ammonia excretion. As a result, these patients are unable to match net acid excretion to endogenous acid production, and acid accumulation ensues. The subsequent metabolic acidosis stimulates reabsorption of bone matrix to release the calcium alkali salts present in bone. During prolonged periods, this can result in progressive osteopenia in adults and in osteomalacia in children.

Distal RTA can be caused by either impaired H^+ secretion (secretory defect) or an abnormally permeable distal tubule, resulting in increased backleak of normally secreted H^+ (gradient defect); it may be genetic or acquired. Certain medications, especially amphotericin, result in increased backleak of protons across the apical plasma membrane, leading to a gradient defect form of distal RTA.

For patients with a secretory defect, the inability to acidify the urine below pH 5.5 results from abnormalities in any of the proteins involved in collecting duct H^+ secretion. Some patients may have an isolated defect in the H^+-K^+-ATPase that impairs H^+ secretion and K^+ reabsorption.[9] A defect confined to the vacuolar H^+-ATPase also results in renal potassium wasting.[10] The development of systemic acidosis tends to diminish net proximal fluid reabsorption with an increase in distal delivery, resulting in volume contraction and activation of the renin-aldosterone system. Increased distal Na^+ delivery coupled to increased circulating levels of aldosterone then leads to increased renal K^+ secretion.[11] Defects in the basolateral anion exchanger (AE1) also can cause distal RTA. In this case, the lack of basolateral HCO_3^- exit leads to intracellular alkalinization, which inhibits apical proton secretion.

Patients with distal RTA have low ammonia secretion rates. The decreased secretion is caused by the failure to trap ammonia in the tubular lumen of the collecting duct as a result of the inability to lower luminal fluid pH. In addition, there is often impaired medullary transfer of ammonia because of interstitial disease. Interstitial disease is frequently present in such patients through an associated underlying disease or as a result of nephrocalcinosis or hypokalemia-induced interstitial fibrosis.

In contrast to proximal RTA, nephrolithiasis and nephrocalcinosis are common.[12] Urinary Ca^{2+} excretion is high secondary to acidosis-induced bone mineral dissolution. Luminal alkalinization also inhibits calcium reabsorption, resulting in further increases in urinary calcium excretion.[13] Calcium phosphate solubility is also greatly lowered at alkaline pH, and calcium phosphate stone formation is accelerated. Stone formation is further enhanced as a result of low urinary citrate excretion. Citrate is metabolized to HCO_3^-, and its renal reabsorption is stimulated by metabolic acidosis, thereby minimizing the severity of metabolic acidosis. Urinary citrate also chelates urinary calcium, decreasing ionized calcium concentrations. Accordingly, the decreased citrate excretion that occurs in chronic metabolic acidosis as a result to distal RTA further contributes to both nephrolithiasis and nephrocalcinosis.

Distal RTA may be a primary disorder, either idiopathic or inherited, but it most often occurs in association with a systemic disease, one of the most common of which is Sjögren syndrome (Box 12.3). Hypergammaglobulinemic states as well as drugs and toxins also may cause this disorder.

A common cause of acquired distal RTA is glue sniffing. Inhalation of toluene from the fumes of model glue, spray paint, and paint thinners can give rise to hypokalemic normal anion gap acidosis through multiple mechanisms. First, toluene inhibits collecting duct proton secretion. Second, metabolism of toluene produces the organic acids hippuric and benzoic acid. These are buffered by sodium bicarbonate,

BOX 12.3 Causes of Hypokalemic Distal (Type 1) Renal Tubular Acidosis

Primary
- Idiopathic
- Familial

Secondary

Autoimmune Disorders
- Hypergammaglobulinemia
- Sjögren syndrome
- Primary biliary cirrhosis
- Systemic lupus erythematosus

Genetic Diseases
- Autosomal dominant RTA: Anion exchanger 1 defect
- Autosomal recessive RTA: H^+-ATPase A4 subunit
- Autosomal recessive with progressive nerve deafness: H^+-ATPase B1 subunit

Drugs and Toxins
- Amphotericin B
- Toluene

Disorders With Nephrocalcinosis
- Hyperparathyroidism
- Vitamin D intoxication
- Idiopathic hypercalciuria

Tubulointerstitial Disease
- Obstructive uropathy
- Renal transplantation

resulting in metabolic acidosis and the production of sodium hippurate and sodium benzoate. If plasma volume is normal, these salts are rapidly excreted in the urine, and a non–anion gap metabolic acidosis develops. If plasma volume is decreased, urinary excretion is limited, these salts accumulate, and an anion gap metabolic acidosis develops.

Distal RTA should be considered in all patients with a non–anion gap metabolic acidosis and hypokalemia who have an inability to lower the urine pH maximally. A urine pH above 5.5 in the patient with systemic acidosis suggests distal RTA, and a UAG value greater than zero or lack of an increase in the UOG is confirmatory. Depending on the duration of the distal RTA, the metabolic acidosis can be mild or very severe, with a serum [HCO_3^-] as low as 10 mmol/l. Urinary potassium losses lead to the development of hypokalemia. Severe hypokalemia (<2.5 mmol/l) may result in musculoskeletal weakness and nephrogenic diabetes insipidus. The latter occurs because hypokalemia decreases aquaporin 2 (AQP2) expression in the collecting duct, thereby minimizing the ability to concentrate urine. An abdominal ultrasound scan or radiograph may reveal nephrocalcinosis.

In patients with minimal disturbances in blood pH and plasma [HCO_3^-], a test of urinary acidification is required. Traditionally, such a test involved oral NH_4Cl administration to induce metabolic acidosis with assessment of the renal response by serial measurement of urine pH. Many patients poorly tolerate NH_4Cl ingestion because of gastric irritation, nausea, and vomiting. An alternative way to test the capacity for distal acidification is to administer furosemide and the mineralocorticoid fludrocortisone simultaneously.[14] The combination of both increased distal Na^+ delivery and mineralocorticoid effect will stimulate distal H^+ secretion by both an increase in the luminal electronegativity and a direct stimulatory effect on H^+ secretion. Normal individuals will lower urine pH to values below 5.5 with either maneuver.

Correction of the metabolic acidosis in distal RTA can be achieved by administration of alkali in an amount only slightly greater than daily acid production, usually 1 to 2 mmol/kg/day. In patients with severe K^+ deficits, correction of the acidosis with HCO_3^-, particularly if it is done with sodium alkali salts such as $NaHCO_3$, can lower serum potassium concentration to dangerous levels. In this setting, potassium replacement should begin before the acidosis is corrected. In general, a combination of sodium alkali and potassium alkali is required for long-term treatment of distal RTA. For the patient with recurrent renal stone disease caused by distal RTA, treatment of the acidosis increases urinary citrate excretion, which slows the rate of further stone formation and may even lead to stone dissolution.

Hyperkalemic Distal Renal Tubular Acidosis (Type 4)

Type 4 RTA is characterized by distal nephron dysfunction, resulting in impaired renal excretion of both H^+ and K^+ and causing hyperchloremic normal gap acidosis and hyperkalemia.[15] (It should be noted that type 3 RTA is most often applied to a rare autosomal recessive syndrome resulting from carbonic anhydrase II deficiency with features of both proximal and distal RTA.)

Type 4 RTA occurs most frequently with mild to moderate impairment in renal function; however, the magnitude of hyperkalemia and acidosis is disproportionately severe for the observed glomerular filtration rate (GFR). Whereas hypokalemic distal (type 1) RTA is also a disorder of distal nephron acidification, type 4 is distinguished from type 1 RTA on the basis of several important characteristics (Table 12.1). Type 4 RTA is also a much more common form of RTA, particularly in adults.

Hyperkalemic distal RTA results from deficient circulating aldosterone or abnormal cortical collecting duct (CCD) function, or it can be related to hyperkalemia. In either case, a defect in distal H^+ secretion develops. Impaired Na^+ reabsorption by the principal cell leads to a decrease in the luminal electronegativity of the CCD, which impairs distal acidification as a result of the decrease in driving force for H^+ secretion into the tubular lumen. The H^+ secretion is further impaired in this segment as well as in the medullary collecting duct as a result of either the loss of the direct stimulatory effect of aldosterone on H^+ secretion or an abnormality in the H^+-secreting cell.

TABLE 12.1 Differentiation of Renal Tubular Acidosis Types

Factor	Type 1	Type 2	Type 4
Serum K^+	Low	Low	High
Renal function	Normal or near normal	Normal or near normal	Stage 3, 4, or 5 chronic kidney disease
Urine pH during acidosis	High	Low	Low or high
Serum HCO_3^- (mmol/l)	10-20	16-18	16-22
Urine citrate	Low	High	Low
Fanconi syndrome	No	May be present	No

A consequence of the decrease in luminal electronegativity in the CCD is impaired renal K^+ excretion. In addition, a primary abnormality in CCD transport can also impair K^+ secretion. The development of hyperkalemia adds to the defect in distal acidification by decreasing the amount of ammonia available to act as a urinary buffer. Some studies suggest that hyperkalemia itself, through its effects on ammonia metabolism, is the primary mechanism by which metabolic acidosis develops in type 4 RTA.

The etiology of type 4 RTA includes disorders associated with decreased circulating levels of aldosterone and conditions associated with impaired CCD function. The most common disease associated with type 4 RTA in adults is diabetes mellitus. In these patients, primary NaCl retention leads to volume expansion and suppression and atrophy of the renin-secreting juxtaglomerular apparatus. Several common drugs, such as nonsteroidal antiinflammatory agents (NSAIDs), angiotensin-converting enzyme (ACE) inhibitors, and high doses of heparin, as used for systemic anticoagulation, can lead to decreased mineralocorticoid synthesis. Impaired function of the CCD can be a feature of structural damage to the kidney, as in interstitial renal diseases such as sickle cell nephropathy, urinary tract obstruction, and lupus. CCD function also may be impaired from use of drugs such as amiloride, triamterene, and spironolactone.[16]

Type 4 RTA should be suspected in a patient with a normal gap metabolic acidosis associated with hyperkalemia. The typical patient is in the fifth to seventh decade of life with a long-standing history of diabetes mellitus with a moderate reduction in the GFR. Plasma [HCO_3^-] is usually 18 to 22 mmol/l and serum [K^+] between 5.5 and 6.5 mmol/l. Most patients are asymptomatic; however, the hyperkalemia may occasionally be severe enough to cause muscle weakness or cardiac arrhythmias. The UOG is not increased and the UAG value is slightly positive, indicating minimal ammonia excretion in the urine. When the disorder is caused by a defect in mineralocorticoid activity, patients typically have urine pH below 5.5, reflecting a more severe defect in ammonia availability than in H^+ secretion (Fig. 12.3). In patients with structural damage to the collecting duct, the urine pH may be alkaline, reflecting both impaired H^+ secretion and decreased urinary ammonia excretion.

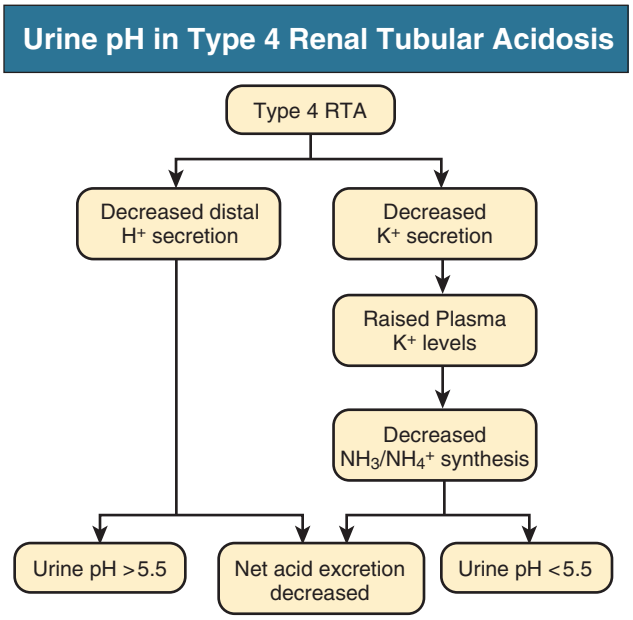

Fig. 12.3 Urine pH in hyperkalemic distal (Type 4) renal tubular acidosis. Net acid excretion is always decreased; however, the urine pH can be variable. In structural disease of the kidney, the predominant defect is usually decreased distal H^+ secretion and the urine pH is above 5.5. In disorders associated with decreased mineralocorticoid activity, urine pH is usually below 5.5.

BOX 12.4 Causes of Hyperkalemic Distal (Type 4) Renal Tubular Acidosis

Mineralocorticoid Deficiency

Low Renin, Low Aldosterone
- Diabetes mellitus
- Drugs
  - Nonsteroidal antiinflammatory drugs (NSAIDs)
  - Cyclosporine, tacrolimus
  - β-Blockers

High Renin, Low Aldosterone
- Adrenal destruction
- Congenital enzyme defects
- Drugs
  - Angiotensin-converting enzyme (ACE) inhibitors
  - Angiotensin II receptor blockers (ARBs)
  - Heparin
  - Ketoconazole

Abnormal Cortical Collecting Duct
- Absent or defective mineralocorticoid receptor
- Drugs
  - Spironolactone, eplerenone
  - Triamterene
  - Amiloride
  - Trimethoprim
  - Pentamidine
- Chronic tubulointerstitial disease

Treatment of patients with type 4 RTA is directed at both the hyperkalemia and the metabolic acidosis. In many patients, lowering serum $[K^+]$ will simultaneously correct the acidosis.[17] Correction of the hyperkalemia allows renal ammonia production to increase, thereby increasing the buffer supply for distal acidification. The first consideration in treatment is to discontinue any nonessential medication that might interfere in either the synthesis or activity of aldosterone or the ability of the kidneys to excrete potassium (Box 12.4). ACE inhibitors and angiotensin receptor blockers usually should be continued because of the beneficial effects on cardiovascular disease and their renoprotective benefits in patients with chronic kidney disease (CKD). In patients with aldosterone deficiency who are neither hypertensive nor fluid overloaded, administration of a synthetic mineralocorticoid such as fludrocortisone 0.1 mg/day can be effective. In patients with hypertension or volume overload, particularly in association with CKD, administration of either a thiazide or a loop diuretic is frequently effective. Loop diuretics are required in patients with estimated GFR below 30 ml/min. Loop and thiazide diuretics increase distal Na^+ delivery and thus stimulate K^+ and H^+ secretion in the collecting duct. Alkali therapy (e.g., $NaHCO_3$) also can be used to treat the acidosis and hyperkalemia, but the patient must be closely monitored to avoid volume overload and worsening hypertension.

Renal Tubular Acidosis in Chronic Kidney Disease

Metabolic acidosis in advanced CKD is caused by failure of the tubular acidification process to excrete the normal daily acid load. As functional renal mass is reduced by disease, there is an adaptive increase in ammonia production and H^+ secretion by the remaining nephrons. Despite increased production of ammonia from each remaining nephron, overall production may be decreased secondary to the decrease in total renal mass. In addition, less ammonia is delivered to the medullary interstitium secondary to a disrupted medullary anatomy.[18] The ability to lower the urinary pH remains intact, reflecting the fact that the impairment in distal nephron H^+ secretion is less than that in ammonia secretion. Quantitatively, however, the total amount of H^+ secretion is small, and the acidic urine pH is the consequence of very little buffer in the urine. The lack of ammonia in the urine is reflected by a positive value for the UAG and lack of an increase in the UOG. Differentiation of RTA from type 4 RTA can be difficult because it is based on the clinician's determination of whether the severity of metabolic acidosis is out of proportion to the degree of renal dysfunction.

Patients with CKD may develop a hyperchloremic normal gap metabolic acidosis associated with normokalemia or mild hyperkalemia as GFR decreases to less than 30 ml/min. With more advanced CKD (GFR <15 ml/min), the acidosis may change to an anion gap metabolic acidosis, reflecting a progressive inability to excrete phosphate, sulfate, and various organic acids. At this stage, the acidosis is commonly referred to as "uremic acidosis."

Correction of the metabolic acidosis in patients with CKD is achieved by treatment with $NaHCO_3$, 0.5 to 1.5 mmol/kg/day, beginning when the HCO_3^- level is less than 22 mmol/l. In some patients, non–sodium citrate formulations can be used. Loop diuretics are often used in conjunction with alkali therapy to prevent volume overload. If the acidosis becomes refractory to medical therapy, dialysis needs to be initiated. Recent evidence suggests that metabolic acidosis in the patient with CKD needs to be aggressively treated because chronic acidosis is associated with metabolic bone disease and may lead to an accelerated catabolic state in patients with CKD.[19,20]

Metabolic Acidosis of Extrarenal Origin

Diarrhea

Intestinal secretions from sites distal to the stomach are rich in HCO_3^-. Accelerated loss of this HCO_3^--rich solution can result in metabolic

acidosis. The resultant volume loss signals the kidney to increase NaCl reabsorption; this combined with the intestinal $NaHCO_3$ losses generates a normal anion gap metabolic acidosis. The renal response is to increase net acid excretion by increasing urinary excretion of ammonia.[21] Hypokalemia, as a result of gastrointestinal losses, and the low serum pH both stimulate the synthesis of ammonia in the proximal tubule. The increase in availability of ammonia to act as a urinary buffer allows a maximal increase in H^+ secretion by the distal nephron.

The increase in urinary ammonia excretion associated with an extrarenal normal anion gap acidosis results in a negative UAG value and an increase in the UOG. Urine pH can be misleading and in chronic diarrhea may be above 6.0 because of substantial increases in renal ammonia metabolism that result in increased urine pH from the buffering ability of the ammonia. Although the clinical history should distinguish between these two possibilities, in a patient with surreptitious laxative abuse, this may not be helpful because diarrhea may not be reported. Colonoscopy may be required to demonstrate characteristic findings of laxative abuse (e.g., melanosis coli) if this diagnosis is being considered.

Treatment of diarrhea-associated metabolic acidosis is based on treatment of the underlying diarrhea. If this is not possible, alkali treatment, possibly including potassium alkali to treat hypokalemia and metabolic acidosis simultaneously, is indicated.

Ileal Conduits

Surgical diversion of the ureter into an ileal pouch is used in the treatment of the patient with neurogenic bladder or after cystectomy. The procedure may be associated rarely with development of a hyperchloremic normal anion gap metabolic acidosis. Acidosis in part is caused by reabsorption of urinary NH_4Cl by the intestine. The ammonia is transported through the portal circulation to the liver or is metabolized to urea to prevent hyperammonemic encephalopathy. This metabolic process consumes equimolar amounts of bicarbonate and therefore can result in the development of metabolic acidosis. Metabolic acidosis also may develop because urinary Cl^- can be exchanged for HCO_3^- through activation of a Cl^--HCO_3^- exchanger on the intestinal lumen. In some patients, a renal defect in acidification can develop and exacerbate the degree of acidosis. Such a defect may result from tubular damage caused by pyelonephritis or high colonic pressures, secondarily causing urinary obstruction.

The severity of acidosis relates to the length of time the urine is in contact with the bowel and the total surface area of bowel exposed to urine. In patients with a ureterosigmoid anastomosis, these factors are increased and the acidosis tends to be more common and more severe than in patients with an ileal conduit. The ileal conduit was designed to minimize the time and area of contact between urine and intestinal surface. Patients with surgical diversion of the ureter who develop metabolic acidosis should be evaluated for an ileal loop obstruction because this would lead to an increase in contact time between the urine and intestinal surface.

ANION GAP METABOLIC ACIDOSIS

Lactic Acidosis

Lactic acid is the end product in the anaerobic metabolism of glucose and is generated by the reversible reduction of pyruvic acid by lactic acid dehydrogenase and reduced nicotinamide adenine dinucleotide (NADH), as shown in the following formula:

$$\text{Pyruvate} + \text{NADH} + H^+ \leftrightarrow \text{Lactate} + NAD^+$$

Under normal conditions, the reaction is shifted toward the right and the normal lactate-to-pyruvate ratio is approximately 10:1. The reactants in this pathway are interrelated, as shown in the following equation:

$$\text{Lactate} = K[(\text{pyruvate})(\text{NADH})(H^+)]/(NAD^+)$$

where K is the equilibrium constant.

On the basis of this relationship, it is evident that lactate can increase for three reasons.[22] First, lactate can increase because of increased pyruvate production alone. In this situation, the normal 10:1 lactate-to-pyruvate ratio will be maintained. An isolated increase in pyruvate production can be seen in the setting of intravenous glucose infusions, intravenous administration of epinephrine, and respiratory alkalosis. Lactate levels in these conditions are minimally elevated, rarely exceeding 5 mmol/l. Second, lactate can increase as a result of an increased NADH-NAD^+ ratio. Under these conditions, the lactate-to-pyruvate ratio can increase to very high values. Third, lactate can increase with a combination of increased pyruvate production and increased NADH/NAD^+. This is common in severe lactic acidosis.

Lactic acidosis occurs when there is an imbalance between the production and the use of lactic acid. The net result is an accumulation of serum lactate and development of metabolic acidosis. The accumulation of the non–chloride anion lactate accounts for the increase in anion gap. Severe exercise and grand mal seizures are examples of lactic acidosis developing as a result of increased production. The short-lived nature of the acidosis in these conditions suggests that a concomitant defect in lactic acid use is present in most conditions of sustained and severe lactic acidosis.

Some of the disorders associated with the development of lactic acidosis are listed in Box 12.5. Type A lactic acidosis is characterized by underperfusion of tissue or acute hypoxia, such as hypotension, sepsis, acute tissue hypoperfusion, cardiopulmonary failure, severe anemia, hemorrhage, and carbon monoxide poisoning. Type B lactic acidosis occurs in the absence of overt hypoperfusion or hypoxia, such as with congenital defects in glucose or lactate metabolism, diabetes mellitus,

BOX 12.5 Causes of Lactic Acidosis

Type A (Tissue Underperfusion or Hypoxia)

- Cardiogenic shock
- Septic shock
- Hemorrhagic shock
- Acute hypoxia
- Carbon monoxide poisoning
- Anemia

Type B (Absence of Hypotension and Hypoxia)

- Hereditary enzyme deficiency (glucose 6-phosphatase)
- Drugs or toxins
  - Phenformin, metformin
  - Cyanide
  - Salicylate, ethylene glycol, methanol
  - Propylene glycol[26]
  - Linezolid[24]
  - Propofol[25]
  - Nucleoside reverse transcriptase inhibitors: Stavudine, didanosine[24]
  - Clenbuterol[27]
  - Isoniazid
- Thiamine deficiency
- Systemic disease
  - Liver failure
  - Malignancy

liver disease, effects of drugs and toxins, and neoplastic diseases.[23-28] Thiamine deficiency is being increasingly recognized as a cause of type B lactic acidosis in subjects with alcoholism, persistent vomiting and severe malnutrition. In clinical practice, many patients will often exhibit features of type A and type B lactic acidosis simultaneously.

Therapy is aimed at correction of the underlying disorder. Restoration of tissue perfusion and oxygenation is attempted if these are compromised. The role of alkali in the treatment of patients with lactic acidosis is controversial; some experimental models and clinical observations suggest that administration of HCO_3^- may depress cardiac function and exacerbate the acidemia. In addition, such therapy may be complicated by volume overload, hypernatremia, and rebound alkalosis after the acidosis has resolved.[29] In general, HCO_3^- should be given when the systemic pH decreases to below 7.1, because hemodynamic instability becomes much more likely with severe acidemia. In such patients, alkali therapy should be directed at increasing the pH above 7.1; attempts to normalize the pH or $[HCO_3^-]$ should be avoided. Acute hemodialysis is rarely beneficial for lactic acidosis induced by tissue hypoperfusion. The hemodynamic instability that can occur with hemodialysis in these critically ill patients may worsen the underlying difficulty in tissue oxygenation.

Diabetic Ketoacidosis

Diabetic ketoacidosis results from the accumulation of acetoacetic acid and β-hydroxybutyric acid. The development of ketoacidosis is the result of insulin deficiency and a relative or absolute increase in glucagon.[30] These hormonal changes lead to increased fatty acid mobilization from adipose tissue and alter the oxidative machinery of the liver such that delivered fatty acids are primarily metabolized into ketoacids. In addition, peripheral glucose use is impaired, and the gluconeogenic pathway in the liver is maximally stimulated. The resultant hyperglycemia causes an osmotic diuresis and volume depletion.

Ketoacidosis results when the rate of hepatic ketoacid generation exceeds renal excretion, causing increased blood ketoacid concentrations. The H^+ accumulation in the extracellular fluid (ECF) decreases HCO_3^- concentration, whereas the ketoacid anion concentration increases. An anion gap metabolic acidosis is the more common finding in the patient with diabetic ketoacidosis, but a normal gap metabolic acidosis also can be seen. In early stages of ketoacidosis, when the ECF volume is almost normal, ketoacid anions that are produced are rapidly excreted by the kidney as Na^+ and K^+ salts. Excretion of these salts is equivalent to the loss of potential HCO_3^-. This loss of potential HCO_3^- in the urine at the same time the kidney is retaining NaCl results in a normal gap metabolic acidosis. As volume depletion develops, renal ketoacid excretion cannot match production rates and ketoacid anions are retained within the body, thus increasing the anion gap.[31]

During treatment, the anion gap metabolic acidosis transforms once again into a normal gap acidosis. Treatment leads to a termination in ketoacid production. As the ECF volume is restored, there is increased renal excretion of the Na^+ salts of the ketoacid anions. The loss of this potential HCO_3^-, combined with the retention of administered NaCl, accounts for the redevelopment of the hyperchloremic normal gap acidosis. In addition, K^+ and Na^+ administered in solutions containing NaCl and KCl enter cells in exchange for H^+. The net effect is infusion of HCl into the ECF. The reversal of the hyperchloremic acidosis takes several days as the HCO_3^- deficit is corrected by the kidney.

Diabetic ketoacidosis can result in a severe metabolic acidosis with serum bicarbonate levels below 5 mmol/l. This diagnosis should be considered in patients with simultaneous metabolic acidosis and hyperglycemia. Diagnosis is confirmed by demonstration of retained ketoacids with nitroprusside tablets or reagent strips in the urine. However, these tests detect only acetone and acetoacetate and not β-hydroxybutyrate. In the patient with lactic acidosis or alcoholic ketoacidosis, acetoacetate may be converted to β-hydroxybutyrate to an extent that depends on the NADH/NAD^+ ratio. With treatment of the diabetic ketoacidosis, acetoacetate is generated as this ratio falls, and the nitroprusside test result may suddenly become strongly positive.

The limitations of the nitroprusside test can be prevented by direct measurement of β-hydroxybutyrate. With uncontrolled diabetes, a serum β-hydroxybutyrate level above 3.0 mmol/l in adults and above 3.8 mmol/l in children confirms diabetic ketoacidosis.[32] Compared with urinary ketone measurements, capillary blood levels of β-hydroxybutyrate better correlate with both the degree of acidosis and the response to therapy.[33]

Treatment consists of insulin and intravenous fluids to correct volume depletion. Deficiencies in K^+, Mg^{2+}, and phosphate are common; therefore these electrolytes are typically added to intravenous solutions. However, diabetic ketoacidosis typically manifests with hyperkalemia secondary to the insulin deficiency. Potassium should be administered only as hypokalemia develops, usually during insulin treatment of diabetic ketoacidosis. If there is significant hypokalemia at presentation, potassium supplementation may be needed before insulin administration to avoid life-threatening worsening of hypokalemia. Alkali therapy is generally not required because administration of insulin leads to the metabolic conversion of ketoacid anions to HCO_3^- and allows partial correction of the acidosis. However, HCO_3^- therapy may be indicated in patients who present with severe acidemia (pH <7.1).[34]

D-Lactic Acidosis

D-Lactic acidosis is a form of metabolic acidosis that can occur in the patient with small bowel resections or in patients with a jejunoileal bypass. Such short bowel syndromes create a situation in which carbohydrates that are normally extensively reabsorbed in the small intestine are delivered in large amounts to the colon. In the presence of colonic bacterial overgrowth, these substrates are metabolized into D-lactate and absorbed into the systemic circulation. Accumulation of D-lactate produces an anion gap metabolic acidosis in which the serum lactate concentration is normal because the standard test for lactate is specific for L-lactate. These patients typically present after ingestion of a large, high-carbohydrate meal, with neurologic abnormalities including confusion, slurred speech, and ataxia. Ingestion of low-carbohydrate meals and antimicrobial agents to decrease the degree of bacterial overgrowth are the principal treatments.

Starvation Ketosis

Abstinence from food can lead to a mild anion gap metabolic acidosis secondary to increased production of ketoacids. The pathogenesis of this disorder is similar to that of diabetic ketoacidosis in that starvation leads to relative insulin deficiency and glucagon excess. As a result, there is increased mobilization of fatty acids while the liver is set to oxidize fatty acids to ketoacids. With prolonged starvation, the blood ketoacid level can reach 5 to 6 mmol/l. The serum $[HCO_3^-]$ is rarely less than 18 mmol/l. More fulminant ketoacidosis is aborted because ketone bodies stimulate the pancreatic islets to release insulin and lipolysis is held in check. This break in the ketogenic process is notably absent in patients with insulin-dependent diabetes.[35] No specific therapy is indicated in starvation ketosis.

Alcoholic Ketoacidosis

Ketoacidosis develops in patients with a history of chronic ethanol abuse, decreased food intake, and often a history of nausea and vomiting. As with starvation ketosis, a decrease in the insulin-to-glucagon ratio leads to accelerated fatty acid mobilization and alters the enzymatic machinery of the liver to favor ketoacid production. However, features unique to this disorder differentiate alcoholic ketoacidosis from simple

starvation ketosis. First, the alcohol withdrawal combined with volume depletion and starvation greatly increases the levels of circulating catecholamines. As a result, the peripheral mobilization of fatty acids is much greater than typically found with starvation alone. This sometimes massive mobilization of fatty acids can lead to marked ketoacid production and severe metabolic acidosis. Second, the metabolism of ethanol leads to accumulation of NADH. The increase in NADH/NAD^+ is reflected by a higher ratio of β-hydroxybutyrate to acetoacetate. As mentioned previously, the nitroprusside reaction may be diminished by this redox shift despite the presence of severe ketoacidosis. Treatment of patients with alcoholic ketoacidosis focuses on glucose administration, which leads to the rapid resolution of the acidosis; stimulation of insulin release leads to diminished fatty acid mobilization from adipose tissue, as well as decreased hepatic output of ketoacids.

Ethylene Glycol and Methanol Intoxications

Ethylene glycol and methanol intoxications are characteristically associated with the development of a severe anion gap metabolic acidosis. Metabolism of ethylene glycol by alcohol dehydrogenase generates various acids, including glycolic, oxalic, and formic acids. Ethylene glycol is present in antifreeze and solvents and is ingested by accident or as a suicide attempt. The initial effects of intoxication are neurologic and begin with drunkenness but can quickly progress to seizures and coma. If left untreated, cardiopulmonary symptoms such as tachypnea, noncardiogenic pulmonary edema, and cardiovascular collapse may appear. From 24 to 48 hours after ingestion, patients may develop flank pain and acute kidney injury, often accompanied by abundant calcium oxalate crystals in the urine (Box 12.6). A fatal dose of ethylene glycol is approximately 100 ml.

BOX 12.6 Ethylene Glycol and Methanol Poisoning

Time course of clinical symptoms and signs after ingestion

Ethylene glycol

- 0-12 hours: Inebriation progressing to coma
- 12-24 hours: Tachypnea, noncardiogenic pulmonary edema
- 24-36 hours: Flank pain, renal failure, urinary calcium oxalate crystals

Methanol

- 0-12 hours: Inebriation followed by asymptomatic period
- 24-36 hours: Pancreatitis, retinal edema progressing to blindness, seizures
- >48 hours: Putamen and white matter hemorrhage leading to Parkinson-like state

Increased anion gap metabolic acidosis

Increased osmolar gap

Treatment

Supportive care

Fomepizole (4-methylpyrazole) is agent of choice (competitor of alcohol dehydrogenase): 15 mg/kg IV loading dose, then 10 mg/kg every 12 hours for 48 hours. After 48 hours, increase dose to 15 mg/kg every 12 hours; increase frequency of dosing to EVERY 4 hours during hemodialysis.

Intravenous ethanol (5% or 10% solution) if fomepizole unavailable: Loading dose of 0.6 g/kg, followed by hourly maintenance dose of 66 mg/kg. Increase maintenance dose when the patient has history of chronic alcohol use and during hemodialysis.

Hemodialysis to accelerate removal of parent compound and metabolites

Bicarbonate therapy to treat acidosis

Methanol is also metabolized by alcohol dehydrogenase and forms formaldehyde, which is then converted to formic acid. Methanol is found in a variety of commercial preparations, such as shellac, varnish, and de-icing solutions, and is also known as wood alcohol. As with ethylene glycol, methanol can be ingested either by accident or as a suicide attempt. Clinically, methanol ingestion is associated with an acute inebriation followed by an asymptomatic period lasting 24 to 36 hours. Abdominal pain caused by pancreatitis, seizures, blindness, and coma may develop. The blindness is caused by direct toxicity of formic acid on the retina. Methanol intoxication is also associated with hemorrhage in the white matter and putamen, which can lead to the delayed onset of a Parkinsonian syndrome (see Box 12.6). The lethal dose of methanol is 60 to 250 ml.

Lactic acidosis is also a feature of methanol and ethylene glycol poisoning and contributes to the elevated anion gap. Together with an elevated anion gap, an osmolar gap is an important clue to the diagnosis of ethylene glycol and methanol poisoning. The osmolar gap is the difference between the measured and calculated osmolality. The formula for the calculated osmolality is as follows:

$$\text{Calculated osmolality} = 2\times Na^+ + BUN/2.8 + \text{glucose}/18 + EtOH/4.6$$

where the blood urea nitrogen (BUN), glucose, and ethanol concentrations are in milligrams per deciliter. Inclusion of the ethanol concentration in this calculation is important because many patients ingest ethylene glycol or methanol while inebriated from ethanol ingestion. The normal value for the osmolar gap is less than 10 mOsm/kg. Each 100 mg/dl (161 mmol/l) of ethylene glycol will increase the osmolar gap by 16 mOsm/kg. Methanol contributes 32 mOsm/kg for each 100 mg/dl (312 mmol/l).

In addition to supportive measures, the patient with ethylene glycol and methanol poisoning is treated with fomepizole (4-methylpyrazole), which inhibits alcohol dehydrogenase and prevents formation of toxic metabolites[36] (see Box 12.6). If fomepizole is unavailable, intravenous ethanol can be used to prevent the formation of toxic metabolites. Ethanol has more than a 10-fold greater affinity for alcohol dehydrogenase than that of other alcohols. Ethanol has its greatest efficacy when levels of 100 to 200 mg/dl are obtained. In addition to both fomepizole and ethanol therapy, the patient should receive hemodialysis to remove both the parent compound and its metabolites. Correction of the acidosis is accomplished with an HCO_3^--containing dialysate or by intravenous infusion of $NaHCO_3$.

Salicylate

Aspirin (acetylsalicylic acid) is associated with a large number of accidental or intentional poisonings. At toxic concentrations, salicylate uncouples oxidative phosphorylation and, as a result, leads to increased lactic acid production. In children, ketoacid production also may be increased. The accumulation of lactic, salicylic, keto, and other organic acids leads to the development of an anion gap metabolic acidosis. At the same time, salicylate has a direct stimulatory effect on the respiratory center. Increased ventilation lowers the carbon dioxide tension (P_{CO_2}), contributing to the development of a respiratory alkalosis. Children primarily manifest an anion gap metabolic acidosis with toxic salicylate levels; a respiratory alkalosis is most evident in adults.

In addition to conservative management, the initial goals of therapy for salicylate poisoning are to correct systemic acidemia and increase the urine pH. By increasing systemic pH, the ionized fraction of salicylic acid will increase, resulting in less accumulation of the drug in the central nervous system. Similarly, an alkaline urine pH favors increased

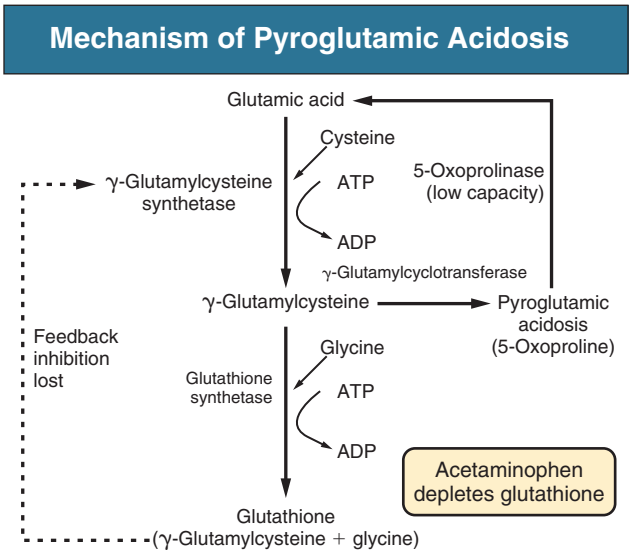

Fig. 12.4 Mechanism of pyroglutamic acidosis. Glutathione is formed from γ-glutamylcysteine and glycine in the presence of glutathione synthetase. Glutathione normally regulates the activity of γ-glutamylcysteine synthetase through feedback inhibition. Depletion of glutathione results in increased formation of γ-glutamylcysteine, which in turn is metabolized to pyroglutamic acid (5-oxoproline) and cystine through γ-glutamylcyclotransferase. Pyroglutamic acid accumulates because the enzyme responsible for its metabolism (5-oxoprolinase) is low capacity. *ADP,* ADENOSINE diphosphate; *ATP,* adenosine triphosphate.

urinary excretion because the ionized fraction of the drug is poorly reabsorbed by the tubule. At serum concentrations above 80 mg/dl or in the setting of severe clinical toxicity, hemodialysis can be used to accelerate drug elimination.

Pyroglutamic Acidosis

Pyroglutamic acid, also known as 5-oxoproline, is an intermediate in glutathione metabolism. An anion gap acidosis caused by pyroglutamic acid has been described rarely in critically ill patients receiving therapeutic doses of acetaminophen[37,38] (Fig. 12.4). Patients present with severe anion gap metabolic acidosis accompanied by alterations in mental status ranging from confusion to coma. High concentrations of pyroglutamic acid are found in the blood and urine. In this setting, glutathione levels are reduced because of the oxidative stress associated with critical illness and by the metabolism of acetaminophen. The reduction in glutathione secondarily leads to increased production of pyroglutamic acid. The diagnosis of pyroglutamic acidosis should be considered in patients with unexplained anion gap metabolic acidosis and recent acetaminophen ingestion.

ALKALI TREATMENT OF METABOLIC ACIDOSIS

Treatment of metabolic acidosis usually involves either sodium bicarbonate or citrate[34] (Table 12.2). $NaHCO_3$ can be taken orally as tablets or powder or given intravenously as a hypertonic bolus or an isotonic infusion, which can be created by adding 150 mmol $NaHCO_3$ to 1 liter of 5% dextrose in water (D5W). This solution is useful if treatment requires both volume expansion and alkali administration.

Citrate may be taken orally as a liquid, as sodium citrate, potassium citrate, or citric acid, or a combination. Many patients find citrate-containing solutions more palatable than oral $NaHCO_3$ as a source of oral alkali therapy. Oral citrate therapy should not be combined with medications that include aluminum. Citrate, which has a −3 charge

TABLE 12.2 Alkali Treatment Options

Therapy	Route	Usual Dose per Unit	Comments
Sodium bicarbonate tablet	PO	650 mg = 8 mmol	May cause gastric gas
Sodium bicarbonate	IV	50 mmol in 50 ml	Hypertonic, may cause hypernatremia
5% Dextrose with water with $NaHCO_3$	IV	150 mmol/l	Useful for simultaneous intravascular volume expansion and alkali administration
Potassium citrate (tablet)	PO	5 and 10 mmol per tablet	Useful for simultaneous K^+ and alkali therapy
Citric acid/potassium citrate/sodium citrate (liquid)	PO	1 mmol of Na^+ and K^+ and 2 mmol of citrate per milliliter	Avoid concomitant aluminum-containing medications such as antacids and sucralfate 1 mmol citrate equivalent to 3 mmol HCO_3^-
Potassium citrate (liquid)	PO	2 mmol of K^+ and 2 mmol of citrate per milliliter	Avoid concomitant aluminum-containing medications

IV, intravenous; *PO,* oral.

under normal conditions, can complex with aluminum (Al^{3+}) in the intestinal tract, resulting in an uncharged moiety that is rapidly absorbed across the intestinal tract and then can dissociate to release free aluminum. This can increase the rate of aluminum absorption dramatically and in some patients, particularly those with severe CKD, has resulted in acute aluminum encephalopathy.

The dose of alkali therapy administered is based on both the total body bicarbonate deficit and the desired rapidity of treatment. Under normal circumstances, the volume of distribution (V_D) for bicarbonate is approximately 0.5 l/kg total body weight. Thus the bicarbonate deficit, in millimoles, can be estimated from the following formula:

$$\text{Bicarbonate deficit} = (0.5 \times LBW_{kg}) \times (24 - HCO_3^-)$$

where LBW_{kg} is the lean body weight in kilograms and *24* is the desired resultant bicarbonate concentration.

Several caveats regarding this equation should be understood. First, edema fluid contributes to the volume of distribution of bicarbonate. Accordingly, an estimation of the amount of edema fluid should be included in this calculation. Second, the volume of distribution for bicarbonate increases as the severity of the metabolic acidosis worsens. When serum $[HCO_3^-]$ is 5 mmol/l or less, the volume of distribution may increase to 1 l/kg or more.

When acute treatment is desired, 50% of the bicarbonate deficit should be replaced during the first 24 hours. If hypertonic $NaHCO_3$ is administered, the increase in serum $[HCO_3^-]$ will be mirrored by an increase in serum $[Na^+]$. After the initial 24 hours of therapy, the response to therapy and the patient's current clinical condition are reevaluated before future therapy is decided. Acute hemodialysis solely for the treatment of metabolic acidosis, other than that associated with renal failure, is rarely beneficial.

SELF-ASSESSMENT QUESTIONS

1. A 65-year-old man presents with the chief complaint of progressive weakness over the last several months. He is normotensive; physical examination is unremarkable with these laboratory results (mmol/l): Na^+ 135, Cl^- 105, K^+ 3.0, HCO_3^- 18, creatinine 1.8, blood urea nitrogen (BUN), glucose 110, PCO_2 28 mm Hg, pH 7.33, hematocrit 25%, WBCs 5600/mm^2, platelets 340,000/mm^3, and urinalysis: trace protein, 1+ glucose, normal sediment, and 4.8 protein g/24 h.
   Which of the following is characteristic of the renal lesion present in this patient?
   A. Nephrocalcinosis will be shown on kidney, ureter, bladder (KUB) film of the abdomen.
   B. Serum HCO_3^- concentration will increase after oral bicarbonate administration but then decrease to 18 mmol/l after therapy is discontinued.
   C. Bicarbonate therapy will cause the serum K^+ to decline slightly because of a shift into cells.
   D. Urine pH will be persistently alkaline.
   E. Urine anion gap will be negative.
2. A 35-year-old woman presents having ingested a large quantity of aspirin after breaking up with her boyfriend. Her medical history is unremarkable, and she is taking no medications. Physical examination shows blood pressure 130/80 mm Hg lying and 110/62 standing, pulse 102, and respiratory rate 24; the remainder of examination is normal. Laboratory tests on admission (millimoles per liter) are Na^+ 138; K^+ 3.2; Cl^- 100; HCO_3^- 13; pH 7.48; PCO_2 21 mm Hg; urinalysis: 1+ ketone, normal sediment; and urine chemistry (mmol/L): Na^+ 38, Cl^- <10, and K^+ 45.
   Which of the following statements is *true* regarding salicylate poisoning?
   A. A 5-year-old child who has accidentally swallowed an unknown quantity of his mother's aspirin is likely to present with similar acid-base findings.
   B. The cause of hyperkalemia is a shift of K^+ into cells because of respiratory alkalosis.
   C. Serum uric acid levels are likely to be low in this patient.
   D. The high urine Na^+ is caused by proximal tubular dysfunction as a result of salicylate nephrotoxicity.
   E. Measurement of serum lactic acid in this patient is likely to be normal.
3. A 65-year-old white man with an extensive smoking history and known chronic obstructive pulmonary disease is admitted to the hospital with hematemesis. On the day of admission, endoscopy shows a nonbleeding duodenal ulcer. The procedure was complicated by the development of aspiration pneumonia and respiratory failure. A continuous infusion of intravenous lorazepam was required to control agitation and minimize peak inspiratory pressures. Admission laboratory results (mmol/l): Na^+ 142, K^+ 4.3, Cl^- 105, HCO_3^- 22, creatinine 1.4 mg/dl, BUN 25 mg/dl, hematocrit 36, pH 7.35, PCO_2 45, and PO_2 75. On hospital day 4, gastrointestinal bleeding recurred, and the patient was taken to the operating room and underwent oversewing of a bleeding duodenal ulcer. The patient remained hemodynamically stable throughout the hospitalization but continued to require intravenous lorazepam for sedation. Laboratory results (mmol/l): Na^+ 138, K^+ 4.8, Cl^- 100, HCO_3^- 10, creatinine 1.8 mg/dl, BUN 28 mg/dl, glucose 120 mg/dl, serum osmolality 330 mOsm/l (osmolar gap = 37).
   Which of the following is the cause of this patient's anion gap metabolic acidosis and increased osmolar gap?
   A. Propylene glycol toxicity
   B. Diabetic ketoacidosis
   C. Lactic acidosis
   D. Uremic acidosis
   E. Isopropyl alcohol administration

13

Metabolic Alkalosis

Alan Segal, F. John Gennari

DEFINITION

Metabolic alkalosis is caused by retention of excess alkali and is defined by a venous [total CO_2] (a measured value) of greater than 30 mmol/l or an arterial [HCO_3^-] (a calculated value) greater than 28 mmol/l. The increase in pH that results from the elevation in [HCO_3^-] induces hypoventilation, producing a secondary increase in arterial P_{CO_2}. Thus the disorder is characterized by coexisting elevations in serum [HCO_3^-], arterial pH, and P_{CO_2}. Because the kidney normally responds to an increase in [HCO_3^-] by rapidly excreting excess alkali, sustained metabolic alkalosis occurs only when some additional factor impairs bicarbonate excretion. Three factors play key roles: chloride depletion, abnormal aldosterone secretion, and hypokalemia.

BICARBONATE TRANSPORT ALONG THE NEPHRON

Figs. 13.1 and 13.2 illustrate the epithelial transporters and channels that participate in HCO_3^- reabsorption and secretion. In the proximal tubule, where most of the filtered HCO_3^- is reabsorbed, H^+ is secreted into the tubule both by the Na^+/H^+ exchanger (NHE3) and by an H^+-ATPase. In the thick ascending limb of the loop of Henle, H^+ is secreted via NHE3; in the collecting duct, H^+ secretion is accomplished primarily via an apical membrane H^+-ATPase that is regulated by aldosterone in concert with Na^+ delivery to this site in the nephron. When body K^+ stores are low, an apical membrane H^+/K^+-ATPase is activated in the α-intercalated cells, further promoting H^+ secretion linked to K^+ reabsorption.[2] Excretion of excess bicarbonate is facilitated by its secretion into the tubule urine by pendrin in β-intercalated cells.[3] Pendrin is activated by alkalemia and requires Cl^- reabsorption in exchange for secreted HCO_3^-. The HCO_3^- secreted into the urine by this transporter can be recaptured again by H^+ secretion further along in the collecting duct, so that excretion of excess alkali requires both stimulation of pendrin and suppression of the collecting duct H^+-ATPase.

FACTORS AFFECTING BICARBONATE REABSORPTION AND SECRETION

Angiotensin II

Ang II stimulates H^+ secretion in the proximal tubule via the apical Na^+/H^+ exchanger (NHE3) and bicarbonate reabsorption via the basolateral Na^+-HCO_3^- cotransporter (NBC).[3] In the distal nephron, Ang II stimulates H^+ secretion via the apical H^+-ATPase in α-ICs, and bicarbonate secretion via the apical Cl^-/HCO_3^- exchanger (pendrin) in β-ICs.[2,4,5]

Aldosterone

Aldosterone normally regulates sodium and potassium homeostasis, as well as proton secretion, via signaling along the distal nephron (see Fig. 13.1).[6] When aldosterone secretion is abnormal (e.g., primary hyperaldosteronism), activation of apical amiloride-sensitive epithelial sodium channel (ENaC) and basolateral Na^+,K^+-ATPase stimulates Na^+ reabsorption coupled to K^+ secretion in principal cells, and activation of apical H^+-ATPase stimulates proton secretion in α-ICs, causing metabolic alkalosis and hypokalemia.[7]

Pendrin

This Cl^-/HCO_3^- exchanger secretes bicarbonate and is stimulated by both Ang II and aldosterone.[2] Under conditions of chloride depletion, however, the reabsorptive effects of Ang II and aldosterone prevail because collecting duct Na^+ reabsorption is secondarily stimulated, providing the driving force for recapturing all secreted bicarbonate.

Hypokalemia

Potassium depletion promotes abnormal retention of filtered bicarbonate via activation of the K^+/H^+-ATPase in the α-ICs. Secretion of H^+ via this apical transporter is accompanied by basolateral reabsorption of bicarbonate (see Fig. 13.1). Hypokalemia also accelerates ammoniagenesis, providing increased ammonia delivery to the collecting duct urine, where it is available to combine with secreted H^+, allowing for increased H^+ excretion at any given urine pH.

PATHOPHYSIOLOGY OF METABOLIC ALKALOSIS

Normally, excess bicarbonate is rapidly excreted by the kidney by (1) an increased filtered load, allowing additional bicarbonate to be delivered to the distal nephron; (2) chloride-dependent secretion of bicarbonate by pendrin, in the cortical collecting duct;[4] and (3) down-regulation of H^+ secretion in the cortical and medullary collecting duct.

Metabolic alkalosis occurs when abnormal H^+ loss or bicarbonate administration is coupled with (1) a reduced filtered load of bicarbonate (e.g., hypoperfusion of the kidney, advanced kidney disease); (2) enhanced bicarbonate reabsorption along the tubule (e.g., effects of angiotensin II, aldosterone, hypokalemia); (3) continued stimulation of H^+ secretion by the α-intercalated cells in the collecting duct (e.g., primary hyperaldosteronism, chloride depletion); and/or (4) impaired bicarbonate secretion by pendrin (e.g., chloride depletion; advanced kidney disease).

With the exception of alkali administration in the setting of severe impairment of kidney function (GFR <30 ml/min), sustained metabolic

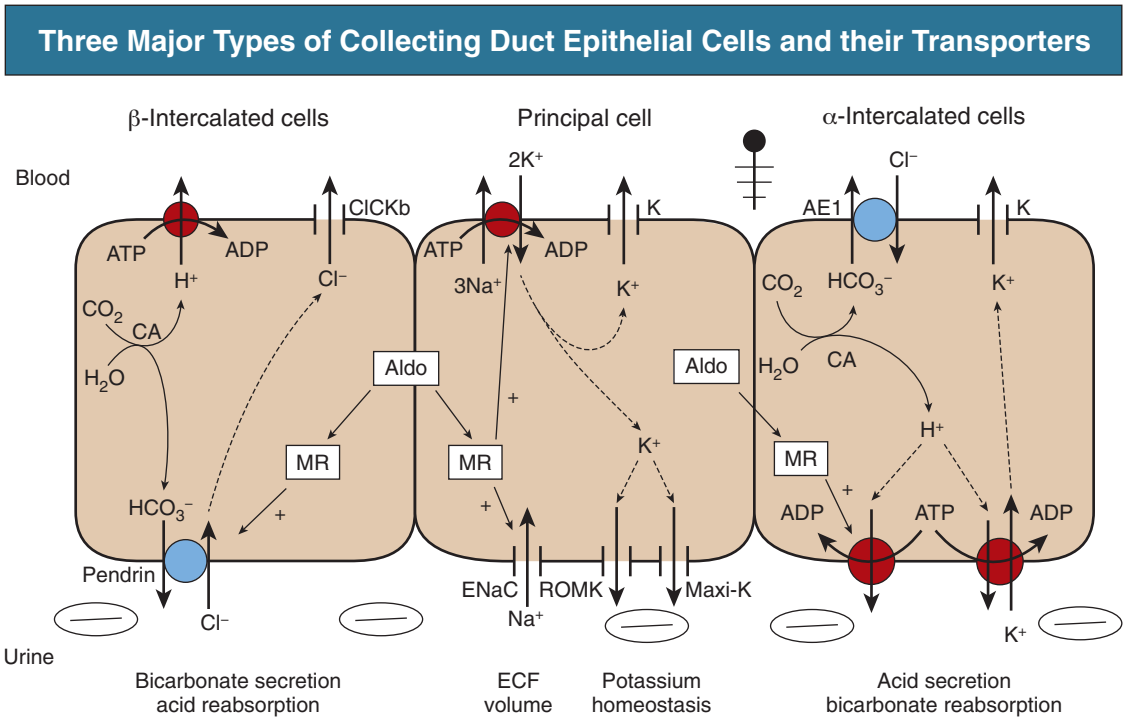

Fig. 13.1 Diagram of the three types of epithelial cells in the collecting duct and key transporters involved in Na^+, K^+, and H^+ reabsorption and secretion. By convention the blood side is electrical ground (⏚). Reabsorption of Na^+ by the principal cell *(middle)* via the epithelial Na^+ channel *(ENaC)* across the apical membrane and then via the Na^+,K^+-ATPase across the basolateral membrane renders the urinary lumen electronegative. This electronegativity (⬭) provides the driving force for K^+ secretion across the *ROMK* and maxi-K channels and facilitates H^+ secretion via the H^+-ATPase in the apical membrane of the α-intercalated cells *(right)*. Proton secretion across the apical membrane is associated with bicarbonate reabsorption across the basolateral membrane via a Cl^-/HCO_3^- antiporter called *AE1*. A H^+-K^+-ATPase in the apical membrane of the α-intercalated cell becomes active under conditions of K^+ depletion. Bicarbonate secretion is accomplished by a Cl^-/HCO_3^- antiporter called *pendrin* in the apical membrane of the β-intercalated cell *(left)*. Chloride exits the basolateral membrane via a Cl^- channel (ClCKb). Several of these processes are stimulated by aldosterone *(Aldo)* via the mineralocorticoid receptor *(MR)*. *ADP,* Adenosine diphosphate; *ATP,* adenosine triphosphate; *CA,* carbonic anhydrase.

alkalosis is always the result of dysregulation of the transporters that control bicarbonate reabsorption and acid secretion by the kidney.

A key feature of this dysregulation is stimulation of collecting duct ion transport (Box 13.1).[9] Most commonly, stimulation of collecting duct ion transport is secondary to abnormalities in Na^+ and Cl^- reabsorption that occur before the urine reaches the collecting duct. Less frequently, metabolic alkalosis is the result of primary stimulation of collecting duct ion transport as a result of abnormal signaling via the mineralocorticoid receptor or because of genetic abnormalities. Fig. 13.3 summarizes the sites along the nephron and the key transport proteins involved in the pathophysiology of the main causes of metabolic alkalosis.

Secondary Stimulation of Collecting Duct Ion Transport

Chloride Depletion

The most common clinical presentations of metabolic alkalosis are generated by Cl^- depletion. The term *contraction alkalosis,* used as a synonym for Cl^- depletion alkalosis, is confusing because it implies that volume contraction itself is responsible for the disorder. The term refers specifically to the increase in serum $[HCO_3^-]$ that follows only one type of extracellular fluid (ECF) volume contraction—that caused by selective Cl^- losses. Moreover, it is likely that volume contraction is neither necessary nor instrumental in inducing this change in serum $[HCO_3^-]$.[10]

BOX 13.1 Pathophysiological Classification of Causes of Metabolic Alkalosis

Secondary Stimulation of Collecting Duct Ion Transport*
- Extrarenal Cl^- losses and secondary K^+ losses
- Renal Cl^- losses and secondary K^+ losses
  - Pharmacological (diuretics)
  - Inactivating gene mutations of Cl^- linked Na^+ cotransporters

Primary Stimulation of Collecting Duct Ion Transport*
- Mineralocorticoid excess
- Activating genetic mutations of ENaC or its signal pathway

Alkali Administration in Setting of Impaired HCO_3^- excretion (e.g. kidney failure)

ENaC, Epithelial sodium channel in collecting duct.
*Na^+ uptake, H^+ and K^+ secretion.

Cl^- depletion, induced by vomiting or nasogastric aspiration, increases serum $[HCO_3^-]$.[11] The degree of alkalosis generated is greater when H^+ loss also occurs (Fig. 13.4), but it may occur even when H^+ loss is minimized by administration of a proton pump inhibitor. In either setting, maintenance of the disorder depends on sustained depletion

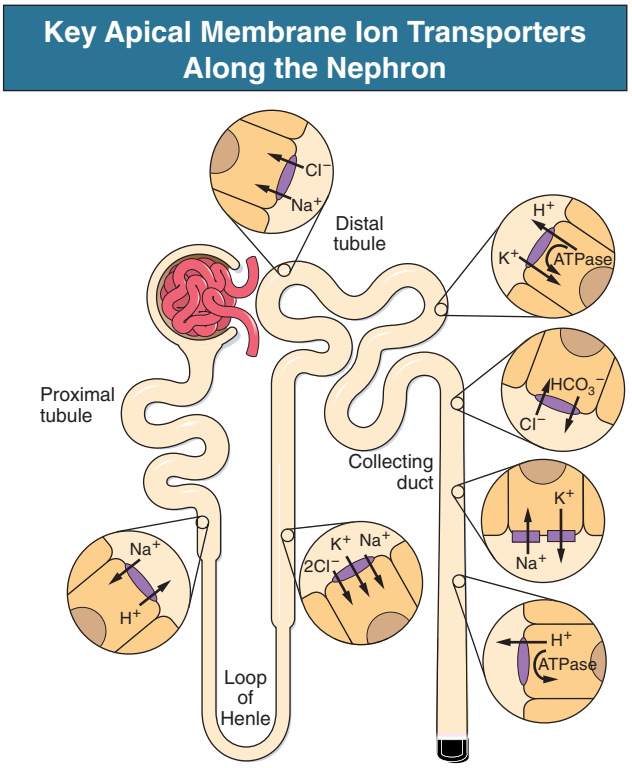

Fig. 13.2 Key apical membrane ion transporters along the nephron. Bicarbonate ions (HCO_3^-) are recaptured by H^+ secretion along the nephron. In the proximal tubule and loop of Henle, H^+ secretion is directly linked to Na^+ reabsorption through the Na^+/H^+ exchanger. In addition, H^+ secretion occurs in the proximal tubule through an apical membrane H^+-ATPase (not shown). In the collecting duct, H^+ secretion is indirectly coupled to Na^+ uptake via ENaC in the principal cells increasing lumen electronegativity, which promotes transport via the H^+-ATPase in the α-intercalated cells. Chloride-linked Na^+ reabsorption in the loop of Henle and early distal tubule affects H^+ secretion by determining Na^+ delivery to the collecting duct. Bicarbonate secretion occurs in the distal tubule and cortical collecting duct under conditions of alkalemia through a Cl^--linked exchanger (pendrin). Potassium reabsorption in states of K^+ depletion is linked to H^+ secretion through a H^+-K^+-ATPase.

of body Cl^- stores; serum [HCO_3^-] returns to normal when sufficient Cl^- is given to replenish losses.

Chloride-depletion metabolic alkalosis always causes concomitant K^+ depletion, but Cl^- administration can correct the alkalosis even if the K^+ deficit is deliberately maintained.[12] Despite this experimental finding, secondary K^+ depletion plays a key role in maintaining alkalosis. When K^+ depletion is sustained, much larger amounts of Cl^- are needed to fully correct the disorder.[13]

The metabolic alkalosis induced by gastrointestinal Cl^- losses can be very severe; serum [HCO_3^-] levels greater than 60 mmol/l have been reported.[14,15] A less severe metabolic alkalosis, without evident H^+ loss, is generated by the administration of loop or thiazide diuretics, and by two genetic abnormalities in Cl^- reabsorption, Bartter and Gitelman syndromes (see Chapter 47), which mimic the action of loop and thiazide diuretics, respectively.

When metabolic alkalosis is induced by Cl^- depletion and dietary Cl^- intake is restricted, a characteristic sequence of changes in electrolyte excretion occurs (see Fig. 13.4).[11] Sodium and HCO_3^- excretion increase transiently and then decrease rapidly to low levels, accompanied by abnormal K^+ excretion. The increase in K^+ excretion is also transient but nonetheless produces K^+ depletion. In the new steady state, urinary K^+ excretion matches intake despite K^+ depletion (see Fig. 13.4). As a result, hypokalemia is a cardinal feature of chloride-depletion metabolic alkalosis.

Maintenance of systemic alkalemia in the steady state (i.e., when the net acid excretion rate matches net acid production rate) indicates a failure to downregulate H^+ secretion in the collecting duct. The contributions of Cl^- and K^+ depletion to the maintenance of metabolic alkalosis is shown diagrammatically in Fig. 13.5.

Potassium Depletion

Potassium depletion downregulates both the Na^+-K^+-$2Cl^-$ cotransporter and the Na^+-Cl^- cotransporter,[16] increasing Na^+ delivery to the collecting duct and further stimulating collecting duct H^+ secretion (see Fig. 13.5). When K^+ deficiency is severe, this effect results in abnormal Cl^- excretion despite Cl^- depletion and sustained metabolic alkalosis even when NaCl is administered.[17] Finally, K^+ depletion stimulates renal NH_4^+ production, facilitating the acid excretion needed to sustain metabolic alkalosis (see Fig. 13.5). Although the apical Cl^-/HCO_3^- exchanger (pendrin) is activated by metabolic alkalosis, its activation in turn stimulates collecting duct H^+ secretion, resulting in reabsorption of all the secreted HCO_3^- and continued acid excretion.[18]

Induction of net K^+ loss by severe restriction of dietary K^+ intake produces a small increase in serum [HCO_3^-].[13] When dietary Cl^- intake is concomitantly restricted, however, the resultant alkalosis is four times as great, illustrating the synergistic and complementary roles of Cl^- and K^+ in regulating renal HCO_3^- reabsorption. Depletion of body K^+ stores is probably the most important factor in producing and sustaining the rarer forms of metabolic alkalosis, discussed below.

Primary Stimulation of Collecting Duct Ion Transport

Primary stimulation of collecting duct ion transport accounts for less than 5% of the causes of metabolic alkalosis, of which the most common cause is primary hyperaldosteronism.[19] This disorder is characterized by persistently high and unregulated aldosterone secretion. As discussed earlier, aldosterone activates ENaC in the principal cell, and H^+-ATPase in the α-IC (see Figs. 13.1 and 13.3). Thus the effect of sustained aldosterone secretion is to increase Na^+ reabsorption and H^+ secretion in the collecting duct by a direct effect, leading to an increase in K^+ secretion and depletion of body K^+ stores. Sodium retention leads to hypertension and also ensures continued Na^+ delivery to the collecting duct, sustaining the cycle of increased Na^+ reabsorption and increased K^+ and H^+ secretion. Aldosterone also stimulates bicarbonate secretion via pendrin. This would act to mitigate the alkalosis, so the resultant bicarbonate level is determined by the stimulation of pendrin relative to ENaC stimulation.

As a result of all these events, metabolic alkalosis is sustained despite dietary Cl^- intake.

Exogenous Alkali

Normally the kidney responds rapidly to excess alkali by increasing HCO_3^- excretion, so sustained metabolic alkalosis does not occur unless massive amounts of alkali are administered. When lesser amounts of $NaHCO_3$ are ingested on a daily basis, serum [HCO_3^-] does not increase unless dietary Cl^- intake is severely restricted[20] or a second process associated with metabolic alkalosis (e.g., vomiting) is present.[21]

In contrast, if HCO_3^- excretion is impaired as a result of kidney failure, even minimal daily alkali administration can cause a sustained metabolic alkalosis independent of Cl^- intake.[22] End-stage renal disease results in impaired HCO_3^- excretion. Any added alkali remains in the body until it is consumed in buffering strong acids produced by protein metabolism or excreted via the gastrointestinal tract.

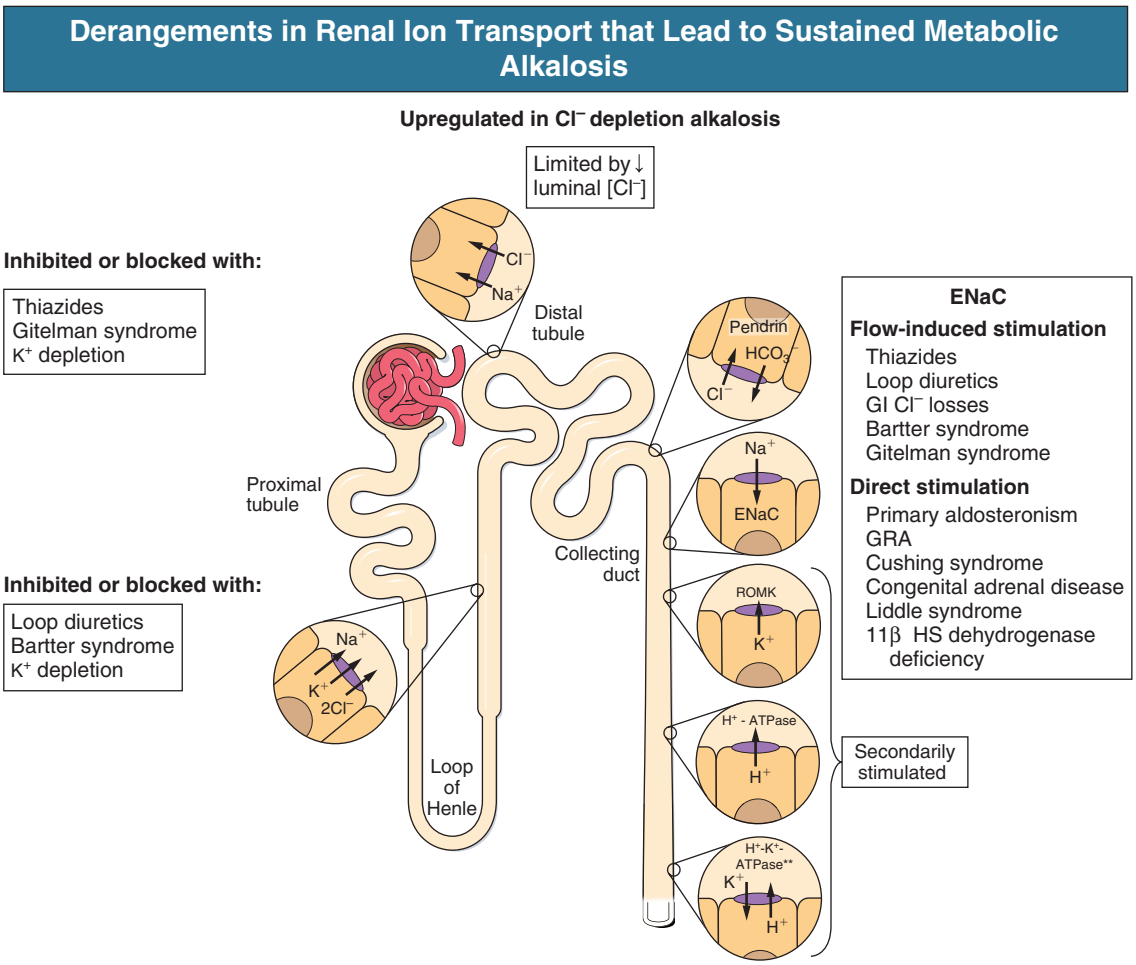

Fig. 13.3 Derangements in renal ion transport that lead to sustained metabolic alkalosis. Schematic depiction of key apical membrane transport proteins in the loop of Henle and distal nephron and the ways in which their function is altered to impair renal HCO_3^- excretion and sustain K^+ excretion in the face of K^+ depletion. Bartter and Gitelman syndromes are caused by genetic abnormalities that impede the activity of or inactivate Cl^--linked Na^+ reabsorption in the loop and early distal tubule, respectively. The epithelial Na^+ channel in the collecting duct is stimulated directly in primary hyperaldosteronism and in several genetic abnormalities. One of these causes aldosterone secretion to respond to adrenocorticotropic hormone rather than to angiotensin II (GRA); one blocks downregulation of the channel (Liddle syndrome), and one allows cortisol to act as a mineralocorticoid (11β-hydroxysteroid dehydrogenase type 2 deficiency). *ENaC,* Amiloride-sensitive epithelial sodium channel; *GI,* gastrointestinal; *GRA,* Glucocorticoid remediable aldosteronism; *HS,* hydroxysteroid.

Secondary Response to the Alkalemia Induced by HCO_3^- Retention

Regardless of cause, body pH increases in metabolic alkalosis and elicits secondary hypoventilation, increasing arterial P_{CO_2}. The response is a potent one, occurring despite the concomitant development of hypoxemia. On average, P_{CO_2} increases by 0.7 mm Hg (0.1 kilopascal [kPa]) for each 1 mmol/l increase in serum $[HCO_3^-]$. Assuming a normal $[HCO_3^-]$ of 24 mmol/l and normal P_{CO_2} of 40 mm Hg (5.5 kPa), the predicted P_{CO_2} for any given serum $[HCO_3^-]$ in metabolic alkalosis can be calculated as follows:

$$P_{CO_2}(\text{mm Hg}) = 40 + 0.7 \times ([HCO_3^-]\,(\text{mmol/l}) - 24)$$

Although this formula is helpful in determining whether the ventilatory response to metabolic alkalosis is appropriate, it implies a precision that does not exist in nature. Variations of up to 5 to 7 mm Hg between the observed and calculated P_{CO_2} may occur. Moreover, when serum $[HCO_3^-]$ exceeds 60 mmol/l, the formula is not a reliable predictor of the respiratory response. Even when metabolic alkalosis is severe (serum $[HCO_3^-]$ >50 mmol/l), however, the P_{CO_2} (in mm Hg) virtually always exceeds the value for the serum $[HCO_3^-]$ (in mmol/l).[14]

Fig. 13.6 illustrates the ameliorating effect of increasing P_{CO_2} on pH in metabolic alkalosis. While it mitigates the alkalemia, the increase in P_{CO_2}, when sustained, directly stimulates renal HCO_3^- reabsorption, increasing serum $[HCO_3^-]$ further.[23] This effect is small and unimportant in the clinical setting.

ETIOLOGY

The major causes of metabolic alkalosis are subdivided into three groups based on pathophysiology (see Box 13.1).[9] The first group (secondary stimulation) is manifested by chloride and potassium depletion. The second group (primary stimulation) includes the metabolic alkaloses

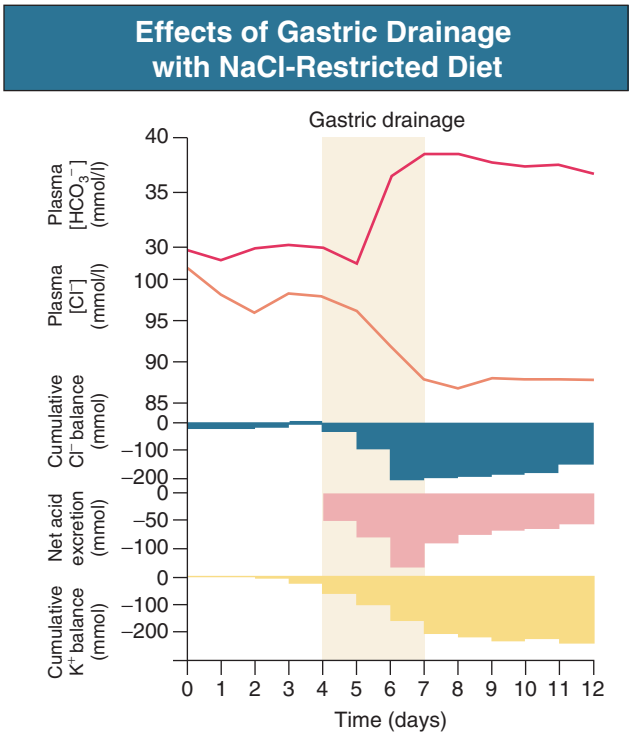

Fig. 13.4 Effect of gastric drainage on plasma $[HCO_3^-]$ and $[Cl^-]$ and on the net balance of $[Cl^-]$ and $[K^+]$ in the body in a normal individual ingesting a NaCl-restricted diet. Changes in net acid excretion are also shown. Gastric drainage on three consecutive nights in this subject increased plasma $[HCO_3^-]$ by 9 mmol/l, a change that persisted after gastric drainage was stopped. Potassium depletion occurs as a result of renal K^+ losses during the period of gastric drainage. These losses are not regained, however, after the drainage is discontinued despite the continued daily ingestion of 70 mmol of K^+. Net acid excretion decreases transiently during the period of drainage but then returns to control levels despite sustained metabolic alkalosis. Chloride depletion is maintained by the low dietary intake of this ion.

induced and sustained by excess adrenal corticosteroids, or by collecting duct transport abnormalities that mimic excess mineralocorticoid activity. The third subgroup is caused by alkali administration or ingestion.

This new classification replaces the traditional separation of causes based on treatment response (i.e., chloride-responsive and chloride-resistant).

Secondary Stimulation of Collecting Duct Ion Transport

Box 13.2 lists the causes of metabolic alkalosis caused by stimulation of collecting duct ion transport by abnormal transport events occurring earlier in the nephron.

Vomiting or Nasogastric Drainage

Loss of chloride from the upper gastrointestinal tract, often accompanied by concomitant H^+ losses, produces a metabolic alkalosis that is sustained until body Cl^- stores are replenished (see previous discussion and Fig. 13.4). With continued emesis or nasogastric suction, serum $[HCO_3^-]$ may rise to very high levels.[14,15]

Diuretic Administration

Diuretics that inhibit Cl^- transport proteins in the kidney are the most common cause of metabolic alkalosis (see Box 13.2). The loop diuretics inhibit the Na^+-K^+-$2Cl^-$ cotransporter in the thick ascending limb of the loop of Henle while thiazides and metolazone inhibit the Na^+-Cl^- cotransporter in the early distal tubule (see Fig. 13.3). These agents all impair Cl^- reabsorption, causing selective Cl^- depletion, and stimulate K^+ excretion by increasing Na^+ delivery to the collecting duct. The alkalosis produced is typically mild (serum $[HCO_3^-]$ <38 mmol/l), except in patients who continue to ingest excess salt and have extreme renal Na^+ avidity. Hypokalemia due to K^+ depletion is prominent and a major management problem.[24]

Genetic Impairment of Cl^--Linked Na^+ Transport

Bartter and Gitelman syndromes are hereditary disorders manifested by metabolic alkalosis and hypokalemia without hypertension (see Chapter

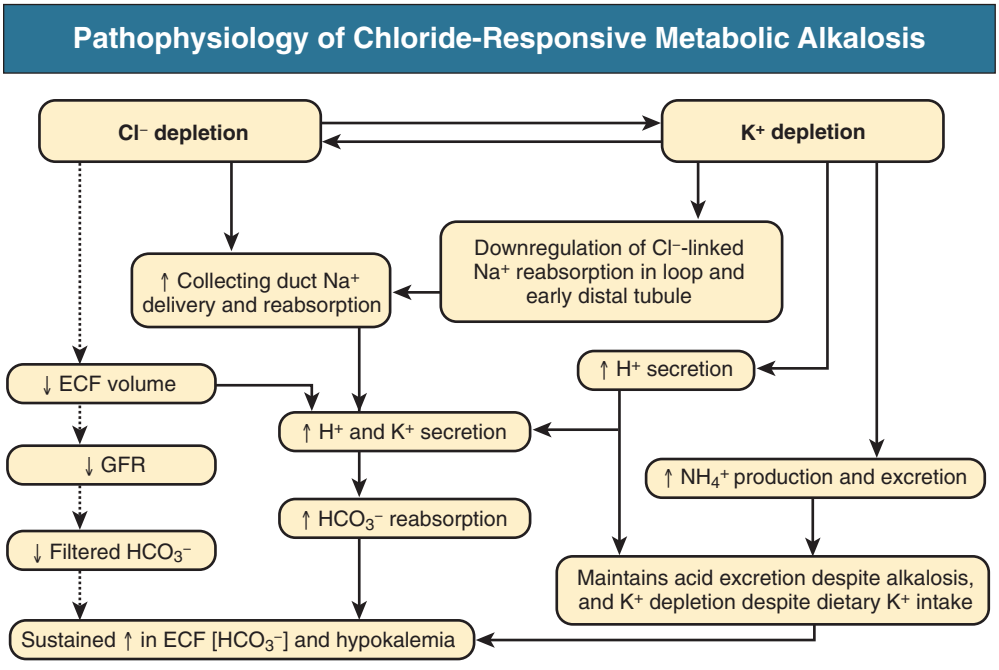

Fig. 13.5 Pathophysiology of metabolic alkalosis caused by depletion of body chloride stores. Chloride depletion stimulates H^+ and K^+ secretion into the collecting duct as a result of disproportionate distal Na^+ delivery and reabsorption. The resultant K^+ depletion further stimulates H^+ secretion and promotes ammonium (NH_4^+) production and excretion as well as downregulating Na^+ reabsorption in the loop of Henle. These events contribute to a sustained increase in serum $[HCO_3^-]$. Chloride depletion also reduces the glomerular filtration rate and therefore HCO_3^- filtration, reducing potential alkali losses. As indicated by the *dashed lines,* the role of this effect in sustaining metabolic alkalosis remains controversial.

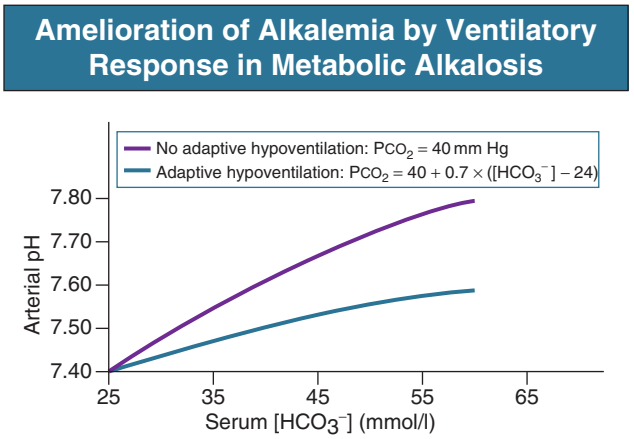

Fig. 13.6 Amelioration of alkalemia by the normal ventilatory response to the increase in serum [HCO_3^-] in metabolic alkalosis. The *red (upper) line* in the graph illustrates the relationship between arterial pH and serum [HCO_3^-] in the absence of adaptive hypoventilation (P_{CO_2} maintained at 40 mm Hg), and the *green (lower) line,* the relationship when P_{CO_2} is increased by the expected level of hypoventilation.

BOX 13.2 Causes of Metabolic Resulting From Secondary Stimulation of Collecting Duct Ion Transport

Chloride loss from the stomach (common)
- Vomiting
- Nasogastric suction

Chloride-depleting diarrheas (rare)
- Congenital chloridorrhea
- Some villous adenomas of the colon
- High-volume ileostomy losses

Diuretic administration (common)
- Thiazides
- Metolazone
- Loop diuretics: furosemide, bumetanide, torsemide, ethacrynic acid

Impaired chloride-linked sodium transport (rare)
- Bartter syndrome
- Gitelman syndrome

Rare causes
- Recovery from chronic hypercapnia
- Gastrocystoplasty
- Cystic fibrosis
- Severe potassium deficiency

47). Bartter syndrome is due to loss of function mutations in one of the transport elements in the thick ascending loop of Henle resulting in impaired function of the Na^+-K^+-$2Cl^-$ cotransporter. Clinically, the phenotype mimics the effect of loop diuretics (see Fig. 13.3).[25]

Patients with this syndrome usually become ill early in life with metabolic alkalosis and volume depletion, features similar to those seen in individuals abusing loop diuretic agents.

Gitelman syndrome is caused by genetic mutations that decrease the activity of the thiazide-sensitive Na^+-Cl^- cotransporter in the early distal tubule (see Fig. 13.3), leading to hypokalemia and metabolic alkalosis similar to that caused by thiazide diuretics. Gitelman syndrome becomes clinically apparent later in life and differs from Bartter syndrome in that hypomagnesemia and hypocalciuria are prominent features.[26,27]

Recovery From Chronic Hypercapnia

Sustained hypercapnia results in an increase in HCO_3^- reabsorption and a decrease in Cl^- reabsorption by the kidney (see Chapter 14). As a result, serum [HCO_3^-] increases and body Cl^- stores are reduced. When P_{CO_2} is restored to normal, renal excretion of excess HCO_3^- requires repletion of the Cl^- losses incurred during adaptation. If these Cl^- losses are not replaced, recovery from hypercapnia can result in persistent metabolic alkalosis.

Congenital Chloridorrhea

This rare form of diarrhea is caused by an inactivating mutation in the "downregulated in adenoma" *(DRA)* gene, an apical membrane Cl^-/HCO_3^- exchanger in the small intestine. The result is a large-volume diarrhea that is rich in Cl^-, causing selective loss of this ion as well as H^+ and K^+ losses. The resultant metabolic alkalosis is ameliorated by K^+ and Cl^- administration, but correction is difficult because of continuing losses. The volume of diarrhea can be reduced by proton pump inhibition, which reduces gastric Cl^- secretion and presumably reduces Cl^- delivery to the small intestine.[28]

Other Causes of Excessive Chloride Losses

Villous adenomas occur in the distal colon and typically secrete 1 to 3 liters of fluid a day that is rich in Na^+, Cl^-, and K^+. Because the volume of secreted fluid is relatively low, these tumors are only occasionally associated with metabolic alkalosis, and it is usually mild if present.[29] Cystic fibrosis is characterized by high sweat [Cl^-] and, with excessive sweating, Cl^- losses can be large enough to cause metabolic alkalosis. In children and adolescents, this acid-base disorder can be the presenting symptom.[30] Patients with high-volume chloride-rich ileostomy losses can sometimes develop severe metabolic alkalosis.[31] The use of gastric tissue to augment bladder size (gastrocystoplasty) can occasionally lead to transient metabolic alkalosis as a result of gastrin-induced Cl^- secretion into the urine.[32]

Severe K^+ Deficiency

In patients with severe K^+ depletion (serum [K^+] <2 mmol/l), metabolic alkalosis can be sustained despite Cl^- administration.[17] Chloride resistance in this setting is probably due to the impairment of renal Cl^- reabsorption induced by K^+ depletion and activation of the K^+-H^+-ATPase in the α-ICs (see earlier discussion). Partial repletion of K^+ stores rapidly reverses this problem and renders the alkalosis Cl^- responsive.

Primary Stimulation of Collecting Duct Ion Transport

Box 13.3 lists the causes of metabolic alkalosis secondary to primary stimulation of collecting duct ion transport.

Mineralocorticoid Excess

The metabolic alkalosis induced by aldosterone and other mineralocorticoids is typically mild (serum [HCO_3^-] 30 to 35 mmol/l) and is associated with more severe hypokalemia (K^+ often <3 mmol/l) than is observed with Cl^- depletion alkalosis.[16,19] Primary hyperaldosteronism is the most common cause of this form of metabolic alkalosis (see Chapter 38), but it also can occur with rarer hereditary defects in cortisol synthesis or in the regulation of aldosterone secretion (see Box 13.3). Glucocorticoid-remediable aldosteronism (Chapter 47) is caused by a mutation that results in aldosterone secretion falling under the control of adrenocorticotropic hormone (ACTH) rather than angiotensin. Fludrocortisone, an oral mineralocorticoid drug, as well as inhaled 9α-fluoro-prednisolone can induce metabolic alkalosis if used inappropriately. Corticosteroids, when administered in very high doses, increase renal K^+ excretion nonspecifically and produce a mild increase

BOX 13.3 Causes of Metabolic Alkalosis Resulting From Primary Stimulation of Collecting Duct Ion Transport

Mineralocorticoid Excess
- Primary hyperaldosteronism: Adenoma, hyperplasia
- Cushing syndrome
- Corticotropin-secreting tumor
- Renin-secreting tumor
- Glucocorticoid-remediable aldosteronism
- Adrenogenital syndromes
- Fludrocortisone treatment
- 9α-Fluoro-prednisolone (inhaled)

Apparent Mineralocorticoid Excess
- Licorice
- Carbenoxolone
- Liddle syndrome
- 11β-Hydroxysteroid dehydrogenase deficiency

Glucocorticoids (High Dose)
- Methylprednisolone

in serum [HCO_3^-]. High aldosterone levels induced by hyperreninemia in renovascular or malignant hypertension are associated with hypokalemia and, occasionally, with very minor increases in serum [HCO_3^-].

Apparent Mineralocorticoid Excess Syndromes

Several inherited abnormalities produce a metabolic alkalosis that is clinically indistinguishable from hyperaldosteronism but without measurable aldosterone (see Chapter 47). Liddle syndrome results from a genetic mutation that prevents the removal of ENaC from the urinary membrane of collecting duct epithelial cells (see Fig. 13.3). As a result, hyperreabsorption of Na^+ via ENaC cannot be downregulated, causing the same cascade of events seen in hyperaldosteronism. Because continuous stimulation of Na^+ reabsorption expands ECF volume and decreases ECF [K], aldosterone levels are vanishingly low. This condition is also called *pseudohyperaldosteronism* because the phenotype makes it appear that aldosterone levels are high when in fact aldosterone (and renin) levels are negligible.

In another rare familial disorder, the syndrome of apparent mineralocorticoid excess, a mutation inactivates 11β-hydroxysteroid dehydrogenase type 2, an enzyme adjacent to the mineralocorticoid receptor that rapidly converts cortisol to cortisone, minimizing cortisol binding.[34] When the enzyme is inactivated, cortisol activates the receptor, stimulating Na^+ reabsorption and K^+ secretion and producing metabolic alkalosis and hypertension. Glycyrrhizic acid (a component of black licorice), carbenoxolone, and gossypol (an agent that retards spermatogenesis) all inhibit the activity of 11β-hydroxysteroid dehydrogenase type 2 and can cause the same clinical picture.[16] Just as in Liddle syndrome, aldosterone and renin levels are negligible, so this is another form of pseudohyperaldosteronism.

Alkali Administration

Table 13.1 lists the causes of metabolic alkalosis induced by alkali administration. Unless given in massive amounts, exogenous alkali produces metabolic alkalosis in individuals with normal kidney function only when body K^+ or Cl^- stores are deficient (see earlier discussion and Fig. 13.3).[20] In acute or chronic kidney disease, alkali administration or ingestion can produce metabolic alkalosis independent of K^+ and Cl^- stores.[22]

TABLE 13.1 Causes of Metabolic Alkalosis Associated with Alkali Administration

Renal Status	Causes
Normal kidney function*	$NaHCO_3$, citrate, acetate, lactate, amino acid anions
Kidney failure	$NaHCO_3$, citrate, acetate, lactate, amino acid anions Milk alkali syndrome Aluminum hydroxide with K^+ exchange resin

*Only in presence of K^+ depletion or very low NaCl intake

TABLE 13.2 Potential Sources of Alkali

Alkali or Alkali Precursors	Source
Bicarbonate	$NaHCO_3$: Pills, intravenous solutions Proprietary preparations (e.g., Alka-Seltzer), baking soda $KHCO_3$: Pills, oral solutions
Lactate	Ringer solutions Peritoneal dialysis solutions
Acetate, glutamate, propionate	Parenteral nutrition solutions
Citrate	Blood products Plasma exchange, K^+ supplements Alkalinizing agents
Calcium compounds*	Calcium supplements and phosphate binders ($CaCO_3$, calcium acetate, calcium citrate)

*Alkalinizing effect minimal when given orally.

Milk-alkali syndrome is characterized by the concomitant presence of metabolic alkalosis and kidney damage, brought on by the ingestion of $NaHCO_3$ in combination with excess calcium (either in milk or as $CaCO_3$).[35,36] Kidney damage is caused by calcium deposition (facilitated by an alkaline urine). Metabolic alkalosis is maintained because HCO_3^- excretion is limited in the face of continued ingestion. Metabolic alkalosis is usually relatively mild in these patients unless they develop concomitant vomiting.[21] In hospitalized patients with kidney failure, a wide variety of alkali sources or alkali precursors can cause metabolic alkalosis (Table 13.2). A common offender is acetate used to replace chloride in parenteral nutrition solutions. Although aluminum hydroxide is only rarely administered now, its use in combination with sodium polystyrene sulfonate (Kayexalate) can cause metabolic alkalosis because aluminum binds to the resin in exchange for Na^+. As a result, the HCO_3^- normally secreted into the duodenum is not titrated by H^+ (which was neutralized by the aluminum hydroxide), nor does it form an insoluble salt with aluminum. Instead, it is completely reabsorbed from the gut, increasing serum [HCO_3^-].[37]

Other Causes

Citrate, an organic anion used as an anticoagulant in blood products, can produce metabolic alkalosis because full metabolism of sodium citrate ($C_6H_5O_7Na_3$) yields 3 molecules of $NaHCO_3$. Metabolic alkalosis can occur after (1) massive blood transfusions resulting from the large amount of new HCO_3^- generated acutely; (2) in patients with impaired kidney function treated with plasma exchange using fresh frozen plasma

because this solution contains a high concentration of sodium citrate[38]; and (3) when using regional citrate anticoagulation during continuous dialysis procedures.[39]

Refeeding after starvation causes an abrupt increase in serum [HCO_3^-] from the low levels characteristic of the fasting state. In some instances, serum [HCO_3^-] increases transiently above normal, causing mild metabolic alkalosis. The mechanisms are multiple, including HCO_3^- generation from metabolism of accumulated organic anions and K^+ and Cl^- depletion.

Administration of either vitamin D or parathyroid hormone causes a small increase in serum [HCO_3^-].[40,41] Despite this experimental finding, hyperparathyroidism is not associated with clinically significant metabolic alkalosis. Hypercalcemia and vitamin D intoxication have been associated with metabolic alkalosis, but in most instances, the alkalosis can be explained by the vomiting that accompanies these disorders.

CLINICAL MANIFESTATIONS

Mild to moderate metabolic alkalosis is well tolerated, with few clinically important adverse effects. Patients with serum [HCO_3^-] levels as high as 40 mmol/l are usually asymptomatic. The adverse effect of most concern is hypokalemia, which increases the likelihood of cardiac arrhythmias in patients with underlying cardiac dysfunction.[41] With more severe metabolic alkalosis (serum [HCO_3^-] >45 mmol/l), arterial P_{O_2} often falls to less than 50 mm Hg (<6.6 kPa) secondary to hypoventilation, and ionized calcium decreases (due to alkalemia). Patients with serum [HCO_3^-] greater than 50 mmol/l may develop seizures, tetany, delirium, or stupor. Changes in mental status and cardiac irritability also can occur and are probably multifactorial in origin, as a result of alkalemia, hypokalemia, hypocalcemia, and/or hypoxemia.

DIAGNOSIS

Diagnosis of metabolic alkalosis involves three steps (Fig. 13.7). The first step, detection, is most often based on the finding of elevated venous [total CO_2]. The second step is evaluation of the secondary response (hypoventilation), excluding the possibility that a respiratory acid-base abnormality is also present. This step requires measurement of arterial pH and P_{CO_2}. The third step is determination of the cause.

Serum [total CO_2] levels above 30 mmol/l in association with hypokalemia are virtually pathognomonic of metabolic alkalosis. The only other cause of an elevated value is chronic respiratory acidosis, and hypokalemia is not a feature of this disorder (see Chapter 14). Because the diagnosis is usually evident and the disorder is almost always uncomplicated, one need not measure pH and P_{CO_2} in most patients. If the alkalosis is severe (serum [HCO_3^-] >38 mmol/l), if the cause of the elevated [HCO_3^-] is unclear, or if a mixed acid-base disorder is suspected, however, one should always fully characterize the disorder to confirm the presence of alkalosis and allow an estimation of whether the degree of hypoventilation is appropriate for the elevation in serum [HCO_3^-] (see Fig. 13.7 and earlier equation). A major deviation in P_{CO_2} from the expected value indicates the presence of a complicating respiratory acid-base disorder (either respiratory acidosis or alkalosis; see Chapter 14). The anion gap is not increased in mild to moderate metabolic alkalosis, but it can be increased by as much as 3 to 5 mmol/l when alkalosis is severe. If the anion gap is greater than 20 mmol/l, the disorder is most likely complicated by superimposed metabolic acidosis (see Chapter 12).

In most instances, the third step, elucidation of the cause, is straightforward. In more than 95% of cases, metabolic alkalosis is caused either by diuretic use or by Cl^- losses from the gastrointestinal tract. This information is easily obtained from the history, and attention can be directed toward appropriate treatment. If the cause is unclear, measurement of urine [Cl^-] may help. Unless the patient has recently taken a diuretic agent, urine [Cl^-] should be less than 10 mmol/l if the metabolic alkalosis is due to Cl^- depletion. Urine Cl^- excretion is also usually low in bulimic patients, but may be elevated if measured shortly after a vomiting episode (see earlier in discussion of pathophysiology). In this setting or with surreptitious diuretic use, urine [Cl^-] may be high, causing a diagnostic dilemma that may lead to an extensive workup for rarer forms of metabolic alkalosis. Urinary screens for specific diuretic compounds may be necessary to establish the correct diagnosis. If the cause is not apparent from this analysis, rarer forms of metabolic alkalosis caused by tubule transport abnormalities should be considered. In these forms of metabolic alkalosis, urine [Cl^-] is typically greater than 30 mmol/l.

In the patient with hypertension and adequate chloride intake who is not taking any diuretic agents, the most common cause of metabolic alkalosis is primary hyperaldosteronism. Measurement of serum renin and serum or urine aldosterone levels can distinguish mineralocorticoid excess syndromes from the rarer syndromes of pseudohyperaldosteronism (Fig. 13.7, see Chapter 38). In the normotensive or hypotensive patient who is not taking any diuretic agents and has metabolic alkalosis *despite adequate chloride intake,* Bartter or Gitelman syndrome should be considered. Aldosterone and renin levels are not helpful in making these diagnoses because the levels can be low or high, depending on the patient's ECF volume at the time of measurement. Familial genetic studies can establish these diagnoses with high specificity.

TREATMENT

Chloride Depletion Metabolic Alkalosis

In the patient with metabolic alkalosis secondary to nasogastric drainage or vomiting, some degree of ECF volume depletion is virtually always a concomitant feature and treatment is straightforward. Administration of intravenous NaCl will correct both the alkalosis and volume depletion. Potassium losses also should be replaced by oral or intravenous KCl. Typically the K^+ deficit is 200 to 400 mmol. When nasogastric drainage must be continued, H^+ and Cl^- losses can be reduced by administration of drugs that inhibit gastric acid secretion.

In contrast to patients with gastrointestinal losses, NaCl administration is not indicated in patients with metabolic alkalosis caused by diuretics unless clinical signs of volume depletion are present. Potassium chloride supplements should be given to minimize K^+ depletion and mitigate the severity of the metabolic alkalosis. The addition of a potassium-sparing diuretic, such as amiloride, triamterene, spironolactone, or eplerenone, can assist in minimizing these abnormalities. Complete repair of diuretic-induced metabolic alkalosis is often difficult because of continued Cl^- and K^+ losses. Fortunately, such a therapeutic goal is not necessary in most instances.

The metabolic alkalosis and hypokalemia seen in Bartter and Gitelman syndromes is the most difficult to manage. In addition to oral KCl supplements (and magnesium supplements in Gitelman syndrome), nonsteroidal antiinflammatory drugs have been used with moderate success. These drugs help minimize renal Cl^- losses.

Mineralocorticoid and Apparent Mineralocorticoid-Induced Metabolic Alkalosis

Management of metabolic alkalosis caused by mineralocorticoids or tubule transport abnormalities that mimic mineralocorticoid excess depends on the underlying cause. If the alkalosis is caused by an adrenal adenoma, the disorder may be corrected by surgical removal (see Chapter 38) but often can be managed medically using spironolactone or

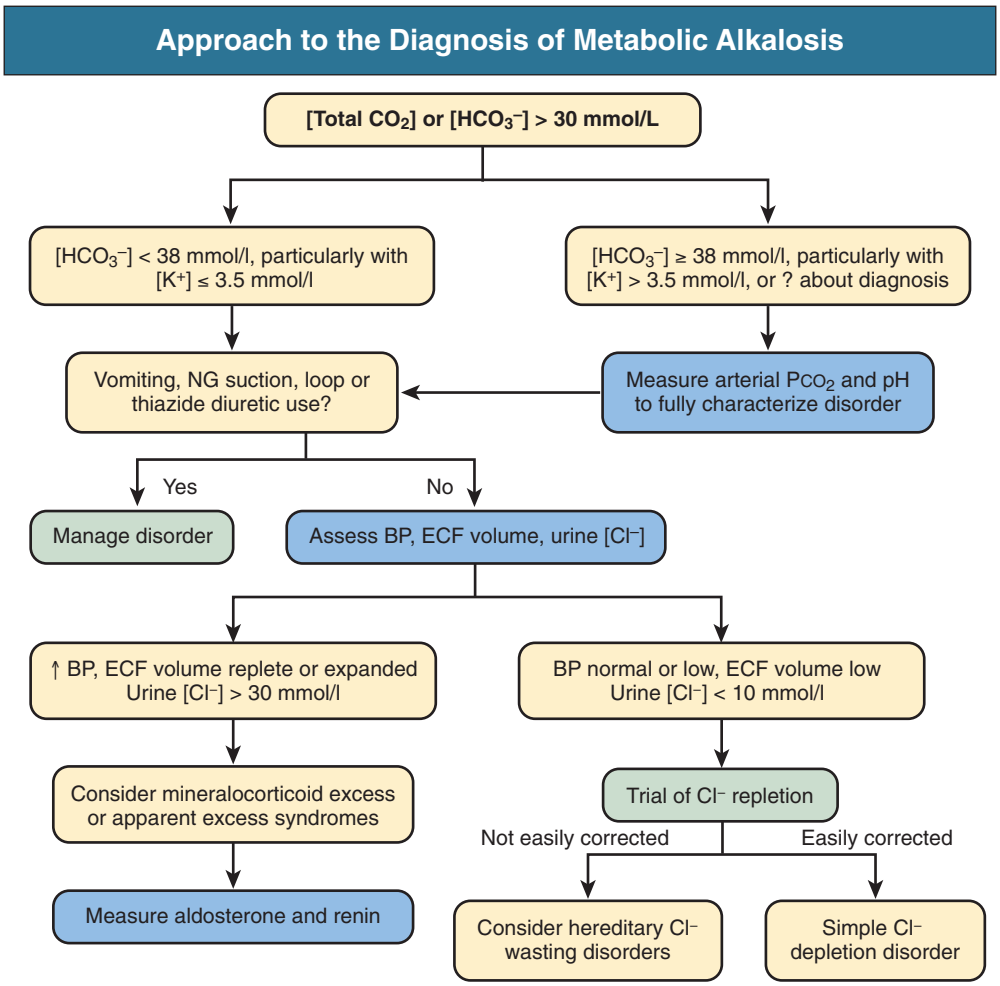

Fig. 13.7 Approach to diagnosis of metabolic alkalosis. If the increase in [total CO_2] (or serum [HCO_3^-]) is mild and hypokalemia is present, arterial gas measurements are usually not necessary, and a simple algorithm can be used to diagnose the cause of the metabolic alkalosis. If hypokalemia is not present, if the increase in serum [total CO_2] is severe, or if there is a question about the diagnosis, arterial measurement of pH and Pco_2 is recommended to determine whether the condition is due to metabolic alkalosis, respiratory acidosis, or a mixed disorder. *BP,* Blood pressure; *ECF,* extracellular fluid; *NG,* nasogastric.

eplerenone. In other forms of primary hyperaldosteronism, the alkalosis can be minimized by dietary NaCl restriction and aggressive replacement of body K^+ stores. Spironolactone or eplerenone can also correct the disorder. In glucocorticoid-remediable aldosteronism, the disorder is corrected by dexamethasone administration, which suppresses ACTH secretion and thereby reduces aldosterone secretion. In Liddle syndrome, amiloride is the most effective treatment. Amiloride is not as effective for 11β-hydroxysteroid dehydrogenase deficiency; eplerenone may be the best treatment, especially in children, because it specifically blocks the mineralocorticoid receptor and unlike spironolactone does not bind to estrogen and androgen receptors.[42,43]

Alkali Ingestion

Identification and discontinuation of the offending alkali (Table 13.2) is the first approach to treatment. In the intensive care unit, care should be taken to look for sources of exogenous alkali.

SPECIAL PROBLEMS IN MANAGEMENT

Management of metabolic alkalosis is a more difficult undertaking in patients with severe congestive heart failure or kidney failure. In patients with heart failure and fluid overload who still have adequate kidney function, acetazolamide can be used to reduce serum [HCO_3^-]. This carbonic anhydrase inhibitor impairs H^+-linked Na^+ reabsorption, causing excretion of both Na^+ and HCO_3^-. Acetazolamide decreases extracellular volume and serum [HCO_3^-], but it also promotes K^+ excretion, exacerbating hypokalemia. Its use should be accompanied by aggressive K^+ replacement therapy.

In patients with kidney failure, serum [HCO_3^-] can be reduced in a timely fashion by renal replacement therapy. Continuous venovenous hemofiltration can remove as much as 30 l/day of an ultrafiltrate of plasma, and a bicarbonate-free replacement solution can be used to reduce serum [HCO_3^-] and increase serum [Cl^-]. Serum [HCO_3^-] also can be lowered by continuous slow low-efficiency dialysis, with the dialysate [HCO_3^-] adjusted to 23 mmol/l. Standard hemodialysis or peritoneal dialysis is less useful because these treatments are designed to add alkali to the blood. However, hemodialysis machines allow adjustment of the dialysate [HCO_3^-] to as low as 30 mmol/l, and this has been used to treat severe metabolic alkalosis successfully.[14]

If renal replacement therapy is unavailable, titration with HCl is an alternative therapy. This approach is limited by the concentration of HCl that can be administered without producing hemolysis or venous

coagulation. Although some investigators have used higher concentrations, the recommended safe level of H^+ should not exceed 100 mmol/l (0.1 N HCl). Even at this concentration, HCl must be administered through a central vein. Because the apparent space of distribution of HCO_3^- is approximately 50% of body weight, 350 mmol of H^+ is required to reduce serum [HCO_3^-] by 10 mmol/l in a 70-kg patient. The volume of fluid required for this titration using HCl, unfortunately, is 3.5 liters. Ammonium chloride (NH_4Cl) and arginine monohydrochloride are not recommended for the treatment of metabolic alkalosis because of the life-threatening complications of ammonia intoxication and severe hyperkalemia, respectively.[44]

SELF-ASSESSMENT QUESTIONS

1. Sustained metabolic alkalosis is always due to:
   A. Impaired renal excretion of excess bicarbonate
   B. Depletion of body chloride stores
   C. Depletion of body potassium stores
   D. Increased production of mineralocorticoids
2. You are asked to see a 45-year-old woman with the following venous blood laboratory results:

Na^+	138 mmol/l
K^+	3.2 mmol/l
Cl^-	88 mmol/
Total CO_2	37 mmol/l
Creatinine	1.3 mg/dl

   The most useful information for diagnosing the cause of these abnormal laboratory values will come from which of the following data?
   A. Arterial pH and Pco_2 measurements
   B. Urine chloride concentration
   C. Aldosterone and renin measurements
   D. History and physical examination
3. Which of the following ion transporters appears to play a central role in the pathogenesis of all causes of metabolic alkalosis:
   A. The $Na^+/K^+/2Cl^-$ cotransporter
   B. The sodium channel ENaC
   C. The potassium channel ROMK
   D. The H^+-ATPase hydrogen secretory transporter
4. You see a patient with hypertension (BP 150/95) and the following laboratory values. She is asymptomatic, save for some constipation. She has no edema. She has a normal appetite and her BMI is 26. She was adopted, so no family history is available.

Na^+	143 mmol/l
K^+	2.8 mmol/l
Cl^-	102 mmol/
Total CO_2	34 mmol/l
Creatinine	0.9 mg/dl

   Which of the following laboratory tests will provide you with the most helpful data in seeking the cause of her problem?
   A. Urine chloride concentration
   B. Abdominal CT scan
   C. Arterial pH and Pco_2
   D. Serum aldosterone and renin levels

14

Respiratory Acidosis, Respiratory Alkalosis, and Mixed Disorders

Horacio J. Adrogué, Nicolaos E. Madias

Deviations of systemic acidity in either direction can have adverse consequences and, when severe, can be life-threatening to the patient. Therefore it is essential for the clinician to recognize and properly diagnose acid-base disorders, understand their impact on organ function, and be familiar with their treatment and the potential complications of treatment.[1,2]

RESPIRATORY ACIDOSIS (PRIMARY HYPERCAPNIA)

Definition

Respiratory acidosis is the acid-base disturbance initiated by an increase in CO_2 tension (Pco_2) of body fluids and whole-body CO_2 stores. The secondary increment in serum bicarbonate ion concentration (serum [HCO_3^-]) observed in acute and chronic hypercapnia is an integral part of respiratory acidosis.[3] The level of arterial CO_2 tension ($Paco_2$) is greater than 45 mm Hg in patients with simple respiratory acidosis, as measured at rest and at sea level. (To convert values from millimeters of mercury [mm Hg] to kilopascals [kP], multiply by 0.1333.) An element of respiratory acidosis may still occur with lower $Paco_2$ in patients residing at high altitude (i.e., above 4000 m or 13,000 ft) or with metabolic acidosis, in which a normal $Paco_2$ is inappropriately high for this condition.[4] Another special case of respiratory acidosis is the presence of arterial eucapnia, or even hypocapnia, occurring together with severe venous hypercapnia, in patients having an acute, profound decrease in cardiac output but relative preservation of respiratory function.[5,6] This disorder is known as pseudo–respiratory alkalosis and is examined in the discussion of respiratory alkalosis.

Etiology and Pathogenesis

The ventilatory system is responsible for eucapnia by adjustment of alveolar minute ventilation ($\dot{V}_A$) to match the rate of CO_2 production. Its main elements are the respiratory pump, which generates a pressure gradient responsible for airflow, and the loads that oppose such action.

CO_2 retention can occur from an imbalance between the strength of the respiratory pump and the extent of respiratory load (Fig. 14.1). When the respiratory pump is unable to balance the opposing load, respiratory acidosis develops. Respiratory acidosis may be acute or chronic (Tables 14.1 and 14.2). Certain causes of chronic respiratory acidosis (e.g., chronic obstructive pulmonary disease [COPD]) can superimpose an element of acute respiratory acidosis during periods of decompensation (e.g., pneumonia, major surgery, heart failure). Life-threatening acidemia of respiratory origin can occur during severe, acute respiratory acidosis or with respiratory decompensation in patients with chronic hypercapnia. A vital capacity less than 1 liter in patients with myasthenic crisis predicts impending acute respiratory failure with CO_2 retention.

A simplified form of the alveolar gas equation at sea level and on breathing of room air (Fio_2, 21%) is as follows:

$$P_Ao_2 = 150 - 1.25\,Paco_2$$

where P_Ao_2 is alveolar O_2 tension (millimeters of mercury). This equation demonstrates that patients breathing room air cannot reach $Paco_2$ levels much greater than 80 mm Hg (10.6 kP) because the hypoxemia that would occur at greater values is incompatible with life. Therefore extreme hypercapnia occurs only during O_2 therapy, and severe CO_2 retention is often the result of uncontrolled O_2 administration.

Secondary Physiologic Response

Adaptation to acute hypercapnia elicits an immediate increment in serum [HCO_3^-] as a result of titration of non-HCO_3^- body buffers; such buffers generate HCO_3^- by combining with H^+ derived from the dissociation of carbonic acid, as follows:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow HCO_3^- + H^+ \text{ and } H^+ + B^- \leftrightarrow HB$$

where B^- refers to the base component and *HB* refers to the acid component of non-HCO_3^- buffers. This adaptation is completed within 5 to 10 minutes from the increase in $Paco_2$, and, assuming a stable level of hypercapnia, no further change in acid-base equilibrium is detectable for a few hours.[7] Moderate hypoxemia does not alter the adaptive response to acute respiratory acidosis. However, preexisting hypobicarbonatemia (whether it is caused by metabolic acidosis or chronic respiratory alkalosis) enhances the magnitude of the HCO_3^- response to acute hypercapnia; this response is diminished in hyperbicarbonatemic states, whether caused by metabolic alkalosis or chronic respiratory acidosis).[8,9]

The adaptive increase in serum [HCO_3^-] during chronic hypercapnia is larger than the corresponding increase in response to acute hypercapnia and is achieved by renal HCO_3^- generation.[10] In addition, the renal response to chronic hypercapnia includes a reduction in the rate of Cl^- reabsorption, resulting in depletion of body Cl^- stores. Complete adaptation to chronic hypercapnia requires 3 to 5 days.[7] Table 14.3 provides quantitative aspects of the secondary physiologic responses to acute and chronic hypercapnia. More recently, a substantially steeper slope for the change in serum [HCO_3^-] in chronic respiratory acidosis was reported (0.51 mmol/l for each 1 mm Hg chronic increase in $Paco_2$), but this study was based on only 18 arterial blood gas (ABG) measurements and its findings should be viewed with caution.[11] The renal response to chronic hypercapnia is not altered appreciably by dietary Na^+ or Cl^- restriction, moderate K^+ depletion, alkali loading, or moderate hypoxemia. However, recovery from chronic hypercapnia is crippled

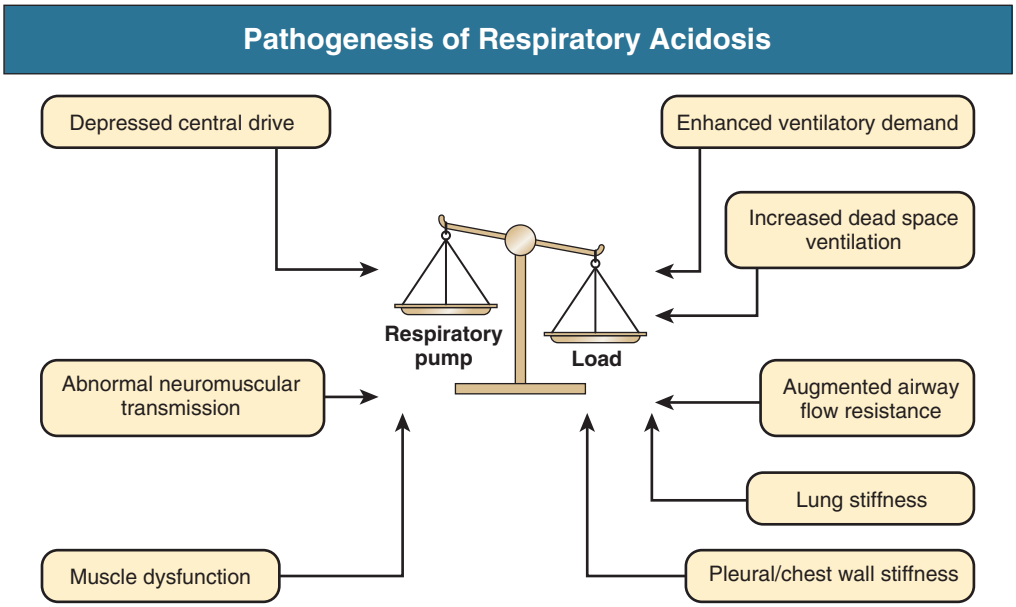

Fig. 14.1 Pathogenesis of Respiratory Acidosis.

by a diet deficient in Cl^-; [HCO_3^-] remains elevated despite correction of the level of $Paco_2$, leading to posthypercapnic metabolic alkalosis.

Clinical Manifestations

Because clinical hypercapnia almost always occurs in association with hypoxemia, it is often difficult to determine whether a specific manifestation is the consequence of elevated $Paco_2$ or reduced Pao_2. Nevertheless, several characteristic manifestations of neurologic or cardiovascular dysfunction help diagnose the condition accurately and treat it effectively.[4,7]

Neurologic

Hypercapnia results in systemic vasodilatation via a direct action on vascular smooth muscle; this effect is most obvious in the cerebral circulation, where blood flow increases in direct relation to the level of $Paco_2$. Acute hypercapnia is often associated with marked anxiety, severe breathlessness, disorientation, confusion, incoherence, and combativeness. A narcotic-like effect can occur in patients with chronic hypercapnia, and drowsiness, inattention, memory loss, irritability, confusion, and somnolence may be observed. Motor disturbances, including tremor, myoclonic jerks, and asterixis, are frequently observed with both acute and chronic hypercapnia. Sustained myoclonus and seizure activity also can develop. Signs and symptoms of increased intracranial pressure (ICP) such as pseudotumor cerebri are occasionally evident in patients with either acute or chronic hypercapnia and are related to the vasodilating effects of CO_2 on cerebral blood vessels. Headache is a frequent complaint. Blurring of the optic discs and frank papilledema can be found when hypercapnia is severe. Hypercapnic coma characteristically occurs in patients with acute exacerbations of chronic respiratory insufficiency who are treated injudiciously with high-flow O_2.[12]

Cardiovascular

Acute hypercapnia of mild to moderate degree is usually characterized by warm and flushed skin, bounding pulse, sweating, increased cardiac output, and normal or increased blood pressure. By comparison, severe hypercapnia might be attended by decreases in both cardiac output and blood pressure. Cardiac arrhythmias occur frequently in patients with either acute or chronic hypercapnia, especially those receiving digoxin. CO_2 retention can produce vasoconstriction in the pulmonary circulation resulting in pulmonary hypertension and right heart failure (cor pulmonale).

Renal

Mild to moderate hypercapnia results in renal vasodilation, but acute increments in $Paco_2$ to levels above 70 mm Hg (9.3 kP) can induce renal vasoconstriction and hypoperfusion. Salt and water retention commonly attend sustained hypercapnia, especially in the presence of cor pulmonale. In addition to the effects of heart failure on the kidney, other factors include stimulation of the sympathetic nervous system and the renin-angiotensin-aldosterone axis, increased renal vascular resistance, and elevated levels of antidiuretic hormone (ADH) and cortisol.[12]

Diagnosis

Whenever CO_2 retention is suspected, ABG values should be obtained, which allow assessment of acid-base status and pulmonary gas exchange.[12] Venous blood sampling also can be used effectively to assess acid-base status and obtain information about tissue oxygenation. If the patient has hypercapnia in association with acidemia, at least an element of respiratory acidosis must be present. However, hypercapnia can be associated with a normal or even an alkaline pH if certain additional acid-base disorders are also present. Information from the patient history, physical examination, and ancillary laboratory data should be used to assess whether part or all of the increase in $Paco_2$ reflects an adaptive response to metabolic alkalosis rather than being primary in origin.

Treatment

CO_2 retention (whether acute or chronic) is always associated with hypoxemia in patients breathing room air. Consequently, O_2 administration represents a critical element in the management of respiratory acidosis.[1,13] However, supplemental O_2 may lead to worsening hypercapnia, especially in patients with chronic obstructive pulmonary disease (COPD).[14] Although a depressed respiratory drive seems to play a role in CO_2 retention, other factors include an increase in dead space ventilation and ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatch caused by the loss of hypoxic pulmonary vasoconstriction and the Haldane effect (decreased hemoglobin affinity for CO_2 in the presence of increased O_2 saturation), which mandates an increase in ventilation to eliminate the excess CO_2.[7]

TABLE 14.1 Causes of Acute Respiratory Acidosis

Increased Load	Depressed Pump
Enhanced Ventilatory Demand	**Depressed Central Drive**
Hyperthermia	General anesthesia
Agitation	Sedative overdose (opiates, benzodiazepines, tricyclic antidepressants, barbiturates)
Seizures	Head trauma
High-carbohydrate diet	Cerebrovascular accident
High-carbohydrate dialysate (peritoneal dialysis)	Obesity-hypoventilation syndrome
Sorbent-regenerative hemodialysis	Cerebral edema
	Brain tumor
	Encephalitis
	Brainstem lesion
Increased Dead Space Ventilation	**Abnormal Neuromuscular Transmission**
Acute lung injury	High spinal cord injury
Multilobar pneumonia	Guillain–Barré syndrome
Cardiogenic pulmonary edema	Status epilepticus
Pulmonary embolism	Botulism, tetanus
Positive-pressure ventilation	Crisis in myasthenia gravis
Supplemental oxygen	Familial periodic paralysis
	Drugs or toxic agents (e.g., curare, succinylcholine, aminoglycosides, organophosphate poisoning)
Augmented Airway Flow Resistance	**Muscle Dysfunction**
Upper Airway Obstruction	
Coma-induced hypopharyngeal obstruction	Fatigue
Aspiration of foreign body or vomitus	Hyperkalemia
Laryngospasm	Hypokalemia
Angioedema	
Inadequate laryngeal intubation	
Laryngeal obstruction after intubation

TABLE 14.2 Causes of Chronic Respiratory Acidosis

Increased Load	Depressed Pump
Increased Dead Space Ventilation	**Depressed Central Drive**
Emphysema	Central sleep apnea
Pulmonary fibrosis	Obesity-hypoventilation syndrome
Pulmonary vascular disease	Methadone/heroin addiction
	Brain tumor
	Bulbar poliomyelitis
	Hypothyroidism
Augmented Airway Flow Resistance	**Abnormal Neuromuscular Transmission**
Upper Airway Obstruction	
Tonsillar and peritonsillar hypertrophy	High spinal cord injury
Paralysis of vocal cords	Poliomyelitis
Tumor of vocal cords or larynx	Multiple sclerosis
Airways stenosis after prolonged intubation	Muscular dystrophy
Thymoma, aortic aneurysm	Amyotrophic lateral sclerosis
	Diaphragmatic paralysis
Lower Airway Obstruction	
Chronic obstructive pulmonary disease	
Lung Stiffness	**Muscle Dysfunction**
Severe chronic interstitial lung disease	Myopathic disease (e.g., polymyositis)
Pleural and Chest Wall Stiffness	
Kyphoscoliosis	
Thoracic cage disease	
Thoracoplasty	
Obesity	

TABLE 14.3 Secondary Response to Alterations in Acid-Base Status

Condition	Initiating Mechanism	Expected Response: Change (Δ) in $[HCO_3^-]$ or $PaCO_2$	Maximal Level of Response
Respiratory acidosis	Increase in $PaCO_2$		
Acute		Increase in $[HCO_3^-] \approx 0.1\ \Delta PaCO_2$	30 mmol/l
Chronic		Increase in $[HCO_3^-] \approx 0.35\ \Delta PaCO_2$	45 mmol/l
Respiratory alkalosis	Decrease in $PaCO_2$		
Acute		Decrease in $[HCO_3^-] \approx 0.2\ \Delta PaCO_2$	16-18 mmol/l
Chronic		Decrease in $[HCO_3^-] \approx 0.4\ \Delta PaCO_2$	12-15 mmol/l
Metabolic acidosis	Decrease in $[HCO_3^-]$	Decrease in $PaCO_2 \approx 1.2\ \Delta[HCO_3^-]$	10 mm Hg (1.3 kP)
Metabolic alkalosis	Increase in $[HCO_3^-]$	Increase in $PaCO_2 \approx 0.7\ \Delta[HCO_3^-]$	65 mm Hg (8.7 kP)

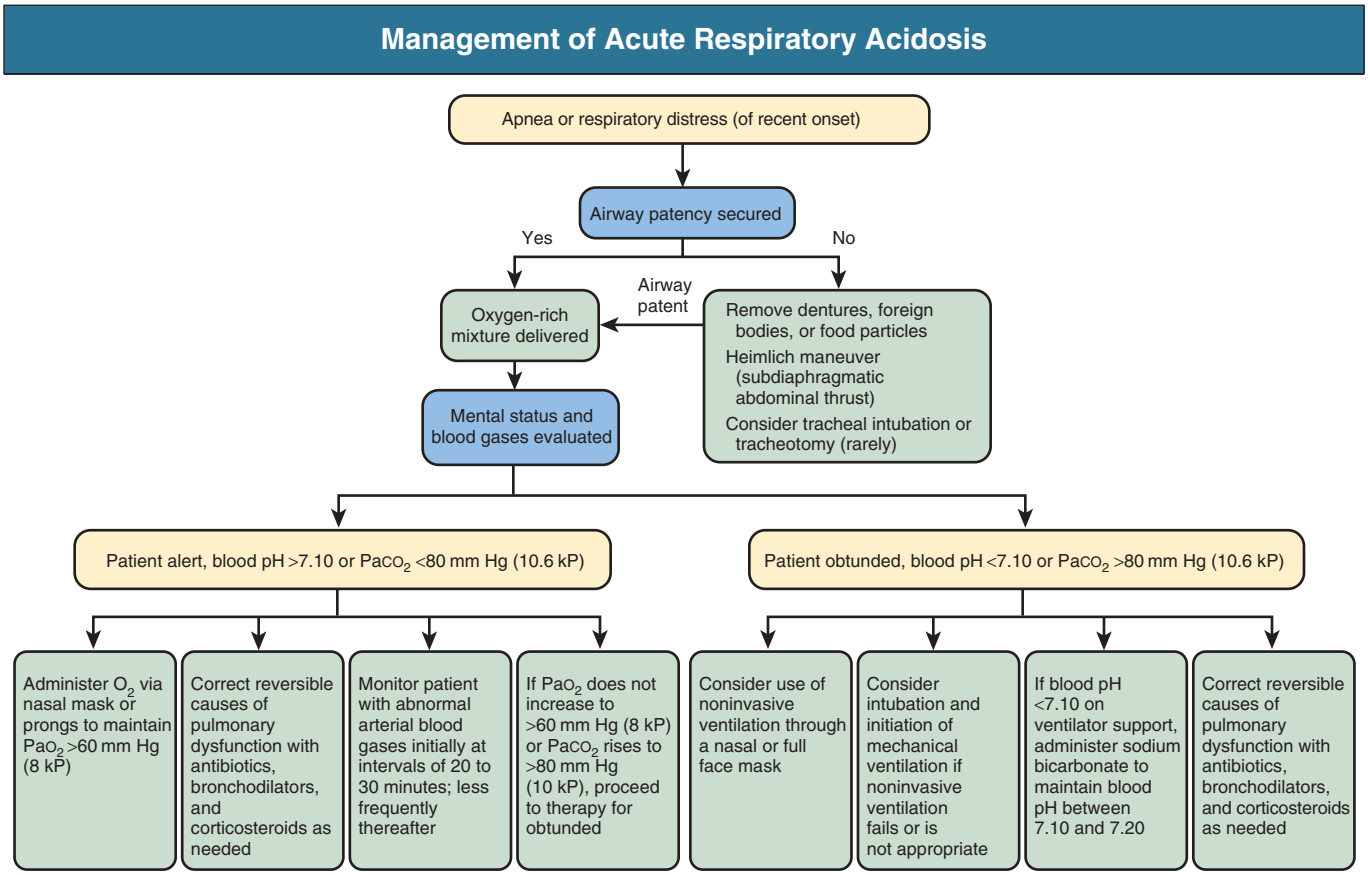

Fig. 14.2 Management of Acute Respiratory Acidosis.

Figs. 14.2 and 14.3 outline the management of acute respiratory acidosis and chronic respiratory acidosis. When possible, treatment must be directed at removal or amelioration of the underlying cause. Immediate efforts should focus on securing a patent airway and delivering supplemental oxygen to maintain a Pao_2 of at least 60 mm Hg but not higher than 100 mm Hg and peripheral oxygen saturation greater than 90%.[15] Supplemental O_2 can be administered to the spontaneously breathing patient with nasal cannulas, Venturi masks (calibrated to deliver Fio_2 between 24% and 50%), or nonrebreathing masks. Oxygen flow rates up to 5 l/min can be used with nasal cannulas; each increment of 1 l/min increases the fraction of inspired O_2 concentration (Fio_2) by approximately 4%. Venturi masks are most useful in patients with COPD because the Po_2 can be titrated, thus minimizing the risk for CO_2 retention. Patients expected to require low levels of supplemental O_2 may be started at 1 to 2 l/min via nasal cannula or 24% to 28% FiO_2 via Venturi mask, with gradual increases of 1 l/min or 4% to 7% FiO_2.

If the target Po_2 is not achieved with these measures and the patient is conscious, cooperative, hemodynamically stable, and able to protect the lower airway, a method of noninvasive ventilation through a mask can be used, such as bilevel positive airway pressure (BiPAP). With BiPAP, the inspiratory-pressure support decreases the work of breathing and the expiratory-pressure support improves gas exchange by preventing alveolar collapse.

Endotracheal intubation and mechanical ventilation should be initiated if adequate oxygenation cannot be secured by noninvasive measures, if progressive hypercapnia or obtundation develops, or if the patient is unable to cough and clear secretions.[16] Minute ventilation should be raised so $Paco_2$ gradually returns to near its long-term baseline and excretion of excess HCO_3^- by the kidneys is accomplished (assuming that Cl^- is provided). By contrast, overly rapid reduction in the $Paco_2$ risks the development of posthypercapnic alkalosis, with potentially serious consequences. If it develops, posthypercapnic alkalosis can be ameliorated by providing Cl^- (usually as KCl), and administering acetazolamide at doses of 250 to 500 mg once or twice daily. Vigorous treatment of pulmonary infections, bronchodilator therapy, and removal of secretions can be beneficial. Avoidance of tranquilizers and sedatives, use of naloxone when indicated, gradual reduction of supplemental oxygen, aiming at a Pao_2 of about 60 mm Hg (8 kP), and treatment of a superimposed metabolic alkalosis will optimize the ventilatory drive.

Mechanical ventilation with tidal volumes of 10 to 15 ml/kg body weight often leads to alveolar overdistention and volutrauma. Therefore an alternative approach called *permissive hypercapnia* (or controlled mechanical hypoventilation) has been successfully applied to prevent barotrauma.[4,17] In this form of treatment, lower tidal volumes of less than 6 ml/kg and lower peak inspiratory pressures are used. Further, $Paco_2$ is allowed to increase as high as 80 mm Hg, and blood pH can decrease to as low as 7.00 to 7.10, while adequate oxygenation is maintained. Because the patient usually requires neuromuscular blockade, accidental disconnection from the ventilator can cause sudden death. Contraindications to permissive hypercapnia include cerebrovascular disease, brain edema, increased ICP, seizures, depressed cardiac function, arrhythmias, and severe pulmonary hypertension. Correction of acidemia attenuates the adverse hemodynamic effects of permissive hypercapnia.[18] It appears prudent, although still controversial, to keep the blood pH at approximately 7.30 by the administration of intravenous alkali when controlled hypoventilation is prescribed.[1,19]

Cardiopulmonary bypass represents a form of mechanical cardiopulmonary support often applied intraoperatively to facilitate cardiac

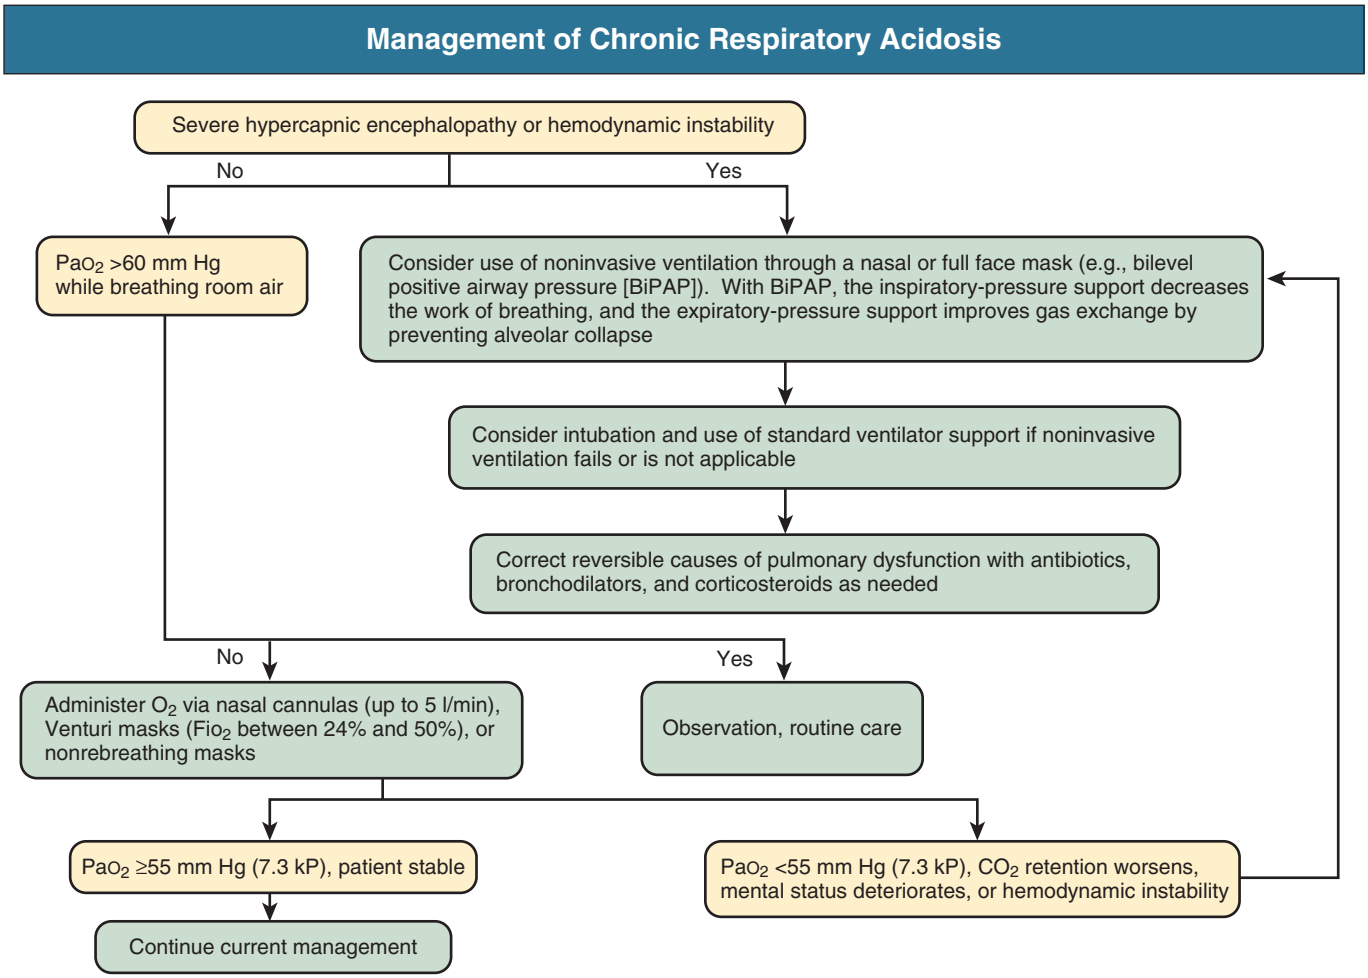

Fig. 14.3 Management of Chronic Respiratory Acidosis.

surgery. A more prolonged type of extracorporeal life support, known as extracorporeal membrane oxygenation (ECMO), can be used in the intensive care unit in neonates, children, and adults to secure tissue oxygenation and CO_2 removal. Application of ECMO involves either a venoarterial (VA) or venovenous (VV) vascular access. Both types provide respiratory support but only VA ECMO provides hemodynamic support.

RESPIRATORY ALKALOSIS (PRIMARY HYPOCAPNIA)

Definition

Respiratory alkalosis is initiated by a reduction in CO_2 tension of body fluids and in whole body CO_2 stores. The secondary decrease in serum [HCO_3^-] observed in acute and chronic hypocapnia is an integral part of the respiratory alkalosis. Whole-body CO_2 stores are decreased and $Paco_2$ is less than 35 mm Hg (4.7 kP) in patients with simple respiratory alkalosis (at rest and at sea level). An element of respiratory alkalosis still may occur with higher levels of $Paco_2$ in patients with metabolic alkalosis, in whom a normal $Paco_2$ is inappropriately low.

Etiology and Pathogenesis

Respiratory alkalosis is the most frequent acid-base disorder encountered because it occurs in normal pregnancy and with high-altitude residence.[2,20,21] It is also the most common acid-base abnormality in critically ill patients, occurring either as the simple disorder or as a component of mixed disturbances, and is an adverse prognostic sign, especially if $Paco_2$ is below 20 to 25 mm Hg (2.7 to 3.3 kP). The hyperventilation syndrome is characterized by episodes of acute hyperventilation associated with fear, anxiety, and sense of impending doom in the absence of significant cardiopulmonary disease.[22] The presence of hypocapnia signifies transient or persistent alveolar hyperventilation relative to the prevailing CO_2 production, thus leading to negative CO_2 balance. Primary hypocapnia might also originate from the extrapulmonary elimination of CO_2 by dialysis or other extracorporeal circulation (e.g., heart-lung machine).

Table 14.4 provides the major causes of respiratory alkalosis.[12] In most patients, primary hypocapnia reflects alveolar hyperventilation caused by increased ventilatory drive arising from the lung, the peripheral chemoreceptors (carotid and aortic), the brainstem chemoreceptors, or signals originating in other brain centers.

The response of the brainstem chemoreceptors to CO_2 can be augmented by systemic diseases (e.g., liver disease, sepsis), pharmacologic agents, and volition. Hypoxemia is a major stimulus of alveolar ventilation, but Pao_2 values below 60 mm Hg (8 kP) are required to elicit this effect consistently. Alveolar hyperventilation can be the result of maladjusted mechanical ventilators, psychogenic hyperventilation, and central nervous system lesions.

In severe circulatory failure, arterial hypocapnia may coexist with venous and therefore tissue hypercapnia; under these conditions, the body CO_2 stores have been enriched, so there is respiratory acidosis rather than respiratory alkalosis. This entity, which we have termed *pseudorespiratory alkalosis,* develops in patients with profound

TABLE 14.4 Causes of Respiratory Alkalosis

Hypoxemia or Tissue Hypoxia	Drugs and Hormones
Decreased inspired O_2 tension	Respiratory stimulants (doxapram, nikethamide, ethamivan, progesterone, medroxyprogesterone)
High altitude	Salicylates
Bacterial or viral pneumonia	Nicotine
Aspiration of food, foreign body, or vomitus	Xanthines
Laryngospasm	Dinitrophenol
Drowning	Pressor hormones (epinephrine, norepinephrine, angiotensin II)

depression of cardiac function and pulmonary perfusion but relative preservation of alveolar ventilation, including patients with advanced circulatory failure and those undergoing cardiopulmonary resuscitation (CPR). The severely reduced pulmonary blood flow limits the CO_2 delivered to the lungs for excretion, thereby increasing the venous P_{CO_2}. However, the increased $\dot{V}/\dot{Q}$ ratio causes a larger than normal removal of CO_2 per unit of blood traversing the pulmonary circulation, thereby giving rise to arterial eucapnia or frank hypocapnia. A progressive widening of the arteriovenous difference in pH and P_{CO_2} develops in circulatory failure and during cardiac arrest (Fig. 14.4). In both situations, there is severe tissue O_2 deprivation and it can be completely disguised by the reasonably preserved arterial O_2 values. Appropriate monitoring of acid-base composition and oxygenation in patients with advanced cardiac dysfunction requires mixed (or central) venous blood sampling in addition to the sampling of arterial blood.

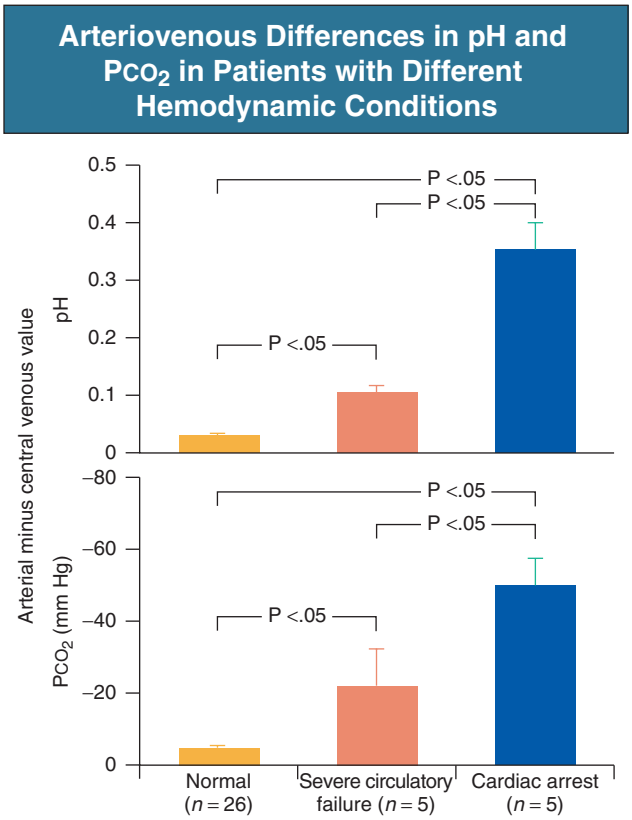

Fig. 14.4 Arteriovenous Differences in pH and P_{CO_2} in Patients With Different Hemodynamic Conditions.

Secondary Physiologic Response

Adaptation to acute hypocapnia is characterized by an immediate decrement in serum $[HCO_3^-]$ that results from nonrenal mechanisms, principally alkaline titration of the non-HCO_3^- body buffers (see second equation under Respiratory Acidosis). This adaptation is completed within 5 to 10 minutes of the onset of hypocapnia, and if there is no further change in P_{aCO_2}, no additional changes in acid-base equilibrium occur for several hours.[7]

Adaptation to chronic hypocapnia entails an additional, larger decrease in serum $[HCO_3^-]$ as a consequence of renal adjustments that reflect a damping of renal H^+ secretion over approximately 2 to 3 days.[10] Quantitative aspects of the secondary physiologic responses to acute and chronic hypocapnia are shown in Table 14.3.

Clinical Manifestations

A rapid decrease in P_{aCO_2} to half-normal values or lower is typically accompanied by numbness and paresthesias of the extremities, chest discomfort (especially in patients manifesting increased airway resistance), circumoral numbness, lightheadedness, dyspnea, frequent sighing, and confusion. These manifestations are regularly expressed in patients with hyperventilation syndrome. These patients also report dyspnea at rest; they need to sigh frequently, and minimal exertion may result in significant dyspnea. Muscle cramps, increased deep tendon reflexes, carpopedal spasm, and generalized seizures occur infrequently. Cerebral vasoconstriction occurs during acute hypocapnia; in severe cases, cerebral blood flow might decrease below 50% of normal values. Hypocapnia can have deleterious effects on the brain of premature infants; in patients with traumatic brain injury, acute stroke, or general anesthesia; and

after sudden exposure to very high altitude.[23] Long-term neurologic sequelae can develop when immature brains are exposed to $Paco_2$ levels below 15 mm Hg (2 kP) for even short periods. Furthermore, abrupt correction of hypocapnia in these patients leads to cerebral vasodilation, which might cause reperfusion injury or intraventricular hemorrhage.

Brain injury caused by hypocapnia probably results from cerebral ischemia. Other factors include hypocapnia itself, alkalemia, pH-induced shift of the oxyhemoglobin (HbO_2) dissociation curve, decreased serum levels of ionized calcium and potassium, depletion of the antioxidant glutathione by cytotoxic excitatory amino acids, increases in anaerobic metabolism, cerebral oxygen demand, neuronal dopamine, and seizure activity.

The cardiovascular manifestations of respiratory alkalosis differ in passive and active hyperventilation. The induction of acute hypocapnia in anesthetized patients (i.e., passive hyperventilation) results in a decrease in cardiac output, an increase in peripheral resistance, and a decrease in the systemic blood pressure. By contrast, active hyperventilation does not change or might even increase cardiac output and leaves systemic blood pressure virtually unchanged. This discrepant response probably reflects the decrease in venous return caused by mechanical ventilation in passive hyperventilation and the reflex tachycardia consistently observed in active hyperventilation. Sustained hypocapnia induced by exposure to high altitude for several weeks results in a cardiac output within control values or higher. Although it does not lead to cardiac arrhythmias in normal individuals, acute hypocapnia appears to contribute to the generation of atrial and ventricular tachyarrhythmias in patients with ischemic heart disease; such arrhythmias are frequently resistant to standard forms of therapy. Chest pain and ischemic ST-T wave changes have been observed in acutely hyperventilating subjects with no evidence of fixed lesions on coronary angiography.

The view that hypocapnia poses minimal risk to health under most conditions is not accurate. Substantial hypocapnia (<25 mm Hg) in hospitalized patients, whether spontaneous or deliberately induced, may result in transient or permanent damage in the brain as well as the respiratory and cardiovascular systems.[23]

Diagnosis

Evaluation of the patient history, physical examination, and ancillary laboratory data are required to establish the diagnosis of respiratory alkalosis.[12,20] Careful observation can detect abnormal patterns of breathing in some patients, although marked hypocapnia can occur without a clinically evident increase in respiratory effort. ABG determinations are required to confirm the presence of hyperventilation.

The diagnosis of respiratory alkalosis, especially the chronic form, is frequently missed; physicians often misinterpret the electrolyte pattern of hyperchloremic hypobicarbonatemia as indicative of normal anion gap metabolic acidosis. If the acid-base profile reveals hypocapnia in association with alkalemia, at least an element of respiratory alkalosis must be present. However, hypocapnia might be associated with a normal or an acidic pH because of the concomitant presence of additional acid-base disorders. Mild degrees of chronic hypocapnia may leave blood pH within the high-normal range. The diagnosis of respiratory alkalosis can have important clinical implications; it often suggests an unrecognized, serious disorder or signals the gravity of a known underlying disease.

Treatment

Fig. 14.5 summarizes the management of patients with respiratory alkalosis. Severe hypocapnia in hospitalized patients must be prevented whenever possible, and if it is present, abrupt correction should be avoided because rapid correction of severe hypocapnia leads to vasodilation of ischemic areas, resulting in reperfusion injury in the brain and lung. Severe alkalemia caused by acute primary hypocapnia requires corrective measures that depend on whether serious clinical manifestations are present. Such measures can be directed at reducing serum [HCO_3^-], increasing $Paco_2$, or both. Even if baseline serum [HCO_3^-] is moderately decreased, reducing it further is effective with relatively little risk. Rebreathing into a closed system (e.g., a paper bag) is not recommended for the acute management of the hyperventilation syndrome because of the potential of hypoxemia in patients with underlying respiratory or cardiovascular disease. The long-term management of the hyperventilation syndrome centers on education regarding the nature of the underlying condition and cognitive-behavioral therapy. Other measures may include breathing retraining, β-blockers, benzodiazepines, and serotonin reuptake inhibitors.

Respiratory alkalosis resulting from severe hypoxemia requires O_2 therapy. The oral administration of 250 to 500 mg acetazolamide twice daily can be beneficial in the management of signs and symptoms of high-altitude sickness, a syndrome characterized by hypoxemia and respiratory alkalosis.[20] Hypocapnia in patients receiving mechanical ventilation often can be corrected by resetting the ventilator. Patients maintained on chronic hemodialysis who develop an acute illness resulting in marked hyperventilation may require dialysis using low-bicarbonate dialysate. Management of pseudorespiratory alkalosis must be directed at optimizing systemic hemodynamics.

MIXED ACID-BASE DISTURBANCES

Definition

Mixed acid-base disturbances are defined as the simultaneous presence of two or more acid-base disorders. Such association might include two or more simple acid-base disorders (e.g., metabolic acidosis and respiratory alkalosis), two or more forms of a simple disturbance having different time course or pathogenesis (e.g., acute and chronic respiratory acidosis or high anion gap and hyperchloremic metabolic acidosis, respectively), or a combination of these two forms.[24] The secondary or adaptive response to a simple acid-base disorder cannot be taken as one of the components of a mixed disorder.

Etiology and Pathogenesis

Mixed acid-base disturbances are seen in hospitalized patients, especially in the critically ill.[25] Careful characterization of these is required to ensure appropriate therapy. Clinical settings are commonly associated with mixed acid-base disorders, including cardiorespiratory arrest, sepsis, drug intoxications, diabetes mellitus, and organ failure (especially renal, hepatic, and pulmonary failure). Patients with severe renal impairment or end-stage renal disease (ESRD) are prone to mixed acid-base disturbances of great complexity and severity.[26] In these conditions, metabolic acidosis of the high anion gap type is frequently accompanied by a component of hyperchloremic acidosis, inability to mount an appropriate secondary response to chronic respiratory acidosis or alkalosis, inability to respond to a load of fixed acids (e.g., lactic acid) or a primary loss of alkali (e.g., diarrhea) with the expected increase in net acid excretion, and inability to respond to an alkali load with bicarbonaturia despite an increased serum [HCO_3^-]. Thus these patients are particularly vulnerable to the development of both extreme acidemia and extreme alkalemia.

A practical classification of mixed acid-base disorders recognizes three main groups of disturbances (Fig. 14.6). Representative examples are depicted in Table 14.5.

Metabolic Acidosis and Respiratory Acidosis

The expected hypocapnia secondary to metabolic acidosis is estimated by $\Delta Paco_2/\Delta[HCO_3^-] = 1.2$ mm Hg/mmol/l (Δ indicates change). If

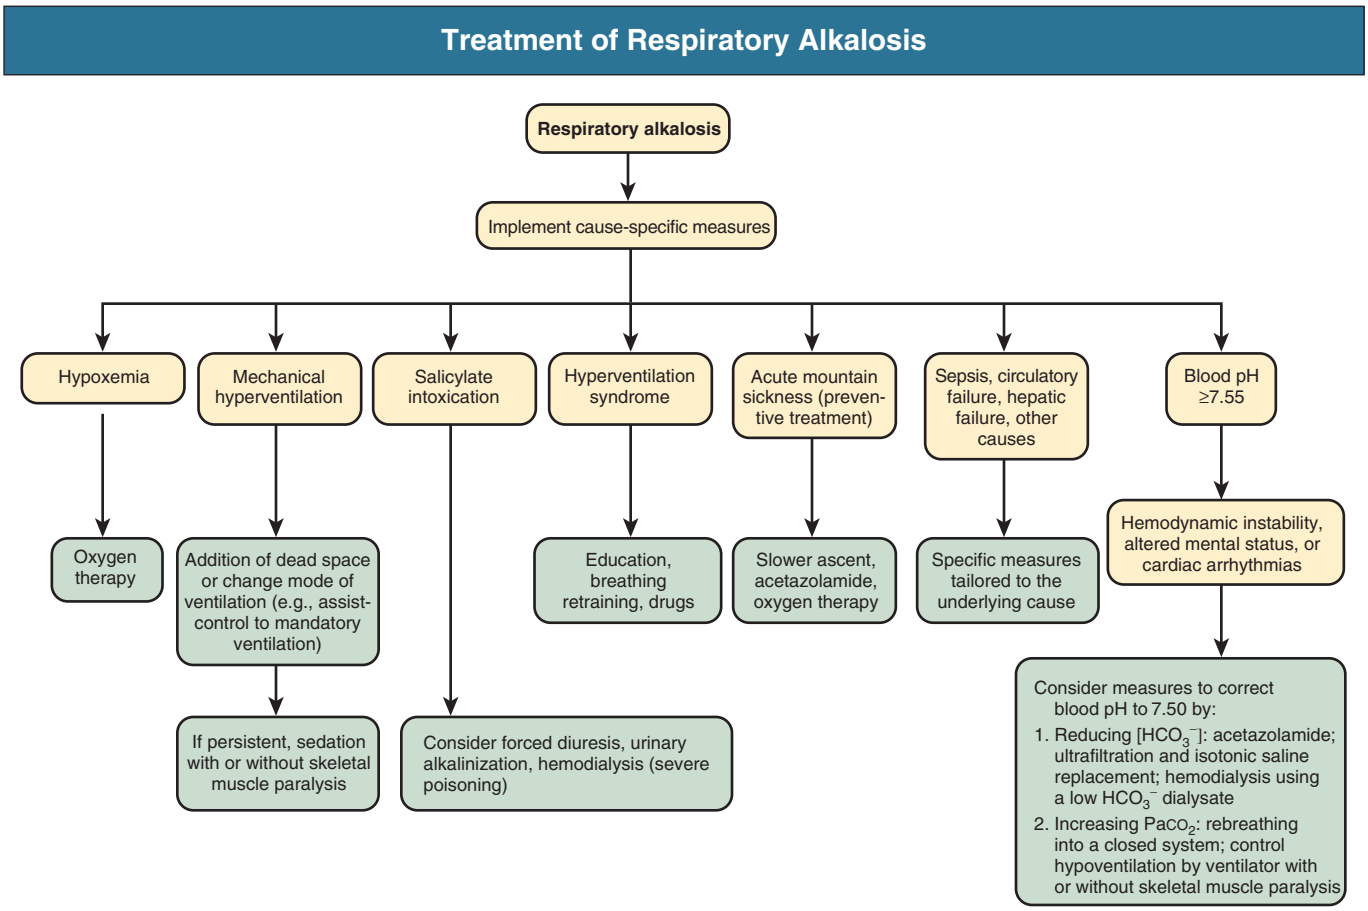

Fig. 14.5 Treatment of Respiratory Alkalosis.

measured $Paco_2$ exceeds 5 mm Hg of the estimated value, respiratory acidosis is also present. The expected ventilatory response to metabolic acidosis also can be estimated by applying the Winters formula, $Paco_2 = 1.5 \times [HCO_3^-] + 8 \pm 2$. Clinical examples of metabolic acidosis combined with respiratory acidosis include untreated cardiopulmonary arrest, circulatory failure in patients with COPD, severe renal failure associated with hypercapnic respiratory failure, various intoxications, and hypokalemic (or less frequently hyperkalemic) paralysis of respiratory muscles in patients with diarrhea or renal tubular acidosis (RTA) (Fig. 14.7; see Table 14.5, Example 4).

Metabolic Alkalosis and Respiratory Alkalosis

Metabolic alkalosis combined with respiratory alkalosis may be encountered in patients with primary hypocapnia associated with chronic liver disease who develop metabolic alkalosis from a variety of causes, including vomiting, nasogastric drainage, diuretics, profound hypokalemia, and alkali administration (e.g., absorption of antacids; infusion of lactated Ringer solution, alimentation solutions, citrated blood products), especially in the patient with renal impairment. Mixed metabolic/respiratory alkalosis also occurs in critically ill patients, particularly those undergoing mechanical ventilation, and in patients with respiratory alkalosis, caused by either pregnancy or heart failure, who experience metabolic alkalosis attributable to diuretics or vomiting (Fig. 14.8; see Table 14.5, Example 6).

Metabolic Alkalosis and Respiratory Acidosis

Metabolic alkalosis and respiratory acidosis is one of the most frequently encountered mixed acid-base disorders. The usual clinical setting is COPD in conjunction with diuretic therapy, but it can occur with other causes of metabolic alkalosis (e.g., vomiting, administration of corticosteroids) (Fig. 14.9; see Table 14.5, Example 5). Critically ill patients with respiratory failure caused by acute respiratory distress syndrome and occasionally those with profound hypokalemia with diaphragmatic muscle weakness also might develop mixed metabolic alkalosis and respiratory acidosis.

Metabolic Acidosis and Respiratory Alkalosis

As with respiratory acidosis and metabolic alkalosis, the combination of metabolic acidosis and respiratory alkalosis is characterized by normal or near-normal blood pH; its two components exert offsetting effects on systemic acidity (Fig. 14.10). This disorder is common in the intensive care unit and is generally associated with high mortality. Causes of the primary hypocapnia include fever, hypotension, gram-negative septicemia, pulmonary edema, hypoxemia, and mechanical hyperventilation. The component of metabolic acidosis in turn might be lactic acidosis (e.g., complicating shock, hepatic failure) or renal acidosis. Respiratory alkalosis and lactic acidosis may occur in acute severe asthma. In some patients, the lactic acidosis appears to be caused by excessive use of β_2-adrenergic agonists and corticosteroids. The resulting increased ventilatory demands might worsen abnormal lung mechanics and precipitate ventilatory failure.[27,28] Salicylate intoxication is another cause of mixed metabolic acidosis and respiratory alkalosis. Stimulation of the ventilatory center in the brainstem accounts for the respiratory alkalosis, whereas the accelerated production of organic acids including pyruvic, lactic, and ketoacids, and, to a lesser extent the accumulation of salicylic acid itself are responsible for the metabolic acidosis.

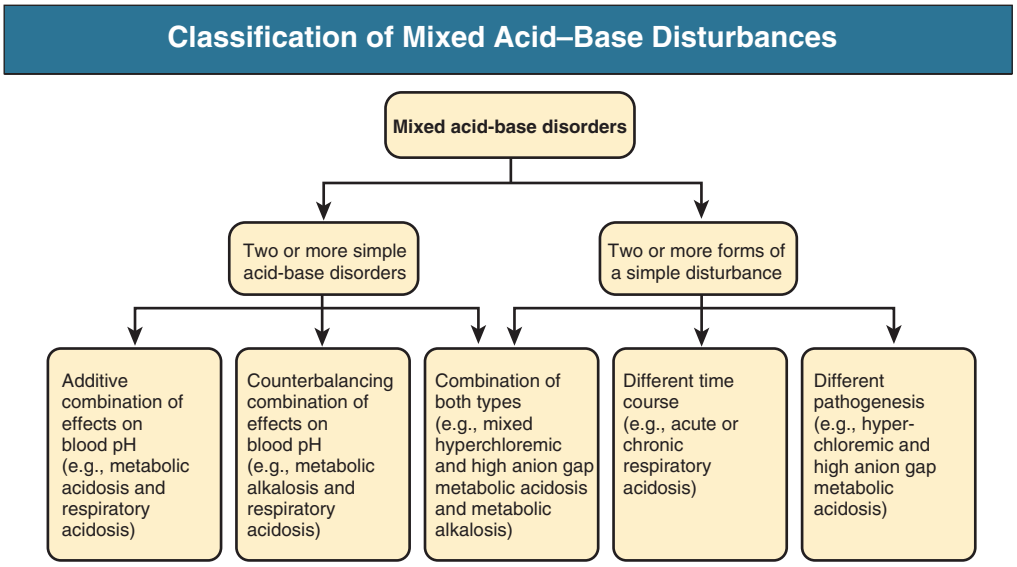

Fig. 14.6 Classification of Mixed Acid-Base Disturbances.

TABLE 14.5 Representative Examples of Mixed Acid-Base Disorders

Type of Mixed Disorder	No.*	pH	$Paco_2$† (mm Hg)	HCO_3^- (mmol/l)	Na^+ (mmol/l)	K+ (mmol/l)	Cl^- (mmol/l)	Anion gap (mmol/l)	Clinical Circumstances

COPD, Chronic obstructive pulmonary disease.
Anion gap is calculated as $[Na^+] - ([Cl^-] + [HCO_3^-])$

Metabolic Acidosis and Metabolic Alkalosis

Metabolic acidosis and metabolic alkalosis are typically observed in patients with alcoholic liver disease who develop fasting ketoacidosis or lactic acidosis in conjunction with metabolic alkalosis caused by vomiting, diuretics, or other causes (see Table 14.5, Examples 2 and 3). Protracted vomiting or nasogastric suction superimposed on uremic acidosis, diabetic ketoacidosis, or metabolic acidosis caused by diarrhea also might generate this offsetting metabolic combination. A similar picture might develop after administration of alkali during CPR or as therapy for diabetic ketoacidosis.

Mixed Metabolic Acidosis

Mixed high anion gap metabolic acidosis in patients with diabetic or alcoholic ketoacidosis may be combined with lactic acidosis resulting from circulatory failure. Uremic patients with associated lactic acidosis or ketoacidosis provide another example of mixed high anion gap acidosis. Mixed hyperchloremic metabolic acidosis is seen in patients with RTA or those receiving carbonic anhydrase inhibitors who also have substantial fecal losses of HCO_3^- caused by severe diarrhea. Mixed hyperchloremic and high anion gap metabolic acidosis occurs in patients with profuse diarrhea whose circulation becomes sufficiently

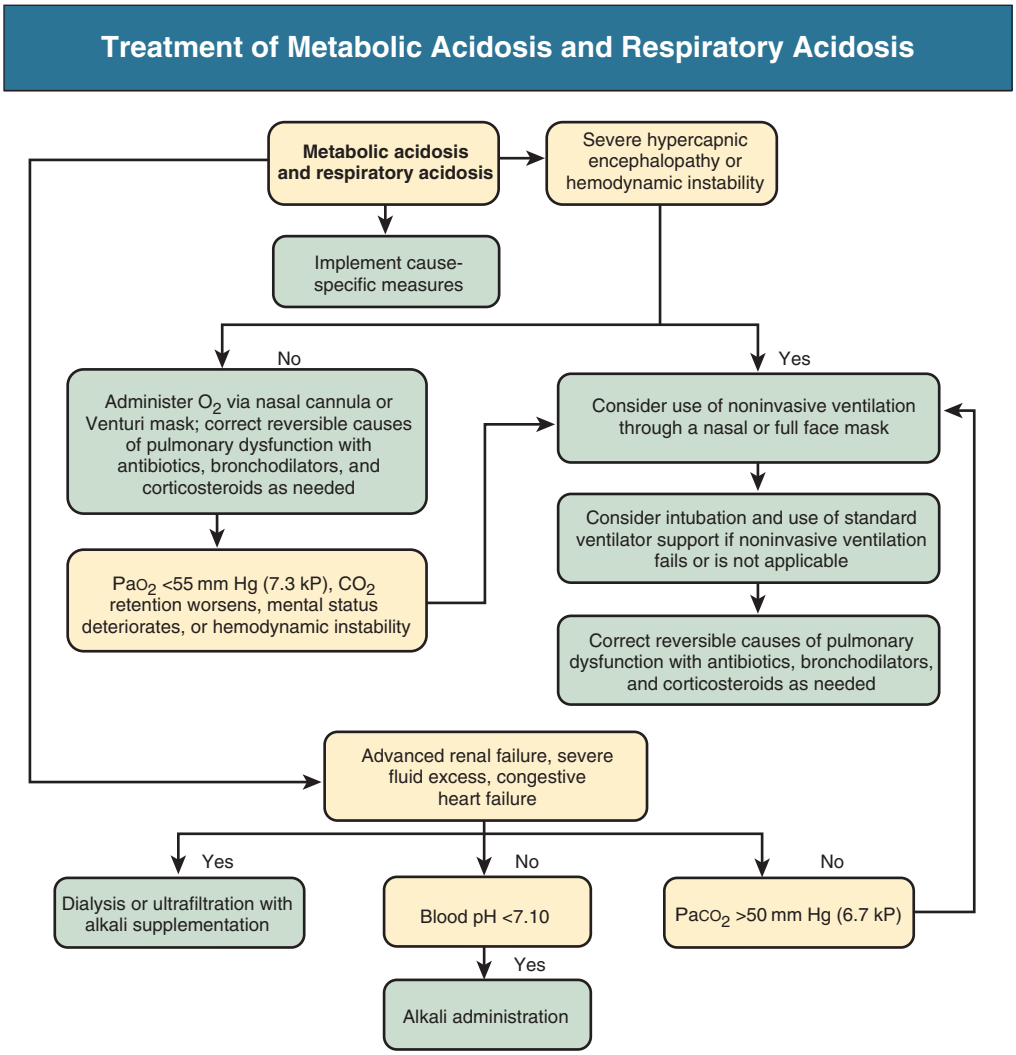

Fig. 14.7 Treatment of Metabolic Acidosis and Respiratory Acidosis.

compromised to generate in turn a high anion gap metabolic acidosis from renal failure or lactic acidosis. Patients with diabetic ketoacidosis whose renal function is maintained at reasonable levels by adequate salt and water intake might develop an element of hyperchloremic metabolic acidosis because of preferential excretion of ketone anions and conservation of Cl^- (see Table 14.5, Example 1).[29]

Mixed Metabolic Alkalosis

The coexistence of several processes with each contributing to a primary increase in serum [HCO_3^-], including diuretic therapy, vomiting, mineralocorticoid excess, and severe potassium depletion, will give rise to mixed metabolic alkalosis.

Triple Disorders

The most frequent triple disorders comprise two cardinal metabolic disturbances in conjunction with either respiratory acidosis or respiratory alkalosis, such as in severely ill patients with COPD and CO_2 retention who simultaneously develop metabolic alkalosis (usually caused by diuretics and a Cl^--restricted diet) and metabolic acidosis (usually lactic acidosis caused by hypoxemia, hypotension, or sepsis). This type of triple disorder also might be encountered during CPR when an element of metabolic alkalosis caused by alkali administration is superimposed on preexisting respiratory acidosis and metabolic (lactic) acidosis. Patients with respiratory alkalosis caused by advanced congestive heart failure also might have diuretic-induced metabolic alkalosis and lactic acidosis from tissue hypoperfusion. Such triple acid-base disorders also can be seen in patients with chronic alcoholism who develop metabolic alkalosis from vomiting, lactic acidosis from volume depletion or ethanol intoxication, and respiratory alkalosis from hepatic encephalopathy or sepsis.

Less common triple disorders encompass two cardinal respiratory disturbances in combination with either metabolic acidosis or metabolic alkalosis. Typically, this is seen in critically ill patients with chronic respiratory acidosis who experience an abrupt reduction in $Paco_2$ because of mechanical ventilation and superimposed metabolic acidosis (usually lactic acidosis, reflecting circulatory failure) or metabolic alkalosis (e.g., from gastric fluid loss or diuretics). With superimposed metabolic alkalosis, extreme alkalemia might ensue because of the concomitant presence of hypocapnia and hyperbicarbonatemia. Even more infrequently, this same clinical setting might lead to a quadruple acid-base disorder in which all four cardinal acid-base disturbances coexist.

Clinical Manifestations

The symptoms and signs of the underlying disease that give rise to the observed mixed acid-base disorder dominate the clinical picture, but the development of severe abnormalities in either $Paco_2$ (severe

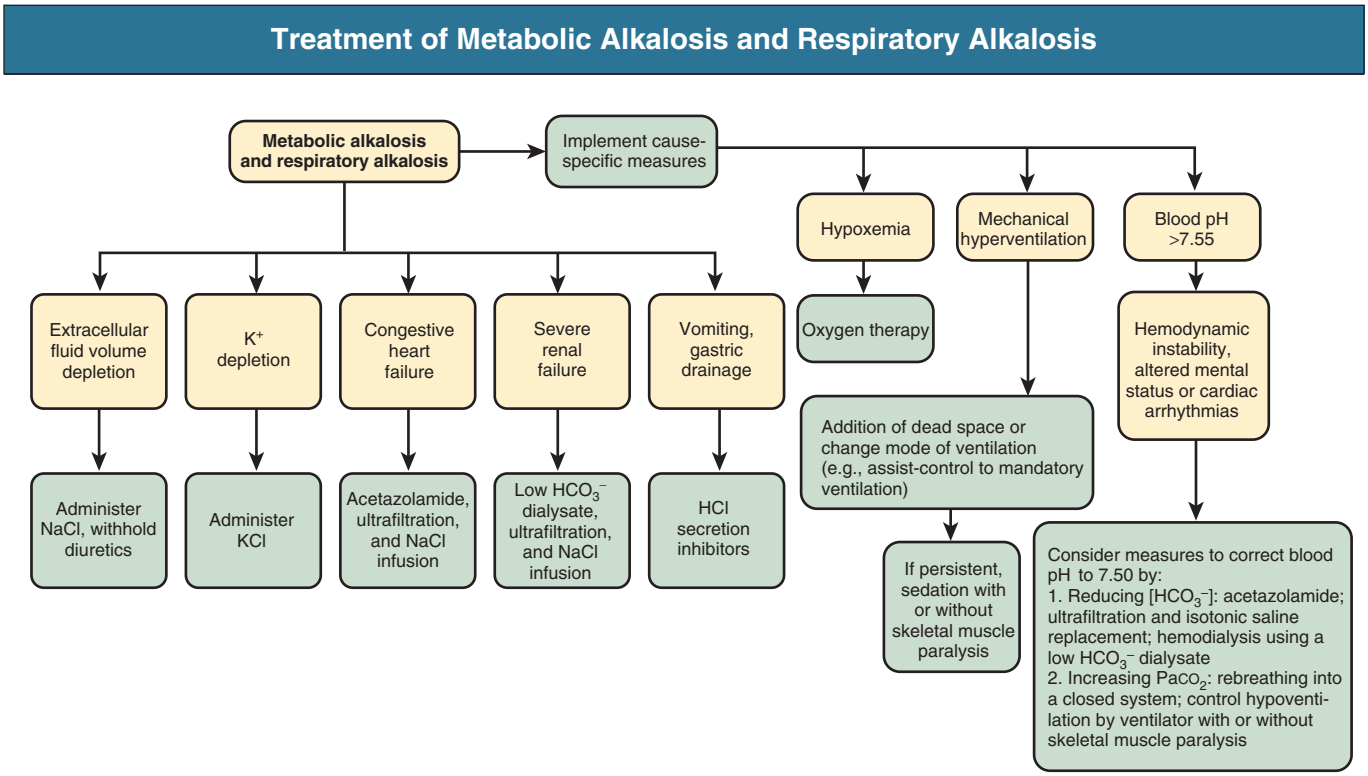

Fig. 14.8 Treatment of Metabolic Alkalosis and Respiratory Alkalosis.

hypocapnia or hypercapnia) or systemic acidity (profound acidemia or alkalemia) might be responsible for the superimposition of additional clinical manifestations. On the one hand, profound hypocapnia might induce obtundation, generalized seizures, and occasionally even coma or death due to a critical reduction in cerebral blood flow. Rarely, angina pectoris also might occur. On the other hand, severe hypercapnia might generate a profound encephalopathy with the classic features of pseudotumor cerebri, including headaches, obtundation, vomiting, and bilateral papilledema, caused by increased ICP. Extreme acidemia results in depression of the central nervous system as well as the cardiovascular system.[7] Reduction in myocardial contractility and peripheral vascular resistance triggered by acidemia might result in severe hypotension. Profound alkalemia might elicit paresthesias, tetany, cardiac dysrhythmias, or generalized seizures.

Diagnosis

The basic principles underlying the diagnosis of mixed acid-base disorders are identical to those required for the identification of simple acid-base disturbances. These include a careful history and physical examination (which will provide important insights into the prevailing acid-base status, as well as useful clues to the differential diagnosis), assessment of the accuracy of the acid-base data by ensuring the available values for pH, $Paco_2$, and serum [HCO_3^-] satisfy the mathematical constraints of the Henderson-Hasselbach equation; analysis of the serum anion gap and other ancillary laboratory data; and knowledge of the quantitative aspects of the adaptive response to each of the four simple acid-base disturbances. Even experienced clinicians risk misdiagnosis of the prevailing acid-base status by bypassing this systematic approach.[3]

Normal acid-base values do not prove normal acid-base status, because they might be the fortuitous result of mixed acid-base disorders (e.g., high anion gap acidosis treated with alkali infusion, diarrhea-induced metabolic acidosis in conjunction with vomiting-induced metabolic alkalosis). A given set of acid-base parameters is never diagnostic of a particular acid-base disorder, but it is consistent with a range of acid-base abnormalities. An apparently clear-cut simple acid-base disorder might actually reflect the interplay of a number of coexisting acid-base disturbances.

A critical component of the diagnostic process is the examination of the serum anion gap (Table 14.6), which provides important insights into the nature of the prevailing changes in serum [HCO_3^-]. An elevated serum anion gap might offer the first clue to the presence of disordered acid-base status despite normal acid-base parameters. With a serum [HCO_3^-] deficit ($\Delta[HCO_3^-]_p$), a normal or subnormal value for the serum anion gap denotes that the entire decrease in [HCO_3^-] can be attributed to acidifying processes resulting in the loss of alkali (e.g., diarrhea, RTA) or to respiratory alkalosis.

By comparison, with a high anion gap metabolic acidosis, there is usually a close reciprocal stoichiometry between the decrease in serum [HCO_3^-] and the increase in the anion gap, termed the Δ(anion gap). A reduction in serum [HCO_3^-] of 10 mmol/l is therefore associated with a Δ(anion gap) of 10 mmol/l. Addition of the value for the Δ(anion gap) to the prevailing level of serum [HCO_3^-] allows the derivation of the basal value of [HCO_3^-] existing before the development of the high anion gap metabolic acidosis. This helps distinguish between a pure high anion gap metabolic acidosis and a mixed high and normal anion gap metabolic acidosis, and to detect a mixed high anion gap metabolic acidosis and metabolic alkalosis. Additional diagnostic insights may come from other laboratory data, including the serum potassium, glucose, urea nitrogen, and creatinine concentrations; semiquantitative measures for ketonemia or ketonuria; screening of blood or urine for toxins; and estimation of the serum osmolar gap.

Mild acid-base disorders pose particular diagnostic difficulty because of the overlap of values for the simple disturbances near the normal range. In such patients, any of several simple disorders or a variety of

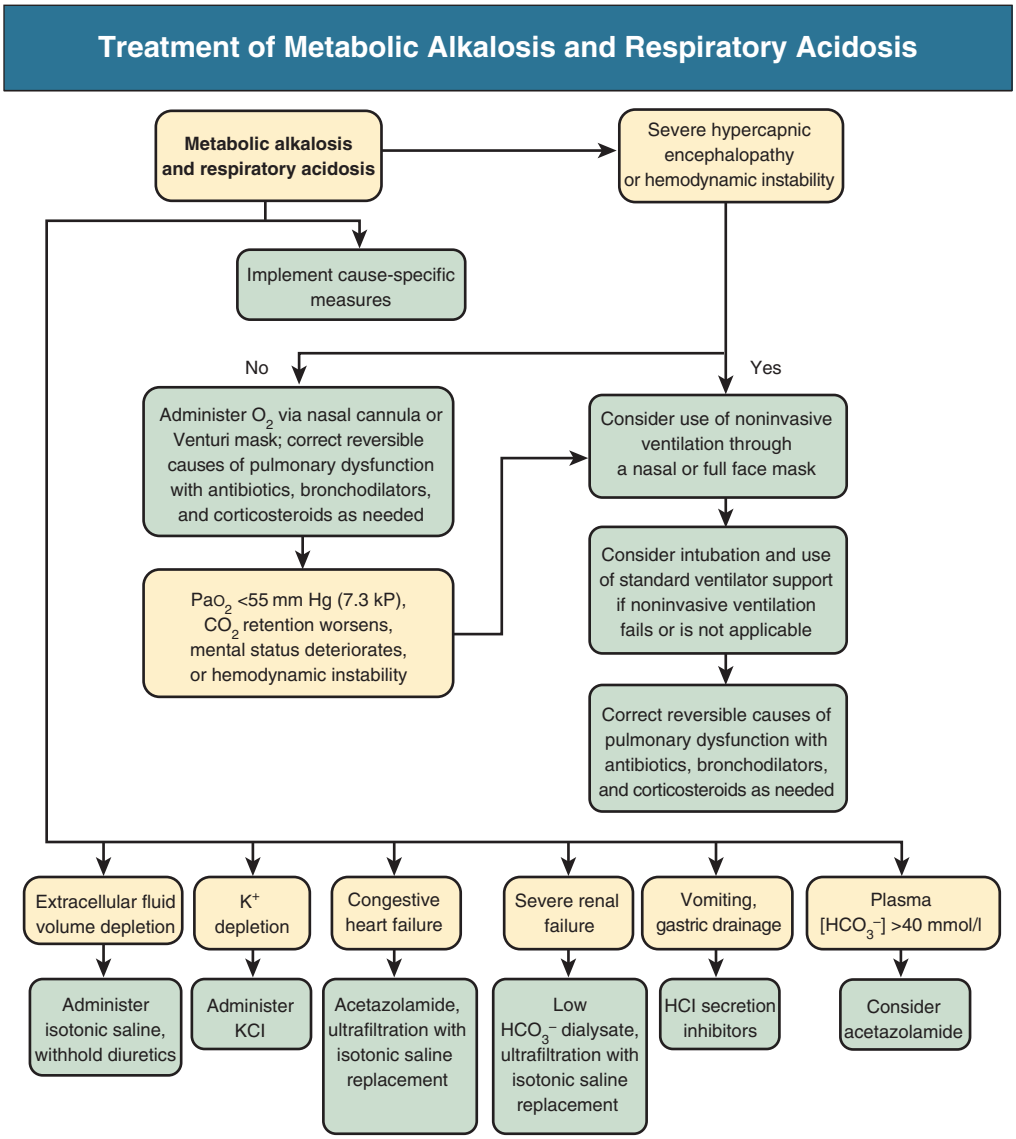

Fig. 14.9 Treatment of Metabolic Alkalosis and Respiratory Acidosis.

TABLE 14.6 Blood Parameters in Diagnosis of Mixed Metabolic Acid-Base Disorders

Blood Composition	Normal	High Anion Gap Acidosis	High Anion Gap and Normal Anion Gap Acidosis	Metabolic Alkalosis	High Anion Gap Acidosis and Metabolic Alkalosis
pH	7.40	7.29	7.10	7.50	7.38
$Paco_2$ (mm Hg)	40	30	20	45	35
Bicarbonate (mmol/l)	24	14	6	34	20
Anion gap (mmol/l)	10	20	20	12	26
ΔBicarbonate	0	−10	−18	+10	−4
ΔAnion gap	0	+10	+10	+2	+16

mixed disturbances might fully account for the acid-base data under evaluation.

Treatment

The management of mixed acid-base disturbances is aimed at restoration of the altered acid-base status by treatment of each simple acid-base disorder involved.[1,2,24,30] Figs. 14.7 to 14.10 provide recommendations for treatment of patients with some common mixed acid-base disturbances.

Given the variable response time to therapy of the individual components, it is crucial to be aware of the effect that graded correction might have on systemic acidity. The asynchronous reversal of the individual components might give therapeutic advantage, but on other occasions might prove catastrophic. For example, extreme acidemia caused by metabolic acidosis and respiratory acidosis or extreme alkalemia caused by metabolic alkalosis and respiratory alkalosis might be safely corrected by a rapid return of $Paco_2$ toward normal. By

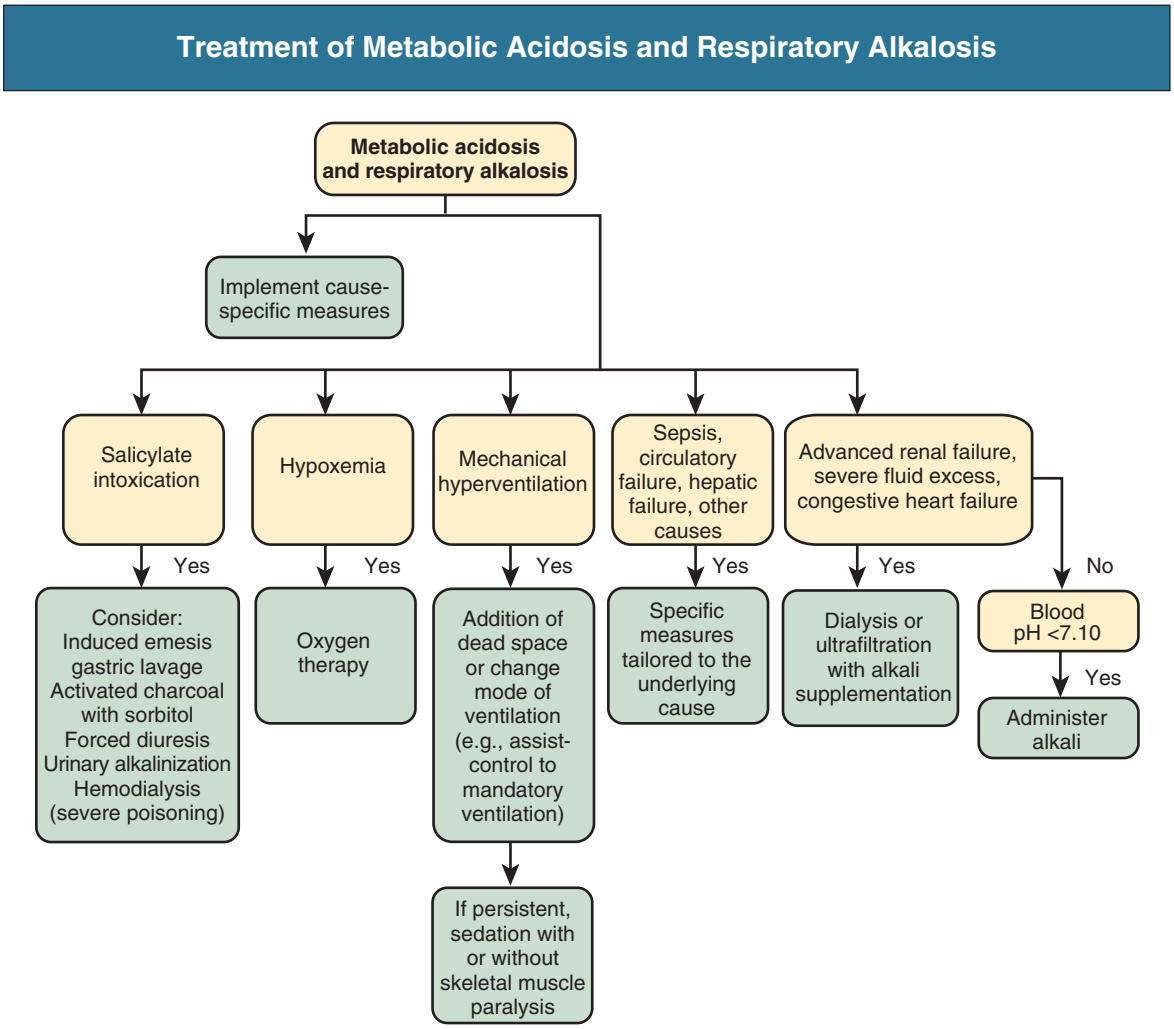

Fig. 14.10 Treatment of Metabolic Acidosis and Respiratory Alkalosis.

comparison, an asynchronous return of $Paco_2$ to normal in a patient with profound metabolic acidosis and superimposed respiratory alkalosis might prove disastrous. Similarly, extreme caution should be exercised in treating patients with respiratory acidosis and metabolic alkalosis, one of the most common mixed acid-base disorders. Although therapeutic measures to improve alveolar ventilation should be instituted, an abrupt decrease in $Paco_2$ risks development of severe alkalemia. Therefore aggressive measures should be taken to treat metabolic alkalosis, making certain that reversal of the metabolic component does not lag behind treatment of the respiratory element. In fact, because the ventilatory drive in patients with chronic respiratory acidosis depends in part on the prevailing acidemia, reversal of a complicating element of metabolic alkalosis regularly results in improved alveolar ventilation, thus achieving a decrease in $Paco_2$ and an increase in Pao_2.

SELF-ASSESSMENTS QUESTIONS

1. Which of the following statements is correct regarding acute and chronic adaptation to respiratory acid-base disorders in patients with end-stage renal disease (essentially without any renal function)?
   A. Both acute and chronic adaptation are normal.
   B. Acute adaptation is normal but chronic adaptation is increased.
   C. Acute adaptation is absent but chronic adaptation is normal.
   D. Both acute and chronic adaptation are absent.
   E. Acute adaptation is normal but chronic adaptation is absent.
2. A 60-year-old man with a history of chronic obstructive pulmonary disease was admitted to the hospital with increasing shortness of breath on exertion and a cough productive of sputum. He was receiving a bronchodilator as an outpatient. On physical examination, he was afebrile, blood pressure was 130/85 mm Hg without orthostatic changes, heart rate was 92 beats/min, and respiratory rate was 24/min. Chest examination revealed scattered expiratory wheezes and diminished breath sounds. Cardiac examination showed no murmurs or gallops. There was 1+ lower extremity edema. Blood work on admission revealed the following:

Sodium	136 mmol/l	pH	7.32
Potassium	3.6 mmol/l	$PaCO_2$	62 mm Hg
Chloride	96 mmol/l	PaO_2	64 mm Hg (O_2 2 l/min)
Bicarbonate	31 mmol/l		

   Which acid-base disorder are these data consistent with?
   A. Acute respiratory acidosis
   B. Chronic respiratory acidosis
   C. Metabolic acidosis
   D. Chronic respiratory acidosis and metabolic acidosis
3. The patient described in question 2 was treated with steroids, antibiotics, and bronchodilators. Because of peripheral edema and a chest radiograph that showed pulmonary congestion, he was given diuretics and maintained on a low-sodium diet. Over the next several days, the patient's breathing symptoms improved. Repeat blood work obtained 72 hours from admission revealed the following:

Sodium	135 mmol/l	pH	7.40
Potassium	3.3 mmol/l	$PaCO_2$	64 mm Hg
Chloride	88 mmol/l	PaO_2	59 mm Hg (O_2 2 l/min)
Bicarbonate	38 mmol/l		

   These data consistent with which acid-base disorder?
   A. Metabolic alkalosis
   B. Acute respiratory acidosis
   C. Chronic respiratory acidosis
   D. Chronic respiratory acidosis and metabolic acidosis
   E. Chronic respiratory acidosis and metabolic alkalosis

Introduction to Glomerular Disease
Clinical Presentations

Jürgen Floege, John Feehally

DEFINITION

Glomerular disease has clinical presentations that vary from the asymptomatic individual who is found to have hypertension, edema, hematuria, or proteinuria at a routine medical assessment to a patient who has fulminant illness with acute kidney injury (AKI) possibly associated with life-threatening extrarenal disease (Fig. 15.1). The most dramatic symptomatic presentations are uncommon. Asymptomatic urine abnormalities are much more common, but less specific, and may also indicate a wide range of nonglomerular urinary tract disease.

CLINICAL EVALUATION OF GLOMERULAR DISEASE

The history, physical examination, and investigations are aimed at excluding nonglomerular disease, finding evidence of associated multisystem disease, and establishing renal function.

History

The majority of glomerular diseases do not lead to symptoms that patients will report. However, specific questioning may reveal edema, hypertension, foamy urine, or urinary abnormalities during prior routine testing (e.g., during scheduled medical examinations). Multisystem diseases associated with glomerular disease include diabetes, hypertension, amyloid, lupus, and vasculitis. Apart from the individual history suggestive of these diseases, a positive family history also may be obtained in some cases and may suggest a genetic cause. Classic genetic causes of renal disease may include Alport syndrome, especially if associated with hearing loss (see Chapter 46); uncommon familial forms of immunoglobulin A (IgA) nephropathy (see Chapter 23); focal segmental glomerulosclerosis (FSGS) secondary to mutations in podocin or other molecules involved in glomerular permeability (see Chapters 18 and 19); some forms of complement-mediated glomerulonephritis (GN) (see Chapter 22); hemolytic uremic syndrome (HUS; see Chapter 29); and other rare conditions (see Chapter 28). Morbid obesity can be associated with FSGS. Certain drugs and toxins may cause glomerular disease, including nonsteroidal antiinflammatory drugs (NSAIDs) and interferon in minimal change disease (MCD); penicillamine, NSAIDs, and mercury (e.g., in skin-lightening creams) in membranous nephropathy; pamidronate and heroin in FSGS; smoking with nodular glomerulosclerosis; and cyclosporine, tacrolimus, mitomycin C, and oral contraceptives in HUS. Recent or persistent infection, especially streptococcal infection, infective endocarditis, and certain viral infections (see Chapters 21, 55, and 56), also may be associated with a variety of glomerular diseases.

Malignant neoplasms associated with glomerular disease include lung, breast, and gastrointestinal (GI) adenocarcinoma in membranous nephropathy; Hodgkin disease in MCD; non-Hodgkin lymphoma in membranoproliferative glomerulonephritis (GN); and renal cell carcinoma in amyloid disease (see Chapter 27). Patients will occasionally present with the renal disease as the first manifestation of a tumor.

Physical Examination

The presence of dependent pitting edema suggests nephrotic syndrome, heart failure, or cirrhosis. In the nephrotic patient, edema is often periorbital in the morning (Fig. 15.2), whereas the face is not affected overnight in edema associated with heart failure (edema distributes by gravity, and patients often cannot lie flat in the setting of heart failure because of orthopnea resulting from pulmonary congestion) or cirrhosis (because of pressure on the diaphragm from ascites). As severity of nephrosis progresses, edema of genitals and the abdominal wall becomes apparent, and accumulation of fluid in body spaces leads to ascites and pleural effusions. Edema is unpleasant, leading to feelings of tightness in the limbs and a bloated abdomen, with practical problems of clothes and shoes no longer fitting. Surprisingly, however, edema may become massive in nephrotic syndrome before patients seek medical help; fluid gains of 20 kg (44 lb) or more are not unusual (Fig. 15.3). The edema becomes firm and stops pitting only when it is long-standing. In children, fluid retention may be striking with nephritic syndrome. Chronic hypoalbuminemia is also associated with loss of normal pink color under the nails, resulting in white nails or white bands if nephrotic syndrome is transient (Muehrcke lines, Fig. 15.4). Xanthelasmas may be present as a result of the hyperlipidemia associated with long-standing nephrotic syndrome (Fig. 15.5).

The presence of pulmonary signs should suggest one of the so-called pulmonary-renal syndromes (see Boxes 24.3 and 24.4). Palpable purpura may be seen in vasculitis, systemic lupus, cryoglobulinemia, or endocarditis.

Fig. 15.3 Nephrotic Edema. Severe peripheral edema in nephrotic syndrome; note the blisters caused by intradermal fluid.

Fig. 15.4 Muehrcke lines (bands) in nephrotic syndrome. The *white line* grew during a transient period of hypoalbuminemia caused by the nephrotic syndrome.

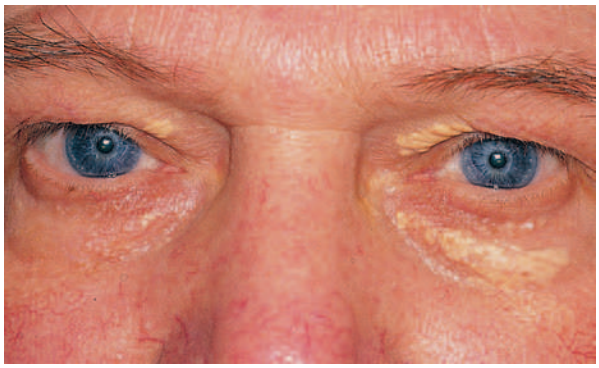

Fig. 15.5 Xanthelasmas in nephrotic syndrome. These prominent xanthelasmas developed within 2 months in a patient with recent onset of severe nephrotic syndrome and serum cholesterol level of 550 mg/dl (14.2 mmol/l).

Laboratory Studies

Assessment of renal function and careful examination of the urine are critical (see Chapters 3 and 4). The quantity of urine protein and the presence or absence of dysmorphic red cells and casts will help classify the clinical presentation (see Fig. 15.1).

Certain serologic tests are helpful. These include antinuclear and anti-DNA antibodies for lupus, cryoglobulins and rheumatoid factor suggesting cryoglobulinemia, anti–glomerular basement membrane (anti-GBM) antibodies for Goodpasture disease, antineutrophil cytoplasmic autoantibody (ANCA) for vasculitis, and antistreptolysin O

TABLE 15.1 Hypocomplementemia in Glomerular Disease

Pathways Affected	Complement Changes	Glomerular Disease	Nonglomerular Disease
Classical pathway activation	C3 ↓, C4 ↓, CH50 ↓	Lupus nephritis (especially Class IV) Cryoglobulinemia Membranoproliferative GN type 1	
Alternative pathway activation	C3 ↓, C4 normal, CH50 ↓	Poststreptococcal GN GN associated with other infection* (e.g., endocarditis, shunt nephritis) HUS	Atheroembolic renal disease
	plus C3 nephritic factor	Dense deposit disease	
Reduced complement synthesis	Acquired		Hepatic disease Malnutrition
	Hereditary C2 or C4 deficiency Factor H deficiency	Lupus nephritis Familial HUS Dense deposit disease	

*Glomerulonephritis *(GN)* with visceral abscesses is generally associated with normal or increased complement (elevations occur because complement components are acute-phase reactants). *CH50,* 50% hemolyzing dose of complement; *HUS,* hemolytic uremic syndrome.

titer or streptozyme test for poststreptococcal GN. Serum and urine electrophoresis will detect monoclonal light chains or heavy chains, and assays for free light chains in serum or urine may aid in their quantification, as in myeloma-associated amyloid or light-chain deposition disease.

Testing for the presence of ongoing bacterial or viral infections is also useful. This includes blood cultures and testing for hepatitis B, hepatitis C, and human immunodeficiency virus (HIV) infection.

Measurement of systemic complement pathway activation by testing for serum C3, C4, and CH50 (50% hemolyzing dose of complement) is often helpful in limiting the differential diagnosis (Table 15.1).

The importance of genetic evaluation in patients with GN is discussed in Chapters 19 and 22.

Imaging

Ultrasound scanning is recommended in the workup to ensure the presence of two kidneys, to rule out obstruction or anatomic abnormalities, and to assess kidney size. Renal size is often normal in GN, although large kidneys (>14 cm) are sometimes seen in nephrotic syndrome associated with diabetes, amyloid disease, or HIV infection. Large kidneys also can occasionally be seen with any acute severe GN and acute interstitial nephritis. The occurrence of small kidneys (<9 cm) and/or severe cortical thinning suggests advanced chronic kidney disease (CKD) and should limit enthusiasm for renal biopsy or aggressive immunosuppressive therapies.

Renal Biopsy

Renal biopsy is generally required to establish the type of glomerular disease and to guide treatment decisions (see Chapter 6). In some patients, however, renal biopsy is not performed. If nephrotic children (age 2 to 12) have no unusual clinical features, the probability of MCD is so high that corticosteroids can be initiated without biopsy (see Chapter 17). In patients with acute nephritic syndrome, if all features point to poststreptococcal GN, especially in an epidemic, biopsy can be reserved for the minority who do not show early spontaneous improvement (see Chapter 55). In Goodpasture disease (see Chapter 24), the presence of lung hemorrhage and rapidly progressive renal failure with urinary red cell casts and high levels of circulating anti-GBM antibody establishes the diagnosis without the need for a biopsy, although a biopsy may still provide valuable prognostic information. In patients with systemic features of vasculitis, a positive ANCA titer, negative blood cultures, and a tissue biopsy specimen from another site showing vasculitis are sufficient to secure a diagnosis of renal vasculitis. Again, however, renal biopsy may provide important clues to disease activity and chronicity. Biopsy is also not generally performed in patients with long-standing diabetes with characteristic findings suggestive of diabetic nephropathy and other evidence of microvascular complications of diabetes (see Chapter 30). Biopsy may not be indicated in many patients with glomerular disease presenting with minor, asymptomatic urine abnormalities and well-preserved renal function because the prognosis is excellent and histologic findings will not alter management.

ASYMPTOMATIC URINE ABNORMALITIES

Urine testing that detects proteinuria or microhematuria is often the first evidence of glomerular disease. The random nature of urine testing in most communities inevitably means that much mild glomerular disease remains undetected. In some countries, symptomless individuals may have a urine test only if they require medical approval for some key life event, such as obtaining life insurance, joining the armed forces, or sometimes for employment purposes. In other countries, for example, Japan, urinalysis is performed routinely in school or for employment. These different practices may partly account for the apparently variable incidence of certain diseases, such as IgA nephropathy, which often manifests as asymptomatic proteinuria and microhematuria. Asymptomatic low-grade proteinuria and microhematuria and the combination of the two, also increase in prevalence with age[1] (Fig. 15.6). Nevertheless, there is no evidence to justify routine population-wide screening for asymptomatic urine abnormalities as renal biopsy and therapeutic intervention are rarely required when renal function is preserved. For certain high-risk populations, such as patients with diabetes or hypertension, evaluation of albuminuria may be useful as it carries increased risk for cardiovascular disease.

Asymptomatic Microhematuria

Microhematuria is defined as the presence of more than two red blood cells (RBCs) per high-power field in a spun urine sediment (3000 rpm for 5 minutes) or more than 10×10^6 RBCs/l. Microhematuria is common in many glomerular diseases, especially IgA nephropathy and thin basement membrane nephropathy, although there are many other causes

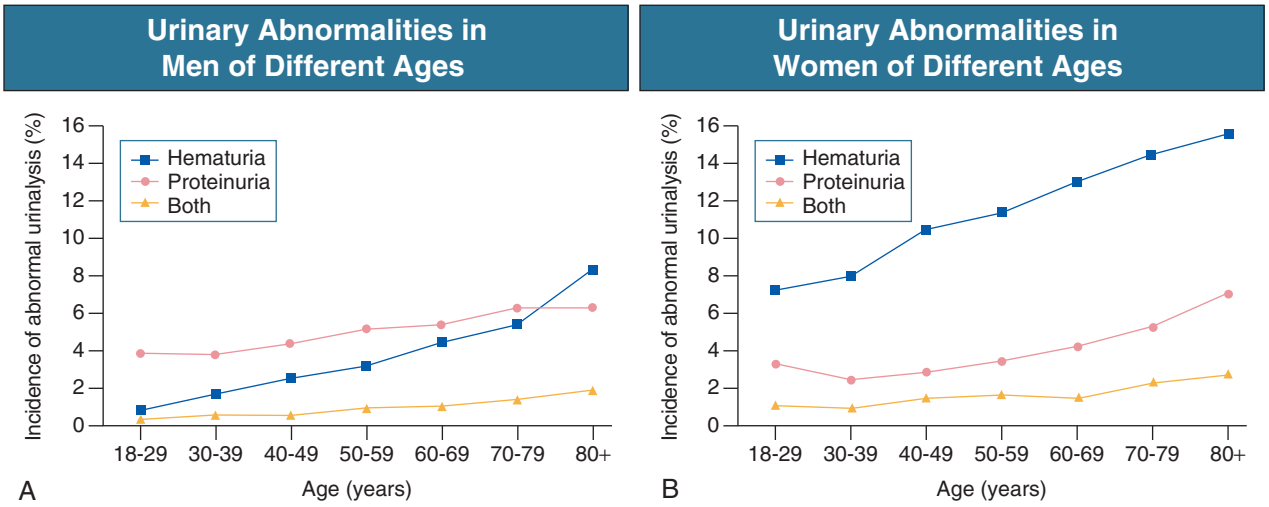

Fig. 15.6 Prevalence of asymptomatic proteinuria and hematuria with age. Mass screening of a population of 107,192 adult men (A) and women (B) in Okinawa, Japan. Hematuria is more common in women. (Modified from reference 1.)

Fig. 15.7 Red blood cell cast. An RBC cast typical of glomerular hematuria.

of hematuria (see Chapters 46 and 59). A glomerular origin especially should be considered if more than 5% of RBCs are acanthocytes or dysmorphic (see Chapter 4) or if the hematuria is accompanied by RBC casts or proteinuria (Fig. 15.7).

Pathogenesis

Glomerular hematuria is thought to result from small breaks in the GBM that allow extravasation of RBCs into the urinary space. This may occur in the peripheral capillary wall but more often occurs in the paramesangial basement membrane, particularly in diseases involving injury to the mesangium (mesangiolysis). As long as the renal tubules are intact, low amounts of serum proteins lost together with RBCs in damaged glomeruli can be fully reabsorbed, resulting in "isolated" microhematuria.

Evaluation

The evaluation of microhematuria, discussed further in Chapters 46 and 59, begins with a thorough history. Urine culture should exclude urinary or prostatic infection. Phase contrast microscopy should follow in cases of persistent microhematuria to search for dysmorphic RBCs and RBC casts. In the absence of urine infection or a bladder catheter, any detectable proteinuria (>0.3 g/24 h) in the patient with asymptomatic microhematuria virtually excludes "urologic" bleeding and strongly suggests a glomerular origin. If this evaluation is nondiagnostic, renal imaging is performed to exclude anatomic lesions such as stones, tumors, polycystic kidneys, or arteriovenous malformations.

In those older than 40 years who have persistent isolated microhematuria without evidence of a glomerular origin (see previous discussion), cystoscopy is mandatory to exclude uroepithelial malignant disease. In people younger than 40 years, such malignant disease is so rare that cystoscopy is not recommended. If all the prior study results are normal, a glomerular cause is likely.[2] The glomerular cause can be determined only by renal biopsy, but this is rarely done because the prognosis is excellent in patients with normal renal function, normal blood pressure, and low-grade proteinuria (<0.5 g/day). However, repeated evaluation and prolonged follow-up are mandatory for as long as the urinary abnormality persists.

Asymptomatic Non-Nephrotic Proteinuria

The hallmark of glomerular disease is the excretion of protein in the urine. Normal urine protein excretion is less than 150 mg/24 h, consisting of 20 to 30 mg of albumin, 10 to 20 mg of low-molecular-weight proteins that undergo glomerular filtration, and 40 to 60 mg of secreted proteins (e.g., Tamm-Horsfall, IgA). Proteinuria is identified and quantified by dipstick testing or by assay in timed urine collections; Chapter 4 discusses test interpretation.

An albumin excretion rate of 30 to 300 mg of albumin per day (previously termed *microalbuminuria*), equivalent to a urine albumin-to-creatinine (gram/gram) ratio of 0.03 to 0.3, is detected by quantitative immunoassay or by special urine dipsticks because this is below the sensitivity of the normal dipstick (see Chapter 30). This measurement is primarily used to identify diabetic individuals at risk for development of nephropathy and to assess cardiovascular risk, for example, in patients with hypertension.

Non-nephrotic proteinuria is usually defined as a urine protein excretion of less than 3.5 g/24 h or a urine protein-to-creatinine ratio of less than 3 g/g. Whereas nephrotic-range proteinuria is absolutely characteristic of glomerular disease, lower levels of proteinuria (<3.5 g/24 h) is much less specific and may occur with a wide range of

nonglomerular parenchymal diseases as well as with nonparenchymal renal and urinary tract conditions that must be excluded by clinical evaluation and investigation.

Increased urine protein excretion may result from alterations in glomerular permeability or tubulointerstitial disease, although only in glomerular disease will it be in the nephrotic range. Protein excretion also can increase if there is greater filtration through normal glomeruli (overflow proteinuria).

Overflow Proteinuria

Overflow proteinuria is typical of urinary light-chain excretion. It is seen in myeloma but can occur in other settings (e.g., release of lysozyme by leukemic cells) and should be suspected when the urine dipstick is negative for albumin despite detection of large amounts of proteinuria by other tests.

Tubular Proteinuria

Tubulointerstitial disease can be associated with low-grade proteinuria (usually <2 g/day). In addition to the loss of tubular proteins such as α_1- or β_2-microglobulin, there will also be some albuminuria secondary to impaired tubular reabsorption of filtered albumin. Tubular proteinuria accompanying glomerular proteinuria is an adverse prognostic sign in various glomerular diseases because it usually indicates advanced tubulointerstitial damage.

Glomerular Proteinuria

Glomerular proteinuria is further classified into transient or hemodynamic (functional) proteinuria, proteinuria that is present only during the day (orthostatic), and persistent or fixed proteinuria.

Functional proteinuria. Functional proteinuria refers to the transient non-nephrotic proteinuria that can occur with fever, exercise, heart failure, and hyperadrenergic or hyperreninemic states. Functional proteinuria is benign, usually assumed to be hemodynamic in origin, and the result of increases in single-nephron flow or pressure.

Orthostatic proteinuria. In children and young adults, low-grade glomerular proteinuria may be orthostatic, meaning that proteinuria is absent when urine is generated in the recumbent position. If there is no proteinuria in early-morning urine, the diagnosis of orthostatic proteinuria can be made. In patients with fixed orthostatic proteinuria, renal plasma flow and glomerular filtration rate (GFR) decrease in the upright position because of a lower systemic blood pressure. As recently proposed, the decreased GFR translates into a lower *streaming potential* across the filtration barrier, which under physiologic conditions, retains albumin within the blood. When GFR and filtration pressure are reduced beyond a certain threshold, albumin is no longer excluded efficiently from the filter by electrophoresis and consequently leaks through the filter, explaining reversible low-grade proteinuria in the upright position in these patients.[3]

Total urine protein in the patient with orthostatic proteinuria is usually less than 1 g/24 h; hematuria and hypertension are absent. Renal biopsy usually shows normal morphology or occasionally mild glomerular change. The prognosis is uniformly good, and renal biopsy is not indicated.[4]

Fixed non-nephrotic proteinuria. Fixed non-nephrotic proteinuria is usually caused by glomerular disease. If GFR is preserved and proteinuria is less than 0.5 to 1 g/day, biopsy is not indicated but prolonged follow-up is necessary if significant proteinuria persists, to rule out the possibility of disease progression. Previous studies indicate that the biopsy findings in these patients can be similar to those seen in nephrotic syndrome (most commonly FSGS or membranous nephropathy), although milder lesions are more common, particularly mesangial proliferative GN or IgA nephropathy. In general, other than regular monitoring and blood pressure control as needed, no treatment is necessary.

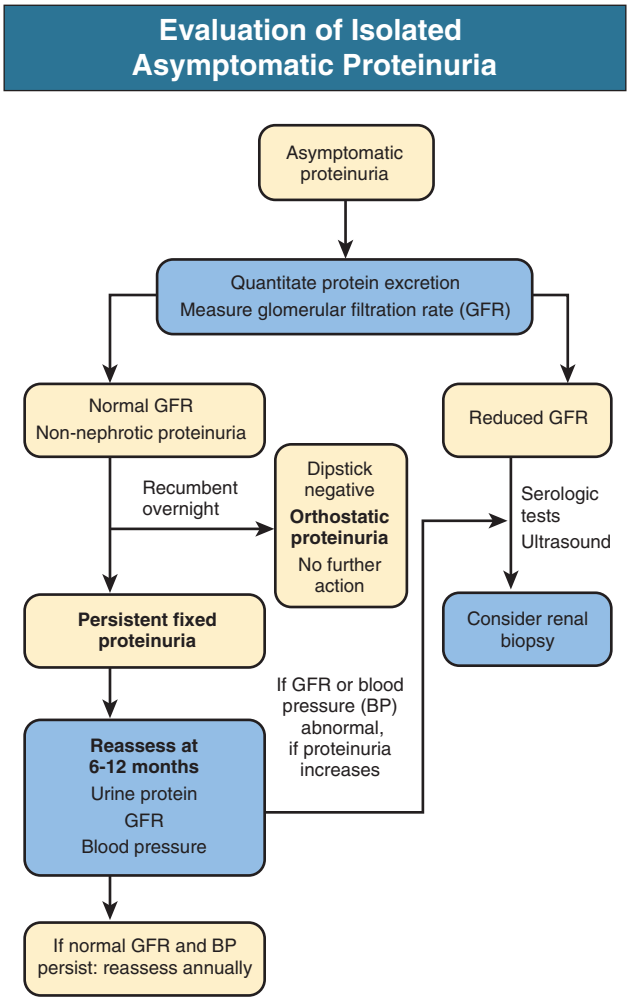

Fig. 15.8 Evaluation of patients with isolated asymptomatic proteinuria.

Although it is controversial, many nephrologists will perform a renal biopsy in patients with normal GFR if non-nephrotic proteinuria exceeds 1 g/day, in particular if it persists after initiation of angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) therapy.

Fig. 15.8 summarizes the evaluation of isolated asymptomatic proteinuria.

Asymptomatic Proteinuria With Hematuria

Patients with coincident asymptomatic hematuria and proteinuria have a much greater risk for significant glomerular injury, hypertension, and progressive renal dysfunction. Minor histologic changes are less common. Renal biopsy is often performed even if urine protein is only 0.5 to 1 g/24 h if there is also persistent microhematuria with casts and/or declining renal function.

MACROHEMATURIA

Episodic painless macrohematuria associated with glomerular disease is often brown or "smoky" rather than red, and clots are unusual. Macrohematuria must be distinguished from other causes of red or brown urine, including hemoglobinuria, myoglobinuria, porphyrias, consumption of food dyes (particularly beetroot), and intake of drugs (especially rifampin/rifampicin).

Macrohematuria caused by glomerular disease is seen mainly in children and young adults and is rare after age 40. Most cases are caused

by IgA nephropathy, but hematuria may occur with other glomerular and nonglomerular renal diseases, including acute interstitial nephritis. Although macrohematuria is typically painless, the patient may have an accompanying dull loin ache that suggests other diagnoses, such as stone disease or loin-pain hematuria syndrome (see Chapter 57). In IgA nephropathy, the frank hematuria is usually episodic, occurring within a day of an upper respiratory tract infection. There is a clear distinction between this history and the 2- to 3-week latency between an upper respiratory tract infection and hematuria that is highly suggestive of postinfectious (usually poststreptococcal) GN; furthermore, patients with poststreptococcal disease usually will have other features of nephritic syndrome.

Macrohematuria requires urologic evaluation, including cystoscopy, at any age unless the history (as described previously) is characteristic of glomerular hematuria.

NEPHROTIC SYNDROME

Definition

Nephrotic syndrome is pathognomonic of glomerular disease. It is a clinical syndrome with a characteristic pentad[5] (see Fig. 15.1). Patients may be nephrotic with preserved renal function, but in many, progressive renal failure will become superimposed when nephrotic syndrome is prolonged.

Independent of the risk for progressive renal failure, the nephrotic syndrome has far-reaching metabolic effects that can influence the general health of the patient. Fortunately, some episodes of nephrotic syndrome are self-limited, and a few patients respond completely to specific treatment (e.g., corticosteroids in MCD). For most patients, however, it is a relapsing or chronic condition. Not all patients with proteinuria above 3.5 g/24 h will have full nephrotic syndrome; some have a normal serum albumin concentration and no edema. This difference presumably reflects the varied response of protein metabolism; some patients sustain an increase in albumin synthesis in response to heavy proteinuria that may even normalize serum albumin.

Etiology

Table 15.2 shows the major causes of nephrotic syndrome. Proteinuria in the nephrotic range in the absence of edema and hypoalbuminemia has similar causes. The relative frequency of the different glomerular diseases varies with age (Table 15.3). Although it is predominant in childhood, MCD remains common at all ages.[6] The prevalence of FSGS in African Americans is increased, which may explain why FSGS is becoming more common in U.S. adults but not in European adults.[7,8]

TABLE 15.2 Common Glomerular Diseases Presenting as Nephrotic Syndrome in Adults

Disease	Associations	Serologic Tests
Minimal change disease (MCD)	Allergy, atopy, NSAIDs, Hodgkin disease	None
Focal segmental glomerulosclerosis (FSGS)	African Americans	—
	HIV infection	HIV antibody
	Heroin, pamidronate	—
Membranous nephropathy (MN)	Idiopathic drugs: Gold, penicillamine, NSAIDs	Anti-PLA_2R antibody
	Infections: Hepatitis B and C; malaria	Hepatitis B surface antigen, anti–hepatitis C virus antibody
	Lupus nephritis	Anti-DNA antibody
	Malignancy: Breast, lung, gastrointestinal tract	—
Membranoproliferative glomerulonephritis (MPGN) type I	C4 nephritic factor	C3 ↓, C4 ↓
Dense deposit disease	C3 nephritic factor	C3 ↓, C4 normal
Cryoglobulinemic MPGN	Hepatitis C	Anti–hepatitis C virus antibody, rheumatoid factor, C3 ↓, C4 ↓, CH50 ↓
Amyloid disease	Myeloma	Plasma free light chains
	Rheumatoid arthritis, bronchiectasis, Crohn disease (and other chronic inflammatory conditions), familial Mediterranean fever	Serum protein electrophoresis, urine immunoelectrophoresis C-reactive protein
Diabetic nephropathy	Other diabetic microangiopathy	None

HIV, Human immunodeficiency virus; *NSAIDs,* nonsteroidal antiinflammatory drugs; *PLA_2R,* phospholipase A_2 receptor.

TABLE 15.3 Age-Related Variations in the Prevalence of Nephrotic Syndrome

	PREVALENCE (%)				
	Child (<15 yr)	Young Adult Whites	Blacks	Middle and Old Age Whites	Blacks
Minimal change disease (MCD)	78	23	15	21	16
Focal segmental glomerulosclerosis (FSGS)	8	19	55	13	35
Membranous nephropathy (MN)	2	24	26	37	24
Membranoproliferative glomerulonephritis (MPGN)	6	13	0	4	2
Other glomerulonephritides	6	14	2	12	12
Amyloid	0	5	2	13	11

Data modified from references 6 and 7.

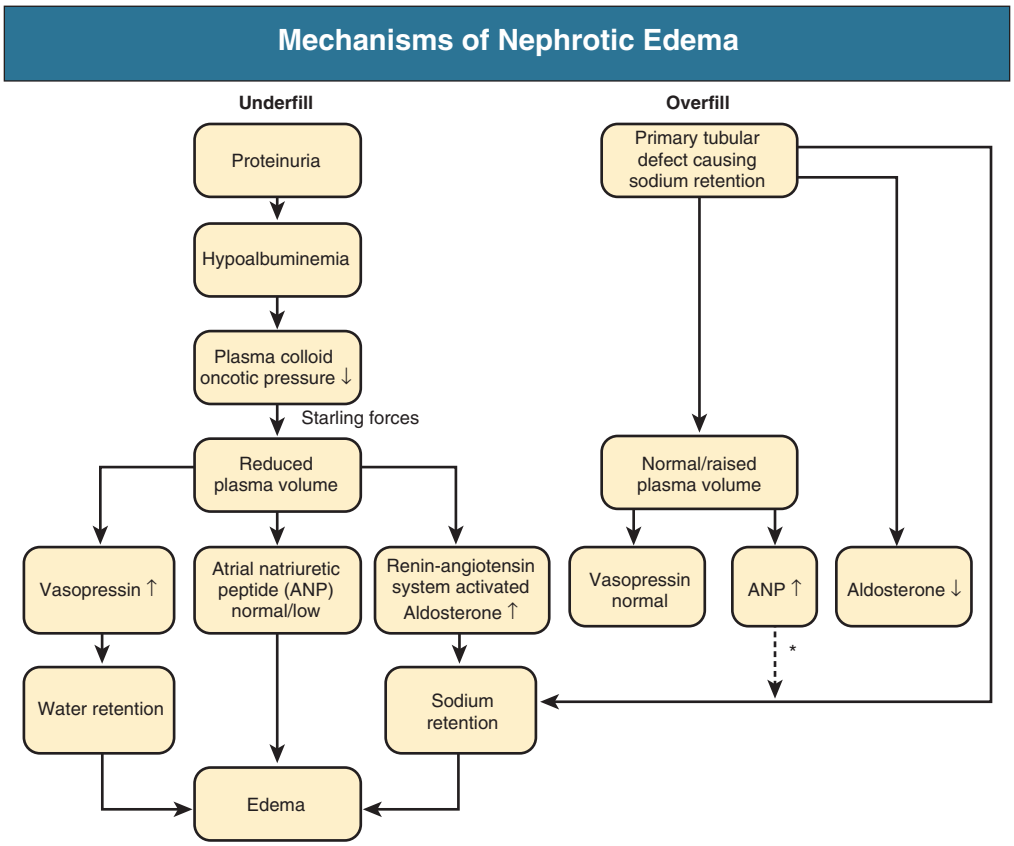

Fig. 15.9 Mechanisms of nephrotic edema.* The kidney is relatively resistant to atrial natriuretic peptide (ANP) in this setting, so ANP has little effect in countering sodium retention.

Hypoalbuminemia

Hypoalbuminemia is mainly a consequence of urinary losses. The liver responds by increasing albumin synthesis, but this compensatory mechanism appears to be blunted in nephrotic syndrome.[9] The end result is that serum albumin falls further. White bands in the nails (Muehrcke lines) are a characteristic clinical sign of hypoalbuminemia (see Fig. 15.4). The increase in protein synthesis in response to proteinuria is not discriminating; as a result, proteins not being lost in the urine may actually increase in concentration in plasma. This is chiefly determined by molecular weight; large molecules will not spill into the urine and will increase in the plasma, whereas smaller proteins, although synthesized to excess, will enter the urine and will decrease in the plasma. These variations in plasma proteins are clinically important in two areas: hypercoagulability and hyperlipidemia (see later discussion).

Edema

At least two major mechanisms are involved in the formation of nephrotic edema: underfill and overfill[10] (Fig. 15.9; see Chapter 7). In the first mechanism, which is more common in children with MCD, the edema appears to result from the low serum albumin, producing a decrease in plasma oncotic pressure, which allows increased transudation of fluid from capillary beds into the extracellular space according to the laws of Starling. The consequent decrease in circulating blood volume *(underfill)* results in a secondary stimulation of the renin-angiotensin system (RAS), resulting in aldosterone-induced sodium retention in the distal tubule. This attempt to compensate for hypovolemia merely aggravates edema because the low oncotic pressure alters the balance of forces across the capillary wall in favor of hydrostatic pressure, forcing more fluid into the interstitial space rather than retaining it within the vascular compartment.

However, a much more common mechanism for edema, occurring in most nephrotic patients, is a primary defect in the ability of the distal nephron to excrete sodium, possibly related to activation of the epithelial sodium channel (ENaC) by proteolytic enzymes that enter the tubular lumen in heavy proteinuria.[11] As a result, there is an increased blood volume; suppression of renin, angiotensin, and vasopressin; and a tendency to hypertension rather than to hypotension. The kidney is also relatively resistant to the actions of atrial natriuretic peptide. An elevated blood volume results *(overfill)*, which, in association with the low plasma oncotic pressure, provokes transudation of fluid into the extracellular space and edema. In addition to activation of the ENaC (see earlier discussion), it has been hypothesized that inflammatory leukocytes in the interstitium, which are found in many glomerular diseases, may impair sodium excretion by producing angiotensin II and oxidants (oxidants inactivate local nitric oxide, which is natriuretic).[12]

Metabolic Consequences of Nephrotic Syndrome

Negative Nitrogen Balance

The heavy proteinuria leads to marked negative nitrogen balance, usually measured in clinical practice by serum albumin. Nephrotic syndrome is a wasting illness, but the degree of muscle loss is masked by edema and not fully apparent until the patient is rendered edema free. Loss of 10% to 20% of lean body mass can occur. Albumin turnover is increased in response to the tubular catabolism of filtered protein rather than merely to urinary protein loss. Increasing protein intake does not improve albumin metabolism because the hemodynamic response to an increased intake is a rise in glomerular pressure, increasing urine

protein losses. A low-protein diet in turn will reduce proteinuria, but also reduces the albumin synthesis rate and in the longer term may increase the risk for a worsening negative nitrogen balance.

Hypercoagulability

Multiple proteins of the coagulation cascade have altered levels in nephrotic syndrome; in addition, platelet aggregation is enhanced.[13] The net effect is a hypercoagulable state that is enhanced further by immobility, coincidental infection, and hemoconcentration if the patient has a contracted plasma volume (Fig. 15.10). Not only is venous thromboembolism common at any site, but spontaneous arterial thrombosis may rarely occur. Arterial thrombosis may occur in adults in the context of atheroma, promoting coronary and cerebrovascular events in particular, but it also occurs in nephrotic children, in whom spontaneous thrombosis of major limb arteries is an uncommon but feared complication. Up to 10% of nephrotic adults and 2% of children will have a clinical episode of thromboembolism. For unexplained reasons, the risk appears particularly high in those with membranous nephropathy.[14] Individual levels of coagulation proteins are not helpful in assessing the risk for thromboembolism, and serum albumin is mostly used as a surrogate marker. Thromboembolic events increase greatly if the serum albumin concentration decreases to less than 2 g/dl.

The hypoproteinemia and dysproteinemia produce a marked increase in erythrocyte sedimentation rate (ESR), which no longer serves as a marker of an acute phase response in nephrotic patients.

Renal vein thrombosis is an important complication of nephrotic syndrome (see Chapter 41). Although once considered possible, renal vein thrombosis is no longer thought to cause nephrotic syndrome. Renal vein thrombosis is reported clinically in up to 8% of nephrotic patients, but when sought systematically by ultrasound or contrast venography, the frequency increases to 10% to 50%. Symptoms when the thrombosis is acute may include flank pain and hematuria; rarely, AKI can occur if the thrombosis is bilateral. However, the thrombosis often develops insidiously with minimal symptoms or signs because of the development of collateral blood supply. Pulmonary embolism is an important complication.

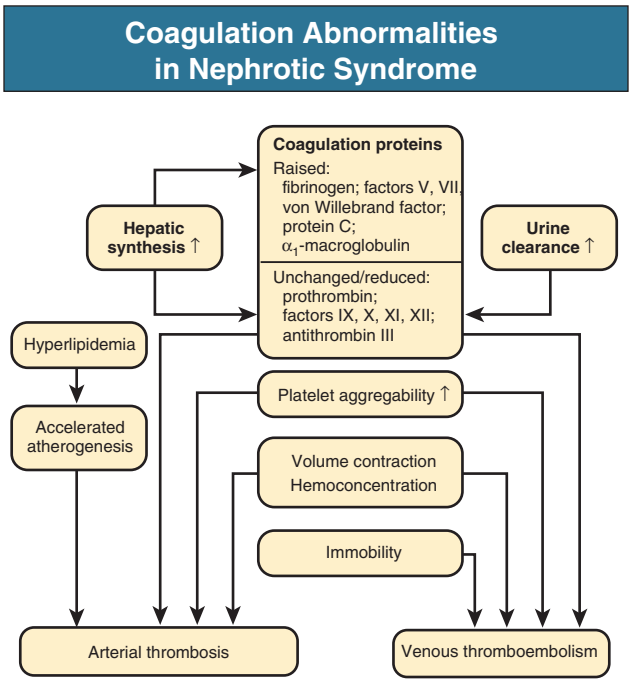

Fig. 15.10 Coagulation abnormalities in nephrotic syndrome.

Hyperlipidemia and Lipiduria

Hyperlipidemia is such a frequent finding in patients with heavy proteinuria that it is regarded as an integral feature of nephrotic syndrome.[15] Clinical stigmata of hyperlipidemia, such as xanthelasmas, may have a rapid onset (see Fig. 15.5). Serum cholesterol concentration can be above 500 mg/dl (13 mmol/l), although serum triglyceride levels are highly variable. The lipid profile in nephrotic syndrome is known to be highly atherogenic in other populations (Fig. 15.11). The presumption that coronary heart disease is increased in nephrotic syndrome because of the combination of hypercoagulation and hyperlipidemia has been difficult to prove. Many patients who are nephrotic for more than 5 to 10 years will develop additional cardiovascular risk factors, including hypertension and uremia, so it is difficult to separate these influences. However, it is now generally accepted that nephrotic patients do have about a fivefold increased risk for coronary death, except for those with MCD, presumably because the nephrotic state is transient before remission with corticosteroid treatment and does not subject the patient with MCD to prolonged hyperlipidemia.

Experimental evidence shows that hyperlipidemia contributes to progressive renal disease by various mechanisms, with protection afforded by lipid-lowering agents. However, clinical evidence to support a role of statins in slowing CKD progression is inconclusive.[16] Adequate prospective clinical studies on this issue remain to be done, and lipid-lowering drugs are indicated in nephrotic syndrome primarily for cardiovascular reasons.

Several mechanisms account for the lipid abnormalities in nephrotic syndrome. These include increased hepatic synthesis of low-density lipoprotein (LDL), very-low-density lipoprotein (VLDL), and lipoprotein(a) secondary to the hypoalbuminemia; defective peripheral lipoprotein

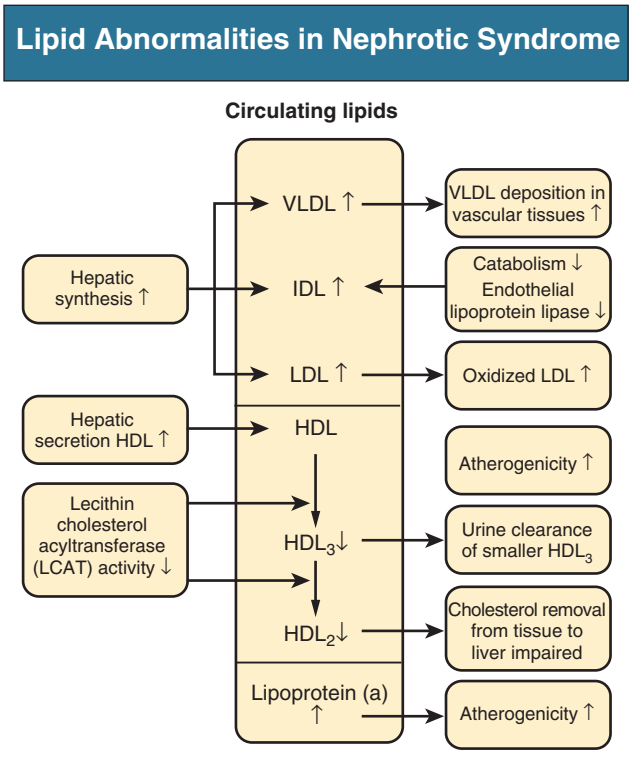

Fig. 15.11 Lipid abnormalities in nephrotic syndrome. Changes in high-density lipoprotein *(HDL)* are more controversial than those in very-low-density lipoprotein *(VLDL). IDL,* Intermediate-density lipoprotein; *LDL,* low-density lipoprotein.

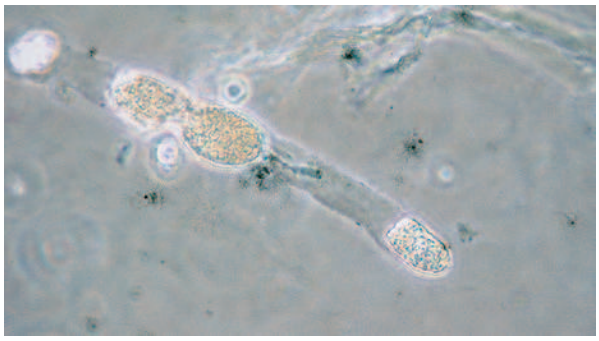

Fig. 15.12 Fat in the urine. This hyaline cast contains oval fat bodies, which are tubular epithelial cells full of fat. Oval fat bodies often appear brown.

BOX 15.1 Causes of Acute Kidney Injury in Nephrotic Syndrome

- Pre-renal failure caused by volume depletion
- Acute tubular necrosis caused by volume depletion and/or sepsis
- Intrarenal edema
- Renal vein thrombosis
- Transformation of underlying glomerular disease (e.g., crescentic nephritis superimposed on membranous nephropathy)
- Adverse effects of drug therapy
- Acute allergic interstitial nephritis secondary to various drugs, including diuretics
- Hemodynamic response to nonsteroidal antiinflammatory drugs (NSAIDs) and angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs)

lipase activity resulting in increased VLDL; and urinary losses of high-density lipoprotein (HDL; see Fig. 15.11).

Lipiduria, the fifth component of the nephrotic syndrome pentad, is manifested by the presence of refractile accumulations of lipid in cellular debris and casts (oval fat bodies and fatty casts; Fig. 15.12). However, the lipiduria appears to be a result of the proteinuria and not the plasma lipid abnormalities.

Other Metabolic Effects of Nephrotic Syndrome

Vitamin D–binding protein is lost in the urine, resulting in low plasma 25-hydroxyvitamin D levels, but plasma free vitamin D is usually normal, and overt osteomalacia or uncontrolled hyperparathyroidism is very unusual in nephrotic syndrome in the absence of renal impairment. Thyroid-binding globulin is lost in the urine and total circulating thyroxine reduced, but again free thyroxine and thyroid-stimulating hormone are normal, and there are no clinical alterations in thyroid status. Occasional patients have been described with copper, iron, or zinc deficiency caused by the loss of binding proteins in the urine.

Drug binding may be altered by the decrease in serum albumin. Although most drugs do not require dose modifications, one important exception is clofibrate, which produces severe myopathy in nephrotic patients when administered at normal doses. Reduced protein binding also may reduce the dose of warfarin (Coumadin) required to achieve adequate anticoagulation or the dose of furosemide required to achieve adequate fluid loss (see later discussion).

Infection

Nephrotic patients are prone to bacterial infection. Before corticosteroids were shown to be effective in childhood nephrotic syndrome, sepsis was the most common cause of death and remains a major problem in the developing world. Primary peritonitis, especially that caused by pneumococci, is particularly characteristic of nephrotic children. It is less common with increasing age; by 20 years most adults have antibodies against pneumococcal capsular antigens. Peritonitis caused by both β-hemolytic streptococci and gram-negative organisms occurs, but staphylococcal peritonitis is not reported. Cellulitis, especially in areas of severe edema, is also common, most frequently caused by β-hemolytic streptococci.

The increased risk for infection has several explanations. Large fluid collections are sites for bacteria to grow easily; nephrotic skin is fragile, creating sites of entry; and edema may dilute local humoral immune factors. Loss of IgG and complement factor B (of the alternative pathway) in the urine impairs host ability to eliminate encapsulated organisms such as pneumococci. Zinc and transferrin are lost in the urine, and both are required for normal lymphocyte function. Neutrophil phagocytic function is impaired in patients with nephrotic syndrome, and several forms of in vitro T cell dysfunction are described, although their clinical significance is unclear.

Acute and Chronic Changes in Renal Function

Acute Kidney Injury

Patients with nephrotic syndrome are at risk for the development of AKI,[17] through a variety of mechanisms (Box 15.1). These include volume depletion or sepsis, resulting in either pre-renal AKI or acute tubular necrosis[18]; transformation of the underlying disease, such as development of crescentic nephritis in a patient with membranous nephropathy; development of bilateral renal vein thrombosis; increased disposition to pre-renal AKI from NSAIDs and ACE inhibitors or ARBs; and increased risk for allergic interstitial nephritis secondary to drugs, including diuretics. In addition, in very rare cases, AKI may result from intrarenal edema with compression of tubules and, as with nephrotic patients with pre-renal azotemia, may respond with diuresis to albumin infusions combined with a loop diuretic.

Chronic Kidney Disease

With the exception of MCD, most causes of nephrotic syndrome are associated with some risk for the development of progressive renal failure. In this regard, one of the greatest risk factors for progression is the degree of proteinuria (see Chapter 79). Progression is uncommon if there is sustained proteinuria of less than 2 g/day. The risk increases in proportion to the severity of the proteinuria, with marked risk for progression when protein excretion is more than 5 g/day (Fig. 15.13). Proteinuria identifies patients with severe glomerular injury; however, experimental and clinical evidence also suggests that proteinuria itself may be toxic, especially to the tubulointerstitium.[19] In experimental models, measures that reduce proteinuria (e.g., ACE inhibitors) also prevent tubulointerstitial disease and progressive renal failure.

NEPHRITIC SYNDROME

In *nephrotic* syndrome, the glomerular injury is manifested primarily as an increase in permeability of the capillary wall to protein. By contrast, in *nephritic* syndrome, there is evidence of glomerular inflammation resulting in a reduction in GFR, non-nephrotic proteinuria, edema and hypertension (secondary to sodium retention), and hematuria with RBC casts.

The classic nephritic syndrome presentation is seen with acute post-streptococcal GN in children, but this complication has become rare.

TABLE 15.4 Differentiation Between Nephrotic Syndrome and Nephritic Syndrome

Typical Features	Nephrotic	Nephritic
Onset	Insidious	Abrupt
Edema	++++	++
Blood pressure	Normal	Raised
Jugular venous pressure	Normal/low	Raised
Proteinuria	++++	++
Hematuria	May/may not occur	+++
Red blood cell casts	Absent	Present
Serum albumin	Low	Normal/slightly reduced

Proteinuria and Prognosis in Glomerular Disease

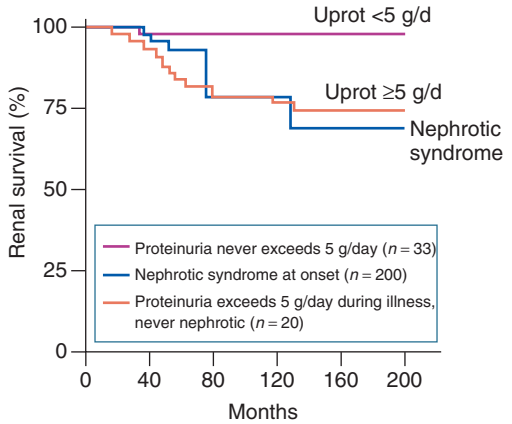

Fig. 15.13 Proteinuria and prognosis in glomerular disease. The influence of heavy proteinuria on long-term renal function in 253 patients with primary glomerular disease at Manchester Royal Infirmary, United Kingdom. Heavy proteinuria at any time during long-term follow-up substantially worsens the prognosis even without frank nephrotic syndrome. (Courtesy Dr. C. D. Short.)

These children usually present with rapid onset of oliguria, weight gain, and generalized edema over a few days. The hematuria results in brown rather than red urine, and clots are not seen. The urine contains protein, RBCs, and RBC casts. Because proteinuria is rarely in the nephrotic range, serum albumin concentration is usually normal. Circulating volume increases with hypertension, and pulmonary edema follows without evidence of primary cardiac disease.

The distinction between typical nephrotic syndrome and nephritic syndrome is usually straightforward on clinical and laboratory grounds (Table 15.4). The use of these clinical descriptions for patients with suspected GN at first presentation helps narrow the differential diagnosis. However, the classification systems are imperfect, and patients with certain glomerular disease patterns, such as membranoproliferative GN, may present with nephrotic syndrome, nephritic syndrome, or a combination of both syndromes.

Etiology

Table 15.5 lists the primary glomerular diseases associated with nephritic syndrome and the serologic tests helpful in diagnosis. The classification is even more challenging than for nephrotic syndrome, because some diseases are identified by histology (IgA nephropathy), others by serology and histology (ANCA-associated vasculitis and lupus nephritis), and others by etiology (postinfectious GN).

TABLE 15.5 Common Glomerular Diseases Presenting As Nephritic Syndrome

Disease	Associations	Serologic Tests
Poststreptococcal glomerulonephritis	Pharyngitis, impetigo	Antistreptolysin titer, streptozyme antibody
Other postinfectious disease		
Endocarditis	Cardiac murmur	Blood cultures, C3 ↓
Abscess	—	Blood cultures, C3, C4 normal or increased
Shunt	Treated hydrocephalus	Blood cultures, C3 ↓
IgA nephropathy	Upper respiratory or gastrointestinal infection	Serum IgA ↑
Lupus nephritis	Other multisystem features of lupus	Antinuclear antibody, anti–double-stranded DNA antibody, C3 ↓, C4 ↓

RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

Rapidly progressive glomerulonephritis (RPGN) describes the clinical situation in which glomerular injury is so acute and severe that renal function deteriorates markedly over days or weeks. The patient may present as a uremic emergency, with nephritic syndrome that is not self-limited but moves on rapidly to renal failure, or with rapidly deteriorating renal function when being investigated for extrarenal disease (many of the patterns of GN associated with RPGN occur as part of a systemic immune illness).

The histologic counterpart of RPGN is crescentic GN. The proliferative cellular response seen outside the glomerular tuft but within Bowman space is known as a "crescent" because of its shape on histologic cross section (see Fig. 16.8). Typically, the glomerular tuft also shows segmental necrosis or focal segmental necrotizing GN; this is particularly characteristic of the vasculitis syndromes.

The term *rapidly progressive* GN is therefore often used to describe acute deterioration in renal function in association with a crescentic nephritis. Unfortunately, not all patients with a nephritic urine sediment and AKI will fit this syndrome. For example, AKI may also occur in milder glomerular disease if it is complicated by accelerated hypertension, renal vein thrombosis, or acute tubular necrosis. This emphasizes the need to obtain histologic confirmation of the clinical diagnosis.

ETIOLOGY

Table 15.6 shows the primary glomerular diseases associated with RPGN and helpful serologic tests. As with nephritic syndrome, different assessment methods are useful for different diseases causing RPGN.

PROGRESSIVE CHRONIC KIDNEY DISEASE

In most types of chronic GN, a proportion of patients (often between 25% and 50%) will have slowly progressive renal impairment. If no

TABLE 15.6 Glomerular Diseases Presenting as Rapidly Progressive Glomerulonephritis

Disease	Associations	Serologic Tests
Goodpasture Syndrome		
	Lung hemorrhage	Anti–glomerular basement membrane antibody (occasionally antineutrophil cytoplasmic antibody [ANCA] present)
Vasculitis		
Granulomatosis with polyangiitis (Wegener granulomatosis)	Upper and lower respiratory tract involvement	Cytoplasmic ANCA
Microscopic polyangiitis	Multisystem involvement	Perinuclear ANCA
Pauci-immune crescentic glomerulonephritis	Renal involvement only	Perinuclear ANCA
Immune Complex Disease		
Systemic lupus erythematosus	Other multisystem features of lupus	Antinuclear antibody, anti–double-stranded DNA antibody, C3 ↓, C4 ↓
Poststreptococcal glomerulonephritis	Pharyngitis, impetigo	Antistreptolysin titer, streptozyme antibody C3 ↓, C4 normal
IgA nephropathy; IgA vasculitis (Henoch-Schönlein purpura [HSP])	Characteristic rash ± abdominal pain in HSP	Serum IgA ↑ (30%) C3 and C4 normal
Endocarditis		
	Cardiac murmur; other systemic features of bacteremia	Blood cultures ANCA (occasionally) C3 ↓, C4 normal

Note the overlap between these diseases and those in Table 15.5. A number of glomerular diseases may present with either nephritic syndrome or RPGN.

clinical event early in the course of the disease brings them to medical attention, patients may present late with established hypertension, proteinuria, and renal impairment. In long-standing GN, the kidneys shrink but remain smooth and symmetric. Renal biopsy at this stage is more hazardous and less likely to provide diagnostic material. Light microscopy often shows nonspecific features of end-stage renal disease (ESRD), consisting of focal or global glomerulosclerosis and dense tubulointerstitial fibrosis, and it may not be possible to define with confidence that a glomerular disease was the initiating renal injury, let alone define the glomerular pattern more precisely. Immunofluorescence may be more helpful; in particular, mesangial IgA may be present in adequate amounts to allow a diagnosis of IgA nephropathy to be made. However, when renal imaging shows small kidneys, only rarely will biopsy be appropriate. For this reason, chronic GN often has been a presumptive diagnosis in patients presenting late with shrunken kidneys, proteinuria, and renal impairment. This is imprecise and has led to an overestimate of the frequency of GN as a cause of ESRD in registry data. GN should be diagnosed only if there is confirmatory histologic evidence.

TREATMENT OF GLOMERULAR DISEASE

General Principles

Before any therapeutic decisions, it should always be ascertained that glomerular disease is *primary* and that no specific therapy is available. For example, treatment of an underlying infection or tumor may result in remission of GN. In the remaining cases, both general supportive treatment (see Chapter 79) and disease-specific therapy should be considered. Supportive treatment includes measures to treat blood pressure, reduce proteinuria, control edema, and address other metabolic consequences of nephrotic syndrome. If successful, these relatively nontoxic therapies can prevent the need for immunosuppressive drugs, which have multiple potential side effects. Supportive therapy is usually not necessary in corticosteroid-sensitive MCD with rapid remission or in patients with IgA nephropathy, Alport syndrome, or thin basement membrane nephropathy, provided the patient exhibits no proteinuria above 0.5 g/day, loss of GFR, or hypertension.

Hypertension

Hypertension is very common in GN; it is virtually universal as chronic GN progresses toward ESRD and is the key modifiable factor in preserving renal function. Sodium and water overload is an important part of the pathogenetic process, and high-dose diuretics with moderate dietary sodium restriction are usually an essential part of the treatment. As in other chronic renal diseases, the aim of blood pressure control is not only to protect against the cardiovascular risks of hypertension, but also to delay progression of the renal disease. In the Modification of Diet in Renal Disease (MDRD) study, patients with proteinuria (>1 g/day) had a better outcome if their blood pressure was reduced to 125/75 mm Hg rather than to the previous standard of 140/90 mm Hg.[20,21] The recent Kidney Disease: Improving Global Outcomes (KDIGO) CKD guideline recommends a blood pressure target below 130/80 mm Hg in proteinuric patients,[22] but the recent SPRINT trial and some other studies suggest that a systolic blood pressure target in the 120s may be more effective in some populations (see Chapters 36 and 79). There are strong theoretical and experimental reasons for ACE inhibitors and ARBs to be first-choice therapy, and this is now well documented in clinical studies.[23-25] Nondihydropyridine calcium channel blockers may also have a beneficial effect on proteinuria as well as on blood pressure. In contrast, dihydropyridine calcium channel blockers may exacerbate proteinuria because of their ability to dilate the afferent arteriole, but these agents are considered relatively safe to use if the patient is receiving either an ACE inhibitor or an ARB. As in primary hypertension, lifestyle modification (salt restriction, weight normalization, regular exercise, and smoking cessation) should be an integral part of the therapy.[22] If target blood pressure cannot be achieved with these measures, antihypertensive therapy should be stepped up according to current guidelines (see Chapter 36).

Treatment of Proteinuria

Besides hypertension, proteinuria represents the second key modifiable factor to preserve GFR in patients with glomerular disease (see Chapters 79 and 80). Most studies suggest that the progressive loss of renal function observed in many glomerular diseases can largely be prevented if proteinuria can be reduced to levels below 0.5 g/d. This may be because many of the measures to reduce protein excretion (e.g., ACE inhibitors, ARBs) also reduce glomerular hypertension, which contributes to progressive renal failure. However, there is also increasing evidence that

proteinuria or factors present in proteinuric urine may be toxic to the tubulointerstitium.[19] In nephrotic patients, a reduction of proteinuria to a non-nephrotic range can induce serum proteins to rise, with alleviation of many of the metabolic complications of nephrotic syndrome.

Most of the agents used to reduce urinary protein excretion do so hemodynamically, by either blocking efferent arteriolar constriction (ACE inhibitors or ARBs) or reducing preglomerular pressure (most other classes of antihypertensive drugs). As mentioned, dihydropyridine calcium antagonists are the exception because they preferentially dilate the afferent arteriole and thereby can increase intraglomerular pressure and thus exacerbate proteinuria. Some of the agents, such as ACE inhibitors and ARBs, also may directly reduce the increased glomerular capillary wall permeability. A consequence of this type of therapy is a reduction in GFR; in general, however, the decrease in GFR is of a lower magnitude than the decrease in protein excretion. The antiproteinuric agents of choice are ACE inhibitors and ARBs, which reduce proteinuria by an average of 40% to 50%, particularly if the patient is on dietary salt restriction. There is little clinical evidence to suggest that ACE inhibitors differ from ARBs in this respect. The combination of ACE inhibitors and ARBs increases the risk for AKI when used in older people with vascular disease and diabetes.[26] Similar concerns relate to the combination of ACE inhibitor or ARB with a direct renin inhibitor.[27] However, the combination of ACE inhibitors and ARBs has additive antiproteinuric effect with low risk in younger patients with glomerular proteinuria.[28]

In addition, whereas other classes of antihypertensive agents will reduce proteinuria coincident with a decrease in systemic blood pressure, particularly the nondihydropyridine calcium channel blockers such as diltiazem, both ACE inhibitors and ARBs usually reduce proteinuria independent of blood pressure. If doses are increased slowly to minimize symptomatic hypotension, treatment with ACE inhibitors and ARBs is usually possible in the normotensive proteinuric patient. Common side effects include hyperkalemia in patients with advanced CKD, which may necessitate a loop diuretic but rarely should lead to cessation of ACE inhibitors and ARBs, and cough with ACE inhibitors, in which case ARBs should be used instead. Because both agents lower GFR, a 10% to 30% increase in serum creatinine concentration may be observed. Unless serum creatinine continues to increase, this moderate increase reflects the therapeutic effect of ACE inhibitors and ARBs and should not prompt their withdrawal. Finally, if proteinuria persists despite maximum allowed or tolerated doses of ACE inhibitors or ARBs, a low dose of an aldosterone antagonist may overcome so-called aldosterone breakthrough and further reduce proteinuria (see Chapter 79). Hyperkalemia is an important safety aspect, similar to the ACE inhibitor and ARB combination mentioned earlier.

The NSAIDs lessen proteinuria by reducing intrarenal prostaglandin production and dipyridamole through adenosine-mediated afferent arteriolar vasoconstriction. Given the safety of the therapies discussed previously, as well as the risk for profound decreases in GFR, salt retention, and diuretic resistance with NSAIDs, these are generally contraindicated despite their potential benefit on proteinuria.

A low-protein diet will lessen proteinuria but must be advised with great care because of the risk for malnutrition.[22] Adequate compensation must be made for urine protein losses,[29] and the patient must be carefully monitored for evidence of malnutrition (see Chapter 86). Whether a low-protein diet is still antiproteinuric in patients treated with a full dose of ACE inhibitor or ARB is not established.

Treatment of Hyperlipidemia

Treatment of hyperlipidemia (or hypercholesterolemia) in patients with glomerular disease should usually follow the guidelines that apply to the general population to prevent cardiovascular disease. A statin or statin/ezetimibe combination is recommended in adults older than 50 with CKD stage 3 to 5. Statins alone are also recommended in adults over 50 with earlier-stage CKD. In younger adults, statins should be considered if the patient has significant comorbidity (coronary disease, diabetes mellitus, stroke) (see Chapter 81). Statin therapy may protect from a decrease in GFR, although this is not firmly established. Dietary restriction alone has only modest effects on hyperlipidemia in glomerular disease, particularly nephrotic syndrome. Side effects of some medications, such as rhabdomyolysis provoked by fibrates, occur more frequently in patients with renal failure. The addition of a bile acid sequestrant such as cholestyramine may lower LDL further and increase high-density lipoprotein, but it is usually not tolerated because of GI effects.

Avoidance of Nephrotoxic Substances

Apart from NSAIDs, which may induce AKI, particularly in patients with preexisting renal impairment and dehydration, other nephrotoxic substances, such as radiocontrast agents, some cytotoxic drugs, and antibiotics (e.g., aminoglycosides), also should be used with caution in patients with glomerular disease and renal impairment or nephrotic syndrome. There is also increasing concern that proton pump inhibitors may be associated with increased risk for both acute interstitial nephritis and CKD, and thus their use should be restricted to documented indications when histamine-2 blockers are not effective.

Special Therapeutic Issues in Patients With Nephrotic Syndrome

Treatment of Nephrotic Edema

In contrast to the lack of therapies in the past (Fig. 15.14), the mainstay of current treatment of nephrotic edema is diuretic therapy accompanied by moderate dietary sodium restriction (60 to 80 mmol/24 h). Nephrotic patients are diuretic resistant even if GFR is normal. Loop diuretics must reach the renal tubule to be effective, and transport from the peritubular capillary requires protein binding, which is reduced in hypoalbuminemia. When the drug reaches the renal tubule, it will become 70% bound to protein present in the urine and therefore be less effective. Oral diuretics with twice-daily administration are usually preferred, given the longer therapeutic effect compared with intravenous diuretics.

Fig. 15.14 Treatment of nephrotic edema before the availability of diuretics. Edema in nephrotic syndrome was very difficult to treat. In 1953, this child with anasarca stands in a bowl while edema fluid drips out through small tubes placed through needles in the skin of the feet. Nevertheless, this was effective treatment. The two pictures of the same child were taken 4 days apart, during which time the child lost 4.5 kg (10 lb), or 18% of body weight. (Courtesy Dr. Robert Vernier.)

However, in severe nephrosis, GI absorption of the diuretic may be uncertain because of intestinal wall edema, and intravenous diuretic by bolus injection or infusion may be necessary to provoke an effective diuresis. Alternatively, combining a loop diuretic with a thiazide diuretic or with metolazone may overcome diuretic resistance (see Chapter 7). A third alternative is adding amiloride to loop diuretics because nephrotic syndrome is associated with activation of the ENAC channel. Significant hypovolemia is not often a clinical problem, provided fluid removal is controlled and gradual. Daily weight is the best measurement of progress; ideally it should decrease by no more than 1 to 2 kg/day. Nephrotic children are much more prone to hypovolemic shock than adults. A stepwise approach to diuretic use is required, aiming at fluid removal in adults of no more than 2 kg daily, moving on to the next drug level if this is not achieved (Fig. 15.15).

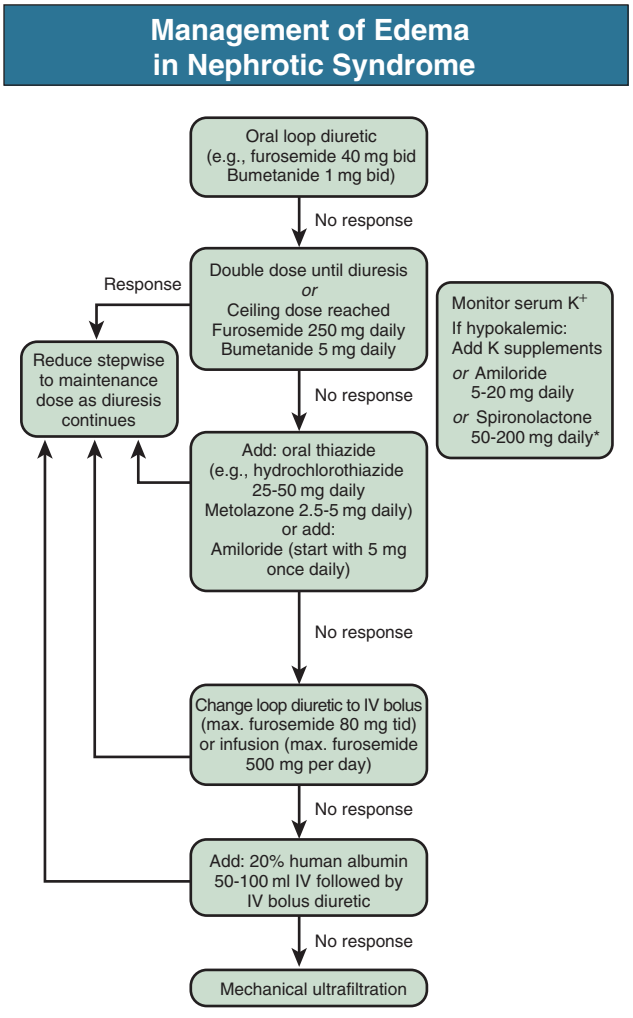

Fig. 15.15 Management of edema in the patient with nephrotic syndrome. Edema is often diuretic resistant, but the response is not predictable. Therefore stepwise escalation of therapy is appropriate until diuresis occurs. Even when there is anasarca, diuresis should not proceed faster than 2 kg/day in adults to minimize the risk for clinically significant hypovolemia. Mechanical ultrafiltration is rarely required for nephrotic edema unless there is associated renal impairment. *Spironolactone is less effective in nephrotic syndrome than in cirrhosis and is often poorly tolerated because of gastrointestinal side effects. Spironolactone should be used with great caution if the glomerular filtration rate is very low. *bid,* Twice daily.

Correction of Hypoproteinemia

In view of the problems associated with either increased protein administration or dietary protein restriction in nephrotic patients, adequate dietary protein should be ensured (0.8 to 1 g/kg/day) with a high carbohydrate intake to maximize use of that protein. In patients with heavy proteinuria, the amount of urinary protein loss should be added to dietary protein intake.

In the rare setting of proteinuria so severe that the patient is dying of the complications of nephrotic syndrome, the physician may need to resort to nephrectomy to prevent continued protein losses. This may be done as a *medical* nephrectomy: the deliberate use of NSAIDs combined with ACE inhibitors and diuretic to lessen proteinuria by provoking AKI. If medical nephrectomy alone does not adequately reduce proteinuria, bilateral renal artery embolization can be considered. It is a painful procedure and is not always as successful as might be expected (perhaps because of collateral arterial supply to the kidneys, which is not blocked by embolization). A final alternative is bilateral nephrectomy, which is increasingly being performed by laparoscopic surgery with reduced morbidity compared to classical surgical removal. Bilateral nephrectomy is commonly used in the management of infants with congenital nephrotic syndrome.

Treatment of Hypercoagulability

The risk for thrombotic events becomes progressively more important as serum albumin values decrease to less than 2.5 g/dl. Immobility as a consequence of edema or intercurrent illness further aggravates the risk. Prophylactic low-dose anticoagulation (e.g., heparin 5000 U subcutaneously twice daily) is indicated at times of high risk, such as relative immobilization in the hospital and albumin levels between 2 and 2.5 g/dl. Full-dose anticoagulation with low-molecular-weight heparin or warfarin should be considered if serum albumin decreases to less than 2 g/dl,[13,30] and this is mandatory if a thrombosis or pulmonary embolism is documented. Heparin is used for initial anticoagulation, but an increased dose may be needed because part of the action of heparin depends on circulating antithrombin III, which is often reduced in nephrotic patients. Warfarin (target international normalized ratio [INR] 2 to 3) is the long-term treatment of choice but should be adjusted with special care because of altered protein binding, which may require dose reductions. Newer oral anticoagulants have not been systematically tested so far in this situation.

Management of Infection

A high degree of clinical suspicion for infection is vital in nephrotic patients. Especially in nephrotic children, ascitic fluid should be examined microscopically and cultured if there is any suspicion of systemic infection. Bacteremia is common even if clinical signs are localized. ESR is unhelpful, but an elevated C-reactive protein level may be informative. Parenteral antibiotics should be started once culture specimens are taken, and the regimen should include coverage for pneumococci. If repeated infections occur, serum immunoglobulins should be measured. If serum IgG is less than 600 mg/dl, evidence in an uncontrolled study showed that infection risk is reduced by monthly administration of intravenous immune globulin (10 to 15 g) to keep the IgG levels above 600 mg/dl.[31]

Disease-Specific Therapies

Specific treatments for glomerular diseases are discussed in the subsequent chapters; the general principles are discussed here. Because most glomerular disease is thought to have an immune pathogenesis, treatment has generally consisted of immunosuppressive therapy aimed at blocking both the systemic and local effects. In the patient

with glomerular disease resulting from ineffectual elimination of a foreign antigen, treatment involves measures to eliminate this antigen whenever possible, such as antibiotics in endocarditis-associated GN or antiviral therapy for cryoglobulinemia resulting from hepatitis C infection.

In general, the more severe and acute the presentation of GN, the more successful is immunosuppressive treatment. Immunosuppression in several patterns of chronic GN has had minimal success. When renal function is declining rapidly, as in RPGN, the toxicity of intensive regimens becomes acceptable for a short period, although it would be unacceptable if prolonged. Furthermore, the nonspecific nature of most immunosuppressive treatments results in widespread interruption of immune and inflammatory events at multiple levels. In the acute situation, this broad-based attack is a virtue; in more indolent disease, more specific treatment is needed but is largely unavailable. Despite great increases in the understanding of immune mechanisms in glomerular disease since the 1970s, most immunosuppressive therapies are not yet much more specific or precise. The mainstays of treatment remain agents that were available in the 1960s—corticosteroids, azathioprine, and cyclophosphamide. Other, newer immunosuppressive agents developed for use in transplantation, including cyclosporine, tacrolimus, and mycophenolate mofetil, or those developed in oncology, including rituximab, have emerging indications in glomerular disease. Novel agents, including some that modify inflammation (e.g., spleen tyrosine kinase inhibitors) or B cell immunity (e.g., inhibitors of B cell activation factor), are now being studied in clinical trials in glomerular disease, but as yet have no proven indications.

The use of immunosuppressive therapies to treat patients with GN has certain drawbacks. In many diseases, treatment is based on small series, and good prospective controlled trials are often lacking. Because of both the rarity and the variable natural history of GN, proof of efficacy for a particular therapy often requires a multicenter approach with prolonged follow-up, which is logistically difficult. If sufficient glomerular damage is present, proteinuria and progressive deterioration of renal function may occur by nonimmune pathways that may not be responsive to immunosuppressive therapies. This is particularly relevant in patients in whom the GN has already resulted in advanced CKD. Unfortunately, good noninvasive markers to assess disease activity are missing in most clinical circumstances. Given the frequent uncertainty of the response to immunosuppressive therapy, it becomes mandatory to weigh the potential benefits against the risks of therapy.

Immunosuppression may be associated with reactivation of tuberculosis and hepatitis B infection and also can lead to a hyperinfection syndrome in patients with *Strongyloides* infection. Therefore high-risk patients should be tested for these diseases before embarking on therapy.

Alkylating agents such as cyclophosphamide and chlorambucil have considerable toxicity. In the short term, leukopenia is common, as is alopecia, although hair will regrow within a few months with discontinuation of therapy. These agents can cause infertility (observed in adults with cumulative doses of cyclophosphamide >200 mg/kg and chlorambucil 10 mg/kg). There is also an increased incidence of leukemias (observed with total doses of cyclophosphamide >80 g and chlorambucil 7 g). Cyclophosphamide is also a bladder irritant, and treatment can result in hemorrhagic cystitis and bladder carcinoma, particularly after therapy lasting more than 6 months.[32] Irritation of the bladder is caused by a metabolite, acrolein. The effect can be minimized in patients receiving intravenous cyclophosphamide by enforcing a good diuresis and administering mesna. The dose of mesna (milligrams) should equal the dose of cyclophosphamide (milligrams); 20% is given intravenously with the intravenous cyclophosphamide, and the remaining 80% should be given in two equal oral doses at 2 and 6 hours. Chlorambucil and cyclophosphamide also require dose reduction in the setting of renal impairment. Given all these concerns, oral treatment with these agents should ideally be limited to 12 weeks.

The modes of action and potential adverse effects of corticosteroids, azathioprine, and other immunosuppressive agents occasionally used in glomerular disease are discussed further in Chapter 101.

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements regarding proteinuria is correct?
   - **A.** Tubular proteinuria is characterized by equal amounts of α_1-microglobulin and immunoglobulins.
   - **B.** Proteinuria exceeding 3.5 g/day (i.e., "nephrotic" proteinuria) inevitably results in hypoalbuminemia.
   - **C.** In orthostatic proteinuria, urinary protein is typically increased with the patient lying down.
   - **D.** Overflow proteinuria is typical of urinary light chain excretion.
   - **E.** Functional proteinuria typically occurs after heavy meals with high protein intake.
2. Which of the following statements regarding general treatment of glomerular disease is *incorrect*?
   - **A.** The KDIGO chronic kidney disease (CKD) guideline recommends a blood pressure target below 130/80 mm Hg in proteinuric patients.
   - **B.** Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) may directly reduce the increased glomerular capillary wall permeability.
   - **C.** Common side effects of ACE inhibitors and ARBs in patients with advanced CKD include hyperkalemia, which may necessitate a loop diuretic.
   - **D.** Statin or a statin-ezetimibe combination is recommended in all adults younger than 50 years with CKD.
   - **E.** A low-protein diet will lessen proteinuria but must be advised with great care because of the risk of malnutrition.
3. Which statement regarding the treatment of nephrotic syndrome is correct?
   - **A.** Nephrotic patients are diuretic resistant only if GFR is greatly impaired.
   - **B.** Patients with heavy proteinuria should be advised to consume a high-protein diet of about 2 to 3 g/kg/d.
   - **C.** Full-dose anticoagulation with low-molecular-weight heparin or warfarin should be considered if serum albumin decreases to less than 2 g/dl.
   - **D.** Ascitic fluid should be examined regularly by microscopy and culture independently of a suspicion of systemic infection.
   - **E.** Nephrotic children are no more prone to hypovolemic shock than adults.

Introduction to Glomerular Disease: Histologic Classification and Pathogenesis

John Feehally, Jürgen Floege

HISTOLOGIC CLASSIFICATION

Glomerular disease may have a wide variety of etiologies and clinical presentations (see Chapter 15). Some glomerular diseases are given the generic title of glomerulonephritis (GN), which implies an immune or inflammatory pathogenesis. Although a specific diagnosis can be made in some patients based on clinical presentation and laboratory tests, in most patients a renal biopsy is useful for both classification and prognosis. Ideally, the renal biopsy should be examined by light microscopy, immunohistology, and electron microscopy (EM). Using this approach, a histologic pattern can be diagnosed. Some histologic patterns can be coupled with other laboratory tests to identify a specific etiology, but in many cases the condition is idiopathic. However, because treatments are often developed for specific histologic patterns, this approach is currently favored in the management of most patients with glomerular disorders.

HISTOPATHOLOGY

The full assessment of a renal biopsy requires light microscopy, EM, and examination for deposits of complement and immunoglobulin by immunofluorescence (IF) or immunoperoxidase (IP) techniques.

Light Microscopy

In GN the dominant, but not the only, histologic lesions are in glomeruli (Fig. 16.1). GN is described as *focal* (only some glomeruli are involved) or *diffuse.* In any individual glomerulus, injury may be *segmental* (affecting only part of any glomerulus) or *global.* Sampling error is possible in a renal biopsy; the extent of a focal lesion may be misjudged in a small biopsy specimen, and sections through glomeruli may miss segmental lesions. Lesions also may be hypercellular because of an increase in endogenous endothelial or mesangial cells (termed *proliferative*) and an infiltration of inflammatory leukocytes (termed *exudative*). Severe acute inflammation may produce glomerular necrosis, which is often segmental. Multiple processes can cause thickening of the walls of the glomerular capillaries, including an increase in glomerular basement membrane (GBM) material and immune deposits. Segmental sclerosis and scarring may occur and are characterized by segmental capillary collapse with the accumulation of hyaline material and mesangial matrix and often with attachment of the capillary wall to the Bowman capsule (synechiae or adhesion formation).

The classic stains used in light microscopy include hematoxylin-eosin (HE) and the periodic acid–Schiff (PAS) reaction, which is particularly effective for evaluating cellularity and matrix expansion. More specific stains include methenamine silver, which stains GBM and other matrix black and may reveal a double contour to the GBM because of the interposition of cellular material or may show increased mesangial matrix not easily seen with other techniques. Trichrome staining is also useful to show areas of scarring (blue) and immune deposits (red).

Crescents are inflammatory collections of cells in Bowman space. Crescents develop when severe glomerular injury results in local rupture of the capillary wall or Bowman capsule, allowing plasma proteins and inflammatory material to enter into the Bowman space. Crescents consist of proliferating parietal and some visceral epithelial cells, infiltrating fibroblasts, and lymphocytes and monocytes/macrophages, often with local fibrin deposition. They are called "crescents" because of their appearance when the glomerulus is cut in one plane for histology. These cell collections are destructive, rapidly increase in size, and may lead to glomerular tuft occlusion (see Fig. 16.1). If the acute injury is stopped, the crescents may either resolve with restitution of normal morphology or heal by fibrosis, causing irreversible loss of renal function. Crescents are most frequently observed with vasculitis, in Goodpasture disease, and in severe acute GN of any cause.

Tubulointerstitial injury and fibrosis can accompany GN and usually are strongly correlated with prognosis (see Chapter 78).

Immunofluorescence and Immunoperoxidase Microscopy

Indirect immunofluorescence (IF) and immunoperoxidase (IP) staining are both used to identify immune reactants (Fig. 16.2). Examination consists of staining for immunoglobulins (IgG, IgA, and IgM), for components of the complement system (usually C3, C4, and C1q), and for the presence of fibrin, which is typically observed in crescents and in capillaries in thrombotic disorders such as hemolytic uremic syndrome (HUS) and the antiphospholipid syndrome. Immune deposits may occur along the capillary loops or in the mesangium. They may be continuous (linear) or discontinuous (granular) along the capillary wall or in the mesangium.

Electron Microscopy

Electron microscopy (EM) is valuable for defining the morphology of the basement membranes, which is abnormal in some forms of hereditary nephropathy (e.g., Alport syndrome and thin basement membrane nephropathy; see Chapter 46), and for identifying fibrils (e.g., in amyloidosis) or tubuloreticular intracellular structures (e.g., in lupus nephritis). EM is also useful for localizing the site of immune deposits, which are usually homogeneous and electron dense (Fig. 16.3). Electron-dense deposits are seen in the mesangium or along the capillary wall on the subepithelial or subendothelial side of the GBM. Infrequently, the electron-dense material follows a linear pattern within the GBM.

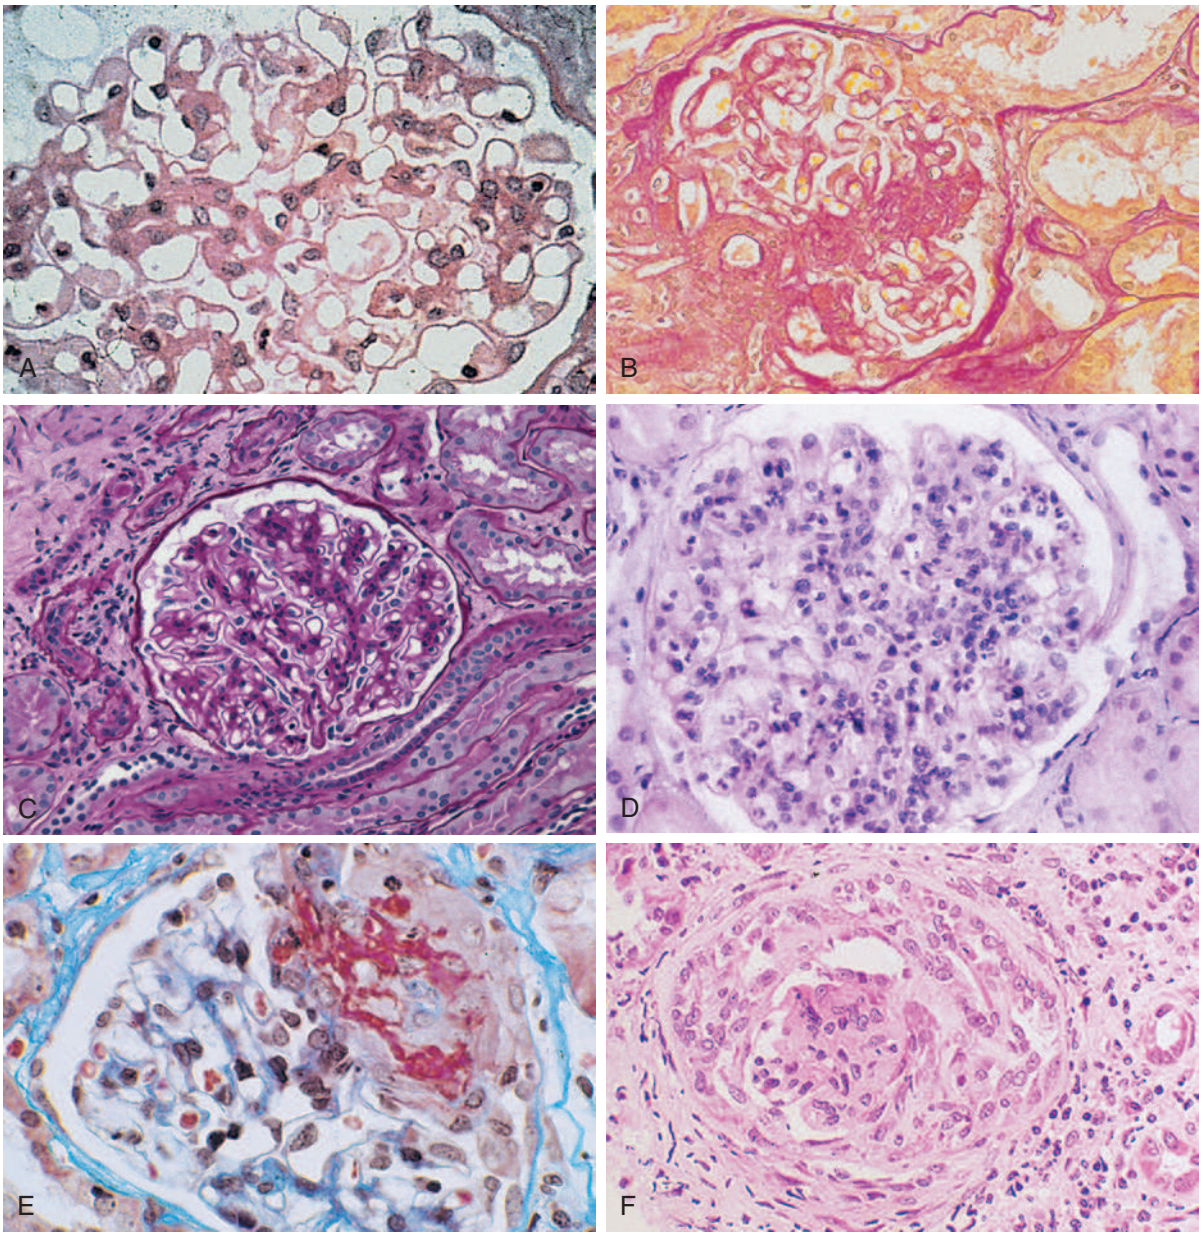

Fig. 16.1 Pathology of glomerular disease: light microscopy. Characteristic patterns of glomerular disease illustrating the range of histologic appearances and the descriptive terms used. (A) Normal glomerulus: Minimal change disease. (B) Segmental sclerosis: Focal segmental glomerulosclerosis. (C) Diffuse mesangial hypercellularity: IgA nephropathy. (D) Diffuse endocapillary hypercellularity: Poststreptococcal glomerulonephritis. (E) Segmental necrosis: Renal vasculitis. (F) Crescent formation: Anti–glomerular basement membrane disease. (A and B, Hematoxylin-eosin; C, D, and F, periodic acid–Schiff; E, trichrome.)

The sites of immune deposits are helpful in the classification of the types of GN.

GENERAL MECHANISMS OF GLOMERULAR INJURY

Proteinuria

Proteinuria, accompanied by variable degrees of hematuria, is the hallmark of glomerular disease. The endothelial glycocalyx and the GBM may repel proteins in part through their highly negative charge (proteins are mostly negatively charged as well) and prevent them from entering Bowman space. The key barrier for protein is the slit diaphragm between the podocyte foot processes[1,2] (Fig. 16.4). The slit diaphragm consists of several transmembrane proteins that extend from adjacent interdigitating foot processes to form a zipper-like scaffold on the outer side of the GBM (Fig. 19.2 and Chapter 1).

The importance of the slit diaphragm in proteinuric states has been documented in numerous hereditary types of nephrotic syndrome in which the mutations involve various slit diaphragm proteins (see Chapter 19). These diseases usually manifest as a type of steroid-resistant minimal change disease (MCD) or focal segmental glomerulosclerosis (FSGS). Whereas most recessive mutations of slit diaphragm or podocyte proteins manifest in childhood or even prenatally, dominant mutations tend to manifest in early adult life.[2] An exception is steroid-resistant autosomal recessive nephrotic syndrome, in which the homozygous mutation in

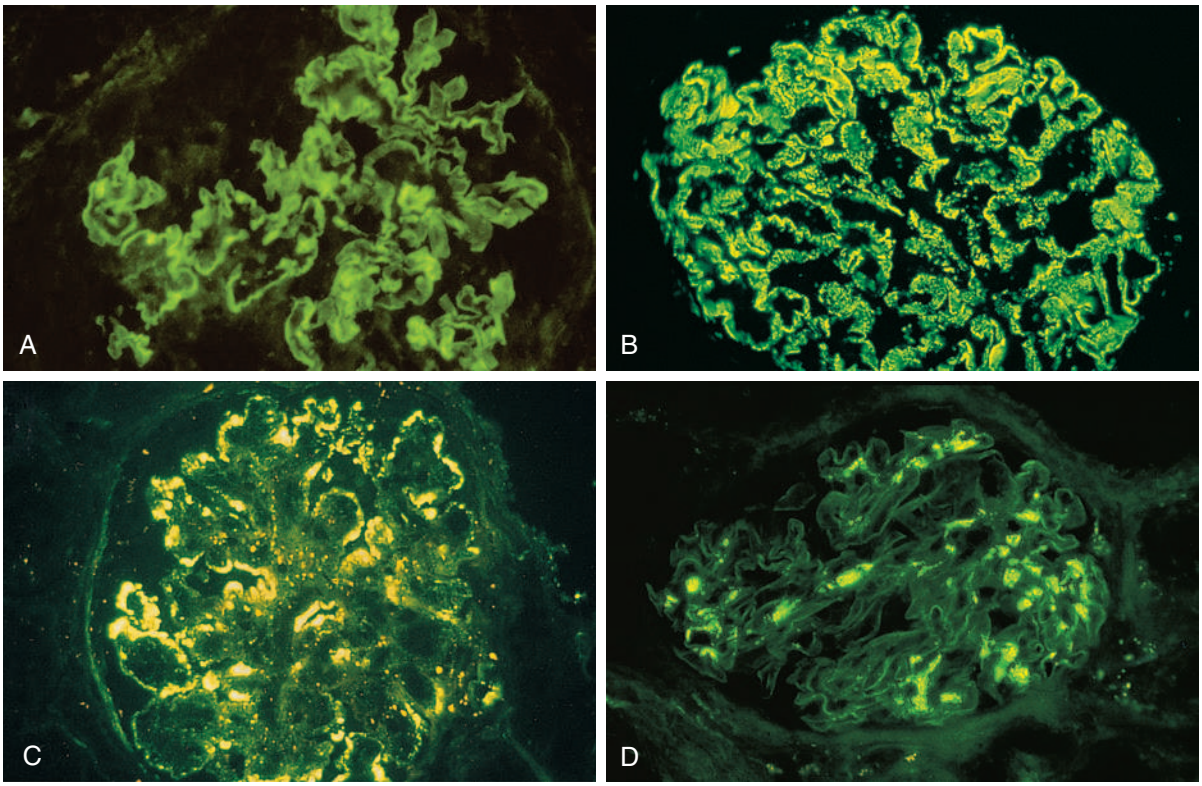

Fig. 16.2 Pathology of glomerular disease: immunofluorescence microscopy. Common patterns of glomerular staining found by immunofluorescence. (A) Linear capillary wall IgG: Anti–glomerular basement membrane disease. (B) Fine granular capillary wall IgG: Membranous nephropathy. (C) Coarse granular capillary wall IgG: Membranoproliferative glomerulonephritis type I. (D) Granular mesangial IgA: IgA nephropathy.

podocin *(NPHS2)* presents in childhood, but the heterozygous mutation, when it coexists with the p.R229Q variant polymorphism, may manifest clinically in young adulthood (age 20 to 35 years of age).[3]

Although it may result from injury or mutation of slit diaphragm proteins, proteinuria may be caused by nonspecific injury to the podocyte in many cases. When the podocyte is injured, it may undergo shape changes with swelling and loss or fusion of the foot processes. Filtration is reduced at sites where the foot processes fuse (possibly accounting for reduction of filtration coefficient K_f seen in nephrotic syndrome), but there are gaps where the podocytes are detached from the GBM. Massive protein filtration may occur at these sites; structurally, the capillary wall defects are likely to correspond to the large pores noted in functional studies[4] (Fig. 16.5). Podocyte immaturity also can result in nephrotic syndrome, perhaps from incomplete differentiation and slit diaphragm development. Congenital nephrotic syndrome with mesangial sclerosis has been linked with mutations in phospholipase C epsilon gene *(PLCE1),* which is important in podocyte development.[5]

In addition to podocyte damage, and in particular slit diaphragm defects, proteinuria also can result from changes in the glomerular endothelium, especially its glycocalyx, as well as from changes in the GBM and altered electrical forces across the GBM.

Severe albuminuria reflects a glomerular defect, but some albumin is normally filtered but then endocytosed and metabolized in the proximal tubule or is transcytosed intact through the tubular cell. Proximal tubular dysfunction can therefore result in albuminuria if endocytosis is impaired, although this is generally in the non-nephrotic range.

Antibody and Antigen

Many glomerular diseases are associated with deposition or glomerular trapping of immunoglobulins, often with components of the complement system, and with the presence of electron-dense deposits by EM. These findings likely represent immune complexes. Experimentally, immune complexes can localize in glomeruli by two major mechanisms. In some conditions, such as mesangial proliferative GN, membranoproliferative GN (MPGN), or lupus nephritis, the immune complexes are thought to originate in the circulation and to be passively trapped in the mesangium or subendothelial areas. However, circulating immune complexes cannot readily pass across the GBM. Therefore the presence of immunoglobulin G (IgG) on the subepithelial aspect of the basement membrane, such as occurs in membranous nephropathy, either results from the direct binding of podocyte antigens by antibody or represents binding of an antibody to an antigen that was temporarily "trapped" or bound at this site (in situ complex formation).[6] GN also may occur only with complement activation in the glomeruli in the absence of IgG, as occurs in dense deposit disease (DDD), in which ribbon-like deposits replace the basement membrane (see Chapter 22). Some antigens may deposit in glomeruli and directly activate the alternative pathway of complement in the absence of IgG, as may occur in poststreptococcal GN (PSGN). Immunoglobulin with aberrant characteristics may also aggregate in glomeruli and activate complement in the absence of antigen, as occurs in IgA nephropathy with aberrantly glycosylated IgA (see Chapter 23).[7]

Normally, immune complexes are removed from the circulation by binding of the complex to the C3b receptors on erythrocytes. The immune complexes are then removed and degraded during transit of the erythrocytes in the liver and spleen. If antigenemia persists or clearance of complexes is impaired (e.g., chronic liver disease), immune complexes may deposit in the glomerulus by binding to Fc receptors on mesangial cells or by passive deposition in the mesangium or subendothelial space. Physical characteristics of the complexes also may favor deposition, including avidity, charge, and size. However, quantification of circulating

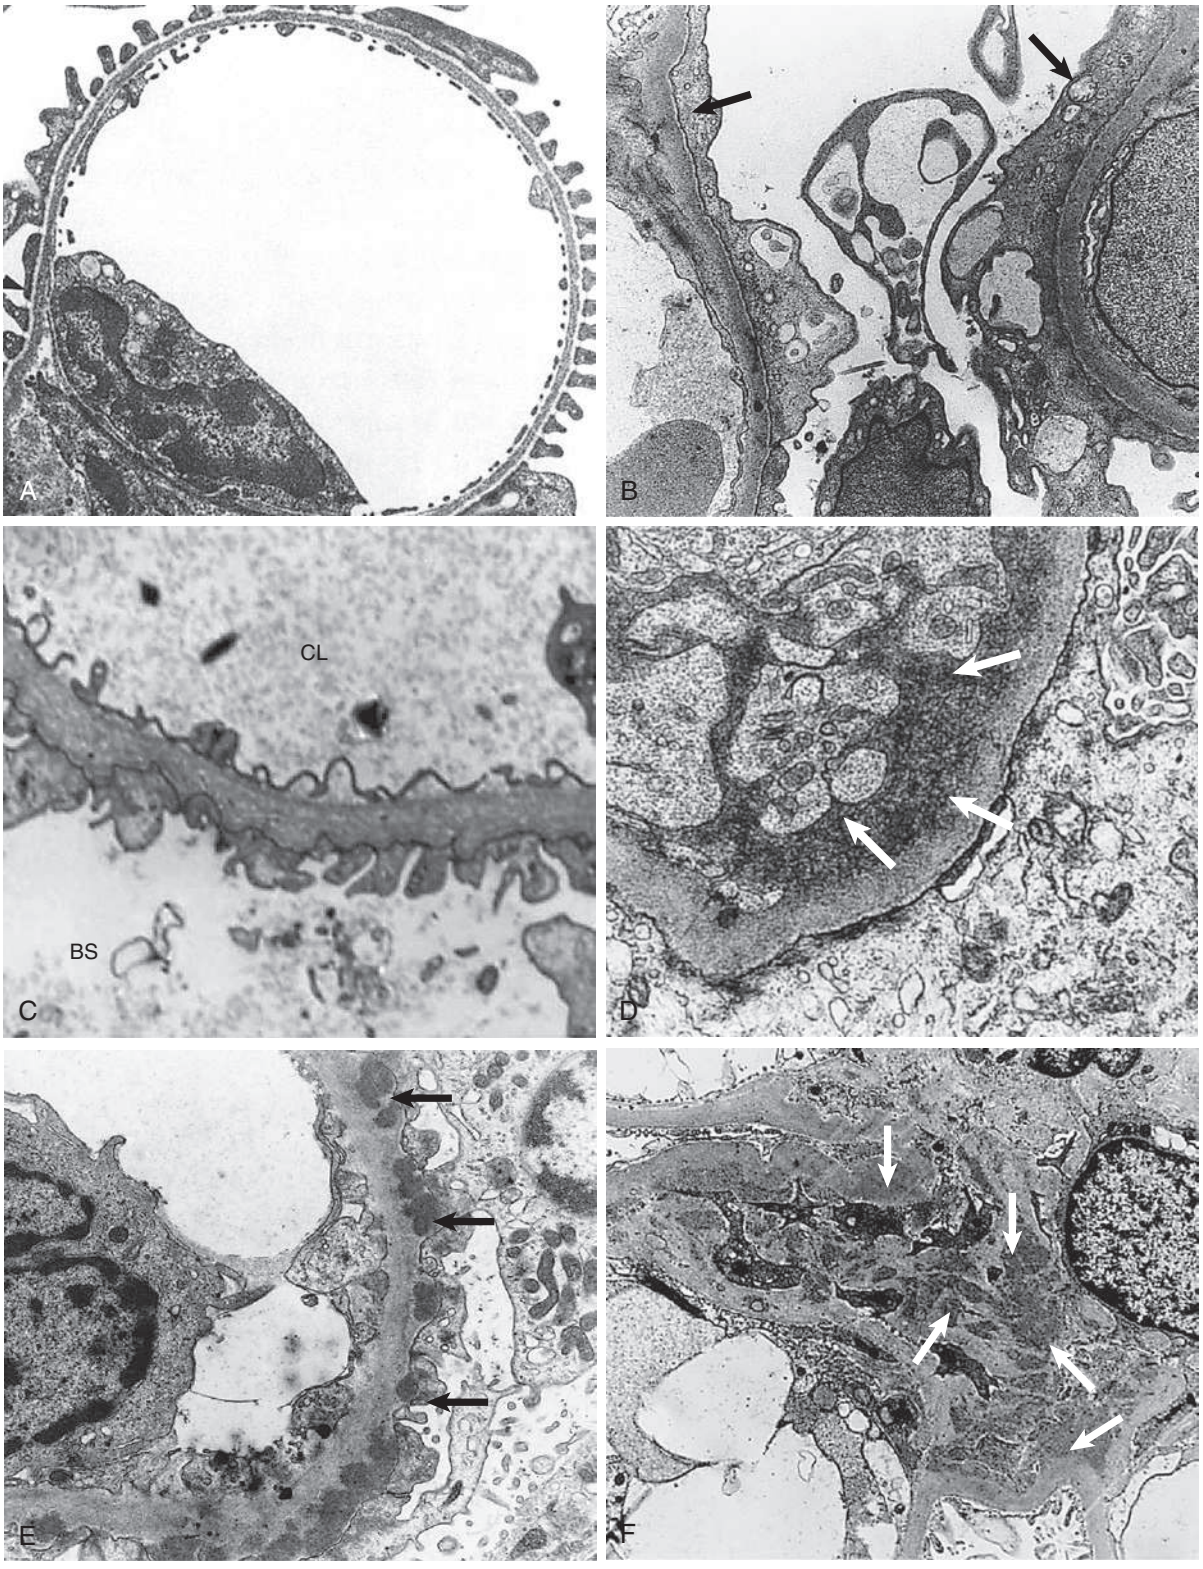

Fig. 16.3 Ultrastructural pathology of glomerular disease. Some characteristic patterns of electron-dense deposits and glomerular basement membrane (GBM) abnormalities seen in glomerular disease. (D) Subendothelial electron-dense deposits *(arrows):* Membranoproliferative glomerulonephritis type I. (E) Subepithelial electron-dense deposits *(arrows):* Membranous nephropathy. (F) Mesangial electron-dense deposits *(arrows):* IgA nephropathy.

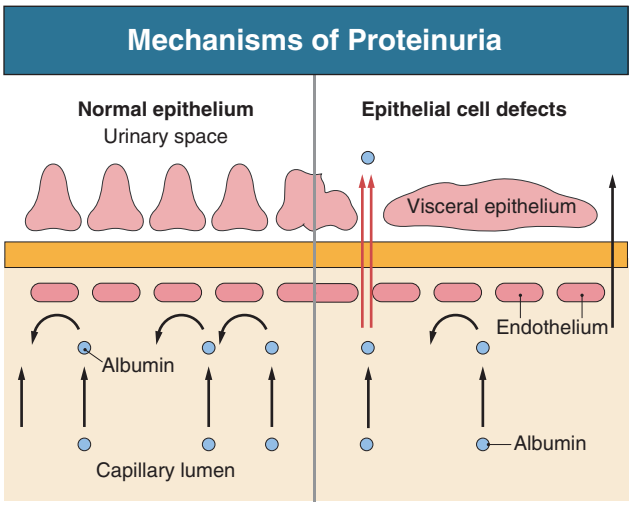

Fig. 16.4 Mechanisms of proteinuria. Normally, negatively charged proteins such as albumin *(blue circles)* are repelled by the negatively charged proteins in the endothelium (sialoglycoproteins) and basement membrane (heparan sulfate proteoglycans) as well as by a size barrier in the glomerular basement membrane (GBM) and at the slit diaphragm so that only small amounts of albumin pass into the urinary space. In most proteinuric states, the podocytes are injured, leading to foot process swelling and injury to the slit diaphragm; in these situations, large amounts of protein (albumin) can pass through the GBM and the gaps between the fused foot processes *(red arrows)*.

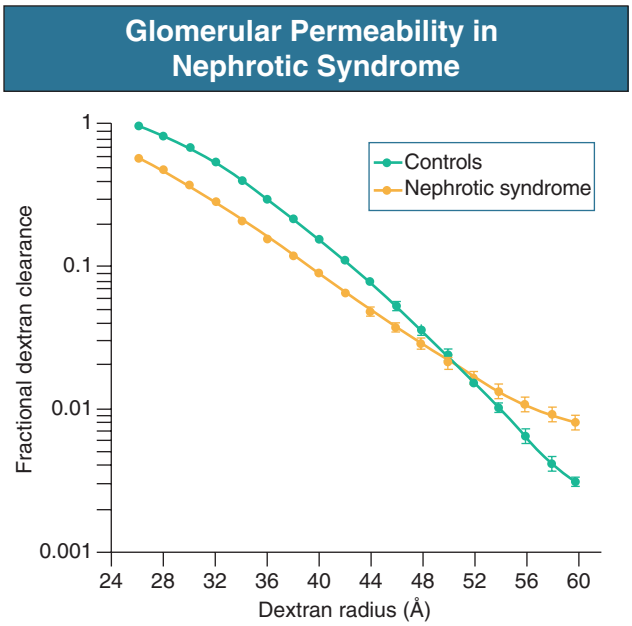

Fig. 16.5 Glomerular permeability in nephrotic syndrome. Dextran sieving curve shows the relative glomerular permeability of different-sized dextrans in normal individuals and nephrotic patients with membranous nephropathy and minimal change disease. Nephrotic patients actually have a lower fractional dextran clearance for small dextrans (26 to 48 Å [2.6 to 4.8 nm]) but have an increased clearance for dextrans of larger molecular weight (52 to 60 Å [5.2 to 6.0 nm]). This is consistent with large pores appearing in the glomerular basement membrane. (Modified from reference 4.)

TABLE 16.1 Antigens Identified in Glomerulonephritis

Disease	Antigens
Poststreptococcal glomerulonephritis (GN)	Streptococcal pyrogenic exotoxin B (SPEB), plasmin receptor
Anti-GBM disease	α3 Type IV collagen (likely induced by molecular mimicry)
IgA nephropathy	Possibly no antigen but rather polymerized polyclonal IgA (? superantigen driven)
Membranous nephropathy	Phospholipase A_2 receptor Thrombospondin type-1 domain-containing 7A Neutral endopeptidase in podocyte (congenital) HBeAg (hepatitis B virus associated)
Staphylococcus aureus–associated GN	*Staphylococcus* superantigens induce polyclonal response; not necessarily antigen in glomeruli
Membranoproliferative GN (MPGN)	HCV and HBsAg in hepatitis-associated MPGN

ANCA, Antineutrophil cytoplasmic autoantibody (antibody); *GBM,* glomerular basement membrane; *HBsAg,* hepatitis B surface antigen; *HCV,* hepatitis C virus; *IgA.*

immune complexes in patients with GN does not correlate reliably with glomerular events and thus is not typically measured.

In some glomerular diseases, the target antigen has been identified (Table 16.1). In other patients, glomerular disease develops as a result of infection with organisms that release superantigens that cause a polyclonal activation of B cells. The classic organism responsible for superantigen-associated GN is *Staphylococcus aureus,* and the pattern of immune deposits often includes the presence of both IgG and IgA. Some infections initiate an immune response that cross-reacts with endogenous antigens. This type of molecular mimicry may be responsible for Goodpasture disease and certain types of vasculitis[8] (see Table 16.1). Once an immune response is initiated, local injury may lead to the release of additional antigens that extend the immune response (epitope spreading). In Goodpasture disease, in which the antigen is α3 chain of type IV collagen, the antigen is present in the lung alveolar basement membrane but is normally sequestered. In tobacco smokers, however, the inhalation results in oxidative injury with exposure of the α3 chain, allowing the binding of antibody.[9] This may explain why lung involvement rarely occurs in nonsmokers with Goodpasture disease.

Complement

The complement system is often activated in glomerular disease (Fig. 16.6). Complement can be activated through three pathways. *Classic pathway* activation involves the binding of C1q to the Fc region of antibody in IgG- and IgM-containing immune complexes and can result in reduced serum C4 and C3. This is common in lupus nephritis, immune complex–induced GN, and cryoglobulinemic MPGN. Complement may be activated by the *alternative pathway,* which is activated independently of immune complexes and can be triggered by polysaccharide antigens, polymeric IgA, injured cells, bacterial products (e.g., streptococcal antigens), and antibodies to complement pathway components (C3 convertase). The alternative pathway appears to be activated in IgA nephropathy, DDD, and PSGN. Serum complement levels are generally normal in IgA nephropathy; in DDD and PSGN, however, the C3 is typically low but C4 is normal. In DDD as well as in C3-glomerulonephritis (C3-GN) (see Chapter 22), the activation of the alternative pathway

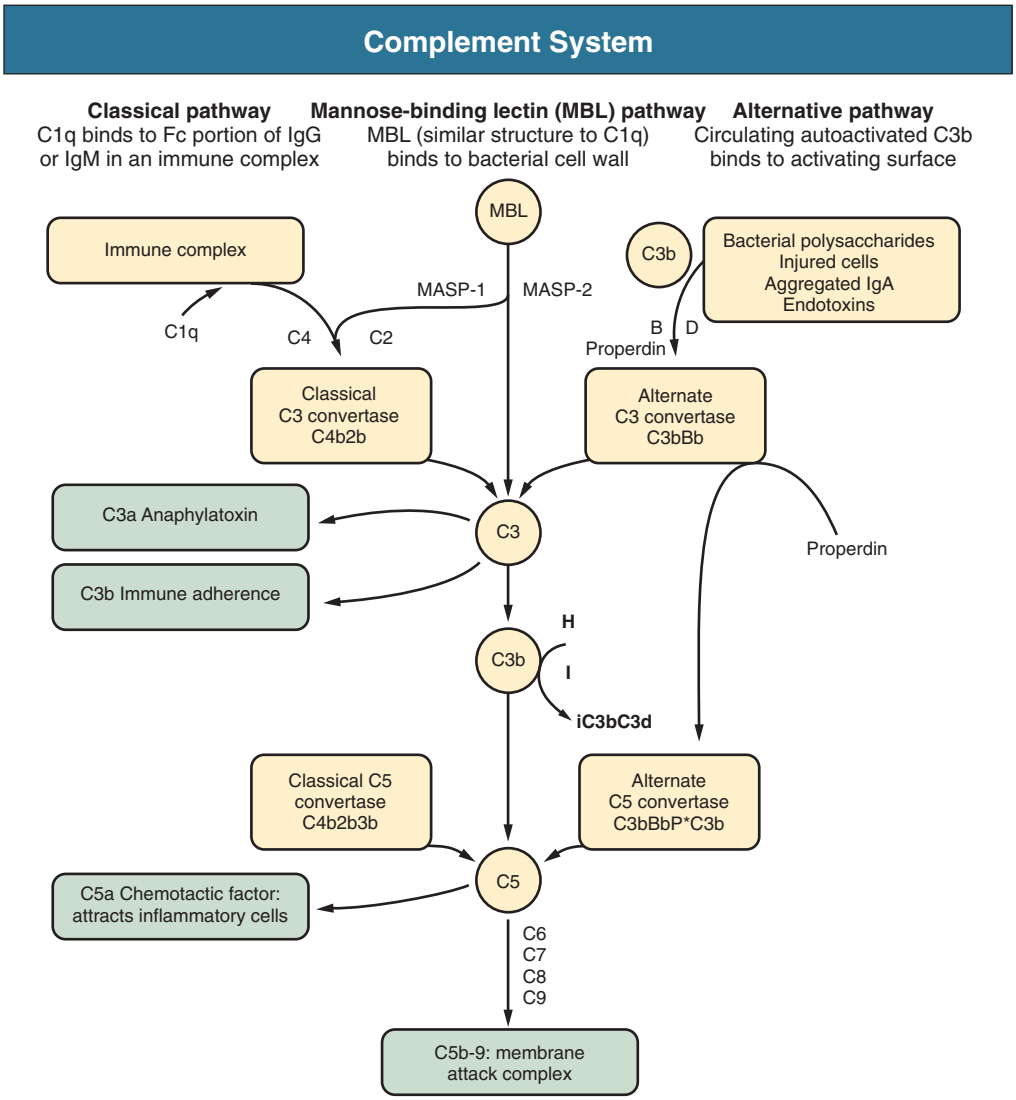

Fig. 16.6 Complement system. The complement system is a self-amplifying cascade of proteins that generates a membrane attack complex, which is cytolytic; the cascade promotes inflammation by the activity of the fragments it produces. The amplifying cascades result from activated fragments of the components combining to make convertase enzymes that degrade C3 and C5. The complement cascade is controlled in part by the short active life of many of its components. There are also inhibitory regulatory proteins, most notably factors H and I inhibiting C3b. Activated fragments of any component are designated *b* (e.g., C3b); anaphylatoxic fragments are designated *a* (e.g., C5a). Inflammatory functions of complement components are shown in green. *IgA,* Immunoglobulin A; *MASP,* MBL-associated serine protease.

may not involve an antigen but rather results from continuous activation of the pathway through altered factor H or an IgG autoantibody (nephritic factor) that stabilizes the C3 convertase (see Chapter 22). Complement also can be activated through the mannose-binding lectin (MBL) pathway initiated by MBL, which has a structure similar to that of C1q. The role of the MBL pathway in GN is emerging in IgA nephropathy and idiopathic membranous nephropathy. However, despite evidence for intraglomerular complement activation in these conditions, serum complement components such as C3 and C4 generally remain in the normal range.

Activation of the complement pathway has several consequences. Leukocyte recruitment is facilitated by the chemotactic factor C5a, and C3b binding is important in the binding and opsonization of the immune complexes by the infiltrating leukocytes. The terminal membrane attack complex of the cascade, C5b-9, inserts into cell membranes, where it can kill cells or more commonly activate them to secrete cytokines, oxidants, and extracellular matrix. C5b-9 likely has a role in mediating injury to the glomerular epithelial cell in membranous nephropathy, in which immune deposits and complement activation occur in the subepithelial space. Complement also can be activated in proteinuric urine because of amidation of C3 by ammonia, which may have a role in mediating tubulointerstitial injury even in conditions not associated with immune complex formation. Experimental studies have emphasized the importance of local synthesis of complement components by the tubular cells as a mechanism that may augment this process.[10]

Activation of complement is controlled by complement regulatory proteins (see Fig. 16.6). A genetic absence or malfunction of factor H or other regulatory proteins can result in increased susceptibility to glomerular endothelial injury, resulting in (HUS; Chapter 29) or less often hereditary forms of GN (see Chapter 22).

Mechanisms of Immune Glomerular Injury

Two major mechanisms account for the presence of immune complexes in glomerular diseases. There may be ineffectual clearance of an antigen from an impaired immune response, as in chronic viral infections caused by hepatitis B or hepatitis C virus (HBV or HCV). Despite a strong humoral response, viral infection persists because the cell-mediated response required for elimination of these viruses is impaired. The consequence is a state of persistent antigenemia with circulating antigen-antibody complexes, which predisposes to glomerular injury. Eradication of the virus with antiviral therapy can be associated with remission of the glomerular disease.

More often, glomerular disease results from autoimmunity. In health, a tension exists between the normal immune response to foreign antigen and tolerance, which is the cellular process that prevents an immune response to self-antigen. Tolerance develops because self-reactive T and B cells are clonally deleted during fetal and neonatal life, although small numbers survive outside the thymus or bone marrow, respectively. Under certain conditions, these peripheral self-reactive cells can be stimulated to generate a cellular and humoral response to a self-antigen. Infection or toxins may play a role in initiating the response by releasing antigens from sequestered sites so they have access to dendritic cells, which carry the antigen to lymph nodes for presentation to T cells, by altering host proteins to make them more immunogenic, or by molecular mimicry, in which antibodies to an exogenous antigen (e.g., those present in infecting organism) cross-react with a native protein.[11] Activation of T cells may be further enhanced by the release of cytokines or endogenous danger-associated molecular patterns, such as Toll-like receptor ligands or inflammasome activators, and the conversion of normally innocuous endogenous renal cells into antigen-presenting cells through the upregulated or de novo expression of human leukocyte antigen (HLA) class II molecules and cytokines.

Regulatory T cells ($CD4^+CD25^+$) have a key role in controlling T cell responses and preventing the development of autoimmunity. However, their role is not well understood and the local regulation of these cells in the kidney by a subset of dendritic cells ($CD103^+$) may be more important than systemic numbers of regulatory T cells.[12]

Variations in HLA molecules and the T cell receptor are under strong genetic influence. Close immunogenetic associations, particularly between HLA expression and various patterns of GN, have been described in IgA nephropathy, membranous nephropathy, and other glomerular diseases. For example, whereas HLA-DR2 identifies a powerful relative risk for the development of Goodpasture disease, some individuals can develop the disease without HLA-DR2, and the vast majority with HLA-DR2 never develop this rare disease. HLA associations also differ among various ethnic groups. To date, HLA associations have no practical diagnostic or therapeutic implications, and HLA typing is not needed in the clinical management of patients with GN.

Inflammation

The presence of glomerular inflammation is largely determined by the site of immune deposits. Immune deposits with direct access to the circulation (subendothelial and basement membrane locations) are usually associated with leukocyte accumulation. Mesangial deposits elicit an intermediate response, whereas immune deposits in the subepithelial space generally are not associated with inflammatory cells.

In GN associated with subendothelial deposits, such as class IV lupus nephritis or MPGN, leukocyte infiltration is common. With acute injury, the predominant infiltrating cells are neutrophils, platelets, and monocytes, and in chronic injury, the predominant cells are monocyte/macrophages and T cells. The primary mechanism for attracting these cells is the secretion of chemokines and the expression of leukocyte adhesion molecules by local endothelial and resident cells; local release of complement activation fragments (C5a) is also important.

Although neutrophils are common with immune complex disease, cell-mediated immunity is important in some glomerular diseases. For example, T cells likely have a role in crescentic nephritis, becoming sensitized to endogenous or exogenous antigen and then recruiting macrophages that mediate crescent formation.

Proliferation, Apoptosis, and Fibrosis

Intrinsic glomerular cells (epithelial, mesangial, and endothelial) are also activated in various glomerular diseases. Mesangial cells can become myofibroblast-like cells that proliferate and produce excessive extracellular matrix. Endothelial cells produce nitric oxide and other antiinflammatory proteins, and injury to this cell population can result in the expression of leukocyte adhesion molecules and activation of the coagulation system. Podocytes are differentiated epithelial cells that when injured undergo shape change (reorganization of the actin filaments) that can lead to disruption of the slit diaphragm, resulting in proteinuria. Interestingly, podocytes also can be induced to express receptors involved in antigen presentation that are similar to those expressed by dendritic cells. Progressive loss of podocytes by apoptosis is associated with the development of glomerulosclerosis. Important growth factors associated with glomerular injury include transforming growth factor β (TGF-β), which mediates matrix deposition; platelet-derived growth factor (PDGF), which mediates mesangial cell proliferation; and vascular endothelial growth factor (VEGF), required for endothelial health.

Crescent formation represents a severe cellular response and is initiated by cytokine-driven proliferation, particularly of the parietal epithelial cells. Local breaks in the GBM or Bowman capsule, mediated by activated leukocytes, are followed by macrophage infiltration, proliferation of parietal epithelial cells and podocytes, and local fibrin deposition (Fig. 16.7).

Glomerular scarring is characterized by proliferation of mesangial cells with loss (apoptosis) of endothelial cells and podocytes. Tubulointerstitial fibrosis also accompanies progressive glomerular disease and correlates with both renal function and prognosis. Proteinuria has been shown to activate tubular cells and induce toxicity, either directly or through the generation of oxidants (from iron proteins excreted in urine) or from complement activation, which can be shown in proteinuric urine. Tubulointerstitial ischemia after loss of glomerular and peritubular capillaries also may drive fibrosis. Finally, loss of renal function may result from leakage of plasma ultrafiltrate into the peritubular space, resulting in a scarring response (misdirected filtration), or stenosis/occlusion of the opening of the proximal tubule from Bowman space, resulting in nonfunctional (atubular) glomeruli. A detailed discussion of current mechanisms involved in glomerulosclerosis is presented in Chapter 78. Specific pathogenic mechanisms in the different patterns of glomerular disease are discussed in subsequent Section IV chapters.

PATHOGENESIS OF SPECIFIC GLOMERULAR SYNDROMES

Minimal Change Disease

Minimal change disease (MCD) is a steroid-sensitive nephrotic syndrome in which the only structural abnormality is podocyte swelling and fusion of foot processes on EM (see Chapter 17). For many years, the podocyte injury in MCD was thought to be caused by a cytokine released from T cells. T cells are activated in MCD, and T cell hybridomas from these patients were reported to secrete a factor that provokes heavy proteinuria in rats.[13] One candidate cytokine is interleukin-13 (IL-13), which is expressed by T cells in patients with MCD, and overexpression of IL-13

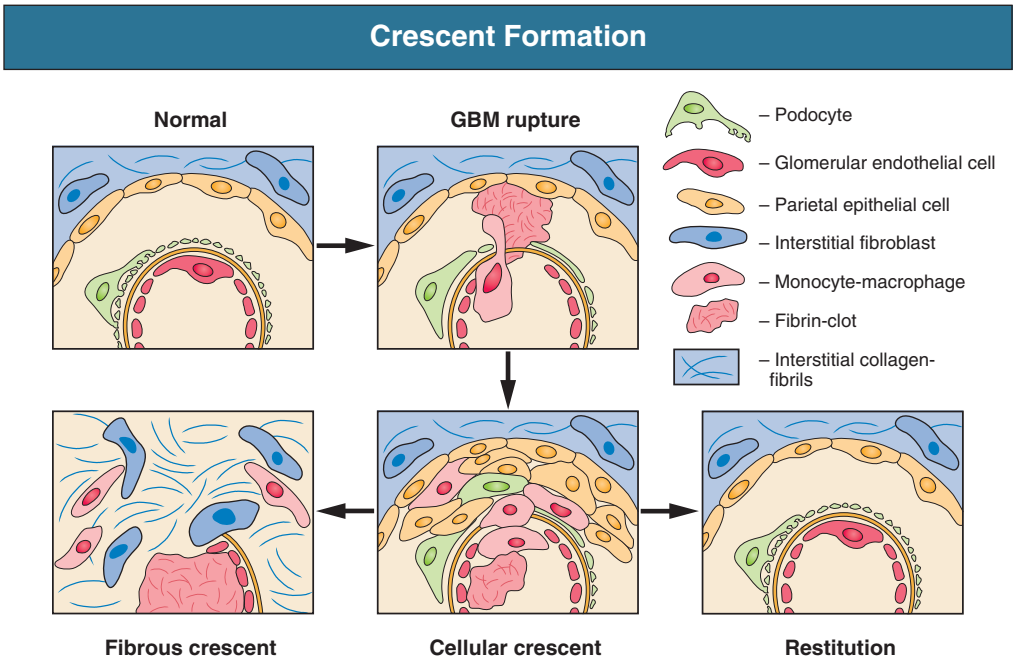

Fig. 16.7 Crescent formation. In early crescent formation, cytokines and growth factors cross the glomerular basement membrane *(GBM)* to initiate proliferation of the parietal epithelial cells. Small breaks in the GBM occur secondary to injury from oxidants and proteases from neutrophils and macrophages, thus allowing the macrophage to enter Bowman space, where it can proliferate. Breaks in Bowman capsule secondary to the periglomerular inflammation also occur, allowing the entrance of more inflammatory cells as well as fibroblasts. The proliferation of parietal and visceral epithelial cells and macrophages is associated with fibrin deposition, slowly choking the glomerular tuft until filtration becomes impossible. In the late stages, the crescent becomes fibrotic and the glomerulus end stage. Alternatively, in less severe cases, complete restitution of the glomerular tuft can occur.

causes nephrotic syndrome and histologic changes consistent with MCD in rats. However, proteinuria can be induced in immunodeficient mice using CD34-positive hematopoietic bone marrow cells of patients with MCD and recurrent FSGS but not by their T cells.[14] Thus the role of T cells in this disorder remains to be clarified.

Evidence also suggests that the podocyte injury is associated with overexpression of angiopoietin-like-4, which is associated with a proteinuric response.[15] This overexpression can be reduced with corticosteroids and *N*-acetyl-D-mannosamine. In addition, patients with MCD show high levels of CD80 (also known as B7.1) in urine and in podocytes, and the level of urinary CD80 correlates with disease activity. CD80 is an antigen that is normally expressed by dendritic cells and B cells.

Focal Segmental Glomerulosclerosis

Focal segmental glomerulosclerosis (FSGS) is a generic term to describe a pattern of glomerular scarring and is therefore nonspecific. Focal segmental sclerosing lesions in the absence of nephrotic syndrome can occur in a range of contexts, including GN, chronic hypertension, obesity, and progressive renal disease of any etiology. These lesions are particularly common in African Americans; recent findings suggest this susceptibility relates to increased frequency of a genetic polymorphism in *APOL1,* a gene coding for a circulating lipoprotein.

When the histologic pattern of FSGS is seen in association with the nephrotic syndrome, immune deposits are absent, but as with MCD, there is a generalized capillary wall defect with foot process fusion (also termed *effacement*) on EM (see Chapter 18). However, unlike MCD, there is segmental scarring (sclerosis) in some glomeruli with FSGS. Some forms of FSGS result from mutations of podocyte proteins (see Chapter 19), whereas others are believed to originate from a circulating factor; cardiotrophin-like cytokine 1 is one candidate molecule, but others are also being investigated as potential circulating factors that may mediate FSGS (see Chapter 18). Although it is unproven, some consider that MCD and FSGS share similar pathogenic mechanisms and are part of a spectrum in which MCD has lower levels of the circulating factor and is therefore more sensitive to corticosteroids. These forms of FSGS may be particularly prone to rapid recurrence, sometimes within hours, after renal transplantation.

A variant of FSGS is *collapsing* FSGS, in which there is proliferation of the normally quiescent podocyte, leading to collapse of the glomerular tuft, often in association with massive proteinuria. The pathogenesis may involve production by the podocyte of growth factors such as VEGF or local inhibition of cell cycle proteins that normally maintain the podocyte in a nonproliferative state.[16]

Membranous Nephropathy

In membranous nephropathy (MN), immune deposits are localized to the subepithelial space, where they had long been considered to represent autoantibody binding to an intrinsic podocyte antigen (see Chapter 20). This antigen has now been identified as the M-type phospholipase A_2 receptor (PLA_2R) in as many as 70% of cases of idiopathic MN.[17] Antibodies to PLA_2R are specific for MN. Circulating anti-PLA_2R reflects the immunologic activity of the disease and may be useful to monitor the clinical course, including patient response to treatment. Other autoantibodies have been found, albeit much less frequently, including those against thrombospondin type-1 domain-containing 7A,[18] against neutral endopeptidase (in the very rare neonatal MN), or against bovine serum albumin (BSA).[19] Some cases of MN may be caused by low-avidity immune complexes, which may dissociate and then re-form at the

subepithelial space; this may be a mechanism for some MN caused by viruses such as HBV.

Most cases of idiopathic MN caused by anti-PLA_2 antibodies are associated with IgG4 deposition, which is an isoform of IgG that does not activate the classic complement pathway. However, there is evidence that the IgG4-PLA_2 complex can activate complement through the MBL complement pathway, resulting in local generation of the membrane attack complex (C5b-9), which may insert into the podocyte to cause activation, injury, and proteinuria.

Membranoproliferative Glomerulonephritis

In MPGN type I, the immune deposits localize to both the mesangium and the subendothelial space (see Chapter 21). A similar pattern is observed in cryoglobulinemic GN, in which the immune complexes contain a monoclonal IgM or polyclonal IgM that acts as a rheumatoid factor by binding to the IgG in the immune complex. In both cases, the disease is thought to occur by passive deposition from the circulation, and the antigen is often a component of the HCV virus, especially in adults. When this pattern is seen in lupus nephritis, it may be facilitated by the binding of extracellular nucleosomes to the complexes. Nucleosomes are cationic nuclear proteins that can interact with the negatively charged proteins within the glomerulus.

Studies in experimental models suggest that the intraglomerular immune complexes cause local complement activation with the generation of chemotactic factors, including C5a, chemokines, and leukotrienes. Leukocyte adhesion molecules on endothelial cells are upregulated (intracellular adhesion molecule 1) or expressed de novo (E- and P-selectin). Proinflammatory cytokines (IL-1 and tumor necrosis factor α) are generated locally and augment the inflammatory response. Neutrophils, platelets, and monocytes/macrophages then localize in the glomerulus and release oxidants, particularly hypohalous acids generated by neutrophil myeloperoxidase, and proteases (elastase, cathepsin G, metalloproteinases) that cause local cellular injury and GBM degradation.

Dense Deposit Disease and C3 Glomerulonephritis

In contrast to MPGN type I, immune complexes are absent in glomeruli of patients with DDD and C3-GN. Initiation results from spontaneous intraglomerular activation of the alternative complement pathway. The most common cause is nephritic factor, an autoantibody that activates the alternative pathway. Some cases may be caused by mutations of the complement regulatory factor H, in which case the location of the mutation within the gene determines whether the disease manifests as DDD or atypical HUS.[20]

Mesangial Proliferative Glomerulonephritis

A mesangial proliferative GN, IgA nephropathy, is the most common type of glomerulonephritis (see Chapter 23). Production of an abnormally glycosylated IgA, possibly by a bacterial superantigen,[21] or perhaps from an altered mucosal immune system, may lead to IgA polymers that deposit in the mesangium; the glomerular capillary wall is relatively spared. Marked yet usually non-nephrotic proteinuria is a common feature of the clinical presentation. Mesangial cell injury may be mediated by binding of the IgA-containing immune complexes to Fcα or other IgA receptors on the mesangial cell, resulting in the release of chemokines and growth factors that provokes leukocyte infiltration as well as mesangial cell proliferation and mesangial matrix production.

Poststreptococcal Glomerulonephritis

Poststreptococcal GN has long been considered the human equivalent of acute serum sickness in rabbits (see Chapter 55). It is observed only in patients infected with specific (nephritogenic strains) of group A streptococci. One antigen responsible for some cases of PSGN, streptococcal pyrogenic exotoxin B, enters the circulation and localizes to glomeruli, resulting in a brisk inflammatory reaction with local endothelial and mesangial cell proliferation and manifestations of nephritic syndrome. Complement activation occurs through the alternative pathway and may result from direct activation of the pathway by streptococcal antigens. Some deposits ("humps") also form in the subepithelial space and may represent the translocation of immune complexes across the GBM.

Goodpasture Disease

Goodpasture disease (anti-GBM disease) is caused by an autoantibody to the α3 chain of type IV collagen present in the GBM and alveolar basement membrane (see Chapter 24). The autoantibody develops in genetically susceptible individuals because of molecular mimicry between the type IV collagen antigens and certain bacterial antigens.[8] Binding of antibody results in complement activation with the infiltration of inflammatory cells, causing local capillary wall damage and proteinuria. Crescent formation also usually occurs and may be mediated by both T cells and macrophages.

Antineutrophil Cytoplasmic Antibody–Associated Vasculitis

A severe form of segmental necrotizing glomerular injury, often in association with crescents, can be observed with vasculitis (see Chapter 25). The two most common types of vasculitis causing this type of injury are granulomatosis with polyangiitis (GPA, formerly known as Wegener granulomatosis) and microscopic polyangiitis (MPA). Both are associated with circulating antibodies against neutrophil cytoplasmic antigens (ANCAs), with antibodies to endopeptidase (proteinase) 3, which give a cytoplasmic pattern by staining (c-ANCA) in most patients with GPA granulomatosis, and antibodies to myeloperoxidase, which give a perinuclear staining pattern (p-ANCA) in subjects with MPA. Experimental evidence suggests that ANCAs are pathogenic by activating neutrophils within the vasculature. The mechanism responsible for triggering autoantibodies to neutrophil antigens remains unclear, although geographic and temporal clustering suggest a role for infection or antigen exposure that may induce an autoimmune response.[11]

Further discussion of specific pathogenic mechanisms in the different patterns of glomerular disease can be found in Chapters 17 to 29.

SELF-ASSESSMENT QUESTIONS

1. Membranous nephropathy (MN) may result from all the following *except:*
   - **A.** Anti–phospholipase A_2 receptor antibodies
   - **B.** Thrombospondin type-1 domain-containing 7A antibodies
   - **C.** Antibodies to cationic bovine serum albumin
   - **D.** Factor H deficiency
   - **E.** Deposition of hepatitis B virus antigens and antibody
2. A low serum C3 level would suggest all the following diseases *except:*
   - **A.** Membranoproliferative glomerulonephritis secondary to hepatitis C virus
   - **B.** Cryoglobulinemic glomerulonephritis accompanying bacterial endocarditis
   - **C.** Class IV lupus nephritis
   - **D.** Goodpasture disease
   - **E.** Class III lupus nephritis
3. Marked proteinuria typically results from damage to which structure?
   - **A.** Mesangial cells
   - **B.** Parietal epithelial cells
   - **C.** Podocytes
   - **D.** Preglomerular arterioles
   - **E.** Loops of Henle
4. Which statement best describes focal segmental glomerulosclerosis (FSGS)?
   - **A.** It is typically a disease of the mesangium.
   - **B.** It usually results in nephrotic syndrome.
   - **C.** FSGS can result from a circulating factor.
   - **D.** FSGS is an autoimmune disease.
   - **E.** Most FSGS cases result from mutations.

Minimal Change Disease

Gabriel Cara-Fuentes, Eduardo H. Garin, Richard J. Johnson, Jürgen Floege

Minimal change disease (MCD), previously known as *lipoid nephrosis* or *minimal lesion*, represents the most common type of nephrotic syndrome in children (~80%), whereas in adults it accounts for 10% to 20% of cases. MCD refers to nephrotic syndrome in which glomeruli appear normal or with very subtle morphologic changes under light microscopy, with podocyte foot process fusion or effacement found on electron microscopy. MCD displays a higher rate of remission after corticosteroid treatment, has better long-term renal outcomes, and has an earlier onset than other patterns of nephrotic syndrome.

EPIDEMIOLOGY

The largest epidemiologic study carried out in children with nephrotic syndrome was the International Study of Kidney Disease in Children (ISKDC).[1] In this study, 363 of 471 (77%) children presenting with nephrotic syndrome had MCD as the underlying histologic diagnosis. MCD accounted for 94% of cases in patients younger than 6 years of age who responded to an 8-week course of oral steroids. In older children with nephrotic syndrome, the proportion with MCD decreases steadily, reaching about 50% of all cases between 8 and 16 years of age. More recent studies, based on smaller populations than that included in ISKDC, found a rising proportion secondary to focal segmental glomerulosclerosis (FSGS) relative to MCD.[2]

The incidence of MCD in children ranges from 1.2 to 7 per 100,000 cases and has a seasonal influence with a greater incidence during winter and shows great variability among different populations.[3] Thus MCD is reported to be as low as 1 per million of the population in the United Kingdom and up to 27 per million in the United States. It is more common in South Asians and Native Americans but is much rarer in African Americans, in whom nephrotic syndrome is much more likely to be caused by FSGS.[4] The prevalence of MCD is approximately 16 in 100,000. MCD is more common in boys (2:1) during childhood but is equally common in male and female adolescents.

ETIOLOGY

Few children have an underlying disease or condition leading to MCD. When it occurs, secondary MCD may be clinically indistinguishable from idiopathic MCD. A list of secondary causes is summarized in Box 17.1. Of these, Hodgkin disease, atopy, exposure to allergens (vaccinations, insect stings, foods), and nonsteroidal antiinflammatory drugs (NSAIDs) (particularly fenoprofen) seems to have a strong clinical association with MCD. The latter is an idiosyncratic reaction and is usually associated with chronic NSAID use that has occurred for several weeks or months. Unlike classic MCD, this syndrome is usually associated with massive nephrotic syndrome with impaired renal function, and renal biopsy shows MCD with features of an acute interstitial nephritis with T cell infiltration.

MCD is the most common type of nephrotic syndrome in patients with Hodgkin disease, but its incidence is low (<1%).[5] In these patients a protein known as C-MIP is overexpressed in Reed-Steinberg cells and podocytes. C-MIP appears to mediate podocyte injury by preventing the interaction of nephrin with the tyrosine kinase Fyn, resulting in decreased phosphorylation of nephrin, which in turn, could lead to cytoskeleton rearrangement and proteinuria.[6]

Relapses of MCD can follow exposure to bee sting, foods, and viral or bacterial respiratory tract infections (URIs). The association of bee sting and MCD is limited to few anecdotal case reports. Food allergens have been reported as triggers of MCD relapses in numerous case reports. This clinical association led to introduction of allergen-free diets for patients with MCD, and case reports and case series have reported that a gluten-free diet, elemental diets, or skin desensitization may result in a decrease in proteinuria.[7] Well-designed, controlled studies are needed to validate these observations.

Rare cases of familial MCD have been reported in Europe but may more likely represent an underlying mutation in genes encoding for slit diaphragm proteins instead of primary or idiopathic MCD (see Chapter 19).[8]

PATHOGENESIS

The pathogenesis of proteinuria in MCD is unknown. Shalhoub,[9] in 1974, proposed that MCD is caused by a circulating factor, thought to be a cytokine, that increases the permeability of the glomerular basement membrane (GBM) to plasma proteins. He suggested that MCD might represent a T cell disorder based on the lack of immune deposits, the rapid response to corticosteroids, the association with Hodgkin disease (a T cell neoplasm), and the observation that remission often occurred during resolution of measles infection, which is associated with a transient inhibition of cell-mediated immunity. This hypothesis remains dominant, although neither the circulating factor nor a T cell–dependent mechanism has been identified. However, several potential pathways that result in podocyte activation and proteinuria have been identified (Fig. 17.1).

Circulating Factor(s)

Several candidate molecules have been considered as possible circulating factors.

Cytokines

Cytokines have been measured in serum, urine, supernatants of peripheral blood mononuclear cells, and mRNA levels in circulating T cells

BOX 17.1 Secondary Causes of Minimal Change Disease

Drugs
- Nonsteroidal antiinflammatory drugs
- Interferon-α
- Lithium: Rare (usually causes chronic interstitial nephritis)
- Gold: Rare (usually causes membranous nephropathy)

Allergy
- Pollens
- House dust
- Insect stings
- Immunizations
- Poison Oak

Malignancy
- Hodgkin disease
- Mycosis fungoides
- Chronic lymphocytic leukemia: Uncommon (usually associated with membranoproliferative glomerulonephritis)

or leukocyte populations. Although some patterns have been observed, especially related to an increase in Th2-derived cytokines (that are associated with allergy), no definitive confirmed pattern has emerged.[10]

Some groups have administered or overexpressed cytokines in laboratory animals to determine if they can induce nephrotic proteinuria. Rats were infused with interleukin-8 (IL-8) to achieve levels found in serum in MCD patients, with a concomitant increase catabolism of GBM heparan sulfate, but the proteinuria was in the non-nephrotic range.[11] In a transgenic rat model that developed elevated serum IL-13 levels, there was an increased podocyte CD80 overexpression attributed to IL13, as well as nephrotic proteinuria.[12] However, the role of IL-13 in MCD patients is debatable because although some MCD patients have elevated IL-13 in serum during relapse, most patients have serum IL-13 levels either within the normal range or even undetectable in serum.

Hemopexin

Hemopexin is synthesized in the liver and is present in human plasma of patients with MCD, which, when infused into the isolated rat kidney, induced proteinuria.[13] However, its role in disease remains controversial because only 50% of the proteinuria was due to albumin; this is a

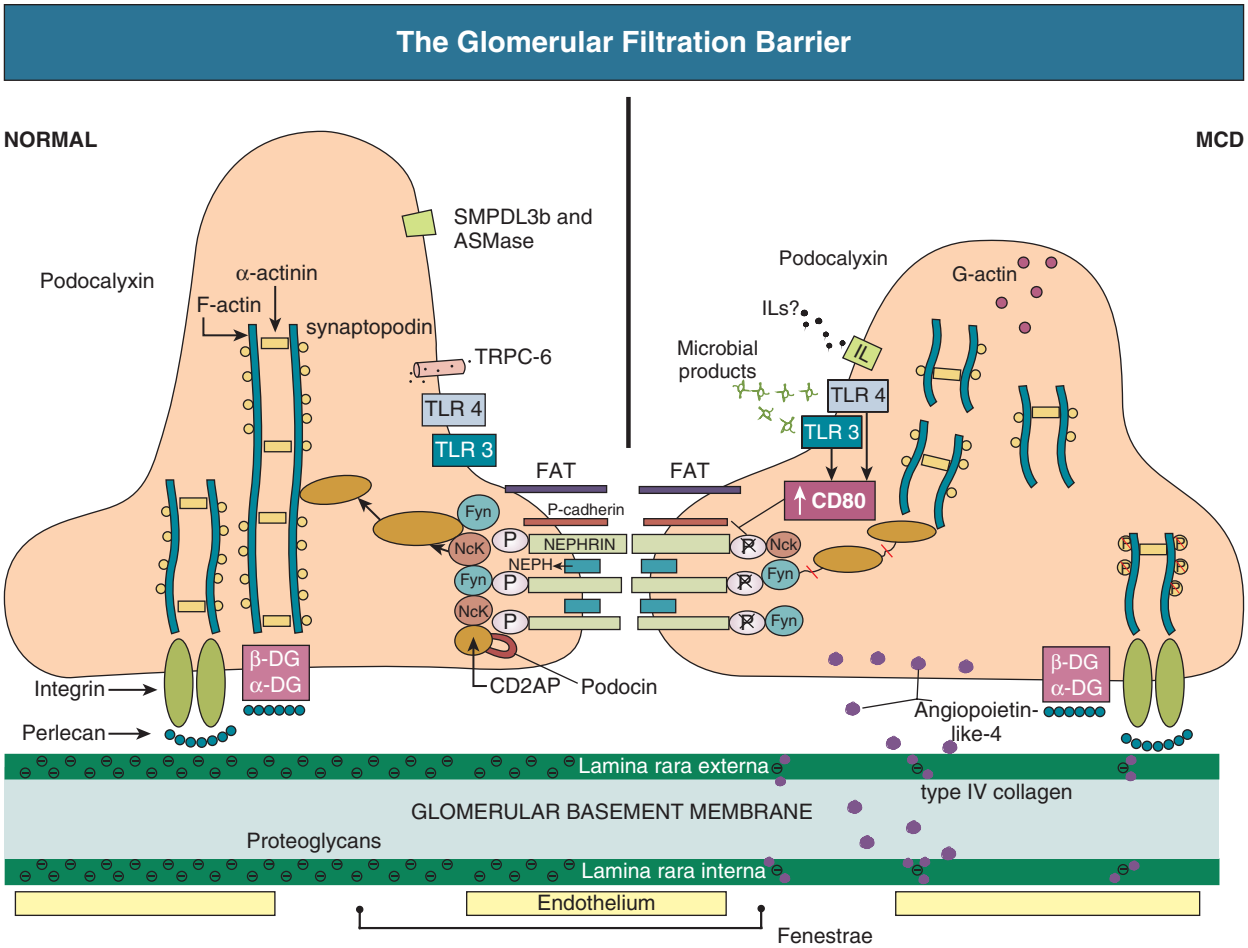

Fig. 17.1 Glomerular filtration barrier in healthy state *(left)* and in minimal change disease *(MCD)* during relapse *(right).* In MCD, microbial products and/or interleukins *(ILs)* bind to Toll-like receptors *(TLRs)* or IL receptors leading to *CD80* expression, which in turn, may interfere with nephrin expression/phosphorylation. Angiopoietin-like-4 is thought to induce proteinuria by reducing anionic sites at the glomerular basement membrane level. *DG,* Dystroglycans.

different pattern from that of MCD because the filtration fraction also contains other protein and MCD patients have low serum levels of hemopexin, likely as a result of urinary losses, and no hemopexin has been detected in their kidneys.

Microbial Products

A role for microbial products as circulating factors is attractive because 70% of MCD patients with relapse have documented viral or bacterial respiratory infections.[14] Two Toll-like receptor (TLR) ligands, lipopolysaccharide (LPS), a component of the outer membrane of gram-negative bacteria, and polyinosinic-polycytidylic acid (poly IC), a viral-like particle, bind to TLR-4 and TLR-3 on podocytes, respectively, and cause proteinuria in animals with podocyte expression of CD80 and increased urinary CD80 excretion, mimicking findings observed in MCD patients during relapse.[15,16]

Mechanism(s) of Proteinuria

Loss of Anionic Charges in the Glomerular Filtration Barrier as a Cause of Minimal Change Disease

Proteinuria in MCD has been proposed to result from a loss of proteins carrying negative charges in the glomerular capillary wall, resulting in disruption of the charge barrier and allowing albumin (which is negatively charged) to pass across in excess quantities.[17] Heparan sulfate proteoglycans, which are the major source of anionic sites in the GBM, are reported to be low or normal in the GBM of MCD patients. Nevertheless, experimental studies in which the charge barrier of the GBM has been altered do not confirm a loss of the charge barrier as a major cause of proteinuria.[18]

Podocyte Dysfunction as a Cause of Minimal Change Disease

More recent studies have focused on podocyte dysfunction in the mechanism of proteinuria. Several suggestions have been proposed, including alteration of slit diaphragm proteins such as reduced nephrin phosphorylation[19] and alteration in integrin-mediated podocyte adhesion. Decreased expression of acid sphingomyelinase-like phosphodiesterase 3b (SMPDL3b), a protein mainly localized in podocytes' lipid rafts, also has been associated with FSGS, although no data are available in MCD.[20] Podocyte expression of two molecules, CD80 (also known as B7.1) and angiopoietin-like-4 (Angptl-4) also have been proposed (see Fig. 17.1).[21,22]

CD80. A major discovery was that the podocyte can become an antigen-presenting cell and can express proteins normally expressed by dendritic cells, such as CD80.[15] CD80 is a costimulatory molecule present on antigen-presenting cells that was found to be expressed on podocytes in children with MCD.[21] It also can be induced in podocytes both in vitro and in vivo by TLR ligands, with the development of transient proteinuria and focal foot process effacement.[15,16] Serum from patients with MCD who are in relapse induces CD80 expression in cultured podocytes but not serum from MCD patients in remission. High levels of CD80 also can be found in the urine of children with steroid-sensitive MCD, and levels decrease to normal with remission.[23] CD80 is regulated by cytotoxic T lymphocyte–associated antigen 4 (CTLA-4), which is a molecule also expressed by podocytes. The administration of CTLA-4 immunoglobulin to a child with recurrent steroid-dependent MCD resulted in rapid decrease in urinary CD80, with the development of remission within 72 hours.[23]

These observations led to the hypothesis that MCD relapse may develop after viral infection in which viral components stimulate TLR-3 podocyte receptors, resulting in overexpression of podocyte CD80. Because of an inadequate CTLA4 response by the podocyte, the increased expression of CD80, by interfering with phosphorylation of nephrin, could lead to changes in podocyte shape affecting the "size barrier," allowing protein to pass through larger physical gaps in the continuity of the podocyte barrier. Consistent with this hypothesis, glomerular nephrin phosphorylation is decreased in MCD.[19]

CD80 is also expressed in glomeruli in other glomerular diseases, and not all studies have observed high glomerular expression in subjects with MCD as well as in other glomerulopathies.[24] However, urinary CD80 is significantly higher in persons with MCD compared with FSGS or other conditions, suggesting that although CD80 may be expressed in many diseases, its expression is greatest in MCD. Indeed, CTLA4 immunoglobulin (Ig) does not appear to be effective in inducing remission in FSGS.[23]

Angptl-4. Angptl-4 is a glycoprotein that has been proposed as a mediator of proteinuria in MCD.[22] In a transgenic rat model characterized by glomerular overexpression of angptl4 and podocin, rats had a marked loss of GBM heparan sulfate proteoglycans, podocyte foot process effacement, and albuminuria.

Nevertheless, data on angptl4 in MCD are scarce. Our group found urinary angptl4 levels to be elevated not only in MCD but also in other nephrotic glomerular diseases (MCD, FSGS, membranous nephropathy) consistent with it being a marker of proteinuria.[25] In addition, angptl4 expression in glomeruli could not be confirmed in glomeruli of MCD subjects in a recent study.[25] Further studies on the role of angptl4 and CD80 in MCD are needed.

PATHOLOGY

MCD received its name because of the minimal, if any, glomerular abnormalities present by light microscopy. Mild changes such as a slight increase in mesangial matrix and hypercellularity may occasionally be observed. A small percentage (<10%) of glomeruli may display global, but not segmental, glomerular sclerosis, which may reflect the natural senescence of glomeruli observed in young adults. In a few cases, minor focal tubular atrophy with segmental interstitial fibrosis may be present. Fat and hyaline droplets also may be found in the proximal tubule.

By immunofluorescence, immunoglobulins or complement deposits are rarely found. If present, deposits are limited to the mesangium. There is a small subset of patients who have IgM deposits, which has been considered by some clinicians to represent an entity distinct from MCD, known as IgM nephropathy and characterized by a poorer clinical outcome. Although mesangial IgM has been considered "passive trapping" and of no pathogenic significance, recent studies suggest IgM may be directed against mesangial antigens and contribute to proteinuria. Some case series have found mesangial C1q deposits, which may be associated with worse outcomes, leading to the concept of C1q nephropathy (see Chapters 22 and 28). However, it remains controversial whether the long-term prognosis is dictated by the presence of C1q deposits or, most likely, by the presence or lack of glomerular sclerosis on light microscopy. Likewise, the mechanism by which C1q would trigger or accelerate podocyte injury is unknown.

Electron microscopy demonstrates podocyte foot process effacement or fusion (Fig. 17.2). Although fusion of foot processes is observed in other nephrotic conditions, in the absence of light microscopy glomerular changes, the finding is pathognomonic for MCD. The GBM is normal, and no electron-dense deposits are observed.

CLINICAL MANIFESTATIONS

Edema is the first sign and is noticeable after a weight gain of at least 5% to 7% of a patient's dry weight. The edema is pitting, worse in the lower extremities, and typically of rapid onset. Some patients present with bilateral periorbital edema, often misinterpreted as an allergic process.

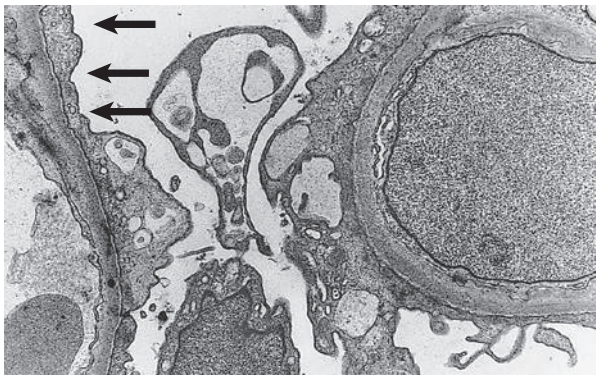

Fig. 17.2 Podocyte foot process fusion in minimal change disease. The epithelial cells *(arrows)* are completely effaced along the glomerular basement membranes. (Electron micrograph; magnification ×6000.) The normal appearance of epithelial cell foot processes is shown in Chapter 1, Figs. 1.6 and 1.7.

Edema may be mild and associated only with fatigue or may be severe, presenting as anasarca with pleural effusions and ascites. Bowel edema may manifest as diarrhea. The mechanism(s) of edema formation in MCD is not fully understood, but may be due to both a decrease in oncotic pressure and an increase in sodium reabsorption in the distal tubule (see Chapter 15).

In contrast with other glomerular diseases, MCD is associated with normal blood pressure. Some patients may develop transient renin-mediated hypertension during relapse from hypovolemia and renal hypoperfusion. Paradoxically, blood pressure will normalize after albumin infusion as the intravascular compartment is restored. Hypertension also can be iatrogenic, secondary to use of steroids, cyclosporine, or tacrolimus. Sustained hypertension questions the diagnosis of MCD.

Abdominal pain and nausea are common manifestations in MCD. Pain is usually dull because of massive ascites and bowel hypoperfusion. This pain resolves after albumin is administered. Severe pain may be due to peritonitis or acute pancreatitis. Hepatomegaly is common in children but may be overlooked in the presence of ascites.

Macroscopic hematuria is not seen in MCD unless there is a complication such as renal venous thrombosis.

Less commonly, patients with MCD may develop "white nails," sometimes in bands (Muehrcke lines) correlating with periods of clinical relapse (see Fig. 15.4). Adults may develop xanthomas and xanthelasmas, especially on the eyelids (see Fig. 15.5).

LABORATORY FINDINGS

Nephrotic syndrome is defined by the combination of nephrotic-range proteinuria, hypoalbuminemia, hyperlipidemia, and edema. In children, nephrotic-range proteinuria is defined as greater than 50 mg/kg/24 h, greater than 40 mg/h/m^2 (urinary specimens collected overnight), 200 mg protein/mmol urine creatinine, or a ratio of urinary protein to creatinine (uPCR) greater than 3 mg/mg.[1] In adolescents and adults, nephrotic-range proteinuria is defined as greater than 3.5 g/24 h. The uPCR in a random sample correlates moderately with proteinuria measured in urine collected over 24 hours from patients with glomerular disease. In MCD, proteinuria is not only massive but selective (see Chapter 15). Urine microscopy shows hyaline casts and fat bodies, as well as microhematuria in 20% of patients.

Hypoalbuminemia is defined by a serum level of albumin below 2.5 g/dl. It is the result of the increased glomerular filtration permeability to plasma proteins. It remains controversial whether there is also an increased catabolism of filtered albumin by proximal tubule cells. The current evidence suggests that albumin is reabsorbed intact at that level. The liver production of albumin is increased in MCD patients, and gastrointestinal losses are minimal. Massive edema usually develops with serum albumin levels below 2 g/dl.

Hyperlipidemia (elevated total cholesterol and low-density lipoprotein [LDL] cholesterol) is a universal feature of patients with MCD in relapse, and if massive proteinuria is persistent, triglycerides and very-LDL (VLDL) are also elevated. Hyperlipidemia results from increased hepatic synthesis of cholesterol and triglycerides and decreased activity of lipoprotein lipase. In addition, urinary losses of lecithin cholesterol acyltransferase lead to a reduction of chylomicrons and VLDL clearance. The hyperlipidemia resolves after resolution of proteinuria.

Renal function is commonly normal. Some patients have transient acute kidney injury (AKI) with oliguria during relapse secondary to reduction of intravascular compartment. AKI is more common in adolescents and young adults than children. Similarly to persistent hypertension and macroscopic hematuria, sustained renal injury should raise a concern for a complication such as renal venous thrombosis, interstitial nephritis (i.e., secondary to drugs), or a different glomerular disease.

Mild hyponatremia is common during relapse and may represent pseudohyponatremia as a result of hyperlipidemia. Indirect ion-sensitive electrode only measures the aqueous phase of the plasma specimen in contrast to direct ion-sensitive electrode. If the latter is not available, a fast way to determine whether the patient has true hyponatremia or pseudohyponatremia is by measuring plasma osmolality.

Total serum calcium and vitamin D levels may be low because of hypoalbuminemia with decreased protein-bound calcium and lower circulating levels of vitamin D–binding proteins as a result of loss in the urine, respectively, and ionized calcium is usually normal and no treatment is indicated. Bone disease, however, may develop if prolonged courses of steroids are required.

Elevated hemoglobin and hematocrit levels and thrombocytosis are usually found in MCD patients during relapse as result of plasma volume contraction.

Other Presentations (Complications)

MCD patients exhibit an increased risk for infections (sepsis, peritonitis, cellulitis, and pneumonia). Low serum IgG (but not IgM) may be present in patients with persistent proteinuria or frequent relapses secondary to excessive urinary losses. This together with the urinary losses of factor B and properdin may predispose MCD patients to infections caused by encapsulated organisms. Serum C3 levels are elevated in MCD. *Streptococcus pneumoniae, Haemophilus influenza,* and other encapsulated bacteria are the most common cause of peritonitis in these patients. Therefore clinicians must ensure that patients are properly immunized. Peritonitis is rare in adults, who usually have developed protective antibodies. Varicella may develop a severe course in those patients receiving immunosuppressive therapy.

The combination of a hypercoagulability state (decreased anti–thrombin III and proteins C and S and increased fibrinogen, coagulation factors V, VII, VIII, X, and XII, and platelet aggregability among others), along with immobilization (in the setting of anasarca) and the presence of hypovolemia (and thrombocytosis as a result), put MCD patients at high risk for thrombosis, including pulmonary emboli, sagittal venous thrombosis, renal vein thrombosis, or peripheral venous thrombosis and less frequently arterial thrombosis.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

MCD is the most common type of idiopathic nephrotic syndrome in children. So, renal biopsy is not routinely done in children (younger

than 10 years of age) presenting with idiopathic nephrotic syndrome. However, if there are features that are not characteristic for MCD, such as hypertension, red cell casts, gross hematuria, or renal dysfunction (estimated glomerular filtration rate persistently <80 ml/min/1.73 m^2), renal biopsy is performed at presentation. In addition, for children who fail to respond to a 4- to 6-week course of corticosteroids, a renal biopsy is performed. These steroid-resistant cases almost never have MCD and more likely represent a form of hereditary nephrotic syndrome (see Chapter 19).

In adults, in whom there is a wide differential diagnosis for nephrotic syndrome and corticosteroid responsiveness is less likely, a renal biopsy is required to establish the diagnosis.

Pathologic findings need to be carefully interpreted, along with the response to steroids. A patient with normal-appearing glomeruli who is not responding could have a hereditary disease associated with a podocyte mutation (e.g., congenital nephrotic syndrome, see Chapter 19). Some patients may have FSGS and may have a relatively low percentage of glomeruli showing FSGS that is not evident on the initial biopsy sample because of a sampling error. Indeed, there is an ongoing debate about whether MCD and FSGS represent different diseases or whether they are the same disease at different stages. MCD patients with steroid dependence or resistance often have findings consistent with FSGS in subsequent kidney biopsies.

NATURAL HISTORY

Children and adults with MCD classically present with nephrotic syndrome with normal renal function, and spontaneous remission is low in the absence of corticosteroid treatment. Corticosteroid treatment is usually effective in inducing remission, but relapse is common and repeated therapy often required. Among children with MCD, 25% never relapse, 25% relapse infrequently, and 50% have numerous relapses. The last group are classified as frequent relapsers if they have at least four relapses per year and steroid dependent if relapse occurs during the steroid taper or soon after it is stopped (Table 17.1).

There is no support for the concept that disease resolves during puberty, and it is not unusual to see children with MCD undergoing relapses during adulthood. However, is claimed that patients in remission for more than 5 years are less likely to relapse.[26]

Two thirds of relapses occur during an upper or lower respiratory infection. A short course (5 days) of prednisolone started at the clinical onset of URI decreases the rate of relapse (from 59% to 34%) and the number of relapses per patient.[27]

Long-term renal function in MCD patients is normal unless renal venous thrombosis develops. This is in contrast to the decreased function leading to renal failure in FSGS patients. Hence, MCD can be viewed as having a good long-term prognosis.

TABLE 17.1 Definition of Terms Used in Nephrotic Syndrome in Adults and Children

Classification	Definition
Nephrotic syndrome	Edema, uPCR ≥2000 mg/g (≥200 mg/mmol), or ≥3.5 g/day proteinuria, or 3+ protein on urine dipstick, hypoalbuminemia ≤2.5 g/dl (≤25 g/l)
Complete remission	uPCR <200 mg/g (<20 mg/mmol) or <1+ of protein on urine dipstick for 3 consecutive days (children) Reduction of proteinuria to ≤0.20 g/day and serum albumin >3.5 g/dl (adults)
Partial remission	Proteinuria reduction of 50% or greater from the presenting value and absolute uPCR between 200 and 2000 mg/g (20-200 mg/mmol) (children) Reduction of proteinuria to between 0.21 g/day and 3.4 g/day ± decrease in proteinuria of ≥50% from baseline (adults)
No remission	Failure to reduce urine protein excretion by 50% from baseline or persistent excretion uPCR >2000 mg/g (>200 mg/mmol)
Initial responder	Attainment of complete remission within initial 4 wk of corticosteroid therapy
Initial nonresponder/ steroid resistance	Failure to achieve complete remission after 8 wk of corticosteroid therapy (children) Persistence of proteinuria despite prednisone therapy, 1 mg/kg/day for 16 wk (adults)
Relapse	uPCR ≥2000 mg/g (≥200 mg/mmol) or ≥3+ protein on urine dipstick for 3 consecutive days (children) Proteinuria ≥3.5 g/day occurring after complete remission obtained for >1 month (adults)
Infrequent relapse	One relapse within 6 mo of initial response, or one to three relapses in any 12-mo period
Frequent relapse	Two or more relapses within 6 mo of initial response, or four or more relapses in any 12-mo period
Steroid dependence	Two consecutive relapses during corticosteroid therapy, or within 14 days of completing corticosteroid therapy
Late nonresponder	Persistent proteinuria during ≥4 wk of corticosteroids after one or more remissions

Modified from reference 53.
uPCR, Ratio of urine protein to creatinine.

TREATMENT

General Considerations

Management of nephrotic syndrome follows standard approaches, as discussed in Chapter 15, including a low-sodium diet to control edema. Bed rest should be avoided because of the increased risk for thromboembolic events. Diuretics are infrequently used in children because of potential further volume depletion, but diuretics are often used to control extracellular fluid volume in adults, in whom hypovolemia before treatment is less common. In patients with pronounced hypoalbuminemia (i.e., serum albumin <2 g/dl) and in those with prolonged nephrotic syndrome, thrombosis prophylaxis may be considered. Treatment of hyperlipidemia with statins is rarely necessary because of the rapid response to corticosteroids.

Treatment of Children

Initial Treatment

Corticosteroids are the first-line therapy to induce remission in children with idiopathic nephrotic syndrome and biopsy-proven MCD (Fig. 17.3), because 95% of MCD patients respond to this therapy. In patients with a contraindication for steroids (e.g., patients with diabetes), cyclosporine has been used as initial therapy.

The induction phase consists of administering prednisone 60 mg/day/m^2 (equivalent to 2 mg/kg, with a maximum of 60 mg/day for children and 80 mg/day for adolescents) for 4 weeks. Although the

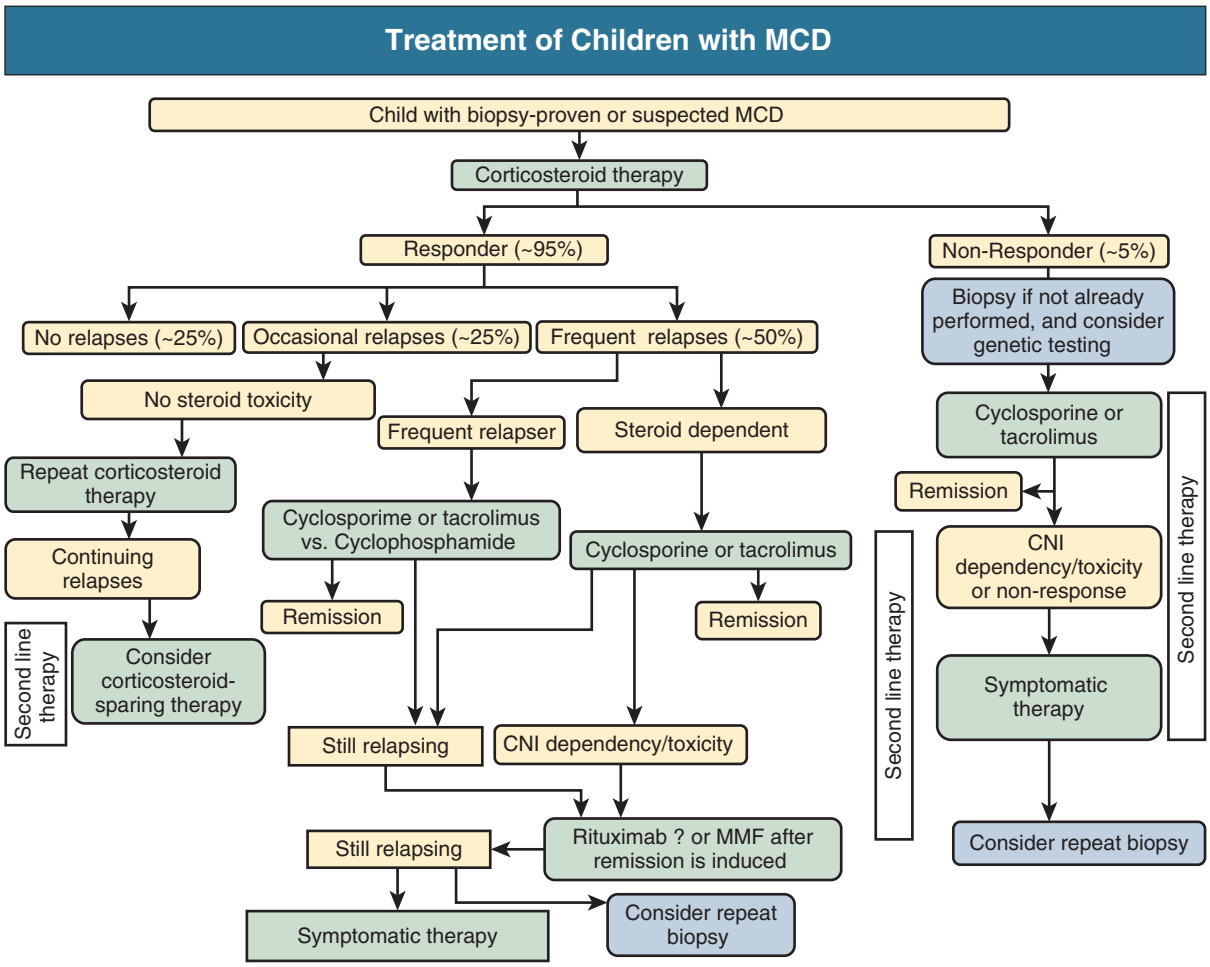

Fig. 17.3 Algorithm for treatment of childhood minimal change disease. For definitions, see Table 17.1. The patient or parents should be involved in the decision after the potential side effects of the second-line treatment are considered in the rare patient who is a nonresponder to standard corticosteroid therapy and by definition "corticosteroid resistant." *CNI,* Calcineurin inhibitor; *MMF,* mycophenolate mofetil.

ISKDC recommends dosing in 3 divided doses per day, most nephrologists administer 2 mg/kg of prednisone as a single morning daily dose based on evidence that it provides equal efficacy,[28] because single dosing results in less adrenal insufficiency and better adherence.

Whether the initial dosing of 60 mg/day/m^2 should be for 4 weeks ("short duration", ISKDC recommendation) or 6 weeks ("extended therapy") was addressed by the Arbeitsgemeinschaft für Pädiatrische Nephrologie (APN).[29] The cumulative rate of patients with sustained remission after 2 years was significantly higher in the extended therapy group than the short regimen. In addition, the frequent relapsing pattern was observed more often in patients under the short compared with the extended prednisone regimen (57% and 29%, respectively). However, these results were not confirmed by the Southwest Pediatric Nephrology Study Group (SWPNS).[30] At the end of the SWPNS study, the relapse rate was not statistically different between patients receiving the short versus extended induction therapy with prednisone.

Given these results, the 2012 Kidney Disease: Improving Global Outcomes (KDIGO) guidelines recommend treatment of the initial episode of nephrotic syndrome in children with daily oral prednisone or prednisolone at 60 mg/m^2/day or 2 mg/kg/day (maximum 60 mg/day) as induction therapy for 4 to 6 weeks.[31] The addition of cyclosporine to full dose of prednisone in the induction phase did not increase the remission rate or shorten the timing of remission.[29]

Most children will undergo remission during the induction phase, but treatment is continued to the 4-week or 6-week time point and then there is a tapering phase in which prednisone is slowly reduced to lower the risk for side effects. During the tapering phase, it is widely accepted that prednisone should be administered on alternate days. Similar to the induction phase, there is no agreement on the duration of the tapering phase or the dose of prednisone. Thus the tapering duration varies from a 4-week period followed by abrupt discontinuation as proposed by the ISKDC to a slow tapering that ranged from 6 weeks to 7 months.

A Cochrane systematic review in 2015 concluded, based on three well-designed randomized controlled trials (RCTs), that a 6-month prednisone course does not reduce the risk for relapse compared with a 2- or 3-month course in children aged 1 to 17 years at presentation.[32] The 2012 KDIGO guidelines for children with idiopathic nephrotic syndrome recommend, based on these studies, to give oral prednisone at 40 mg/m^2 or 1.5 mg/kg on alternate days and continue for 2 to 5 months with tapering of the dose.

Treatment of Relapses

Similar to the treatment of the initial episode, there is no consensus on the use of prednisone in the induction and tapering phases. The ISKDC recommends prednisone at 60 mg/m^2/day until response (maximum of 4 weeks) followed by prednisone 40 mg/m^2/day for 3

consecutive days in a week for a total of 4 weeks.[1] The ISKDC provided arbitrary definitions regarding the relapse pattern, grouping patients as steroid dependent and frequent relapsers (see Table 17.1).[1] These are widely used, but the distinction between steroid dependent and frequent relapser should be made carefully, to select appropriate therapy based on the available studies. Definitions of steroid dependence can vary among different centers. For example, longer tapering schedules (>8 weeks) will lead to a higher number of patients with a steroid-dependent pattern. In addition, the definition of steroid dependence does not take into consideration the role of URI as triggers of nephrotic syndrome.

Whereas initial treatment of relapsing patients usually involves repeated courses of corticosteroids, repeated or prolonged course of steroids can be associated with significant toxicity, including behavioral changes, growth impairment, and diabetes. This led to the use of alternative therapies in MCD patients who are steroid dependent and relapse frequently.

Chlorambucil 0.15 mg/kg/day for 56 days or cyclophosphamide 2 mg/kg/day orally for 56 days used in combination with low-dose prednisone can induce sustained remission (72% patients at 30 months after cytotoxic drug) in MCD patients with multiple relapses.[33] The ISKDC found fewer episodes of relapse (48% vs. 88% at 22 months) among patients with multiple relapses treated with a 6-week course of cyclophosphamide 5 mg/kg/day until induction of cytopenia, followed by 1 to 3 mg/kg/day along with prednisone 10 mg/m^2/day for 10 days compared with those on an intermittent dose of prednisone 40 mg/m^2 for 3 of 7 days for 6 months.[34] Cyclophosphamide should not be started until the patient has achieved complete remission with prednisone to avoid hemorrhagic cystitis. In addition, to avoid gonadal toxicity, it is recommended not to exceed a cumulative dose of 168 and 8 mg/kg, respectively, for cyclophosphamide and chlorambucil. Second courses of these medications should not be administered.

The optimal length of cyclophosphamide therapy is debatable. The APN reported a higher probability of remission after 2-year follow-up in patients receiving cyclophosphamide for 12 weeks compared with those treated for 8 weeks (67% vs. 22%, respectively).[35] No such difference was observed after 5 years in another study (24% vs. 25%, respectively).[36]

These prior studies did not differentiate between steroid-dependent patients and frequent relapsers, but the response to cyclophosphamide is better for those with a frequent relapsing pattern (70% remission) versus those who are steroid dependent (38% remission).[37] Therefore we do not recommend the routine use of either cyclophosphamide or chlorambucil in the steroid-dependent MCD patient.

Cyclosporine and tacrolimus may be considered as alternative therapeutic agents in MCD patients who relapse frequently. Treatment with cyclosporine results in a similar rate of remission compared with cyclophosphamide and chlorambucil. However, its long-term efficacy is hampered by frequent relapse shortly after calcineurin inhibitor (CNI) withdrawal.[38] Cyclosporine is recommended at an initial dose of 5 mg/kg/day with dose adjustment to maintain trough serum levels between 100 and 150 ng/ml. The length of therapy varies from 12 to 24 months. Mild to moderate cyclosporine-associated nephrotoxicity has been reported in up to one third of MCD patients treated with cyclosporine for more than 3 years. Tacrolimus appears to have efficacy similar to that of cyclosporine.[39]

Mycophenolate mofetil (MMF) has been used in MCD patients with multiple relapses in RCTs but is less efficacious than cyclosporine.[40,41] An RCT also concluded that azathioprine has no effect in the relapse rate of children with steroid-sensitive nephrotic syndrome.[42] Likewise, levamisole is an anthelminthic agent that was found to possibly reduce the risk for relapse in patients with frequent relapse and steroid-dependent nephrotic syndrome in single-center studies.[43] However, the use of levamisole is hampered by the lack of a large multicenter RCT confirming its efficacy and because in drug users it has been associated with development of antineutrophil cytoplasmic antibody (ANCA)-positive vasculitis.

More recently, rituximab has been used for steroid-dependent nephrotic syndrome in children.[44-46] Rituximab and lower doses of prednisone and CNIs were not inferior to standard doses of steroids in patients with steroid-dependent nephrotic syndrome.[44] Nevertheless, 75% of patients in the rituximab group had relapsed at 1-year follow-up. In a second study, children received a single dose of rituximab while in remission. Proteinuria was lower at 3 months in the rituximab group, although it did not reach statistical significance. Only 34% of patients in the rituximab group relapsed at 1 year in contrast with the 75% previously reported by the same group. Iijima and colleagues[46] studied patients with "complicated" steroid-dependent or frequently relapsing nephrotic syndrome. Patients were administered rituximab for 4 weeks after remission had been induced. Those who received rituximab had a significantly longer relapse-free period and fewer relapses compared with those patients receiving placebo. Unfortunately, although initial response showed a better response for rituximab, most patients relapsed (17 of 20 vs. 23 of 23, rituximab vs. control, respectively) by the end of the study, and it is unclear whether frequently relapsing and steroid-dependent patients had a similar response to rituximab. In summary, whether rituximab is beneficial in MCD is not conclusive. Rituximab may prolong remission, but RCTs with a larger and well-defined cohort of patients and long-term follow-up (>1 year) are needed to assess the efficacy and safety of rituximab before its widespread use in children MCD.

Treatment of Adults

Initial Treatment

Studies comparing different corticosteroid regimens in adults with MCD are limited, and the treatment recommendations given here are in line with KDIGO guidelines[47] (Fig. 17.4) and are extrapolated from successful approaches in children with steroid-sensitive nephrotic syndrome, although often with slightly lower doses of oral prednisolone (1 mg/kg/day, up to maximum 80 mg/day). There is no good evidence that alternate-day corticosteroids (prednisolone 2 mg/kg, up to maximum 120 mg) offer any clinical advantages over daily dosing; however, induction with methylprednisolone pulses may lead to more rapid responses and fewer relapses.[48]

Response is often delayed in comparison with that in children, and 25% fail to remit after 3 to 4 months[49] (Fig. 17.5). Although unclear, the reason may be that adults are often given a smaller dose of corticosteroids or that a greater proportion of adults have FSGS, missed on the original biopsy, which is more likely to be corticosteroid resistant.

Based on meta-analyses of pediatric studies, the recommended corticosteroid treatment should be at least 3 to 4 months (KDIGO recommends up to 6 months, but based on very-low-grade evidence). The initial high dose of corticosteroids, if tolerated, should be maintained for a minimum of 4 weeks if complete remission is achieved and for a maximum of 16 weeks if complete remission is not achieved. The rate of dose tapering and total length of treatment of the initial episode may need to be reduced in individual patients if steroid toxicity is significant (e.g., uncontrolled diabetes, psychiatric complications, patient with severe osteoporosis). If the patient has not responded after 12 to 16 weeks, consideration should be given to adherence with corticosteroid treatment or failure of absorption. The latter is unusual unless the patient is vomiting or has diarrhea, in which case some recommend intravenous methylprednisolone, with anecdotal success, although initial treatment with pulse methylprednisolone and lower doses of oral corticosteroid does not seem to be beneficial. A repeat biopsy should be considered in patients failing to respond.

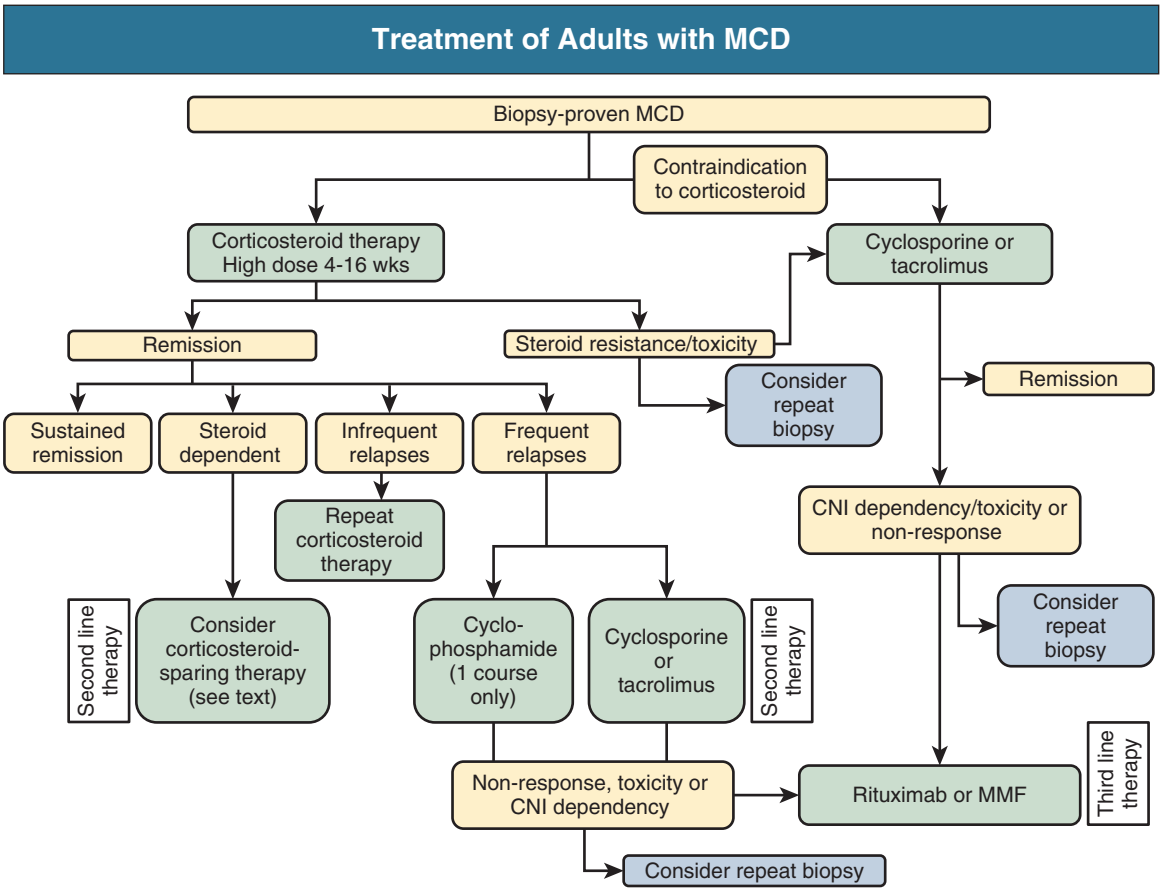

Fig. 17.4 Algorithm for treatment of adult minimal change disease. *CNI,* Calcineurin inhibitor; *MMF,* mofetil mycophenolate.

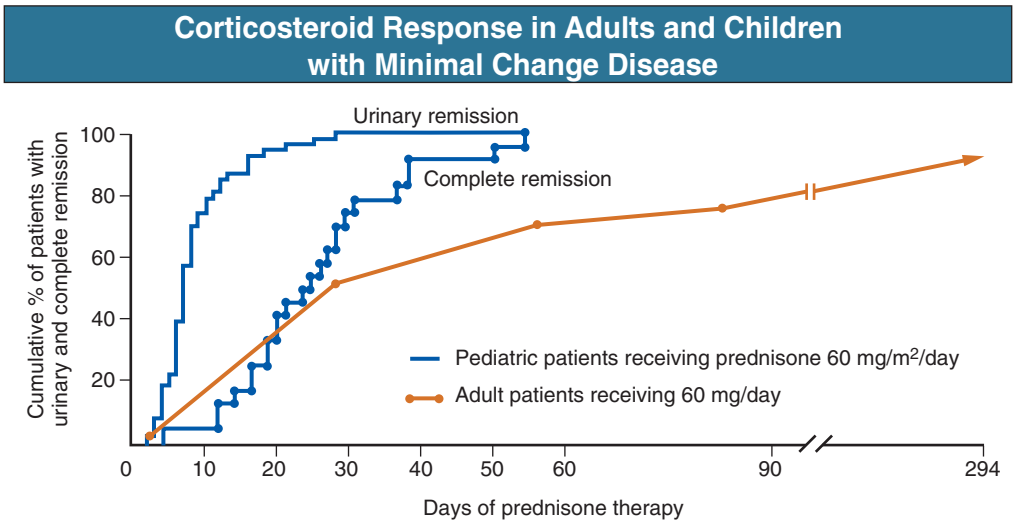

Fig. 17.5 Corticosteroid response in adults and children with minimal change disease (MCD). Adults with nephrotic syndrome and MCD take longer to respond than children and are less likely to remit. *Orange line* shows the cumulative percentage of adults with complete remission (i.e., reduction of proteinuria ≤0.2 g/day and serum albumin concentration >35 g/l). *Blue lines* show the cumulative percentage of pediatric patients with urinary remission and with complete remission.

Infrequent relapses should be treated in the same way as the initial presentation, but there is even less evidence that a prolonged course of corticosteroids is beneficial in reducing the frequency of subsequent relapse. Therefore steroid tapering can start a week after remission, with a taper to finish over 4 to 6 weeks, although this is not evidence based.

Frequently Relapsing and Corticosteroid-Dependent Minimal Change Disease

Adults relapse less often than children (30% to 50%). Relapse may occur in up to 40% of adults who had MCD in childhood.[50] As in children, some adults have transient non-nephrotic relapses, so it is

important to establish that a full relapse has developed with persistent heavy proteinuria, a low albumin level, and fluid retention before recommencing steroids. Frequently relapsing and corticosteroid-dependent patients should receive second-line therapy with cyclophosphamide or cyclosporine, but the timing of this decision will vary between physicians and patients. Many factors will influence the decision to abandon repeated corticosteroid courses, including steroid toxicity and tolerance and level of steroid dependence; 5 to 10 mg/day may be acceptable for several months, but more than 20 mg/day would not. The patient should be involved in the decision after explanation of the relative risks with further courses of corticosteroids and the alternative treatments.

A 12-week course of oral cyclophosphamide 2 to 2.5 mg/kg/day induces a permanent remission more often in adults than children (75% and 66% at 2 and 5 years, respectively).[51] Although there are no satisfactory studies comparing 8-week and 12-week courses in adults, the 12-week course is logical on the basis of the pediatric experience. If this treatment is selected, the opportunity for banking sperm or retrieval of ova should be considered before treatment, although the azoospermia or amenorrhea risk at this dose is low. Intravenous cyclophosphamide has been recommended to limit the cumulative dose: intravenous cyclophosphamide 0.5 g/m^2 per month adjusted upward to 1 g/m^2 on the basis of the leukocyte count after 2 weeks with a target nadir of 3000 cells/mm^3.

Some nephrologists prefer calcineurin inhibitors before cyclophosphamide, especially in younger adults and those who want to maximize future fertility. Cyclosporine 4 to 6 mg/kg/day, aiming for trough whole-blood levels of 50 to 150 ng/ml for at least 12 months, is effective, but relapse usually follows dose reduction or withdrawal. Cyclosporine is a good short- to medium-term management strategy because remission occurs in 50% to 75% of patients.[52] However, careful monitoring is required because nephrotoxicity is common after more than 1 year of therapy.[53]

Tacrolimus has effectiveness similar to that of cyclosporine and may have a more favorable side-effect profile. Initial target levels are 4 to 8 ng/ml, but higher levels may be required to maintain remission. A Chinese randomized trial found in 119 adults with MCD that 10 days of methylprednisolone 0.8 mg/kg/day followed by tacrolimus was as effective as a purely corticosteroid-based first-line therapy and led to fewer adverse events.[54] Thus tacrolimus may be particularly attractive as first- or second-line therapy in patients with contraindications for or intolerance of high-dose corticosteroids.

Several uncontrolled reports suggest that MMF may have a place in management of corticosteroid- and cyclosporine-dependent patients, but more data on efficacy, dosage, and duration of treatment are needed before these could be widely recommended. However, MMF did not appear as efficacious as cyclosporine in controlled trials in children.[40,41]

Rituximab has been reported to induce remission in adults with frequently relapsing disease unresponsive to other treatments, but some caution is needed because RCTs have not been performed. Two nonrandomized studies in adults with corticosteroid-dependent or frequently relapsing MCD suggested that rituximab is beneficial, with an up to 10-fold reduction in annual relapse rate.[55,56] Whether a dosing regimen of 1 or 2 infusions of 1 g rituximab or up to 4 infusions of 375 mg/m^2 is superior, remains to be established.

Minimal Change Disease With Non-Nephrotic Proteinuria

In patients with well-documented MCD who have the rare relapse in which the proteinuria is non-nephrotic, treatment does not require corticosteroids but rather can include angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) therapy. If there is any question as to diagnosis, repeated biopsy may be indicated because other conditions can mimic MCD.

Treatment of Secondary Minimal Change Disease

MCD secondary to NSAIDs requires discontinuation of the offending medication. Many patients are treated with a course of corticosteroids for MCD (higher dose) or for acute interstitial nephritis (see Chapter 60), but evidence of benefit is uncertain. Secondary MCD from Hodgkin disease usually responds to treatment of the lymphoma. Some patients will also receive a drug regimen for MCD as adjunctive therapy in addition to the chemotherapy directed at the tumor in particular if MCD remission does not occur quickly with adequate chemotherapy.

SELF-ASSESSMENT QUESTIONS

1. Which of the following conditions or drugs has *not* been associated with minimal change disease (MCD) in children or adults?
   - **A.** Asthma
   - **B.** Hodgkin disease
   - **C.** Interferon-α
   - **D.** Rhabdomyosarcoma
   - **E.** Eczema
2. Which of the following factors has been implicated in the pathogenesis of nephrotic-range proteinuria in MCD?
   - **A.** CD4
   - **B.** Interleukin-1 (IL-1)
   - **C.** Vascular endothelial growth factor
   - **D.** CD80/B7.1
   - **E.** Hepcidin
3. Which of the following statements regarding the therapy of MCD in adults is correct?
   - **A.** Adults usually achieve remission with relatively low doses of prednisolone (maximum 20 mg every other day).
   - **B.** Good evidence suggests that alternate-day corticosteroids are more effective than daily dosing.
   - **C.** Spontaneous remission is rare.
   - **D.** The total length of corticosteroid therapy should not exceed 1 month.
   - **E.** Patients with infrequent relapses should receive a 12-week course of oral cyclophosphamide (2-2.5 mg/kg/day)

Primary and Secondary (Non-Genetic) Causes of Focal and Segmental Glomerulosclerosis

Gerald B. Appel, Vivette D. D'Agati

Focal segmental glomerulosclerosis (FSGS), a histologic pattern of glomerular injury, defines a number of clinicopathologic syndromes that may be primary (idiopathic) or secondary to diverse causes[1-4] (see Chapter 19). Early in the disease process, the pattern of glomerulosclerosis is focal, involving a minority of glomeruli, and segmental, involving a portion of the glomerular tuft.[4] Alterations of podocyte cytoarchitecture on electron microscopy (EM) are relatively diffuse, underscoring the pathogenetic importance of podocyte injury. As FSGS progresses, more diffuse and global glomerulosclerosis evolves.[4] Although it accounts for only a small percentage of cases of nephrotic syndrome in young children, FSGS represents as many as 35% of cases in adults[1,2] and is a major cause of end-stage renal disease (ESRD) in certain populations.[5]

Diverse pathogenetic mechanisms have been identified and often manifest as particular histologic subtypes of disease. Through podocyte depletion and dysregulation, structural deterioration of the glomerular tuft leads to FSGS as a final common pathway.[4,6] Although primary (idiopathic) FSGS is potentially treatable and curable in many patients, the optimal type and duration of immunosuppressive, as well as adjunctive therapy, remain controversial. For secondary FSGS, effective therapies exist to slow or modify the disease course (see Chapter 79).

ETIOLOGY AND PATHOGENESIS

FSGS represents a common phenotypic expression of diverse clinicopathologic syndromes with distinct causes (Box 18.1). Causes include genetic mutations in podocyte components (see Chapter 19), circulating permeability factors, viral infections, drug toxicities, maladaptive responses to a reduced number of functioning nephrons, and hemodynamic stress placed on an initially normal nephron population. In all these forms of FSGS, injury directed to or inherent within the podocyte is a central pathogenetic mediator.[1,4,6] These injuries promote altered cell signaling, reorganization of the actin cytoskeleton, and resulting foot process effacement. Critical levels of injury cause podocyte depletion through detachment or apoptosis. Stress placed on the remaining podocytes may lead to local propagation of damage (see Chapter 78). Injury to podocytes may spread to adjacent podocytes by reduction in supportive factors such as nephrin signaling, increased toxic factors such as angiotensin II (Ang II), or mechanical strain on remnant podocytes.[6-8] Cell-to-cell spread of podocyte injury until the entire glomerular lobule is captured could explain the characteristic segmental nature of the sclerosing lesions.[7,8]

Minimal Change Disease Versus Focal Segmental Glomerulosclerosis

By definition, the etiology of idiopathic or primary FSGS is unknown. Some clinical data support etiologic factors similar to those at work in minimal change disease (MCD; see Chapter 17). Certain corticosteroid-responsive patients who exhibit MCD on initial biopsy subsequently relapse and display FSGS on repeated biopsy. In some, this may simply represent a sampling error in the initial biopsy. In others with well-documented repeated relapses and responses of the nephrotic syndrome and multiple biopsies over years, FSGS truly appears to have evolved from an initial MCD pattern. Moreover, the pathologic changes in the nonsclerotic glomeruli of idiopathic FSGS resemble glomeruli of MCD.[4] In addition, sequential biopsy samples of recurrent FSGS in the allograft show it may pass through an early stage that mimics MCD.[9] Thus MCD and FSGS are often considered together under the rubric of "podocytopathies."

Both MCD and primary FSGS are thought to be mediated by circulating permeability factors.[10] Recent studies suggested the permeability factors in FSGS and MCD differ and that the diseases can be distinguished using biomarkers. Elevated CD80 (also known as B7-1), a costimulatory factor expressed on podocytes and B cells, is found in the urine of corticosteroid-sensitive MCD[11] but not in FSGS. Angiopoietin-like-4, a podocyte-secreted glycoprotein, is upregulated in podocytes and is elevated in the serum of animal models and patients with MCD.[12] In animal models, induction of urokinase plasminogen activator receptor (uPAR), derived from immature myeloid cells of the bone marrow, produces podocyte effacement, proteinuria, and FSGS.[13,14] In initial studies, patients with primary FSGS were reported to have higher levels of circulating soluble uPAR (suPAR) than equally proteinuric patients with MCD or membranous nephropathy (MN), and treatment-induced reduction in proteinuria was associated with reduction in suPAR levels in patients with FSGS.[13] Moreover, patients with recurrent FSGS in the allograft also had high circulating suPAR levels, which were reduced by plasma exchange in parallel with reductions in proteinuria.[13] However, subsequent studies found that higher suPAR levels correlated with lower glomerular filtration rate (GFR) irrespective of the underlying kidney disease and the induction of proteinuria by suPAR was not confirmed.[15,16] Thus the balance of evidence does not support suPAR as a specific mediator or biomarker of FSGS.

More recently, B7-1 (also known as CD80) has been proposed as a podocyte biomarker and potential therapeutic target in FSGS.[17] Initial studies suggested that abatacept (CTLA4-Ig) bound to induced podocyte B7-1 and led to remission of proteinuria in native kidneys with FSGS and recurrent FSGS in the allograft.[17] However, other investigators have not been able to identify B7-1 expression by podocytes in experimental models of FSGS or human FSGS and could not demonstrate therapeutic efficacy of abatacept in patients with recurrent FSGS in the allograft.[18,19] Given these limitations, podocyte B7-1 expression cannot currently be considered a biomarker or a proven therapeutic target in FSGS.

Alterations in glomerular capillary wall permeability may occur in response to circulating "humoral" substances that act on the podocyte

BOX 18.1 Etiologic Classification of Focal Segmental Glomerulosclerosis

Primary (Idiopathic) FSGS
- Probably mediated by circulating/permeability factor(s)

Secondary FSGS

Familial/Genetic*
- Mutations in nephrin *(NPHS1)*
- Mutations in podocin *(NPHS2)*
- Mutations in α-actinin 4 *(ACTN4)*
- Mutations in transient receptor potential cation channel *(TRPC6)*
- Mutations in Wilms tumor suppressor *(WT1)*
- Mutations in inverted formin-2 *(INF2)*
- Mutations in phospholipase C epsilon 1 *(PLCE1)*
- Risk alleles for apolipoprotein L1 *(APOL1)*

Virus Associated
- HIV-1 (HIV-associated nephropathy)
- Parvovirus B19
- Simian virus 40 (SV40)
- Cytomegalovirus (CMV)

Drug Induced
- Heroin ("heroin-nephropathy")
- Interferon
- Lithium
- Pamidronate
- Sirolimus
- Anabolic steroids
- Tyrosine kinase inhibitors

Mediated by Adaptive Structural-Functional Responses

Reduced Renal Mass
- Oligomeganephronia
- Very low birth weight
- Unilateral renal agenesis
- Renal dysplasia
- Reflux nephropathy
- Sequela to cortical necrosis
- Surgical renal ablation
- Chronic allograft nephropathy
- Any advanced renal disease with reduction in functioning nephrons

Initially Normal Renal Mass
- Hypertension
- Atheroemboli or other acute vaso-occlusive processes
- Obesity
- Increased lean body mass
- Cyanotic congenital heart disease
- Sickle cell anemia

*For complete list of genetic causes see Chapter 19.

to promote foot process effacement. Circulating permeability factors that enhance in vitro permeability of glomeruli to albumin have been found in some FSGS patients. The presence of such permeability factors has been used to predict the recurrence of FSGS in transplanted FSGS patients.[10] Some patients with FSGS with recurrence of nephrotic syndrome after transplantation achieve remissions of nephrotic syndrome after plasma exchange or use of a protein A adsorption column, supporting the role of a circulating factor[1,10,20] (see Chapter 111). However, none of several candidate proteins, including suPAR, B7-1, or cardiotrophin-like cytokine 1 (CLC1), a member of the IL-6 family of interleukins, has been proven to be the permeability factor in human FSGS.[21]

In contrast to MCD, the proteinuria in FSGS is usually nonselective, including albumin and higher-molecular-weight macromolecules. In human FSGS and toxin-induced animal models of FSGS, such as puromycin or doxorubicin (Adriamycin) nephrosis, nonselective proteinuria develops in conjunction with detachment of podocyte foot processes from the glomerular basement membrane (GBM), a finding not seen in MCD.[1,6] The susceptibility gene to doxorubicin toxicity in Balb/c mice has been identified as *PRKDC,* required for double-stranded DNA break repair. Animals deficient in this DNA repair machinery develop mitochondrial DNA depletion after doxorubicin exposure, leading to podocyte cell death and FSGS.[1] This mechanism illustrates how long-lived cells such as podocytes, which lack the ability to repair themselves by cell division, are especially vulnerable to genotoxic stress. In humans, repeated and diverse stresses to the podocyte could explain the development of FSGS pattern of injury in age-related nephrosclerosis and glomerular senescence.[1,6]

Glomerular hypertrophy (or glomerulomegaly) may identify children with MCD at risk for development of FSGS. In early idiopathic FSGS and in many secondary forms of FSGS, such as obesity related, there is initially glomerular hypertrophy and a high GFR, supporting roles for hyperfiltration and increased intracapillary glomerular pressures (glomerular hypertension).[1,21] Similarly, in secondary forms of FSGS with reduced nephron numbers, maladaptive hemodynamic alterations may be associated with glomerular hyperfiltration. Intraglomerular coagulation and abnormalities of lipid metabolism may also contribute to glomerulosclerosis in these patients (see Chapter 78). Although IgM and C3, commonly found in all forms of FSGS, are generally regarded as nonspecifically trapped in areas of sclerosis, recent murine evidence suggests they may actively contribute to glomerular injury through activating complement and binding antigens.[22,23] Recent studies document both reparative and sclerosing roles for parietal epithelial cells in FSGS. In vivo microscopy has illustrated the ability of parietal cells to rapidly cover sites of podocyte denudation and depletion in FSGS, but there is limited contribution to podocyte regeneration.[24,25] They also may directly contribute to glomerulosclerosis by migrating onto the glomerular tufts and synthesizing extracellular matrix proteins, as shown in both animal models and human biopsy samples with forms of primary and secondary FSGS.[1,26]

Genetic Variants of Focal Segmental Glomerulosclerosis

Genetic and familial forms of FSGS are covered in detail in Chapter 19. Many cases of apparently primary FSGS may harbor unidentified mutations or polymorphisms in podocyte genes that go unrecognized because of lack of genetic testing. In primary FSGS, a genetic predisposition may underlie the susceptibility to a "second hit," whereby viral factors or other immune stimuli lead to the initiation of disease. Mutations in podocyte genes also may predispose to FSGS induced by such secondary causes as obesity, systemic hypertension, and infectious agents, allowing multifactorial podocyte stress. For example, genetic studies have identified *APOL1* gene variants, encoding for apolipoprotein L-1, as a major predisposing factor for FSGS, as well as for HIV nephropathy, chronic hypertensive nephrosclerosis, and progressive lupus nephritis among African Americans.[27] G1 and G2 mutations in *APOL1* are

protective against infection by *Trypanosoma brucei,* the parasite that causes African sleeping sickness. Similar to the gene for sickle cell disease, which confers selective advantage against malaria, this genetic mutation became prevalent in a population because it was protective against an infectious pathogen. Although *APOL1* is expressed by glomerular endothelial cells and podocytes, it is not entirely clear how sequence variations in *APOL1* mechanistically cause glomerulosclerosis.[28] In vitro studies have proposed increased podocyte membrane pores promoting intracellular potassium depletion and induction of stress-activated protein kinases.[29] A recent podocyte-specific inducible transgenic model of *APOL1*-associated FSGS suggests impairment of podocyte endocytic functions and autophagy.[30]

Viral Induction of Focal Segmental Glomerulosclerosis

Although a number of studies have noted a relationship between prior viral infection with parvovirus or other viruses and FSGS, in particular collapsing FSGS, these data have not been consistent.[31] By contrast, the role of HIV infection in the pathogenesis is well established (see Chapter 56).

Drug-Induced Focal Segmental Glomerulosclerosis

A number of drugs and medications have been associated with the FSGS phenotype, including heroin, lithium, pamidronate, sirolimus, calcineurin inhibitors, tyrosine kinase inhibitors, and interferons α, β, and γ[1,32,33] (see Box 18.1). Heroin has been associated with the nephrotic syndrome and FSGS (heroin nephropathy), although its incidence has diminished markedly in the modern era. Pamidronate, a bisphosphonate used to prevent bone resorption in myeloma and metastatic tumors, has been associated with both collapsing FSGS and MCD.[33] Stabilization of renal function and resolution of nephrotic syndrome may follow withdrawal of the offending medication (e.g., interferon, heroin, pamidronate). Long-term anabolic steroid abuse among bodybuilders has been associated with the development of FSGS.[34] Many of these individuals also consume high-protein diets and potentially injurious supplements, including growth hormone. Putative mechanisms of glomerular injury include direct toxic effects of anabolic steroids on glomerular cells, as well as adaptive responses to a very elevated lean body mass.[34] Patients who develop FSGS secondary to interferon therapy have been shown to carry double *APOL1* risk alleles and to activate a viral innate immunity program in podocytes upon interferon exposure, supporting a two-hit model of podocyte injury.[35]

Structural Maladaptation Leading to Focal Segmental Glomerulosclerosis

Many secondary forms of FSGS are mediated by adaptive structural-functional responses.[1,2,4] These adaptive forms include patients with both congenital and acquired reduction in the number of functioning nephrons, whereas other secondary forms are associated with hemodynamic stress placed on an initially normal nephron population (see Box 18.1). Obesity-related glomerulopathy (ORG), is increasingly common worldwide and may be associated with metabolic syndrome, including hypertension, diabetes, and hyperlipidemia. In most studies obesity has been defined by a body mass index (BMI) greater than 30 kg/m^2, although some Chinese studies have used a definition of greater than 28 kg/m^2. ORG usually lacks the full nephrotic syndrome and has a low risk for progression to ESRD.[21] Secondary FSGS resembling ORG in nonobese, highly muscular body builders may be mediated in part by hyperfiltration as well as direct podocyte effects of anabolic steroids.[34] Low birth weight associated with prematurity and reduced nephron endowment also may lead to glomerular hypertrophy, with secondary FSGS developing in adolescence or adulthood.[36] Biopsy specimens with secondary adaptive FSGS typically show glomerulomegaly and perihilar lesions of segmental sclerosis and hyalinosis. These conditions resemble experimental models of renal ablation in which the surgical reduction in renal mass causes functional hypertrophy of remnant nephrons with increased glomerular plasma flows and pressures. Whereas these changes are initially "adaptive," the resultant hyperfiltration and increased glomerular pressure become "maladaptive" and serve as mechanisms for progressive glomerular damage.[4,6]

Pathogenesis of Progressive Renal Failure in Focal Segmental Glomerulosclerosis

Although much attention has been focused on the pathogenesis of proteinuria in FSGS, the segmental and eventual global glomerulosclerosis in association with interstitial fibrosis and tubular atrophy clearly underlie the progression to renal failure. Podocytes in some forms of FSGS, such as the collapsing variant, display a dysregulated phenotype with dedifferentiation, proliferation, and apoptosis.[37] Such biopsy samples have altered podocyte expression of cell cycle–related proteins.[38] In renal biopsy specimens of patients with FSGS, the expression levels of transforming growth factor (TGF) β1, thrombospondin-1, and TGF-β2 receptor proteins are all increased, as are podocyte markers of the phosphorylated Smad2/Smad3 signaling pathway.[38] Reduction in vascular endothelial growth factor synthesis after podocyte loss and increased parietal cell coverage may contribute to capillary collapse. Thus pathways that promote podocyte depletion and overproduction of extracellular matrix (ECM) converge to produce a sclerosing phenotype.

EPIDEMIOLOGY

There is a large variability in the frequency of various primary glomerular diseases between different geographic and among racial populations.[1,2,39,40] The exact reasons for these differences may be multifactorial (e.g., bias in referral patterns and who undergoes biopsy, environmental or racial predispositions such as the presence of *APOL1* genetic variants in people of African descent). Some studies of renal biopsies show an increasing prevalence of FSGS in both adults and children in a number of countries on different continents.[1,2,40] For example, in Brazil, FSGS is the most common primary renal disease.[1,2] In the United States, one study found FSGS to be the most common lesion in adults with idiopathic nephrotic syndrome.[40] An analysis of the prevalence of ESRD in the United States caused by FSGS during a 21-year period shows an increase from 0.2% in 1980 to 2.3% in 2000, and FSGS is the most common primary glomerular disease leading to ESRD.[1,2,5] Although some changes in prevalence may relate to changes in biopsy practice or disease classification, the true frequency of FSGS has likely increased over time.

Primary FSGS is slightly more common in males than females, and the incidence of ESRD secondary to FSGS in males of all races is 1.5 to 2 times higher than in females. The incidence in both children and adults is higher in African Americans than in Whites and those of Asian descent.[1,3] This most likely relates to the presence of G1 and G2 variants of the apolipoprotein L1 genes in African Americans.[27,41] In the United States, FSGS is the most common cause of idiopathic nephrotic syndrome in adult African Americans.[1,2,40,41] African Americans have a fourfold greater risk for ESRD from FSGS than Whites. Even in an almost entirely White U.S. population, a clear increase in the incidence of FSGS has been documented over a 30-year period,[42] whereas this has not been the case in some White populations in Europe.[43]

CLINICAL MANIFESTATIONS

Patients with primary FSGS can present with asymptomatic proteinuria or the full nephrotic syndrome.[1-3] In some countries where routine medical checks are more common, 10% to 30% of children with

asymptomatic proteinuria are detected in school and sports physical examinations; in adults, asymptomatic detection occurs at military induction examinations, obstetric checkups, and insurance or employment physical examinations. The incidence of nephrotic-range proteinuria at onset in children is 70% to 90%, whereas only 50% to 70% of adults with FSGS present with nephrotic syndrome. Secondary forms of FSGS associated with hyperfiltration typically have lower levels of proteinuria, and many such patients have subnephrotic proteinuria and a normal serum albumin concentration.[1-3,21]

Hypertension is found in 30% to 65% of children and adults with FSGS at diagnosis. Microhematuria is found in 30% to 75% of these patients, and a decreased GFR is noted at presentation in 20% to 50%.[1-3] Daily urinary protein excretion ranges from less than 1 to more than 30 g/day. Proteinuria is typically nonselective. Complement levels and other serologic test results are normal. Occasional patients will have glycosuria, aminoaciduria, phosphaturia, or a concentrating defect indicating functional tubular damage and glomerular injury.

Different histologic patterns of FSGS may display different clinical features. Patients with the tip variant of FSGS have clinical features more similar to those of MCD.[44] They often present with an abrupt clinical onset of the full nephrotic syndrome (almost 90%), shorter time course from onset to renal biopsy, more severe proteinuria, and less chronic tubulointerstitial disease than in FSGS not otherwise specified (NOS).[44,45] The cellular variant also typically manifests with greater proteinuria and higher incidence of nephrotic syndrome than FSGS NOS.[46] The collapsing variant usually manifests with greater proteinuria, more full-blown nephrotic syndrome, and lower GFR.[45-48]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

With the exception of genetic forms of FSGS, it is impossible to establish a firm diagnosis without a renal biopsy. Tests for permeability factors are neither reliable nor available in routine clinical practice. In children with FSGS, most of whom present with nephrotic syndrome, the major differential is between MCD and other variants of corticosteroid-resistant nephrotic syndrome. In adults with subnephrotic proteinuria, the differential includes almost all glomerular diseases without positive serologic results. In adults with nephrotic syndrome, MN and MCD may present in an identical manner, and only a renal biopsy will clarify the diagnosis. Focal sclerosing lesions caused by other glomerulopathies (e.g., segmental scarring from chronic glomerulonephritis) must be excluded pathologically. Moreover, because the defining glomerular lesion of FSGS is focal and may be confined to deeper juxtamedullary glomeruli early in the disease, it may not be sampled on renal biopsy. A large glomerular sample of more than 20 glomeruli for light microscopy increases the likelihood of identifying the diagnostic segmental lesions.

Even after the diagnosis of FSGS is established, the primary (idiopathic) form must be distinguished from secondary forms by careful clinicopathologic correlation (see Box 18.1). In general, many forms of adaptive FSGS have lower levels of proteinuria than primary FSGS, a lower incidence of hypoalbuminemia, and, on biopsy, lesser degrees of foot process effacement. In patients younger than 25 years and especially in those with a family history of FSGS, genetic screening for mutations in podocin, TRPC6, α-actinin-4, inverted formin 2, or other podocyte genes may be useful (see Chapter 19). However, in adults with sporadic FSGS genetic testing is currently not recommended given a very low detection rate of pathogenetic mutations.

PATHOLOGY

The pathologic manifestations of FSGS are heterogeneous, both qualitatively and with respect to the location of lesions within the glomerular tuft.[1,4] A classification of FSGS by histologic variants (Box 18.2) can be applied to both primary and secondary forms of FSGS (see Box 18.1).[49] Subtypes include *classic,* or NOS; *perihilar* variant, in which more than 50% of glomeruli with segmental lesions display hyalinosis and sclerosis involving the vascular pole region; *cellular* variant, manifesting endocapillary hypercellularity; *collapsing* variant, in which at least one glomerulus has global collapse and overlying visceral cell hypertrophy and hyperplasia; and *tip* variant, with segmental lesions involving the tubular pole. This working classification has been applied successfully to retrospective and prospective biopsy series. Other, more controversial histologic variants of FSGS include FSGS with diffuse mesangial hypercellularity and C1q nephropathy (see Chapter 28). Some think these are distinct disease entities, whereas others think they are merely subgroups of FSGS.[50,51]

BOX 18.2 Morphologic Variants of Focal Segmental Glomerulosclerosis

- FSGS, not otherwise specified (NOS; also known as classic FSGS)
- FSGS, perihilar variant
- FSGS, cellular variant
- FSGS, collapsing variant (also known as collapsing glomerulopathy)
- FSGS, tip variant

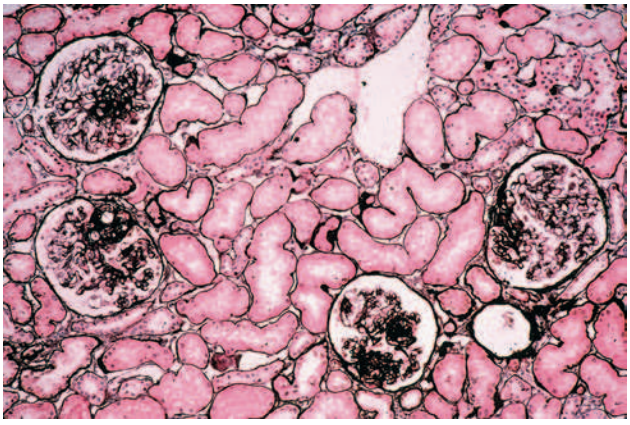

Fig. 18.1 Focal segmental glomerulosclerosis, not otherwise specified (FSGS NOS). A low-power view shows four glomeruli with discrete lesions of segmental sclerosis involving a portion of the tuft. The adjacent nonsclerotic capillaries are unremarkable. In this example, there is no evidence of tubulointerstitial injury. (Jones methenamine silver stain; magnification ×100.)

Classic Focal Segmental Glomerulosclerosis (FSGS Not Otherwise Specified)

FSGS NOS is the common generic form of the disease. FSGS NOS requires exclusion of the more specific subtypes described later. It is defined by accumulations of ECM that occlude glomerular capillaries, forming discrete segmental solidifications (Fig. 18.1).[49] There may be hyalinosis (plasmatic insudation of amorphous glassy material beneath the GBM), endocapillary foam cells, and wrinkling of the GBM (Fig. 18.2). Adhesions or synechiae to the Bowman capsule are common, and overlying visceral epithelial cells often appear swollen and form a cellular "cap" over the sclerosing segment. Glomerular lobules unaffected by segmental sclerosis appear normal on light microscopy, except for mild podocyte swelling. Tubular atrophy and interstitial fibrosis are commensurate with the degree of glomerulosclerosis. Immunofluorescence

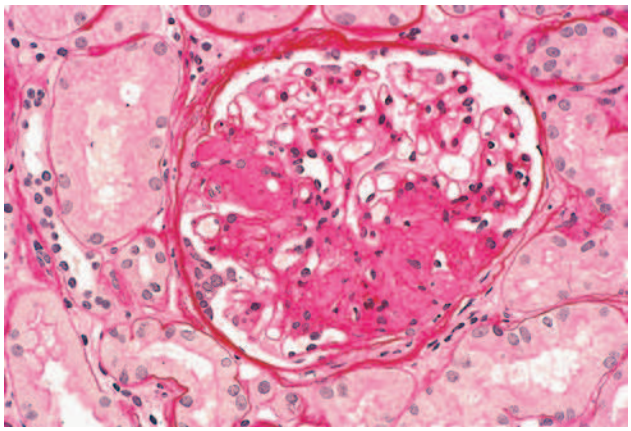

Fig. 18.2 Focal segmental glomerulosclerosis, not otherwise specified. The lesions of segmental sclerosis display increased extracellular matrix and hyalinosis. There is adhesion to the Bowman capsule without significant podocyte hypertrophy. The nonsclerotic capillaries have glomerular basement membranes of normal thickness and mild podocyte swelling. (Periodic acid–Schiff [PAS] reaction; ×400.)

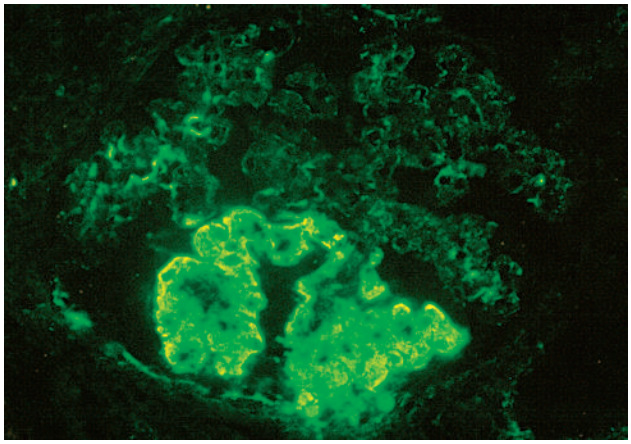

Fig. 18.3 Focal segmental glomerulosclerosis, not otherwise specified. The lesions of segmental sclerosis contain deposits of immunoglobulin M (IgM) corresponding to areas of increased matrix and hyalinosis. Weaker staining for IgM is also seen in the adjacent mesangium. (Immunofluorescence micrograph; ×400.)

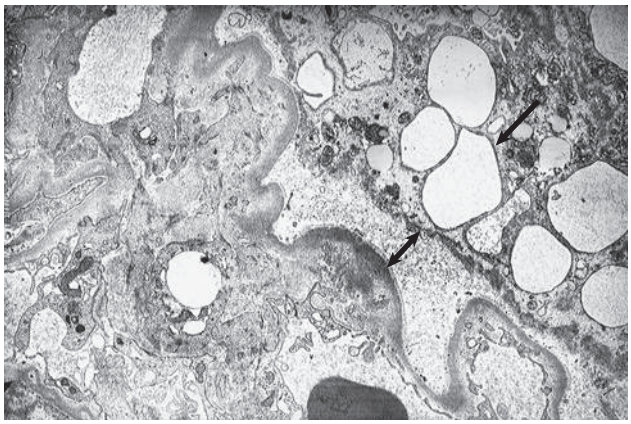

Fig. 18.4 Focal segmental glomerulosclerosis, not otherwise specified. Electron micrograph illustrates the lesion of segmental sclerosis with obliteration of the glomerular capillaries by increased extracellular matrix with wrinkled and retracted glomerular basement membranes. The overlying podocytes are detached, with complete effacement of foot processes *(double-headed arrow)* and numerous electron-lucent intracellular transport vesicles *(arrow)*. (×2500.)

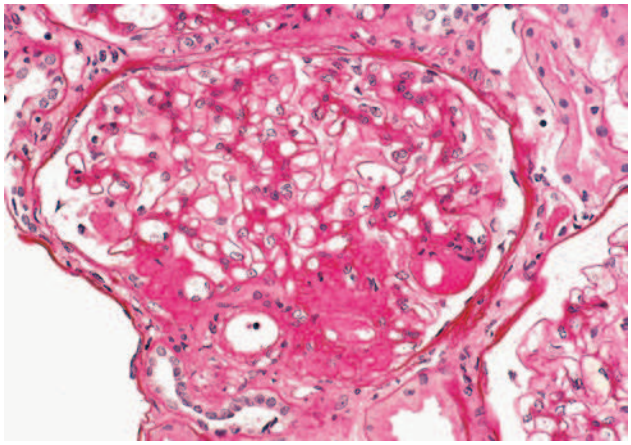

Fig. 18.5 Focal segmental glomerulosclerosis (FSGS), perihilar variant. A discrete lesion of segmental sclerosis and hyalinosis is located at the glomerular vascular pole (i.e., perihilar). The glomerulus is hypertrophied. The patient had secondary FSGS in the setting of solitary kidney as a result of contralateral renal agenesis. (PAS; ×250.)

(IF) typically reveals focal and segmental granular deposition of immunoglobulin M (IgM), C3, and more variably C1q in the distribution of the segmental glomerular sclerosis (Fig. 18.3). On EM, segmental sclerotic lesions exhibit increased ECM, wrinkling and retraction of the GBM, accumulation of inframembranous hyaline, and resulting narrowing or occlusion of the glomerular capillary lumina (Fig. 18.4). No electron-dense deposits are found. Overlying the segmental sclerosis, there is often podocyte detachment with parietal cell coverage. The adjacent nonsclerotic glomerular capillaries show foot process effacement with variable microvillous transformation (slender projections resembling villi along the surface of podocytes). This is the most frequent variant and may occur in primary or secondary forms of FSGS, including genetic forms.

Perihilar Variant of Focal Segmental Glomerulosclerosis

The perihilar variant is defined as perihilar hyalinosis and sclerosis involving more than 50% of glomeruli with segmental lesions.[49] This category requires exclusion of the cellular, tip, and collapsing variants. Podocyte hyperplasia is uncommon. Although the perihilar variant may occur in primary FSGS, it is particularly frequent in secondary forms of FSGS mediated by adaptive structural-functional responses, accompanied by glomerular hypertrophy (glomerulomegaly) and relatively mild foot process effacement (Fig. 18.5). In this setting, reflex dilation of the afferent arteriole and the greater filtration pressures at the proximal end of the glomerular capillary bed may favor the development of lesions at the vascular pole.[1,4,21]

Cellular Variant of Focal Segmental Glomerulosclerosis

The cellular variant is characterized by focal and segmental endocapillary hypercellularity that may mimic a form of focal proliferative glomerulonephritis.[46,49] Glomerular capillaries are segmentally occluded by endocapillary hypercellularity, including foam cells, infiltrating leukocytes, karyorrhectic debris, and hyaline (Fig. 18.6). There is often hyperplasia of the visceral epithelial cells, which may appear swollen, sometimes forming pseudocrescents. Foot process effacement is typically severe. This variant requires that tip lesions and collapsing lesions

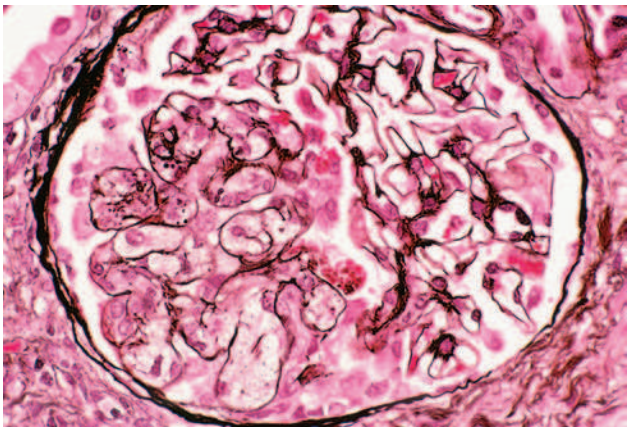

Fig. 18.6 Focal segmental glomerulosclerosis, cellular variant. The glomerular capillary lumina are segmentally occluded by endocapillary cells, including foam cells, infiltrating mononuclear leukocytes, and pyknotic debris. The findings mimic a proliferative glomerulonephritis because of the hypercellularity and absence of extracellular matrix material. There are hypertrophy and hyperplasia of the overlying visceral epithelial cells, some of which contain protein resorption droplets. (Jones methenamine silver; ×400.)

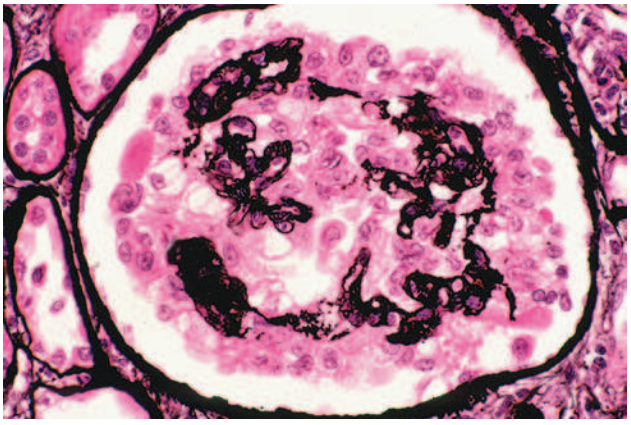

Fig. 18.7 Focal segmental glomerulosclerosis, collapsing variant. There is global implosive collapse of the glomerular tuft with obliteration of capillary lumina. The overlying visceral epithelial cells appear hypertrophied and hyperplastic with enlarged nuclei and nucleoli. There are no adhesions to the Bowman capsule. (Jones methenamine silver; ×400.)

be excluded. Cellular FSGS is thought to represent an early stage in the development of segmental lesions and is usually primary.

Collapsing Variant of Focal Segmental Glomerulosclerosis

The collapsing variant is defined by at least one glomerulus with segmental or global collapse and overlying hypertrophy and hyperplasia of visceral epithelial cells (Fig. 18.7). In these areas, there is occlusion of glomerular capillary lumina by implosive GBM wrinkling and collapse.[47-49] The collapsing lesion is more often global than segmental. Overlying visceral epithelial cells display hypertrophy and hyperplasia and express proliferation markers. Glomerular epithelial cells often contain prominent intracytoplasmic protein resorption droplets and may fill the Bowman space, forming pseudocrescents (Figs. 18.8 and 18.9). Although visceral cell hyperplasia is found in both the collapsing and the cellular variant of FSGS, collapsing glomerulopathy is distinguished by the absence of endocapillary hypercellularity. Studies suggest that dysregulated podocytes, activated parietal cells (expressing claudin

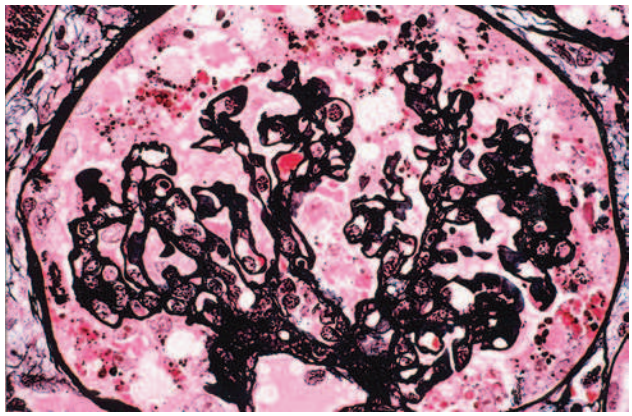

Fig. 18.8 Focal segmental glomerulosclerosis, collapsing variant. In this example, exuberant proliferation of glomerular epithelial cells forms a pseudocrescent that obliterates the urinary space. The pseudocrescent lacks the spindle cell morphology, ruptures of the Bowman capsule, or pericellular matrix typically seen in true inflammatory crescents of parietal epithelial origin. (Jones methenamine silver; ×400.)

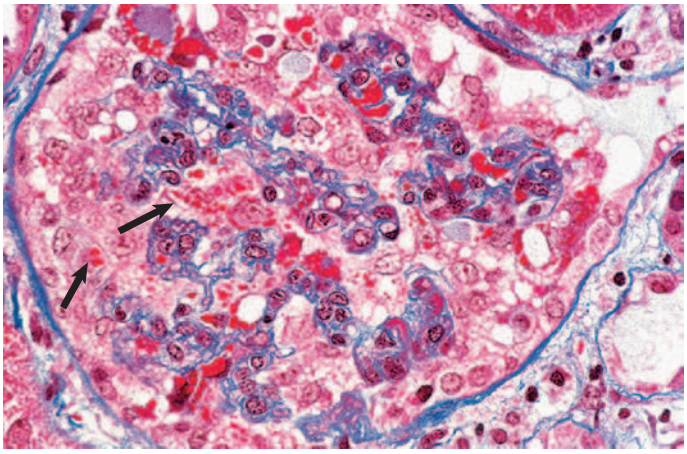

Fig. 18.9 Focal segmental glomerulosclerosis, collapsing variant. The crescent-like proliferation of glomerular epithelial cells contains numerous intracytoplasmic vacuoles and trichrome-red protein resorption droplets *(arrows)*. (Masson trichrome; ×400.)

and CD44), and progenitor cells (expressing stem cell markers CD133 and CD24) that line the Bowman capsule contribute to the glomerular epithelial cell hyperplasia and glomerulosclerosis.[4,6,37,52]

In collapsing FSGS, there is prominent tubulointerstitial disease, including tubular atrophy, interstitial fibrosis, interstitial edema, and inflammation. A distinctive feature is the presence of dilated tubules forming microcysts that contain proteinaceous casts. On EM, there is typically severe foot process effacement affecting both collapsed and noncollapsed glomeruli (Fig. 18.10). Collapsing glomerulopathy may occur as a primary form of FSGS.[1,47] It is also frequently observed in secondary FSGS caused by HIV infection, parvovirus B19 infection, lupus podocytopathy, hemophagocytic syndrome, interferon therapy, tyrosine kinase inhibitor use, or pamidronate toxicity[1,2,31-33] (Fig. 18.11). The presence of endothelial tubuloreticular inclusions helps identify collapsing glomerulopathy secondary to HIV-associated nephropathy, lupus podocytopathy, or interferon therapy.

Tip Variant of Focal Segmental Glomerulosclerosis

The tip variant is defined by the presence of at least one segmental lesion involving the tip domain, the outer 25% of the tuft next to the

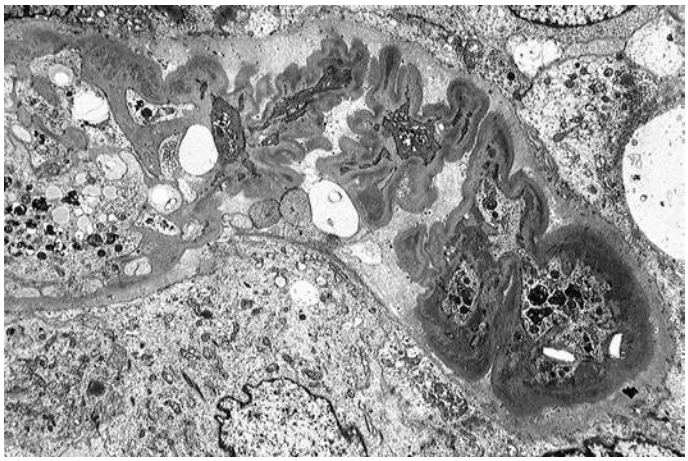

Fig. 18.10 Focal segmental glomerulosclerosis, collapsing variant. On electron microscopy, there is tight collapse of the glomerular capillaries with corrugated glomerular basement membrane. The overlying visceral epithelial cells appear detached and hypertrophied, with complete loss of foot processes. (×2500.)

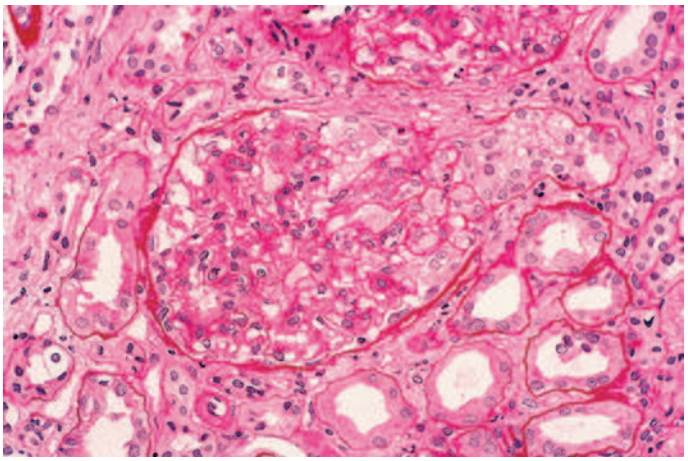

Fig. 18.12 Focal segmental glomerulosclerosis, tip lesion variant. A cellular tip lesion displays engorgement of glomerular capillaries by foam cells and adhesion of the involved segment to the origin of the proximal tubule (tubular pole). (PAS; ×250.)

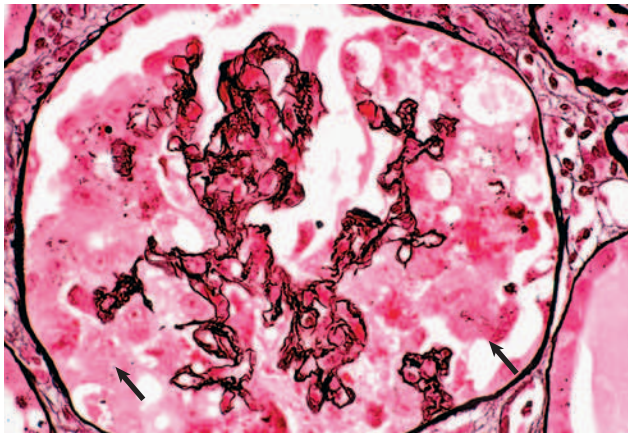

Fig. 18.11 Focal segmental glomerulosclerosis, collapsing variant, from pamidronate toxicity. The glomerular tuft is retracted, without appreciable increase in matrix material. The overlying visceral epithelial cells are enlarged and hyperplastic *(arrows),* with numerous intracytoplasmic vacuoles and protein resorption droplets. (Jones methenamine silver; ×400.)

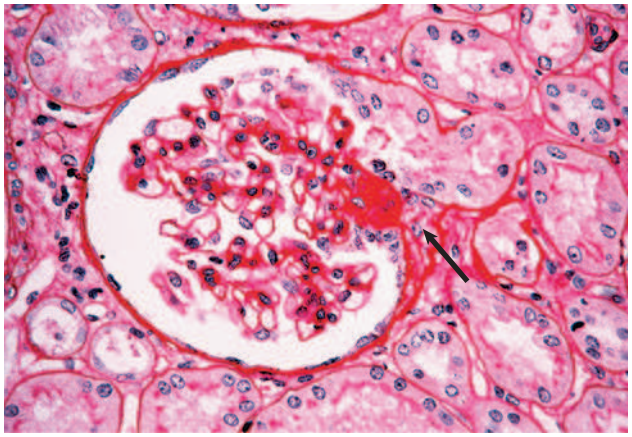

Fig. 18.13 Focal segmental glomerulosclerosis, tip lesion variant. A sclerosing tip lesion forms an adhesion to the tubular pole *(arrow).* (PAS; ×250.)

origin of the proximal tubule.[44,45,49] There is either adhesion between the tuft and Bowman capsule or confluence of swollen podocytes with parietal or tubular epithelial cells at the tubular lumen or neck. The segmental lesions may be cellular or sclerosing (Figs. 18.12 and 18.13). These lesions may evolve more centrally. The presence of perihilar sclerosis or collapsing sclerosis rules out the tip variant. In one study of FSGS tip lesions, biopsy specimens had glomerular tip lesions alone in 26% and glomerular tip lesions plus other peripheral FSGS lesions in the other 74%.[44] The degree of foot process effacement is usually severe. Most cases are primary and resemble MCD clinically. Higher shear stress and tuft prolapse at the tubular pole are likely to play a role in the morphogenesis of this lesion.[4]

Other Variants of Focal Segmental Glomerulosclerosis

Two histologic variants often included within the FSGS spectrum are FSGS with diffuse mesangial hypercellularity and C1q nephropathy (see Chapter 28).[1,50,51] FSGS with *diffuse mesangial hypercellularity* has lesions of FSGS on a background of generalized hypercellularity. By IF, there is diffuse mesangial positivity for IgM, with more variable mesangial staining for C3. EM reveals extensive foot process effacement without glomerular electron-dense deposits. This variant occurs almost exclusively in young children.

C1q nephropathy is defined by dominant or codominant IF staining for C1q, mesangial electron-dense deposits, and light microscopic findings resembling FSGS or MCD with variable mesangial hypercellularity. In one study, 17 patients had a light microscopic appearance of FSGS (including six collapsing and two cellular) and three of MCD.[50] In addition to C1q staining, biopsy specimens may show deposition of other immunoglobulins (particularly IgG) and complement components (C3), making it important to exclude other clinical disease such as lupus nephritis. In C1q nephropathy, electron-dense deposits are typically located in the paramesangial region subjacent to the GBM reflection. There is variable foot process effacement. The largest series of C1q nephropathy supports that many cases represent a subgroup of primary FSGS or MCD, whereas others are an idiopathic immune complex–mediated glomerulonephritis.[51]

Distinguishing Pathologic Features of Secondary Focal Segmental Glomerulosclerosis

Although the pathology of some secondary forms of FSGS resembles closely that of primary FSGS, there are several noteworthy differences.

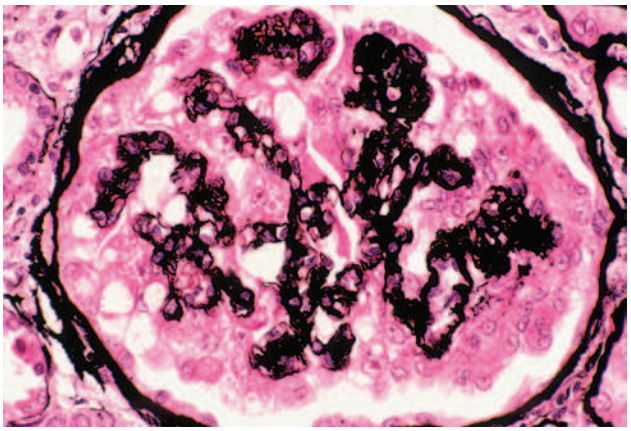

Fig. 18.14 HIV-associated nephropathy. A globally collapsed glomerulus shows marked visceral cell hypertrophy and hyperplasia. (Jones methenamine silver; ×400.)

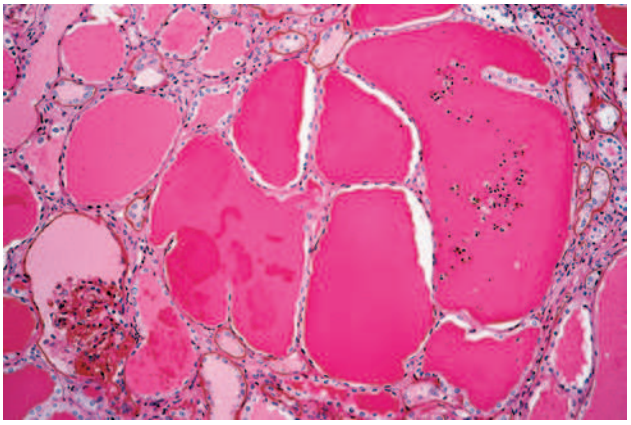

Fig. 18.15 HIV-associated nephropathy. At low power, the renal parenchyma contains abundant tubular microcysts with proteinaceous casts. The glomerulus is collapsed with dilated urinary space. (PAS; ×80.)

Whereas the light microscopic findings in HIV-associated nephropathy are similar to those of primary collapsing FSGS (Fig. 18.14), tubular microcysts are particularly common (Fig. 18.15). On EM, a major difference is the abundance of tubuloreticular inclusions in the glomerular endothelial cells of HIV-associated nephropathy. These "interferon footprints" consist of 24-nm interanastomosing tubular structures located within dilated cisternae of endoplasmic reticulum (Fig. 18.16). Tubuloreticular inclusions have become less frequent in patients treated with antiretroviral therapy.[53]

In secondary adaptive forms of FSGS, renal biopsy typically shows glomerulomegaly and predominantly perihilar lesions of segmental sclerosis and hyalinosis. In secondary FSGS resulting from loss of renal mass, such as from reflux nephropathy or hypertensive arteriosclerosis, FSGS is usually seen on a background of extensive global glomerulosclerosis, tubular atrophy, interstitial fibrosis, and arteriosclerosis. In secondary FSGS related to sickle cell disease, glomerular hypertrophy and sclerosis are associated with capillary congestion by sickled erythrocytes and double contours of the GBM resembling those seen in chronic thrombotic microangiopathy. Importantly, in adaptive forms of FSGS, the degree of foot process effacement tends to be relatively mild, affecting less than 50% of the total glomerular capillary surface area, with correspondingly shorter foot process width (Fig. 18.17). In one study, a cutoff of more than 1500 nm for mean foot process width was able to distinguish primary from adaptive FSGS.[54]

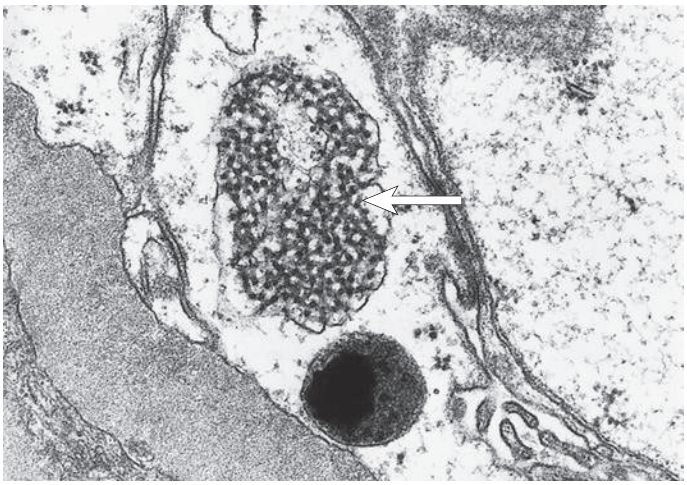

Fig. 18.16 HIV-associated nephropathy. The glomerular endothelial cell pictured here contains a large intracytoplasmic tubuloreticular inclusion ("interferon footprint"; *arrow*) composed of interanastomosing tubular structures within a dilated cisterna of endoplasmic reticulum. (Electron micrograph; ×15,000.)

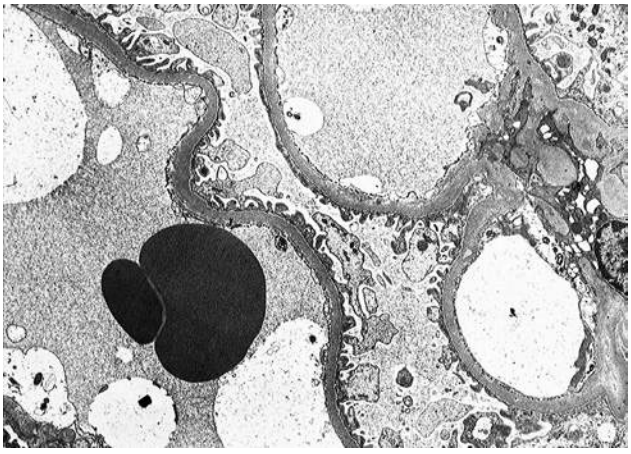

Fig. 18.17 Secondary focal segmental glomerulosclerosis (FSGS) from obesity. This patient with morbid obesity had glomerular hypertrophy and predominantly perihilar lesions of segmental sclerosis and hyalinosis on light microscopy. The foot processes show mild effacement involving approximately 20% of the glomerular capillary surface area despite the presence of nephrotic-range proteinuria. This mild degree of foot process effacement is less than that usually seen in primary FSGS. (Electron micrograph; ×2500.)

NATURAL HISTORY AND PROGNOSIS

The natural history of FSGS is varied.[31] Without response to therapy, the majority of patients with primary FSGS experience a progressive increase in proteinuria and progression to renal failure. Although some untreated patients undergo a spontaneous remission of proteinuria,[1,2] most unresponsive children and adults have a similar course and develop ESRD 5 to 20 years from presentation, with approximately 50% of such patients reaching ESRD by 10 years[1,2,55-57] (Fig. 18.18).

Certain epidemiologic, clinical, and histologic findings at diagnosis help predict the long-term course of patients with FSGS[1-3] (Box 18.3). Even after controlling for severity of proteinuria, hypertension, and other features, African Americans with FSGS experience a more rapid progression to ESRD than people of other races. At biopsy, reduced GFR, greater degrees of proteinuria, and greater degrees of interstitial

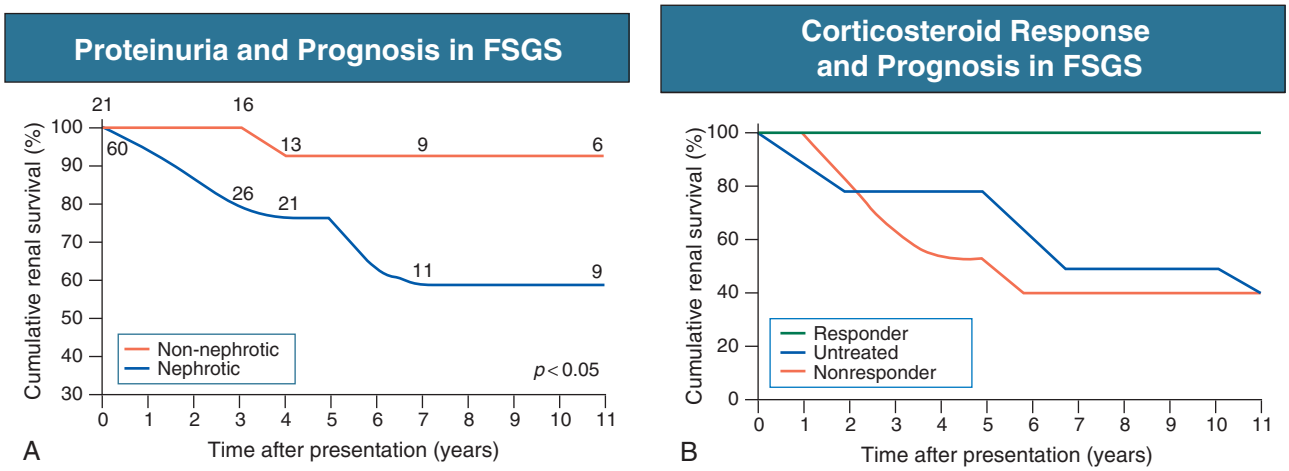

Fig. 18.18 Prognosis in primary focal segmental glomerulosclerosis (FSGS). (A) The risk for development of renal failure is related to the extent of proteinuria. Those with nephrotic-range proteinuria are much more likely to develop renal failure than those with low-grade proteinuria. The figures indicate the number of at-risk patients at different time points. (B) Corticosteroid-responsive patients are significantly less likely to develop renal failure than nonresponders and untreated patients. (Modified from reference 73.)

BOX 18.3 Risk Factors for Progressive Renal Disease in Focal Segmental Glomerulosclerosis

Clinical Features at Biopsy
- Severity of nephrotic-range proteinuria
- Elevated serum creatinine
- Black race

Histopathologic Features at Biopsy
- Collapsing variant
- Tubulointerstitial fibrosis

Clinical Features During Disease Course
- Failure to achieve partial or complete remission

fibrosis predict a more progressive course.[1,2,56] The degree of glomerulosclerosis has been much less consistent as a prognostic finding. Patients who experience a remission of proteinuria and the nephrotic syndrome have much better renal survival than those who do not.[1-3,48,57] Even patients with a partial remission of nephrotic syndrome have a lower rate of long-term renal failure.[57]

In general, outcomes are best for tip variant and worst for collapsing variant of primary FSGS, with intermediate outcome in FSGS NOS.[1,2,45,46] These differences held true even in a cohort of children and young adults with initially corticosteroid-resistant FSGS.[56] In a comparative series, the percentage of complete and partial remission was greatest for tip lesion (76%), lowest for collapsing variant (13%), and intermediate for cellular (44%) and FSGS NOS (39%).[46] There was a strong inverse correlation between remission rates and progression to ESRD among these subgroups. Accordingly, the likelihood of ESRD was greatest for collapsing variant (65%), lowest for tip lesion (6%), and intermediate for cellular variant (28%) and FSGS NOS (35%).[46] Although collapsing variant has the worst outcome among the FSGS variants, when patients with collapsing variant are matched with patients with FSGS NOS for baseline levels of renal function, proteinuria, and immunosuppression, responses to treatment are similar, highlighting the importance of early detection and aggressive therapy.[48]

TREATMENT

There is considerable debate about the appropriate treatment of patients with primary FSGS[1-3,59,60] (Fig. 18.19). In part, this relates to confusion between primary and secondary forms of the disease, including unrecognized genetic variants. Even after biopsy, it is not always clear whether an obese person with glomerulomegaly, FSGS, and nephrotic-range proteinuria has secondary or primary disease. Given any doubts, most clinicians would favor attempting to treat patients with nephrotic FSGS as if they had primary disease as long as the treatment does not have undue side effects. Moreover, the course of FSGS is variable, and only recently have clear prognostic features, such as histologic pattern, degree of proteinuria and presence of nephrotic syndrome, and degree of interstitial fibrosis, been defined.[45,46,56] Finally, although FSGS is common in adults, there are many therapeutic options with few randomized controlled trials (RCTs) on which to base judgment.[59] However, almost all patients with FSGS will benefit from good supportive care (e.g., blockade of the renin-angiotensin-aldosterone system), as described in Chapter 79.

In early studies, only 10% to 30% of patients with FSGS treated with corticosteroids or other immunosuppression for short periods experienced a remission of proteinuria and the relapse rate was high. Thus many nephrologists considered FSGS to be untreatable. A classic study documented that 44% of children with FSGS treated with immunosuppressive agents experienced a remission.[55] Although the response rate for treated adults was similar (39%), most of the adults never received immunosuppressive therapy. In general, in most patients with nephrotic syndrome, treatment will potentially benefit from a trial of immunosuppressive therapy.[58,60] However, benefit from use of immunomodulatory medicines in patients with asymptomatic proteinuria or sub-nephrotic proteinuria is unproven. Recent retrospective studies support the use of corticosteroids and other immunosuppressive agents over no treatment in preventing ESRD in FSGS.[58]

Corticosteroids

In trials using 6 months or longer courses of corticosteroids in primary FSGS, many patients experience a remission of nephrotic syndrome. In adults, therapy is usually with prednisone or prednisolone 1 mg/kg/day (maximum of 80 mg/day) or 1.5 to 2 mg/kg (maximum of 120 mg) every other day, for an initial period of 4 to 8 weeks, with subsequent

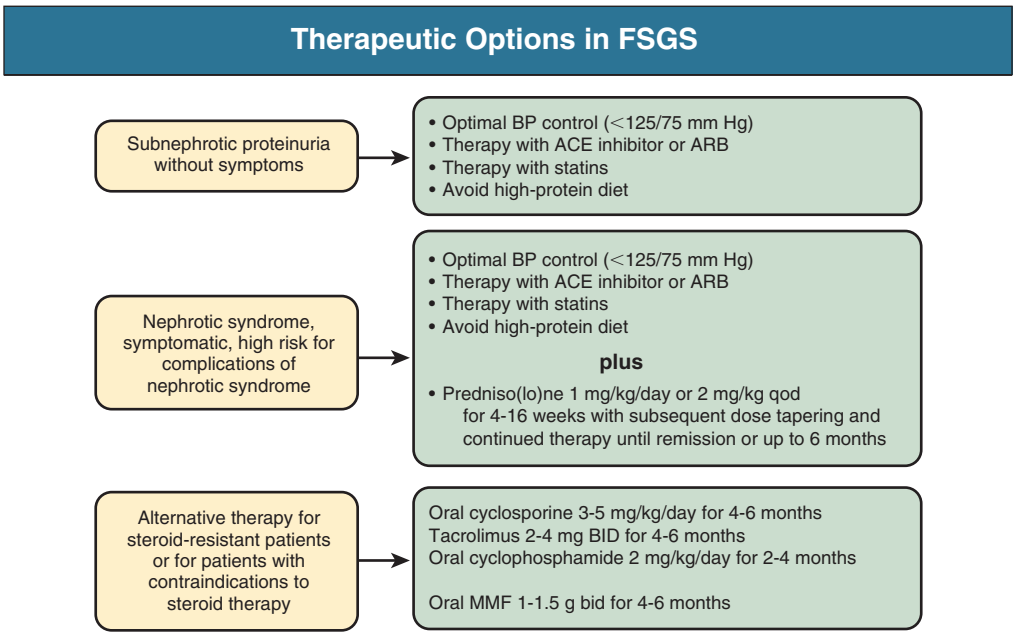

Fig. 18.19 Therapeutic options in focal segmental glomerulosclerosis (FSGS). Treatment of secondary FSGS should be directed at the underlying cause whenever possible. For HIV-associated nephropathy, treatment with highly active antiretroviral therapy (HAART); for pamidronate nephrotoxicity, discontinue the medication; and for obesity-related glomerulopathy, weight loss. *ACE,* Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *BP,* blood pressure; *MMF,* mycophenolate mofetil.

tapering of the dose.[1-3,60] Initial response rates range from 40% to 80%. Nephrotic children typically receive an empiric 4- to 6-week course of prednisone (60 mg/m^2 body surface area) before a renal biopsy is performed if there is no remission. In children with biopsy-documented FSGS, 20% to 25% will achieve a complete remission with a short course of corticosteroids, but as many as 50% will remit with more intensive therapy. In adults, although no large prospective RCTs are available, more prolonged use of corticosteroids has led to much higher remission rates of nephrotic syndrome than in earlier studies.[1,2,60] The median duration of corticosteroid treatment for complete remission to be achieved is 3 to 4 months; most patients respond by 6 months. Thus most clinicians would treat all adult patients with nephrotic primary FSGS and those at risk for progressive disease with a prolonged course (at least 6 months) of daily or every-other-day corticosteroid therapy or other immunosuppressive medication in the hope of inducing a remission of nephrotic syndrome and preventing eventual ESRD. The Kidney Disease: Improving Global Outcomes (KDIGO) study guidelines recommend initial prednisone therapy in nephrotic patients with primary FSGS, with the high dose to be continued for a minimum of 4 weeks and a maximum of 16 weeks, with a slow taper over 6 months after achieving complete remission.[60] If there is no remission or significant reduction in proteinuria, many clinicians would rapidly taper off the daily prednisone or just discontinue the alternate-day corticosteroids without taper and proceed to another therapy.

Other Immunosuppressive Agents and Corticosteroid Resistant Patients

For many years, either chlorambucil or cyclophosphamide combined with corticosteroids was the treatment of choice for corticosteroid-resistant FSGS.[1,60,61] However, KDIGO guidelines specifically suggest that cyclophosphamide not be given to children with corticosteroid-resistant nephrotic syndrome and to use alternative medicines such as calcineurin inhibitors (CNIs) or mycophenolate mofetil.[60] In adults with FSGS treated with oral cyclophosphamide or chlorambucil, pooled data showed a high response rate for patients with corticosteroid dependence or intolerance, but a remission rate of less than 20% for corticosteroid-resistant patients.

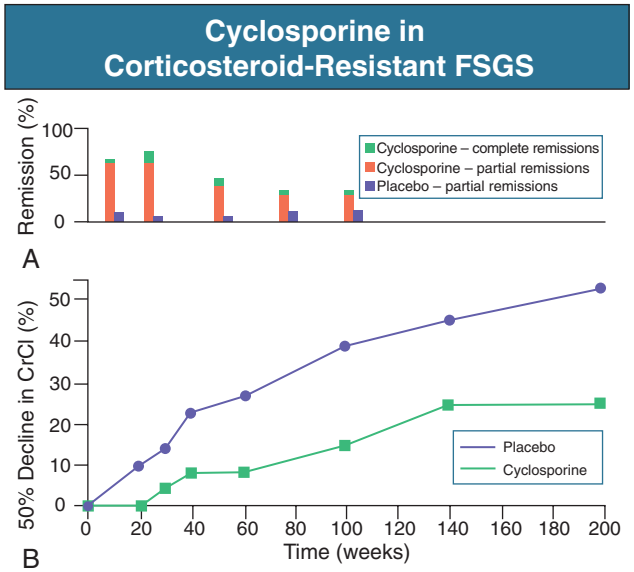

Fig. 18.20 Cyclosporine in corticosteroid-resistant focal segmental glomerulosclerosis (FSGS). Randomized controlled trial of 6 months of treatment with prednisolone and either cyclosporine or placebo. (A) Cyclosporine induces a partial or complete remission significantly more often than placebo. (B) Cyclosporine treatment results in a lower rate of decline in renal function than with placebo, even after 4 years; *CrCl,* creatinine clearance. (Modified from reference 54.)

Several studies have used low-dose cyclosporine, 3 to 6 mg/kg/day for 2 to 6 months, to treat corticosteroid-resistant FSGS[58,60,61] (Fig. 18.20). Complete plus partial remission has been achieved in 60% to 70% with cyclosporine versus only 17% to 33% in the placebo groups. In North

America, steroid-resistant adult patients with FSGS randomized to either cyclosporine with low-dose corticosteroids or the same low dose of corticosteroids alone for a 6-month period exhibited a much higher remission rate (12% complete and >70% complete or partial) in the group treated with cyclosporine.[60,61] Despite some relapses after cyclosporine discontinuation, the treated group still had significantly more remitters and better preserved GFR at long-term follow-up. Because there is a high relapse rate when cyclosporine is discontinued after only 6 months, many clinicians use a 1-year course with slow taper in patients who have had a favorable reduction of proteinuria with cyclosporine.[1,2,60] Although data on tacrolimus are more limited, results have been similar.[62] Because the major side effects of nephrotoxicity, hypertension, and hyperkalemia are the same for both cyclosporine and tacrolimus, choice may depend on other less severe, adverse side effects (e.g., gum swelling, tremor, hirsutism). Tacrolimus has been effective in some patients who are resistant to or intolerant of cyclosporine. Although CNIs are used to treat many patients with FSGS, almost all studies deal with corticosteroid-resistant patients, and there are no large RCTs comparing the two regimens. One recent large retrospective study of children and adults with FSGS found 173 treated with corticosteroids, 90 treated with CNIs with or without corticosteroids, and 183 not treated with immunosuppression.[53] Therapy with either corticosteroids or CNIs was associated with better renal survival than no immunosuppression. However, despite a suggestion of lower likelihood of ESRD in patients treated with other immunosuppression versus corticosteroids, the superiority of CNIs over corticosteroids could not be proven.[58] Additional studies are needed to determine whether CNI therapy for FSGS is superior to corticosteroids as a first-line therapy.[59]

Mycophenolate mofetil (MMF; mycophenolic acid) has been used successfully in several uncontrolled series of patients with FSGS.[63] A multicenter prospective RCT compared cyclosporine and a regimen of oral MMF plus dexamethasone in 138 children and adults up to age 40 who had corticosteroid-resistant FSGS.[64] The partial or complete remission rates were not significantly different. KDIGO guidelines suggests MMF and dexamethasone be considered for corticosteroid-resistant patients who do not tolerate CNIs.[60]

The use of sirolimus has been limited since the drug was reported to induce proteinuria and FSGS lesions in kidney transplant patients. In one series, sirolimus was associated with worsening of renal function, episodes of acute kidney injury, and no remissions of the nephrotic syndrome.[65] The addition of plasma exchange to immunosuppressive medications, which has been successful in treating some patients with recurrent FSGS in the renal allograft (see Chapter 111), has given mixed results in patients with disease in their native kidneys.[60] Likewise, use of low-density lipoprotein apheresis and galactose (a monosaccharide sugar with a high affinity for CLC1, a putative permeability factor in patients with FSGS) have been anecdotal.

Rituximab has been used in several studies of small numbers of patients with FSGS who have either failed other treatments or become dependent on these therapies.[66-68] It has proved more successful for steroid-dependent than steroid-resistant patients. Rituximab has not yet been studied in an RCT of patients with FSGS. Abatacept, which has proved effective in inducing remissions of nephrotic syndrome in only some patients with FSGS, is currently being studied in patients with resistant MCD and FSGS in a controlled cross-over trial.[17] Corticotropin (adrenocorticotropic hormone) has been beneficial in small numbers of patients with FSGS resistant to multiple other immunosuppressive agents, but it also has not been studied in large RCTs.[69]

Other Forms of Therapeutic Interventions

The role of immunosuppressive agents in the treatment of patients with sub-nephrotic levels of proteinuria and little damage on renal biopsy is unclear. Most nephrologists would not use corticosteroids to treat these patients. However, most would treat all patients with FSGS who have no contraindications with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs), as well as statins, similar to other progressive glomerular diseases (see Chapter 79).

How best to prevent renal fibrosis in patients with FSGS is of particular interest. Neither pirfenidone, an oral TGF-β inhibitor, nor a monoclonal antibody against TGF-β have proven safe and effective in preventing progressive renal disease in FSGS.[70]

For patients with secondary forms of FSGS, attempts to treat the underlying cause should be the initial step in management. Patients with FSGS secondary to obesity and heroin nephropathy have had remissions of proteinuria after weight reduction or cessation of heroin use, respectively. In HIV-associated nephropathy, therapy with highly active antiretroviral drugs and blockers of the renin-angiotensin system has proven useful (see Chapter 56). The role of immunosuppression has not yet been proven in RCTs in any form of secondary FSGS. In all forms of secondary FSGS, supportive therapy as outlined in Chapter 79 is essential to prevent progressive renal disease. In patients with primary idiopathic or a secondary form of FSGS who remain nephrotic, fluid retention and edema can be managed with salt restriction and diuretics (see Chapter 15).

TRANSPLANTATION

Approximately 30% of patients with primary FSGS who develop ESRD and undergo renal transplantation develop recurrent FSGS in the allograft.[1,9,71,72] Children with early-onset FSGS, those with more severe proteinuria and a more rapid course to renal failure in their native kidneys, and, in the United States, White patients are all at greater risk for recurrence. In other countries non-Whites have a greater recurrence rate.[71,72] Those who have lost a prior allograft due to recurrent FSGS are at highest risk for recurrence. Recurrent FSGS is further discussed in Chapter 111.

SELF-ASSESSMENT QUESTIONS

1. Use of which of the following medications has *not* been associated with proteinuria and the histologic pattern of focal segmental glomerulosclerosis (FSGS)?
   - **A.** Interferon β
   - **B.** Pamidronate
   - **C.** Sirolimus
   - **D.** Amlodipine
   - **E.** Lithium
2. Which histologic feature on renal biopsy suggests a "secondary" FSGS pattern related to "structural-functional adaption"?
   - **A.** Adhesions or synechiae to the Bowman capsule
   - **B.** Glomerulomegaly and perihilar segmental sclerosis and hyalinosis
   - **C.** Hypertrophy and hyperplasia of the visceral epithelial cells
   - **D.** Diffuse mesangial hypercellularity
   - **E.** Collapse of part of or all the glomerular tuft
3. Which of the following statements about the prognosis of idiopathic focal segmental glomerulosclerosis is *true*?
   - **A.** The outcome is worse for patients with the "tip" variant versus other patterns.
   - **B.** The outcome is better for patients with the collapsing variant versus other patterns.
   - **C.** Remission of proteinuria is a strong predictor of a favorable outcome.
   - **D.** African Americans have a prognosis similar to that of Whites if controlling for hypertension and degree of proteinuria.
   - **E.** The degree of glomerular sclerosis is the strongest histologic predictor of a poor renal outcome.

Inherited Causes of Nephrotic Syndrome

Shazia Ashraf, Friedhelm Hildebrandt

CLINICAL FEATURES OF NEPHROTIC SYNDROME

Nephrotic syndrome (NS) is caused by malfunction of the glomerular filter that leads to significant proteinuria (>3.5 g/day) with hypoalbuminemia, which in turn causes edema.[1,2] NS is classified by response or lack of response to a standardized corticosteroid therapy into steroid-sensitive (SSNS) versus steroid-resistant nephrotic syndrome (SRNS), respectively. SRNS accounts for approximately 15% of childhood cases with NS and frequently leads to chronic kidney disease (CKD).[3–6] SRNS constitutes the second most frequent cause of CKD in children.[6a] It carries a 33% risk for relapse in a renal transplant, thereby causing recurrence of CKD.[2] Adult-onset NS is heterogeneous and may include causes such as diabetic nephropathy, amyloid nephropathy, etc. SRNS manifests histologically as focal segmental glomerulosclerosis (FSGS), a lesion characterized by sclerosis and podocyte foot process effacement in a few capillary segments of a fraction of glomeruli.[7] Diffuse mesangial sclerosis (DMS) is a pathogenic finding that may occur in patients with early-onset NS. In DMS, light microscopy shows podocyte hypertrophy, mesangial matrix expansion, thickened basement membranes, and decreased size of glomerular capillary lumina. SRNS may rarely be associated with extrarenal manifestations such as neurologic defects[8] (Fig. 19.1).

MONOGENIC CAUSES OF NEPHROTIC SYNDROME ELUCIDATE ITS PATHOGENESIS

In the last 15 years, more than 44 recessive and 8 dominant genes have been discovered to cause NS in humans, if mutated[6] (Tables 19.1 and 19.2, Fig. 19.2). Identification of these single-gene causes of NS has revealed that the glomerular podocyte and the glomerular slit membrane that it maintains are the primary sites at which the pathogenesis of NS unfolds.[1,9] The power of identification of such single-gene causes of NS lies in the fact that recessive mutations almost always convey full penetrance and thereby represent the cause of NS (i.e., the etiology) rather than representing only an increased risk for acquiring disease (Box 19.1). Thus, if strict genetic criteria are being followed for the decision, in which mutations in the 52 monogenic genes are considered causative (Boxes 19.1 and 19.2), identification of the causative mutation allows for (1) unequivocal molecular genetic diagnosis, (2) establishment of genotype–phenotype correlations, (3) transfer of mutations into genetic animal models with detailed study of their detrimental effects, (4) etiologic stratification of participants for therapeutic studies by specific causative gene and mutation, and (5) discovery of distinct mutations that may be amenable to treatment.[6]

The capillary tuft of the renal glomerular filtering apparatus consists of four major components: (1) the fenestrated endothelial cell layer, (2) the glomerular basement membrane (GBM), (3) the epithelial podocyte layer, and (4) the mesangial cells that help shape the glomerular tuft (see Fig. 19.2) (see Chapter 1). Interdigitations of podocyte foot processes form the glomerular slit membrane between them, which is critical for the filtering process and retention of protein in the blood stream.[9a] The integrity of the glomerular slit membrane is lost in NS. Thus identification of monogenic causes of NS revealed dozens of proteins, each of which is an indispensable component of glomerular function, because loss of their function in a monogenic form of NS inescapably leads to proteinuria and FSGS. Therefore the discovery of genes that, if mutated, cause monogenic forms of NS significantly increased our understanding of glomerular filtration barrier physiology and of pathogenic mechanisms of NS.

This discovery started with the genes encoding the slit membrane proteins nephrin *(NPHS1)*,[10] podocin *(NPHS2)*,[11] and phospholipase C epsilon 1 (*PLCE1*).[12] In the meantime, acceleration of whole-exome sequencing and next-generation sequencing has permitted identification of more than 52 monogenic causes of NS, and this number is rapidly increasing (see references in Tables 19.1 and 19.2) (see Fig. 19.2). The majority of the patients with NS, in whom a single-gene cause is detected, show no response to steroid treatment. The encoded proteins map back onto distinct structural protein complexes and signaling pathways that reveal what is essential for glomerular function (see Fig. 19.2). These functional complexes include proteins involved in coenzyme Q_{10} (CoQ_{10}) biosynthesis, sphingosine-1-phosphate (S1P) metabolism, nuclear transcription factors, nucleoporins, lysosomal proteins, actin-regulating small GTPases of the Rho/Rac/Cdc42 family, glomerular slit membrane–associated components, actin-binding proteins, tRNA modification (KEOPS complex) and laminin/integrin receptors (focal adhesions) (see Fig. 19.2). Very recently, six genes *(EMP2, TNS2, DLC1*, *CDK20, ITSN1, ITSN2)* were identified in which recessive mutations surprisingly caused partially treatment-sensitive NS (see Table 19.1).[13,42]

GENOTYPE PHENOTYPE CORRELATIONS

Recessive Versus Dominant Steroid-Resistant Nephrotic Syndrome

One of the most important genotype–phenotype correlations in SRNS is the distinction between recessive versus dominant SRNS genes (see Tables 19.1 and 19.2). In recessive mutations, family history is most likely negative, because parents of individuals with recessive mutations will be healthy heterozygous carriers, and no one in the ancestry will have had the disease. If there is any inherited mutation, it will be occurring heterozygous only in ancestors. However, in dominant disease, one of the parents of an affected individual will most likely be affected, and the disease may have been handed down through multiple generations

BOX 19.1 Assignment of Autosomal Recessive Mutations as Disease Causing

Basic assumptions: (1) Defined clinical phenotype. (2) Known genes with similar phenotype have been excluded. (3) "Mutation" implies that an allele causes a disease phenotype. (4) Full penetrance (age related). (5) Two mutated alleles present, because disease genes are recessive.

Include Allele as Disease Causing if:

- Truncating mutation (stop, abrogation of start or stop, obligatory splice, frame-shift) in an expressed gene (well annotated mRNA, conservation, protein expression) or:
- Missense mutation if:
  - Continuously conserved at least up to *Danio rerio (zebrafish)* OR:
  - Loss of function in human allele is supported by functional data AND
  - Allele segregates with the affected status in the family.

Exclude Allele as Disease Causing if:

- Heterozygous allele frequency >1% (in EVS server: 13,000 control chromosomes) or reported homozygous in ExAC (The Exome Aggregation Consortium).
- Nonsegregation (e.g., "compound heterozygous" in cis; *affected* family member is *without* the variant; *unaffected* parent has homozygous variant).

Modified from Lovric et al, NDT 2015.

BOX 19.2 Assignment of Autosomal Dominant Mutations as Disease Causing

Include Allele as Disease Causing if:

- Truncating mutation (stop, abrogation of start or stop, obligatory splice, frame-shift) in an expressed gene (well annotated mRNA, conservation, protein expression) or:
- Missense mutation if:
  - Continuously conserved at least up to *Danio rerio (zebrafish)* OR:
  - Loss of function in human allele is supported by functional data AND:
  - Allele segregates with the affected status in the family AND:
  - Mutations in known genes with similar phenotype have been excluded.

Exclude Allele as Disease Causing if:

- Reported homozygous or heterozygous (allele frequency >0.1%) in ExAC (The Exome Aggregation Consortium).
- Nonsegregation (e.g., *affected* family member is *without* the variant; but if an affected family member is with the allele, consider "incomplete penetrance" and "variable expressivity").

Modified from Lovric et al, NDT 2015.

Alleles considered as disease causing for recessive (Box 19.1) and dominant (Box 19.2) genes are then confirmed via Sanger sequencing for segregation with the phenotype within the family.

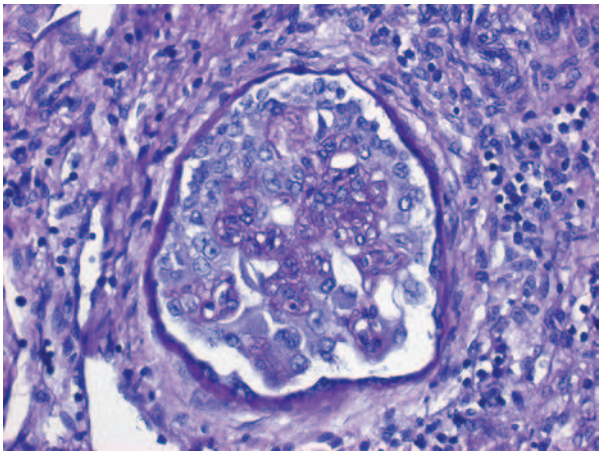

Fig. 19.1 Renal histologic image of an individual with steroid-resistant nephrotic syndrome. Periodic acid–Schiff (PAS) reaction staining reveals diffuse mesangial sclerosis (DMS). (Original magnification, ×40.) (Courtesy Prof. Kerstin Amann, University of Erlangen, Germany.)

(except for situations of incomplete penetrance or in the case of de novo mutations). Therefore the detection of dominant mutations has important clinical implications, such as in situations of a planned living-related donor kidney transplantation. Here, it will be important to exclude the presence of the disease-causing mutation in the related donor, in whom SRNS may not yet have manifested because of incomplete penetrance, which can be a feature of autosomal dominant inheritance.

Gene-Specific Phenotypes

Specific SRNS genes or distinct mutations (alleles) in the same SRNS gene may cause characteristic phenotypes, and this may pertain to age of onset of disease.[5,14] A recent study employed next-generation sequencing and tested a large international cohort of patients with SRNS manifesting before 25 years of age (1783 families).[5] The diagnostic panel included 21 genes with a recessive mode of inheritance and 6 genes with a dominant mode of inheritance. A genetic diagnosis was established in 526 of 1783 families (29.5%) in whom the condition manifested before 25 years of age.[5] Stringent criteria for calling mutations "disease causing" were applied (see Boxes 19.1, 19.2). This study showed that four genes were major SRNS genes: *NPHS2* (9.93%), *NPHS1* (7.34%), *WT1* (4.77%), and *PLCE1* (2.17%). The highest rate of mutation detection of 69.4% was in the youngest group of patients (0 to 3 months), and this percentage decreased with older age (Fig. 19.3). The second important finding from this study was that mutations in some recessive genes such as *NPHS1, LAMB2,* or *PLCE1* caused onset of NS in early childhood, whereas other recessive genes, such as *NPHS2,* lead to onset in later childhood (see Fig. 19.3). There is a tendency that mutations in dominant SRNS genes (*TRPC6, INF2, ANLN,* and *ARHGAP24*) cause adult-onset SRNS,[15–18] with the exception of *WT1*,[5] whereas mutations in recessive genes cause childhood-onset of NS. In this study, mutations in *WT1* showed a biphasic distribution with a first peak at 4 to 12 months and a second peak for age of onset beyond 18 years (see Fig. 19.3).[5] The most prevalent SRNS dominant genes are *INF2, TRPC6,* and *ACTN4* (see Fig. 19.3).[14]

Allele-Specific Phenotypes

"Multiple allelism" is a genetic mechanism in which specific mutations within the same gene may determine a phenotypic range, such as for age of onset of SRNS. For instance, in *NPHS2* mutations, the mutation R138Q causes onset in early childhood,[19,20] whereas the mutation R229Q in compound heterozygosity with specific second mutations causes later onset SRNS.[21] Currently only "strong" mutations are labeled disease causing (see Boxes 19.1 and 19.2), but it is very likely that a high percentage of adult-onset SRNS is caused by "weak" recessive alleles, which have not yet been revealed as deleterious (such as the allele R229Q of

*Disease caused by mutations in this gene can be found at http://ncbi.nml.nih.gov/OMIM.
FSGS, Focal segmental glomerulosclerosis; *NS,* nephrotic syndrome.

NPHS2). One of the most important tasks in the future of renal genetics is to define, using cell-based and animal model systems, deleteriousness of "weak" recessive mutations that cause adult-onset SRNS.

SYNDROMIC PROTEINURIC RENAL DISEASE

Galloway-Mowat Syndrome

Galloway-Mowat syndrome is clinically defined by microcephaly, abnormal cerebral gyral patterns, seizures, psychomotor retardation, cranial dysmorphia, and a renal glomerulopathy that is inherited in an autosomal recessive pattern. The renal disease generally presents as NS within the first few months of life, with rapid progression to ESRD. Most affected children die before age 6 years. Recessive mutations of *WDR73* gene have been identified in patients with Galloway-Mowat syndrome.[22] Very recently, recessive mutations have been identified in KEOPS complex genes (*LAGE3*, *OSGEP*, *TP53RK*, and *TPRKB*) as new monogenic causes of Galloway-Mowat syndrome.[43]

Denys-Drash and Frasier Syndromes

Denys-Drash syndrome (DDS) and Frasier syndrome (FS) are two rare and related conditions caused by mutations of the Wilms tumor gene, *WT1*. The gene responsible for both DDS and Frasier syndrome is *WT1*,

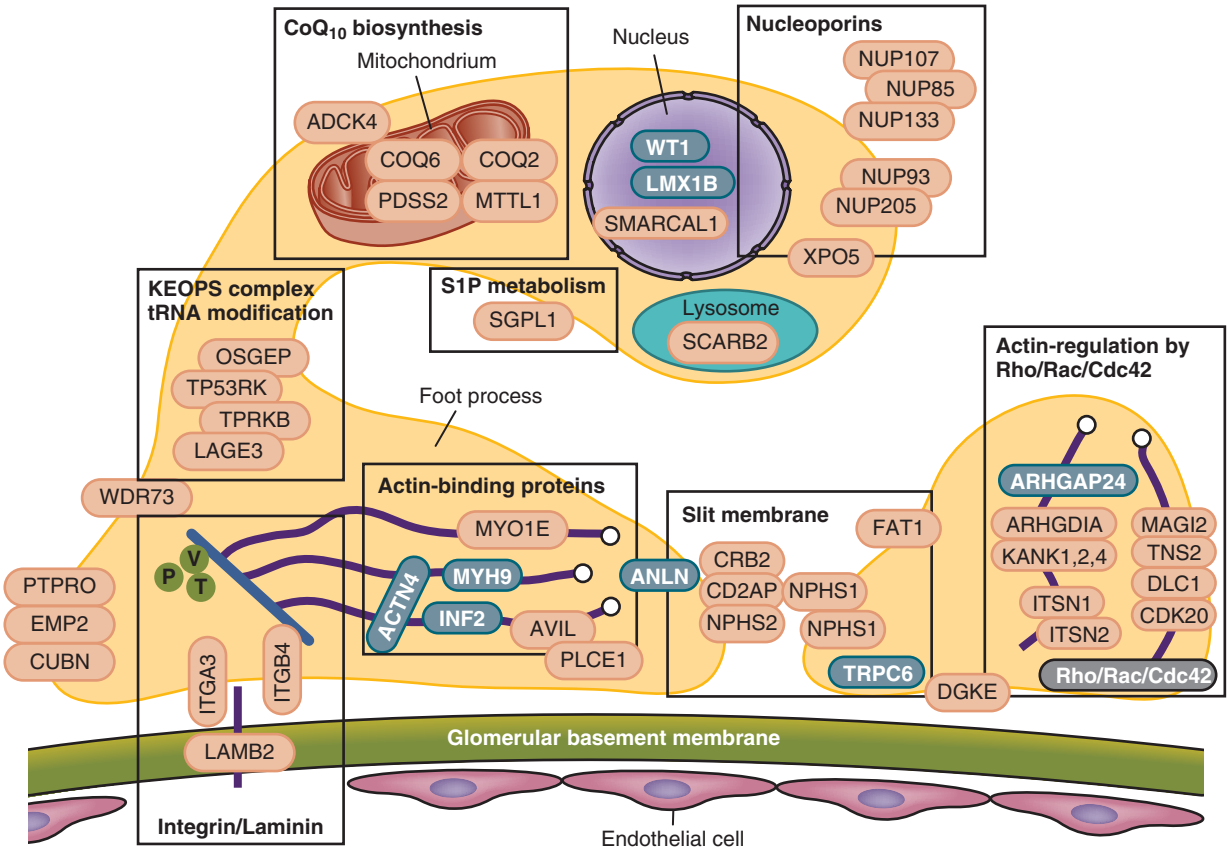

Fig. 19.2 Proteins whose genes, if mutated, cause monogenic steroid-resistant nephrotic syndrome define essential podocyte functions. Identification of 52 single-gene (monogenic) causes of steroid-resistant nephrotic syndrome (SRNS) has revealed the renal glomerular epithelial cell, the podocyte, as central to the pathogenesis of SRNS, because all of the related genes are relevantly expressed in podocytes. Identification of genes that, if mutated, cause SRNS revealed distinct proteins and functional pathways as essential for glomerular function, because a mutation in any single one of them is sufficient to cause SRNS. This figure depicts a simplified cross section through a podocyte *(vanilla color)* and a neighboring podocyte foot process, which is attached to the glomerular basement membrane *(green)* by laminin-integrin receptors. Forty-four proteins whose genes, if mutated, cause recessive monogenic forms of SRNS are shown in *red,* and eight proteins whose genes, if mutated, cause dominant forms of SRNS are shown in *blue* (see Tables 19.1 and 19.2). The 52 SRNS-related proteins were found to be part of protein–protein interaction complexes that participate in defined structural components or signaling pathways of podocyte function (shown within *black dashed frames*). These proteins include proteins involved in coenzyme Q_{10} biosynthesis, S1P metabolism, nuclear transcription factors, nucleoporins, lysosomal proteins, actin-regulating small GTPases of the Rho/Rac/Cdc42 family, glomerular slit membrane–associated components, actin-binding proteins, tRNA modification (KEOPS complex), and laminin/integrin receptors (focal adhesions). Proteins that are encoded by recessive NS genes are marked in *red:* ADCK4, aarF domain containing kinase 4; ARHGDIA, Rho GDP dissociation inhibitor (GDI) α; AVIL, advillin; CD2AP, CD2-associated protein; CDK20, cyclin-dependent kinase 20; COQ2, coenzyme Q2 4-hydroxybenzoate polyprenyltransferase; COQ6, coenzyme Q_{10} monooxygenase 6; CRB2, crumbs family member 2; CUBN, cubilin (intrinsic factor-cobalamin receptor); DGKE, diacylglycerol kinase; DLC1, deleted in liver cancer 1; EMP2, epithelial membrane protein 2; FAT1, FAT tumor suppressor homolog 1; ITGA3, integrin, α3; ITGB4, integrin, β4; ITSN1, intersectin 1; ITSN2, intersectin 2; KANK, KN motif and ankyrin repeat domains 1/2/4; LAGE3, L antigen family member 3; LAMB2, laminin, β2; MAGI2, membrane-associated guanylate kinase, WW and PDZ domain containing 2; MTTL1, mitochondrial tRNA leucine 1; MYO1E, *Homo sapiens* myosin 1e; NPHS1, nephrin; NPHS2, podocin; NUP85, nucleoporin 85 kDa; NUP93, nucleoporin 93 kDa; NUP107, nucleoporin 107 kDa; NUP133, nucleoporin 133 kDa; NUP205, nucleoporin 205 kDa; OSGEP, O-sialoglycoprotein endopeptidase; PDSS2, prenyl (decaprenyl) diphosphate synthase, subunit 2; PLCE1, phospholipase C, ε 1; PTPRO, protein tyrosine phosphatase, receptor type O; SCARB2, scavenger receptor class B member 2; SGPL1, sphingosine-1-phosphate lyase 1; SMARCAL1, SWI/SNF-related, matrix-associated, actin-dependent regulator of chromatin, subfamily a-like 1; TNS2, tensin 2; TP53RK, TP53-regulating kinase; TPRKB, TP53RK-binding protein; WDR73, WD repeat domain 73; and XPO5, exportin 5. Proteins that are encoded by dominant NS genes are marked in *blue:* ACTN4, actinin, α4; ANLN, anillin; ARHGAP24, Rho GTPase-activating protein 24; INF2, inverted formin, FH2 and WH2 domain containing; LMX1B, LIM homeobox transcription factor 1-β; MYH9, myosin, heavy chain 9; TRPC6, transient receptor potential cation channel, subfamily C, member 6; WT1, Wilms tumor 1. (Modified from reference 6.)

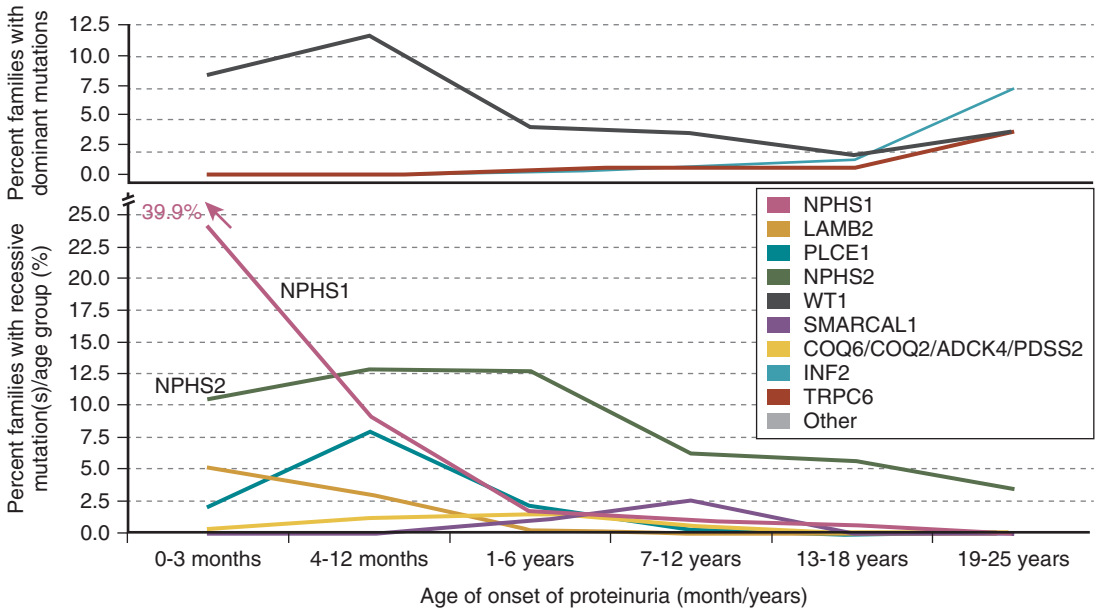

Fig. 19.3 Relative distribution of SRNS-causing genes by their age of onset. Percentages of families in an international cohort with SRNS that manifested at 25 years of age and resulted from mutations in monogenic genes are interconnected by lines between age groups and shown in different colors for each causative gene (*lower panel* for recessive genes, *upper panel* for dominant genes). *NPHS1* mutations *(red), LAMB2 (orange),* and *PLCE1 (dark blue)* have early age of onset and are rarely found in patients older than 6 years. The dominant genes *INF2 (light blue)* and *TRPC6 (brown)* manifest in early adulthood and *WT1 (black)* shows a biphasic distribution with a first peak at 4 to 12 months and a second peak for age of onset beyond 18 years *(upper panel).* These findings are compatible with the notion that mutations in recessive disease genes are found more frequently in early-onset disease, whereas mutations in dominant genes more frequently cause adult-onset disease. (Modified from reference 5.)

which is a transcription factor involved in gonad and kidney development. Both syndromes are characterized by male pseudohermaphroditism, progressive glomerulopathy, and development of genitourinary tumors. DDS and FS have been distinguished by differences in nephropathy, with patients with DDS developing DMS in contrast to focal and segmental glomerulosclerosis (FSGS) that occurs in patients with FS. Patients with DDS have a high incidence of severe hypertension and rapid progression to ESRD by 3 years of age. In FS, male pseudohermaphrodites typically present in phenotypic females with amenorrhea or NS, or both. NS may be slowly progressive, usually over 10 years, and is typically steroid resistant. These patients develop ESRD in the second or third decade of life, with most cases occurring at puberty (see Fig. 19.3). Some cases manifest in much younger children.[23] Rarely, an XX karyotype with a less severe phenotype may not be identified clinically as Frasier syndrome and may manifest only with renal disease.

Nail-Patella Syndrome

Nail-patella syndrome (hereditary onycho-osteodysplasia; Fong syndrome) is an autosomal dominant disease, caused by mutations in the LIM homeodomain transcription factor *LMX1B,* involving abnormalities of the skeleton, nails, eyes, and kidneys (see Chapter 46). Affected patients have nail dysplasia, absence of or poorly developed patellas, dysplasia of the iliac horns and elbows, cataracts, glaucoma, and glomerulopathy with NS.

Pierson Syndrome

In 1963 Pierson and colleagues described cases of congenital NS with distinct eye abnormalities.[24] In this rare syndrome, patients present with hypoplasia of the ciliary body and iris, resulting in fixed narrowing of the pupil (microcoria) as well as massive proteinuria at birth and rapid progression to ESRD. Most patients die before 2 months of age. DMS exemplifies the renal pathology findings in the Pierson syndrome. The resultant mutation is in *LAMB2,* which codes for the laminin β2 chain.

GENETIC TESTING BY WHOLE EXOME SEQUENCING

Because of the high likelihood (~30%) of finding a causative monogenic mutation in SRNS with onset before 25 years of age,[5,14] and because of the many important implications for disease management, it is advisable to suggest genetic testing to all individuals with FSGS or with persistent proteinuria that manifests before the age 25 years. In many parts of the world, such testing, that is, by whole-exome sequencing (WES) is currently only available as part of research initiatives (www.genetests.org, www.renalgenes.org). In adult-onset FSGS, genetic testing is indicated if there is a positive family history. The likelihood of finding a causative (recessive) mutation is even higher in individuals with SRNS from consanguineous marriages. Recent advances in high-throughput sequencing, and the continuous reduction in cost for WES, have made mutation analysis less time and cost intensive.[25] WES allows sequencing of all approximately 330,000 exons in the human genome (i.e., the exome). WES to identify causative mutations is currently available by commercial genetic diagnostics or on a research basis (www.renalgenes.org). Exon-containing fragments of DNA are first enriched from the patient's DNA sample, using solid-phase/array-based hybridization of the patient's DNA fragments with bait probes that represent the sequences of all exons to capture the entire exome.[26] It is

currently assumed that WES offers a theoretical likelihood of 86% of detecting the disease-causing mutation in a recessive disease.[27] Besides its use to detect mutations in an established list of known disease-causing genes, WES was also very successfully applied to detecting novel disease-causing genes (e.g., *ADCK4, EMP2, CRB2, FAT1, NUP93, KEOPS* complex, and *TNS2*).[25,28–32,42,43] After exome capture, all exon fragments are sequenced using a high-throughput next-generation sequencing platform.[33] The sequences are then compared with the human reference genome (www.genome.ucsc.edu) for genetic sequence variants that differ between the patient and a normal reference sequence. Any given two individuals differ by approximately 2000 genetic variants.[34] However, in a monogenic disease, only one or two variants in a single gene represent the causative mutation. Finding the relevant causative genetic mutation requires an elaborate a priori reduction process, by genetic mapping,[35] application of stringent genetic criteria (see Boxes 19.1 and 19.2), or applying algorithms on "deleteriousness" of genetic variants. Before mutation analysis is performed, genetic counseling is advisable.

SPECIFIC THERAPIES FOR HEREDITARY NEPHROTIC SYNDROME

The identification of causative monogenic mutations may have important therapeutic consequences in some cases. This is very important for patients who carry mutations in a gene of CoQ_{10} biosynthesis (*COQ2, COQ6, ADCK4,* or *PDSS2*).[28,36] In these patients, treatment with CoQ_{10} may be indicated. An illustrative example was recently published: a 5-year old girl presented with SRNS, and a causative homozygous mutation was detected in the *COQ6* gene.[36] She had previously responded partially to the treatment with cyclosporine A. The treatment with CoQ_{10} was commenced during the remission, and her proteinuria was minimal. After the inadvertent interruption of CoQ_{10} administration, the proteinuria relapsed into the nephrotic range, but after the reinstitution of therapy the proteinuria normalized.[36] Individuals with recessive mutations in *PLCE1, EMP2, TNS2, DLC1, CDK20, ITSN1,* or *ITSN2* may respond fully to the treatment with steroids or cyclosporine A.[12,29,42] The individuals with *CUBN* may benefit the treatment with vitamin B_{12},[37] and those with *ARHGDIA* mutations theoretically may be responsive to the eplerenone treatment.[38] Donor splice-site heterozygous mutations in intron 9 of the *WT1* gene have been reported to alter the alternative splicing leading to two WT1 isoforms, with (+) or without (−) three amino acids, lysine-threonine-serine (KTS), between zinc fingers 3 and 4. The detection of *WT1* mutations often has clinical consequences as, for instance, KTS+ mutations, depending on karyotype, may confer a risk for gonadoblastoma.[39] TRPC6 mutations may potentially be amenable to treatment with calcineurin inhibitors.[15,40] In childhood SRNS, that manifests beyond the first year of life, often one treatment attempt is made applying standard steroid therapy.[41] If a response is lacking, treatment attempts are made with calcineurin inhibitors, and more recently mycophenolate or rituximab. In summary, identifying monogenic causes of SRNS also may help define important genotype–phenotype correlations and may provide molecular genetic diagnosis to the families involved.

FUTURE DIRECTIONS

The recent identification of monogenic causes of NS that manifests before 25 years of age in the surprisingly high fraction of approximately 12% to 45% in individuals worldwide[5] has offered many advantages for future management of NS. With the available sequencing technology and the continuous reduction in sequencing cost, WES on a commercial or research basis should now be offered to every patient with persistent proteinuria occurring before 25 years of age, or in patients with FSGS manifesting after age 25 years and positive family history, if the patient consents for clinical genetic testing for the following reasons: (1) it will provide the patient and families with an unequivocal cause-based diagnosis, (2) it may uncover a form of NS that is amenable to treatment (e.g., coenzyme Q_{10}–related genes), (3) it may allow avoidance of a renal biopsy procedure, (4) it will further unravel the puzzle of pathogenic pathways of NS, and (5) it will permit personalized treatment options for NS, based on genetic causation in way of "precision medicine." Very recently, single-gene causes of partially steroid-sensitive NS (SSNS) also have been discovered, and the discovery of these genes may offer inroads into understanding the therapeutic actions of glucocorticoids in SSNS.[42]

SELF-ASSESSMENT QUESTIONS

1. A 23-year-old man is admitted to the hemodialysis unit after inpatient hemodialysis initiation for end-stage renal disease (ESRD) secondary to focal segmental glomerulosclerosis (FSGS). In your initial evaluation, you obtain a detailed family history in which the patient discloses that his maternal grandfather, mother, and two brothers have all received dialysis. You suspect familial FSGS as the cause of renal disease in this family. Based on the pattern of kidney disease occurrence in his family, what mode of inheritance would you suspect in this patient?
   A. Autosomal recessive
   B. X-linked recessive
   C. Autosomal dominant
   D. X-linked dominant
2. You are called to consult on a patient with newly diagnosed FSGS. Her family history is significant for multiple family members with advanced chronic kidney disease (CKD) or ESRD requiring renal replacement therapy. Three family members are known to have had renal transplants without recurrence of disease. You construct a family pedigree that suggests an autosomal dominant inheritance pattern. Of the known genetic mutations to cause autosomal dominant FSGS, which gene may be affected in this patient?
   A. CD2AP
   B. MYO1E
   C. CTN4
   D. NPHS2 (podocin)
3. Genetic mutations affecting which of the following cell populations have been identified as a cause of familial FSGS?
   A. Glomerular epithelial
   B. Glomerular endothelial
   C. Glomerular mesangial
   D. Tubular epithelial
4. What is the approximate likelihood of finding a monogenic cause of steroid-resistant nephrotic syndrome that manifests by 25 years of age?
   A. 10%
   B. 30%
   C. 50%
   D. 80%
5. You are consulted on a 5-year-old girl with significant nephrotic range proteinuria. On genetic analysis, she is found to have a homozygous missense mutation in the COQ6 gene. Which of the following would be the most appropriate treatment that could help improve her condition?
   A. Steroids
   B. Coenzyme Q_{10}
   C. Eplerenone
   D. Calcineurin Inhibitors

Membranous Nephropathy

David J. Salant, Daniel C. Cattran

Definition

Membranous nephropathy (MN) is an immune complex glomerular disease in which immune deposits of immunoglobulin G (IgG) and complement components develop predominantly or exclusively beneath podocytes on the subepithelial surface of the glomerular capillary wall. Podocyte injury resulting from the immune deposits increases glomerular permeability to plasma proteins, which results in proteinuria and potentially in nephrotic syndrome.[1,2] *Primary* (formerly called *idiopathic*) MN is an organ-specific autoimmune disease. It accounts for about 75% to 80% of patients with MN and typically occurs in the absence of any identifiable initiating event. It is the most common cause of primary nephrotic syndrome in older (>60 years) white adults, but the age range is broad and patients may present for the first time as teenagers.[3] Various conditions have been identified in association with MN, some of which are likely to be causal, and are known as *secondary* MN (Table 20.1). The term *membranous* refers to thickening of the glomerular capillary wall on light microscopy of a renal biopsy, but the entity now referred to as *membranous nephropathy* is defined by immunofluorescence and electron microscopy (EM). These techniques reveal diffuse, finely granular immune deposits on immunofluorescence and electron-dense deposits in the subepithelial space that are now regarded as pathognomonic of MN. Consequently, MN is a pathologic diagnosis made in patients with proteinuria whose glomeruli exhibit these immune deposits without associated hypercellularity or inflammatory changes.

ETIOLOGY AND PATHOGENESIS

Experimental Membranous Nephropathy

Much of what we know about the pathogenesis of MN derives from observations in animal models.[4] Studies of the Heymann nephritis model of MN in rats in the late 1970s established that the subepithelial immune deposits form in situ when circulating antibodies bind to an intrinsic ("fixed") antigen in the glomerular capillary wall. The antigen was subsequently identified as *megalin,* a large (~600 kD) transmembrane receptor of the low-density lipoprotein receptor family expressed on the basal surface of rat podocytes. Binding of circulating antimegalin antibodies induces capping and shedding of the antigen-antibody complexes, where they bind to the underlying glomerular basement membrane (GBM), resist degradation, and persist for weeks or months as immune deposits characteristic of MN (Fig. 20.1A). In this model, proteinuria is caused by antibodies in the immune deposits that overcome local complement regulatory mechanisms and activate complement in situ. The primary mechanism involves sublethal podocyte injury induced by the complement membrane attack complex C5b-9, which triggers a cascade of structural and functional changes, including oxidative injury, calcium influx, activation of cytosolic phospholipase A_2, production of arachidonic acid metabolites and cytokines, endoplasmic reticulum stress, DNA damage, alterations in the ubiquitin-proteasome system, and disruption of the actin cytoskeleton[4] (Fig. 20.2). Podocyte foot process effacement is likely the result of the collapse of the actin cytoskeleton and loss of cell-GBM adhesion complexes, and the loss and displacement of slit diaphragms are associated with the onset of severe, nonselective proteinuria. Podocyte injury also leads to the production of new extracellular matrix (ECM) proteins that are laid down between and around the immune deposits, giving rise to the characteristic "spikes" and GBM thickening that are hallmarks of MN.

Another mechanism of subepithelial immune deposit formation involves planted antigens[2] (see Fig. 20.1B). This is best exemplified by animal models immunized with cationized bovine serum albumin (cBSA). The cBSA binds to negatively charged residues in the GBM, where it serves as a target for circulating anti-BSA antibodies. As in the Heymann nephritis model, podocyte injury and proteinuria result from local complement activation.

Human Membranous Nephropathy

Evidence has recently been obtained that both fixed and planted antigen mechanisms are involved in human MN (see Fig. 20.1). The first demonstration that circulating antibodies reactive with an intrinsic podocyte antigen may be involved in MN was provided by an unusual case of antenatal MN induced by the transplacental passage of alloantibodies to neutral endopeptidase (NEP), a known podocyte protein.[5] The mother of the affected child was found to be deficient in NEP and had been immunized during a previous pregnancy and, like subsequent cases, produced complement-fixing anti-NEP alloantibodies. Although antibodies to anti-NEP do not account for primary MN, alloantibodies probably explain the development of de novo MN after renal transplantation and MN in the setting of chronic graft-versus-host disease after allogeneic hematopoietic stem cell transplantation (see Table 20.1). The predominant autoimmune system responsible for primary MN is that associated with autoantibodies directed at the M-type phospholipase A_2 receptor (PLA_2R) on podocytes.[6] Circulating anti-PLA_2R antibodies are detectable in the serum of 75% to 80% of patients with primary MN from all ethnic groups and are rarely found in secondary MN.[2,7] The antibodies are predominantly IgG4 and, as in the Heymann nephritis model, the antigen (PLA_2R) and antibodies (anti-PLA_2R) co-localize in the immune deposits in primary (but not in secondary) MN.[8,9] PLA_2R is a transmembrane protein of the mannose receptor family[10] (Fig. 20.3).[11-13] Although it has been shown to undergo constitutive endocytosis and is involved in the production of eicosanoids, reactive oxygen

TABLE 20.1 Classification of Conditions and Agents Associated With Membranous Nephropathy

Primary		
Anti-PLA_2R associated (70%-80%)		
Idiopathic (20%-30%)		
Anti-THSD7A (up to 5%)		
Secondary	**Common**	**Uncommon**
Autoimmune diseases	Class V lupus nephritis	Rheumatoid arthritis Autoimmune thyroid disease IgG4-related systemic disease Anti-GBM and ANCA-associated crescentic glomerulonephritis
Infections	Hepatitis B	Hepatitis C virus (HCV) Human immunodeficiency virus (HIV) Syphilis Schistosomiasis
Malignancy	Solid tumors (colon, stomach, lung, prostate)	Non-Hodgkin lymphoma Chronic lymphocytic leukemia (CLL) Melanoma
Drugs or toxins	Nonsteroidal anti-inflammatory drugs and cyclooxygenase-2 (COX-2) inhibitors	Mercury-containing compounds Gold salts D-Penicillamine, bucillamine
Miscellaneous		Sarcoidosis Anticationic bovine serum albumin
Alloimmune		
Graft-versus-host disease after hematopoietic stem cell transplantation		
De novo membranous nephropathy in renal allograft		
Fetomaternal alloimmunization to neutral endopeptidase		

ANCA, Antineutrophil cytoplasmic antibody; *GBM,* glomerular basement membrane; *IgG,* immunoglobulin G; *Anti-THSD7A,* anti-thrombospondin type 1 domain–containing 7A.
The list excludes conditions for which only a single case has been reported or the lesions were atypical of membranous nephropathy.

species, DNA damage, and cellular senescence, its role in podocytes is unknown. Recently, antibodies to a second podocyte antigen, thrombospondin type 1 domain–containing 7A (THSD7A) were identified in patients with anti-PLA_2R-negative MN.[14] THSD7A is also expressed on podocytes and like PLA_2R redistributes to form the subepithelial immune deposits. It accounts for about 5% of cases of primary MN in Western countries, but appears to be more prevalent in Japanese patients with primary MN.[15] Reactivity to certain intracellular antigens, including aldose reductase, SOD2, and enolase, has been detected in primary MN and may contribute to the progression of podocyte injury. The best evidence of a planted antigen mechanism in MN is that described in children with MN who have been exposed to cBSA, presumably in bottled milk. In such cases, as in the animal models, the cBSA localizes in the GBM, where it forms complexes with circulating anti-BSA.[16] Planted antigens also may be responsible for immune deposition in class V (membranous) lupus nephritis and hepatitis B virus (HBV)–associated MN.

The resolution of MN depends on remission of the immune response, the extent of podocyte damage, and expansion of the GBM. In cases

BOX 20.1 Clinical Features of Membranous Nephropathy

- Rare in children: Less than 5% of total cases of nephrotic syndrome
- Common in adults: 15% to 50% of total cases of nephrotic syndrome, depending on age; increasing frequency after 40
- Males > females in all adult groups
- Whites > Asians > African Americans > Hispanics
- Nephrotic syndrome in 60% to 70%
- Normal or mildly elevated blood pressure at presentation
- "Benign" urinary sediment
- Nonselective proteinuria
- Tendency to thromboembolic disease*
- Other features of secondary causes: Infection, drugs, neoplasia, systemic lupus erythematosus

*Deep venous thrombosis, renal vein thrombosis, and pulmonary embolism.

in which immunologic remission occurs before extensive podocyte loss and GBM remodeling, complete recovery is possible. On the other hand, proteinuria may persist for several weeks or months until the normal architecture is restored. Once there is extensive podocyte loss, proteinuria persists despite immunologic remission, and glomerular sclerosis, tubular atrophy, and interstitial fibrosis may ensue.

EPIDEMIOLOGY AND GENETICS

MN may occur at any age and in all ethnic groups, but primary MN is twice as common in men than in women and is rare in children. Primary MN has its peak incidence during the fourth and fifth decades of life (Box 20.1). In comparison, MN in childhood is more often secondary (e.g., caused by HBV). Primary MN is the most common cause of nephrotic syndrome in nondiabetic white adults, with an estimated annual incidence of 8 to 10 cases per 1 million population in Western countries. Reported variation in incidence may reflect specific country/physician indication for kidney biopsy but could also represent real differences related to socioeconomic status, ethnicity, or environment. Although association with certain human leukocyte antigen (HLA) class II immune response genes indicated a genetic predisposition, primary MN is not a familial disease, except in rare patients with more than one affected family member. The genetic predisposition became more evident after the discovery of PLA_2R as the major antigen, when studies from Korea and Taiwan documented a significant association with nonsynonymous single-nucleotide polymorphisms (SNPs)[17,18] in the first C-type lectin-like domain (CTLD) of PLA_2R (see Fig. 20.3), a region that is known to undergo conformational changes, as well as another in CTLD7. A subsequent genome-wide association study conducted by a European consortium revealed strong associations with a noncoding SNP in *PLA2R1* (rs4664308) and another in HLA-DQA1 (rs2187668), a member of HLA class II that includes isoforms that predispose carriers to autoimmunity.[19] Although each of these two associated SNPs was significant alone, the odds ratio of MN was almost 80 in individuals who were homozygous for both HLA-DQA1 and *PLA2R1* variants. Despite this, no unique coding variants have been found in *PLA2R1* that explain the association. Other genetic studies have suggested that *PLA2R1* variants may contribute to the severity or likelihood of MN progression. Alternatively, the interaction of *PLA2R1* with the autoimmune predisposition conferred by HLA class II may set the stage for an external trigger to initiate MN.[1,2] An example of such a trigger might be exposure to environmental pollutants.[20]

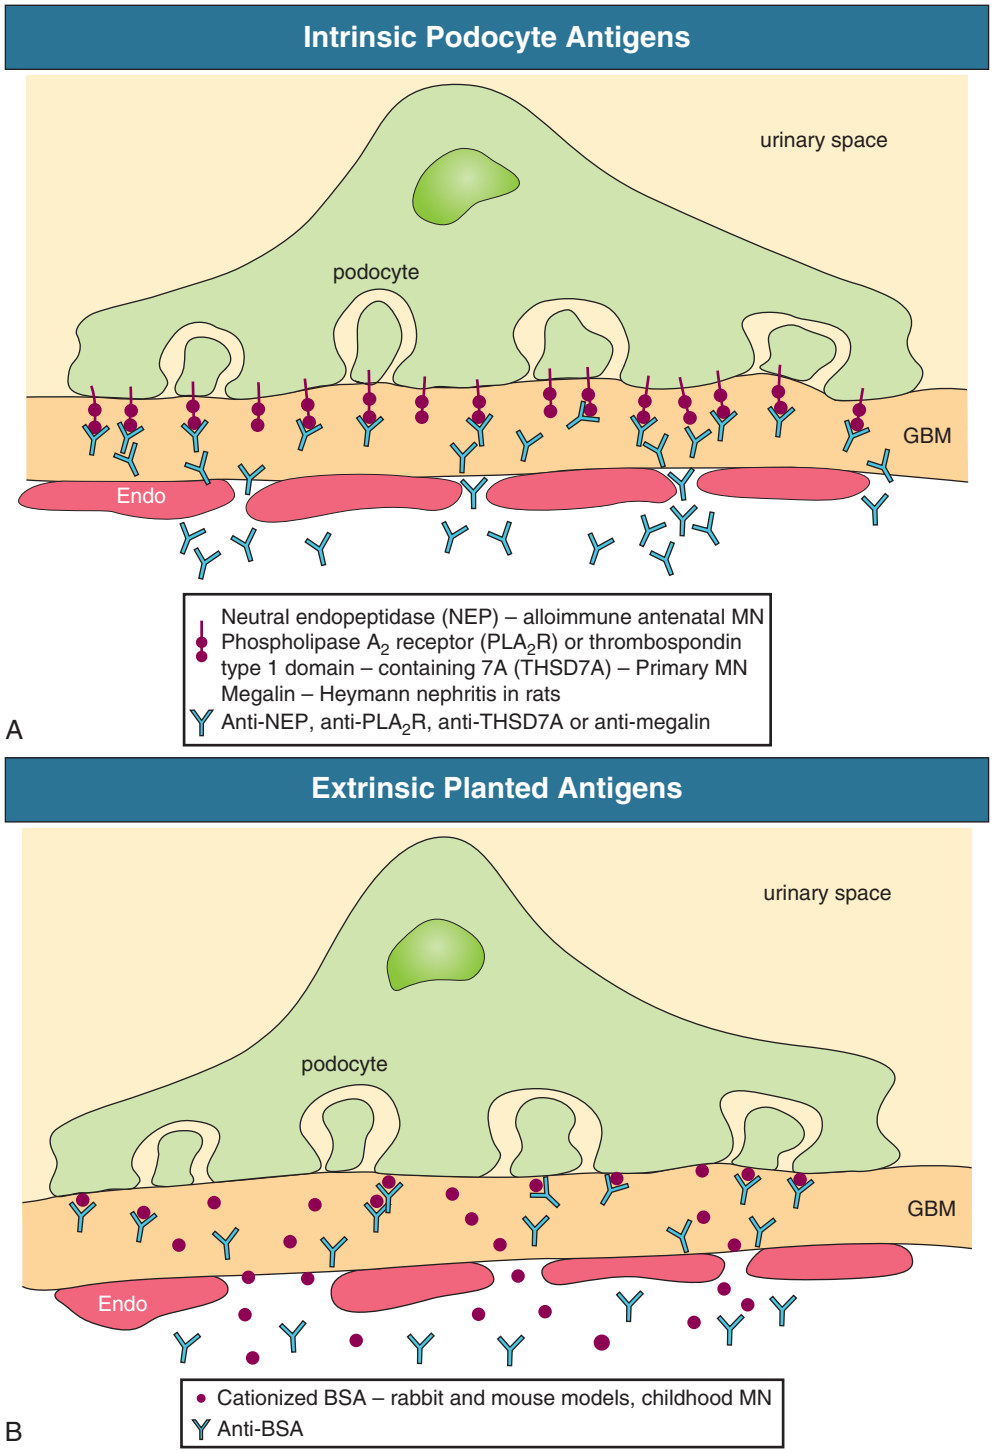

Fig. 20.1 Mechanisms of in situ immune complex formation in experimental and human membranous nephropathy (MN). (A) Circulating antibodies may cross the glomerular capillary wall and bind to podocyte *(Podo)* antigens exposed on the foot process, as in Heymann nephritis in rats (megalin), alloimmune MN (neutral endopeptidase), and primary MN (PLA_2R or THSD7A). *Endo,* Glomerular endothelial cell; *GBM,* glomerular basement membrane. (B) Certain extrinsic antigens such as cationized bovine serum albumin *(BSA)* may bind to sites in the GBM and serve as planted antigens and form deposits with circulating antibody.

CLINICAL AND SEROLOGIC MANIFESTATIONS

From 70% to 80% of all patients with MN present with the nephrotic syndrome. The remaining 20% to 30% present with asymptomatic subnephrotic proteinuria (<3.5 g/24 h). Proteinuria is nonselective. Microscopic hematuria is common (30% to 40%), but red blood cell (RBC) casts are rare and suggest a different glomerular pathologic process. In primary MN, serologic tests for anti-PLA_2R are positive in 75% to 80% of cases,[1,2] whereas serum complement levels are normal despite evidence of intraglomerular complement activation and serologic

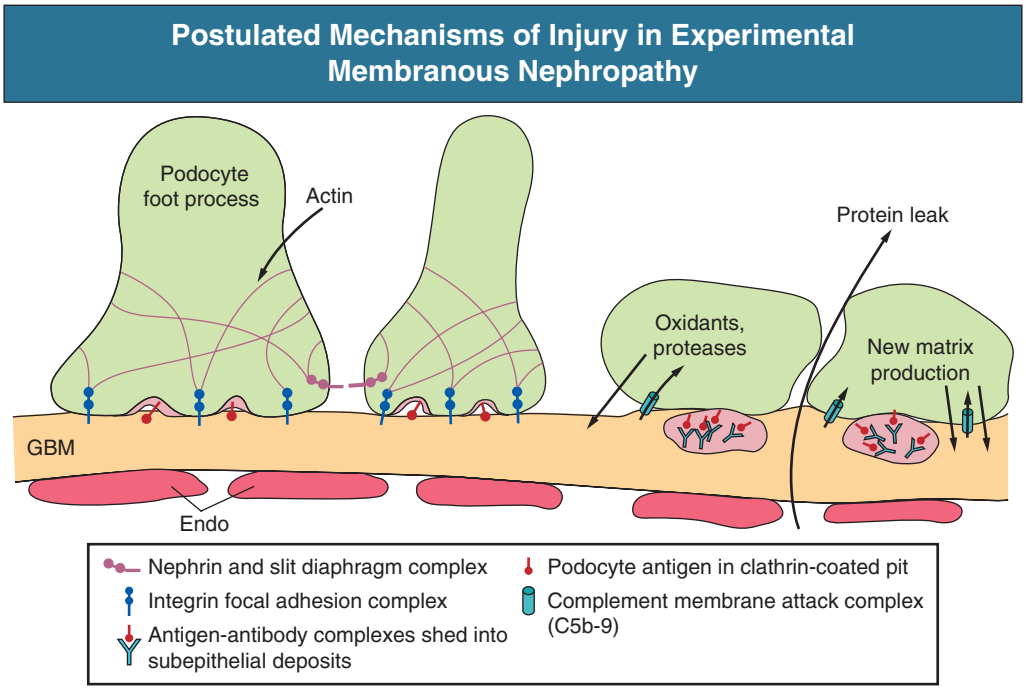

Fig. 20.2 Postulated mechanisms of injury in experimental membranous nephropathy. Antibodies against a podocyte antigen in clathrin-coated pits on the foot processes (left podocyte) form complexes that are shed to form deposits in the subepithelial space (right podocytes) and induce complement activation leading to formation of C5b-9. Insertion of C5b-9 is insufficient to cause lysis but stimulates the podocyte to release a host of inflammatory mediators. Disruption of the actin cytoskeleton causes altered cell-matrix adhesion and loss or displacement of slit diaphragms, leading to foot process effacement and loss of the filtration barrier to protein. New matrix production by the damaged podocytes expands the glomerular basement membrane *(GBM)* between and around the deposits. *Endo,* Glomerular endothelial cells.

markers (e.g., antinuclear antibodies, antineutrophil cytoplasmic antibody [ANCA], rheumatoid factor) are normal or absent. At diagnosis, only 10% to 20% of MN patients have hypertension. Renal function is usually normal at presentation, with only a small fraction (<10%) presenting with renal impairment (Table 20.2). These presenting features can be modulated by age or preexisting hypertension; tubulointerstitial and vascular changes on biopsy may be related to these factors rather than to the severity of the MN.[21] This is supported by recent evidence that age per se does not influence the rate of progression in MN but does influence the glomerular filtration rate (GFR) at presentation. Other complications related to nephrotic syndrome include dyslipidemia, a high prevalence of thromboembolic events and increases in cardiovascular events (see later discussion).

PATHOLOGY

The earliest pathologic feature of MN is the formation of subepithelial immune complexes of IgG and complement along the outer surface of the capillary wall in which glomeruli appear histologically normal and therefore may be mistaken for minimal change disease (MCD) if only light microscopy is performed. MN begins with the formation of immune complexes at the interface of the podocyte and GBM, with subsequent changes in the podocyte, deposition of new ECM material between and around the immune deposits, thickening of the GBM (membranous change), and, in some cases, focal glomerulosclerosis, tubular atrophy, and interstitial fibrosis.

Light Microscopy

In the earliest stages of MN, the glomeruli and interstitium appear normal on light microscopy, and the diagnosis is made by immunohistologic examination and EM (Fig. 20.4A). The next stage of MN involves a homogeneous thickening of the capillary wall, seen with light microscopy in sections stained with hematoxylin and eosin or with periodic acid–Schiff (PAS) reagent (see Fig. 20.4B). On silver methenamine staining, early projections of the GBM between deposits may be detected in a characteristic spike-like configuration (see Fig. 20.4C). Later, lucencies may develop in the GBM as immune deposits are resorbed, resulting in craters within the thickened GBM.

Leukocyte infiltration is absent in glomeruli in MN, probably because chemotactic products of complement activation follow filtration forces into the urinary space rather than diffusing backward into the capillary lumen, and the intervening GBM prevents immune adherence mechanisms from being operative. As a result, the pathologic lesion of MN is characterized only by changes in podocytes and basement membrane, without associated glomerular hypercellularity.

The podocyte response to this form of injury includes effacement of foot processes visible only by EM. In general, there are no visible mesangial or endothelial cell abnormalities. The presence of significant mesangial hypercellularity suggests immune deposit formation in the mesangium and is more consistent with a secondary MN, such as class V lupus nephritis (see Chapter 26). In some patients with heavy proteinuria and progressive disease, glomeruli exhibit reduced podocyte numbers and areas of focal sclerosis that resemble secondary focal segmental glomerulosclerosis (FSGS; see Chapter 18). These patients often have a more rapidly progressive course and a poor response to therapy. These sclerotic lesions may be a consequence of glomerular hypertrophy accompanied by an inability of terminally differentiated podocytes to proliferate leading to areas of denuded GBM, attachment to the Bowman capsule, and subsequent capillary collapse. As in all glomerular diseases, tubulointerstitial injury is common and correlates

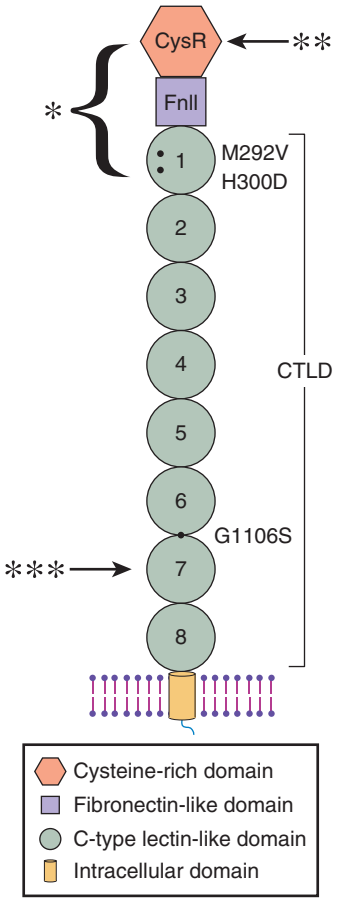

Fig. 20.3 Structural domains of phospholipase A_2 receptor (PLA_2R). The M-type phospholipase A_2 receptor is a transmembrane protein and receptor for secretory PLA_2 (CTLD5). The N-terminal region from the cysteine-rich domain through CTLD4 of other members of the mannose receptor family is known to exist in extended or folded configurations. PLA_2R is involved in the production of eicosanoids, reactive oxygen species, DNA damage, and cellular senescence. Its role in podocytes is unknown. The sites of polymorphisms associated with primary membranous nephropathy are shown as black dots and the location of epitopes identified by anti-PLA_2R are shown as asterisks.[14-16] *CysR,* Cysteine-rich (ricin B) domain; *FnII,* fibronectin II-like domain; *CTLD,* C-type lectin-like domains 1-8; *SNPs,* single-nucleotide polymorphisms.

with both renal function and the level of proteinuria. Some studies suggest the long-term outcome correlates in general with the severity of the tubulointerstitial damage (see Chapter 78).

Immunohistology

The pattern of granular glomerular capillary wall staining for IgG in MN is characteristic and easily recognizable by immunohistologic findings (Fig. 20.5A). Positive staining for IgG marks the finely granular subepithelial deposits, which are present on the outer surface of all capillary walls. The predominant IgG subclass in primary MN is IgG4. Positive staining for IgG1 or IgG3, IgA, IgM, or significant staining in the glomerular mesangium suggests lupus or other causes of secondary MN as an underlying mechanism.[22] κ and λ light-chain staining are typically equal, but rare cases of MN secondary to monoclonal IgG, including anti-PLA_2R have been reported.[23] Complement C3 is also present in most cases of active disease and usually reflects staining for C3c, a breakdown product of C3b that is rapidly cleared. Consequently, positive C3 staining probably reflects active, ongoing immune deposit formation. When sought, staining for C5b-9 is generally present as well, consistent with the proposed pathogenetic role of C5b-9 in this disease.[4] Strong C1q staining is not typically found in primary MN (<20% of cases) and is more common in lupus-associated MN.[24] Positive staining for C4d in the absence of C1q also has been described in primary MN.[25] Another feature that helps distinguish primary and secondary MN is the presence of PLA_2R staining in the immune deposits in a pattern that co-localizes with IgG in anti-PLA_2R–associated MN but not in secondary MN (see Fig. 20.5B).[6,8,9] Thus several histopathologic features help distinguish primary and secondary forms of MN (Table 20.3).

TABLE 20.2 Diagnosis and Management of Patients With Membranous Nephropathy

Patient Groups	Test
All patients	Blood pressure Renal function (serum creatinine and creatinine clearance) Urinalysis Urine protein excretion (24-hour urine or urine protein-creatinine ratio) Serum albumin Serum cholesterol, including LDL/HDL Renal biopsy Anti-PLA_2R
Associated disease	Hepatitis B (HBs antigen) Hepatitis C (HCV antibody) Antinuclear antibody (ANA), anti–double-stranded DNA (hallmark of systemic lupus erythematosus) Complement C3, C4 (usually normal in idiopathic MN)
Selected Patients	
With suspected thromboembolic events, flank pain, hematuria, acute renal failure	Renal venous Doppler ultrasound Contrast CT, MRI
With sudden decrease in renal function, development of active urine sediment	Anti-GBM antibody Antineutrophil cytoplasmic antibody (ANCA) Assess for interstitial nephritis
Suggestive symptoms or age >50 years	Diagnostic testing for cancer (see text)

Anti-PLA_2R, Anti–phospholipase A_2 receptor antibody; *CT,* computed tomography; *GBM,* glomerular basement membrane; *LDL/HDL,* low-density/high-density lipoprotein; *MRI,* magnetic resonance imaging.

Electron Microscopy

The finding of subepithelial electron-dense deposits by EM parallels IgG staining. In primary MN, immune deposit formation occurs in a subepithelial distribution; subendothelial deposits are not seen, and mesangial deposits are rare (see Table 20.3). These deposits in early stages of the disease process are homogeneous and may even be confluent in some areas, with overlying podocyte foot process effacement and little change in the underlying GBM (stage I). As the disease persists, basement membrane material is laid down between the deposits and corresponds to the spikes seen on light microscopy with use of a silver methenamine stain and are easily visible by EM (stage II; Fig. 20.6A). Later, the spikes extend and deposits may become surrounded by new

TABLE 20.3 Histopathologic Features That Help Distinguish Primary From Secondary Membranous Nephropathy

Primary	Secondary
Immunofluorescence Microscopy	
IgG4 > IgG1, IgG3	IgG1, IgG3 > IgG4
IgA, IgM absent	IgA, IgM may be present
Mesangial Ig staining absent	Mesangial Ig staining may be present
C1q negative or weak	C1q positive
PLA_2R positive and co-localizes with IgG	PLA_2R negative
Electron Microscopy	
Subepithelial deposits only ± mesangial deposits rarely	Subepithelial deposits ± mesangial and subendothelial deposits

Ig, Immunoglobulin; *PLA_2R,* phospholipase A_2 receptor.

basement membrane–like material (stage III; see Fig. 20.6B). In stage IV disease, the basement membrane is overtly thickened, the deposits incorporated in it become more lucent, and the spikes are less apparent (stage IV; see Fig. 20.6C). Although clearly reflecting the duration of disease, these GBM changes do not correlate well with clinical manifestations or outcome. The overlying podocyte foot processes are effaced with condensation of the actin cytoskeleton; the filtration slits between the foot processes may be occluded; and in those still open, the slit diaphragms may be displaced or disrupted. Microvillous changes of the podocyte membrane are common, as are protein reabsorption droplets within podocytes and proximal tubular cells. The presence of tubuloreticular inclusions in the endothelial cells is strongly suggestive of lupus-associated MN, although these may rarely be found in primary MN as well.[26,27]

Diagnosis and Differential Diagnosis

When the initial presentation includes nephrotic syndrome, the differential diagnosis includes MCD, FSGS, the membranoproliferative

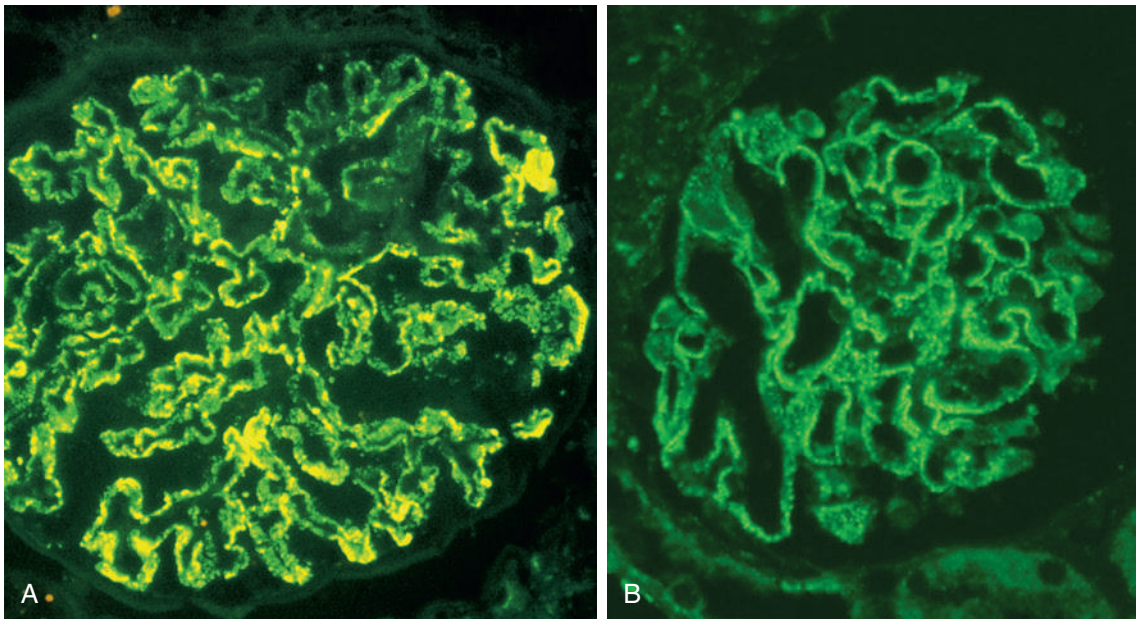

Fig. 20.5 Immunofluorescence in membranous nephropathy (MN). (A) *Left panel:* Glomerulus with diffuse, finely granular deposits of immunoglobulin G (IgG) along outer surface of all capillary walls. In primary MN, the antibodies eluted from the glomeruli are reactive with PLA_2R. (Courtesy C. E. Alpers.) (Original magnification ×400.)

glomerulonephritis spectrum of diseases (including C3 glomerulopathies and immune complex glomerulonephritis [GN]; see Chapters 21 and 22), amyloidosis, light-chain deposition disease, lupus nephritis, and diabetic nephropathy. In the 20% to 25% of patients whose initial presentation is asymptomatic non-nephrotic proteinuria, the differential is even more extensive. Although clinical clues in proteinuric patients may increase the likelihood of one specific histologic pattern over another, confirmation that MN is the underlying cause of nephrotic syndrome generally requires a kidney biopsy. However, the diagnosis can be confidently made with a positive serologic test for anti-PLA_2R or anti-THSD7A when a biopsy cannot be performed. On the other hand a negative test for anti-PLA_2R anti-THSD7A does not exclude primary MN, because a few patients may have positive glomerular staining for PLA_2R or THSD7A despite negative serology.[1,11] In addition, some patients have all the features of primary MN but lack evidence of PLA_2R- or THSD7A-associated MN.

Secondary MN represents 20% to 30% of all cases (see Table 20.1); the most common causes are systemic lupus, hepatitis B, malignant neoplasms, and drugs. In addition to a careful history and physical examination, appropriate laboratory evaluation for potential secondary causes should include a complement profile, antinuclear antibodies, hepatitis serology, chest radiography, stool testing for occult blood, mammography in women, and prostate-specific antigen testing with digital rectal examination in men. In women age 20 to 50, a high index of suspicion is warranted for underlying lupus. This diagnosis can be particularly difficult to make because most of these patients have no systemic symptoms, and serologic markers of systemic lupus erythematosus are often absent. Membranous lupus accounts for 8% to 27% of cases of lupus nephritis (see Chapter 26).

In adults, regardless of age, malignancy is an important secondary cause of MN (see Table 20.1). The colon, kidney, and lung are the most common primary sites, and in some patients, the tumor may not be evident at presentation. Although the diagnosis of PLA_2R-associated MN tends to exclude the concurrent existence of an associated malignancy,[28] given the therapeutic implications regarding immunosuppression versus treatment for cancer, each case should still be carefully assessed and evaluations beyond routine age-appropriate health maintenance tests considered if patients have risk factors for cancer. All PLA_2R-negative cases merit a more thorough search for a malignant tumor, as do patients with THSD7A-associated MN.[29]

Hepatitis B virus–associated MN is also a common secondary cause in countries where HBV is endemic. It can affect both adults and children who are chronic carriers of HBV (positive HBsAg, HBcAg, and usually HBeAg). This can occur with or without a history of overt liver disease. In children, HBV-associated MN most often manifests as nephrotic syndrome and usually follows a benign course.[3] In adults, progressive renal impairment is a more common outcome but may be prevented by treatment with antiviral therapy and tacrolimus.[30]

MN secondary to drugs usually resolves after discontinuation of the offending agent. The time to resolution, however, varies significantly, from as early as 1 week for the drugs more commonly implicated (and used) today (e.g., for nonsteroidal antiinflammatory drugs [NSAIDs] and proton pump inhibitors [PPIs]), as compared with several years for the more classic but rarely used drugs such as gold and D-penicillamine. Many other renal disorders have been seen in association with or superimposed on MN, including IgA nephropathy, FSGS, anti-GBM disease, ANCA vasculitis, acute interstitial nephritis, and diabetic nephropathy.

Clinical Course, Outcomes, and Complications

The clinical course of MN varies widely. Spontaneous remissions in proteinuria have been reported in up to 30% of patients. As the severity of proteinuria at presentation increases, the frequency of spontaneous remission appears to decrease. Female gender and lower grade (non-nephrotic) proteinuria at presentation are the only two features associated with a higher likelihood of spontaneous remission.[31] This is likely to produce a bias in renal survival because most studies reporting 10-year outcomes in untreated patients have included those with subnephrotic

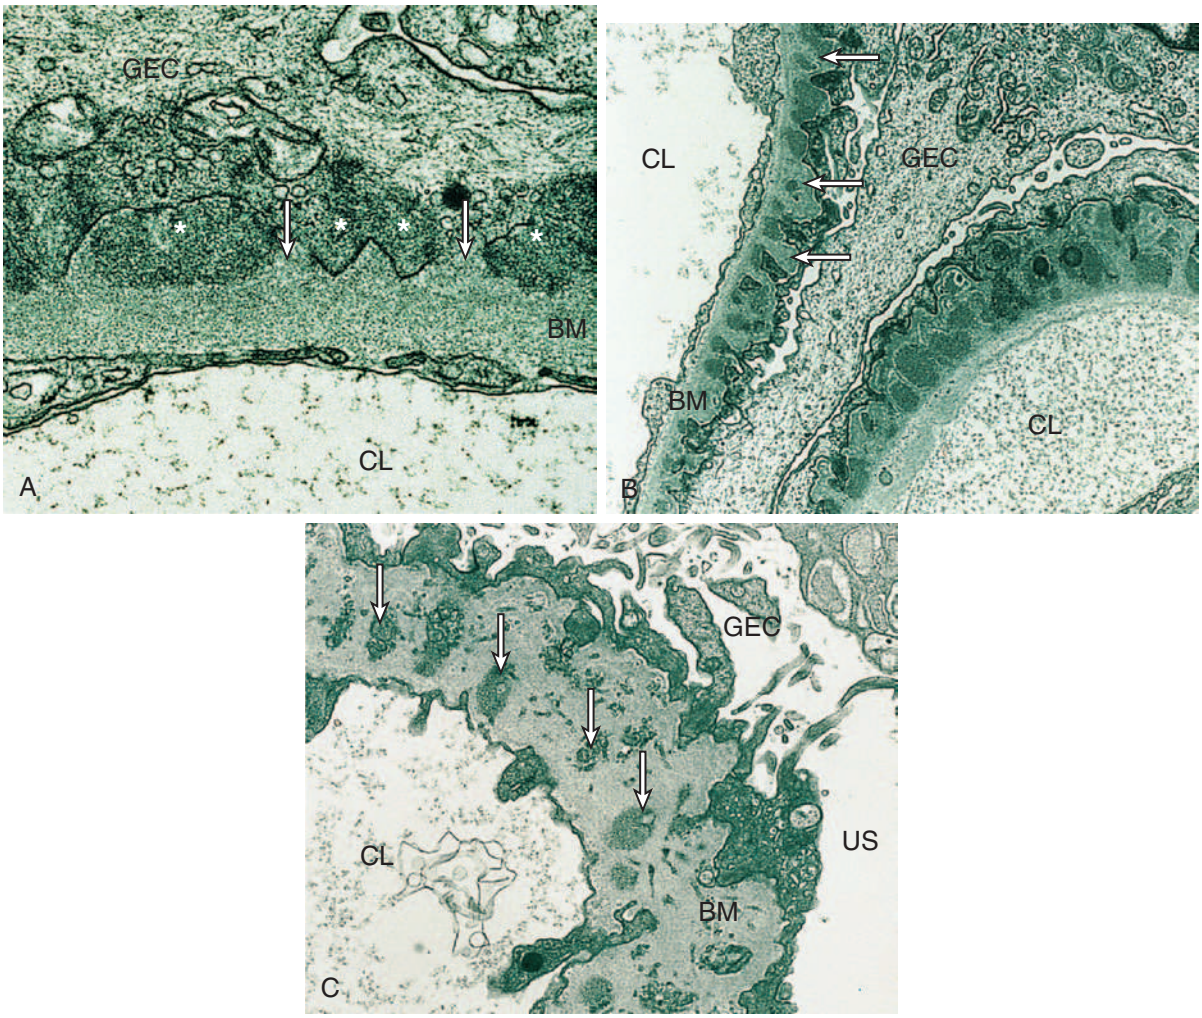

Fig. 20.6 Electron microscopy in membranous nephropathy (MN). (A) Early (stage II) MN. Glomerular capillary wall with discrete, electron-dense deposits on the subepithelial surface of the basement membrane *(BM)* corresponding to granular deposits of immunoglobulin G (IgG) detected by immunofluorescence microscopy (corresponding to light micrograph in (B). There are diffuse, granular immune complex deposits *(white asterisks)* along outer surface of the capillary wall, with effacement of overlying podocyte foot processes. Small extensions of BM between deposits *(arrows)* are also evident and represent the projections that are seen as spikes by light microscopy with silver methenamine staining. *CL,* Capillary lumen; *GEC,* glomerular epithelial cell. (B) More advanced (stage III) MN. Two glomerular capillary loops show involvement of the BM by the immune complex deposition *(arrows).* There is prominent membrane synthesis surrounding and incorporating these deposits into the BM (corresponding to spikes seen on silver-stained histologic preparations). Overlying cells continue to demonstrate widespread effacement of foot processes. (C) Morphologically advanced (stage IV) MN. Capillary BM is diffusely thickened; scattered electron-dense immune deposits *(arrows)* are present throughout its thickness, in addition to scattered subepithelial deposits. Overlying GECs continue to demonstrate effacement of foot processes. *US,* Urinary space. (Original magnifications ×18,000.) (Courtesy C. E. Alpers.)

proteinuria (<3.5 g/24 h). For example, one study reported a 72% renal survival at 8 years for 100 untreated patients, but 37% of the patients were non-nephrotic at presentation and more than 50% had less than 5 g/day.[32] In addition, deaths were excluded from the kidney survival analysis. Even so, there was a 25% end-stage renal disease (ESRD) rate by 8 years and almost 50% by 15 years. Thus, patients presenting with less than 3.5 g/day of proteinuria, no RBC casts, no hypertension, normal renal function, and no systemic features suggestive of a secondary cause have a relatively benign prognosis. However, these patients must be monitored, because up to 50% are likely to develop nephrotic-range proteinuria at some time in the disease course, most within the first 2 years after presentation.

In summary, although most patients with MN do reasonably well long term, MN is still the second or third leading cause of ESRD in patients with primary GN. The factor still missing from most MN survival data is the much higher-than-expected mortality from cardiovascular disease or thromboembolic events seen in patients who remain nephrotic. When another renal condition is superimposed on MN, there is often an associated acceleration in the rate of renal function loss. The most common conditions to consider in this setting are drug-induced interstitial nephritis; superimposed crescentic GN, including anti-GBM disease; and renal vein thrombosis.

Patients with primary MN who develop ESRD are generally suitable candidates for kidney transplantation, although the disease may recur

TABLE 20.4 Univariate Factors Associated With Worse Renal Survival in Membranous Nephropathy

Factors	Predictor	PPV (%)
Clinical Features		
Age	Older > younger	43
Gender	Male > female	30
HLA type	HLA/B18/DR 3/Bffl present	71
Hypertension	Present	39
Serum Levels		
Albumin	<1.5 g/dL	56
Creatinine	Above normal	61
Urine Protein		
Nephrotic syndrome	Present	32
Proteinuria	>8 g for >6 months	66
IgG excretion	>250 mg/day	80
β_2-Microglobulin excretion	>54 μg/mmol creatinine <54	79
C5b-9 excretion	>7 mg/mg creatinine	67
Biopsy Changes		
Glomerular focal sclerosis	Present	34
Tubulointerstitial disease	Present	48

(*PPV,* Positive predictive values modified from reference 37.)
Univariate factors associated with increased likelihood of progression and their positive predictive value.

TABLE 20.5 Risk Categories of Renal Disease Progression in Membranous Nephropathy

Low Risk	Medium Risk	High Risk
Normal serum creatinine and creatinine clearance plus proteinuria <4 g/day over 6 mo of observation	Normal or near-normal creatinine clearance and persistent proteinuria 4-8 g/day over 6 mo despite maximum conservative treatment	Deteriorating renal function and/or persistent proteinuria >8 g/day for 3 (up to 6) mo of observation

in up to 50% (see Chapter 108). Recurrence may be asymptomatic and found only on protocol biopsy, but those with recurrence of nephrotic syndrome have a high rate of graft loss. A high titer positive serologic test for anti-PLA_2R at transplantation may forecast early recurrence.[33-35]

Predictors of Poor Outcome

Given the wide variation in the natural history of MN, markers that predict individual outcome would be valuable. Testing for circulating anti-PLA_2R autoantibody has the potential to detect increases in MN immunologic activity before changes in classic laboratory parameters become apparent.[1,36] Table 20.4 lists the more traditional factors associated with progression and the strength of those associations. Male sex and increasing age are associated with a higher risk for renal failure, but both have limitations as prognostic factors. Age seems to be related to the underlying pathologic process at presentation rather than the severity of disease, because age does not influence rate of deterioration in function, and the gender of the patient seems more closely related to the severity of proteinuria at presentation rather than representing an independent risk factor for progression. The severity of chronic changes seen on the biopsy specimen (i.e., degree of glomerulosclerosis, tubulointerstitial fibrosis, and vascular disease) has been associated with a poor prognosis but more closely reflects initial GFR than the subsequent rate of renal functional deterioration.[21] Other pathologic features, including the percentage of glomeruli with glomerulosclerosis and the configuration of the immune deposits (synchronic/single stage or heterogeneous/multistage) on EM also have been suggested as predictors of outcome and response to treatment. However, these features have not been validated in prospective studies. The degree of renal impairment at presentation also has been found to correlate with long-term renal survival, but a better and more sensitive predictor of long-term prognosis is the ongoing rate of renal function loss, as measured by the decline in creatinine clearance over time.

One of the best models to calculate risk for MN takes into consideration the initial creatinine clearance, the slope of the creatinine clearance during a fixed period, and the lowest level of proteinuria during that observation period[37] (see Table 20.3). This risk score has a reported sensitivity of 60% to 89%, specificity of 86% to 92%, and overall accuracy of 79% to 87% in validation studies. The model predicts that patients with a normal creatinine clearance at presentation that remains stable for 6 months, and with persistent proteinuria of less than 4 g/24 h, have less than a 5% chance of progression, and only conservative treatment is recommended. In contrast, patients with proteinuria of 4 to 8 g/24 h during the same time frame have a 55% probability for development of chronic renal impairment; and those with persistent proteinuria greater than 8 g/24 h have a 66% to 80% probability of progression to chronic kidney disease within 10 years (Table 20.5). Recent data also suggest that a greater than 50% reduction in the baseline proteinuria estimate at 1 year is an independent predictor of spontaneous remission.[38] Other biomarkers, including urinary α_1-microglobulin, β_2-microglobulin, IgM, and IgG have also been strongly associated with MN progression. These markers measured together at a single time point have a higher positive predictive value than proteinuria alone, but none has yet been validated in an independent dataset.

Several studies have examined the relationship of anti-PLA_2R antibodies and clinical course. In general, the presence and titer of anti-PLA_2R antibody help define the diagnosis of primary MN, predict who might have spontaneous remission, monitor the disease activity and response to therapy, identify those at risk for progression, and, most significantly, decide when to minimize or stop treatment.[1]

Relapse After Complete Remission or Partial Remission

Relapse from a complete remission occurs in approximately 25% to 40% of MN cases, but the timing is unpredictable. Relapses have been reported up to 20 years after the primary remission. However, the majority of patients will relapse only with subnephrotic-range proteinuria and will maintain stable long-term kidney function with conservative management alone.[39] In contrast, the relapse rate is as high as 50% in those achieving only a partial remission. Achievement of either a complete or a partial remission, however, significantly slows progression and increases renal survival. Review of 348 nephrotic patients with MN documented a 10-year renal survival in patients with a complete remission of 100%; with partial remission, 90%; and with no remission, only 45%.[40] A recent update suggested durability of remission, whether complete or partial, drug-induced or spontaneous, is closely related to the long-term outcome.[41] This offers hope that complete and partial remission may become acceptable end-points for clinical trials rather than reduction in GFR, which commonly takes years to evolve in MN.[42]

TREATMENT

Nonimmunosuppressive Therapy

Conservative management of MN is directed at control of edema, hypertension, hyperlipidemia, and proteinuria and is similar to that used for nephrotic syndrome of any etiology (see Chapter 15). Blood pressure control is important for both renal and cardiovascular protection. For patients with proteinuria of more than 1 g/day, the target for blood pressure is 125/75 mm Hg unless contraindicated for clinical reasons. Numerous studies have shown that angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are cardioprotective and can reduce proteinuria and slow progression of renal disease in both diabetic and nondiabetic patients with chronic nephropathy (see Chapter 79). A recent meta-analysis of the largest renal protection trials using ACE inhibitors showed that the degree of protection is closely correlated to the degree of proteinuria reduction. None of these studies has focused on the specific effect of renin-angiotensin system (RAS) blockade in MN. In secondary analyses, the number of patients with MN has been small, and although the use of ACE inhibitors has been associated with significant improvement in some series, their antiproteinuric effect was modest (<30% reduction in proteinuria) in others. When effective, the benefit of RAS blockade occurs early, usually within the first 3 months of initiation of treatment. Even patients at low risk for progression (proteinuria <4 g/24 h) should be treated with ACE inhibitors or ARBs because this may reduce proteinuria and offer additional renal protection, with minimal risk for significant adverse effect. Patients must also follow a low-salt diet (1.5 to 2 g sodium/day) to achieve the maximum benefit from RAS blockade.

Proteinuria is also an independent risk factor for cardiovascular morbidity and mortality. When proteinuria is in the nephrotic range, there is a clear increase in cardiovascular risk, with a threefold to fivefold increase in both coronary events and death rates in this population.[43] Patients with significant proteinuria almost always have elevated serum cholesterol and triglyceride levels. Although not proven, we recommend the use of statins to reduce low-density lipoprotein cholesterol to 100 mg/dl (2 mmol/l) or lower, especially if treatment has not resulted in attaining subnephrotic range proteinuria (see Chapters 79 and 81).

It is recommended that both RAS blockade and lipid control be initiated early in patients with MN, given that reaching a goal of complete remission or even partial remission in patients at higher risk for progression (with persistent proteinuria >5 g/24 h) with conservative treatment alone is unlikely. Dietary protein intake may be restricted to 0.8 g/kg/day of high-quality protein with additional dietary protein (gram per gram) to correct for urinary losses. Dietary protein restriction has been associated with reduced proteinuria (15% to 25%) and a slowing in renal disease progression, but has never been shown to induce a complete remission or add to effects obtained with RAS blockade. Protein restriction must be carefully monitored in nephrotic patients to avoid malnutrition.

Retrospective reviews have shown that prophylactic anticoagulation is beneficial in reducing fatal thromboembolic episodes in nephrotic patients with MN, without a concomitant increase in the risk for bleeding.[44] No randomized controlled trial (RCT) has ever been done, however, and thus there is no current consensus about prophylactic anticoagulation and no laboratory test that can predict with any accuracy such an event. A thromboembolic event is more likely in certain patients, including those with severe and persistent nephrotic syndrome (proteinuria >10 g/day and/or serum albumin <25 g/l). Two additional recent clinical observations indicate that most thromboembolic events occur within the first 2 years of presentation and that there is an increasing likelihood of an event associated with progressively lower levels of serum albumin once below 30 g/l. Although there is still a tendency for nephrologists to wait until a primary thromboembolic event has occurred before using anticoagulants, recent algorithms suggest that the benefits of prophylactic anticoagulant therapy appear to outweigh the risks in patients with serum albumin below 2 or 2.5 g/l and low to intermediate risk for bleeding.[45]

Other agents that have been tried with modest effects in small numbers of patients with MN include probucol, a lipid peroxidation scavenger, and high-dose intravenous immune globulin, an agent with multiple effects on antibody-mediated tissue injury.[46]

Immunosuppressive Therapy

Several regimens using a variety of immunosuppressive agents can successfully reduce proteinuria in patients with MN. Many questions remain unresolved, however, including duration of conservative therapy while awaiting a spontaneous remission, when to initiate immunosuppressive therapy, most effective and safest of the available agents, and duration of treatment before treatment is considered futile.[47] Many of these issues, based on clinically available evidence, are discussed in the Kidney Disease: Improving Global Outcomes (KDIGO) clinical practice guidelines for glomerulonephritis.[27]

The current evidence suggests that specific immunosuppressive drug therapy should not be considered unless the patient has had persistent nephrotic-range proteinuria (>4 g/day) and the proteinuria has not declined more than 50% from baseline, over a minimum observation period of 6 months, despite maximum antihypertensive and antiproteinuric therapy. Other suggested criteria for early intervention are the presence of severe disabling or life-threatening symptoms related to the nephrotic syndrome or a rise in serum creatinine greater than 30% within 12 months. The latter needs to be documented as related to disease progression and not a complication such as a renal vein thrombosis, transformation to crescentic MN variant, or interstitial nephritis from diuretics. Recent data also suggest that persistent low titers of the PLA_2R antibody are associated with a higher likelihood of spontaneous remission and that very high levels of the anti-PLA_2R might be an indication for early intervention.[8,36]

Corticosteroids

In the three RCTs of corticosteroids in primary MN treatment, the overall consensus has been no significant long-term beneficial effect on proteinuria, rate of disease progression, or renal survival.[48,49] The use of oral corticosteroids as a single agent for the treatment of MN is therefore not recommended. The one exception may be the East Asian (Japanese) population, in whom long-term observational studies have indicated improvement in both proteinuria and renal function preservation with use of corticosteroids as monotherapy.[50]

Cytotoxic Agents Combined With Corticosteroids

In patients at moderate risk for progression, a significant benefit has been described with the combination of corticosteroid and a cytotoxic agent beginning with methylprednisolone pulses 1 g intravenously for 3 days at the start of months 1, 3 and 5 followed by oral methylprednisolone 0.4 mg/kg/day for 27 days, and each cycle followed by 1 month of treatment with a cytotoxic agent (cyclophosphamide or chlorambucil).[51] Complete or partial remission of nephrotic syndrome was seen in almost 80% of treated patients, a threefold to fourfold increase compared with the control group. Both progression rate and renal survival were significantly improved. Both treatment regimens were remarkably safe, although relapses were seen within 2 years in 30% of the treatment group. Similar results were obtained in an RCT ($n = 93$) using this same regimen to treat patients of Asian (East Indian) ethnicity with MN.[52] Because the results of a cyclophosphamide-based regimen were similar

to one based on chlorambucil,[52] cyclophosphamide is most often used because of a better safety profile.

The most recent RCT in MN studied a select population of 108 patients with documented deteriorating renal function (>20% decline in GFR within 3 to 24 months of study entry).[53] The combination of corticosteroids and a cytotoxic drug (chlorambucil) showed better protection against progressive kidney disease than placebo or cyclosporine. A difficult study to complete, trial entry took 10 years, and of the 108 patients entered, only 42% had 1 year of data, and less than 20% had 3 years of data. There were 117 severe adverse events reported, usually hematologic issues in the chlorambucil group, renal function deterioration in the cyclosporine group, and infections in both groups. Statistically, there was a small benefit in terms of preventing further progression in the chlorambucil/corticosteroid group (60% progressed) versus no difference between the cyclosporine compared with the placebo group (80% progressed), a 20% differential. However, the very high dropout rate and inability to manage these therapies safely in patients with MN with significantly declining renal function should give pause to applying any of these options under these conditions.[53]

One smaller RCT ($n = 26$) using intravenous cyclophosphamide in patients at high risk for progression (mean creatinine 2.3 to 2.7 mg/day; proteinuria 11 g/day) noted no statistical differences in proteinuria, remission rate, or rate of decline of renal function between the corticosteroid-alone and the combined-treatment groups.[54] However, this RCT used monthly intravenous doses of cyclophosphamide rather than the oral regimen used in the Italian and Indian studies and in the 2013 UK trial.

In older, smaller studies, these cytotoxic agents, even with appropriate adjustments in dose, have produced variable effects on outcome and significant adverse events in a high percentage of patients. The most recent longer term studies in high-risk patients prospectively studied 65 patients with MN and serum creatinine concentration above 1.5 mg/dl treated with oral cyclophosphamide for 12 months plus corticosteroids (same as previous regimen).[55] Renal survival was 86% after 5 years and 74% after 7 years. Partial remission occurred in 86% of the patients. The relapse rate was similar to earlier cytotoxic-corticosteroid regimens, 30% at 5 years. Treatment-related complications were significant and occurred in two thirds of patients, mainly bone marrow suppression and infections. Most adverse events could be managed by dose reduction, although some required permanent discontinuation of treatment.

A meta-analysis showed that the use of alkylating agents was associated with higher remission rates (partial or complete remission), but no statistical benefit of cytotoxic drug therapy was demonstrated compared with placebo in rates of ESRD or death.[56] The difficulty with this type of analysis is that the end-point of renal survival is far beyond the termination point of most clinical trials. The latest UK study, for example, had few patients still in follow-up after 3 years in any of the three treatment groups, so it was not possible to demonstrate any effect on long-term preservation of renal function.

In summary, cyclophosphamide used in combination with corticosteroids appears to be effective in the treatment of patients with nephrotic-range proteinuria resulting from primary MN, especially if renal function is well preserved at initiation of therapy. This combination may work even in those with impaired renal function, but the supporting evidence is much less compelling, adverse effects are higher, and the likelihood of benefit is reduced, especially in patients with advanced renal failure (GFR <30 ml/min).[55] The favorable effects are maintained beyond the 1-year treatment period, but relapse rates approach 35% by 2 years. The adverse effects of long-term cyclophosphamide therapy are the major drawbacks to the universal application of this treatment. These include increased susceptibility to infections, anemia, thrombocytopenia, nausea, vomiting, sterility, and, over time, malignant disease. Evidence from the membranous nephropathy literature suggests that the incidence of cancer is increased at a much lower level of exposure than previously considered; an increased number of malignant neoplasms with total cyclophosphamide exposure as low as 10–20 g (~100 mg/day for 6 months).[57]

Calcineurin Inhibitors

Early uncontrolled studies using the calcineurin inhibitor (CNI) cyclosporine suggested an initial benefit but a high relapse rate. Cyclosporine may reduce proteinuria not only through its immunosuppressive effects but also by direct effects on the podocyte. In a single-blinded RCT, 51 patients with corticosteroid-resistant MN were treated for 6 months with cyclosporine 2 to 5 mg/kg plus low-dose prednisone and compared with placebo plus prednisone.[58] Complete remission and partial remission were seen in 75% of cyclosporine-treated patients versus 22% of the placebo controls. Cyclosporine was well tolerated, with no adverse events requiring discontinuation of treatment. However, 38% relapsed within 6 months of discontinuation of treatment.

Only one RCT has used cyclosporine in patients with high-grade proteinuria and progressive renal failure.[59] Both proteinuria and rate of renal function loss were reduced with cyclosporine compared with placebo and when the treatment group was compared with their status 6 months before starting cyclosporine. This improvement in proteinuria was sustained for up to 2 years after cyclosporine was discontinued. The entry criteria included documented GFR decline and high-grade proteinuria, but in contrast to the UK study, the cyclosporine was introduced at a lower dose and slowly increased to minimize toxicity (mean treatment dose 3.5 mg/kg/day). Treatment with longer term cyclosporine (i.e., 12 months) has resulted in a higher rate of complete remission and partial remission (84%). In addition, persistence of remission was maintained with doses of cyclosporine as low as 1 to 2 mg/kg, although relapses were still common if the cyclosporine level fell below 100 ng/ml. Time to remission with use of cyclosporine varies from a few weeks to several months.[59a] This suggests that unless there is a significant reduction in proteinuria (>25%) within 3 to 4 months, a change in therapy should be considered.

Significant adverse effects seen with cyclosporine include hypertension, gingival hyperplasia, gastrointestinal complaints, muscle cramps, and, most important, nephrotoxicity. The latter depends on both dose and duration of treatment.

In a 12-month RCT ($n = 48$), monotherapy with tacrolimus, an alternative CNI, was compared with a control group (conservative therapy only).[60] Proteinuria remission was 76% with tacrolimus versus 35% in the control group, and progression rate also was substantially slowed by the CNI. The relapse rate after stopping of the drug, however, approached 50% by the end of 2 years of follow-up.

In summary, RCTs have shown that both cyclosporine and tacrolimus are effective in reducing proteinuria in MN. Although relapses are common after short exposure (6 to 12 months), a longer exposure time and lower maintenance doses of CNI can be used to maintain partial remission. No studies using CNIs have been of sufficient duration to confirm that maintenance of remission in proteinuria prolongs renal survival. Side effects are substantial, with the major concern being nephrotoxicity. This is particularly common if the medication is not introduced at a low dose and slowly increased until an effective drug level is reached. Clinical experience indicates increased potential for nephrotoxicity with the CNIs if the level of renal function is low (GFR <40% of normal), if there is a high degree of interstitial or vascular pathology accompanying the membranous lesion, or if the patient's renal function is rapidly deteriorating.[27,53]

Mycophenolate Mofetil

Studies using mycophenolate mofetil (MMF) in patients with MN report conflicting results. However, even in the most optimistic study, although initial response was high (used in combination with prednisone), the relapse rate within months approached 50%. The most pessimistic study (the only RCT), compared with conservative management only, showed no difference in remission rates in patients with MN.[61,62] Follow-up was limited and numbers in the latter study were small, but the reason for the marked differences between these two trials is not clear. In a small retrospective study in corticosteroid-resistant Asian patients with MN, a higher response with MMF was observed, with the partial remission rate approaching 50%, possibly related to the ethnic characteristics of the population studied. The role of MMF as monotherapy or as an adjunct in the treatment of MN remains unclear.

Rituximab

In several pilot studies, rituximab, despite substantial variations in the dose and timing of the drug, consistently reduced proteinuria by 60% to 70%.[63,64] The response rate to rituximab in patients who previously failed immunosuppressive therapy was similar to patients receiving the drug as first-line therapy. A delayed response in proteinuria reduction was seen, similar to that with cytotoxic therapy, with remissions continuing to occur up to 12 months after the last rituximab infusion. The anti-PLA_2R antibody was measured in the Mayo Clinic cohorts, and a decline in titer preceded proteinuria reductions by as long as 3 months and was associated with patients subsequently achieving a partial or complete remission compared with those with no change in titer.[65] Although the first RCT comparing rituximab plus conservative therapy to conservative therapy alone did not achieve a significant primary end-point of remission at 6 months (35% vs. 22%), anti-PLA2R levels were significantly reduced by rituximab and remission rates after a mean of 17 months of observation, increased to 65% in those treated with rituximab compared with 34% in those treated conservatively ($P < .01$).[66] These results are consistent with those of prior studies showing that immunologic remission precedes clinical remission by several months in patients treated with rituximab.[65] Although the data from these studies are quite compelling, additional RCTs are required before widespread use of this agent is advocated, despite the obvious advantages of an almost guaranteed adherence and low adverse event rate, but counterbalanced by high cost and uncertain long-term toxicity. To that end, RCTs comparing rituximab to cyclosporine or cytotoxic/corticosteroid regimens are underway and will help define the relative efficacy, safety, and relapse rate of rituximab compared with those of standard therapies.

Eculizumab

Eculizumab is a humanized anti-C5 monoclonal antibody designed to prevent the cleavage of C5 into its proinflammatory by-products. An RCT in 200 patients with MN that compared eculizumab with placebo during a total of 16 weeks showed no significant effect on proteinuria or renal function, but effective complement inhibition was not achieved.

Adrenocorticotropic Hormone

Two small studies have reported the use of an intramuscular long-acting synthetic form of adrenocorticotropic hormone (ACTH) in MN.[65] The exact mechanism of action of this agent in MN is unknown but likely unrelated to corticosteroid effects because corticosteroids alone are not beneficial in MN. A dose escalation study showed prolonged remission in the majority of patients with MN treated with the synthetic form of ACTH, 1 to 2 mg weekly intramuscularly for 1 year. In a small RCT ($n = 32$) with a similar dose regimen, ACTH was compared with a standard cytotoxic plus corticosteroids regimen. The remission rate was the same in the two groups, 80% to 90%, but the relapse rate in the ACTH group was lower, 14% versus 30%, after a follow-up of 1 year. Side effects of ACTH were few and included fluid retention, sleep disturbances, and bronze skin discoloration. Potassium supplementation was required in the majority of patients in one trial.[67]

A more recent nonrandomized study using the synthetic agent found a substantially lower response rate and an incidence of adverse events approaching 95%, prompting the authors to suggest this agent not be used in MN.[68] In contrast, a recent dose escalation study using the natural ACTH gel found a significant reduction in proteinuria proportionate to drug exposure in the majority of patients with MN with an acceptable adverse effects profile.[69]

TREATMENT SUMMARY

Control of proteinuria, specifically achieving either complete or partial remission of nephrotic syndrome, is associated with prolonged renal survival and a slower rate of renal disease progression in patients with MN. Supportive or conservative care should be provided to all patients first, including diuretics, antihypertensive agents such as ACE inhibitors and ARBs (potentially renal protective), and lipid-lowering agents, with lifestyle modifications such as salt restriction, weight normalization, and smoking cessation (see Chapter 79). In patients with MN who require disease-specific therapy, the choice of agents remains controversial. Fig. 20.7 outlines a suggested management algorithm based on the level and persistence of proteinuria.

Cytotoxic/corticosteroid combinations, CNIs, and, most recently, rituximab have proved effective in reducing proteinuria in moderate-risk or high-risk MN patients. The physician, in concert with the patient, must consider all risks as well as benefits in deciding which therapy should be used first. These approaches are not mutually exclusive and can be used in sequence if the first one chosen fails to induce a remission or if adverse effects are untenable. Ideally, the approach should leave 2 to 3 months between treatment regimens to help immune system recovery. Alternatively, a second course of the same immunosuppressive regimen could be used, but at the potential cost of cumulative toxicity,

or another treatment regimen may be indicated if the patient's risk profile has changed. Although the risks for malignancy from alkylating agents are reduced by limiting treatment to 6 months (especially with the alternating regimen), tobacco smokers are at increased risk for bladder and lung cancer and might be candidates for an alternative treatment regimen. In addition, men wanting to procreate are advised to bank sperm before treatment with alkylating agents.

Preliminary evidence on the use of long-acting ACTH suggests it may be effective and safer than current regimens; however, the current cost is prohibitive, and efficacy needs to be assessed in an RCT before it is recommended as standard therapy. Patients with severe renal impairment (GFR <30 ml/min), especially if the MN course has been slowly progressive and histopathology indicates significant interstitial fibrosis and glomerular obsolescence, are less likely to benefit from immunosuppressive therapy, and the risks of treatment may favor conservative therapy as the best option for such patients.

Membranoproliferative Glomerulonephritis and Cryoglobulinemic Glomerulonephritis

Sanjeev Sethi, An S. De Vriese, Fernando C. Fervenza

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

Definition

Membranoproliferative glomerulonephritis (MPGN) is a pathologic pattern of glomerular injury resulting from subendothelial and mesangial deposition of immune complexes and/or complement factors and their products, along with proliferative changes in the glomeruli. This pattern does not represent a disease entity per se, but can occur as a result of different pathogenic processes. Other names for MPGN include lobular glomerulonephritis and mesangiocapillary glomerulonephritis.

Epidemiology

MPGN is decreasing in frequency in developed countries (possibly due to better control of infectious diseases) but remains common in patients presenting with nephrotic syndrome in low- and middle-income countries of South America, Asia, and Africa. The incidence of MPGN in most developed countries is fewer than 1 to 2 cases per million population per year.[1] Only about 4% to 5% of kidney biopsy samples showing an MPGN pattern are due to C3 glomerulonephritis (see Chapter 22).

Former Classification

Traditionally, MPGN was classified based on the ultrastructural characteristics as MPGN type I, MPGN type II, and MPGN type III. MPGN type I was defined by the presence of mesangial and subendothelial deposits. MPGN type II, also referred to as dense deposit disease (DDD), was characterized by mesangial and intramembranous highly electron-dense deposits. MPGN type III was defined by the presence of subendothelial, intramembranous, and subepithelial electron-dense deposits. However, results of immunofluorescence (IF) microscopy demonstrated that some cases had glomerular deposition of immunoglobulins and complement components, whereas in others, only complement deposition was present. This insight engendered a new classification. However, older publications regarding epidemiology, therapy, and transplantation may be difficult or impossible to interpret because (with the exception of DDD), immune-complex and complement-mediated MPGN were included together (see later discussion).

Newer Classification Based on Etiology and Pathogenesis

The Mayo Clinic classification of MPGN[2,3] divides MPGN based on two broad pathogenetic pathways: immune complex or monoclonal immunoglobulin deposition in the glomeruli with or without complement deposition and complement deposition subsequent to dysregulation of the complement system.

The MPGN pattern of injury secondary to deposition of immune complexes in the glomeruli can occur when there are persistent circulating antigen-antibody immune complexes resulting from chronic infections, autoimmune diseases, or paraproteinemias. On light microscopy, a proliferative glomerulonephritis is seen in the acute phase with initial influx of neutrophils followed by mononuclear inflammatory cells. In the reparative phase, the injured mesangial cells and endothelium produce new basement membrane and there is expansion of the mesangial matrix. As a result of remodeling, the glomerular basement membrane (GBM) thickens and glomeruli acquire a lobular appearance typical of MPGN pattern. The immune-complex and monoclonal immunoglobulin–mediated MPGN are characterized by the presence of immunoglobulins by IF; in immune complex–mediated MPGN the deposits are polyclonal, whereas in monoclonal immunoglobulin–mediated MPGN the immunoglobulin is monotypic. C3 is also usually present, indicating activation of the complement pathway.

Complement-mediated MPGN is less common than immune complex–mediated MPGN and results from dysregulation of the complement alternative pathway (see Chapter 22).

A third pathogenic pathway with an MPGN pattern can be seen in the absence of immune complex or complement deposition in the setting of chronic endothelial injury or chronic thrombotic microangiopathy. Uncommon causes such as cryofibrinogen glomerulopathy and lipoprotein glomerulopathy that result in endothelial injury and deposition of proteins along the capillary walls also can result in an MPGN pattern of injury (Table 21.1).

Clinical Presentation and Pathology

Infection-Associated MPGN

Chronic viral infections such as hepatitis C (HCV) and B (HBV) are important causes of immune complex–mediated MPGN (cryoglobulinemic glomerulonephritis, see later discussion and Chapter 55).[4,5] The exact mechanism of HCV-related glomerular disease is unknown. Toll-like receptors, particularly TLR3, might play a role in HCV-related MPGN.[6] HBV most frequently causes a membranous nephropathy pattern of injury, but more rarely can be associated with MPGN. The pathology of HBV-related MPGN is likely related to the trapping of circulating immune complexes in the mesangium and subendothelial regions.[7] It is also possible that mesangial cells are directly infected by HBV virions. Rarely, MPGN may be seen with acute viral infections such as with Puumala hantavirus.[8]

Chronic bacterial infections can cause MPGN as a result of continuous low-grade antigenemia.[9,10] Potential causative agents include *Staphylococcus, Mycobacterium tuberculosis,* streptococci, *Propionibacterium acnes, Mycoplasma pneumoniae, Coxiella burnetii, Nocardia, Brucella,* and *Meningococcus*.[11,12] "Shunt nephritis," as may be seen with

TABLE 21.1 Causes of a Membranoproliferative Pattern of Glomerular Injury

Immune complex–mediated	Deposition of immune complexes as a result of an infection	Viral: Hepatitis B and C Bacterial: Endocarditis, infected ventriculoatrial shunt, visceral abscesses, leprosy, meningococcal meningitis Protozoa/other infections: Malaria, schistosomiasis, mycoplasma, leishmaniasis
	Deposition of immune complexes as a result of an autoimmune disease	Systemic lupus erythematosus Sjögren syndrome Rheumatoid arthritis
	Deposition of monoclonal immunoglobulin as a result of a monoclonal gammopathy due to a plasma cell or B-cell disorder	
Complement-mediated (C3 glomerulonephritis and dense deposit disease)	Mutations in complement-regulating proteins: CFH, CFI, CFHR5 Antibodies to complement regulating proteins: C3 nephritic factor, antibodies against CFH, CFI, or CFB Mutations in complement factors: C3, CFB	
Non-immunoglobulin/ complement–mediated	Healing phase of HUS/TTP Anti-phospholipid (anti-cardiolipin) antibodies syndrome POEMS syndrome Radiation nephritis Nephropathy associated with bone marrow transplantation Drug-associated thrombotic microangiopathies Sickle cell anemia and polycythemia Dysfibrinogenemia and other prothrombotic states Transplant glomerulopathy	
Idiopathic	None of the conditions above are present	

Modified from Fervenza FC, Sethi S, Glassock RJ. Idiopathic membranoproliferative glomerulonephritis: does it exist? Nephrol Dial Transplant 2012;27(12):4288-4294, with permission.

ventriculoatrial or ventriculocaval shunts for hydrocephalus or as a result of catheter infections (e.g., parenteral nutrition), is caused most commonly by coagulase-negative staphylococci.

Fungal and parasitic infections are less commonly associated with an MPGN pattern of injury.[13] Leishmaniasis also has been associated with MPGN.[14]

In the setting of viral infections, IF typically shows granular deposition of immunoglobulin M (IgM), C3, and both kappa and lambda light chains (Fig. 21.1). IgG may or may not be present, and C1q is typically negative. On the other hand, the presence of IgG staining stronger than IgM and C3 is more often seen in bacterial infections, although in some cases with chronic infections the immunoglobulin staining may be weak compared with the C3 staining. Electron microscopy (EM) shows mesangial and subendothelial deposits. The capillary walls are thickened with entrapment of cellular elements, subendothelial electron-dense deposits, matrix-like material and new GBM formation manifested by the presence of double contours on light microscopy.

Autoimmune-Associated MPGN

An MPGN pattern of injury is commonly seen in patients with autoimmune diseases such as systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), primary Sjögren syndrome, undifferentiated connective tissue disease, primary sclerosing cholangitis, and Graves disease.[15,16] The majority of patients with Sjögren syndrome and glomerulonephritis (80%) have type II monoclonal cryoglobulinemia and low complement C4 levels.[17] Sjögren syndrome is considered one of the most common causes of non–HCV-related cryoglobulinemia.[18]

On IF, a full house pattern with positive staining for IgG, IgA, IgM, C1q, C3, and kappa and lambda light chains is frequently seen, particularly in the setting of SLE. IgM may be the dominant immunoglobulin in MPGN associated with RA and primary Sjögren syndrome. EM shows mesangial and subendothelial capillary wall electron-dense deposits. Subepithelial deposits also may be present. In such cases, a membranous component of the disease should be considered. Tubuloreticular inclusions are often present in the endothelial cells.

Monoclonal Immunoglobulin–Associated MPGN

Monoclonal gammopathies encompass a heterogenous spectrum of disorders characterized by clonal proliferation of immunoglobulin-producing B lymphocytes or plasma cells. Generally, a monoclonal immunoglobulin can be detected in the blood or urine (M-protein),[19] although in some cases routine serum electrophoresis and immunofixation fail to reveal a monoclonal protein. The physicochemical properties of the monoclonal immunoglobulin often result in renal disease, sometimes in the absence of overt malignancies such as lymphoma, multiple myeloma, or Waldenström macroglobulinemia. In those cases the term *monoclonal gammopathy of renal significance* (MGRS) is used.[20] The glomerular diseases included in this group are proliferative glomerulonephritis with monoclonal immunoglobulin deposits, amyloidosis, fibrillary glomerulonephritis, immunotactoid glomerulopathy, and monoclonal immunoglobulin deposition disease (see Chapter 27).[21-23] Although each of these entities may have a varied morphologic appearance, the common pattern of glomerular injury is MPGN. In the next paragraph, we will discuss proliferative glomerulonephritis resulting from glomerular deposition of monoclonal immunoglobulin.

On kidney biopsy (Fig. 21.2), glomerular deposition of the monoclonal immunoglobulin results in an MPGN pattern of injury in most cases. Less commonly, other patterns of proliferative glomerulonephritis can be seen, including mesangial proliferative, diffuse proliferative, crescentic, and necrotizing, and sclerosing glomerulonephritis.[24,25] IF studies are crucial for the diagnosis and show mesangial and capillary wall monoclonal immunoglobulin deposits. The monoclonal immunoglobulin most

(B and C) Immunofluorescence microscopy showing bright granular staining for (B) IgM, and (C) C3. There was equal staining for kappa and lambda light chains (not shown). (D) Electron microscopy showing subendothelial electron-dense deposits and double contour formation. *Black arrows* point to subendothelial deposits. (**D,** ×13,000).

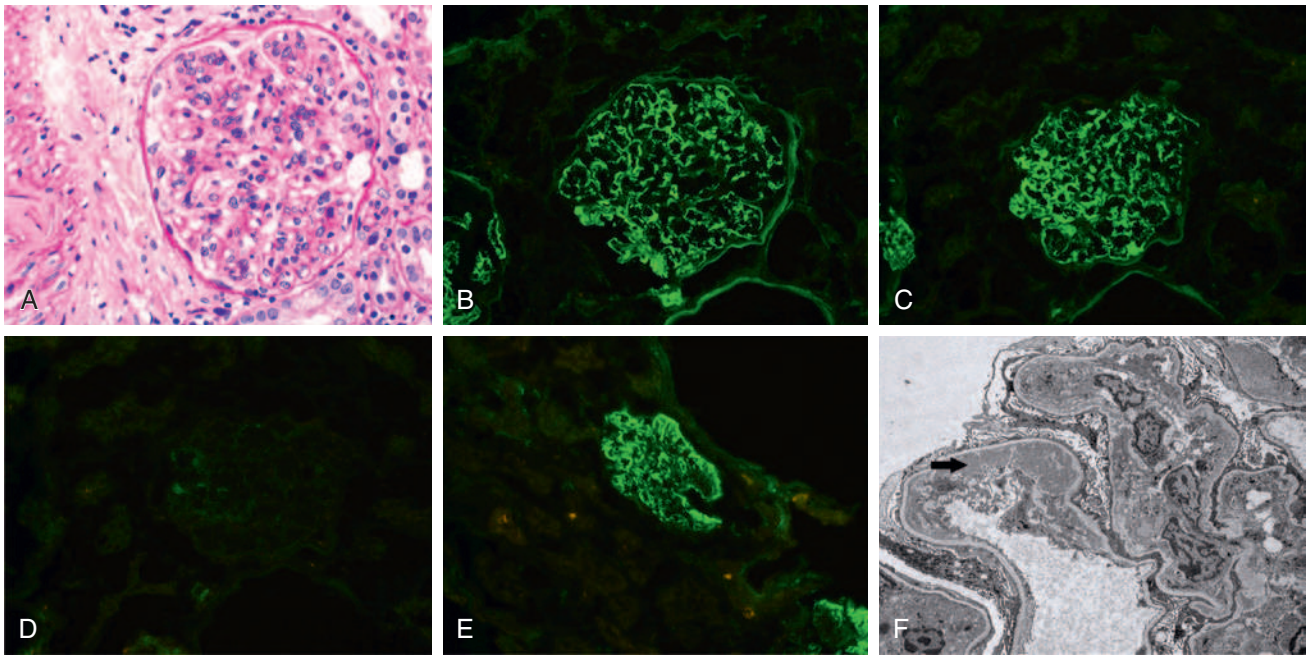

Fig. 21.2 Proliferative glomerulonephritis with monoclonal immunoglobulin deposits. (A) Light microscopy showing an MPGN pattern of injury (periodic acid–Schiff stain, ×40). (B to E) Immunofluorescence microscopy showing bright granular staining for (B) IgG, (C) kappa light chains, (E) IgG3 subtype, and (D) negative staining for lambda light chains. (F) Electron microscopy showing subendothelial electron-dense deposits and double contour formation. *Black arrows* point to subendothelial deposits (**F,** ×4000).

often contains heavy chain IgG, less commonly IgM or rarely IgA, with kappa or lambda light chain restriction. Less commonly, only heavy or light chains may be present. EM shows mesangial and subendothelial electron-dense deposits, and rarely subepithelial and intramembranous deposits. Glomerular capillary wall remodeling with double contour formation is often present.

In cases in which the heavy chain consists of IgG, the IgG3 subclass is the most common subclass. Interestingly, this class of deposits is most likely to have undetectable circulating monoclonal immunoglobulin by routine serum and urine electrophoresis studies.[26]

In a recent study of monoclonal immunoglobulin–associated MPGN, almost all patients had a monoclonal or biclonal band on serum immunofixation studies. Furthermore, bone marrow studies revealed 16 cases of MGRS, of which 2 converted to multiple myeloma, 2 cases of chronic lymphocytic leukemia (CLL), 1 case of lymphoplasmacytic lymphoma/Waldenström macroglobulinemia, 3 cases of low grade B-cell lymphoma not further classifiable, and 6 cases of multiple myeloma.[22] Thus all patients with MPGN associated with monoclonal immunoglobulin should be evaluated for an underlying plasma cell or B-cell proliferative disorder.

MPGN With Masked Immune Deposits

MPGN with isolated C3 deposits rarely occurs in the setting of monoclonal gammopathy.[27] Hypocomplementemia is common. IF on formalin-fixed, paraffin-embedded tissue after protease digestion unmasks monoclonal immunoglobulin glomerular deposits. The immunoglobulin on the glomerular deposits matches the monoclonal protein on serum immunofixation. It is important that these cases are not misdiagnosed as C3 glomerulopathy, because most are associated with a low-grade lymphoma or plasma cell dyscrasia. A C4d stain can be helpful in detecting masked immune deposits.[28,29]

Complement-Mediated MPGN

MPGN is also the most common pattern MPGN seen in C3 glomerulopathy, a lesion that is characterized by dominant C3 staining with minimal or no immunoglobulin staining on IF (see Chapter 22).

MPGN Without Immunoglobulins or Complement

Glomeruli may demonstrate membranoproliferative-like changes in the absence of immunoglobulin or complement deposits in chronic thrombotic microangiopathy (see Chapter 29).

Uncommon Causes of MPGN

Cryofibrinogen-related membranoproliferative glomerulonephritis. Cryofibrinogenemia is a rare disease resulting in an MPGN pattern of injury (Fig. 21.3). Cryofibrinogen is a cryoprecipitate that develops after refrigeration of plasma but not serum (when both serum and plasma form a precipitate on refrigeration, the responsible proteins are called cryoglobulins). Cryofibrinogen may be asymptomatic, but can be associated with thromboembolic disease, particularly affecting the skin.

C4 glomerulopathy. C4 glomerulopathy is characterized by glomerular deposits of predominantly C4 with little or no immunoglobulin or C3 deposition. This glomerulopathy encompasses C4 DDD and C4 glomerulonephritis[30] and may be caused by an overactive lectin pathway of complement. Renal biopsy shows a membranoproliferative pattern of injury with extremely thick glomerular capillary walls.

Collagen type III glomerulopathy. Collagen type III glomerulopathy is a rare disorder characterized by massive accumulation of atypical type III collagen fibrils in the mesangium and subendothelial space (see Chapter 28).

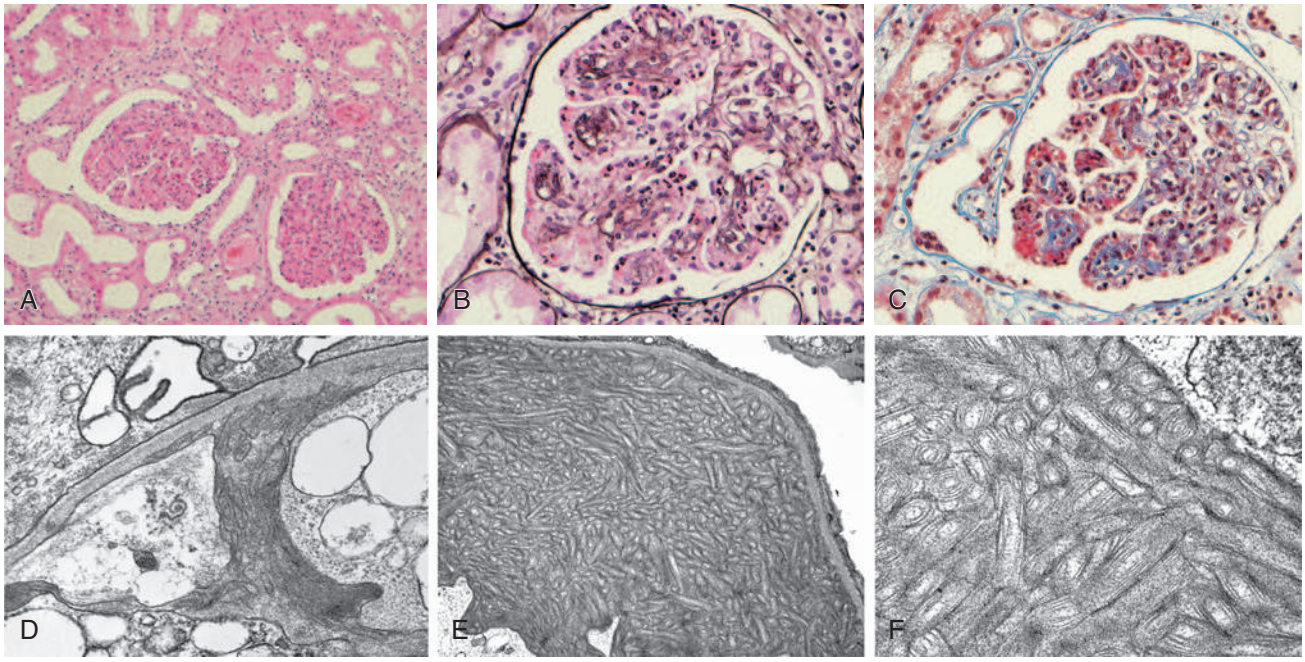

Fig. 21.3 Cryofibrinogen glomerulopathy with a membranoproliferative pattern of injury. (A to C) Light microscopy showing an MPGN pattern of injury. Scattered fuschinophilic material can be seen with some capillary loops in (C) (**A,** Hematoxylin and eosin, ×20; **B,** silver methenamine silver ×40; Masson trichrome stain, ×40). Immunofluorescence microscopy was negative for immune deposits. Electron microscopy showing (**D**) randomly arranged and loosely arranged subendothelial fibrillary deposits with tubular substructures and (**E** and **F**) aggregates of intraluminal tubular deposits with large central bore with double and triple layering (**D,** ×30,000; **E,** ×9300; **F,** ×3000).

Evaluation

The evaluation for MPGN should be guided by the suspected cause, based on clinical presentation and biopsy findings. A standard workup for MPGN should include complement evaluation. Low C3 and C4 is more typical of classic pathway activation, as in immune complex–mediated glomerulonephritis. A low C3 with a normal C4 suggests abnormalities of the alternative complement pathway. These findings along with the biopsy results, particularly IF and EM can further guide detailed evaluation.

Infections

Workup in the evaluation of infection-related MPGN depends on the suspected pathogen (see Chapter 55). In the case of hepatitis-related MPGN, tests should include viral serology examination and quantification of viral load by polymerase chain reaction. The workup for parasitic infection–related MPGN should include blood tests for malaria, urine and stool tests for schistosomiasis, and serologic tests for schistosomiasis and leishmaniasis. Blood cultures, cultures of indwelling catheter tips, imaging studies for deep-seated abscesses, and transthoracic echocardiograms for valvular vegetations should be performed in the case of suspected fungal and bacterial infections. Parasitic and fungal infections are investigated only in the appropriate clinical situation (history of recent travel to endemic regions, prolonged fever of unknown origin, atypical pulmonary infiltrates).

Autoimmune Diseases

The diagnostic tests for autoimmune diseases should follow the established criteria, such as that of the American College of Rheumatology.

Monoclonal Gammopathy

The workup should include serum protein electrophoresis, urine protein electrophoresis, serum and urine immunofixation, and serum free light chain assays. Bone marrow evaluation should be performed to confirm an underlying plasma cell dyscrasia and/or lymphoproliferative disorder.

Treatment

Therapy should be directed to treatment of the underlying condition, for example, chronic infection, autoimmune disease, and malignancy such as myeloma, lymphoma, or CLL.

Treatment of monoclonal immunoglobulin–associated MPGN is complex. Conservative as well as immunosuppressive therapy with the use of corticosteroids (alone or in combination with an alkylating agent), thalidomide, bortezomib, and mycophenolate mofetil (MMF) have been used in a small number of patients with variable outcomes. Preliminary results in seven patients treated with rituximab have been encouraging: five of seven had a complete remission of the nephrotic syndrome and two of seven had a partial response,[31] but our own unpublished observations have not been so encouraging. Treatment also may differ based on the type of the immunoglobulin. In patients with IgM monoclonal proteins, we suggest a regimen used to treat Waldenström macroglobulinemia for initial therapy: rituximab 4 doses of 375 mg/m^2, with or without corticosteroids. For patients with non-IgM monoclonal proteins, a regimen of bortezomib plus dexamethasone or bortezomib, cyclophosphamide, and dexamethasone similar to that used in myeloma could be considered because these regimens are well tolerated and safe for use in renal failure, with minimal dose adjustments needed. We typically treat patients for at least 6 months and then reassess. Some patients also may respond to a 3- to 6-month combined course of prednisone and cyclophosphamide with disappearance of the monoclonal gammopathy. Daratumumab is an IgG1-kappa human monoclonal antibody that binds to the CD38 transmembrane glycoprotein on the surface of tumor cells and induces apoptosis. The molecule showed promise in the treatment of refractory multiple myeloma and is being evaluated in patients with proliferative glomerulonephritis and monoclonal immune deposits. Success has been reported with the use of autologous stem cell transplantation with monoclonal gammopathy of renal significance and light chain proximal tubulopathy, but apart from unpublished anecdotal cases no information is available on its use regarding monoclonal immunoglobulin–associated MPGN.[32] Prospective, controlled studies in larger cohorts of patients with MPGN and monoclonal gammopathy are needed to ascertain optimal therapy.

Similarly, there is no strong evidence to guide treatment in patients with "idiopathic" MPGN.[33] Corticosteroids have been widely used as monotherapy and/or in combination with other immunosuppressives. In a randomized trial, 80 children with nephrotic range proteinuria and preserved renal function were randomly assigned to either prednisone or lactose 40 mg/m^2 every other day for a mean duration of 41 months.[34] Prednisone therapy had a significantly lower rate of treatment failure (40% vs. 55%), but was associated with significant toxicity, particularly hypertension, and it is uncertain whether the findings (published in 1992) are applicable to contemporary practice. No randomized studies with corticosteroids have been performed in adults with idiopathic MPGN.

Cytotoxic agents have been tried, with unimpressive results and significant side effects. Calcineurin inhibitors also have been used in uncontrolled studies, suggesting a modest decline of proteinuria in patients with MPGN not otherwise characterized. Data on the use of MMF in patients with MPGN is limited.[35-37]

A small observational study compared five adults treated with MMF and oral prednisolone to six patients on no immunosuppressive agents.[35] At 18 months, proteinuria fell and glomerular filtration rate (GFR) was preserved or improved in the MMF group, compared with no change in proteinuria and a 40% decline in GFR in patients who were not treated. Whether the benefit was derived from MMF or prednisone cannot be ascertained from the study.

Our own experience with rituximab is limited to four patients with idiopathic MPGN.[38] Rituximab 1000 mg intravenously on days 1 and 15 led to a 65% reduction in proteinuria and preserved the GFR over 1 year.

The Kidney Disease: Improving Global Outcomes (KDIGO) guidelines published in 2012 recognized difficulties in interpreting previous information, because in many instances historical controls were used, studies antedated the use angiotensin II blockade, statistical significance was marginal, or the power to detect substantial differences was small. More importantly, in these studies, the underlying pathogenic processes that lead to MPGN were not taken into account. Thus the KDIGO guidelines only "Suggest that adults or children with presumed idiopathic MPGN accompanied by nephrotic syndrome AND progressive decline of kidney function receive oral cyclophosphamide or MMF plus low-dose alternate-day or daily corticosteroids with initial therapy limited to less than 6 months."[33]

We have taken a pragmatic approach based on our clinical experience, as follows:

- Patients with normal kidney function, no active urinary sediment, and non-nephrotic range proteinuria can be treated conservatively as outlined in Chapter 79, because the long-term outcome is relatively benign in this setting. Frequent follow-up is required initially to detect early deterioration in kidney function. If there is no disease progression, follow-up every 6 months should suffice.
- Patients with nephrotic syndrome and preserved renal function could be treated with a regimen similar to that used in focal segmental glomerulosclerosis, such as prednisone 1 mg/kg/day (maximum dose 60 to 80 mg/day) for 12 to 16 weeks (see Chapter 18). If the patient

responds, prednisone is gradually tapered to alternate-day therapy over 6 to 8 months. If there is less than a 30% reduction in proteinuria after 12 to 16 weeks, we recommend tapering and discontinuation of prednisone. Calcineurin inhibitors may be considered in patients who do not respond to or tolerate glucocorticoids.

- Patients who present with impaired kidney function, with or without nephrotic syndrome and without crescents, also can be considered for treatment with corticosteroids, as mentioned previously. If there is no response, cyclophosphamide 2 mg/kg/day, (reduced to 1.5 mg/kg/day in patients with a serum creatinine greater than 2.5 mg/dL or age greater than 60 years) for 3 to 6 months could be added, realizing that the efficacy of cyclophosphamide in these patients has not been demonstrated.
- Patients presenting with rapidly progressive disease and crescents on biopsy can be treated as in other forms of crescentic glomerulonephritis with pulse methylprednisolone followed by oral corticosteroids and cyclophosphamide (see Chapter 25).
- Patients who present with advanced renal insufficiency and severe tubulointerstitial fibrosis of renal biopsy are unlikely to benefit from immunosuppressive therapy.

Transplantation

Recurrent MPGN after kidney transplantation is discussed in Chapter 108.

CRYOGLOBULINEMIC GLOMERULONEPHRITIS

Definition

Cryoglobulins are immunoglobulins that precipitate at cold temperatures and dissolve when rewarmed. Cryoglobulins can be present in the setting of infections, autoimmune diseases, and monoclonal gammopathy. Thus all of the three above-mentioned causes can present with an MPGN pattern of injury with intraluminal deposits (immune microthrombi) suggestive of cryoglobulins.

Cryoglobulins are often divided into three types (Table 21.2). Type I cryoglobulinemia is characterized by the presence of a single monoclonal immunoglobulin, most often resulting from an underlying B-cell hematologic malignancy, typically Waldenström macroglobulinemia or multiple myeloma. In the absence of criteria for malignancy, the diagnosis of MGRS should be established. The cryoglobulins are usually IgM or IgG, but IgA and monoclonal free light chains also may occur.

In type II mixed cryoglobulinemia, there is a mixture of monoclonal IgM with rheumatoid factor activity directed against a polyclonal IgG. It is most commonly due to chronic infections, generally HCV infection, but also HBV and HIV infections. It also can occur in the context of autoimmune diseases, particularly Sjögren syndrome, in which it is mostly type II cryoglobulins. In patients with HCV infection, cryoglobulinemia may be the first manifestation of liver disease.[5,39]

In type III mixed cryoglobulinemia, the IgG and IgM are polyclonal. Type III cryoglobulinemia is most commonly seen in HCV infection, as well as in chronic inflammatory and autoimmune disease (e.g., SLE and Sjögren syndrome), and in lymphoproliferative malignancies. Thus there is a significant overlap between the underlying causes of type II and III cryoglobulins.

Clinical Presentation

The syndrome of cryoglobulinemia is caused by deposition of antigen-antibody complexes in capillaries and small arterioles and occasionally in small arteries. Most cases are associated with HCV. In the majority of patients with HCV infection, the immune complexes consist of HCV, anti-HCV IgG, and monoclonal IgM anti-IgG (with rheumatoid factor activity) (type II mixed cryoglobulinemia). Clinical presentation of mixed cryoglobulinemia includes weakness, palpable nonpruritic purpura (Fig. 21.4), symmetric arthralgias (arthritis is rare), peripheral neuropathy and, renal involvement.[40] The purpura is usually painless and mainly localized to the extremities and buttocks similar to patients with IgA vasculitis (see Chapter 23). Other manifestations include digital necrosis (Fig. 21.5), congestive heart failure, pulmonary infiltrates, and mesenteric ischemia. The clinical syndrome and dominant symptoms may evolve over time. On the other hand, patients with type I cryoglobulinemia are usually asymptomatic. Renal disease will be manifested in approximately 20% to 60% of the patients. The clinical presentation varies from microscopic hematuria with low-grade proteinuria to a full-blown nephrotic or nephritic syndrome or both. Hypertension is common and can be severe. Renal disease is a major determinant of long-term prognosis and substantially increases mortality.

Evaluation

Laboratory data suggestive of a cryoglobulin are low C4 levels (and normal or mildly decreased C3 levels) and a positive rheumatoid factor. It is crucial that blood is drawn into collection tubes that have been prewarmed to 37° C without anticoagulants, because anticoagulants can produce false-positive results due to cryofibrinogen or heparin-precipitable complexes. However, in as many as 40% of patients with type II and in occasional patients with type III mixed cryoglobulinemia, circulating cryoglobulins may not be detected. In some cases, renal disease presents in the absence of detectable cryoglobulins or other manifestations of mixed cryoglobulinemia such as purpura or arthritis. There is a poor correlation between the clinical manifestations and the cryocrit.

On renal biopsy an MPGN lesion is seen in more than 80% of the cases (Fig. 21.6). Light microscopy findings that point toward a cryoglobulinemic MPGN include a greater number of macrophages than seen in other forms of proliferative glomerulonephritis, as well as the presence of intraluminal thrombi composed of precipitated cryoglobulins. On IF, there is diffuse IgM deposition in capillary loops, and EM may show subendothelial deposits that often have a characteristic "fingerprint" pattern of cryoprecipitates. MPGN with features of cryoglobulins should lead to evaluation for infections (in particular HCV infection), autoimmune diseases (in particular Sjögren syndrome), and monoclonal gammopathies. Features that suggest glomerulonephritis due to monoclonal immunoglobulin–associated cryoglobulins (type I

TABLE 21.2 Cryoglobulin Classification and Associated Diseases

	Cryoglobulin Type	Immunoglobulin Class	Associated Diseases
I.	Monoclonal immunoglobulins	M>G>A>BJP	Myeloma, CLL, Waldenström macroglobulinemia
II.	Mixed cryoglobulins with monoclonal immunoglobulins	M/G≫G/G	Infection (hepatis C), Sjögren syndrome, CLL, lymphoma
III.	Mixed polyclonal immunoglobulins	M/G	Infection (hepatitis B/C), SLE, RA, vasculitis, neoplasia

CLL, Chronic lymphocytic leukemia; *RA,* rheumatoid arthritis; *SLE,* systemic lupus erythematosus; *BJP,* Bence Jones protein (light chains).

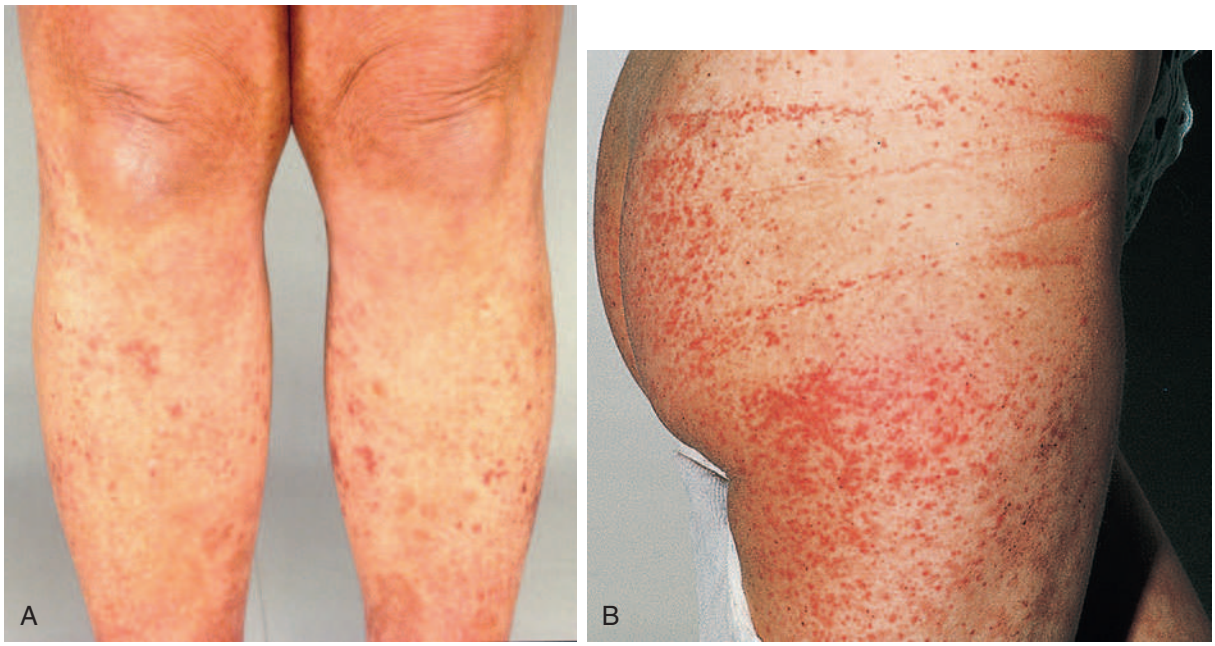

Fig. 21.4 Purpura in patient with hepatitis C virus–associated cryoglobulinemia. **(A)** Palpable nonpruritic purpura affecting the lower extremities in a patient with hepatitis C virus infection and cryoglobulinemia. Raised purpuric lesions are present on the legs. Differential diagnosis for patients with dermatorenal syndromes includes Henoch-Schönlein purpura (IgA vasculitis) and antineutrophil cytoplasmic antibody–associated vasculitis. **(B)** Purpuric lesions are present on the patient's buttocks and thigh. Note the purpuric lesions along the superior and inferior elastic border of the undergarment line.

Fig. 21.5 Necrosis of the fingertips in a patient with cryoglobulinemia.

cryoglobulins) include intraluminal periodic acid–Schiff (PAS) positive (hyaline-like) deposits on light microscopy, intraluminal monoclonal immunoglobulin on IF microscopy, and substructures (microtubules, fibrillary, finger prints) on EM.

Treatment

Patients with a rapidly progressive, organ-threatening, or life-threatening cryoglobulinemic syndrome such as rapidly progressive glomerulonephritis, severe digital ischemia, gastrointestinal vasculitis, rapidly progressive neuropathy, central nervous system vasculitis, and heart failure should be treated with immunosuppressive therapy, regardless of the cause of the mixed cryoglobulinemia.[41] This typically involves a short course of corticosteroids combined with either rituximab, or if this is unavailable, cyclophosphamide.

Patients with life-threatening disease (e.g., acute respiratory failure with pulmonary hemorrhage) or cryoglobulinemia-associated hyperviscosity syndrome should also receive plasmapheresis in addition to immunosuppressive therapy. After disease stabilization, therapy should be directed at the underlying disease. Patients with HCV infection (without decompensated cirrhosis) and mixed cryoglobulinemia should receive antiviral therapy as per current guidelines.[42]

However, patients with severe vasculitic manifestations as described previously and not yet treated with antiviral therapy should receive immunosuppression first, with antiviral therapy delayed for 1 to 4 months in agreement with the European League Against Rheumatism (EULAR) and the Group for the Study of Cryoglobulinemias (GISC) guidelines.[43,44] The rationale is based on the fact that immunosuppression can rapidly improve inflammation and resolve target-organ damage. However, this approach may change with the introduction of newer interferon-free antiviral regimens. The specific antiviral drugs and therapy schemes depend on the HCV genotype, renal function, prior treatment response, type of antiviral agent used, tolerance to treatment, and clinical and laboratory response to treatment.

Patients with a lymphoproliferative disorder should receive disease-specific therapy. Exceptions include mixed cryoglobulinemia secondary to HIV or HBV infections; in such patients, antiviral therapy should be initiated before or concomitantly with immunosuppressive therapy, particularly rituximab.

SELF-ASSESSMENT QUESTIONS

1. A 50-year-old woman is referred for sudden onset of edema and hypertension. Past medical history is unremarkable. Apart from a blood pressure of 155/95 mm Hg and 2+ edema, the physical examination is unremarkable. Serum creatinine is 1.8 mg/dl and proteinuria is 3.2 g/24 h. Urinalysis shows 50 to 100 red blood cells per high-power field, of which more than 25% are dysmorphic. C3/C4 complement levels, antineutrophil cytoplasmic antibody (ANCA), antinuclear antibody (ANA), and anti–glomerular basement membrane (GBM) are all normal or negative. A renal biopsy is performed. Light microscopy shows a membranoproliferative glomerulonephritis (MPGN) pattern of injury on immunofluorescence (IF) immunoglobulin G (IgG) (+++), IgM (+), IgA (–) C3 (+++), C1q (–), kappa (+++), lambda (–) chains, and electron microscopy (EM) duplication of the GBM with subendothelial deposits.
   The most likely diagnosis is:
   A. MPGN secondary to a monoclonal gammopathy
   B. MPGN secondary to underlying infection
   C. MPGN secondary to abnormalities in the alternative pathway of complement
   D. MPGN type I (idiopathic)
2. A 65-year-old man undergoes orthotopic liver transplantation for liver failure secondary to hepatitis C virus (HCV) infection. The immediate post-transplantation course is uneventful. However, 1 year later he presents with recurrence of HCV infection, blood pressure of 150/90 mm Hg, proteinuria of 3 g/24 h, a rising serum creatinine up to 1.8 mg/dl, and a serum albumin of 3.9 g/dl. Urinalysis shows 40 to 50 red blood cells per high-power field, of which more than 25% are dysmorphic. C3 complement is 101 mg/dl (normal 75-115 mg/dl), C4 complement is 2 mg/dl (normal 10-40 mg/dl), and rheumatoid factor is positive.
   In this patient, a renal biopsy is most likely to show:
   A. Focal segmental glomerulosclerosis
   B. Minimal change disease
   C. Membranous nephropathy
   D. Cryoglobulinemic glomerulonephritis
3. Which of the following causes of glomerulonephritis is typically associated with low serum complement C4?
   A. Mixed cryoglobulinemia
   B. Henoch-Schönlein purpura nephritis
   C. Anti-GBM disease
   D. Post-streptococcal glomerulonephritis
4. A 52-year-old woman with a long history of rheumatoid arthritis and Sjögren syndrome is evaluated for new onset of a skin rash on the lower extremities and impaired kidney function. Blood pressure is 150/90 mm Hg. Serum creatinine is 1.8 mg/dl. Urinalysis shows more than 50% red blood cells per high-power field, of which more than 25% are dysmorphic. Proteinuria is 2.8 g/24 h. C3 complement is 82 mg/dl (normal 75-115 mg/dl), C4 complement is less than 5 mg/dl (normal 10-40 mg/dl). ANCA, ANA, anti-DS-DNA and anti-GBM serologic results are negative.
   In this patient a renal biopsy is most likely to show:
   A. MPGN with IgA (+++), C3 (++), IgG (+), kappa (+), lambda (++)
   B. MPGN with linear IgG
   C. MPGN with C3 (+++), IgG (neg), IgM (neg), IgA (neg)
   D. MPGN with IgG (++), IgM (+++), IgA (+) C3 (++), kappa (++), lambda (++)

Glomerulonephritis Associated With Complement Disorders

H. Terence Cook, Matthew C. Pickering

Glomerular diseases associated with abnormalities of the complement system include thrombotic microangiopathy (see Chapter 29) and glomerulonephritides. Activation of complement in most cases of glomerulonephritis is secondary to other processes in the glomerulus such as deposition of immune complexes. However, in a small number of cases, abnormalities of the complement system itself, both genetic and acquired, are the cause of glomerulonephritis and it is those that are discussed in this chapter. Abnormalities of the classic pathway of complement have been associated with glomerulonephritis. Most importantly there is an association between deficiencies of early components of the classic pathway of complement, autoimmunity, and glomerulonephritis.[1] This is most clearly seen in the very rare individuals with C1q deficiency, almost all of whom have a lupus-like illness. This is thought to be due to the failure of clearance of immunogenic apoptotic bodies and other cellular debris in the absence of normal classic pathway complement activation.

The largest group of patients with complement abnormalities and glomerulonephritis is that in which there is an abnormality of control of the alternative pathway of complement activation with glomerular deposition of C3 in the absence of immunoglobulin—now termed C3 glomerulopathy (Box 22.1).

C3 GLOMERULOPATHY

C3 glomerulopathy is a recently introduced term[2] that encompasses glomerular disease characterized by the accumulation of complement component C3 in glomeruli because of abnormal control of complement activation, deposition, or degradation, particularly abnormal control of the alternative pathway of complement activation (Fig. 22.1). Characteristically, glomeruli show strong immunohistologic staining for C3 without significant staining for immunoglobulins or for components of the classic pathway of complement activation, C1q and C4. C3 glomerulopathy, thus defined, is distinct from atypical hemolytic uremic syndrome (aHUS), which also may be associated with alternative pathway activation, because in aHUS complement activation is on the renal endothelium and is not associated with well-defined deposits on electron microscopy (EM; see Chapter 29). C3 glomerulopathy may show a variety of appearances on light microscopy, including mesangial proliferation, a membranoproliferative pattern (see Chapter 21), endocapillary proliferation, and crescent formation. Importantly, it is now recognized that many cases previously classified morphologically as membranoproliferative glomerulonephritis (MPGN) are cases of C3 glomerulopathy. This includes cases that had been classified as MPGN types I, II, or III. Indeed, it appears that most cases that have previously been called MPGN type III (see Chapter 21) are examples of C3 glomerulopathy. However, monoclonal gammopathy–associated MPGN also may be misclassified as C3 glomerulopathy, if the glomerular immunoglobulin deposits are masked and only become detectable after protease digestion of the histologic section (see Chapter 21).

On EM, C3 glomerulopathy also may have a variety of appearances. Common is dense deposit disease (DDD), which is characterized by replacement of the glomerular basement membrane (GBM) by dense bands on EM (Fig. 22.2). In some cases the light microscopic appearance in DDD resembles that of MPGN, explaining the older term MPGN type II (see also Chapter 21). However, as will be discussed later in more detail, most cases of DDD do not have MPGN morphology on light microscopy.

Cases of C3 glomerulopathy that do not have typical highly dense deposits of DDD show a range of appearances on EM with deposits that may be mesangial, subendothelial, or subepithelial and may be more or less well defined. The relevance of the site of the deposits has not been defined, although it is likely, by analogy with diseases such as lupus nephritis, that capillary wall deposits are associated with more glomerular inflammation and higher levels of proteinuria. These cases of non-DDD C3 glomerulopathy have been given the collective name of C3 glomerulonephritis (C3GN).[3,4]

Etiology and Pathogenesis

The pathogenesis of C3 glomerulopathy involves dysregulation of the alternative pathway of complement (see Fig. 21.1). In health the alternative pathway is constantly being activated, but at a very low rate. This means there is a constant generation of small amounts of activated C3, and this low-grade activation allows the pathway to be rapidly switched on when needed. In the presence of pathogens, rapid amplification of C3b is achieved through a positive feedback loop (termed the C3b amplification loop) that can generate millions of C3b molecules within minutes. Because this amplification can progress so rapidly, very efficient systems are needed to prevent inappropriate activation of the pathway. The most important regulator of the alternative pathway is factor H (CFH). CFH does this in three ways: (1) it blocks the formation of alternative pathway C3 convertases by binding to C3b and thereby inhibiting interaction between C3b and factor B, (2) it promotes the spontaneous dissociation of these convertases, and (3) it works together with another plasma protein, factor I, to cleave C3b to iC3b. Mice that have been genetically engineered to lack factor H have undetectable circulating C3 because their C3 is constantly consumed by the uncontrolled alternative pathway.[5]

CFH is an abundant single chain glycoprotein predominantly made in the liver. It is composed of protein subunits, termed short consensus repeat (SCR) domains. The activity of CFH can be modulated by a group

of closely related proteins called factor H–related (CFHR) proteins.[6] There are five in CFHR proteins in humans (CFHR1-5) encoded by individual genes adjacent to the *CFH* gene. The CFHR proteins, like CFH, are composed of SCR domains and share considerable sequence similarity with CFH. This has led to genomic rearrangements within the *CFH-CFHR* locus, which include both polymorphisms and mutations. The most common polymorphism is a combined deletion of the *CFHR1* and *CFHR3* genes. This is present in homozygosity in 5% to 20% of healthy individuals depending on ethnic origin. It is now clear that some CFHR proteins are able to compete with the binding of CFH to C3b.[7] This is important because, unlike CFH, the CFHR proteins are unable to inhibit complement activation. Furthermore, the CFHR-C3b interaction prevents CFH from negatively regulating C3b production. Consequently, the CFHR-C3b interaction promotes C3b amplification, a process termed CFH deregulation (Fig. 22.3). In many cases of C3 glomerulopathy the pathogenesis is a failure of CFH to control the activation of the alternative pathway in the circulation, and this is associated with low levels of circulating C3 because of uncontrolled consumption. Up to 80% of patients with DDD and up to half of patients with C3GN have low levels of serum C3.[3] Many of these patients have a C3 nephritic factor (C3Nef). C3Nefs are autoantibodies that stabilize the alternative pathway C3 convertase by preventing CFH from carrying out its normal functions. It therefore seems likely that C3Nef plays an important etiologic role in these patients. C3Nef can be identified in 40% to 60% of cases of C3GN and 80% to 90% of cases of DDD.[3,8] However, our understanding of the role of C3Nef is complicated by the fact that C3Nefs also may be found in patients with other forms of glomerulonephritis and even in healthy patients. In other cases, genetic mutations lead to failure of alternative pathway control. These cases include patients with complete CFH deficiency secondary to gene deletion,[9,10] mutations in CFH that interfere with its binding to C3b,[11,12] and mutations in C3 that change its structure so that it cannot be inhibited by CFH.[13] In some patients, failure of

BOX 22.1 Definitions

C3 glomerulopathy—A *disease process* secondary to abnormal control of complement activation, deposition, or degradation characterized by predominant glomerular C3 fragment deposition with electron-dense deposits on electron microscopy.

Dense deposit disease—A form of C3 glomerulopathy with a characteristic electron microscopy appearance of intensely osmiophilic transformation of the glomerular basement membrane.

C3 glomerulonephritis—C3 glomerulopathy without the characteristic appearances of dense deposit disease.

Glomerulonephritis with dominant C3—A morphologic term for cases of glomerulonephritis with dominant staining for C3c. Dominant is defined as C3c intensity ≥2 orders of magnitude more than any other immune reactant on a scale of 0 to 3 (including 0, trace, 1+, 2+, 3+). Many, but not all, of these will represent cases of C3 glomerulopathy.

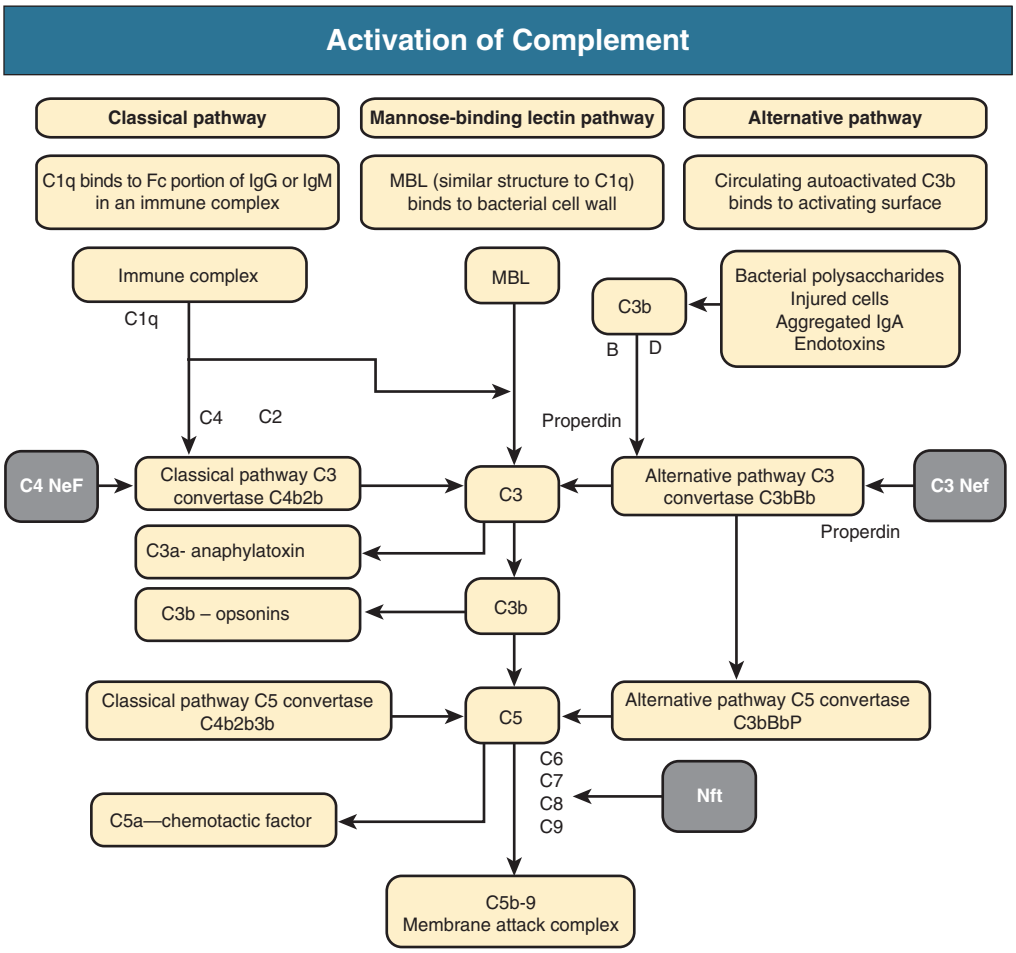

Fig. 22.1 Mechanisms of activation of the complement pathways. These activators include nephritic factors (NeF, Nef). *MBL,* Mannose-binding lectin; *Nft,* Nephritic factor of the terminal pathway.

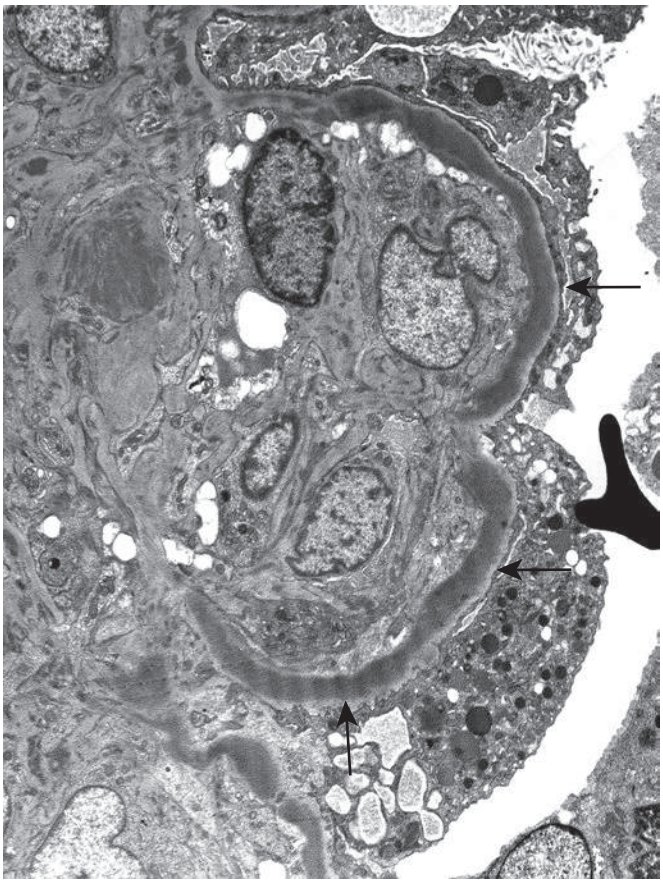

Fig. 22.2 Dense deposit disease (DDD). Electron micrograph of a glomerulus showing typical appearances of DDD with very osmiophilic transformation of the basement membrane *(arrows)*.

alternative pathway control is associated with autoantibodies directed against factor H that target its regulatory domain.

In those cases of C3 glomerulopathy that are not associated with excessive activation of C3 in the circulation, it can be assumed that there is a failure to control the alternative pathway locally within the glomerulus. This might be due to a failure to control activation or inappropriate handling of the fragments of C3 generated by alternative pathway activation. In most cases the pathogenesis is still not clear, but there is an example of a familial form of C3 glomerulopathy (now called CFHR5 nephropathy) without systemic C3 activation. This is a common cause of kidney disease in Cyprus, where the mutation is a duplication of the first 2 exons of the *CFHR5* gene.[14] This leads to an abnormal protein that forms multimers that are able to deregulate the activity of CFH on surfaces.[7] Therefore it appears the abnormal protein interferes with the action of CFH locally within the glomerulus and enhances alternative pathway activation.

Apart from the mutations described previously, several other mutations and polymorphisms in complement genes have been associated with C3 glomerulopathy, but their role is at present uncertain. It is also notable that there appears to be an association between monoclonal gammopathy and C3 glomerulopathy (see Chapter 21).[15-17] In some cases the monoclonal immunoglobulin may act as a C3Nef.

Epidemiology

DDD has been reported to have a prevalence of 2 to 3 per million population and to be primarily a disease of children and young adults. However, in a 2009 series from New York 39% of the adult patients were over 60 years of age.[18] DDD affects males and females equally in many cohorts, although some studies have shown a female predominance. In one large series from France[3] the ratio of C3GN to DDD was approximately 2:1 and patients with C3GN were significantly older, with a mean age at diagnosis of 30 years. In the United Kingdom and Ireland we found a C3GN/DDD ratio of approximately 3:1 and estimated the incidence of C3 glomerulopathy at 1 to 2 per million population per year.[19] It is likely that the apparent incidence of C3GN will increase as the entity becomes better recognized by nephrologists and pathologists. There is no reliable information on geographic variation in incidence, with the notable exception of C3GN resulting from a specific mutation in *CFHR5,* apparently originating in Cyprus several hundred years ago.[14]

Clinical Manifestations

Dense Deposit Disease

At presentation almost all patients have proteinuria, usually with hematuria. Nephrotic range proteinuria is present in two thirds of patients[18,20] and frank nephrotic syndrome in 12% to 65% in different series. In a series of 98 patients from North America[21] about one fifth of patients did not suspect a problem and kidney disease was detected as part of a routine examination. Many patients have initial signs and symptoms of acute nephritic syndrome. In some cases there may be episodes of acute kidney injury that show complete clinical resolution.[22] Decreased kidney function is common at presentation and is more common in adults. Hypertension is commonly found either at presentation or in follow-up. In about half of patients, clinical onset of DDD is preceded by acute infection with elevated antistreptolysin O (ASO) titers in 20% to 40%.

Patients with DDD may develop ocular drusen (Fig. 22.4), lipoproteinaceous deposits of complement-containing debris within the Bruch membrane beneath the retinal pigment epithelium. This pathology is similar to that in age-related macular degeneration (AMD), but, in contrast to AMD, drusen in DDD may be found as early as the second decade of life. There is no correlation between the severity of the disease in the kidney and that in the eye. A small minority of patients with DDD have acquired partial lipodystrophy (APL), a condition with symmetric loss of adipose tissue from the face, arms, and upper portions of the trunk (see Fig. 22.4).

The overall long-term outcome in DDD is poor. In a series of 98 patients from North America, 50% of the patients progressed to end-stage renal disease (ESRD) within 10 years of diagnosis, with young females having the greatest risk for kidney failure.[21]

C3 Glomerulonephritis

C3GN has only recently been recognized, and thus clinical manifestations are less well defined. In a French series, 27% of patients with C3GN had nephrotic syndrome at presentation.[3] Approximately two thirds of patients had microhematuria at presentation, and about one third had elevated blood pressure. In that series the rate of progression to ESRD was similar to that in the patients with DDD.

In CFHR5 nephropathy in Cyprus the major clinical feature in young patients is hematuria. Microhematuria was present in 90%, and 20% of patients reported episodes of macrohematuria often associated with upper respiratory tract infection.[23] Proteinuria became more common with increasing age and was seen in 80% of males and 20% of females over the age of 50. Impaired kidney function was more common with increasing age, particularly in men, and of 18 patients who reached ESRD 78% were male. The cause for the striking gender difference in outcome is unclear.

Laboratory Findings

Low levels of serum C3 are found in approximately 80% of patients with DDD and up to 50% of patients with C3GN. In C3GN secondary

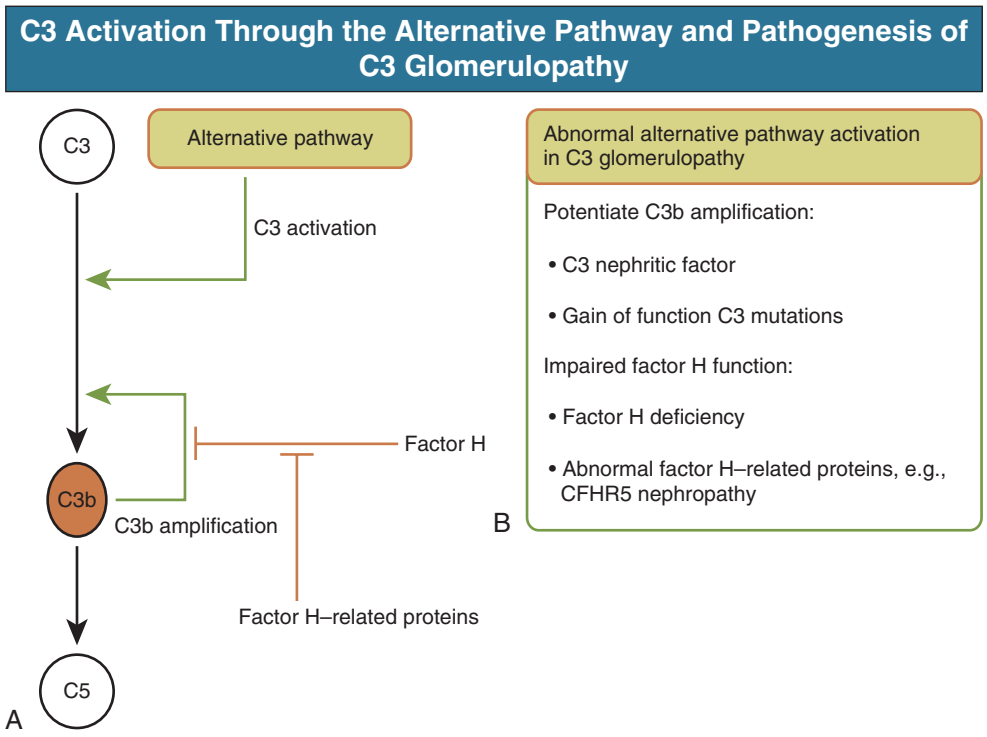

Fig. 22.3 C3 activation through the alternative pathway and pathogenesis of C3 glomerulopathy. (A) Activation of C3 results in the formation of C3b and then C5 activation. C3b production is amplified through a positive feedback loop. Factor H inhibits this amplification (depicted). Some factor H–related proteins (e.g., complement factor H–related protein 5 [CFHR5]) interact with C3b and, unlike factor H, allow C3b amplification to proceed. In this way they antagonize the actions of factor H, in a process termed factor H deregulation. (B) C3 glomerulopathy is associated with abnormal (increased) activation of the alternative pathway. These include situations in which there is enhanced C3b amplification despite normal factor H function, for example, in the presence of C3 nephritic factor, and where there is a defect in the ability of factor H to negatively regulate the alternative pathway. Examples include cases of factor H deficiency (extremely rare); and abnormal factor H–related proteins associated with familial C3 glomerulonephritis (e.g., CFHR5 nephropathy).

BOX 22.2 Serologic and Genetic Evaluation of C3 Glomerulopathy

Tests Recommended in All Patients With C3 Glomerulopathy

- Measurement of serum levels of C3 and C4
- Measurement of C3 nephritic factor
- CH50—classic pathway hemolytic assay, and AH50—alternative pathway hemolytic assay
- Measurement of factor H and factor I
- Serum paraprotein detection
- Testing for the genetic mutation of CFHR5 nephropathy
- Anti–factor H autoantibodies

Tests That Should Be Considered on a Case-by-Case Basis

- Measurement of serum factor B and C5
- Measurement of markers of C3 and C5 activation (e.g., C3d, Bb, soluble C5b9)
- Detection of autoantibodies to factor B
- Mutation testing of complement regulatory genes (e.g., CFH, CFI, CD46), activation protein genes *(C3, CFB),* and assessment of copy number variation across the *CFH-CFHR* locus

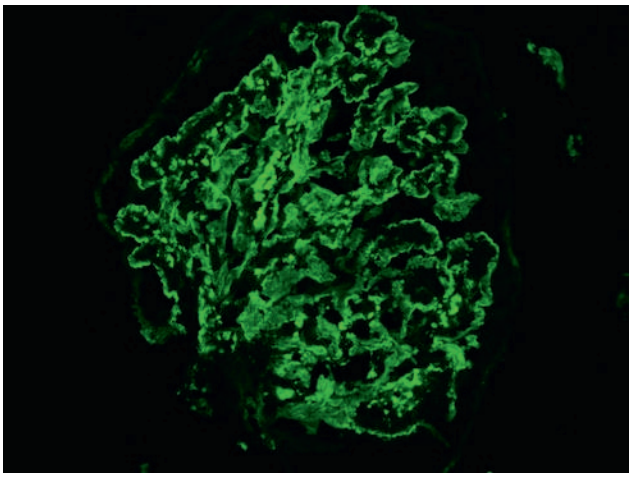

Fig. 22.5 Dense deposit disease (DDD). Immunofluorescence for C3c in a case of DDD. There is widespread staining of capillary walls and focal granular mesangial staining.

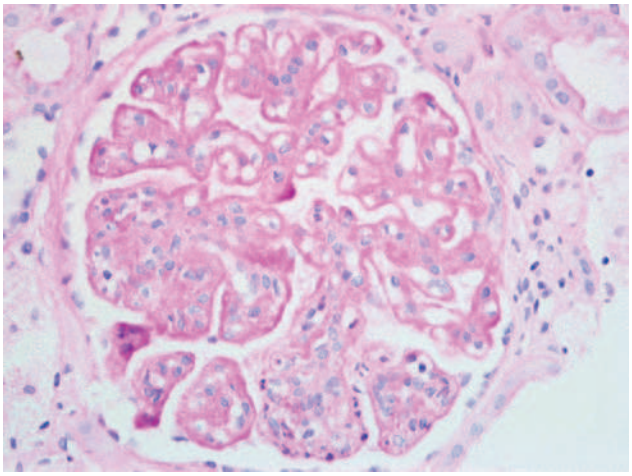

Fig. 22.6 C3 glomerulonephritis. Light microscopy in a case of C3 glomerulonephritis. The glomerulus shows a membranoproliferative pattern of injury, with increased mesangium, capillary wall thickening, and segmental endocapillary hypercellularity. (Periodic acid–Schiff staining.)

to CFHR5 nephropathy, serum C3 levels are typically normal. Serum levels of the early components of the classic pathway (C1q and C4) are usually normal. Most patients with DDD are positive for serum C3NeF and in more than 50% of patients C3NeF persists throughout the clinical course.[24] However, C3NeF is not a specific serologic marker because it also occurs with MPGN type I, lupus nephritis, and poststreptococcal glomerulonephritis. C3Nef can be identified in 40% to 60% of cases of C3GN.[3,8] It is important to note that methods for measuring C3Nef are not standardized.

Box 22.2 shows a list of investigations that may be helpful in C3 glomerulopathy.[25,26] It is recommended that investigations in the second category are discussed with experts and performed in laboratories with experience in complement assays. Complement laboratories across the world are listed on the International Complement Society (www.complement.org) and European Complement Network (www.ecomplement.org) websites. Depending on the clinical scenario, it may be possible to prioritize some of these assays. For example, in patients with C3 glomerulopathy and low serum C3 levels in the absence of C3NeF, it is important to test for anti-CFH autoantibodies. In familial cases of C3 glomerulopathy a search for genetic mutations may be important for elucidating pathogenesis and genetic counseling.

Pathology

The defining feature of C3 glomerulopathy is the presence of C3 (usually detected with an antibody to C3c) in glomeruli on immunohistologic examination (Fig. 22.5). In most cases the C3 staining is seen on capillary walls and in the mesangium, but in some cases the staining may be mainly mesangial. In some cases, particularly in DDD, C3 also may be found on the Bowman capsule or on tubular basement membranes.

The light microscopic appearances are quite variable. In both DDD and C3GN, membranoproliferative changes are common with increased glomerular lobulation, increase in mesangial matrix and cells, and capillary wall thickening with double contour formation (Fig. 22.6). In some cases there may be a predominantly mesangial proliferative pattern. Some cases show endocapillary hypercellularity, in part as a result of influx of macrophages or neutrophils. Sometimes this endocapillary hypercellularity may affect almost all the glomeruli, giving an appearance of diffuse endocapillary proliferative glomerulonephritis similar to that typically seen with postinfectious glomerulonephritis (PIGN). Crescent formation may be sufficiently prominent to merit the designation of crescentic glomerulonephritis (>50% crescents). In a series of 69 cases of DDD[27] the incidence of different histologic patterns was membranoproliferative (25%), mesangial proliferative (45%), crescentic (18%), and acute proliferative and exudative (12%). In a French series of patients with C3GN,[3] 71% showed an MPGN pattern on light microscopy.

The EM appearances of C3 glomerulopathy are also very variable, but in many cases the diagnosis of C3 glomerulopathy can be suspected from the EM changes. By definition, DDD shows the presence of typical osmiophilic dense transformation of the GBM (see Fig. 22.2), with similar features often seen in the Bowman capsule and tubular basement membranes. However, these changes may be segmental within glomeruli, in some cases making it difficult to define DDD with certainty. In DDD there are typically large electron densities in the mesangium.

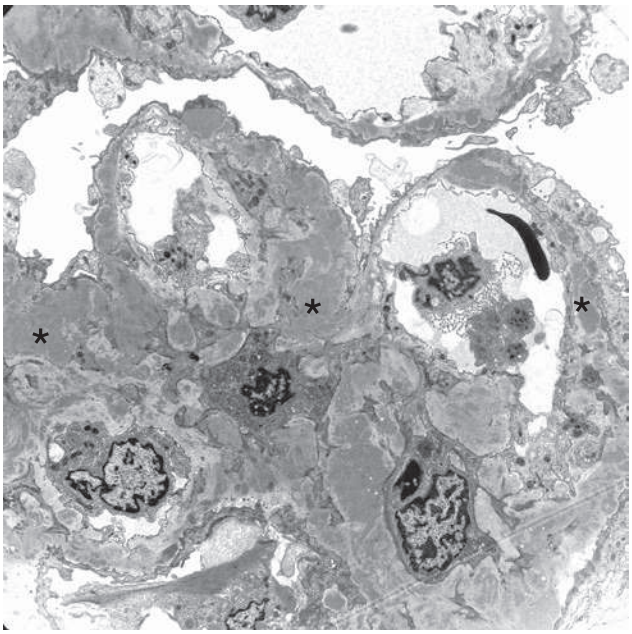

Fig. 22.7 C3 glomerulonephritis. Electron micrograph of a glomerulus in a case of C3 glomerulonephritis. There is a complex pattern of thickening of the glomerular basement membrane with intramembranous electron-dense material. *Similar deposits are also seen in the mesangium.

In some cases of C3GN, there is electron-dense material that expands the GBM similar to the changes in DDD but without such marked electron density; the distinction between these cases and DDD may not be clear-cut and depends on a subjective interpretation by the pathologist.[28] Other cases have more distinct subendothelial and mesangial electron-dense deposits reminiscent of those seen in immune complex glomerulonephritis. Some cases show a very complex pattern of intramembranous deposits that was previously designated as a form of MPGN type 3 (Fig. 22.7).

In both DDD and C3GN subepithelial hump-shaped deposits are frequently seen. These are identical to those characteristically seen in PIGN. Their significance is not clear, although it may be that they are more common in infectious exacerbations of the disease.

There are few data on the relationships between histology, clinical presentation, clinical course, and underlying genetic abnormalities. In several series of DDD the presence of crescents was associated with a more rapid decline in renal function.

Differential Diagnosis

The diagnosis of C3 glomerulopathy is relatively straightforward if there is isolated C3 deposition with typical deposits on EM. However, some patients have otherwise typical appearances of DDD or C3GN but also have small amounts of immunoglobulin in glomeruli, which presents a diagnostic challenge. Evidence suggests that, on immunofluorescence, the criterion with the best balance of sensitivity and specificity is the presence of dominant C3 staining with the intensity of C3, staining at least two orders of magnitude greater than any other immunoreactant (i.e., immunoglobulin G [IgG], IgM, IgA, and C1q).[26,29] This is referred to as glomerulonephritis with dominant C3 (see Box 22.1). In some cases, the initial kidney biopsy may not show C3-dominant GN, but it may appear in subsequent biopsies,[29-31] suggesting that repeat biopsy may be useful in cases with an atypical clinical course.

Another problem is the distinction of C3 glomerulopathy from PIGN. PIGN may show markedly reduced serum C3, and glomeruli may stain for C3 without immunoglobulin. In some cases the distinction from C3 glomerulonephritis may be possible only by following the patient to see if resolution of the disease occurs.[26] It has been suggested that PIGN could be considered a self-limiting form of C3 glomerulopathy. Some patients who have been labeled as having atypical PIGN have C3 glomerulopathy.[32] Cryoglobulinemia also should be considered in the differential diagnosis as cases may present with prominent C3 with only sparse IgG staining.

Treatment

The optimal treatment for C3 glomerulopathy remains undefined. Most information relates to DDD, because C3GN was not previously recognized as a specific diagnostic category. However, in many studies DDD was grouped with forms of MPGN, which makes it difficult to make specific statements about DDD. Treatments that have been tried include renin angiotensin system blockade, corticosteroids and other immunosuppressants, anticoagulants, and plasma exchange.[33] A recent Kidney Disease: Improving Global Outcomes (KDIGO) controversies conference[26] recommended that all patients should receive optimal blood pressure control and patients with moderate disease—defined as urine protein greater than 500 mg/24 h despite supportive therapy, moderate inflammation on renal biopsy, or recent rise in creatinine—should receive prednisone or mycophenolate mofetil (MMF). A recent case series suggested that MMF is effective in C3 glomerulonephritis.[34] In severe disease with proteinuria more than 2 g/24 h, severe disease on biopsy, or progressive creatinine increase, the KDIGO conference suggested the use of methylprednisolone pulse dosing as well as other anticellular immune suppressants.[26]

In many cases of C3 glomerulopathy the deposition of C3 in glomeruli leads to subsequent activation of C5, and there is considerable interest in the possibility of using the anti-C5 antibody eculizumab for treatment. There are a number of case reports and one small open label, nonblinded clinical trial of eculizumab for C3 glomerulopathy.[35] Some but not all patients have shown clinical improvement, and in some there was reduction of glomerular inflammation on repeat biopsy. In the patients who underwent repeat biopsy, IgG-κ was found, consistent with binding of the monoclonal eculizumab to C5 in glomeruli.[36] However, the exact role of eculizumab remains to be defined and the KDIGO conference concluded "Data are insufficient to recommend eculizumab as a first-line agent for the treatment of rapidly progressive disease."[26] Rational treatment of C3 glomerulopathy would involve inhibition of C3 activation, and a number of drugs are in preclinical development that may achieve that and allow more targeted therapy in future.

Immunoglobulin A Nephropathy and IgA Vasculitis (Henoch-Schönlein Purpura)

John Feehally, Jürgen Floege

IgA NEPHROPATHY

Definition

IgA nephropathy (IgAN) is a mesangial proliferative glomerulonephritis characterized by diffuse mesangial deposition of IgA. IgAN was first recognized in 1968 by Jean Berger when immunofluorescence techniques were introduced for the study of renal biopsy specimens. IgAN is unique among glomerular diseases in being defined by the presence of an immune reactant rather than by any other morphologic feature on renal biopsy, and the light microscopy changes are variable. IgAN is the most prevalent pattern of glomerular disease seen in most Western and Asian countries where renal biopsy is widely practiced. It is likely that IgAN is not a single entity but rather a common response to various injurious mechanisms.

Etiology and Pathogenesis

Although there has been much recent progress in understanding the pathogenesis of IgAN, it is not certain that all subjects with IgAN share a single common process leading to mesangial IgA deposition. Fig. 23.1 summarizes some key elements involved in the pathogenesis of IgAN.[1]

IgA Immune System

The regular recurrence of IgAN after renal transplantation in patients with prior underlying IgAN strongly implies an abnormality in the host IgA immune system (see Chapter 108).

IgA is the most abundant immunoglobulin in the body and is chiefly concerned with mucosal defense.[2] It has two subclasses, IgA1 and IgA2. Mucosal antigen challenge provokes *polymeric* IgA (pIgA) production by plasma cells of the mucosa-associated lymphoid tissue; the pIgA is then transported across epithelium into mucosal fluids, where it is released after coupling to secretory component as *secretory* IgA (sIgA). The function of circulating IgA is less clear; it is bone marrow derived and mostly *monomeric* IgA1 (mIgA1). Circulating IgA1 is cleared by the liver through hepatocyte asialoglycoprotein receptors and Kupffer cell Fcα receptors.

The mesangial IgA in IgAN is predominantly pIgA1. The clinical association with mucosal infections or superantigens from *Staphylococcus aureus* originally suggested that the mesangial pIgA1 comes from the mucosal immune system.

Available data on mucosal immune responses in IgAN are not easily synthesized into a single model of pathogenesis. On the one hand, pIgA1 production is downregulated in the mucosa and upregulated in the bone marrow. Moreover, the pIgA response to systemic immunization with common antigens is increased, whereas the response to mucosal immunization is impaired. These findings suggest that impaired mucosal IgA responses allowing enhanced antigen challenge to the marrow could be the primary abnormality in IgAN, although this remains unproven. However, there is also evidence for mucosal hyperresponsiveness to a variety of food antigens in patients with IgAN.[1,2] The mesangial IgA therefore may represent a common response to a variety of foreign antigens and various mucosal abnormalities, each of which facilitates a systemic response to mucosal antigens.

Another unproven hypothesis is that some mucosal IgA-producing plasma cells translocate to the bone marrow in IgAN; this also could explain the variation in glycosylation of serum IgA in IgAN (see later discussion). Tonsillar pIgA1 production is also increased, although IgAN can occur after tonsillectomy, and the tonsil is a very minor source of IgA production compared with the mucosa or marrow. There are reports of sIgA in the mesangium, but this finding is not easily explained by current pathogenic concepts of IgAN. Hepatic clearance of IgA is reduced, possibly because of the altered molecular characteristics of IgA in IgAN (see later discussion).

Serum IgA levels are increased in one third of patients with IgAN. There are elevations in both mIgA and pIgA. However, high serum IgA itself is not sufficient to cause IgAN and serum IgA levels are not useful for diagnosing IgAN. High circulating levels of monoclonal IgA in myeloma or polyclonal IgA in AIDS only infrequently provoke mesangial IgA deposition.

Circulating macromolecular IgA is characteristic of IgAN. Some represent IgA immune complexes, and there are circulating IgA rheumatoid factors (IgA against constant domain of IgG) in 30% of patients with IgAN. Studies in vitro indicate that IgA production by mononuclear cells is exaggerated in IgAN, and that these cells show abnormal patterns of cytokine production. However, the direct relevance of these observations to events in vivo is uncertain.

IgA Glycosylation

A striking feature of IgAN is altered glycosylation of the hinge region of IgA1. IgA1 carries distinctive *O*-linked sugars at its hinge region; IgA2 has no hinge and carries no such sugars. There is good evidence that circulating IgA1 in IgAN has abnormal *O*-linked hinge-region sugars with reduced galactosylation; this is usually named galactose-deficient IgA1 (gd-IgA1) and is found in up to 90% of individuals with IgAN.[1] Some data indicate defective function of the relevant glycosyltransferases that *O*-glycosylate IgA1, possibly with a genetic basis. Other findings suggest that the primary abnormality may be that IgA of the mucosal type, which has glycosylation patterns different from that of serum IgA1, reaches the circulation, for example, by translocation of mucosal lymphocytes to the bone marrow. The latter is consistent with experiments in which immortalized lymphocytes from patients with

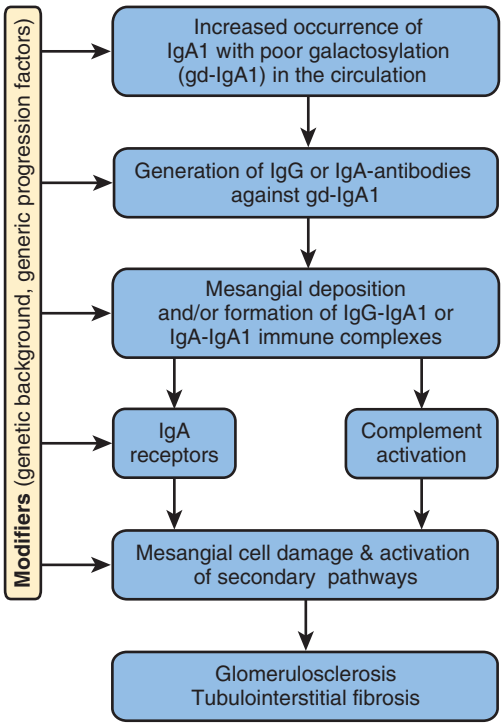

Fig. 23.1 Pathogenesis of IgA nephropathy. Proposed mechanisms leading to mesangial deposition of abnormally glycosylated IgA1 and mesangial injury. (Modified from reference 1.)

IgAN continue to produce dimeric and polymeric IgA with altered galactosylation in vitro.[3]

Mesangial IgA1 in IgAN also has increased gd-IgA1.[4,5] The gd-IgA1 can act as an autoantigen leading to IgG or IgA anti–gd-IgA1 autoantibodies and formation of circulating immune complexes.[6] Mesangial IgA1 may be the result of deposition of these circulating IgA1 immune complexes or of altered IgA1 interactions with matrix proteins and mesangial cell or monocyte Fc receptors. There also may be impaired clearance of gd-IgA1 through inhibition of its interactions with hepatic and circulating myeloid cell IgA receptors.

Increased serum gd-IgA1 is found in the unaffected relatives of subjects with IgAN, suggesting that gd-IgA1 is necessary but not sufficient for the development of IgAN, which requires a "second hit," for example, an event that provokes the formation of autoantibodies against gd-IgA1 and thus provokes tissue injury.

Role of Infection

The clinical association of visible hematuria with upper respiratory tract infection in IgAN indicates the mucosa may be a site of entry for foreign antigens or alternatively may be a site for nonspecific activation of the innate immune system that enhances renal injury. There have been occasional reports of IgAN in association with infection, both bacterial (e.g., *Campylobacter, Yersinia, Mycoplasma, Haemophilus*) and viral (e.g., cytomegalovirus, adenovirus, coxsackievirus, Epstein-Barr virus). A severe form of IgAN, which may be crescentic, has been reported in association with staphylococcal infection (see Chapter 55). However, no organism has been consistently implicated by the finding of microbial antigen in glomerular deposits in typical cases of IgAN.

Glomerular Injury After IgA Deposition

Polymeric IgA deposition in the mesangium is typically followed by mesangial proliferative glomerulonephritis (GN). In animal models, co-deposition of IgG and complement is necessary for inflammation, but this is not mandatory in human disease. Complement deposits are usually C3 and properdin without C1q and C4. There may be complement activation via the mannose-binding lectin pathway. The extent to which IgA engages inflammatory cells in the circulation, especially in the kidney, will determine the intensity of inflammation. Fc receptors for IgA (Fcα receptors) on myeloid and mesangial cells may play a key role.[7]

The mechanisms of mesangial proliferative GN have been studied in detail in animal models, particularly anti–Thy 1 nephritis in the rat. These studies have shown the key role of cytokines and growth factors in mesangial cell proliferation, particularly the B and D isoforms of platelet-derived growth factor[8] (PDGF) and in the subsequent matrix production and sclerosis, particularly transforming growth factor-β (TGF-β). Studies of renal biopsy specimens in human IgAN also support a role for PDGF and TGF-β. These mechanisms are not unique to IgAN but are likely involved in all forms of mesangial proliferative GN, including those without IgA deposition.

Subsequent progressive renal injury involving glomerulosclerosis and tubulointerstitial fibrosis is likely the result of generic mechanisms of damage, rather than specific to IgAN.

Animal Models of IgA Nephropathy

Animal IgA does not have the same characteristics as human IgA1, and some animals also have IgA clearance mechanisms distinct from those in humans. Therefore animal models, even if they provoke mesangial IgA deposits, are not particularly informative about the mechanisms that underlie human mesangial pIgA1 deposition, although they have provided many insights into events after IgA deposits have developed.

Genetic Basis of IgA Nephropathy

Urine abnormalities increase in frequency among the relatives of patients with IgAN, although only in a few pedigrees is IgAN found in multiple generations. More than 90% of all cases of IgAN appear to be sporadic.

Large worldwide genome-wide association studies have identified genetic modulators that seem to affect the prevalence of sporadic IgAN and modulate its course.[9-11] Variations in major histocompatibility gene loci (HLA-DR, -DQ, -DP and HLA-B) have consistently been identified. Other gene loci are less consistent and include inflammatory mediators (tumor necrosis factor and α-defensin), gene loci affecting complement factor H, innate immunity, IgA-regulating cytokines, and mucosal integrity.[11]

Other Modulators of the Course of IgA Nephropathy

Many cases of IgAN probably never come to medical attention, and when the diagnosis is obtained by renal biopsy, only a minority will develop end-stage renal disease (ESRD). Thus, in addition to genetic factors, there must be potent further modulators of the course of IgAN, such as essential hypertension, obesity, or smoking (see Fig. 23.1; see also Natural History).

Epidemiology

IgA nephropathy is the most prevalent pattern of glomerular disease in most countries where renal biopsy is widely used as an investigative tool. Its estimated frequency is at least 2.5 cases per year per 100,000 adults.[12] However, the striking geographical variation has been associated with the presence of particular gene alleles that protect from IgAN[9] (Fig. 23.2). This racial predisposition is maintained in other locations; in the United States, for example, IgAN is less common in Blacks than in Whites of European origin. Perceived prevalence of IgAN also may be influenced by attitudes to the investigation of microhematuria. A country with an active program of routine urine testing will inevitably

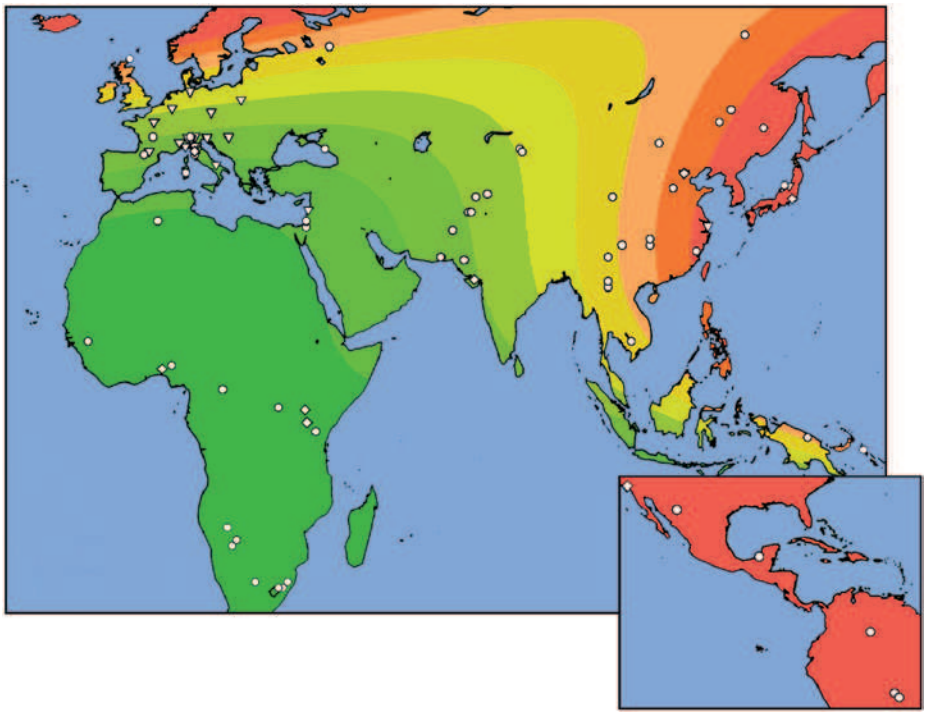

Fig. 23.2 Geographical variation in genetic risk for IgA nephropathy. Genome-wide association studies indicate a geographical gradient of risk from *green* (low risk) to *red* (high risk). (From reference 9.)

identify more individuals with urine abnormalities, but IgAN will be identified only if renal biopsy is performed. Even then, the prevalence of IgAN will be underestimated; a study of kidney donors suggests that the prevalence of IgAN with mesangial proliferative changes and glomerular C3 deposits in the general population in Japan may be 1.6%.[13] This suggests that the vast majority of patients with IgAN never come to medical attention and spontaneously remit.

Clinical Manifestations

IgA Nephropathy

The wide range of clinical presentations of IgAN varies in frequency with age (Fig. 23.3). No clinical pattern is pathognomonic of IgAN. In populations of White descent, IgAN is more common in males than females by a ratio of 3:1, whereas the ratio approaches 1:1 in most Asian populations.

Macroscopic Hematuria

In 40% to 50% of patients with IgAN, the clinical presentation is episodic macroscopic hematuria, most frequently in the second decade of life. The urine is usually brown rather than red, and clots are unusual. There may be loin pain caused by renal capsular swelling. Hematuria usually follows intercurrent mucosal infection, typically in the upper respiratory tract (the term *synpharyngitic hematuria* has been used) or occasionally in the gastrointestinal tract. Hematuria is usually visible within 24 hours of the onset of the symptoms of infection, differentiating it from the 2- to 3-week delay between infection and subsequent hematuria in postinfectious (e.g., poststreptococcal) GN. The macroscopic hematuria resolves spontaneously over a few days. Microscopic hematuria persists between attacks. Most patients have only a few episodes of frank hematuria, which become less frequent and resolve over a few years or sooner. Such episodes may be associated with acute kidney injury (AKI) characterized by tubular injury that is usually reversible.

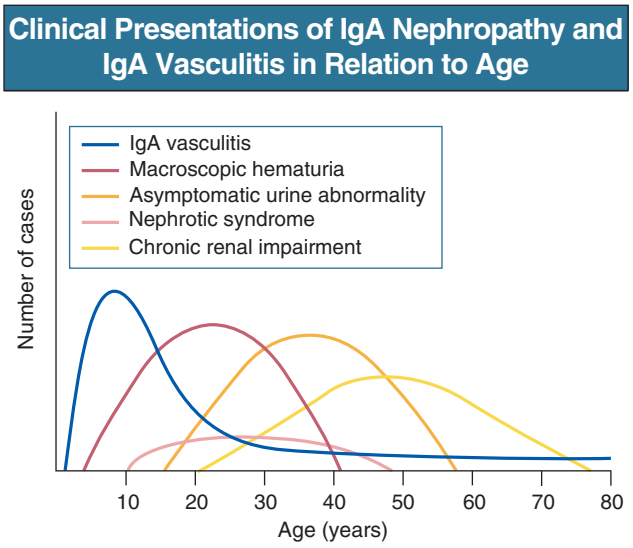

Fig. 23.3 Age in clinical presentation of IgA nephropathy and IgA vasculitis (IgAV). IGAV is most common in childhood but may occur at any age. Macrohematuria is very uncommon after age 40. The importance of asymptomatic urine abnormality as the presentation of IgAN will depend on attitudes to routine urine testing and renal biopsy. It is unclear whether patients presenting late with chronic renal impairment have a disease distinct from that of those presenting younger with macrohematuria. (Data from patients presenting in Leicester, UK, 1980-1995.)

Asymptomatic Hematuria and Proteinuria

As many as 30% to 40% of cases of IgAN are identified during routine testing of urine of asymptomatic individuals. Microhematuria with or without proteinuria (usually <2 g/24 h) is noted. The number of patients identified in this way will depend on local attitudes to urine testing, as

well as on the use of renal biopsy in patients with isolated microscopic hematuria. Most patients with IgAN are asymptomatic and would be identified only when the urine is tested.

Proteinuria and Nephrotic Syndrome

It is rare for proteinuria to occur without microscopic hematuria. Whereas nephrotic-range proteinuria may occur, in particular in the presence of uncontrolled hypertension, full-blown nephrotic syndrome is uncommon, occurring in only 5% of all patients with IgAN. Nephrotic syndrome may occur early in the course of the disease, with minimal glomerular change (in such cases IgAN may coexist with minimal change disease [MCD]) or with active mesangial proliferative GN. Alternatively, it may occur as a late manifestation of advanced chronic glomerular scarring.

Acute Kidney Injury

Although AKI is uncommon in IgAN (<5% of all cases), one study reports that it may be the manifestation in up to 27% of patients older than 65 years.[14] AKI develops by three distinct mechanisms. There may be acute severe immune and inflammatory injury with necrotizing GN and crescent formation (crescentic IgAN); this may be the first presentation of IgAN, or it may be superimposed on established, less aggressive disease. Rapid deterioration in IgAN in pregnancy may be caused by crescentic transformation. Alternatively, AKI can occur with mild glomerular injury when heavy glomerular hematuria leads to tubule occlusion by red blood cells (RBCs). Third, especially in elderly patients, chronic IgAN will predispose to AKI from a variety of incidental renal insults (see Chapter 66).

Chronic Kidney Disease

Some patients already have renal impairment and hypertension when they are first diagnosed with IgAN. These patients tend to be older, and they probably have long-standing disease that previously remained undiagnosed because the patient did not have frank hematuria or undergo routine urinalysis. Hypertension is common, as in other chronic glomerular disease; accelerated hypertension occurs in 5% of patients.

Clinical Associations With IgA Nephropathy

Mesangial IgA deposition, which does not necessarily equal IgAN, is a frequent finding in autopsy studies in chronic liver disease. Although particularly associated with alcoholic cirrhosis, IgA deposition can occur in other chronic liver disease, including that caused by hepatitis B and schistosomiasis. It is thought to result from impaired clearance of IgA by the Kupffer cells, which express Fcα receptors, and hepatocytes, which express the asialoglycoprotein receptor. Clinical evidence of renal disease is more common than previously appreciated, but patients rarely develop ESRD.

A number of case reports have associated IgAN with HIV infection and AIDS. It is not clear whether the polyclonal increase in serum IgA, which is a feature of AIDS, is the predisposing factor.

There are case reports associating IgAN with many other conditions, particularly with a number of immune and inflammatory diseases (Table 23.1). Their relationship to abnormalities of the IgA immune system is not always clear, and some may represent the coincidental development of unrelated but relatively common conditions.

Pathology

Immune Deposits

Diffuse mesangial IgA is the defining hallmark of IgAN (Fig. 23.4A). C3 is co-deposited in up to 90% of cases. IgG in 40% and IgM in 40% of cases also may be found in the same distribution. IgA also may deposit along capillary loops, a pattern more common in IgAV; in IgAN, this pattern is associated with a worse prognosis. C5b-9 is found with properdin but not C4, indicating alternative complement pathway

TABLE 23.1 Diseases Reported in Association With IgA Nephropathy: Common, Reported, and Rare

Disease Group	Common	Reported	Rare
Rheumatic and Autoimmune Disease	Ankylosing spondylitis Rheumatoid arthritis Reiter syndrome Uveitis	Behçet syndrome* Takayasu arteritis† Myasthenia gravis	Sicca syndrome
Gastrointestinal Disease	Celiac disease	Ulcerative colitis	Crohn's disease Whipple's disease
Hepatic Disease	Alcoholic liver disease Nonalcoholic cirrhosis Schistosomal liver disease		
Lung Disease	Sarcoid		Pulmonary hemosiderosis
Skin Disease	Dermatitis herpetiformis		
Malignancy		IgA monoclonal gammopathy	Bronchial carcinoma Renal carcinoma Laryngeal carcinoma Mycosis fungoides Sézary syndrome
Infection	HIV, hepatitis B (in endemic areas)	Brucellosis	Leprosy
Miscellaneous		Wiskott-Aldrich syndrome‡	

Rare associations have been made in one or two reported cases only. In a disease as common as IgA nephropathy, it is therefore uncertain whether these are truly related.

*Behçet syndrome: Systemic vasculitis typified by orogenital ulceration and chronic uveitis.

†Takayasu arteritis: Systemic vasculitis involving the aorta and its major branches, most often found in young women.

‡Wiskott-Aldrich syndrome: X-linked disorder in which increased serum IgA is associated with the triad of recurrent pyogenic infection, eczema, and thrombocytopenia.

HIV, Human immunodeficiency virus.

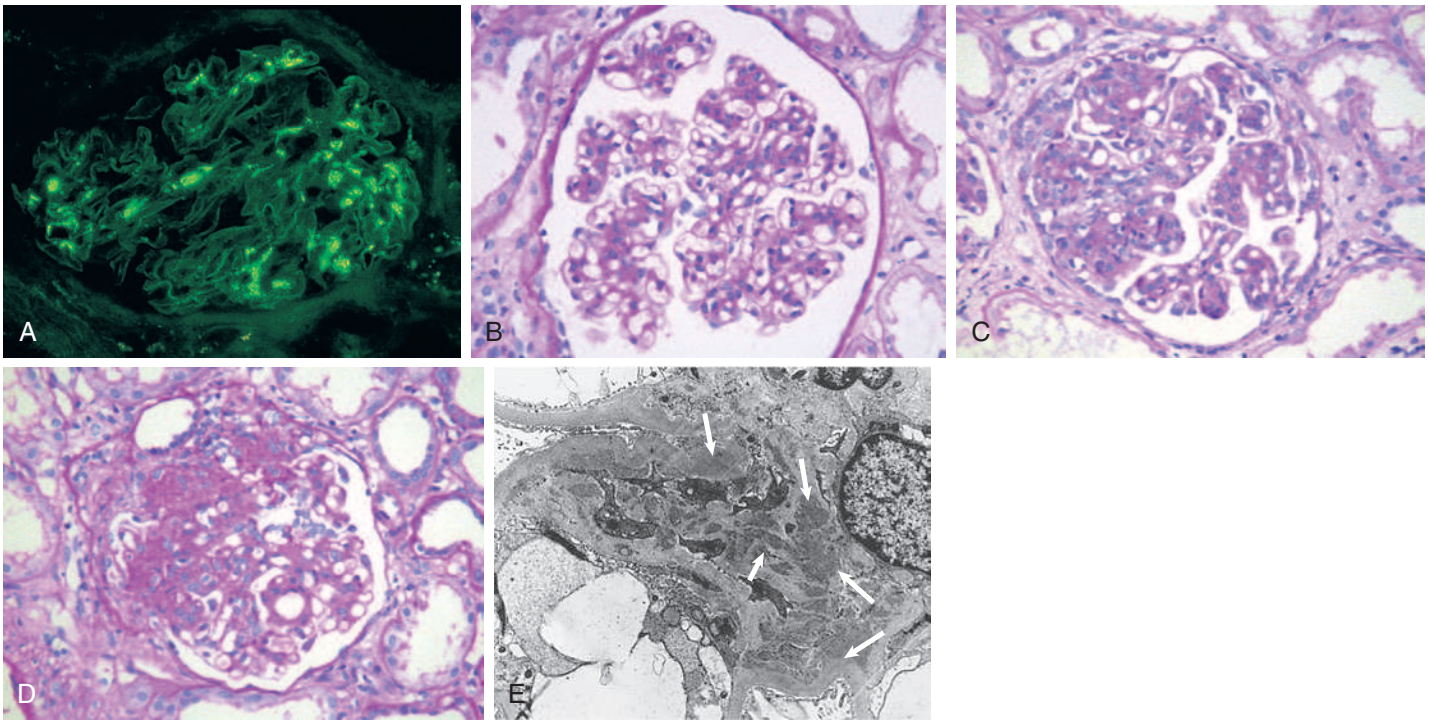

Fig. 23.4 Renal pathology in IgA nephropathy. (A) Diffuse mesangial IgAN seen on indirect immunofluorescence with fluorescein isothiocyanate–anti-IgA (magnification ×3300). (B) Diffuse mesangial hypercellularity (M1, Oxford classification). (C) Endocapillary hypercellularity (E1). (D) Segmental sclerosis (S1). (**B, C,** and **D,** Light microscopy with periodic acid–Schiff reaction; ×3300). **E,** Mesangial electron-dense deposits *(arrows)* (electron micrograph; ×316,000). (**B, C,** and **D** courtesy Professor I. Roberts.)

activation. Disappearance of IgA deposits after prolonged clinical remission has been documented in both children and adults. About one third of the patients also have deposits of sIgA in the mesangium and are characterized by more severe disease.[15]

Light Microscopy

Light microscopy changes are remarkably variable and do not correlate topographically with the IgA deposits. There can be almost normal glomerular architecture, mesangial hypercellularity that may be diffuse (see Fig. 23.4B) or segmental, or in rare cases, focal segmental necrotizing GN with extracapillary proliferation. Typical cases are characterized by an increase in mesangial cells and mesangial matrix with normal-appearing capillary loops, although endocapillary hypercellularity can occur (see Fig. 23.4C). Focal segmental or global glomerular sclerosis indicates that the disease has been ongoing for some time (see Fig. 23.4D). In addition to glomerular changes, the preglomerular arterial vessels often exhibit wall hyalinosis and subintimal fibrosis even in patients with only mild arterial hypertension. In long-standing disease, tubulointerstitial inflammation leads to interstitial fibrosis and tubular atrophy in a pattern no different from that of other progressive glomerular diseases. On occasion, IgAN and minimal change nephrotic syndrome coincide (see Differential Diagnosis), in which case light microscopy is normal but there are mesangial IgA deposits.

Morphology is of value in predicting prognosis in patients with slowly progressive disease. The Oxford (MEST) classification of IgAN is now being widely accepted.[16] This classification identifies four features of prognostic value and can be easily scored on light microscopy: mesangial hypercellularity (M1 when present, M0 when absent), endocapillary hypercellularity (E1), segmental sclerosis (S1), and three degrees of tubular atrophy and interstitial fibrosis (T0, T1, T2). Examples of these glomerular features are shown in Fig. 23.4.

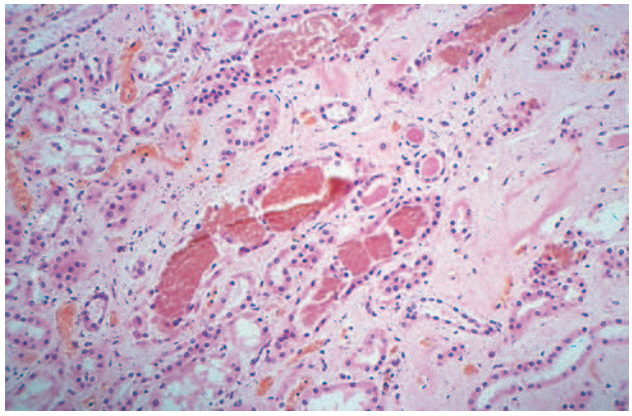

Fig. 23.5 Acute kidney injury in IgA nephropathy. Tubular occlusion by red blood cells. This appearance may be associated with only minor glomerular changes. (Hematoxylin and eosin stain; ×300.)

Histologic patterns of injury in AKI include tubular occlusion by RBCs with acute tubular epithelial injury in AKI associated with macroscopic hematuria (Fig. 23.5) or necrotizing GN and cellular crescent formation. Such crescentic IgAN may develop on a histologic background of established chronic renal injury caused by IgAN or may be the first presentation of IgAN. Small numbers of crescents may be seen in hypertensive patients with stable renal function and no other pathologic evidence of severe glomerular inflammation; the term *crescentic IgAN* should not be used for such patients, in whom the prognosis is often favorable.

Electron Microscopy

Electron-dense deposits correspond to the mesangial (or capillary loop) IgA (see Fig. 23.4E). Typically, electron-dense deposits are confined to mesangial and paramesangial areas, although subepithelial and subendothelial deposits also can be seen. Up to one third of patients will have some focal thinning of the glomerular basement membrane (GBM). On occasion, there will be extensive GBM thinning, suggesting a coincident diagnosis of thin basement membrane nephropathy (see Chapter 46).

Differential Diagnosis

The diagnosis of IgAN or IgAV nephritis requires identification of mesangial IgA in the glomeruli. Therefore it cannot be made without a renal biopsy, no matter how suggestive the clinical presentation. Serum IgA is often increased, and there may be IgA in cutaneous blood vessels in IgAN and in both affected and unaffected skin in IgAV. Neither finding, however, is reliable enough to support the diagnosis without a renal biopsy. Serum complement components are normal in most patients.

Mesangial IgA occurs in other conditions and can usually be differentiated by clinical, serologic, and histologic criteria (Box 23.1). None of the light microscopic features alone is diagnostic of IgAN.

An important differential diagnosis is IgA-dominant acute postinfectious glomerulonephritis (APIGN), in which IgA is the dominant immunoglobulin in glomerular deposits (see Chapter 55). It usually occurs in association with staphylococcal infections. Risk factors particularly include diabetes. Compared with IgAN, patients with IgA-dominant APIGN are more likely to be older and have AKI, documented staphylococcal infection, hypocomplementemia, diffuse glomerular endocapillary hypercellularity with prominent neutrophil infiltration on light microscopy, stronger immunofluorescence staining for C3 than IgA, and the presence of subepithelial humps on electron microscopy.[17]

Hematuria

Nonglomerular causes of hematuria, particularly stones and neoplasia, must be excluded by appropriate investigations (see Chapter 59). In its most characteristic clinical setting—recurrent macroscopic hematuria coinciding with mucosal infection in a man in the second or third decade of life—the diagnosis can be strongly suspected. Such a diagnosis, however, cannot be made without a biopsy because recurrent macroscopic hematuria also occurs in other glomerular diseases (e.g., Alport syndrome and MPGN), particularly in children and young adults. In young adults, thin basement membrane nephropathy is the most important differential diagnosis for isolated microhematuria.

Nephrotic Syndrome

Patients with IgAN occasionally develop nephrotic syndrome, which is indistinguishable from that in MCD. There is a sudden onset of nephrosis, with biopsy evidence of glomerular epithelial cell foot process effacement and a prompt complete remission of proteinuria in response to corticosteroids. Only hematuria and mesangial IgA deposits persist after treatment. This pattern occurs particularly in children. These patients are usually regarded as having two separate common glomerular diseases, IgAN and MCD.[18]

Other patients with IgAN may develop nephrotic syndrome with more structural glomerular damage and lack the response to corticosteroids. The clinical differential diagnosis includes common causes of nephrotic syndrome appropriate for the age of the patient (see Chapter 15).

Chronic Kidney Disease: Hypertension, Proteinuria, Renal Impairment

In this context, IgAN will be clinically indistinguishable from many forms of chronic kidney disease (CKD). The renal biopsy may be diagnostic by identifying mesangial IgA, even when structural damage is so advanced on light microscopy that it has the nonspecific features of ESRD.

Acute Kidney Injury

When AKI occurs in a patient known to have IgAN, renal biopsy should be performed unless there is rapid improvement in renal function, after at least 5 days from the onset of kidney function worsening, in response to supportive care and vigorous hydration.[19] Renal biopsy may be required to differentiate the tubular occlusion and acute tubular necrosis that occasionally follow heavy glomerular hematuria from crescentic IgAN or other coincidental causes of AKI (see Fig. 23.5).

Natural History

IgA Nephropathy

The overall prognosis of IgAN has been reevaluated in recent long-term natural history studies.[20,21] After 20 years, one fourth of patients will have ESRD and a further 20% will have progressive impairment of renal function.

Although an active approach to the investigation of microhematuria will increase the size of the cohort of patients found to have IgAN, it will include more with a good prognosis, thus altering the perceived risk for disease progression. Episodes of macrohematuria do not confer a worse prognosis. This may indicate that such episodes occur only early in the natural history of the disease and patients doing less well from the point of diagnosis in fact were identified at a later stage in their disease. This is also suggested by the adverse influence on outcome of advancing age at diagnosis.

The risk for ESRD is not uniform. As in any chronic glomerular disease, the presence of hypertension, proteinuria, and reduced glomerular filtration rate (GFR) at presentation, as well as histologic evidence of glomerular and interstitial fibrosis, identifies at the time of diagnosis those with a poor prognosis (Table 23.2). Hyperuricemia, smoking, and increased body mass index are also independent risk factors for progression. However, during follow-up, only hypertension and proteinuria, in particular time-averaged proteinuria, are reliable predictors of risk for progression. Canadian and French studies indicate

BOX 23.1 Differential Diagnosis of Immunoglobulin a Nephropathy: Conditions Associated With Mesangial IgA Deposition

- IgA nephropathy
- IgA vasculitis

- Lupus nephritis*
- Alcoholic liver disease
- IgA monoclonal gammopathy
- Schistosomal nephropathy
- IgA-dominant Staphylococcus-associated glomerulonephritis (more common in diabetics)

*Distinguishing lupus nephritis (especially International Society of Nephrology/Renal Pathology Society classes II and III) may cause difficulty. The finding of C1q deposition is useful. It indicates classical pathway involvement found in lupus nephritis but not in IgAN.

TABLE 23.2 Prognostic Markers at Presentation in Immunoglobulin A Nephropathy

Clinical	Histopathologic
Poor Prognosis	
• Hypertension	• Mesangial hypercellularity
• Renal impairment	• Endocapillary proliferation
• Severity of proteinuria	• Segmental glomerulosclerosis
• Smoking	• Tubular atrophy
• Hyperuricemia	• Interstitial fibrosis
• Gross obesity	• Capillary loop IgA deposits
• Long duration of preceding symptoms	• Crescents (controversial)
• Increasing age	
Good Prognosis	
• Recurrent macroscopic hematuria	
No Impact on Prognosis	
• Gender	• Intensity of IgA deposits
• Serum IgA level	

None of the clinical or histopathologic adverse features, except capillary loop IgA deposits is specific to IgA nephropathy.

that risk for progression is negligible when proteinuria remains below 0.2 g/24 h with normal blood pressure.[20,21]

If a renal biopsy documents IgAN in patients with mild disease (i.e., those manifesting with isolated microhematuria, little or no proteinuria, normotension, and normal GFR), the 7- to 10-year prognosis is mostly good.[22,23] However, up to 40% of the patients will develop increasing proteinuria and up to 5% will lose GFR over this period, implying the need for regular follow-up in such patients. Large studies with long-term follow-up indicate a slow attrition.

Pathologic findings and clinical findings together inform prognosis.[24] The MEST classification of IgAN has shown that mesangial hypercellularity, endocapillary proliferation, and segmental sclerosis, as well as tubular atrophy and interstitial fibrosis, each add prognostic information even when clinical features (proteinuria, hypertension, GFR) are known at presentation and during follow-up.

Transplantation

Recurrent IgA Nephropathy

Transplant registry data show that transplant outcome is not affected for the first 10 years if IgAN is the patient's primary renal disease; thereafter, however, recurrent disease may lead to accelerated graft loss (see also Chapter 108). Mesangial IgA deposits recur in the donor transplant kidney in up to 60% of patients with IgAN.[25] They may occur within days or weeks, but the risk increases with the duration of the transplant. The deposits seem benign in the short term and are not often associated initially with light microscopy changes. In pooled series, recurrent IgAN is 30% in living related transplants versus 23% in cadaveric grafts, but this does affect graft survival only beyond 10 years after transplantation.[25] Living related donation should not be discouraged. However, any urinary abnormality in a potential related donor requires thorough evaluation, including, if necessary, a renal biopsy. Recurrence of crescentic IgAN with rapid graft failure occurs infrequently and is generally resistant to treatment.

In a few unwitting experiments, cadaver kidneys with IgA deposits have been transplanted into recipients without IgAN. In all cases, the IgA rapidly disappeared, supporting the concept that abnormalities in IgAN lie in the IgA immune system and not in the kidney.

Treatment

Although specific early treatment intervention might influence the IgA immune system abnormalities that underlie IgAN, the mechanisms of chronic disease progression are unlikely to be unique. Therefore studies of such patients with IgAN may provide information applicable to many forms of chronic GN for which IgAN is the paradigm.

The balance of risk against benefit for immunosuppressive therapy is often unfavorable in patients with IgAN, except in the unusual circumstance of crescentic IgAN.

Fig. 23.6 provides a treatment algorithm for IgAN that is based on the current Kidney Disease: Improving Global Outcomes (KDIGO) guidelines.[19] The approach distinguishes among the following[26]:

- The "good prognosis" patient, with minor urinary abnormalities, normal GFR, and normotension, who needs only sporadic follow-up for a prolonged period (>10 years)
- The "intermediate prognosis" patient, with significant proteinuria, hypertension, and slow reduction of GFR, who particularly benefits from comprehensive supportive care
- The "poor prognosis" patient, with a rapid loss of GFR, who may require more aggressive immunosuppression

Slowly Progressive IgA Nephropathy ("Intermediate Prognosis")

Minimal evidence exists to suggest the events of progressive glomerular injury are unique to IgAN. Comprehensive supportive therapy following the strategies outlined in Chapter 79 therefore remains central in the therapeutic approach to patients at risk for progressive IgAN (see Fig. 23.6).

Antihypertensives and proteinuria-lowering drugs. There is compelling evidence for the benefit of lowering blood pressure (BP) in the treatment of chronic progressive glomerular disease such as IgAN. In patients with IgAN, there is also evidence that casual clinic BP readings underestimate BP load, as judged by ambulatory monitoring and echocardiographic evidence of increased left ventricular mass.[27] Two prospective, controlled trials strongly support the use of angiotensin-converting enzyme (ACE) inhibitors in patients with IgAN as first-choice hypotensive agents to lower BP.[28,29] In a randomized study of IgAN, achieving a mean BP of 129/70 mm Hg prevented the decrease in renal function over 3 years seen in patients achieving mean BP of 136/76 mm Hg.[30]

Observational studies indicate that the risk for progression in IgAN decreases significantly if proteinuria can be reduced to less than 1 g/d by any therapeutic maneuver.[21] Another compelling indication for the role of lowering proteinuria in IgAN is based on the superior effectiveness of ACE inhibitors over other antihypertensive agents.[28,29]

Fish oil. The favorable effects of supplementing the diet with omega-3 fatty acids in the form of fish oil include reductions in eicosanoid and cytokine production, changes in membrane fluidity and rheology, reduced platelet aggregability, and reduced proliferation of renal cells in response to PDGF. The evidence for a beneficial action of fish oil in IgAN is weak; its suggested use in patients at risk in the 2012 KDIGO guidelines is supported by only low-level evidence.[19] However, fish oil treatment does not have the drawbacks associated with immunosuppressive treatment. Fish oil is safe except for a decrease in blood coagulability, which is not usually a practical problem, and an unpleasant taste, with flatulence, which may make compliance difficult. Some fish oil preparations contain significant amounts of cholesterol, necessitating close surveillance if such treatment is initiated. A further confirmatory study of fish oil would be of great value.

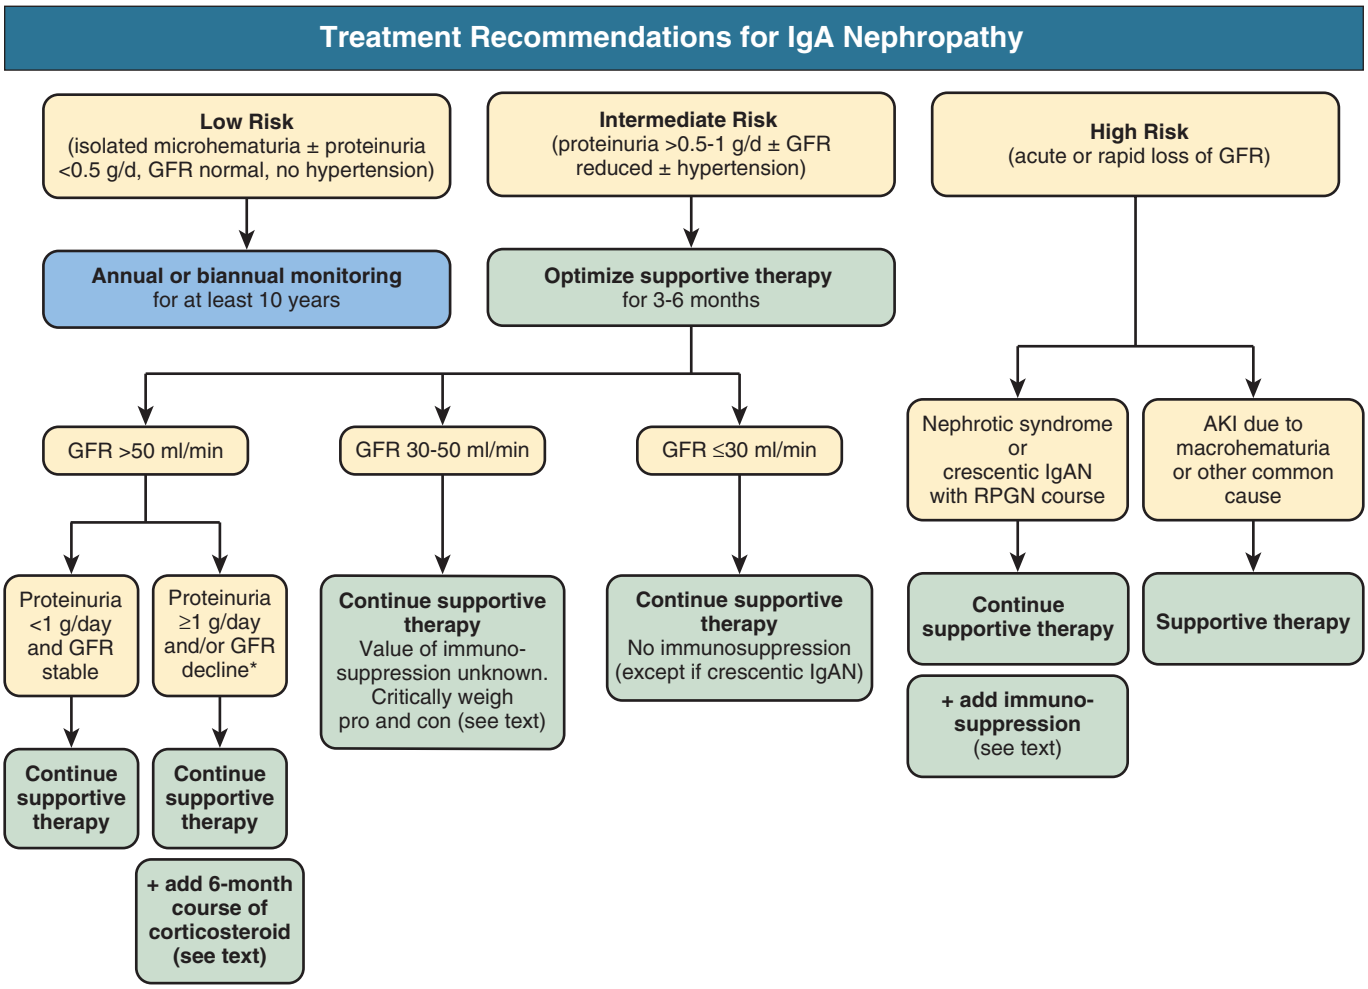

Fig. 23.6 Treatment recommendations for IgA nephropathy. *AKI,* Acute kidney injury; *GFR,* glomerular filtration rate; *RPGN,* rapidly progressive glomerulonephritis. (Modified from reference 26.)

Immunosuppressive or Antiinflammatory Regimens

Corticosteroids. A meta-analysis and retrospective data suggest that corticosteroids are beneficial in IgAN, in particular in adults with proteinuria exceeding 3 g/d.[31,32] However, there are also several trials that failed to demonstrate benefit from corticosteroids and dosage was somewhat lower in two of three negative versus the positive trials.[26] Several trials did not optimize supportive therapy, in particular renin-angiotensin system (RAS)-blockers, or required that such drugs be temporarily halted before the trial. The 2012 KDIGO guidelines thus suggest that corticosteroids should be initiated in high-risk patients only if proteinuria remains above 1 g/d after supportive care has been optimized for 3 to 6 months and only if GFR remains above 50 ml/min. At present, no evidence supports a more intense or complex regimen of intravenous as well as oral corticosteroid therapy over a purely oral prednisolone regimen, starting with 1 mg/kg/day for 2 months, then reduced by 0.2 mg/kg/day/month.[26]

The previously mentioned recommendations have recently been challenged by two large prospective trials of oral corticosteroids in IgAN added to optimized supportive care (STOP-IgAN and TESTING). In the German STOP-IgAN trial an extensive 6-month optimization of supportive measures abolished any subsequent benefit from high-dose corticosteroids in adult patients with IgAN with an average baseline GFR of 60 ml/min and a baseline proteinuria around 1.7 g/d.[33] The largely Chinese-based TESTING trial on high-dose corticosteroids in adults with a baseline GFR of 60 ml/min and a baseline proteinuria of 2.4 g/d was terminated early after an excess of severe, sometimes fatal infections was noted in the corticosteroid arm.[34] These two trials strongly emphasize the values of a comprehensive optimization of supportive measures in high-risk patients with IgAN.

Full-blown nephrotic syndrome may occur when MCD and IgAN coincide, in which case the nephrotic syndrome will be fully and promptly corticosteroid responsive. A trial of high-dose corticosteroid therapy analogous to that used in MCD (see Chapter 17) is therefore justified in patients with IgAN who have nephrotic syndrome associated with minimal glomerular injury.

An alternative approach to corticosteroid dosing has been evaluated: a phase II trial evaluating the role of an enteric corticosteroid (budesonide) preparation in patients with "intermediate prognosis" IgAN (NEFIGAN) showed a reduction in proteinuria and better preservation of renal function in the treated patients.[35]

Cyclophosphamide and azathioprine. Cyclophosphamide has been used in combination with warfarin and dipyridamole in two RCTs, with inconsistent results. Both showed modest reduction in proteinuria, but only one preserved renal function. Cyclophosphamide followed by azathioprine combined with prednisolone preserved renal function in patients with a poor prognosis, although BP control was suboptimal.[36] The same regimen, however, was ineffective in the STOP-IgAN trial and led to a death from pulmonary sepsis.[33] In another recent study, adding azathioprine to corticosteroids in patients with proteinuric IgAN with a GFR greater than 50 ml/min had no added benefit and only

increased side effects.[37] Neither agent is therefore recommended by the 2012 KDIGO guidelines in patients with intermediate risk IgAN.[19]

Other immunosuppressive approaches. Mycophenolate mofetil (MMF) has been used in several controlled trials in high-risk patients. Three trials in White patients failed to demonstrate a benefit, whereas a study in Chinese patients noted reduced proteinuria and preservation of GFR.[26,38] Whether racial effects underlie these discrepant results remains to be clarified. In another Chinese trial, 4 of 32 patients with IgAN receiving MMF plus corticosteroids died of *Pneumocystis* pneumonia.[39] MMF is therefore not recommended by the 2012 KDIGO guidelines in patients with intermediate risk IgAN.[19]

Cyclosporine has been used in one controlled trial in IgAN.[40] Patients showed a reversible decrease in proteinuria along with a decrease in creatinine clearance, suggesting the changes were a hemodynamic effect of cyclosporine rather than an immunomodulating effect.

Rituximab (two infusions of 1 g) failed to reduce levels of undergalactosylated IgA and autoantibodies against this IgA in a small open-label trial in adult patients with high-risk IgAN and did not affect proteinuria over the course of 1 year.[41]

Pooled human immunoglobulin has given encouraging preliminary results in patients with IgAN who have an aggressive clinical course. Proteinuria was reduced, deterioration of GFR slowed, and histologic activity lessened on repeated renal biopsies.[42] No RCT is available for this approach.

Dipyridamole and warfarin. Two RCTS with dipyridamole and warfarin showed mutually inconsistent results. There was no benefit in one and preserved renal function in the other. Neither drug is currently recommended in IgAN patients.[19]

Rapidly Progressive IgA Nephropathy ("Poor Prognosis")

In this uncommon situation of rapidly progressive renal failure associated with crescentic IgAN, the risk-to-benefit ratio most strongly favors intensive immunosuppressive therapy, because, if untreated, the patient will rapidly progress to ESRD. Treatment has often combined plasma exchange with prednisolone and cyclophosphamide.[43] Early clinical response is favorable, as in other crescentic nephritis. Medium-term results, however, are disappointing; kidney survival at 5 years was only 30% and not different in immunosuppressed and nonimmunosuppressed patients.[44]

A subset of patients with circulating IgG–antineutrophil cytoplasmic antibody (ANCA) may have a more favorable response to immunosuppressive therapy similar to that seen in other ANCA-positive crescentic nephritis.[45] With no randomized controlled trials (RCTs) of treatment, it is not possible to be certain which elements of the regimen (corticosteroids, cyclophosphamide, or plasma exchange) are mandatory.

Other Therapeutic Approaches to Progressive IgA Nephropathy

Reduction of IgA production. Tonsillectomy reduces the frequency of episodic hematuria when tonsillitis is the provoking infection. In all other patients with IgAN, tonsillectomy is not routinely recommended[19]; there is no role for prophylactic antibiotics. Dietary gluten restriction, used to reduce mucosal antigen challenge, has not been shown to preserve renal function.[2]

Prevention and removal of IgA deposits. The ideal treatment of patients with IgAN would remove IgA from the glomerulus and prevent further IgA deposition. This remains a remote prospect while the pathogenesis remains incompletely understood.

Transplant recurrence. There is no evidence that newer immunosuppressive agents have modified the frequency of recurrent IgA deposits or are of value in recurrent disease. There is, however, registry evidence that transplant outcome is improved if corticosteroids are continued long term and if the immunosuppression includes MMF.[46,47]

In patients with established IgAN recurrence, most clinicians merely optimize supportive care. When crescentic IgAN recurs with rapidly deteriorating graft function, treatment as for primary crescentic IgAN has been used, although evidence of its success is sparse.

IgA VASCULITIS

Definition

IgA vasculitis (IgAV), previously termed Henoch-Schönlein purpura, is a small-vessel vasculitis affecting the skin, joints, gut, and kidneys that predominantly affects children. It is defined by tissue deposition of IgA. Typically, there is clinical involvement in the skin, gut, and kidneys. The nephritis associated with IgAV is characterized by diffuse mesangial IgA deposition. Indeed, the renal histologic features of IgAV are indistinguishable from those of IgAN.

Epidemiology

In children, IgAV is usually diagnosed on clinical grounds without biopsy confirmation of tissue IgA deposition. Transient urine abnormalities are common in the acute phase. However, only those with persistent urine abnormalities or with more overt renal disease will come to renal biopsy. Therefore the incidence of IgAV is almost certainly underestimated, with many unidentified mild and transient cases. There is no information on geographical variations in IgAV.

Despite some differences in age at onset and natural history of IgAN and IgAV,[48] there is much evidence to support a close link between the two conditions. Monozygotic twins who developed IgAN and IgAV, respectively, at the same time have been described. The evolution of IgAN into IgAV in the same patient is described in both adults and children, and patients with IgAV and ESRD receiving a renal transplant may experience recurrent disease in the form of IgAN.

Pathogenesis

Many of the abnormalities of IgA production and handling reported in IgAN are also detected in IgAV, including circulating IgA-rheumatoid factors in 55% of cases, and increased serum gd-IgA1, which is found in IgAV when there is nephritis, but it is not clear if gd-IgA1 is also predictive of extrarenal manifestations of IgAV. No studies have investigated whether gd-IgA1 is in mesangial deposits in IgAV. There is no animal model for IgAV to facilitate studies of pathogenesis.

Although infective episodes precede IgAV in up to 50% of cases, no evidence indicates a role for any specific antigen.

Genetics

Subjects with IgAV have been excluded from recent large-scale genome-wide association studies in IgAN, and the genetic background to IgAV has not been systematically studied.

Clinical Manifestations

Although most prevalent in the first decade of life, IgAV may occur at any age. A palpable purpuric rash, which may be recurrent, occurs on extensor surfaces (Fig. 23.7). There may be polyarthralgia (usually without joint swelling) and abdominal pain caused by gut vasculitis. This may be severe, with bloody diarrhea if intussusception develops. In practice, the diagnosis is made by clinical criteria in the great majority of children, in whom IgAV is often a self-limiting illness. In adults, clinical features include purpura, arthritis, and gastrointestinal symptoms in 95%, 60%, and 50% of patients, respectively.[49] Renal involvement in adults with IgAV does not differ from that in isolated IgAN. Tissue confirmation of IgA deposition by renal or skin biopsy is necessary to establish the diagnosis of IgAV.

Much renal involvement in IgAV is transient. Urine abnormalities are noted during the acute presentation but may disappear. Of those

Fig. 23.7 Henoch-Schönlein Purpura. The rash is a palpable purpuric vasculitis on the lower limbs spreading on extensor surfaces to the buttocks and occasionally to the upper limbs. Histology shows leukocytoclastic vasculitis with IgA deposits in blood vessel walls.

referred to a nephrologist, asymptomatic urine abnormality is still the most frequent clinical manifestation. Nephrotic syndrome occurs in 20% to 30% of patients. AKI may develop as a result of crescentic GN.

Pathology

The renal histopathologic findings in IgAN and IgAV nephritis may be indistinguishable (see Fig. 23.4). The predictive value of the MEST score has not yet been shown for IgAV with renal involvement.

Differential Diagnosis

In children, the diagnosis of IgAV is usually made on the basis of clinical criteria. Confirmatory evidence of tissue IgA deposition will not be obtained unless persistence of renal disease results in a renal biopsy. In adults, the differential diagnosis is much wider and includes other forms of systemic vasculitis, requiring diagnosis by clinical, serologic, and histologic characteristics (see Chapter 25).

Natural History

The natural history for IgAV is less well defined than for IgAN. Observations are restricted to patients referred for renal biopsy, which excludes the majority of patients with minor transient renal involvement, who have an excellent prognosis. The renal prognosis is worse in adults than in children with IgAV. In adults, up to 40% will have CKD or ESRD 15 years after biopsy. One series reports an increased mortality from lung and gastrointestinal malignancy.[49]

Transplantation

IgAV can recur as isolated IgA deposits in the graft (~50% of transplants), as full-blown yet isolated IgAN, or rarely as a full recurrence of systemic involvement, including a rash. The clinical and pathologic characteristics of renal recurrence are similar to those of recurrent IgAN.[25] Delay of transplantation once ESRD is reached does not reduce the risk for IgAV recurrence.

Treatment

Many patients have transient nephritis during the early phase of IgAV, which spontaneously remits and requires no treatment. There are no prospective RCTs to guide the treatment of IgAV. Most therapeutic studies of IgAN exclude those with IgAV, so it is unclear whether the potential treatments for IgAN have a role in IgAV.[19] Commonly used treatments for IgAV are shown in Box 23.2.

BOX 23.2 Treatment Recommendations for Nephritis in IgA Vasculitis

Crescentic nephritis: Regimen is as for crescentic IgA nephropathy (see Fig. 23.6).

All other Nephritis in IgA Vasculitis (including nephrotic syndrome): Regimen is as for IgA nephropathy (see Fig. 23.6).

Hypertension: Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers are agents of first choice; target blood pressure: 130/80 mm Hg if proteinuria is <1 g/24 h, 125/75 mm Hg if proteinuria is >1 g/24 h.

Transplantation: Cadaveric donor may be preferable to living related donor in children (controversial).

Rapidly Progressive Chronic Kidney Disease Caused by Crescentic Nephritis

Crescentic nephritis is more common in IgAV than in IgAN, particularly early in the course of the disease. There is little specific information on treatment in adults or children, but regimens based on those for other forms of systemic vasculitis are widely used. These have included corticosteroids and cyclophosphamide, with the addition of plasma exchange or pulse methylprednisolone in some cases. However, a randomized French study in adults with severe IgAV failed to detect a benefit of cyclophosphamide plus steroids over steroids alone.[50]

Active IgA Vasculitis Without Renal Failure

There is little information about less aggressive IgAV. Corticosteroids alone, although often considered more effective than in IgAN, have never been shown to be beneficial for renal involvement in IgAV, although used with apparent benefit for extrarenal manifestations. There is no evidence that early use of corticosteroids in patients with IgAV prevents nephritis.[19] Promising findings with combination therapy of corticosteroids, cyclophosphamide, and antiplatelet agents have been reported in only small, nonrandomized studies.[19] A nonrandomized study reported that prednisolone and azathioprine preserved renal function and improved histologic appearances, but relied on historical controls.[51]

Slowly Progressive Chronic Kidney Disease

Although the renal histology and clinical course of slowly progressive IgAV and IgAN may be indistinguishable, patients with IgAV have not been included in studies of slowly progressive IgAN. Therefore there is no evidence that fish oil is beneficial in IgAV. Tight BP control with ACE inhibitors or angiotensin receptor blockers (ARBs) is recommended for proteinuric IgAV as for IgAN. The 2012 KDIGO guidelines recommend a similar indication for corticosteroids in slowly progressive IgAV as in patients with intermediate-risk IgAN.[19]

Transplant Recurrence

No treatment is known to reduce the risk for recurrence. There is some evidence that recurrence is more common and more likely to lead to graft loss in children receiving kidneys from living rather than deceased donors, although this is not confirmed in adults.[52,53] If crescentic IgAV recurs, intensive immunosuppression may be justified as for primary disease. This, however, has not been thoroughly evaluated.

SELF-ASSESSMENT QUESTIONS

1. Based on the 2012 KDIGO guidelines, which of the following statements regarding the therapy of IgA nephropathy is correct?
   - **A.** Fish oil is not recommended for patients at risk for progressive glomerular filtration rate (GFR) loss.
   - **B.** Tonsillectomy should be routinely performed in patients at risk for progressive GFR loss.
   - **C.** In patients at risk for progressive loss of GFR, prednisolone should be given at 1 mg/kg for a minimum of 10 weeks.
   - **D.** Mycophenolate mofetil is not recommended in patients at risk for progressive GFR loss.
   - **E.** Azathioprine is recommended in patients at risk for progressive GFR loss.
2. The Oxford (MEST) classification of histopathologic changes in IgA nephropathy includes pathologic features predictive of outcome. Which of the following is *not* one of the predictive features?
   - **A.** Mesangial hypercellularity
   - **B.** Segmental glomerulosclerosis
   - **C.** Tubulointerstitial damage and fibrosis
   - **D.** Hypertensive vascular changes (nephrosclerosis)
   - **E.** Endocapillary hypercellularity
3. Which of the following statements is *true* about IgA nephropathy?
   - **A.** IgAN is more common in Europe than any other part of the world.
   - **B.** Measurement of abnormally glycosylated serum IgA is a diagnostic test for IgAN.
   - **C.** The renal pathologic features can be identical to those in IgA vasculitis (Henoch-Schönlein purpura).
   - **D.** Acute kidney injury with macrohematuria in IgA nephropathy is almost always caused by crescentic IgAN.
   - **E.** The risk for recurrence after kidney transplantation is reduced when MMF is part of the immunosuppressive regimen.
4. In IgA vasculitis (Henoch-Schönlein purpura) (IgAV), which of the following statements is *true*?
   - **A.** IgA vasculitis never occurs after age 40.
   - **B.** There is altered glycosylation of serum IgA1.
   - **C.** Delay in transplantation reduces the risk for recurrence.
   - **D.** Cyclophosphamide is of proven benefit for slowly progressive IgA vasculitis.
   - **E.** Corticosteroids given at onset of the rash reduce the risk for subsequent nephritis.

Anti–Glomerular Basement Membrane Disease and Goodpasture Disease

Richard G. Phelps, A. Neil Turner

The syndrome of renal failure and lung hemorrhage was associated with the name of Ernest Goodpasture by Stanton and Tange in their description of nine cases in 1958.[1,2] All nine patients presented with lung hemorrhage and acute renal failure and died within hours or days. These features had been prominent in the case of a young man who died during the influenza pandemic of 1919, whose postmortem findings were memorably reported by Goodpasture[1]: "The lungs gave the impression of having been injected with blood through the bronchi so that all the air spaces were filled" (Fig. 24.1).

Several diseases are now recognized as being associated with alveolar hemorrhage and rapidly progressive glomerulonephritis (RPGN). Nevertheless, this remains a striking clinical entity with relatively few causes and few pathogenetic mechanisms.

Because the first recognized mechanism was anti–glomerular basement membrane (anti-GBM) antibody formation and deposition, Goodpasture's name is firmly associated with anti-GBM disease (Goodpasture disease), even though this is responsible for only a proportion of patients with Goodpasture syndrome of lung hemorrhage and RPGN. The terminology used in this chapter is defined in Table 24.1.

ETIOLOGY AND PATHOGENESIS

Autoimmunity to a Component of Glomerular Basement Membrane

Goodpasture disease is caused by autoimmunity to the carboxyl terminal, noncollagenous (NC1) domain of a type IV collagen chain, α3(IV)NC1, also known as the Goodpasture antigen[3,4] (Fig. 24.2). Type IV collagen is an essential constituent of all basement membranes. In most tissues, it is composed of trimers comprising two α1 chains and one α2 chain, but there are also four tissue-specific chains, α3 through α6.[5,6] Three of these, α3 through α5, are found in GBM as well as in the basement membranes of the alveolus, the cochlea, parts of the eye (including corneal basement membrane and Bruch membrane), the choroid plexus of the brain, and some endocrine organs.

All patients with RPGN, lung hemorrhage, and anti-GBM antibodies have antibodies to α3(IV)NC1, usually binding predominantly to a single or a very restricted set of epitopes. Some patients also have antibodies to other basement membrane constituents, including other collagen IV chains, usually in low titer.

Predisposing Factors

Both environmental and genetic factors appear to be important in etiology. There are strong associations between Goodpasture disease and human leukocyte antigen (HLA) class II alleles, including *DRB1*1501* and *DR4* alleles, whereas *DR1* and *DR7* confer strong and dominant protection.[7] Some diseases and treatments predispose, as described in the following section.

Precipitating Factors

Theories of pathogenesis include precipitating factors that alter antigen processing to generate peptides that are usually destroyed or hidden, and to which tolerance is therefore deficient,[8,9] and molecular mimicry.[10] None of these is proved. Reports of temporal and geographic clustering of cases suggest an environmental trigger,[11,12] but no specific infectious agent has been consistently identified. Hydrocarbon exposure has been linked to disease onset in several striking case reports; but such exposure may simply trigger lung hemorrhage in patients who already have the disease. Furthermore, exposures of this kind are very common in the modern world. Similarly, cigarette smoking may precipitate lung hemorrhage in patients who already have circulating autoantibodies, but there is no evidence for a role in causation.

In several cases, renal trauma or inflammation has preceded the development of the disease (Box 24.1). These may alter α3(IV)NC1 turnover and metabolism qualitatively or quantitatively, providing an opportunity for self-tolerance to be broken. Qualitative changes in the basement membrane epitopes presented to T cells could be a result of overloading of the usual or recruitment of alternative processing pathways, such as extracellular processing by proteases released into inflamed glomeruli. The quantity of α3(IV)NC1 presented to T cells may be greater where there has been damage to the basement membrane, as occurs in small-vessel vasculitis (see Chapter 25). Some features suggest that an anti-GBM response may be a secondary phenomenon in some patients with vasculitis.[13,14] The association with membranous nephropathy (MN) is interesting because the thickened GBM in that disease contains increased amounts of the tissue-specific type IV collagen chains, including the Goodpasture antigen. The same could apply to a possible association with long-standing type 1 diabetes mellitus.[15]

Mechanisms of Renal Injury

The α3(IV)NC1 autoantibodies are central in the pathogenesis of Goodpasture disease[16,17] (Fig. 24.3). Antibodies eluted from the kidneys of patients who had died of Goodpasture disease rapidly bind to the GBM and cause glomerulonephritis (GN) when they are injected into monkeys.[18] The deposited antibodies are predominantly immunoglobulin G1 (IgG1). Contributions to renal injury mediated by such antibodies come from complement and from neutrophil and macrophage infiltration. T cells are essential for driving autoantibody production by T cell–dependent B cells, and, in experimental renal disease they are critical in producing glomerular crescents,[16,19] which are a usual feature of Goodpasture disease. Moreover, in mice engineered to express the human

susceptibility HLA allele *DRB1*1501,* α3(IV)NC1-specific CD4 T cells are sufficient to transfer disease between animals.[20]

Agents that downregulate inflammation by inhibiting interleukin-1 or tumor necrosis factor, or that inhibit recruitment of inflammatory cells by blockade of adhesion molecules or chemoattractants, suppress injury in experimental models of anti-GBM disease. Evidence in humans and in experimental animals supports the severity of renal injury being increased by proinflammatory cytokines or by stimuli likely to elicit them, such as bacteremia.[19] Crescent formation is seen in aggressive inflammatory GN, as described in Chapter 16 (see Fig. 16.8).

Lung Hemorrhage

Lung hemorrhage in Goodpasture disease (but not in small-vessel vasculitis, the other major cause of Goodpasture syndrome) occurs only if there is an additional insult to the lung, which is usually cigarette smoke. However, infection, fluid overload, toxicity from inhaled vapors or other irritants, and the systemic effects of some cytokines are also possibilities. The higher risk of kidney disease as compared with lung hemorrhage may be because alveolar capillary endothelial cells more effectively block circulating immunoglobulin from reaching the underlying basement membrane. In the glomerulus, antibodies have more direct access to the GBM via the diaphragm-free fenestrations of glomerular endothelium. Other sites at which the Goodpasture antigen is found are not involved in Goodpasture disease, except possibly the choroid plexus, where the endothelium is again fenestrated, and more rarely the eye.

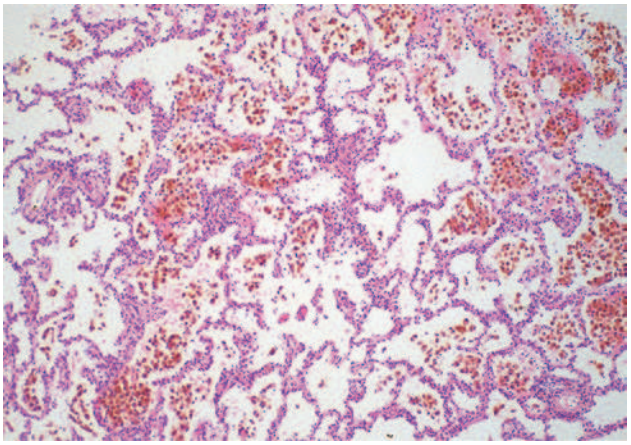

Fig. 24.1 Alveolar hemorrhage. Open lung biopsy sample in a patient with Goodpasture disease shows alveolar hemorrhage. (Courtesy Dr. E. Mary Thompson, St Mary's Hospital, London.)

EPIDEMIOLOGY

Goodpasture disease is rare, with an incidence in both White and Chinese populations approaching 1 case per 1 million population per year.[15] The incidence in Black populations appears to be lower. The incidence in other racial groups is uncertain. There is a slight male predominance. Lung hemorrhage is more common in younger patients. Age incidence is bimodal, with peaks in third and sixth decades.[15]

CLINICAL MANIFESTATIONS

Between 50% and 75% of patients present with acute symptoms of lung hemorrhage and advanced renal failure. Symptoms are usually confined to the preceding few weeks or months, but rapid progression (during days) or much slower progression (during many months) may occur. A lack of systemic symptoms, other than those related to anemia, is typical, although an apparently minor infection often triggers the clinical presentation.

Lung Hemorrhage

Lung hemorrhage may occur with renal disease or in isolation. Presenting symptoms may include cough and hemoptysis, but lung hemorrhage may result in marked iron-deficiency anemia and exertional dyspnea, even in the absence of hemoptysis. Examination findings may include pallor, dry inspiratory crackles, signs of consolidation, or respiratory distress. Recent lung hemorrhage typically is shown on the radiograph as central shadowing that may traverse fissures and give rise to the

BOX 24.1 Predisposing Events Associated With the Presentation of Goodpasture Disease

Possibly Induce Autoimmune Response and Disease
- Systemic small-vessel vasculitis affecting glomeruli
- Membranous nephropathy
- Lithotripsy of renal stones
- Urinary obstruction
- Alemtuzumab therapy for multiple sclerosis

Precipitate Pulmonary Hemorrhage
- Cigarette smoke
- Hydrocarbon exposure
- Pulmonary infection
- Fluid overload

TABLE 24.1 Definition of Terms Associated With Anti–Glomerular Basement Membrane Disease and Goodpasture Syndrome

Term	Definition	Pathogenesis
Pulmonary-renal syndrome	Renal and respiratory failure	Many causes (see Box 24.3)
Goodpasture syndrome	RPGN and alveolar hemorrhage	Several causes (see Box 24.4)
Anti-GBM disease	Disease associated with antibodies specific for (any) components of GBM	Most important are Goodpasture disease and Alport syndrome post-transplant anti-GBM disease
Goodpasture disease	Disease associated with autoantibodies specific for α3(IV)NC1 May include RPGN, lung hemorrhage, or both	Autoimmunity to α3(IV)NC1
Alport syndrome post-transplant anti-GBM disease	Glomerulonephritis associated with anti-GBM antibodies developing after renal transplantation in patients with Alport syndrome	Immunity to foreign collagen IV chains not expressed in patients with Alport syndrome, usually α3 or α5(IV)NC1

GBM, Glomerular basement membrane; *RPGN,* rapidly progressive glomerulonephritis.

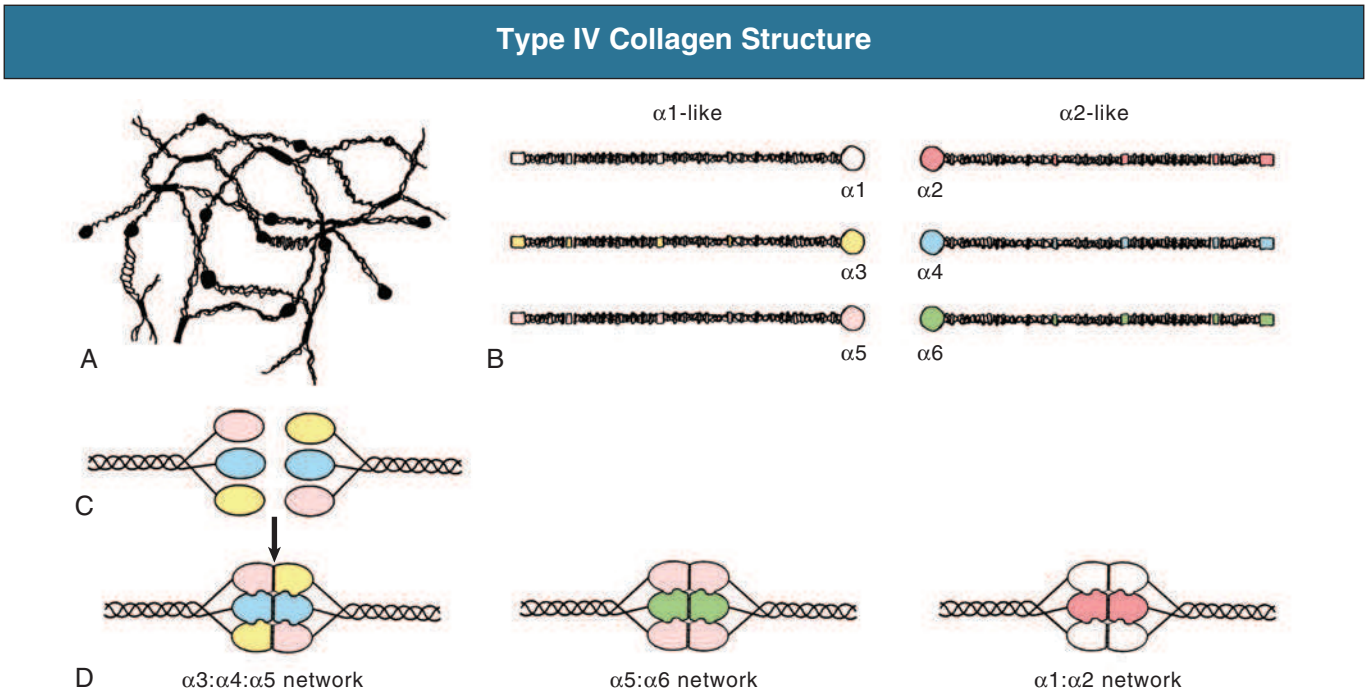

Fig. 24.2 Type IV collagen structure. (A) The type IV collagen network makes a "chicken wire" structure in the GBM. (B) Six paired type IV collagen genes, *COL4A1* to *COL4A6,* encode type IV collagen monomers α1 to α6. These associate in two or three defined monomer types per protomer (carboxyl terminal domains of α3:α4:α5 shown in (C) to form three recognized networks shown in (D) α1:α2 is present in almost all basement membranes; α3:α4:α5 is the major constituent of GBM and is a significant component of alveolar basement membrane and other locations; and α5: α6 is found in Bowman capsule, skin, esophagus, and other locations.

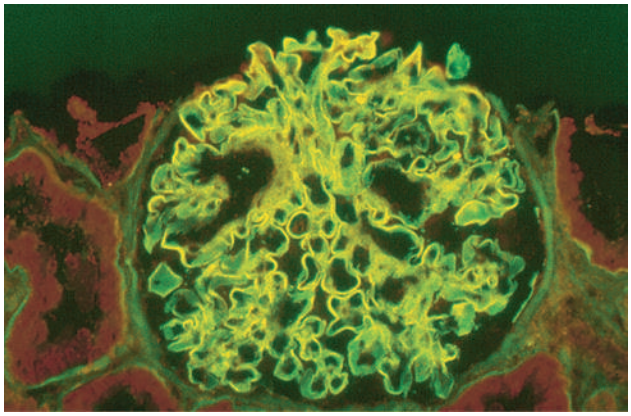

Fig. 24.3 Autoantibodies to Goodpasture antigen bound to a normal glomerulus. Direct immunofluorescence of normal kidney with sera from a patient with Goodpasture disease shows the antigen in a patient with lung hemorrhage and hematuria. (Courtesy Dr. Richard Herriot, Aberdeen Royal Infirmary, UK.)

appearance of an air bronchogram (Fig. 24.4). However, even lung hemorrhage sufficient to reduce the hemoglobin concentration may cause only minor or transient radiographic changes, and these cannot be distinguished radiologically from other causes of alveolar shadowing, notably edema or infection. The most sensitive indicator of recent lung hemorrhage is an increased uptake of inhaled carbon monoxide (DLCO). Patients with lung hemorrhage are usually current cigarette smokers.

In apparently isolated lung disease, progressive alveolar or fibrotic disease or pulmonary hemosiderosis may be suspected, although hematuria is usually found to be present if sought. This may continue for months or in rare cases recurrently for years before significant renal disease occurs.

Glomerulonephritis

Patients with GN may notice dark or red urine, but progression to oliguria is sometimes so rapid that this phase, if it occurs, is missed. In a third to half of patients, GN occurs in the absence of lung hemorrhage. In this subgroup, because systemic symptoms are generally not prominent, presentation is often late with renal failure.

Whatever the early pattern of disease, once significant renal impairment has occurred, further deterioration in renal function is usually rapid. Presentation at or shortly after acceleration of the disease process is common, and patients may demonstrate very rapid loss of renal function and life-threatening lung hemorrhage. Urinalysis always reveals hematuria (even in apparently isolated pulmonary disease), usually modest proteinuria, and dysmorphic red blood cells (RBCs) and RBC casts on microscopy. The kidneys are generally of normal size but may be enlarged. Hematuria may be substantial or associated with loin pain in acute disease.

PATHOLOGY

Renal biopsy is essential because it provides diagnostic and prognostic information. Typical appearances are of diffuse proliferative GN with variable degrees of necrosis, crescent formation, glomerulosclerosis, and tubular loss (Fig. 24.5). The degree of crescent formation and tubular loss correlates with renal prognosis. Characteristically, the crescents all appear to be of similar age and cellularity. When biopsy is performed

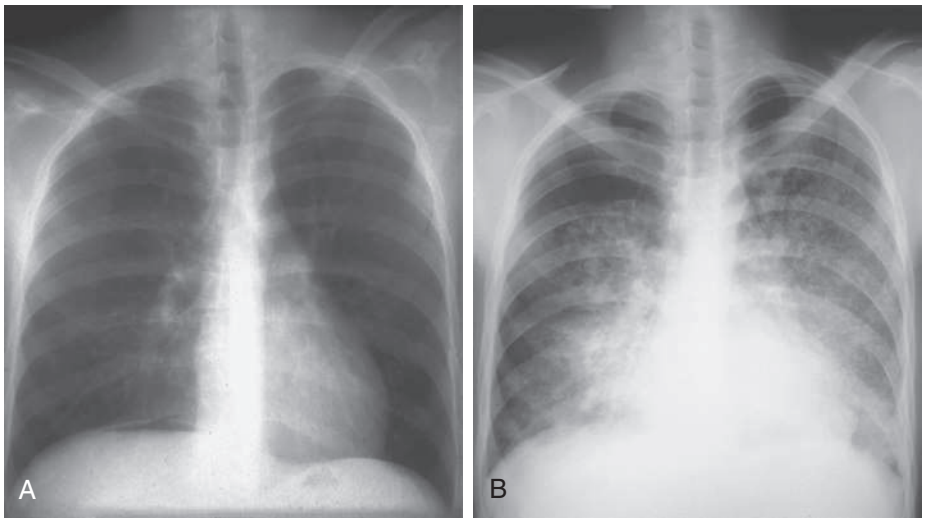

Fig. 24.4 Lung hemorrhage. (A) Patient with early pulmonary hemorrhage. The chest radiograph still appears normal. (B) Radiograph taken 4 days later shows the evolution of alveolar shadowing caused by lung hemorrhage.

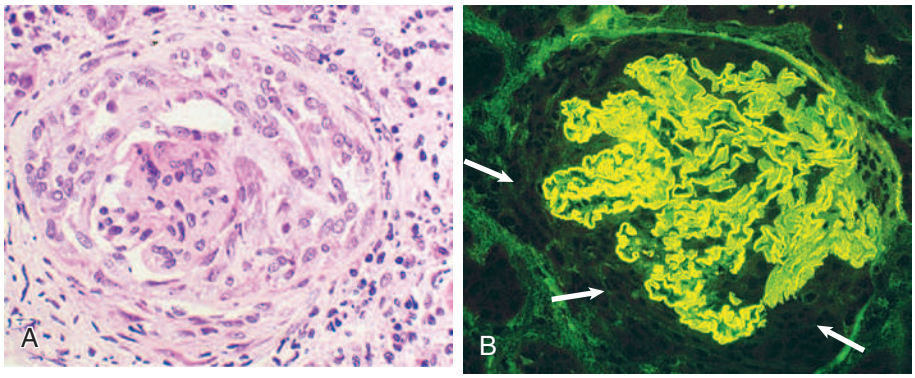

Fig. 24.5 Renal biopsy in Goodpasture disease. (A) Glomerulus from a patient with Goodpasture disease showing a recent, mostly cellular crescent. (B) Direct immunofluorescence study showing ribbon-like linear deposition of IgG along the glomerular basement membrane. The glomerular tuft is slightly compressed by cellular proliferation (exhibiting no immunofluorescence), forming a crescent *(arrows)*. (Courtesy Dr. Richard Herriot, Aberdeen Royal Infirmary, UK.)

earlier in the disease, changes may be limited to focal and segmental mesangial expansion, with or without necrosis. This progresses to hypercellularity and then to more general changes, including fractures of the GBM and Bowman capsule, neutrophils in the glomeruli, and glomerular capillary thrombosis.[21]

Immunohistology

In the presence of severe glomerular inflammation, linear deposition of immunoglobulin along the GBM is pathognomonic. The immunoglobulin is usually IgG, sometimes (10% to 15%) with IgA or IgM, but, rarely, IgA alone is detected. Linear deposition of C3 is detectable in about 75% of biopsies. Linear immunofluorescence (IF) with anti-immunoglobulin reagents is occasionally seen in other conditions, usually without glomerular inflammation (Box 24.2). In most such cases, the deposited immunoglobulin is less abundant than in Goodpasture disease and is either nonspecifically deposited or bound to GBM components other than type IV collagen chains.

Circulating IgG anti-GBM antibodies are almost invariably present and may be detected and quantified by use of immobilized Goodpasture antigen in an immunoassay. The titer of anti-GBM antibody at presentation correlates with the severity of nephritis, but sometimes is at

BOX 24.2 Conditions Associated With Linear Binding of Immunoglobulin to the Glomerular Basement Membrane

Specific Binding to GBM
- Goodpasture syndrome
- Alport syndrome after renal transplantation

Nonspecific Binding to GBM
- Diabetes
- Cadaver kidneys
- Light chain disease
- Fibrillary glomerulopathy
- Systemic lupus erythematosus (possibly specific but not considered directly pathogenic)

GBM, Glomerular basement membrane.

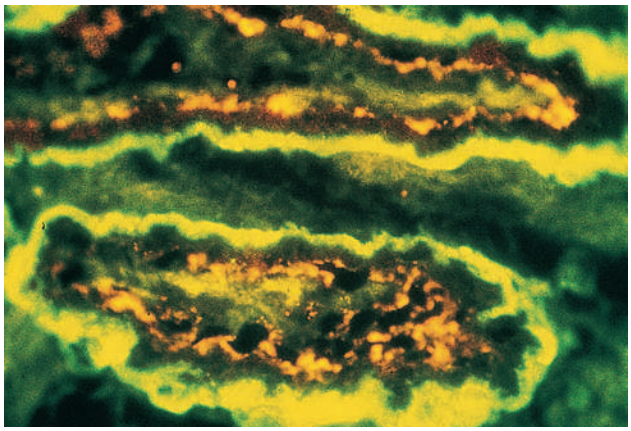

Fig. 24.6 IgG binding to choroid plexus. Direct immunofluorescence study showing binding of IgG to the choroid plexus of a patient who died of Goodpasture disease. (Courtesy Dr. Stephen Cashman, Imperial College, London.)

a very low level despite significant disease; interpretation may require knowledge of the local laboratory's approach to classifying assay results. Treatment and relapse are often mirrored by changes in titer.

Pathology in Other Tissues

Pathologic changes in lung tissue can be difficult to interpret because the changes, including immunoglobulin deposition, are often patchy and may be missed. Frequently, the only findings are mild, chronic inflammation and hemosiderin-laden macrophages, which are consistent with other more common pathologic diagnoses. This makes negative bronchoscopic or open-lung biopsy findings unhelpful in excluding the diagnosis.

Other tissues in which α3(IV)NC1 is expressed are rarely available for pathologic analysis, but even if antibody is deposited in these other sites, it is rarely associated with clinical disease. A number of case reports describe neurologic syndromes, particularly seizures, that may be related to antibody deposition in the choroid plexus, but may have other explanations in patients with acute kidney injury (Fig. 24.6). Other reports have described retinal detachment, in one case with antibody deposition, but again, this is rare. Placental tissue also contains the Goodpasture antigen and has been reported in a single case to act as a "sink" that binds anti-GBM antibody during pregnancy, resulting in exacerbation of glomerulonephritis after delivery.

DIFFERENTIAL DIAGNOSIS

Diagnosis of Goodpasture disease in patients who present with Goodpasture syndrome does not usually present difficulties once the possibility has been raised, although the urgency is often not appreciated. Direct IF on renal tissue and assay for circulating anti-GBM antibodies are the most rapid techniques, and renal biopsy is always indicated. Diagnosis is often delayed when patients present with subacute disease affecting the lung or the kidney in isolation. Patients with subacute lung hemorrhage may not report hemoptysis and may present with diffuse lung disease, which has many causes. Testing for hematuria is important.

Detection of Anti–Glomerular Basement Membrane Antibodies

Direct immunohistology is very sensitive for detection of anti-GBM antibody production, because the GBM selectively adsorbs and concentrates low levels of circulating antibody. However, in some circumstances, GBM may also adsorb antibody nonspecifically (see Box 24.2). Detection of anti-GBM antibodies in serum requires immunoassays based on preparations of human or animal GBM or recombinant antigen. The quality of these assays is variable. Confirmation of the specificity of anti-GBM antibodies may be obtained by Western blotting of serum onto solubilized human GBM or recombinant α3(IV)NC1, usually at a reference laboratory. Indirect immunohistology (putting patient serum onto normal kidney sections) is too insensitive for reliable diagnostic use.

False-positive results may be encountered in sera from patients with inflammatory diseases that often exhibit increased nonspecific binding. This places greater emphasis on the purity of antigen used for anti-GBM assays. False-negative results are usually encountered in patients with low titers of antibodies in association with isolated lung disease or with very early or subacute renal disease. Low titers also may be associated with anti-GBM disease that occurs after renal transplantation in patients with Alport syndrome (see later discussion).

In very advanced disease, linear antibody deposition may not be seen because of extensive destruction of GBM structure. Otherwise, deposited immunoglobulin remains detectable for some months after immunoassays have become negative.

Patients With Anti-GBM Antibodies and Other Diseases

Antineutrophil Cytoplasmic Antibody and Systemic Small-Vessel Vasculitis

Anti-GBM antibodies are sometimes detected in patients with antineutrophil cytoplasmic antibody (ANCA), especially ANCA with specificity for myeloperoxidase (see Chapter 25). Such "double-positive" patients may have a clinical course and response to treatment more typical of vasculitis than of Goodpasture disease and have possibly developed anti-GBM antibodies secondary to vasculitic glomerular damage.[8-11] Anti-GBM titers tend to be lower in ANCA-positive anti-GBM antibody–positive patients than in patients with anti-GBM antibodies alone. Recovery of renal function may be more likely if ANCAs are present, even if patients are dialysis dependent when treatment is started, although newer series have failed to detect the differences described in early reports.

Membranous Nephropathy

Anti-GBM antibodies are occasionally identified in patients with MN, usually coincident with an accelerated decline in renal function and the formation of glomerular crescents.[5,15,22] About two thirds of studies report evidence of evolution from preexisting nephrotic syndrome, and about half report a previous kidney biopsy showed typical MN. Progression to end-stage renal disease has usually been rapid, but the diagnosis has rarely been made at a stage early enough to expect intensive treatment to be successful. Three patients with Goodpasture disease later developed typical MN.

Alemtuzumab Treatment

It is now clear that treatment of multiple sclerosis (MS) with alemtuzumab, a monoclonal antibody targeting CD52 on B and T cells, is associated with the development of new autoimmunity in approximately 30% of patients, including rare cases of anti-GBM disease, sometimes as late as 4 years after treatment.[23] It remains to be established whether carriage of *DRB1*1501,* which is overrepresented in MS, influences the risk for developing anti-GBM disease after alemtuzumab therapy.

Pulmonary-Renal Syndromes

A wide variety of conditions may cause simultaneous pulmonary and renal disease. The term *pulmonary-renal syndrome* implies failure of both organs, the most common cause being fluid overload in a patient with renal failure of any cause (see Box 24.3). Then there are diseases associated with pulmonary haemorrhage and RPGN, sometimes called Goodpasture syndrome (Box 24.4).

BOX 24.3 Nonimmune Causes of Pulmonary-Renal Syndrome

With Pulmonary Edema
- Acute kidney injury with hypervolemia
- Severe cardiac failure

Infective
- Severe bacterial pneumonia (e.g., *Legionella*) with renal failure
- Hantavirus infection
- Opportunistic infections in the immunocompromised patient

Other
- Acute respiratory distress syndrome with renal failure in multiorgan failure
- Paraquat poisoning
- Renal vein/inferior vena cava thrombosis with pulmonary emboli

BOX 24.4 Causes of Lung Hemorrhage and Rapidly Progressive Glomerulonephritis

Diseases Associated With Antibodies to the GBM (20%-40% of Cases)
- Goodpasture disease (spontaneous anti-GBM disease)

Diseases Associated With Systemic Vasculitis (60%-80% of Cases)
- Granulomatosis with polyangiitis (Wegener) (common)
- Microscopic polyangiitis
- Systemic lupus erythematosus
- Eosinophilic granulomatosis with polyangiitis (Churg-Strauss)
- IgA vasculitis (Henoch-Schönlein purpura)
- Henoch-Schönlein purpura
- Behçet syndrome
- Essential mixed cryoglobulinemia
- Rheumatoid vasculitis
- Drugs: Penicillamine, hydralazine, propylthiouracil

The two classes of disease in Box 24.4 can sometimes be differentiated clinically, but serology and renal biopsy are usually required. Renal biopsy also provides valuable prognostic information.

NATURAL HISTORY

There is some variability in the pattern of early disease. Most patients present acutely with lung hemorrhage or advanced renal failure and report that the illness developed over weeks or a few months. However, there are several reports of patients presenting with mild respiratory symptoms or incidental microhematuria, with disease progressing much more slowly during months or years; some have abruptly developed the full acute syndrome. Microhematuria preceded renal failure in all the patients who developed anti-GBM disease while being monitored after alemtuzumab treatment of MS.

Once RPGN has developed, renal function is rapidly and often irretrievably lost. Progression is often much more rapid than in RPGN occurring in other contexts, such as microscopic polyangiitis, perhaps because more glomeruli are simultaneously affected. Consequently, there is a much narrower window of opportunity for effective treatment than when other diseases cause the syndrome.

Although a severe exacerbation of lung disease usually coincides with deterioration of renal function, the natural history of isolated lung disease critically depends on continued exposure to irritants.

Response to Immunosuppressive Treatment in a Patient with Goodpasture Disease

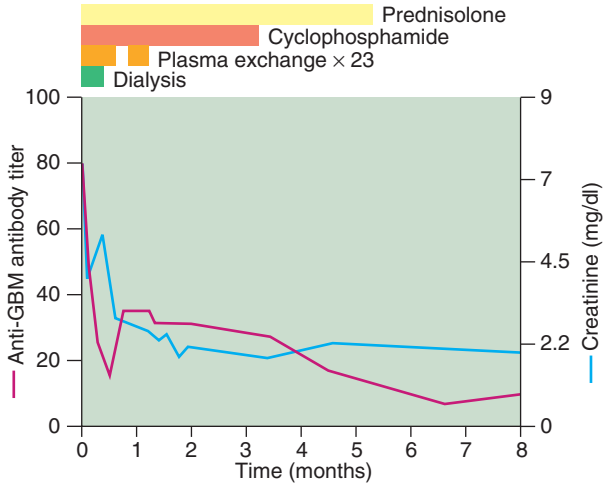

Fig. 24.7 Response to immunosuppressive treatment in Goodpasture disease. The patient required dialysis but had no lung hemorrhage. The good response to treatment was unusual but not unique. The renal biopsy showed that 85% of glomeruli contained recent (mostly cellular) crescents, suggesting very acute disease, which may be indicative of a more favorable response to treatment.

TREATMENT

Immunosuppressive Regimens

Before the introduction of immunosuppressive treatment, most patients died shortly after the development of renal impairment or lung hemorrhage.[19] Lung hemorrhage now usually can be arrested within 24 to 48 hours. Renal function can be protected if impairment is mild, and even severe renal impairment can be reversed in some patients. However, dialysis-dependent patients rarely recover kidney function despite immunosuppression and should probably be immunosuppressed only if lung hemorrhage occurs.

Fig. 24.7 shows a chart recording the treatment of a patient with Goodpasture disease. Treatment recommendations for acute severe disease were devised to reduce levels of circulating pathogenic antibodies as rapidly as possible, as well as lessen their contribution to rapid glomerular destruction (Table 24.2). However, this regimen is almost certainly effective through a much broader range of mechanisms, including T cell depletion. Once the disease is controlled, immunosuppression usually can be tapered off over 3 months, and subsequent relapse is uncommon. The immune response is self-limited in the absence of immunosuppression, with antibodies disappearing over 1 to 2 years. Spontaneous remissions and effectiveness of relatively brief periods of immunosuppression are in striking contrast to the more prolonged immunosuppression generally required to prevent relapse of vasculitis and suggest a greater capacity for restoration of usual tolerance to α3(IV)NC1[24] than to targets in vasculitis.

In RPGN with no evidence of an infective cause, immunosuppressive therapy should be started immediately, sometimes before the renal biopsy findings are available. If therapy is stopped after a few days, the patient will have incurred minimal risk (as long as pulse high-dose corticosteroids are avoided) but may have much to gain from earlier treatment.

TABLE 24.2 Treatment Regimen for Acute Goodpasture Disease

Therapy	Recommendation
Prednisolone	1 mg/kg/24 h orally. Reduce at wkly intervals to achieve one sixth of this dose by 8 wk. For a starting daily dose of 60 mg, use wkly reductions to 45, 30, 25, 20, and 15 mg; then 2 wkly to 12.5 and 10 mg. Maintain this dose to 3 mo; then taper to stop by 4 mo.
Cyclophosphamide	3 mg/kg/24 h orally, rounded down to the nearest 50 mg. Patients older than 55 yr receive a reduced dose of 2.5 mg/kg. Discontinue after 3 mo.
Plasma exchange	Daily exchange of 1 volume of plasma for 5% human albumin for 14 days or until the circulating antibody is suppressed. In the presence of pulmonary hemorrhage or within 48 hr of invasive procedure, 300 to 400 ml of fresh-frozen plasma is given at end of each treatment or according to coagulation tests.
Monitoring	Daily blood count during plasma exchange and while antibody titer remains elevated. At least twice wkly during first mo, wkly thereafter. If white blood cell count decreases to $<3.5 \times 10^9$/l, stop cyclophosphamide until the count recovers. Resume at lower dose if cessation has been necessary. Baseline DLCO, with further measurements as indicated. Daily coagulation tests during plasma exchange to monitor for significant depletion of clotting factors. Initially, daily checks of renal and hepatic function and glucose.
Prophylaxis against complications of treatment	Oral antifungal lozenges or rinse; proton pump inhibitor. Cotrimoxazole prophylaxis against *Pneumocystis jiroveci*. Avoid nonessential lines and catheters.

DLCO, Inhaled carbon monoxide.

Plasma Exchange and Immunosuppression

The regimen described in Table 24.2 dramatically improved the outlook for patients when it was introduced in the 1970s. An early randomized trial suggested some additional benefit of plasma exchange, but the interpretation was complicated by the recipient group's less severe disease at presentation.[25] It showed that milder disease can be effectively treated with corticosteroids and cyclophosphamide alone, although the overall outcomes for all patients were not as good as described with more intensive regimens.[25] Historical evidence suggests that treatment with corticosteroids alone, or corticosteroids with azathioprine, is less effective. Plasma exchange is of value only if it is accompanied by adjunctive immunosuppressive therapy. Immunoadsorption to protein A also lowers anti-GBM antibodies rapidly and does not deplete complement components or clotting factors, and a few reports suggest that it is as effective as plasma exchange. Information is lacking on the effectiveness of newer immunosuppressive agents such as mycophenolate mofetil (MMF) or anti–B cell antibodies, which tend to have only a slow effect on antibody production but may affect antigen presentation. Therefore it is difficult to justify their use over proven therapy in the acute phase of this often rapidly progressive disease, but there may be a role in particular circumstances. Rituximab has anecdotally led to reductions in antibody titer in patients with autoimmune responses persisting or relapsing after usual therapy.[26] In contrast to advanced renal failure, in which treatment is unlikely to lead to recovery of renal function, even severe lung hemorrhage is likely to respond to treatment with full or almost full recovery of lung function.

Lung hemorrhage occurring alone tends to be relapsing and remitting, so there have been many reports of treatments (e.g., bilateral nephrectomy) that may help. Pulse methylprednisolone has been advocated, but high doses of corticosteroids fail to alter the underlying pathogenetic immune response and put the patient at increased risk for infectious and other complications. We recommend treating seriously ill patients with moderate doses of corticosteroids plus plasma exchange and cyclophosphamide.

In other acute severe diseases, daily administration of cyclophosphamide often has been superseded by pulse administration. We still prefer to use daily oral administration because it is known to work and requires only 3 months of therapy. Patients unable to take the drug orally can be given daily intravenous therapy at the usual oral dose. Dose does not need to be reduced in severe renal failure provided the white blood cell count is monitored closely, but reductions for older patients are important (see Table 24.2) and close monitoring of leukocyte counts is imperative in all patients. If pulsed therapy were chosen, the CYCLOPS (Randomised trial of daily oral versus pulse Cyclophosphamide as therapy for ANCA-associated Systemic Vasculitis) regimen would be a reasonable if untested option (see Chapter 25).

Results from all series show that recovery of renal function is unlikely if, at initiation of treatment, the patient is oliguric, has a very high proportion of glomeruli with circumferential crescents, or has a serum creatinine level above 5.5 to 6.5 mg/dl (~500 to 600 µmol/l).[27] This is a notably different experience from that encountered in systemic vasculitis or idiopathic RPGN (see Chapter 25), in which renal disease of apparently similar severity (using histology and serum creatinine) can be salvaged by similar treatment protocols.[28] This has led to the suggestion that immunosuppressive treatment should be withheld from patients with only slight chance of recovery (Table 24.3; also see later).

Supportive Treatment

The most likely cause of death in the first few days is respiratory failure caused by lung hemorrhage. Lung hemorrhage may be precipitated or exacerbated by the following:

- Fluid overload
- Smoking and other pulmonary irritants, possibly including high Fio_2
- Local or distant infection
- Anticoagulation used during dialysis or plasma exchange
- Thrombocytopenia, defibrination, and depletion of clotting factors as a consequence of plasma exchange

It is therefore advisable to ensure correct fluid balance, to prohibit smoking, to use the lowest fractional inspired oxygen concentration (Fio_2) that gives adequate oxygenation, and to minimize the use of heparin.

Plasma exchange (see Table 24.2) should be monitored by daily blood counts, calcium concentration (if regional citrate anticoagulation is used), and coagulation tests. Diminished clotting factor levels should be replenished by administration of fresh-frozen plasma or clotting factor preparations at the end of each plasma exchange session, as required.

After the first few days, the major cause of morbidity and mortality is infection. Infection carries the added risk for potentiating glomerular and lung inflammation and injury, so precautions to reduce risk, such as minimizing indwelling cannulas, are important. If leukopenia below

TABLE 24.3 Factors in Decision to Treat Goodpasture Disease Aggressively

	Factors Favoring Aggressive Treatment	Factors Against Aggressive Treatment
Pulmonary hemorrhage	Present	Absent
Oliguria	Absent	Present
Creatinine	<5.5 mg/dl (~500 μmol/l)	>5.5-6.5 mg/dl (~500-600 μmol/l) and ANCA negative Severe damage on kidney biopsy No desire for early kidney transplantation
Other factors	Creatinine >5.5-6.5 mg/dl (~500-600 μmol/l) *but* Rapid and recent progression ANCA positive Glomerular damage less severe than expected Crescents recent, nonfibrous Early renal transplantation desired	
Associated disease	Absent	Unusually high risk from immunosuppression

ANCA, Antineutrophil cytoplasmic antibody.

3.5×10^9/l or neutropenia develops, cyclophosphamide should be discontinued and resumed at a lower dose when the neutrophil count recovers, if necessary with the assistance of granulocyte colony-stimulating factor.

Monitoring Effect of Treatment on Disease Activity

The effect of treatment on the renal disease is monitored by following serum creatinine values. Indicators of recent lung hemorrhage include hemoptysis, decreases in hemoglobin concentration, chest radiograph changes, and increases in the DLCO, with the last being the most sensitive. Any worsening of symptoms during treatment may indicate inadequate immunosuppression, but it is frequently a consequence of intercurrent infection exaggerating immunologic injury or fluid overload or other factors precipitating lung hemorrhage.

Monitoring of anti-GBM titers during, and particularly 24 hours after, the last planned plasma exchange treatment is useful for confirming effective suppression of autoantibodies. They should be undetectable within 8 weeks, but even without treatment, autoantibodies generally become undetectable by an average of 14 months.

Duration of Treatment and Relapses

Corticosteroid treatment may be gradually reduced and cyclophosphamide discontinued at 3 months. In contrast to treatment of small-vessel vasculitis, immunosuppression longer than this is usually not necessary. Longer treatment is appropriate for patients who are positive for both anti-GBM antibody and ANCA (see later discussion). Late increases in anti-GBM level may predict clinical relapse, although antibodies are generally permanently suppressed in patients who have completed the immunosuppressive regimen. If there is recurrence, success has been achieved by treating as at first presentation.

Electing Not to Treat

Advanced renal failure, frequently already established at presentation, is generally not salvaged by any current treatment.[27,29,30] Furthermore, the immunosuppressive regimen outlined carries significant risks and careful monitoring is required. For these reasons, it may be reasonable not to initiate immunosuppression in patients who present with advanced renal failure without lung hemorrhage. The decision not to treat is strengthened if the renal biopsy specimen shows widespread glomerulosclerosis and tubular loss and the patient is dialysis dependent at presentation (see Table 24.3). The risk for development of late lung hemorrhage in these patients seems to be low but warrants particular care to avoid the major precipitating factors, smoking and pulmonary edema, in at least the first few months. However, patients who are dialysis dependent usually should be treated if the renal histopathologic changes are unexpectedly mild or very recent (highly cellular crescents, even if 100% of glomeruli are involved, or acute tubular necrosis). Several reports describe good outcomes in these patients even after prolonged oliguria.

Treatment of Double-Positive Patients

Patients with both ANCA and anti-GBM antibodies may have other extrarenal disease requiring treatment (see Table 24.3). There is conflicting evidence as to whether their renal prognosis is the same as or better than that of other patients with anti-GBM antibodies. Earlier series suggested a better prognosis, but this was not confirmed in two later reports.[13,14] Because of the risk for serious disease in other organs, double-positive patients should usually receive an immunosuppressive regimen similar to that given for small-vessel vasculitis, with continuing immunosuppression with azathioprine after 3 months of cyclophosphamide (see Chapter 25).

TRANSPLANTATION

Renal transplantation in patients who have had Goodpasture disease carries the additional risk for disease recurrence. Recurrence with consequent loss of the graft has been reported and appears more likely when circulating anti-GBM antibodies are still detectable at transplantation. Therefore it is reasonable to delay transplantation until circulating anti-GBM antibodies have been undetectable for 6 months and to monitor graft function, urinary sediment, and circulating anti-GBM antibody levels to detect recurrent disease (see Chapter 108). Biopsy samples of well-functioning grafts sometimes show linear deposition of immunoglobulin on the GBM without clinical or histologic disease or apparently an adverse prognosis.

ALPORT SYNDROME POST-TRANSPLANT ANTI–GLOMERULAR BASEMENT MEMBRANE DISEASE

Patients with Alport syndrome have mutations in a gene encoding one of the tissue-specific type IV collagen chains, usually α5. Because these chains assemble with each other during biosynthesis, the resulting phenotype in the case of most mutations often has all the tissue-specific chains (α3 through α5) missing from the basement membranes, where

they are normally coexpressed. Altered expression may lead to absent or inadequate immunologic tolerance to these proteins and to preservation of the capacity to mount a powerful (allo)immune response to the type IV collagen chains expressed in a normal donor kidney after renal transplantation. Most patients with Alport syndrome accommodate renal transplants with conventional immunosuppression without development of anti-GBM nephritis. However, development of low titers of anti-GBM antibodies is shown by many such patients having linear deposition of IgG on the GBM of the transplanted kidney on direct IF, without disease. This alone does not justify treatment.

Up to 2% of patients with Alport develop RPGN in the transplanted kidney. It is clinically indistinguishable from spontaneous anti-GBM disease but without lung hemorrhage. This is more likely if the patient has a large gene deletion causing the disease rather than a point mutation, with the inference that the immune system has never been exposed to the mature protein. Typically, graft function is lost despite treatment for presumed acute rejection. Disease is usually encountered some months or longer after a first renal transplant, after weeks in a second, and after days in a third.[29] However, regrafting has been successful in two cases known to us and in two further cases in the literature. If the disease is recognized early, there are sound theoretical reasons for treating with the regimen recommended for Goodpasture disease, but there are few data on its effectiveness.[31]

In contrast to spontaneous Goodpasture disease, the specificity of anti-GBM antibodies in Alport post-transplant anti-GBM disease is not always to α3(IV)NC1. In many patients, possibly in most, the autoantibodies are specific for α5(IV)NC1, encoded by the *COL4A5* gene usually implicated in causation of the disease.[32] This is important because immunoassays for anti-GBM antibodies are optimized for detection of the anti-α3(IV)NC1 antibodies of spontaneous Goodpasture disease and they may have low sensitivity for anti-α5(IV)NC1 antibodies. In the absence of widely available assays for these uncommon antibodies, renal biopsy with immunohistology is the only reliable method of diagnosis.

SELF-ASSESSMENT QUESTIONS

1. A 65-year-old man presenting with acute renal failure and pulmonary hemorrhage was diagnosed after appropriate investigation as having Goodpasture (anti–glomerular basement membrane [GBM]) disease and treated with plasma exchange (10 × 4 liters over 2 weeks), oral cyclophosphamide (150 mg/day) and prednisolone (week 1: 60 mg/day; week 2: 45 mg/day; week 3: 30 mg/day; week 4: 25 mg/day; week 5: 20 mg/day; week 6: 15 mg/day; weeks 7 and 8: 20 mg alternate days). Cyclophosphamide (CYP) had to be omitted for 5 days, then restarted at 100 mg/day in week 4 because of neutropenia.

   At review 3 months after treatment commenced, the patient is entirely well with estimated glomerular filtration rate (eGFR) of 36 ml/min, Hb of 110 g/l, and white blood cell count of 2.4 × 10^3 per µl. Anti-GBM antibodies remain detectable just above the reporting threshold of the local assay. How should his immunosuppression be managed?

   A. Replace CYP with azathioprine or mycophenolate mofetil (MMF), and maintain with steroids to at least 1 year
   B. Discontinue CYP and steroids with close outpatient monitoring
   C. Continue CYP at reduced dose with prednisolone (10 mg/day) or equivalent to at least 1 year
   D. Reinstitute plasmapheresis

2. A 45-year-old nonsmoking executive collapses at a meeting and in the emergency room is found to have a serum creatinine of 1800 µmol/l, Hb 90 g/l, K 7.2 mmol/l, BP 165/92, and normal-sized unobstructed kidneys on ultrasound scan. After appropriate acute dialysis and BP control, a renal biopsy sample is taken, which shows severe crescentic glomerulonephritis affecting 32/32 sampled glomeruli. On silver staining, breaks could be seen in multiple capillary loops and in the Bowman capsule of most glomeruli. Linear deposition of IgG along the residual GBM and strong positivity for serum anti-GBM antibodies establishes a diagnosis of Goodpasture disease. ANCA is negative, and there is no evidence of lung hemorrhage. What treatment would you recommend for this patient with Goodpasture disease?

   A. Plasma exchange, CYP, and oral prednisolone for at least 3 months
   B. Plasma exchange, CYP, and oral prednisolone with plan for early
   C. Close monitoring with a goal of avoiding immunosuppression
   D. CYP, and oral prednisolone for at least 3 months

3. A 26-year-old man has a deceased donor renal transplant after 10 months on hemodialysis. His renal failure is of unknown cause. Eight months post-transplant, kidney function is found to have deteriorated dramatically with creatinine rising from 130 to 800 µmol/l at routine clinic visits 3 weeks apart. A biopsy shows 100% crescentic nephritis with strong linear binding of IgG to the GBM. Serum anti-GBM titers are negative. The most likely diagnosis is:

   A. Anti-GBM (Goodpasture) disease
   B. Alport anti-GBM disease
   C. Antibody-mediated rejection
   D. Polyomavirus infection

Renal and Systemic Vasculitis

J. Charles Jennette, Ronald J. Falk

DEFINITION

The kidneys are targets for a variety of systemic vasculitides, especially those that affect small vessels.[1-4] This is not surprising given the large number and variety of renal vessels. Vasculitis involving the kidneys can produce a wide variety of clinical manifestations, depending mainly on the type of renal vessel affected. Vasculitides can be categorized as large-vessel vasculitis, medium-vessel vasculitis, and small-vessel vasculitis (Figs. 25.1 and 25.2). The 2012 Chapel Hill Consensus Conference definitions are used throughout the chapter (Table 25.1).[4]

Several of the vasculitides listed in Fig. 25.2 are covered in other chapters and are not reviewed in detail here except in the context of differential diagnosis, for example, cryoglobulinemic vasculitis (Chapter 21), immunoglobulin A (IgA) vasculitis (Henoch-Schönlein purpura, Chapter 23), and anti–glomerular basement membrane (anti-GBM) disease (Chapter 24). Nephrologists most often encounter patients with small-vessel vasculitides because these often cause glomerulonephritis (GN). Therefore small-vessel vasculitis is the primary focus of this chapter.

Small-Vessel Vasculitis

Small-vessel vasculitis is necrotizing vasculitis that affects predominantly vessels smaller than arteries, including capillaries, venules, and arterioles; however, arteries, especially small arteries, also may be involved.[4] The most common renal target for small-vessel vasculitis is glomerular capillaries, and therefore the most common renal clinical manifestations are those of GN.

Medium-Vessel Vasculitis

Medium-vessel vasculitis is necrotizing arteritis that affects predominantly major visceral arteries.[4] In the kidneys, the interlobar arteries and arcuate arteries are affected most frequently, although any arteries from the main renal artery to the smallest interlobular arteries may be affected. Inflammation and necrosis of arteries may result in thrombosis or rupture, which causes renal infarction and hemorrhage, respectively.

Large-Vessel Vasculitis

Large-vessel vasculitis is chronic granulomatous arteritis that affects the aorta and its major branches more often than other forms of vasculitis.[4] When there is renal involvement, the ostia of the renal arteries and the main renal arteries are most often affected. The most common clinical renal manifestation is renovascular hypertension.

SMALL-VESSEL PAUCI-IMMUNE VASCULITIS

Small-vessel vasculitis can be divided into *immune complex* small-vessel vasculitis with moderate to marked vessel wall deposits of immunoglobulin and *pauci-immune* small-vessel vasculitis with few or no immune deposits in vessel walls.[4] Pauci-immune small-vessel vasculitis often is associated with circulating antineutrophil cytoplasmic autoantibodies (ANCAs).[1] The ANCA-associated vasculitides share an indistinguishable form of necrotizing small-vessel vasculitis that affects capillaries, venules, arterioles, and small arteries.[1-5] Some patients with *ANCA-associated vasculitis* (AAV) have no evidence of involvement of arteries, even though they have involvement of glomerular capillaries, causing GN; pulmonary alveolar capillaries, causing pulmonary hemorrhage; or dermal venules, causing purpura. The clinicopathologic variants of pauci-immune small-vessel vasculitis are categorized on the basis of clinical, laboratory, and pathologic findings, as follows[4]:

- *Microscopic polyangiitis* (MPA) is pauci-immune small-vessel vasculitis occurring in the absence of evidence for necrotizing granulomatous inflammation.
- *Granulomatosis with polyangiitis* (Wegener) (GPA) is pauci-immune vasculitis associated with necrotizing granulomatous inflammation, most often affecting the respiratory tract.
- *Eosinophilic granulomatosis with polyangiitis* (Churg-Strauss) (EGPA) is pauci-immune vasculitis associated with asthma, eosinophilia, and necrotizing granulomatous inflammation.

MPA, GPA, and, less frequently, EGPA share an indistinguishable pattern of GN that is the expression of the vasculitis in glomerular capillaries.[1] In the acute phase, the GN usually has necrosis and crescents, and an absence or paucity of immunoglobulin deposition, and is often designated *pauci-immune crescentic glomerulonephritis*. When occurring in the apparent absence of systemic vasculitis, pauci-immune crescentic GN is sometimes referred to as *renal-limited vasculitis.*

Pathogenesis

MPA, GPA, EGPA, and renal-limited pauci-immune crescentic GN are all associated with ANCAs.[4-6] The most common antigen specificities of ANCAs in patients with vasculitis and GN are for proteinase 3 (PR3) and myeloperoxidase (MPO).[7,8]

The strong association of ANCAs with this distinctive form of small-vessel vasculitis suggests that ANCAs are involved in the pathogenesis.[4-6] The report of a neonate who developed GN and pulmonary hemorrhage possibly caused by transplacental passage of MPO-ANCA IgG is intriguing but has not been substantiated by additional reports.[9] The observation that ANCA titers correlate with disease activity also suggests a pathogenic role; however, this correlation is not strong and some patients with clinically and pathologically typical MPA, GPA, or renal-limited pauci-immune crescentic GN are negative using conventional serologic testing for ANCAs. MPO-ANCA epitope specificity determines not only the pathogenicity but also the detectability and clinical predictive value of circulating MPO-ANCA.[10] For example, ANCAs with certain epitope specificities occur only in patients with active disease, whereas other

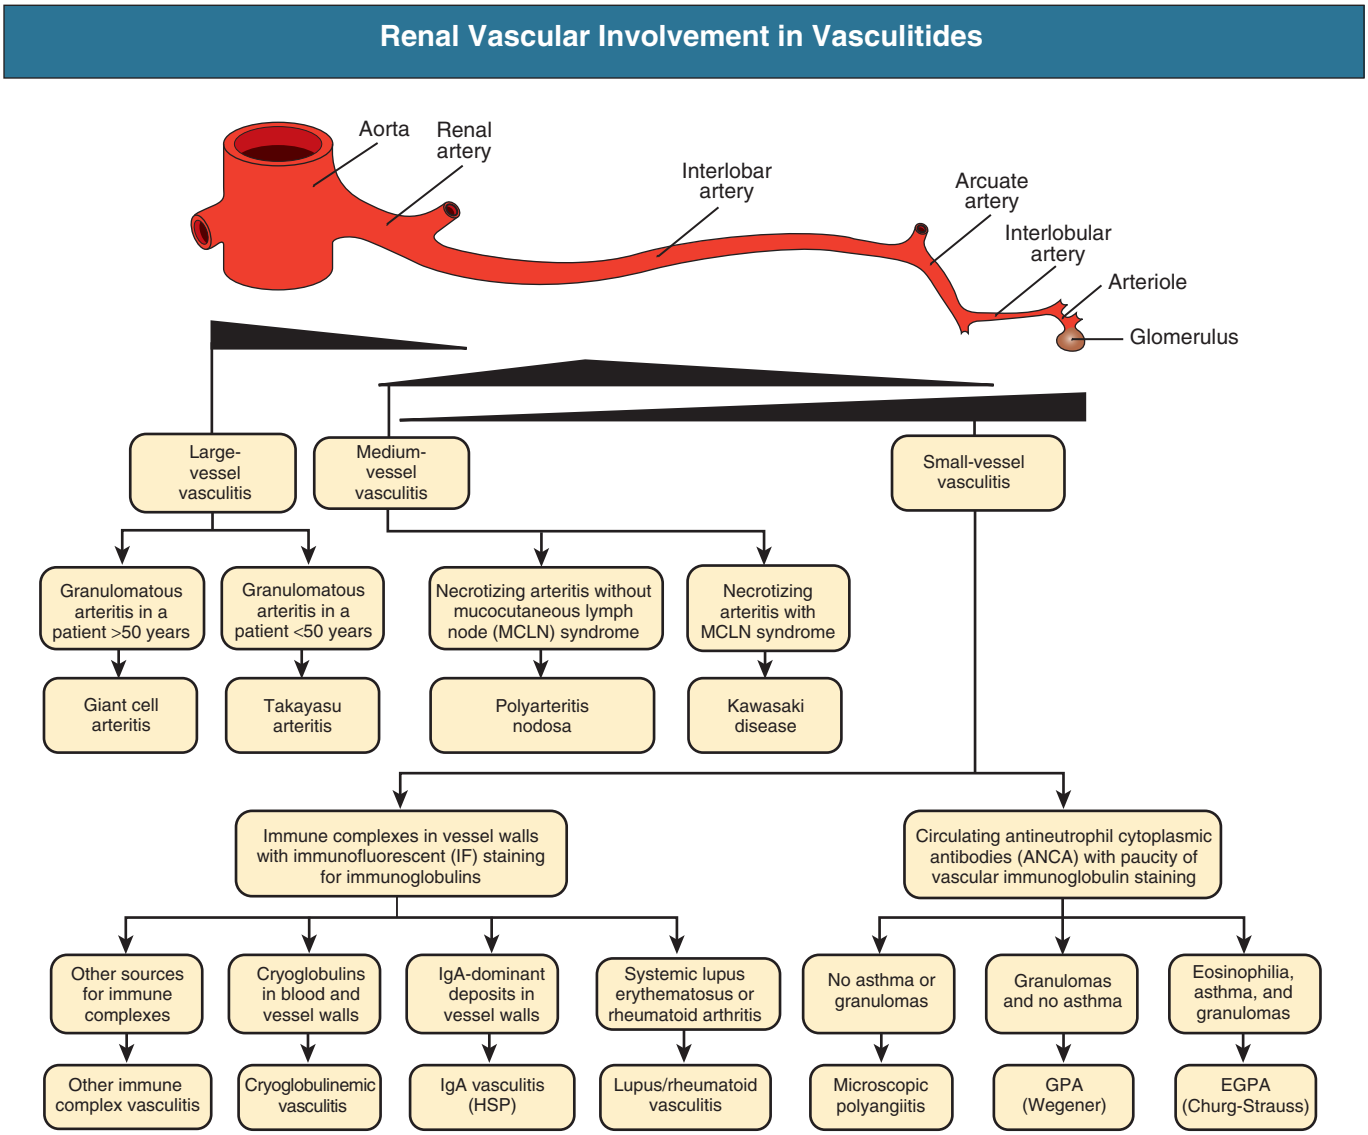

Fig. 25.1 Renal vasculitis. Predominant distribution of renal vascular involvement by a variety of vasculitides. The heights of the trapezoids represent the relative frequency of involvement of different portions of the renal vasculature by the three major categories of vasculitis. *EGPA,* Eosinophilic granulomatous polyangiitis; *GPA,* granulomatous polyangiitis; *HSP,* Henoch-Schönlein purpura.

MPO-ANCA epitope specificities occur not only in patients with active disease but also in patients in remission and even in healthy controls (natural ANCAs), although at very low titers. Some patients with AAV who are negative by conventional serologic testing have MPO-ANCA with very restricted epitope specificity that can be detected with special unmasking techniques.[10]

The pathogenic potential of ANCAs is supported by the observation that administration of certain drugs, such as propylthiouracil, hydralazine, and penicillamine, can induce AAV.[11] Cocaine adulterated with levamisole also can induce AAV associated with high titers of MPO-ANCA, PR3-ANCA, and ANCA specific for another neutrophil granule protein elastase.[11] Levamisole-induced vasculitis has frequent cutaneous leukocytoclastic angiitis and upper respiratory tract involvement, but rarely renal or lung involvement.

A number of in vitro observations suggest mechanisms by which ANCAs can cause vascular injury.[5,6] Priming of neutrophils by cytokines, as would occur with a viral infection, causes neutrophils to increase expression of ANCA antigens on their surfaces, where they are accessible to interact with ANCAs. Cytokine-primed neutrophils that are activated by ANCAs release lytic enzymes from granules, generate toxic oxygen metabolites, and kill cultured endothelial cells. ANCA-antigen complexes adsorb onto endothelial cells, where they could participate in in situ immune complex formation. ANCA activation of neutrophils is mediated to a minor degree by both $F(ab')_2$ binding to neutrophils and to a greater degree by Fc receptor engagement. Neutrophils that have been activated by ANCAs adhere to endothelial cells and release mediators of inflammation and cell injury. These events cause vasculitis as a result of neutrophils adhering to, penetrating, and destroying vessel walls (Fig. 25.3).

The ability of ANCA IgG to cause pauci-immune necrotizing and crescentic GN and vasculitis has been demonstrated in multiple animal models induced with MPO-ANCA, although no widely accepted model of PR3-ANCA disease has been developed.[6] Wild-type or immunodeficient mice that are injected with anti-MPO antibodies intravenously

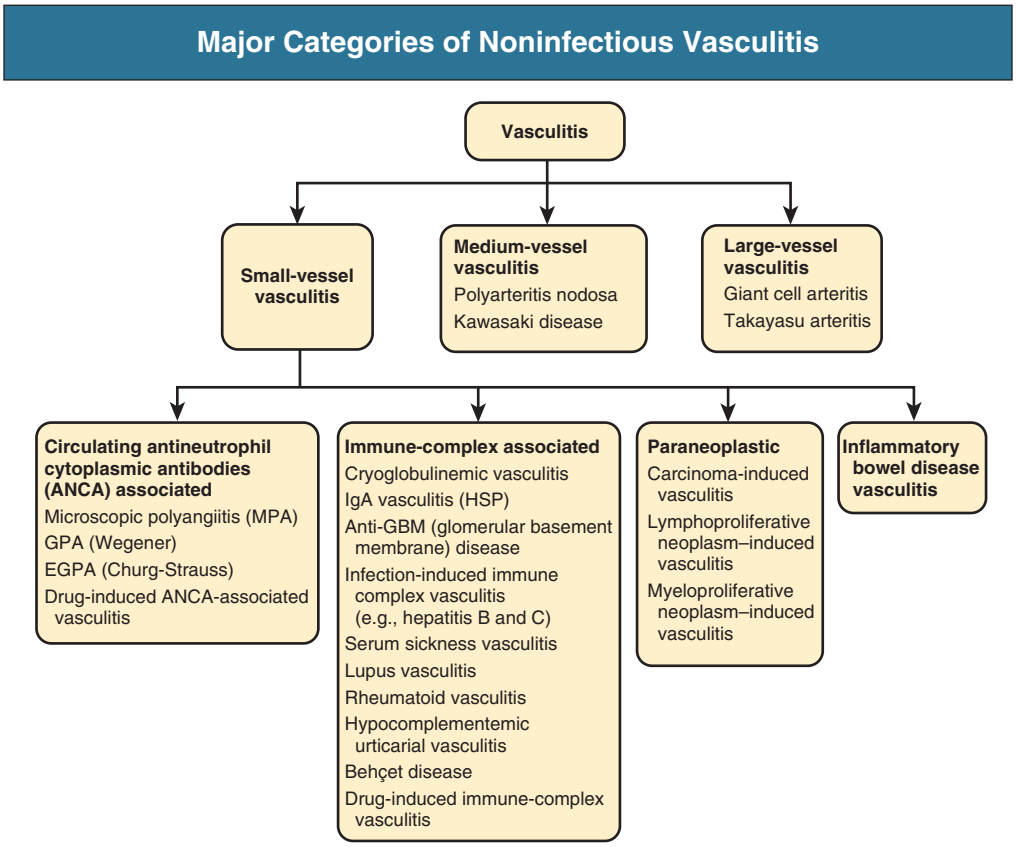

Fig. 25.2 Major categories of noninfectious vasculitis. Not included are vasculitides that are known to be caused by direct invasion of vessel walls by infectious pathogens, such as rickettsial vasculitis and neisserial vasculitis. *EGPA,* Eosinophilic granulomatous polyangiitis; *GPA,* granulomatous polyangiitis; *HSP,* Henoch-Schönlein purpura.

develop pauci-immune focal necrotizing GN with crescents.[12] A rat model of pauci-immune necrotizing and crescentic GN has been developed by immunizing rats with human MPO, resulting in the development of antibodies that cross-react with rat MPO and are able to induce pauci-immune glomerular necrosis and crescents.[13] MPO-ANCA GN in mice is mediated by neutrophil activation, modulated by the Fc γ receptor repertoire, and can be prevented by neutrophil depletion.[6,12] Activation of the alternative complement pathway plays a role in amplifying ANCA-induced inflammation.[14] ANCA-activated neutrophils release factors that activate the alternative complement pathway, resulting in the generation of C5a, which is strongly chemotactic for neutrophils and primes neutrophils to facilitate further activation by ANCAs.[15] The relevance of these experimental observations in patients is supported by a report that patients with AAV have increased plasma levels of alternative pathway activation markers C3a, C5a, soluble C5b-9, and Bb during active disease but no remission, and that the plasma level of Bb correlated with percentage of cellular crescents in the renal biopsy samples and with Birmingham Vasculitis Activity Scores.[16] Clinical trials are underway to identify a role for blockade of complement activation in the treatment of AAV.

Thus the clinical and experimental data indicate that ANCAs can activate neutrophils and cause vasculitis, especially if there are concurrent synergistic proinflammatory stimuli. The requirement for a synergistic neutrophil-priming inflammatory process may be reflected in the frequent association of the onset of ANCA small-vessel vasculitis with an influenza-like syndrome.[17]

The basis for the ANCA autoimmune response is less well understood but involves having human leukocyte antigen (HLA) molecules with specific molecular recognition capabilities to initiate the PR3 or MPO autoimmune response.[18,19] This also may entail abnormally high expression of *MPO* and *PR3* genes in leukocytes and recognition of autoantigen complementary (antisense) peptides that initiates an immune response that induces anti-idiotypic antibodies that react with sense peptides (autoantigen epitopes).[6]

Epidemiology

GPA, MPA, and EGPA usually begin during the fifth, sixth, and seventh decades of life, with a peak incidence of 65 to 75 years, but may occur at any age. There is a slight male predominance. AAV has geographical and race/ethnic differences in prevalence.[20] In the United Kingdom, GPA (148 per million) is more common than MPA (65 per million), and MPA is more common than EGPA (46 per million). In France, the prevalence of AAV is twice as high in Europeans (105 per million) compared with non-Europeans (53 per million). In North America, the incidence is disproportionately greater in Whites than in African Americans, which may be caused by HLA differences.[21]

In the United Kingdom and northern Europe, PR3-ANCA (usually associated with GPA) is more common than MPO-ANCA; however, in Southern Europe, Asia, and India, MPO ANCA and MPA are more common than PR3-ANCA and GPA.[20] In the United States there is a similar trend with more PR3-ANCA and GPA in northern states and more MPO-ANCA-and MPA in southern states. Geographical and racial

TABLE 25.1 Names and Definitions of Vasculitis

Category/Name	Definition
Large-Vessel Vasculitis	
Takayasu arteritis	Arteritis, often granulomatous, predominantly affecting the aorta and/or its major branches. Onset usually in patients younger than 50 yr.
Giant cell arteritis	Arteritis, often granulomatous, usually affecting the aorta and/or its major branches, with predilection for branches of carotid and vertebral arteries; often involves temporal artery. Onset usually in patients older than 50 yr and often associated with polymyalgia rheumatica.
Medium-Vessel Vasculitis	
Polyarteritis nodosa	Necrotizing arteritis of medium or small arteries without GN or vasculitis in arterioles, capillaries, or venules and not associated with ANCA.
Kawasaki disease	Arteritis associated with mucocutaneous lymph node syndrome and predominantly affecting medium and small arteries; coronary arteries are often involved; aorta and large arteries may be involved. Usually occurs in infants and young children.
Small-Vessel Vasculitis	
ANCA-Associated Small-Vessel Vasculitis	
Necrotizing vasculitis, with few or no immune deposits, predominantly affecting small vessels (capillaries, venules, arterioles, small arteries), associated with MPO-ANCA or PR3-ANCA. Not all patients have ANCA. Add prefix indicating ANCA reactivity, e.g., PR3-ANCA, MPO-ANCA, ANCA-negative.	
Microscopic polyangiitis (MPA)	Necrotizing vasculitis, with few or no immune deposits, predominantly affecting small vessels (capillaries, venules, arterioles). Necrotizing arteritis involving small and medium arteries may be present. Necrotizing GN is common. Pulmonary capillaritis often occurs. Granulomatous inflammation is absent.
Granulomatosis with polyangiitis (Wegener) (GPA)	Necrotizing granulomatous inflammation usually involving upper and lower respiratory tract and necrotizing vasculitis affecting predominantly small to medium vessels (capillaries, venules, arterioles, arteries, veins). Necrotizing GN is common.
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss) (EGPA)	Eosinophil-rich and necrotizing granulomatous inflammation often involving the respiratory tract, and necrotizing vasculitis predominantly affecting small to medium vessels and associated with asthma and eosinophilia. ANCA is more common when GN is present.
Immune Complex Small-Vessel Vasculitis	
Vasculitis with moderate to marked vessel wall deposits of immunoglobulin and/or complement components predominantly affecting small vessels (capillaries, venules, arterioles, small arteries). GN is common.	
Anti–glomerular basement membrane (anti-GBM) disease	Vasculitis affecting glomerular capillaries, pulmonary capillaries, or both, with basement membrane deposition of anti–basement membrane autoantibodies. Lung involvement causes pulmonary hemorrhage, and renal involvement causes GN with necrosis and crescents.
Cryoglobulinemic vasculitis	Vasculitis with cryoglobulin immune deposits affecting small vessels (predominantly capillaries, venules, or arterioles) and associated with cryoglobulins in serum. Skin, glomeruli, and peripheral nerves are often involved.
IgA vasculitis (IgAV) (Henoch-Schönlein purpura)	Vasculitis, with IgA1-dominant immune deposits, affecting small vessels (predominantly capillaries, venules, or arterioles). Often involves skin and gastrointestinal tract and frequently causes arthritis. GN indistinguishable from IgA nephropathy may occur.
Hypocomplementemic urticarial vasculitis (anti-C1q vasculitis)	Vasculitis accompanied by urticaria and hypocomplementemia affecting small vessels (capillaries, venules, arterioles) and associated with anti-C1q antibodies. GN, arthritis, obstructive pulmonary disease, and ocular inflammation are common.

Modified from reference 71.
ANCA, Antineutrophil cytoplasmic antibody; *GN,* glomerulonephritis; *IgA,* immunoglobulin A.
Adopted by the 2012 chapel hill consensus conference on the nomenclature of systemic vasculitis. Note that all three categories affect arteries, but only small-vessel vasculitis has a predilection for vessels smaller than arteries.

differences may be related to HLA differences, which can influence the prevalence of PR3-ANCA and MPO-ANCA.[18,19]

Clinical Manifestations

Generalized nonspecific manifestations of systemic inflammatory disease, such as fever, malaise, anorexia, weight loss, myalgias, and arthralgias, often are present. Many patients with vasculitis trace the onset of their disease to a flu-like illness.[17]

The clinical manifestations of GPA, MPA, and EGPA are extremely varied because they are influenced by the organs affected by vasculitis. The three categories of vasculitis share features caused by the small-vessel vasculitis, and patients with GPA and EGPA have the additional features that define each of these syndromes.[4,22,23]

Renal involvement occurs often in GPA and MPA and is uncommon in EGPA (Table 25.2). The most common renal manifestations are hematuria, proteinuria, and renal failure. The renal failure often has

TABLE 25.2 Organ System Involvement in Small-Vessel Vasculitis

	FREQUENCY OF INVOLVEMENT (%)				
Organ System	Microscopic Polyangiitis	GPA (Wegener)	EGPA (Churg-Strauss)	IgA Vasculitis (HSP)	Cryoglobulinemic Vasculitis
Kidney	90	80	20	50	55
Skin/cutaneous	40	40	40	90	90
Lungs	50	90	90	<5	<5
Ear, nose, throat	35	90	70	<5	<5
Musculoskeletal	60	60	50	75	70
Neurologic	30	50	40	10	40
Gastrointestinal	50	50	40	60	30

EGPA, Eosinophilic granulomatosis with polyangiitis; *GPA,* granulomatosis with polyangiitis; *HSP,* Henoch-Schönlein purpura; *IgA,* immunoglobulin A.

the characteristics of rapidly progressive glomerulonephritis (RPGN) in GPA and MPA but usually is less severe in EGPA. A cohort of more than 300 patients with pauci-immune crescentic GN evaluated at renal biopsy had a mean age of 56 years (range 2 to 92 years), male-to-female ratio of 1.0:0.9, mean serum creatinine concentration of 6.5 mg/dl (range 0.8 to 22.1 mg/dl; 69 to 1900 µmol/L), and proteinuria of 1.9 g/day (range 0.1 to 18 g/day).[24]

Cutaneous involvement occurs frequently in small vessel vasculitis. Purpura is a manifestation of GPA, MPA, and EGPA (Fig. 25.4). The purpura is most common on the lower extremities and tends to occur as recurrent crops. The purpura may be accompanied by small areas of ulceration. Nodular cutaneous lesions are more frequent in GPA and EGPA than MPA. Nodules can be caused by dermal or subcutaneous arteritis and granulomatous inflammation.

Upper respiratory tract involvement is most common in GPA and EGPA but also occurs in MPA.[25] In all three categories, patients can have pulmonary hemorrhage caused by alveolar capillaritis. Patients with GPA and to a lesser extent EGPA also can have pulmonary injury caused by necrotizing granulomatous inflammation, which may be detected radiographically as nodular or cavitating lesions. By definition, patients with MPA do not have granulomatous respiratory tract lesions.[4]

Manifestations of upper respiratory tract disease include subglottic stenosis, sinusitis, rhinitis, nasal septal collapse, otitis media, and ocular inflammation. These features are most common in GPA but may occur

in EGPA and MPA. The upper respiratory inflammation in MPA is caused by angiitis alone, without granulomatous inflammation. Destruction of bone, for example, resulting in septal perforation and saddle nose, results from necrotizing granulomatous inflammation and therefore does not occur in MPA.

Cardiac disease is identified in approximately 50% of patients with EGPA (usually myocarditis) but in less than 20% of patients with GPA or MPA. Cardiac manifestations in GPA and MPA are predominantly transient heart block and ventricular hypokinesis that respond to immunosuppressive treatment, although infarction, endocarditis, pericarditis, and severe life-threatening myocarditis may occur.

Peripheral neuropathy, usually with a mononeuritis multiplex pattern, is the most common neurologic manifestation. Central nervous system involvement is less common and most often results from vasculitis within the meninges. Gastrointestinal involvement typically causes abdominal pain and blood in the stool, with mesenteric ischemia and rarely intestinal perforation. Vasculitis in the pancreas and liver can mimic pancreatitis and hepatitis symptomatically and cause elevated serum pancreatic and liver enzymes.

Antineutrophil Cytoplasmic Autoantibody

Serologic testing for ANCAs is a useful diagnostic procedure for pauci-immune small-vessel vasculitis and pauci-immune crescentic GN but should be interpreted in the context of other characteristics of the patient, and the performance characteristics of the assay system.[7,26-28] The antigen specificity of ANCA for PR3 versus MPO not only is helpful for diagnosis but has predictive value with respect to clinical course and outcome.[8,28] Laboratory testing for ANCA should include both indirect immunofluorescence microscopy assay (IFA) and enzyme immunoassay (EIA).[27] IFA using normal human neutrophils as substrate produces two major staining patterns (Fig. 25.5): cytoplasmic (C-ANCA), in which staining occurs diffusely throughout the cytoplasm, and perinuclear (P-ANCA). By EIA, most C-ANCAs have specificity for proteinase 3 (PR3-ANCA) and most P-ANCAs have specificity for myeloperoxidase (MPO-ANCA). For adequate diagnostic accuracy, all serologic testing for ANCAs should include an immunochemical analysis for antigen specificity, such as an EIA.[7,27,28] High-quality EIA alone can be used alone as a screening test for AAV.[28] Although positive results are rare in completely healthy individuals, approximately one fourth of patients with other inflammatory renal diseases (especially lupus) have a false-positive IFA result (usually with a P-ANCA pattern) and approximately 5% have a false-positive EIA result (usually at low titer).[27]

ANCA testing has good sensitivity for AAV (80% to 90%). The specificity and predictive value depend on the population of patients and the quality of the assay.[7] Although ANCAs are most frequent in patients with pauci-immune crescentic GN, one fourth to one third of patients with anti-GBM crescentic GN and one fourth of those with idiopathic immune complex crescentic GN with 50% or more crescents are ANCA positive.[24,29] Some of these patients have well-recognized types of immune complex GN complicated by ANCAs, such as membranous nephropathy and IgA nephropathy, whereas others have non-lupus IgG-dominant immune complex disease that cannot be categorized further. Patients with concurrent ANCAs and anti-GBM antibodies have a worse prognosis than patients with ANCAs alone. The anti-GBM antibodies typically disappear after treatment and do not recur, whereas ANCAs and associated vasculitis may recur.

Table 25.3 provides an estimate of the relative frequencies of PR3-ANCA/C-ANCA and MPO-ANCA/P-ANCA in the different clinical phenotypes of AAV, although this is influenced by geographical and racial influences, as discussed earlier.[5,20] PR3-ANCA/C-ANCA are most prevalent in GPA, and MPO-ANCA/P-ANCA are most prevalent in

TABLE 25.3 Antineutrophil Cytoplasmic Antibody in Small-Vessel Vasculitis

Disorder	FREQUENCY (%)		
	Proteinase 3 (PR3, usually c-ANCA)	Myeloperoxidase (MPO, usually p-ANCA)	Negative
Granulomatosis with polyangiitis (Wegener)	70	25	5
Microscopic polyangiitis	40	50	10
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss)	5	40	55
Renal-limited pauci-immune crescentic GN	20	70	10

GN, Glomerulonephritis.
Approximate frequency of antibody in small-vessel vasculitis (ANCA) with specificity for proteinase 3 (PR3/c-ANCA) and for myeloperoxidase (MPO/p-ANCA) in patients with different categories of pauci-immune small-vessel vasculitis and crescentic glomerulonephritis.

renal-limited pauci-immune crescentic GN and EGPA. Patients with MPA have a more equal distribution of PR3-ANCA/C-ANCA and MPO-ANCA/P-ANCA, although this varies among geographical regions.[20] Patients with EGPA have the lowest overall frequency of ANCAs, but the frequency of ANCAs is much higher in EGPA patients with GN (75%) than in those with no GN (26%).[30] The ANCA specificity correlates with clinical symptoms, with PR3-ANCA having the highest frequency (~90% when ANCA present) in patients who have destructive upper respiratory tract disease, especially saddle nose.[25]

Changes in ANCA titers over time may correlate with disease activity but are not dependable markers and thus must be interpreted with caution.[7,27,28,31] In general, titers decrease with treatment and increase before or at disease recurrence. An increase in ANCA titer should prompt careful evaluation of the patient for corroborating evidence of exacerbation, but most physicians do not modify treatment based on an increase in titer without accompanying clinical signs. There is evidence that epitope-specific assays may provide much better correlation with and prediction of disease outcome.[10] MPO-ANCAs with certain epitope specificities occur only in patients with active disease, disappear with remission, and reappear during relapse, whereas MPO-ANCAs with other specificities remain during disease remission.

From 10% to 20% of patients with pauci-immune necrotizing and crescentic GN and pauci-immune small-vessel vasculitis will be ANCA negative. The clinicopathologic and outcome characteristics of these patients are indistinguishable from those of ANCA-positive patients.[32] In the same epitope-specific assays previously mentioned, some patients with AAV who are negative by current clinical assays have MPO-ANCA with restricted epitope specificity that can be detected with sensitive assays that remove a masking factor.[10]

ANCAs may be positive but not associated with vasculitis in inflammatory conditions other than vasculitis, including inflammatory bowel disease (IBD), rheumatoid disease, chronic inflammatory liver disease, bacterial endocarditis, and cystic fibrosis. In IBD, specificity of the ANCAs usually is not against PR3 or MPO but against other neutrophil antigens, including lactoferrin, cathepsin G, and anti–bactericidal/permeability-increasing protein (BPI).[27,28]

Pathology

The acute vascular lesion of the pauci-immune small-vessel vasculitides is segmental fibrinoid necrosis, often accompanied by leukocyte infiltration and leukocytoclasia[1,33-35] (leukocyte fragmentation; Figs. 25.6 and 25.7). The earliest vasculitic lesions have infiltrating neutrophils that are quickly replaced by predominantly mononuclear leukocytes. The acute necrotizing lesions evolve into sclerotic lesions and may be complicated by thrombosis.

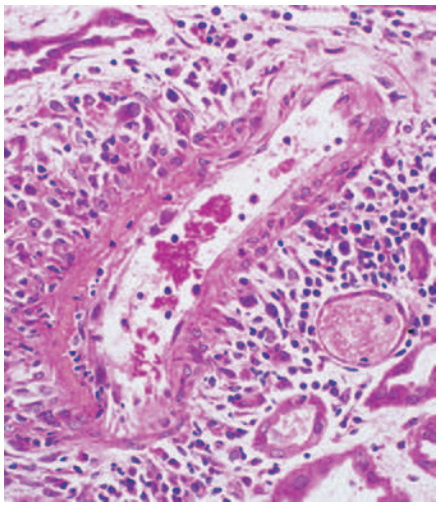

Fig. 25.6 Necrotizing arteritis of interlobular artery in patient with ANCA-associated small-vessel vasculitis. There is segmental fibrinoid necrosis with adjacent perivascular leukocyte infiltration. (Hematoxylin and eosin [HE] stain, ×50.)

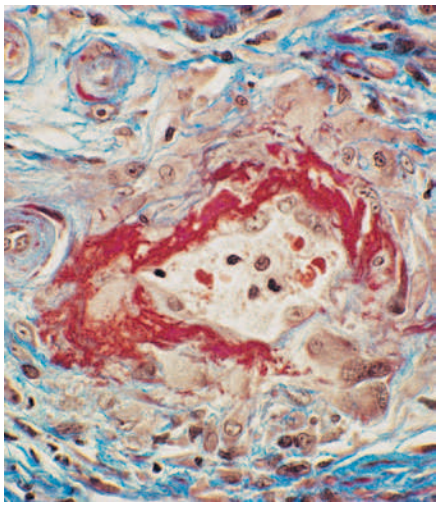

Fig. 25.7 Necrotizing arteritis of interlobular artery in patient with ANCA-associated small-vessel vasculitis. The fibrinoid necrosis is indicated by the *red* staining. (Masson trichrome, ×100.)

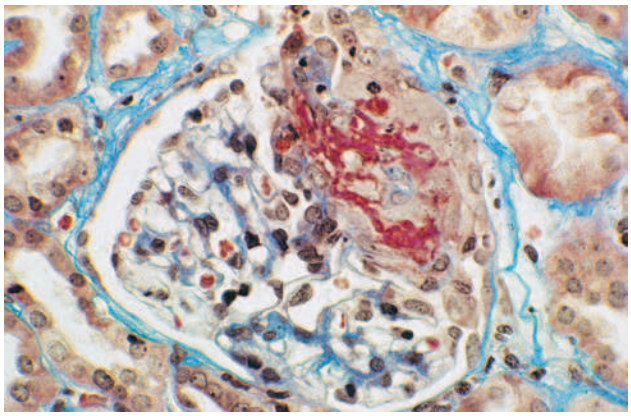

Fig. 25.8 Segmental glomerular necrosis and crescent formation in patient with ANCA-associated small-vessel vasculitis. The fibrinoid material is *red*. The uninvolved segments appear normal. (Masson trichrome, ×150.)

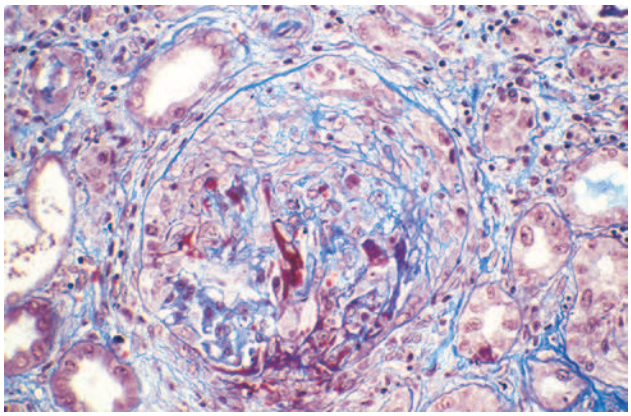

Fig. 25.9 Global glomerular necrosis and circumferential crescent formation in a glomerulus from patient with ANCA-associated small-vessel vasculitis. (Masson trichrome, ×150.)

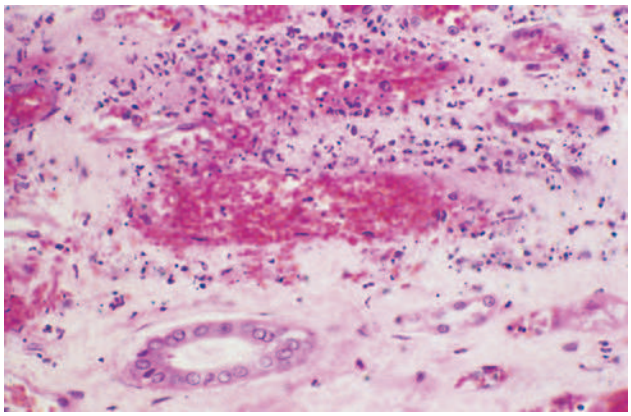

Fig. 25.10 Medullary leukocytoclastic angiitis involving vasa recta in a patient with granulomatosis with polyangiitis. (HE stain, ×150.)

These focal necrotizing lesions can affect many different vessels, thus causing many different signs and symptoms. For example, involvement of glomerular capillaries causes nephritis; of alveolar capillaries, pulmonary hemorrhage; of dermal venules, purpura; of upper respiratory tract mucosal venules, rhinitis and sinusitis; of abdominal visceral arteries, abdominal pain; and of epineural arteries, mononeuritis multiplex.

A shared glomerular lesion of the pauci-immune small-vessel vasculitides is a necrotizing GN, usually with resultant crescent formation.[1,33-35] Early mild lesions have segmental fibrinoid necrosis with or without an adjacent small crescent (Fig. 25.8). Severe acute lesions may have essentially global necrosis with large circumferential crescents (Fig. 25.9). In a cohort of 181 renal biopsy specimens from patients with ANCA-associated GN, 90% had glomerular crescents that on average affected 50% of glomeruli, with half having crescents in more than 50% of glomeruli.[24] Non-necrotic segments within segmentally injured glomeruli (see Fig. 25.8) and glomeruli without necrosis typically have slight or no histologic abnormalities.

As mentioned previously, approximately one fourth of patients with anti-GBM crescentic GN and one fourth of patients with immune complex–mediated crescentic GN will be ANCA positive.[24] By contrast, less than 5% of patients with immune complex GN who do not have crescents will be ANCA positive. Therefore, even in patients with immune complex GN, the presence of ANCAs is associated with an increased incidence of crescents (and also inflammation in vessels other than glomerular capillaries). A histopathologic classification has been proposed for AAV GN: sclerotic class (≥50% globally sclerotic glomeruli), focal class (≥50% normal glomeruli), crescentic class (≥50% of glomeruli with cellular crescents), or mixed class if none of these features predominated.[35] Renal survival at 5 years was 93% for the focal class, 76% for crescentic class, 61% for mixed class, and 50% for sclerotic class. Validation studies are underway to better understand the utility of this classification.

In addition to GN, patients with AAV also may have renal arteritis, most often affecting interlobular arteries (see Figs. 25.6 and 25.7), and medullary angiitis affecting the vasa recta (Fig. 25.10). The medullary angiitis may be severe enough to cause papillary necrosis, although this is a rare complication.

Patients with GPA and EGPA have pathologic lesions in addition to the necrotizing small-vessel vasculitis.[1,3,4] The necrotizing granulomatous inflammation of GPA occurs most often in the respiratory tract and is characterized by zones of necrosis surrounded by mixed infiltrates of neutrophils, lymphocytes, monocytes, and macrophages, often including scattered multinucleated giant cells. In patients with GPA and EGPA, extravascular granulomatous inflammation is rare in kidneys and even rarer in kidney biopsy specimens. Varying numbers of eosinophils may be present in the lesions of GPA, but these are more conspicuous in the necrotizing granulomatous inflammation of EGPA. Eosinophils also are typically conspicuous in the vasculitic lesions of EGPA, but this is not a pathognomonic observation because numerous eosinophils may be present in the vasculitic lesions of GPA, MPA, polyarteritis nodosa (PAN), and other vasculitides.

Differential Diagnosis

ANCA-associated small-vessel vasculitis must be differentiated from other forms of small-vessel vasculitis that can produce the same signs and symptoms.[1,3,4] In addition, an attempt should be made to distinguish MPA, GPA, and EGPA, although in some patients this cannot be accomplished conclusively and is not required for initiation of therapy. In addition to clinicopathologic classification, patients should be categorized as MPO-ANCA, PR3-ANCA, or ANCA-negative, because the serotype has independent predictive value about clinical course and outcome.[5,8,25] Pathologic confirmation of the granulomatous inflammation seen in ANCA disease is particularly difficult because small biopsy specimens often show only nonspecific acute and chronic inflammation and necrosis. Thus findings other than histologic lesions, such as nodular or cavitating lung lesions observed radiographically or destructive bone lesions in the nasal septum, often must be used as markers of necrotizing

TABLE 25.4 Differential Diagnostic Features of Select Forms of Small-Vessel Vasculitis

Features	Microscopic Polyangiitis	GPA (Wegener)	EGPA (Churg-Strauss)	IgA Vasculitis (HSP)	Cryoglobulinemic Vasculitis
Vasculitic signs and symptoms*	+	+	+	+	+

Cryoglobulins in blood and vessels	—	—	—	—	+
ANCAs in blood	+	+	+	—	—
Necrotizing granulomas	—	+	+	—	—
Asthma and eosinophilia	—	—	+	—	—

Modified from reference 3.
*These vasculitides can manifest any of the shared features of small-vessel vasculitides, such as nephritis, purpura, abdominal pain, peripheral neuropathy, myalgias, and arthralgias. Each is distinguished by the presence and, just as important, by the absence of certain specific features.
ANCAs, Antineutrophil cytoplasmic antibodies; *EGPA,* eosinophilic granulomatosis with polyangiitis; *GPA,* granulomatosis with polyangiitis; *HSP,* Henoch-Schönlein purpura.

granulomatous inflammation to categorize patients. Because of the toxicity of the treatment, even in a patient with substantial clinical and serologic evidence of ANCA disease, pathologic confirmation of vasculitis is warranted. This can be accomplished with biopsy of many different involved sites, including skin, muscle, nerve, gut, and kidney. When the patient has substantial renal involvement, renal biopsy findings also can be useful for predicting response to treatment and clinical outcome.[33-35]

All forms of small-vessel vasculitis listed in Fig. 25.2 are capable of producing clinically indistinguishable overlapping features of disease, such as nephritis, purpura, peripheral neuropathy, myalgias, arthralgias, and abdominal pain. Table 25.4 lists a number of features that help distinguish several important categories of small-vessel vasculitis.[3] Accurate differentiation is very important for proper patient management because the natural histories and appropriate treatments vary greatly. For example, a patient presenting with nephritis, arthralgias, and abdominal pain could have IgA vasculitis (IgAV, formerly Henoch-Schönlein purpura), MPA, cryoglobulinemic vasculitis, or several other small-vessel vasculitides. A number of serologic and pathologic observations are useful for reaching the correct diagnosis (see Table 25.4). A positive ANCA assay (confirmed by EIA to be MPO-ANCA or PR3-ANCA) supports a diagnosis of MPA or one of the other pauci-immune small-vessel vasculitides. A negative ANCA assay and positive cryoglobulin assay (especially accompanied by hypocomplementemia and positive hepatitis C serology) support a diagnosis of cryoglobulinemic vasculitis. A negative ANCA assay, negative cryoglobulin assay, and normal complement levels support a diagnosis of IgAV, especially in a patient younger than 21 years. The age of a patient influences the likelihood of a specific diagnosis. For example, approximately 80% of children younger than 10 years who have purpura, nephritis, and arthralgias will have IgAV, whereas approximately 80% of adults older than 60 years with the same symptoms will have an AAV. However, each disease can occur at any age.

Exposure to drugs that may provoke AAV must be considered, including penicillamine, hydralazine, and propylthiouracil,[11] as well as cocaine adulterated with levamisole.[11] Cholesterol embolization also can mimic the clinical features of small-vessel vasculitis with lower extremity rash or livedo reticularis, but ANCA assay is negative. The differential diagnosis of lung hemorrhage and nephritis includes anti-GBM disease, alone or with ANCA disease.

Natural History

Before the advent of immunosuppressive therapy, the survival of patients with MPA and GPA was poor, with most patients dying in less than 1 year. With adequate immunosuppressive therapy, 5-year renal and patient survival is 65% to 75%.[5,36,37] The likelihood of success of long-term maintenance of renal function is inversely correlated with the serum creatinine concentration when therapy begins, which indicates the importance of early diagnosis and prompt initiation of appropriate treatment. The likelihood of patient survival increases with early treatment of pulmonary hemorrhage and sepsis and avoidance of overimmunosuppression leading to life-threatening infections. Adverse events from therapy, including infections, are the leading cause of death in the year after diagnosis.[36] Older age, higher serum creatinine concentration at presentation, pulmonary hemorrhage, and especially dialysis-dependent renal failure correlate with an overall poor outcome. However, even dialysis-dependent renal failure may resolve with aggressive early therapy. Respiratory tract disease and PR3-ANCA are predictors of higher relapse rates.[37] Pathologic features that correlate with renal outcome include histologically normal glomeruli, glomerular sclerosis, interstitial leukocyte infiltration, tubular necrosis, and tubular atrophy.[35] Increased numbers of histologically normal glomeruli or glomeruli with cellular crescents correlated with a better prognosis than higher proportions of globally sclerotic glomeruli, suggesting that active inflammatory lesions may be suppressed if not reversed by treatment, whereas chronic injury at initiation of treatment may be irreversible.

When severe GN is present, the renal prognosis is similar for patients with MPA, GPA, or EGPA, and renal-limited pauci-immune crescentic GN. Renal involvement, however, is much less common and usually less severe in patients with EGPA. Cardiac involvement is the most frequent cause of death in patients with EGPA, but only rarely causes mortality in MPA or GPA. GPA has a broad spectrum of clinical manifestations, from localized indolent disease to fulminant multisystem disease. For example, some patients have disease limited to the upper respiratory tract or the upper and lower respiratory tract. Such limited disease may have a more benign natural history than systemic disease with substantial renal involvement and may warrant less aggressive treatment.

Patients with MPO-ANCA have a slightly better renal outcome than those with PR3-ANCA, even though they have more renal impairment and more chronic renal pathologic changes at presentation. Patients with PR3-ANCA have more extrarenal organ manifestations (especially respiratory tract disease), higher chance for relapse, and higher mortality than patients with MPO-ANCA. Regardless of the category of ANCA disease, the best clinical predictor of renal outcome is the glomerular filtration rate (GFR) at diagnosis.

Treatment

This section focuses on patients with ANCA-associated small-vessel vasculitis affecting the kidneys, aiming not to overtreat mild disease

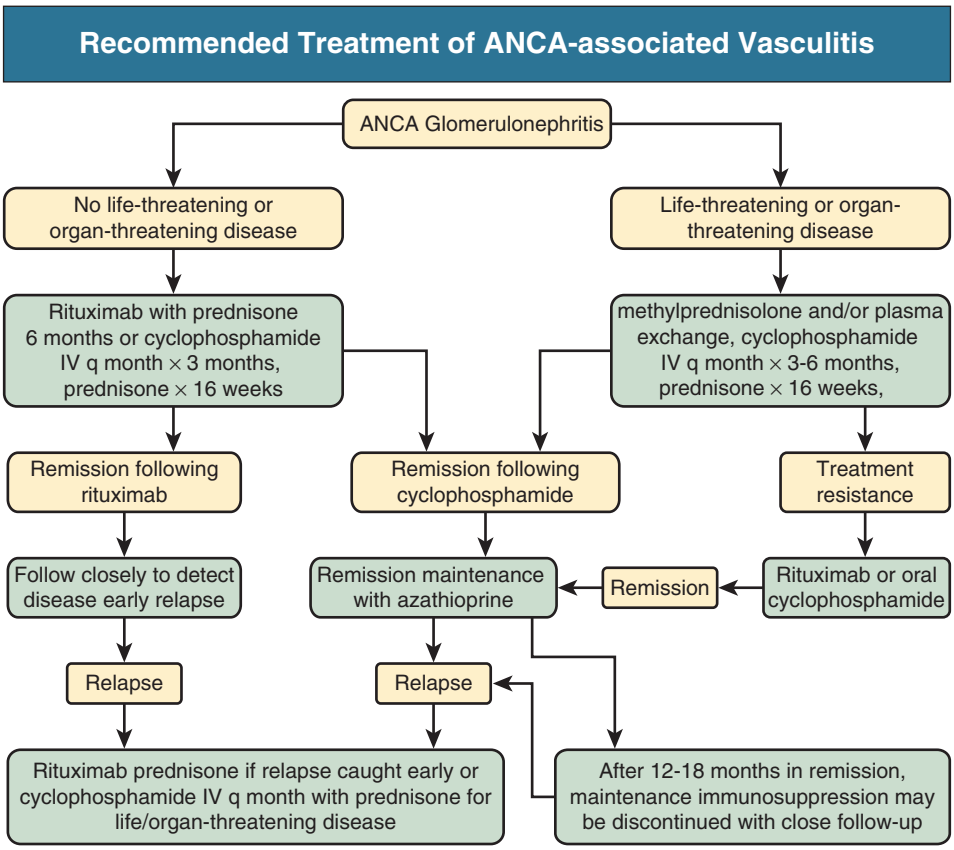

Fig. 25.11 Recommended treatment for ANCA-associated vasculitis.

and not to undertreat severe disease. GN that is severe enough to cause renal impairment is an indication for immunosuppressive treatment in patients with GPA, MPA, EGPA, and renal-limited pauci-immune crescentic GN. Patients with AAV who have concurrent immune complex disease should be treated similarly to patients with AAV alone. Patients with AAV who have concurrent anti-GBM disease should be treated similarly to patients with anti-GBM disease alone. Treatment involves three phases: induction of remission, maintenance of remission, and treatment of relapse (Fig. 25.11).

Induction Therapy

The standard induction therapy for AAV combines corticosteroids with an immunomodulatory agent such as cyclophosphamide or rituximab.[5,37-50] Combined treatment with corticosteroid and cyclophosphamide induces remission in approximately 75% of patients at 3 months and 90% at 6 months. The specifics of combined induction regimens vary with respect to agents, doses, route of administration, and duration. One induction approach is to begin with methylprednisolone 7 mg/kg/day intravenously (IV) for 3 days, followed by oral prednisone 1 mg/kg/day, tapering to an alternate-day regimen and discontinuing within 3 to 6 months.[39] Alternatively, the corticosteroids can be administered as prednisolone 1 mg/kg/day tapered to 0.25 mg/kg/day by 3 months.[43] The corticosteroid treatment is combined with oral cyclophosphamide 2 mg/kg/day or cyclophosphamide at 0.5 g/m^2 IV per month adjusted upward to 1 g/m^2 on the basis of the leukocyte count after 2 weeks, with a target nadir of 3000 cells/mm^3. The dose of oral cyclophosphamide can be reduced by 25 mg for patients older than 60. A comparison by the European Vasculitis Study Group (CYCLOPS trial) indicated that intravenous cyclophosphamide results in the same remission rates as oral cyclophosphamide while reducing the total dose of cyclophosphamide.[47]

The U.S. Food and Drug Administration (FDA) and European Medicines Agency (EMA) have approved rituximab for use as induction therapy for AAV based on the results of two randomized controlled trials (RCTs) noting that rituximab-based cyclophosphamide-sparing strategies were comparable to traditional cyclophosphamide induction protocols.[45,46] The Rituximab for ANCA-Associated Vasculitis (RAVE) trial noted no difference in remission off all therapy in 6 months between patients treated with four infusions of 375 mg/m^2 rituximab plus prednisone and those receiving oral cyclophosphamide with prednisone (64% in rituximab arm, 55% in cyclophosphamide arm). The RITUXVAS trial compared 6 to 10 infusions of cyclophosphamide followed by maintenance therapy with azathioprine to four infusions of 375 mg/m^2 rituximab in combination with two infusions of cyclophosphamide without maintenance therapy. There was no difference in remission rates at 12 months between the groups. In both RAVE and RITUXVAS, enthusiasm is tempered by higher adverse event rates, including infection and neoplasms, that may signify no improvement in safety over cyclophosphamide. This is somewhat disappointing because there was hope that targeted B cell therapy would have fewer adverse events than broader spectrum immunosuppression. Rather than using four infusions of rituximab, our current approach is to use two 1-g doses 14 days apart. Of note, in the current health care systems in many countries, the cost and insufficient reimbursement for rituximab may be problematic.

Plasma exchange may be of benefit in patients with life-threatening pulmonary hemorrhage[48] and patients who have dialysis-dependent renal failure at presentation.[49] With pulmonary hemorrhage, 20 of 20 patients treated with early plasma exchange had resolution of pulmonary bleeding compared with a 50% mortality in historical controls.[48] A trial by the European Vasculitis Study Group (MEPEX) evaluated the efficacy

of intravenous methylprednisolone as induction therapy or plasma exchange in patients who had a serum creatinine of more than 500 µmol/l.[49] Results from this study suggest that plasma exchange compared with pulse methylprednisolone in this population increases the rate of recovery from renal failure. Patient survival and adverse events were similar in patients who did or did not receive plasma exchange. Plasma exchange was associated with a 24% reduced risk for progression to end-stage renal disease (ESRD), from 43% to 19% at 1 year.

Maintenance Therapy

The duration of induction therapy and the intensity of maintenance therapy should be decreased as much as possible to reduce toxic side effects. This is a difficult challenge because of the tendency of AAV to recur. A number of approaches have been used to reduce the cyclophosphamide dose, such as giving less cyclophosphamide through intravenous rather than oral schedules, substituting a less toxic maintenance drug after 3 to 6 months, and discontinuing therapy earlier in patients with lower risk for relapse. Intravenous cyclophosphamide regimens afford one third to one half the total dose of cyclophosphamide given in oral regimens. Long-term follow-up, however, notes longer time to relapse in the oral cyclophosphamide treated group, at the cost of increased leukopenia.[50] Another approach to reducing cyclophosphamide dose is to substitute azathioprine after 3 to 6 months of therapy.[43] In the European Vasculitis Study Group (CYCAZAREM) trial, cyclophosphamide was replaced with azathioprine 2 mg/kg/day after 3 to 6 months with no change in the relapse rate at the end of the study.[43] Azathioprine 2 mg/kg/day has been compared with mycophenolate mofetil (MMF) 2 g/day in a randomized control fashion, noting that relapses were more common in the MMF group compared with the azathioprine group (unadjusted hazard ratio [HR] for MMF 1.69; 95% confidence interval [CI] 1.06 to 2.70). Adverse events, disease activity score, GFR, and proteinuria did not differ between the groups.[51]

Cyclophosphamide dose also could be reduced by alternative induction therapies. The French Vasculitis Study Group examined methotrexate compared with azathioprine as maintenance therapy in patients with GPA and MPA.[52] In this study, methotrexate was as effective as azathioprine for maintenance of remission, but methotrexate did not have fewer side effects. But methotrexate should not be used in patients with low GFR. An attractive alternative is to stop all immunosuppressive therapy at 6 to 12 months if the patient is in full remission, especially if the patient is at lower risk for relapse.[37]

Rituximab is another option for maintenance of remission.[52,53] The MAINRITSAN trial compared rituximab to azathioprine for maintenance in patients with MPA and GPA in remission after induction treatment with cyclophosphamide and glucocorticoids. Rituximab was more effective than azathioprine for preventing relapse, including renal relapse.[52] Rituximab has a significant amount of immunogenic mouse protein as part of its structure, so a growing number of patients have become sensitized to this biologic agent, and some have developed serum sickness–like disease. If sensitivity develops as a result of use for maintenance, if these patients need rituximab for clinical disease activity, it may not be an option. The expense of rituximab may become prohibitive for some patients.

The role of antimicrobial agents such as trimethoprim-sulfamethoxazole in maintenance of remission is controversial. Some studies have suggested a benefit, but others have not because of an increased likelihood of relapse.[54] Trimethoprim-sulfamethoxazole (TMP-SMX) may be useful adjunct therapy, especially in patients with upper respiratory tract disease, but should not be used in the absence of immunosuppressive drugs with more proven efficacy (e.g., cyclophosphamide, azathioprine) for induction or maintenance therapy for systemic vasculitis or GN.

Relapse Therapy

Approximately one fourth to one half of patients with AAV will experience a relapse within several years. Relapses are diagnosed on the basis of clinical and pathologic evidence of recurrent disease, not by an increase in ANCA titer alone.[31] However, an increase in ANCA titer increases the likelihood of a relapse, and some advocate preemptive immunosuppressive therapy if the ANCA titer increases by at least fourfold.[31] We prefer to identify clear-cut clinical or pathologic evidence of relapse before increasing immunosuppressive therapy.[39]

Observational data suggest that the best treatment for relapses may be rituximab. There is evidence that use of rituximab for relapse is superior to cyclophosphamide.[45] Reinstitution of treatment similar to an induction regimen is used most often, but less intensive or less toxic therapy may be adequate.[39] Lifetime exposure to cyclophosphamide is a consideration when selecting treatment for relapses. In addition to rituximab or cyclophosphamide, a number of therapies can be used in the treatment of relapse, including azathioprine, MMF, methotrexate, or combinations of these drugs tailored to the individual patient with recalcitrant disease.

In some individuals, long-term therapy may not be required, especially if there is a very low risk for relapse. In prospective observational studies from the Glomerular Disease Collaborative Network, the relative risk for relapse was increased in those individuals who had PR3-ANCA and respiratory tract disease.[37] Patients had more than a threefold risk for relapse compared with those individuals with MPO-ANCA and without lung or ear, nose, and throat disease. In a follow-up study, this model of relapsing disease was investigated in a separate registry in France, in which PR3-ANCA and lung disease was the most important predictive marker.[55] Thus, in those who have a much smaller risk for relapse, all therapy may be stopped, provided the patient and physician pursue a monitoring course in which the risk for early relapse is detected (e.g., home urinary dipstick testing to monitor for recurrence of hematuria). The risk for relapse is about 10% to 15% even with remission maintenance therapy.

Transplantation

Renal transplantation is not contraindicated in patients with ESRD caused by AAV. In a multicenter experience, the vasculitis relapse rate was 0.02 per patient per year[56] (see Chapter 108). A positive ANCA titer at the time of transplantation does not increase the risk for recurrent disease in the transplant.[57] Recurrent ANCA GN in a renal transplant responds similarly to recurrent disease in native kidneys. As with native kidney disease, an increase in ANCA titer and an active urine sediment should suggest recurrent GN, but the diagnosis requires pathologic confirmation. ANCA GN recurrence in a transplant usually is treated with cyclophosphamide and corticosteroids. Rituximab also has been used successfully and avoids increasing the risk for cyclophosphamide toxicity.[58]

POLYARTERITIS NODOSA

PAN is a systemic necrotizing arteritis that affects predominantly main visceral arteries and their intraparenchymal branches.[2,23,59] The Chapel Hill nomenclature system limits the diagnosis of PAN to patients who have only arteritis.[4] The presence of vasculitis in capillaries and venules excludes a diagnosis of PAN and indicates some form of small-vessel vasculitis. Thus GN excludes a diagnosis of PAN. When PAN is distinguished from MPA by this approach, the two categories of vasculitis have not only different pathologic characteristics but also different clinical features and natural histories, which justifies the nosologic distinction between PAN and MPA.[60]

Pathogenesis

The etiology and pathogenesis of PAN are unknown and probably are diverse.[2] When PAN is separated from MPA, the latter but not the former is associated with ANCAs. An immune complex trigger for PAN has been proposed but has not been confirmed as the major pathogenetic process. A minority of patients have hepatitis B virus (HBV) infection, suggesting that the HBV infection is producing immune complexes that are localizing in arterial walls and inducing inflammation.[2] However, the evidence that HBV infection is causing vascular immune complex deposition is stronger in certain forms of GN and small-vessel vasculitis than in PAN.

Epidemiology

When defined by the Chapel Hill nomenclature system, PAN has a low prevalence of approximately 1.5 per million.[20] The prevalence is higher in regions that have higher levels of endemic hepatitis B virus infection, which can cause PAN. PAN affects males and females equally and is found in all races. Onset occurs most frequently between ages 40 and 60 years.

Clinical Manifestations

The usual clinical presentation of PAN includes nonspecific constitutional symptoms, such as fever, malaise, arthralgias, myalgias, and weight loss, as well as manifestations of arteritis.[34,60,61] Peripheral neuropathy, typically in the form of a mononeuritis multiplex, is a common manifestation. This is caused by inflammation of small epineural arteries and is clinically indistinguishable from the peripheral neuropathy caused by other forms of vasculitis that can affect epineural arteries, such as MPA, GPA, and EGPA. Gastrointestinal involvement occurs in about half of patients, usually manifesting as abdominal pain and blood in the stool. Bowel infarction is uncommon and perforation rare. Renal involvement produces infarction and hemorrhage, as indicated by flank pain and hematuria. Rupture of an arterial aneurysm with retroperitoneal or peritoneal hemorrhage is an uncommon but potentially lethal renal complication. Approximately one third of patients develop hypertension, which rarely reaches the malignant range. Red, tender inflammatory nodules are the most common cutaneous manifestation. Infarction, ulceration, and livedo reticularis may be present.

Arterial aneurysms may be detected by angiography in patients with PAN (Fig. 25.12). This is not a completely specific determination because any necrotizing arteritis that affects arteries large enough to be seen by angiography can produce this finding.

Pathology

Any artery in the kidney can be affected by PAN, from the main renal artery to the interlobular arteries, although the interlobar and arcuate arteries are affected most often.[16] Nodular inflammatory lesions and aneurysms (pseudoaneurysms) can be observed grossly when medium-sized arteries are involved. Inflammation in small arteries can be observed only by microscopy.

The characteristic acute lesion is segmental transmural fibrinoid necrosis of arteries, usually accompanied by infiltrating leukocytes with leukocytoclasia[3] (Fig. 25.13). The earliest lesions have numerous neutrophils, and later lesions have predominantly mononuclear leukocytes. Acute lesions may be complicated by thrombosis or hemorrhage. Older lesions develop fibrosis and endarterial remodeling. The aneurysms of necrotizing arteritis are not true aneurysms but rather inflammatory pseudoaneurysms. That is, the walls of the arteries are not dilated but rather have been eaten away by the necrotizing inflammation, which then erodes into the surrounding perivascular tissue to create an enlarged lumen at the site of inflammation. This explains the propensity for such lesions to induce thrombosis or undergo rupture.

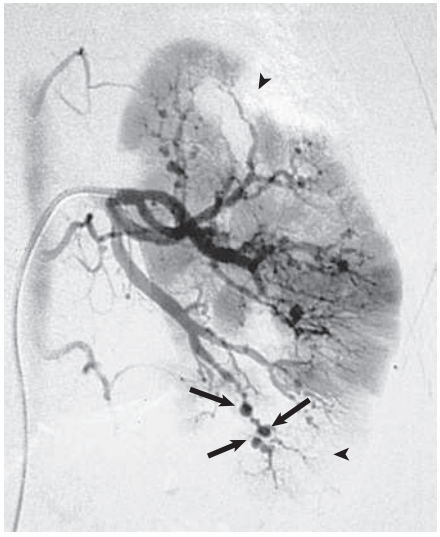

Fig. 25.12 Renal angiogram in polyarteritis nodosa. Angiogram shows patchy renal perfusion defects *(arrowheads)* and aneurysms *(arrows)*.

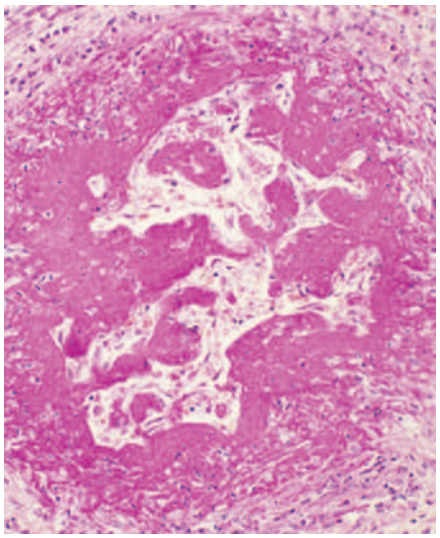

Fig. 25.13 Necrotizing arteritis in arcuate artery of patient with polyarteritis nodosa. The lumen is partially occluded by thrombotic material that is continuous with the fibrinoid material that has replaced the entire wall of the artery. (HE stain, ×50.)

The necrotizing arteritis of PAN cannot be distinguished by light microscopy from arteritis caused by other necrotizing vasculitides affecting arteries.[2,3] For example, necrotizing arteritis in a skeletal muscle biopsy specimen or a peripheral nerve biopsy specimen is histologically identical whether caused by PAN, MPA, GPA, or EGPA. For these vasculitides to be distinguished, additional clinical and serologic information is required.

Differential Diagnosis

Clinical features may assist in distinguishing PAN from other forms of vasculitis, especially other forms of necrotizing vasculitis that can affect arteries, such as MPA[2,3,23] (Table 25.5). A positive ANCA test result supports the diagnosis of one of the ANCA-associated small-vessel vasculitides rather than PAN. The presence of GN indicates some form of small-vessel vasculitis rather than PAN. Vasculitic pulmonary disease is

TABLE 25.5 Clinical Differences Between Polyarteritis Nodosa and Microscopic Polyangiitis

Clinical Feature	Polyarteritis Nodosa	Microscopic Polyangiitis
Microaneurysms by angiography	Yes	No (rare)
Rapidly progressive nephritis	No	Yes (very common)
Pulmonary hemorrhage	No	Yes
Renovascular hypertension	Yes (10%-33%)	No
Peripheral neuropathy	Yes (50%-80%)	Yes (10%-20%)
Positive hepatitis B serology	Uncommon	No
Positive ANCA	Rare	Frequent
Relapses	Rare	Frequent

Modified from reference 23.
ANCA, Antineutrophil cytoplasmic antibody.

rare in PAN but common in MPA, GPA, and EGPA. Peripheral neuropathy or muscle tenderness with arteritis in epineural or skeletal muscle arteries is not a useful differentiating feature because it often occurs in PAN, as well as in the ANCA-associated small-vessel vasculitides. Kawasaki disease causes necrotizing arteritis but is distinguished from PAN by the presence of the mucocutaneous lymph node syndrome.

Natural History

The natural history of PAN is difficult to determine because most of the early studies of outcome grouped MPA with PAN. PAN with multisystem involvement has a poor prognosis without therapy.[23] The 10-year survival with appropriate treatment is approximately 80%. Approximately 15% of patients who enter remission develop a relapse, which is much less frequent than with MPA. Relapse is more likely if treatment is delayed.

Treatment

PAN in patients with no evidence of HBV infection is treated with corticosteroids and cytotoxic drugs (usually cyclophosphamide) if there is life-threatening major organ involvement.[23,60,61] The regimens vary and include treatment approaches similar to those described earlier for MPA and GPA. However, in patients with no risk factors for poor outcome (e.g., age >50 years; cardiac, gut, or renal involvement), corticosteroids alone may be adequate and are less toxic therapy than corticosteroids combined with cytotoxic agents.[61]

Aggressive immunosuppressive therapy without initial antiviral therapy is contraindicated in patients with HBV-associated PAN because of potential adverse effects on the outcome of the HBV infection. Short-term corticosteroid treatment combined with antiviral agents and possibly plasma exchange should precede more extensive immunosuppression in such patients.

KAWASAKI DISEASE

Definition

Kawasaki disease is an acute febrile illness that usually occurs in young children, often under 1 year, and is characterized by the mucocutaneous lymph node (MCLN) syndrome (see later discussion).[2,4,62-64] Necrotizing arteritis is a complication of Kawasaki disease that is present in some but not all patients. Clinically significant renal involvement is very rare; therefore Kawasaki disease is rarely encountered by nephrologists. If untreated, approximately 20% to 25% of children develop coronary artery aneurysms that may cause myocardial infarction.[63] However, most patients who undergo autopsy examination after fatal myocardial infarction caused by coronary artery arteritis also have vasculitis in the renal arteries.[62]

Pathogenesis

The occasional occurrence of Kawasaki disease as an endemic or epidemic disease suggests that the cause may be an infectious agent or an environmental toxin.[2] Both cell-mediated and antibody-mediated mechanisms have been incriminated, as well as dysregulated innate immunity, possibly mediated by innate immune pathogen-associated molecular patterns.[64] At present, the etiology and pathogenesis of Kawasaki disease are unknown.

Epidemiology

Kawasaki disease usually occurs in children younger than 5 years and has a median age of 2 to 3 years.[63] It was first described in Japan, but it occurs worldwide. The disease is more common in Asians and Polynesians than in Whites and Blacks. In Japan, the incidence is 50 in 100,000 children younger than 5 years, with 50% of the children younger than 2.[20,63] Kawasaki disease occasionally occurs in an endemic or epidemic pattern but usually is sporadic. Kawasaki disease is not transmitted person to person and does not occur in clusters within households, schools, or nurseries.[64]

Clinical Manifestations

The MCLN syndrome is the characteristic clinical manifestation of Kawasaki disease.[4,63,64] This includes fever (temperature of usually 38° to 40° C), mucosal inflammation, swollen red tongue (strawberry tongue), polymorphous erythematous rash, indurative edema of the extremities, erythema of palms and soles, desquamation from the tips of digits, conjunctival injection, and enlarged lymph nodes. The frequency of active arteritic lesions peaks during the first week of the illness and is greatly reduced after 1 month. Arteritis most often is manifested as cardiac disease. Thrombosis of inflamed coronary arteries in patients with Kawasaki disease is the most common cause of childhood myocardial infarction. Clinically significant renal disease is uncommon. This is somewhat surprising because autopsy reveals arteritis in renal vessels in up to three fourths of patients.[62]

Pathology

The arteritis of Kawasaki disease involves small and medium-sized arteries. The acute histologic lesion is necrotizing inflammation with less fibrinoid necrosis and more vessel wall edema than usually observed with PAN[62] (Fig. 25.14). Aneurysm (pseudoaneurysm) formation and thrombosis may occur. The most frequent site of arteritis is the coronary arteries, followed by the renal arteries.[62] Arteritis most often affects interlobar arteries, occasionally arcuate arteries, and only rarely interlobular arteries.

Differential Diagnosis

Kawasaki disease has sometimes been misdiagnosed as childhood PAN. The differentiation of Kawasaki disease from PAN is important because corticosteroid treatment may increase the risk for coronary artery aneurysms in Kawasaki disease. Arteritis in a child younger than 5 years should always raise the possibility of Kawasaki disease. The presence or absence of the MCLN syndrome is the basis for distinguishing between Kawasaki disease and other forms of arteritis.[4]

Natural History

Kawasaki disease usually is self-limited, with an uneventful recovery if treated promptly with intravenous gamma globulins.[62,63] Recurrence occurs in less than 5% of patients.[63]

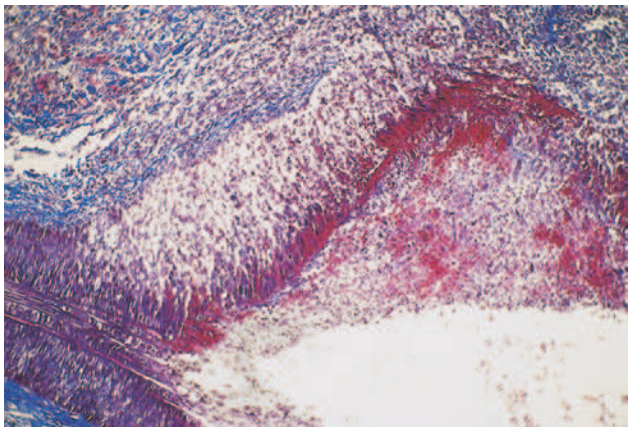

Fig. 25.14 Kawasaki disease arteritis affecting renal interlobar artery in a young child. The artery wall is intact on the *far left.* The remainder of the wall has extensive edema, infiltration by mononuclear leukocytes, and a band of fuchsinophilic *(red)* fibrinoid material roughly at the junction between the inflamed intima and muscularis. (Masson trichrome, ×25.)

Treatment

Aspirin and intravenous gamma globulin are the standard therapy for Kawasaki disease.[62,63] The role of corticosteroid treatment is controversial, but this may be beneficial in patients with severe disease that does not respond well to aspirin and intravenous immunoglobulin.

TAKAYASU ARTERITIS AND GIANT CELL ARTERITIS

Takayasu arteritis and giant cell arteritis affect the aorta and its major branches more often than other forms of vasculitis.[4,65,66] Giant cell arteritis has a predilection for the extracranial branches of the carotid artery but can affect arteries in almost any organ. Takayasu arteritis has a predilection for major arteries supplying the extremities. Both diseases cause chronic vascular inflammation, often with a granulomatous appearance that may include multinucleated giant cells. Giant cell arteritis, but not Takayasu arteritis, is associated with polymyalgia rheumatica. The relation of Takayasu arteritis and giant cell arteritis is not known. The striking demographic differences suggest, but do not prove, that they are distinct pathophysiologic entities.

Pathogenesis

The etiology and pathogenesis of giant cell arteritis and Takayasu arteritis are unknown.[2] Because of the histologic changes and the nature of the infiltrating leukocytes, cell-mediated immune mechanisms are incriminated. The inciting antigen or autoantigen has not been identified.

Epidemiology

Takayasu arteritis is seen most frequently in Asia. Giant cell arteritis occurs most often in individuals of northern European ancestry. Takayasu arteritis has a female-to-male ratio of approximately 9:1 and giant cell arteritis of 4:1. Takayasu arteritis usually is diagnosed in those between ages 10 and 20 years and is rare after age 50. Giant cell arteritis is rare before age 50. Takayasu arteritis has a uniform global incidence of 1 to 2 per million.[20] Race and ethnicity affect the vascular distribution of Takayasu arteritis, with the aortic arch and its branches affected mainly in Japanese patients, abdominal aorta and its branches affected mainly in Indian patients, lower abdominal aorta affected mainly in African populations, and renal involvement most common in Asian and African populations.[66]

Giant cell arteritis is probably the most common form of vasculitis, with an incidence that is highest in populations of Scandinavian descent, with an annual incidence of 15 to 35 per 100,000 over 50 years of age.[20]

Clinical Manifestations

In addition to nonspecific constitutional symptoms, such as fever, arthralgias, and weight loss, the major clinical manifestations of Takayasu arteritis and giant cell arteritis are caused by arterial narrowing and resultant ischemia.[2,65] The major clinical manifestations of Takayasu arteritis are reduced pulses (95% of patients), vascular bruits, claudication, and renovascular hypertension. Renovascular hypertension is a major cause of morbidity and mortality and results from renal ischemia caused by renal artery stenosis or aortic coarctation.[67] Reduced aortic elasticity and impairment of carotid artery baroreceptors also may play a role in some patients. The European League Against Rheumatism (EULAR) recommends thorough imaging assessment (see later discussion) of the entire major arterial tree when a diagnosis of Takayasu arteritis is suspected.[68]

Headache is the most common presenting symptom in patients with giant cell arteritis. Temporal artery tenderness, nodularity, or decreased pulsation is present in about half of patients. Additional common symptoms include blindness, deafness, jaw claudication, tongue dysfunction, extremity claudication, and reduced pulses. More than half of patients with giant cell arteritis have polymyalgia rheumatica, characterized by stiffness and aching in the neck and the proximal muscles of the shoulders and hips. Clinically significant renal disease is much rarer in giant cell arteritis than in Takayasu arteritis. There are case reports of necrotizing and crescentic GN associated with giant cell arteritis, but these may represent examples of GPA or MPA with temporal artery involvement.

Computerized tomography (CT), magnetic resonance angiography (MRA), fludeoxyglucose positron emission tomography-computerized tomography (FDG-PET/CT), and contrast-enhanced ultrasonography are used in diagnosis and to assess the activity of vascular inflammation in Takayasu arteritis and giant cell arteritis.[66] CT and MRA are used to identify structural changes (e.g., stenosis, aneurysms). FDG-PET/CT detects active inflammation even in vessels that show no overt structural changes by other imaging techniques.

Pathology

The aortitis and arteritis of Takayasu arteritis and giant cell arteritis cannot be confidently differentiated by pathologic examination.[4] Both are characterized in the active phase by inflammation with a predominance of mononuclear leukocytes, often with scattered multinucleated giant cells (Fig. 25.15). The chronic phase is characterized by progressive fibrosis that may cause severe narrowing of vessels, with resultant ischemia. Major renal arteries are often found to be involved at autopsy in both patients with Takayasu arteritis and those with giant cell arteritis. However, clinically significant renal disease is relatively common in Takayasu arteritis but rare in giant cell arteritis. A glomerular lesion characterized by nodular mesangial matrix expansion and mesangiolysis may occasionally be a component of Takayasu arteritis.[69]

Differential Diagnosis

There is a great deal of overlap between the clinical manifestations and pathologic features of Takayasu arteritis and giant cell arteritis. Patient age and presence or absence of polymyalgia rheumatica are the best factors for discriminating between these two vasculitides.[4] Giant cell arteritis also has been called "temporal arteritis," but this is misleading because not all patients have temporal artery involvement and patients

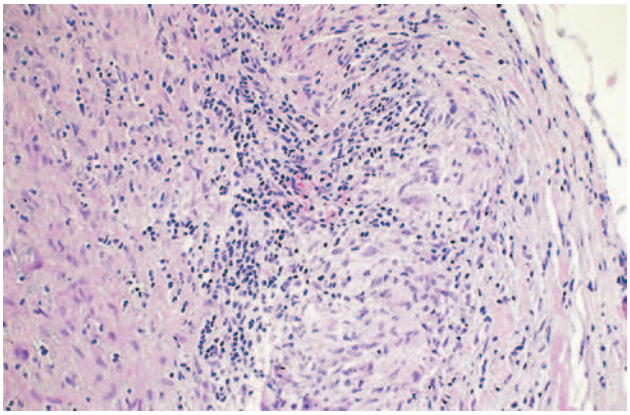

Fig. 25.15 Severe giant cell arteritis affecting a main renal artery. This caused marked renal atrophy and renovascular hypertension. (HE stain, ×50.)

with other types of vasculitis (PAN, GPA, MPA) can have involvement of the temporal arteries. Some of the reported examples of necrotizing GN associated with temporal arteritis probably represent GPA or MPA with temporal artery involvement.

Treatment

Corticosteroids are the usual treatment of giant cell arteritis and Takayasu arteritis.[68] EULAR recommends initial daily therapy with prednisolone 1 mg/kg for 1 month followed by tapering over several months.[68] More prolonged treatment may be dictated by persistent disease activity. Cytotoxic agents such as cyclophosphamide may be required in patients with recalcitrant disease. Patients with giant cell arteritis also should receive low-dose aspirin to protect against thrombotic vascular events.[68]

Management of renal disease is not an issue with typical giant cell arteritis, although rare patients have ischemic renal manifestations. Renovascular hypertension is the major renal problem caused by Takayasu arteritis.[66,67] When bilateral renal artery involvement occurs, angiotensin-converting enzyme inhibitors may precipitate renal failure in patients with Takayasu arteritis.[70] When medical management fails, the renovascular hypertension in patients with Takayasu arteritis may be controlled by vascular surgery or endovascular angioplasty.[66,67] Reconstructive vascular surgery should be performed during a quiescent phase of the disease.[68] The management of renovascular hypertension is covered in Chapter 41.

SELF-ASSESSMENT QUESTIONS

1. In a patient who has systemic vasculitis affecting multiple organs, a renal biopsy showing a glomerulonephritis (GN) that is a component of the systemic vasculitis is definitive evidence that the systemic vasculitis is a:
   A. Large-vessel vasculitis
   B. Small-vessel vasculitis
   C. Medium-vessel vasculitis
   D. Variable-vessel vasculitis
2. If pathologic and serologic studies in a patient with crescentic GN are diagnostic for anti–glomerular basement membrane (GBM) disease, antineutrophil cytoplasmic antibody (ANCA) testing is:
   A. Unnecessary because it is unlikely to be positive
   B. Unnecessary because it would not change the prognosis if positive
   C. Necessary because it is positive in one fourth to one third of patients and changes the prognosis
   D. The disease is more like anti-GBM disease
3. Which of the following is most common in patients with polyarteritis nodosa (PAN)?
   A. Glomerulonephritis
   B. Pulmonary hemorrhage
   C. Polymyalgia rheumatica
   D. Hepatitis B infection
4. Which of the following is the most common clinical sign or symptom caused by Takayasu arteritis?
   A. Flank pain caused by renal infarction
   B. Acute renal failure
   C. Hematuria
   D. Hypertension
5. Is targeted B-cell therapy with rituximab an acceptable component of induction therapy for ANCA-associated vasculitis and glomerulonephritis?
   A. Yes, because induction with rituximab has fewer adverse events than induction with cyclophosphamide.
   B. Yes, because clinical trials have shown noninferiority between induction therapy with rituximab compared with cyclophosphamide.
   C. No, because clinical trials have shown that induction therapy with rituximab is inferior to induction with cyclophosphamide.
   D. No, because rituximab is not FDA approved for induction therapy.

Lupus Nephritis

Shikha Wadhwani, David Jayne, Brad H. Rovin

DEFINITION

Lupus nephritis (LN), the prototypical immune complex glomerulonephritis (GN), is common and serious in patients with systemic lupus erythematosus (SLE). SLE is defined by clinical and laboratory features as outlined in the 1997 American College of Rheumatology (ACR) criteria for the diagnosis of SLE (Box 26.1). The Systemic Lupus International Collaborating Clinics (SLICC) criteria introduced in 2012 (see Box 26.1) have shown greater diagnostic sensitivity and fewer misclassifications than the ACR criteria.[1,2] The SLICC criteria include biopsy-proven nephritis compatible with LN in the presence of either antinuclear antibody (ANA) or anti–double-stranded (ds)DNA antibody as sufficient evidence for the diagnosis of SLE, but eliminated dipstick-positive albuminuria as sufficient to confirm kidney involvement in LN. The SLICC criteria may influence the apparent incidence of LN.

EPIDEMIOLOGY

The incidence and prevalence of lupus and LN are influenced by age, gender, ethnicity, geographical region, diagnostic criteria used, and method of ascertainment, but across populations, clinically important kidney disease (Table 26.1) will occur in about 50% of patients with SLE.[3,4] The peak incidence of lupus is between the ages of 15 and 45 years, with women outnumbering men 8 to 15:1. Female predominance is less pronounced in children and older individuals. Among patients with lupus, LN affects both sexes equally, is more severe in children and men, and is less so in older adults. The incidence of LN is about 30% in White, 60% in Black and Hispanic, and 40% to 80% in Asian patients with SLE.[3,5] The higher frequency of LN in Black patients with lupus in the United States persists after adjusting for socioeconomic status.[6] Black and Hispanic patients with SLE develop LN earlier and have worse outcomes, including death and end-stage renal disease (ESRD), than White patients. The prevalence of LN in a U.S. Medicaid population was 31 in 100,000.[6]

Approximately 10% of patients with LN will develop ESRD[3]; however, this depends on histologic class. The risk for ESRD over 15 years was found to be as high as 44% in class 4 LN.[4]

SLE patients with LN die earlier than those without nephritis and have a standardized mortality ratio of 6 to 6.8 versus 2.4 in lupus without renal involvement.[7,8] This increases to 14 for those with chronic kidney disease and 63 for those with ESRD.[9] However, if LN remission is achieved through treatment, 10-year survival doubles to 95%.[10]

ETIOLOGY AND PATHOGENESIS

Genetics and Environment

A genetic predisposition to SLE is supported by disease clustering in families, twin concordance, racial differences in susceptibility, and the high frequency of autoantibodies and other autoimmune disorders in uninvolved family members of SLE patients.[11] A Taiwanese study found that the relative risk for lupus in families of those with SLE was 316 for twins, 24 for siblings, 11 for parents, 14 for children of patients, and 4.4 for nonrelated spouses, leading to estimates that heritability contributed 44% to the risk for SLE, shared environmental exposures contributed 26%, and nonshared environmental exposures 30%.[12]

Homozygous deficiency of early complement cascade components (C1q, C2, C4) carries a high risk for development of SLE; this is also true for certain Fc γ RIII receptor polymorphisms. Genome-wide association studies have identified over 100 loci associated with an increased risk for SLE, although the individual contribution of each gene to overall risk is low. Genetic risk scores are lowest in Europeans, higher in Asians, and highest in those of African ancestry.[13] Genes involved in lupus risk include those affecting B cell signaling, neutrophil function, interferon regulation, immune complex clearance, and Toll-like receptors.[11] A disproportionate number of transcription factors have been identified, suggesting an important contribution of gene dysregulation to lupus.[14] HLA genes are strongly associated with lupus risk, at least in European populations.[15] A meta-analysis of HLA class II alleles associated with SLE identified four DR allele families as conferring increased susceptibility or resistance to the development of LN when compared with healthy controls.[16] This study involved mostly White and Asian patients, and the findings may not be applicable to other patient groups. Independent of causation, other polymorphisms in genes such as MYH-9, ACE, TNIP-1, and APOL-1 (in Blacks) confer a worse prognosis for LN.

External environmental factors such as ultraviolet light exposure and smoking play a role in the onset and exacerbation of SLE and LN.[17] Viral infections may be triggers for lupus, but conclusive evidence for a viral pathogenesis of SLE or LN has yet to be produced. Exposure to certain medications (e.g., procainamide, hydralazine, quinidine, and anti-TNF biologics) has been linked to SLE or SLE-like syndromes, but LN occurs infrequently in such individuals. The internal environment also appears to be relevant given the strong female predominance of SLE, disease exacerbations during or shortly after pregnancy, and the effects of hormone treatment and ablation in animal models of LN.

Autoimmunity in Systemic Lupus Erythematosus

Patients with SLE typically develop multiple autoantibodies, many of which are directed against nucleic acids and proteins involved in transcription and translation, such as nucleosomes (DNA-histone), chromatin antigens, and small nuclear and cytoplasmic ribonuclear proteins.[18] In the early stages of disease, clearance of apoptotic cells is impaired and nuclear autoantigens released from these cells stimulate expression of interferon-α (IFN-α), which facilitates the generation of antigen-presenting cells, promotes the differentiation of autoreactive B cells into plasma cells, and fosters the development of T helper cells. Antigen

BOX 26.1 American College of Rheumatology (ACR) and Systemic Lupus International Collaborating Clinics (SLICC) Criteria for the Diagnosis of Lupus

ACR Criteria	SLICC ACR Criteria	
Presence (cumulative) of four or more of the following:	Presence (cumulative) of four or more of the following (with at least 1 clinical and 1 immunologic criteria) *OR* biopsy-proven lupus nephritis with positive ANA or anti-dsDNA	
	Clinical Criteria	**Immunologic Criteria**
1. Malar rash	1. Acute OR subacute cutaneous lupus	1. Positive ANA
2. Discoid rash	2. Chronic cutaneous lupus	2. Positive anti-dsDNA antibody
3. Photosensitivity	3. Nonscarring alopecia	3. Positive anti-Sm antibody
4. Oral or nasopharyngeal ulcers	4. Oral **OR** nasal ulcers	4. Positive antiphospholipid antibody (includes presence of a lupus anticoagulant, false-positive RPR, anticardiolipin antibody or anti-β_2 glycoprotein antibody)
5. Nonerosive arthritis (involving ≥2 joints, characterized by tenderness, swelling, or effusion)	5. Synovitis ≥2 joints (swelling or effusion) **OR** tenderness in 2 or more joints and ≥30 min of morning stiffness	5. Low complement (C3, C4, or CH50)
6. Pleuritis or pericarditis	6. Serositis	6. Direct Coombs test (in the absence of hemolytic anemia)
7. Renal disease (proteinuria >500 mg/day **OR** 3+ by dipstick **OR** cellular casts)	7. Renal disease (red blood cell casts **OR** proteinuria ≥500 mg/day on 24-hr urine collection **OR** spot ratio of urine protein to creatinine ratio ≥0.5)	
8. Neurologic disorder	8. Neurologic disorder	
9. Hematologic disorder	9. Hemolytic anemia	
10. Immunologic disorder (positive anti-dsDNA antibody **OR** positive anti-Sm antibody **OR** positive antiphospholipid antibody (includes presence of a lupus anticoagulant, false-positive treponemal test, positive anticardiolipin antibody)	10. Leukopenia **OR** lymphopenia	
11. Positive ANA	11. Thrombocytopenia	

ANA, Antinuclear antibody.

TABLE 26.1 Frequency of Kidney Manifestations in Lupus Patients With Renal Involvement

Manifestation	Prevalence (%)
Proteinuria	100
Nephrotic syndrome	45-65
Hematuria	
Microscopic	80
Gross	1-2
Red blood cell casts	10
Cellular casts	30
Reduced renal function	40-80
Rapidly progressive glomerulonephritis	10-20
Acute kidney injury	1-2
Hypertension	15-50
Hyperkalemia	15

mimicry, in which there is exposure to viral or bacterial peptides with sequences similar to those of native antigens, also may lead to induction of autoantibody-producing cell lines. Both autoreactive B and T cells clonally expand in lupus, facilitated by failure of apoptotic mechanisms to silence autoreactive cells (i.e., loss of tolerance as well as an increased expression of B cell trophic factors). The nature of antigen presentation also may be important, with certain nuclear antigens capable of triggering an immunogenic response through interactions with a variety of intracellular Toll-like receptors.

PATHOGENESIS OF LUPUS NEPHRITIS

Autoantibodies are crucial to the pathogenesis of LN, and the hallmark of LN is the accumulation of immune complexes in glomeruli.[19] Patients with LN have autoantibodies against dsDNA, Sm antigen, C1q, nucleosomes, and other antigens. There is direct binding of dsDNA antibodies to the glomerular basement membrane (GBM), and cross-linking of positively charged nucleosome components such as chromatin between autoantibodies and GBM.[19] In proliferative LN, immune complexes are found in the subendothelial space, whereas in membranous LN, immune complexes are found in the subepithelial space. The localization of immune complexes within glomeruli is influenced by size, charge, specificity, and avidity of the antigen and antibody, as well as by the clearance capacity of mesangium and local hemodynamics.

Glomerular immune complexes, especially in the subendothelial space, activate proinflammatory mechanisms, including the complement pathway, leukocyte Fc receptors, cytokines that regulate cell proliferation, and matrix formation and procoagulant factors.[19-21] Nucleosomes also can activate resident dendritic cells through binding to Toll-like receptors 2 and 9.[22] These activated pathways result in complement-mediated kidney damage, intraglomerular hypertension and coagulation, and Fc receptor–mediated leukocyte infiltration with release of proteolytic

enzymes. Subepithelial immune complexes are associated with less inflammation but increased production of GBM components and more podocyte injury.

T cells contribute to the progression of LN by facilitating B cell differentiation and expansion. Additionally, T helper cell (Th1) cytokines are overexpressed in kidneys of patients with LN and promote intrarenal inflammation by activation of macrophages, complement, and the Fc receptor pathway. Kidney biopsies of LN patients also contain Th17 cells, which secrete interleukin-17 (IL-17), thought to sustain renal inflammation by driving T cells away from maturing into a regulatory phenotype ($CD4^+CD25^{hi}FoxP3^+$) capable of suppressing autoantibody production and attenuating the immune response.[23] CD8 T cells may gradually lose effector function and express inhibitory receptors under persistent antigen exposure, and in essence become "exhausted." Although exhaustion may, for example, result in an inability to clear a viral infection, it may be protective against relapse in autoimmune diseases. LN patients whose peripheral T cells displayed an exhausted phenotype had a nonrelapsing disease course.[24] It is unknown whether T cell exhaustion can be translated into a therapeutic approach for SLE.

In SLE and LN, neutrophils undergo a novel form of cell death called NETosis, in which a chromatin meshwork (or NET) is released.[22] These NETs are a source of autoantigens and are not properly degraded in lupus patients. In addition, lupus patients have an increased number of low-density granulocytes that are more susceptible to NETosis. NET material has been found in LN biopsy samples, and the subset of SLE patients with LN often do not degrade. The NETs induce production of IFN-α by plasmacytoid dendritic cells, which are also found in LN kidneys.[22]

Within the tubulointerstitial compartment, T and B cells are often found in close proximity to each other and appear to be interacting, in some cases even forming germinal centers.[25] Interstitial B cells aggregating with T cells may show clonal expansion and somatic hypermutation, suggesting the possibility of intrarenal autoantibody production against kidney-specific antigens, such as vimentin. Such interactions may contribute to interstitial inflammation in LN, and interstitial injury is a major determinant of long-term renal survival.[25]

CLINICAL MANIFESTATIONS

Immune complex kidney involvement (LN) is usually heralded by proteinuria and active urinary sediment with microhematuria, dysmorphic urine erythrocytes, and erythrocyte casts (see Table 26.1). More severe LN may present with the nephritic syndrome in association with proliferative GN, hypertension, and a decline in glomerular filtration rate (GFR). Less frequently, renal disease in lupus presents as a tubulointerstitial disorder such as renal tubular acidosis (Chapter 12), isolated interstitial nephritis, or as a thrombotic microangiopathy associated with or without a antiphospholipid antibody syndrome (see Chapter 28).

Extrarenal Manifestations

Patients with active SLE often present with nonspecific complaints of malaise, low-grade fever, poor appetite, and weight loss. Other common features include patchy alopecia, oral or nasal ulcerations, arthralgias, nondeforming arthritis, and a variety of skin findings, including photosensitivity, Raynaud's phenomenon, and a "butterfly" (malar) facial rash. Livedo reticularis is seen in up to 15% of cases and may be associated with miscarriage, thrombocytopenia, and antiphospholipid antibodies. Neuropsychiatric involvement presents with headache, nerve palsies, psychoses, or frank coma. Serositis, in the form of pleuritis or pericarditis, affects up to 40% of patients. Pulmonary hypertension can develop silently as a result of multiple pulmonary emboli or intravascular coagulation in association with antiphospholipid antibodies, or may be caused by nonthrombotic pulmonary arterial disease. Mitral valve prolapse, and less commonly Libman-Sacks endocarditis, are both seen in SLE. Splenomegaly and lymphadenopathy are present in about one fourth of patients, and hematologic abnormalities can affect all three cell lines. SLE-associated anemia can result from impaired erythropoiesis, autoimmune hemolysis, or bleeding. Thrombocytopenia and leukopenia may occur as part of the disease process or as complications of therapy. Thrombotic events are not uncommon and should prompt a search for antiphospholipid antibodies and other pro-coagulant abnormalities.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Although the diagnosis of lupus may be obvious in a young woman with classic manifestations and serologic markers, less typical presentations are common and often result in multiple physician consultations and diagnostic delay. This is in part a result of the varied features of the disease and because signs and symptoms evolve over time. The presence of four or more ACR criteria carries a 96% sensitivity and specificity for lupus (see Box 26.1). However, the ACR diagnostic criteria were developed for clinical studies and do not always prove useful in an individual patient. In the SLICC classification system (see Box 26.1), SLE can be diagnosed with biopsy-proven immune complex nephritis in the presence of ANA or anti-dsDNA, without other extrarenal disease manifestations.

Several autoimmune diseases mimic the extrarenal manifestations of SLE, and some are associated with kidney involvement and GN, including fibromyalgia, Sjögren syndrome, thrombotic microangiopathies, primary antiphospholipid syndrome, dermatomyositis, systemic sclerosis, and mixed connective tissue disease. Conversely, several common forms of GN must be distinguished from LN because of similar clinical features, including immunoglobulin A (IgA) vasculitis (Henoch-Schönlein purpura, see Chapter 23), antineutrophil cytoplasmic antibody (ANCA)–associated GN (see Chapter 25), bacterial endocarditis, and cryoglobulinemia. ANCAs of uncertain significance are detected in 20% of LN patients.

Immunologic Tests in Lupus

Antinuclear antibodies (ANAs) are found in more than 90% of untreated patients with lupus. Although highly sensitive, neither the presence nor pattern (e.g., diffuse, speckled) are specific for SLE. Autoantibodies against dsDNA are more specific, being present in 75% of untreated lupus patients, but are less sensitive than ANAs. Whereas high titers of anti-dsDNA antibodies correlate with the presence of SLE and are often used to follow the course of LN, antibodies to single-stranded DNA (ssDNA) are found in many rheumatologic conditions and do not correlate with the course of LN. Sm antibodies are strongly associated with the diagnosis of lupus and the presence of nephritis but are present in only about 25% to 30% of patients. Antibodies to C1q (anti-C1q) have been more closely associated with the activity of LN than anti-dsDNA antibodies and may have a prognostic role in the follow-up of patients with LN.[26]

Serum levels of total hemolytic complement and complement components C3 and C4 are often depressed in untreated SLE and especially in LN. In general, both C3 and C4 are depressed. Preferential C4 depression in lupus patients may reflect activation of the classic complement pathway. In some cases, low C4 with normal C3 in a patient with lupus may reflect genetic C4 deficiency or the presence of cryoglobulins. Preferential depression of C3 is observed in patients with postinfectious glomerulonephritis (PIGN) and the C3 glomerulopathies (see Chapters 22 and 55) rather than in SLE/LN.

TABLE 26.2 The ISN/RPS Classification of Lupus Nephritis and Associated Clinical Correlations

Class	Definition	Urine Findings	Clinical Findings
I: Minimal mesangial LN	Normal glomeruli by LM, but mesangial immune deposits by IF	Usually unremarkable	None relevant to kidney; excellent renal prognosis*
II: Mesangial proliferative LN	Mesangial hypercellularity and/or expansion with mesangial immune deposits	Microscopic hematuria; proteinuria, if present, is usually low-grade	Preserved renal function; hypertension infrequent; excellent renal prognosis*
III: Focal LN III (A): Purely active lesions: focal proliferative LN III (A/C): Active and chronic lesions: focal proliferative and sclerosing LN III (C): Chronic inactive lesions with glomerular scars: focal sclerosing LN	Segmental or global endocapillary or extracapillary glomerulonephritis affecting less than 50% of glomeruli with mesangial and subendothelial immune deposits	Microscopic hematuria; proteinuria	Hypertension possible; renal insufficiency and nephrotic syndrome not unusual; variable renal prognosis
IV: Diffuse LN IV-S (A) or IV-G (A): Purely active lesions: diffuse segmental (S) or global (G) proliferative LN IV-S (A/C) or IV-G (A/C): Active and chronic lesions: diffuse segmental or global proliferative and sclerosing LN IV-S (C) or IV-G (C): Inactive with glomerular scars: diffuse segmental or global sclerosing LN S: >50% of affected glomeruli have segmental lesions G: >50% of affected glomeruli have global lesions	Segmental (S) or global (G) endocapillary or extracapillary glomerulonephritis affecting 50% or more of glomeruli with mesangial and subendothelial immune deposits	Microscopic hematuria; proteinuria	Hypertension; renal insufficiency and nephrotic syndrome frequent; variable renal prognosis
V: Membranous LN	Glomerular basement membrane thickening with subepithelial and mesangial immune deposits	High-grade proteinuria; microscopic hematuria possible	Preserved renal function; nephrotic syndrome common; renal prognosis good* Anti-PLA2R antibody negative
VI: Advanced sclerosing LN	≥90% of glomeruli globally sclerosed without residual disease activity	Microscopic hematuria; proteinuria not unusual	Renal insufficiency/failure expected

IF, Immunofluoresence microscopy; *LM,* light microscopy; *LN,* lupus nephritis.
*As long as no transformation to a proliferative class.

RENAL BIOPSY IN SYSTEMIC LUPUS ERYTHEMATOSUS

Although nephritis may be suspected based on clinical symptoms and laboratory markers, a renal biopsy is required for confirmation, subclassification, prognosis, and management decisions. Indications for biopsy include persistent proteinuria greater than 0.5 mg/mg (0.5 g/day), glomerular hematuria or leukocyturia without proteinuria, and/or unexplained fall in estimated GFR (eGFR). The risks for biopsy-related bleeding are increased when serologic features of the antiphospholipid syndrome are present. A repeat renal biopsy can be considered when there is deterioration or persistence in markers of renal disease with uncertainty as to future treatment.

PATHOLOGY

Although LN may affect all the structures of the kidney, glomerular involvement has been the best characterized. Often, the degree and type of glomerular involvement correlates with the clinical presentation and disease course and also influences treatment decisions. LN is currently classified by the International Society of Nephrology (ISN)/Renal Pathology Society (RPS) system (Table 26.2), which is based on glomerular histology using light and immunofluorescence microscopy. Examples of the different histologic classes are shown in Figs. 26.1 through 26.5.

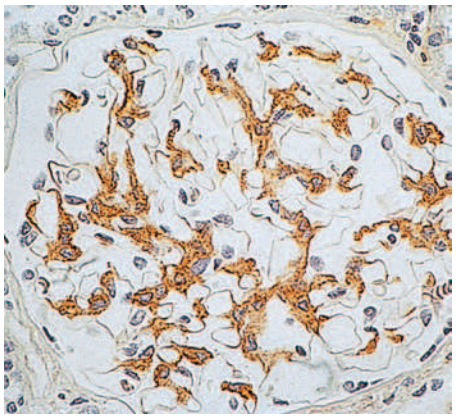

Fig. 26.1 ISN/RPS class I: minimal mesangial lupus nephritis. Light microscopy is normal, but immunoperoxidase shows C1q localization (associated with IgG and C3) throughout the mesangial area (magnification 400X).

Less common glomerular pathologies omitted from the ISN/RPS system include lupus podocytopathy (see later discussion) and pauci-immune crescentic GN (analogous to ANCA-associated renal vasculitis).

Although IgG is generally the dominant glomerular immunoglobulin in LN, IgA and IgM along with the complement components C1q and C3 are often seen as well, giving the "full-house" pattern that is highly

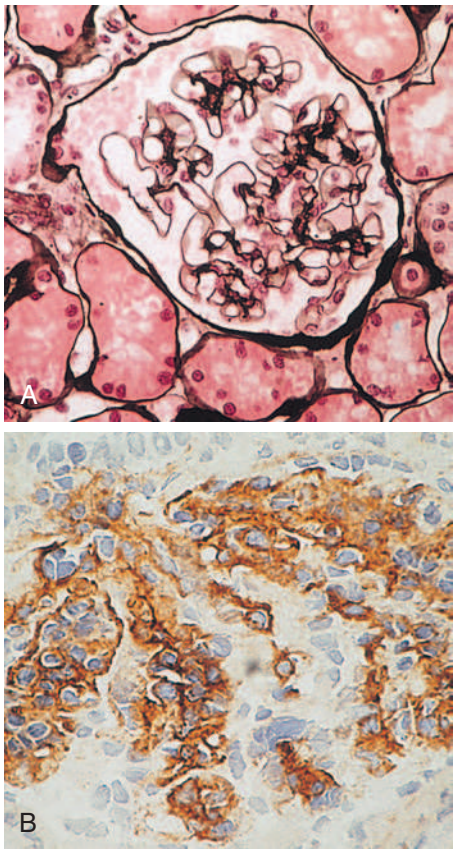

Fig. 26.2 ISN/RPS class II: lupus nephritis (mesangial disease). (A) Mesangial expansion but little increase in tuft cellularity (magnification 400X), and the peripheral capillary walls are normal. (Silver methenamine stain.) (B) Extensive mesangial IgG deposits shown by immunoperoxidase (magnification 400X); the aggregates are just beginning to invade peripheral capillary walls.

suggestive of LN. Strong glomerular C1q staining is also suggestive of LN. Fibrin staining, corresponding to active lesions, is often noted in the glomerular tuft, especially in crescents, if present.

On electron microscopy (EM), the distribution of immune deposits corresponds to immunoglobulin deposits identified by immunohistology. Some electron-dense immune deposits have an organized substructure known as *fingerprinting,* corresponding to the presence of curvilinear microtubular or fibrillar structures in the deposits. Tubuloreticular inclusions, which are tubular structures located in the endoplasmic reticulum of renal endothelial cells, are often found in biopsy specimens of LN patients and are thought to reflect a high interferon milieu.

Tubulointerstitial and Vascular Disease

A deficit of the ISN/RPS classification system is that it does not assess the tubulointerstitial or vascular compartments of the kidney, even though interstitial and vascular damage predicts kidney outcomes.[27] About 50% of patients with LN, predominantly those with proliferative glomerular lesions, have immune aggregates along tubular basement membranes. Interstitial inflammatory cell infiltrates, including T cells, B cells, and monocytes are frequently found, and tubulitis can be seen in active disease (Fig. 26.6). In chronic disease, the interstitium is often expanded by fibrosis and sparser infiltrates. Infrequently, tubulointerstitial nephritis is seen in the absence of glomerular disease and may result in acute kidney injury or renal tubular acidosis.

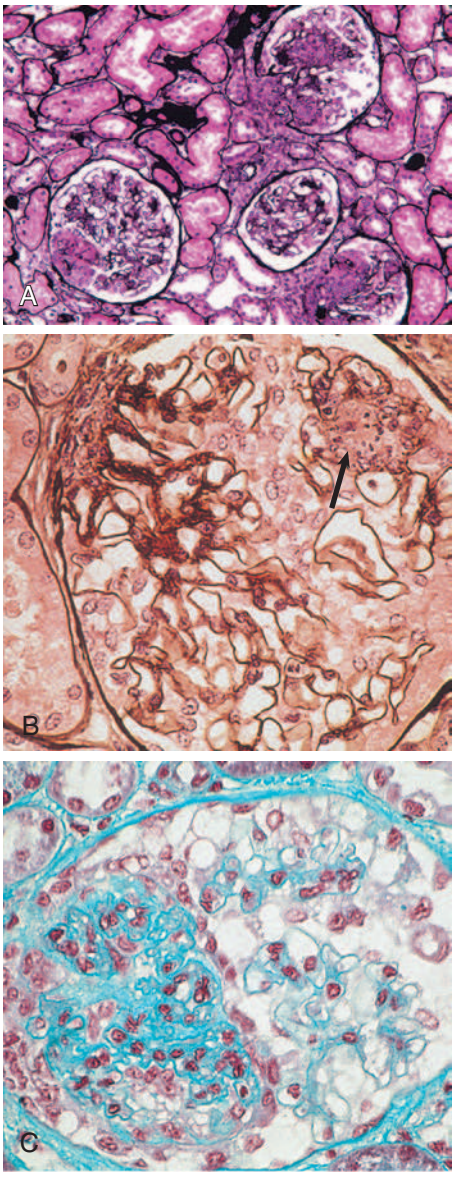

Fig. 26.3 ISN/RPS class III: focal proliferative lupus nephritis. (A) Low-power magnification shows focal and segmental proliferative lesion–active (class IIIA) with less than 50% of glomeruli affected (magnification 100X). (Hematoxylin-eosin [HE] stain.) (B) Area of focal necrosis containing cellular debris, karyorrhexis *(arrow),* is surrounded by an area of cellular proliferation (magnification 400X). (Silver methenamine/HE.) (C) Major focal and segmental proliferative lesion is affecting almost half the glomerular capillary tuft (magnification 400X). (Hematoxylin/lissamine green.)

True vasculitis is rare in LN, but several other vascular lesions can be seen (Fig. 26.7). For example, fibrinoid vessel necrosis or thrombotic microangiopathy may be found in severe proliferative LN.

Transformation of Histologic Appearance and "Silent" Lupus Nephritis

The ISN/RPS class found at diagnostic kidney biopsy for LN is not fixed for an individual's entire clinical course. Those successfully treated for proliferative (class III/IV) LN may transform to a less serious histology, such as class II, or have resolution of inflammatory lesions with scarring and move from an active to a chronic histologic pattern. Conversely, patients initially diagnosed with class II or V LN may transform to proliferative LN, usually class IVG (global).

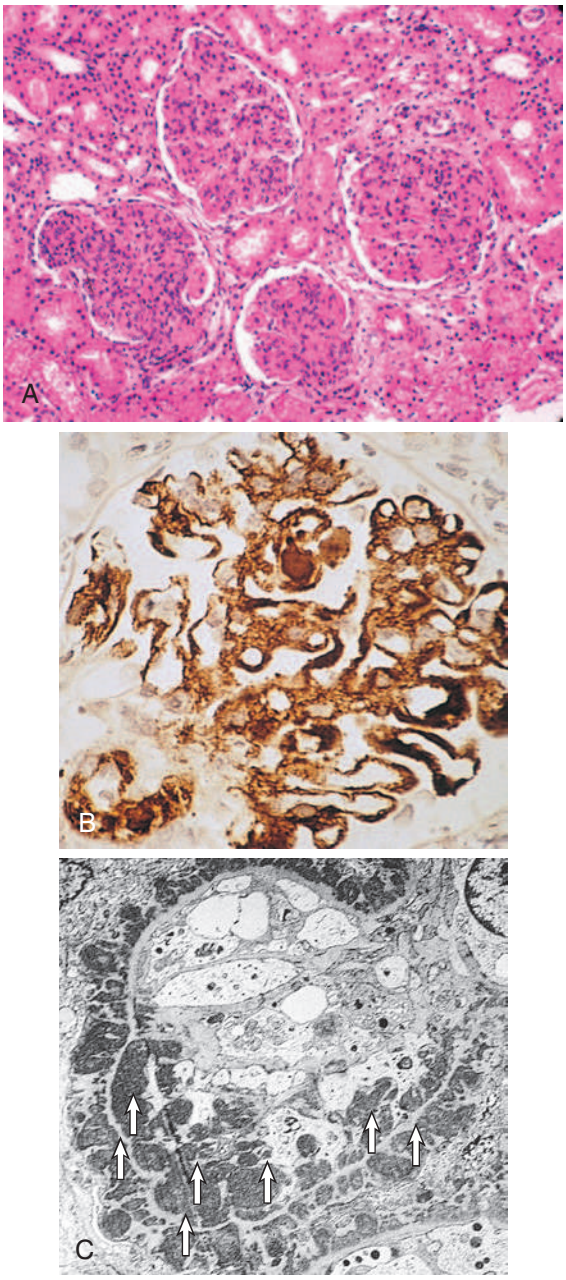

Fig. 26.4 ISN/RPS class IV: lupus nephritis. (A) Active, diffuse proliferative lupus nephritis (magnification 100X). (B) Immunoperoxidase staining shows dense, irregular aggregates of IgG along the peripheral capillary walls (magnification 400X). (C) Electron microscopy reveals the immune aggregates as electron-dense deposits *(arrows)*, predominantly in the subendothelial location.

This class switch is often heralded by increasing proteinuria and activity of the urine sediment.[28] Switching between class IVS (segmental) and G subtypes is not seen and may reflect different pathogenic mechanisms.

The concept of silent LN has been proposed based on kidney biopsies done in patients with SLE but no clinically obvious kidney involvement.[29] A few hundred such patients have been reported, with normal kidney function and no hematuria or proteinuria but with immune complexes in their glomeruli and a histologic pattern most often consistent with class I/II LN. A few such patients even display class III, IV, or V LN. Silent LN may represent a preclinical stage in the evolution of LN.

Clinical, Laboratory, and Histopathologic Correlations and Outcomes

Given the highly variable clinical presentations of LN and the overlap in the clinical features of patients with different types of glomerular injury, kidney biopsy remains the gold standard for diagnosis and subsequent management of LN. Table 26.2 summarizes the typical clinicopathologic correlations of LN. Lupus membranous nephropathy may be distinguished from idiopathic membranous nephropathy by the absence of anti-PLA2r autoantibodies in the circulation and by the presence of all IgG isotypes in the immune deposits, although restriction to the IgG4 isotype has been rarely observed in LN patients.

The importance of the kidney biopsy is underscored by the significant number of patients with SLE and kidney injury who do not have classic LN. For example, up to 24% of patients may have a renal thrombotic microangiopathy, either alone or associated with LN.[30] A small (1.3%) but important subset of patients with SLE present with nephrotic syndrome, with or without acute kidney injury, but their kidney biopsies appear normal on light microscopy, mimicking minimal change disease (MCD), or show segmental sclerosis, mimicking focal segmental glomerulosclerosis (FSGS).[31] EM shows diffuse podocyte effacement, without immune complexes. These patients, although not classified by ISN/RPS, have lupus podocytopathy and like MCD or FSGS, often respond to corticosteroids alone. A recent Chinese study showed that remission in response to corticosteroids for 12 weeks occurred in 75% of patients with podocytopathy and more than 90% when those with FSGS-like lesions were excluded.[32] The risk for relapse exceeded 50%, and at repeat kidney biopsy half of the relapsed patients had transformed to class IV or V LN. Although these results may not be generalizable to a non-Asian population, they underscore the importance of histology-driven treatment decision analysis.

Long-Term Prognosis and Kidney Histology

Features of reversible (active) or irreversible (chronic) damage on kidney biopsy are captured by the National Institutes of Health (NIH) activity and chronicity indices (Table 26.3). Similar to other types of GN, long-term kidney prognosis is poor if the biopsy sample shows extensive glomerulosclerosis or interstitial fibrosis and tubular atrophy. In patients with less extensive scarring the activity and chronicity indices at diagnostic biopsy may not correlate with the course of LN.[28] In contrast, after treatment, persistent activity (activity index >2) on repeat kidney biopsy is associated with a worse long-term renal prognosis; high chronicity (chronicity index >6) at repeat biopsy shows a similar trend.[28]

TREATMENT

It is useful to divide the treatment of patients with active proliferative LN into initial and maintenance phases. The *initial or induction phase* addresses acute life- or organ-threatening disease. The *maintenance phase* focuses on consolidating remissions, preventing relapses and the long-term management of chronic, more indolent disease.

The ISN/RPS biopsy classification should guide initial therapy (see Table 26.2). In general, the immunosuppressive treatment of extrarenal lupus manifestations is sufficient for class I and II LN. The combination of high-dose corticosteroids plus an immunosuppressive agent is mainly used for patients with active focal proliferative LN (classes IIIA and IIIA/C), active diffuse proliferative LN (classes IVA and IVA/C), and membranous lupus (class V).

Although the goal of initial therapy is to induce a complete renal remission, this occurs in only 30% to 40% of LN patients by 12 months.[33] Most studies define complete renal response as a reduction in proteinuria

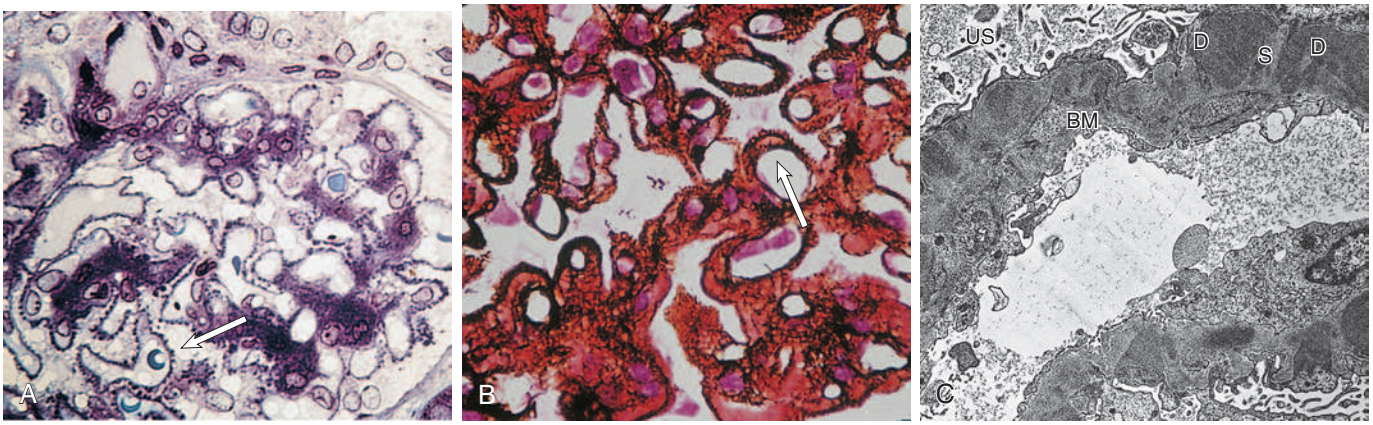

Fig. 26.5 ISN/RPS class V: membranous lupus. (A) Thick (~0.5 mm) araldite-embedded section stained with toluidine blue shows not only the extramembranous material in dark blue *(arrow)* but also the presence of mesangial deposits, which are common in lupus membranous nephropathy (magnification 400X). (B) Silver methenamine–stained section shows some double contouring of the silver-positive basement membrane *(arrow)* and subendothelium-deposited material, as well as the characteristic silver-positive spikes of basement membrane–like material (magnification 400X). (C) Electron micrograph shows the predominantly subepithelial electron-dense deposits *(D)* separated by protrusions of basement membrane material (spikes, *S*). *BM*, Basement membrane; *US*, urinary space.

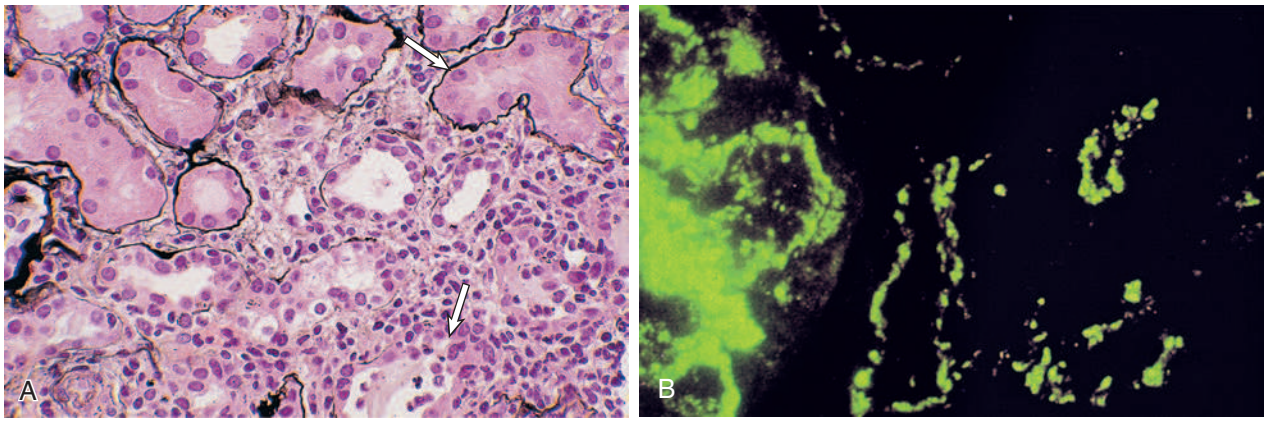

Fig. 26.6 Interstitial lupus nephritis. (A) Interstitial infiltrate invading and destroying tubules (tubulitis). Tubular basement membranes, which stain black with silver, are digested in the areas of tubulitis *(arrow)* (magnification 400X). (B) Immunofluorescence shows aggregates of C3 in the tubular basement membrane *(right)* as well as within the glomerulus *(left)*. Such tubular basement membrane aggregates are common in lupus nephritis, being found in 60% to 65% of biopsy specimens overall and with increasing frequency from class II (20%) to class IV (75%).

TABLE 26.3 The Point System Used to Calculate Lupus Nephritis Biopsy Activity and Chronicity Indices*

	LESIONS CONTRIBUTING TO ACTIVITY INDEX						LESIONS CONTRIBUTING TO CHRONICITY INDEX			
Semiquantitative Lesion Score*	Cellular Crescents	Glomerular Necrosis: Karyorrhexis	Glomerular Neutrophils	Endocapillary Proliferation	Large Subendothelial Immune Deposits	Interstitial Inflammation	Glomerular Sclerosis	Fibrous Crescent	Tubular Atrophy	Interstitial Fibrosis
None	0	0	0	0	0	0	0	0	0	0
Mild	2	2	1	1	1	1	1	1	1	1
Moderate	4	4	2	2	2	2	2	2	2	2
Severe	6	6	3	3	3	3	3	3	3	3

*Maximum activity index is 24; maximum chronicity index is 12.

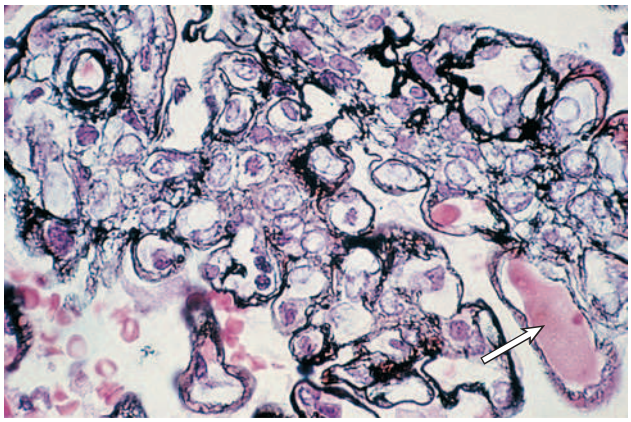

Fig. 26.7 Vascular damage in lupus nephritis. Thrombus *(arrow)* occludes a glomerular capillary loop in this class IV biopsy specimen. Such a thrombus contains platelets and cross-linked fibrin as well as immunoglobulins and thus has some characteristics of true thrombus (magnification 400X). (Silver methenamine/hematoxylin stain.)

to less than 0.5 or a ratio of urine protein to creatinine of less than 0.5 absence of glomerular hematuria or red blood cell (RBC) casts, and normalization or stabilization of GFR. The predictive value of glomerular hematuria in the definition of remission has recently been questioned.[34] It may be best to view induction as the first step of controlling renal inflammation to allow healing of kidney injury, which translates clinically into stabilization or improvement of renal function, attenuation of proteinuria, and reduction in urine sediment activity. However, all of these kidney parameters may not normalize by the end of induction. The term *partial response* has required a 50% reduction in proteinuria to subnephrotic levels and stability or improvement in GFR and is usually achieved before complete response criteria are met.

Evidence in support of specific therapeutic agents and regimens should be treated with caution because of small study sizes, uncontrolled or nonblinded methods, and heterogeneity in both LN presentations and responses to therapy. Therapeutic toxicity is a major contributing factor to morbidity and mortality, so claims of efficacy must be balanced against adverse events. Other factors, such as ethnicity, referral practice, center experience, and use of concomitant medications vary across studies and over time, reducing the generalizability of some study results.

In addition to the immunosuppressive regimens discussed next, the kidney protective measures outlined in Chapter 79 should be used as appropriate. Furthermore, unless contraindicated, all patients with LN should be treated with an antimalarial agent because this was associated with a lower risk for developing LN and ESRD and improved responses to LN treatment.[35]

Proliferative Lupus Nephritis: Induction

Corticosteroids

High-dose corticosteroids are used in all current induction regimens and are considered the standard of care. Prednisone (or prednisolone) is most often started at 0.5 to 1 mg/kg/day ideal body weight (no more than 80 mg/day) and then reduced to approximately 10 mg/day or less by 3 to 6 months. There is variation in the use of intravenous methylprednisolone infusions (0.5 to 1 g daily for 1 to 3 days) either as a routine component of induction therapy followed by lower oral corticosteroid dosing or for nephritis perceived to be severe. Adverse effects of corticosteroids have led to attempts to minimize prolonged courses of high-dose corticosteroid therapy in lupus patients. A study comparing cyclophosphamide alone to cyclophosphamide plus high-dose corticosteroids as initial therapy in a White population with mild-moderate disease showed comparable complete and partial remission rates at 2 years.[36] An observational study (RITUXILUP) used anti–B cell therapy (rituximab) plus 2 doses of intravenous methylprednisolone followed by maintenance with mycophenolate mofetil (MMF) in the absence of oral steroids.[37] The overall complete plus partial renal response rate was 88%, with a median time to remission of 9 months. During the follow-up period 19 LN flares occurred at a median of 24 months after remission and 79% were managed without oral steroids.

Immunosuppressive Agents

Although corticosteroids effectively control proliferative LN, long-term kidney function was better preserved with fewer LN relapses at 3 to 5 years if corticosteroids were combined with cyclophosphamide during initial therapy.[38] These data highlight the need for long-term follow-up in assessing initial LN therapies. Both daily oral and intravenous pulses of cyclophosphamide are effective in LN, although intravenous cyclophosphamide given as 6-monthly pulses of 0.5 to 1 g/m^2 (NIH protocol) has been the standard of care for several years. The Euro-Lupus Nephritis Trial compared lower dose (500 mg) cyclophosphamide intravenously every 2 weeks for 3 months (total of 3 g) followed by azathioprine maintenance to the NIH protocol, and similar efficacy with less toxicity and fewer infections short term[39] and after 5 to 10 years.[40] Although the Euro-Lupus cyclophosphamide regimen was initially tested in a mainly White population, similar rates of remission induction are achieved with low-dose cyclophosphamide in Black, Hispanic, and Southeast Asian patients.[41,42]

Several randomized clinical trials involving multiethnic cohorts have shown that oral MMF plus corticosteroids for 6 months followed by maintenance therapy is at least as effective as 6-monthly pulses of cyclophosphamide (NIH protocol) plus corticosteroids followed by maintenance therapy.[33] MMF also showed similar treatment response rates to the Euro-Lupus regimen at 24 weeks.[42] Cyclophosphamide has been favored in patients presenting with marked renal impairment or severe class IV LN on biopsy, but there are no convincing differences in outcome between MMF and cyclophosphamide induction for such patients.[43] No improvement in overall mortality or severe infections has been seen with MMF; gastrointestinal disturbances are more frequent, but the risk for amenorrhea is lower than with cyclophosphamide.

Optimal MMF dosing and adjustment for different patient subgroups remains unclear. A dosing range of 2 to 3 g/day has been recommended as a target with dose reduction for intolerance and in certain ethnic subgroups. The MMF metabolite mycophenolic acid (MPA) has been pharmacokinetically monitored as the area under the concentration-time curve (AUC) in patients receiving MMF for LN induction or maintenance. However, monitoring yields highly variable AUCs after empiric MMF dosing with no correlation between AUCs and trough drug levels, and as yet there is no consensus on a target MPA AUC and no correlation of adverse events with AUC.[44]

Long-term follow-up of patients who participated in clinical trials of MMF versus cyclophosphamide found no differences in renal outcome, although one study reported a non-significant increase in renal flares in patients induced with MMF.[45] Differences in response between ethnic and geographical subgroups have been suggested but not confirmed.[46] However, a retrospective analysis of a Korean cohort showed similar remission rates for MMF and cyclophosphamide, but more relapses and a higher incidence of ESRD in the MMF group.[47] A meta-analysis showed a reduction in the 10- and 15-year risk of ESRD from LN between 1970 and the mid-1990s, coincident with the use of cyclophosphamide as standard-of-care induction therapy. It is of some concern that from the mid-1990s until the late 2000s ESRD plateaued, but then increased slightly, coincident with the era of MMF induction.[4]

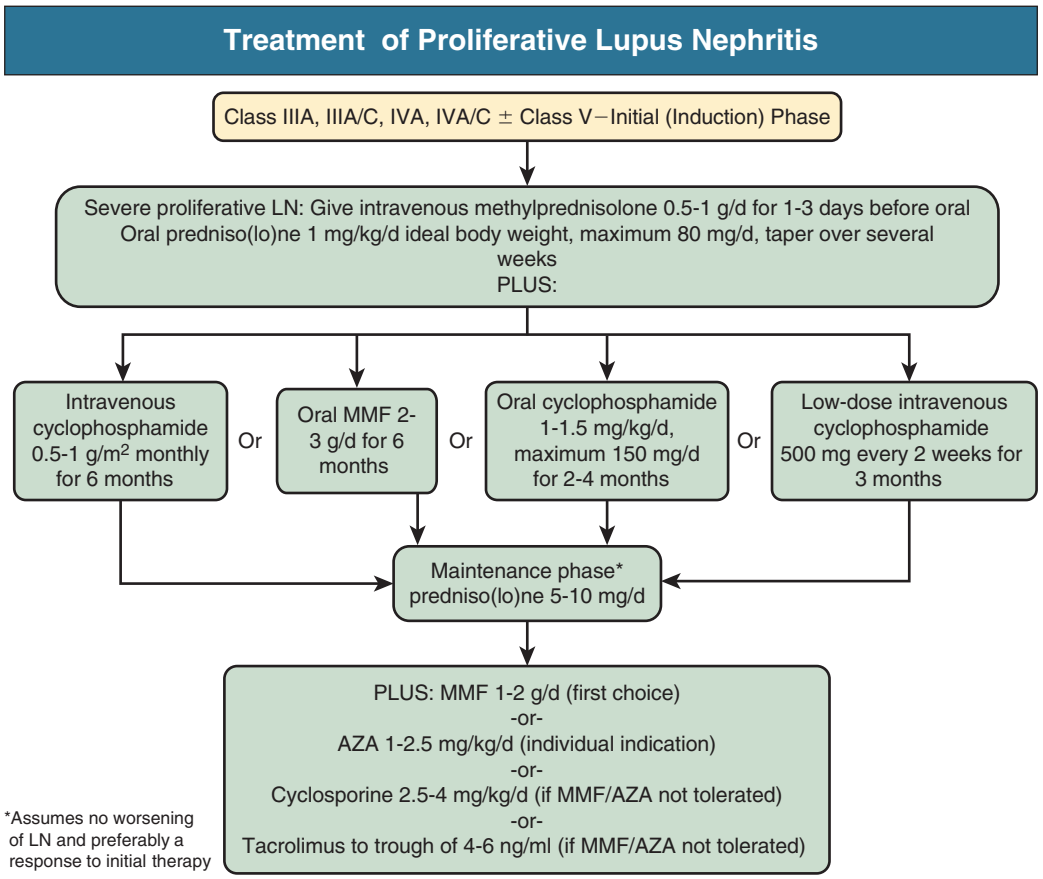

Fig. 26.8 Approach to the induction and maintenance treatment of proliferative lupus nephritis (LN). *AZA,* Azathioprine; *MMF,* mycophenolate mofetil.

The ACR, the Kidney Disease: Improving Global Outcomes (KDIGO), and the European League Against Rheumatology/European Renal Association (EULAR/ERA) have independently developed evidence-based guidelines for LN therapy. These are synthesized in the treatment algorithm presented in Fig. 26.8.[48-50]

Other Immunosuppressive Strategies

Azathioprine (AZA) has been used in combination with corticosteroids for the induction of remission in proliferative LN. A randomized trial comparing AZA with cyclophosphamide found no difference in eventual outcome but more relapses, doubling of serum creatinine concentration, and more chronicity on repeat biopsy in the AZA group.[51] Although AZA is not recommended as first-line therapy by the major LN guidelines, it remains an option when MMF or cyclophosphamide are unavailable, undesirable, or contraindicated.

The calcineurin inhibitors (CNIs) tacrolimus and cyclosporine have been tested as LN induction therapies and compared favorably in the short term.[33] A trial from Hong Kong randomized 150 patients to tacrolimus or MMF for 6 months, with responders receiving AZA for maintenance.[52] Complete remission rates were approximately 60% in each group, although there was a trend toward more renal flares at 5-year follow-up in the tacrolimus group. Additionally, the primary proteinuria end-point was less than 1 g/day, which may have inflated the complete response rate. Another Asian study took a multitargeted approach, randomizing patients to tacrolimus plus MMF and corticosteroids or the NIH protocol of cyclophosphamide plus corticosteroids. The multitarget induction regimen was associated with a higher remission rate than cyclophosphamide but more patients in the multitarget group withdrew because of adverse events at 6 months, despite lower rates of leukopenia and upper gastrointestinal symptoms in this group.[53] Although short-term, a preliminary report indicated a higher 6-month complete renal response rate (33% vs. 19%) in a multiethnic LN cohort treated with the CNI voclosporin plus corticosteroids and MMF compared with corticosteroids and MMF alone.[54] In future studies, it will be important to verify preservation of long-term kidney function and improvements in histology in CNI-treated LN patients. Furthermore, it is not clear that proteinuria is an appropriate renal remission end-point for comparing a CNI-based regimen to other drugs because of the known nonimmune antiproteinuric effects of CNIs.

Biologic Agents

Rituximab, an anti-CD20 monoclonal antibody that depletes B cells, has led to improved disease control in patients with LN with relapsing or refractory disease in retrospective and nonrandomized trials. However, in a large randomized, prospective trial, when used in combination with MMF and corticosteroids for induction, rituximab did no better at 1 year than placebo.[55] The role of rituximab in LN is therefore currently uncertain, but it may be considered when other therapies have failed.

Abatacept, a fusion protein of CTLA4 and the immunoglobulin heavy chain, blocks T and B cell co-stimulation. In two large randomized controlled trials of proliferative LN, abatacept proved no better than placebo on a background of MMF and corticosteroids[56] or a background of low-dose cyclophosphamide and corticosteroids.[41] However, a retrospective analysis of data from the first trial using different definitions of remission suggested that abatacept may have been effective with somewhat less stringent response criteria.

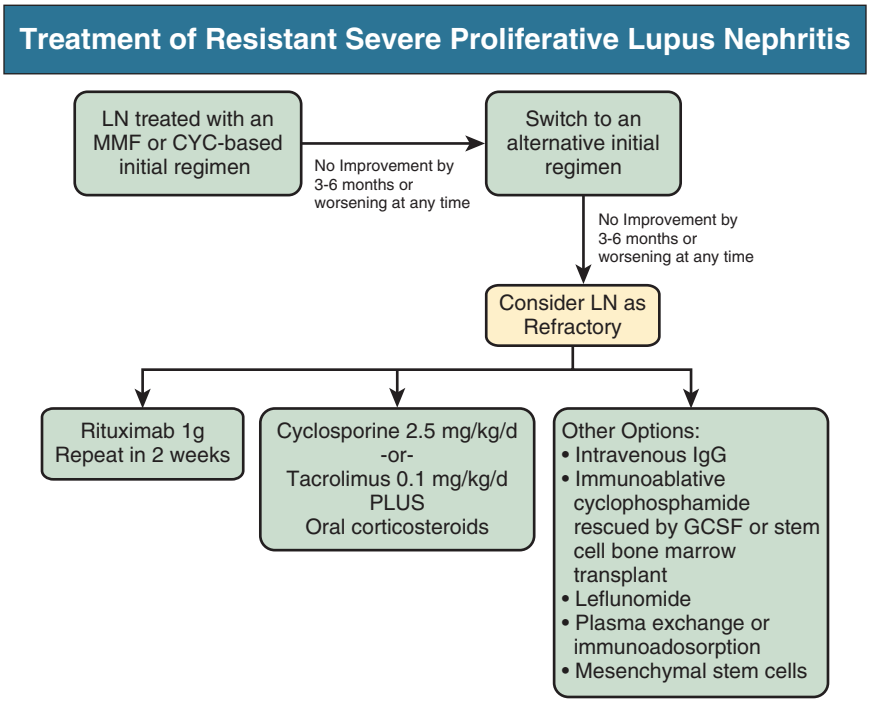

Fig. 26.9 Treatment of resistant proliferative lupus nephritis (LN). *CYC,* Cyclophosphamide; *GCSF,* granulocyte colony-stimulating factor; *IgG,* immunoglobulin G; *MMF,* mycophenolate mofetil.

Other pathogenic mediators currently being targeted in SLE or LN with monoclonal antibodies are the B cell–stimulating cytokine BAFF and the type 1 interferon, IFN-α. Studies using an anti–IL-6 antibody and an anti-TWEAK antibody failed to show efficacy in proliferative LN.[57,58]

Resistant Proliferative Lupus Nephritis

There is no uniformly accepted definition of resistant or refractory LN. Up to one third of proteinuric nonresponders to induction therapy have inactive histologic findings on repeat biopsy. Fig. 26.9 outlines therapies that have been attempted for refractory disease. Most of these therapies were investigated in small, uncontrolled, and retrospective studies.

Rituximab has had some success in patients with refractory disease, benefitting about 30% of nonresponders.[59] In a registry, three different rituximab regimens often in combination with other immunosuppressives were tried in 68 patients, and after 12 months 31% were in complete renal remission.[60] Although no benefit was seen with the addition of plasma exchange to immunosuppressive therapy for remission induction in LN, the removal of circulating antibodies and other immune reactants may be considered for patients with high serologic activity and progressive refractory nephritis or thrombotic microangiopathy.[61] Intravenous immunoglobulin and CNIs have shown benefit in small series of patients with resistant LN.[62,63] Infusion of allogeneic mesenchymal stem cells derived from umbilical cord or bone marrow has been tested in a cohort of patients with refractory LN.[64] At 12 months, about 23% of patients had a complete renal response, but 40% of patients were considered to have treatment failures. Finally, for patients with life-threatening resistant disease, small pilot studies have tested total lymphoid irradiation and immunoablation by high-dose cyclophosphamide and antithymocyte globulin, with or without autologous stem cell reconstitution. These approaches have led to sustained treatment-free remissions, but toxicity and treatment-related mortality needs to be carefully weighed against potential benefit.[65]

Renal Response to Initial Therapy

Achieving complete remission of LN predicts a good long-term outcome with more than 90% 5-year patient and renal survival rates compared with only 69% and 45% for the group not achieving remission.[10] Partial remissions are also associated with improved outcomes. Complete and partial renal responses to MMF or cyclophosphamide range from 18% to 85% at 6 months and 32% to 85% at 12 months, and about half of treated LN patients achieve a complete or partial response by 1 year, with an additional 25% by 2 years.[66] Predictors of remission at the start of treatment have traditionally included lower baseline serum creatinine concentration, lower baseline urinary protein excretion, favorable renal histologic class, lower chronicity index, stable GFR after 4 weeks of therapy, and White race.

A post-hoc analysis of the Euro-Lupus low-dose cyclophosphamide trial found an absolute level of proteinuria less than 0.8 g/day 1 year after starting induction treatment was the single best predictor of good renal outcome after at least 7 years of follow-up.[34] The other 12-month predictors examined were serum creatinine concentration below 1 mg/dl (88 μmol/l) and fewer than 5 urine RBCs per high-power field. In another study after induction with low-dose cyclophosphamide, an absolute level of proteinuria less than 0.7 g/day 1 year after starting induction treatment again was the single best predictor of good renal outcome after at least 7 years of follow-up .[67] However, the negative predictive value of proteinuria alone was low in both analyses, and many patients who did not achieve proteinuria less than 0.7 to 0.8 g/day at 1 year still maintained good kidney function over time. Additionally, most of these patients were White.

Proliferative Lupus Nephritis: Maintenance Therapy

Because it generally takes months for proteinuria and serum creatinine concentrations to decrease to baseline levels after beginning LN treatment,[68] one important aspect of maintenance immunosuppression is to consolidate renal responses into complete and partial remissions using drugs with a lower side effect profile than induction drugs. Additionally,

maintenance therapy should ideally prevent renal flares and attenuate or abrogate the development of chronic kidney disease. Current strategies for LN maintenance therapy are presented in Fig. 26.8.

Early investigations showed maintenance cyclophosphamide was superior to corticosteroids alone.[38,69] Subsequent work demonstrated that less intense maintenance immunosuppression with AZA or MMF was as effective as maintenance cyclophosphamide and was associated with improved patient morbidity and survival.[70]

Corticosteroids, tapered from the initial treatment period, are generally continued during the maintenance period, but at low dose (see Fig. 26.8). Both daily and alternate-day corticosteroid regimens have been used, but there is no consensus as to the optimal duration of corticosteroid therapy.

Two randomized clinical trials compared AZA 2 mg/kg/day and MMF 2 g/day for LN maintenance. In multiethnic patients who received induction with cyclophosphamide or MMF, MMF maintenance therapy was better than AZA at preventing renal flares, preserving renal function over 3 years, and delaying progression to ESRD.[45] In a study of mainly European White patients (MAINTAIN Nephritis trial), AZA and MMF were equally effective at preventing renal flares over 4 years after initial treatment with low-dose cyclophosphamide.[71] Although MMF appears to be the maintenance drug of choice for most LN patients, therapy should be individualized. In some patients, AZA may be preferred, such as for patients in complete remission who want to become pregnant. Finally, two randomized trials compared the CNIs tacrolimus and cyclosporine to AZA for maintenance.[72,73] Although both trials were underpowered and the tacrolimus trial had only 6 months of follow-up, both demonstrated that CNIs were as effective as AZA in preventing renal flares. Given fewer data for tacrolimus and cyclosporine, and concerns over long-term nephrotoxicity, CNIs are best reserved for patients who are unable to take MMF or AZA.

The duration of maintenance therapy, and whether maintenance can ever be stopped in patients with LN remain open questions. In general, LN patients are placed on maintenance immunosuppression for several years. Withdrawal of maintenance therapy is the subject of an ongoing RCT (NCT01946880). Therapy reduction was examined retrospectively in European LN patients who had achieved complete remission with normal kidney function, proteinuria of 0.5 g/day or less, inactive urine sediment, and no extrarenal SLE signs or symptoms.[74] The cohort started with 73 patients, 20 of whom experienced flare when prednisone was tapered to a very low dose. Therapy was completely stopped in the other 52 patients, a median of 73 months after beginning induction therapy. These patients were then followed for a median of 172 months, and 61% never relapsed. There were 15 cases of LN and 5 nonrenal flares that occurred at a median of 37 months after stopping maintenance. Risk factors for LN flare after withdrawal of therapy in this cohort included shorter duration of overall treatment, decreased use of antimalarials, and lack of maintenance cytotoxic drug use.

Membranous Lupus Nephropathy

Membranous nephropathy is often diagnosed in association with proliferative forms of LN. In these patients, treatment is directed at the proliferative component. Alternatively, the combination of low doses of corticosteroids, MMF, and a CNI, the so-called multitarget regimen, has shown considerable success in an Asian cohort of mixed membranous and proliferative LN.[75]

The optimal treatment of pure class V LN remains unclear, but a reasonable treatment algorithm is presented in Fig. 26.10. KDIGO

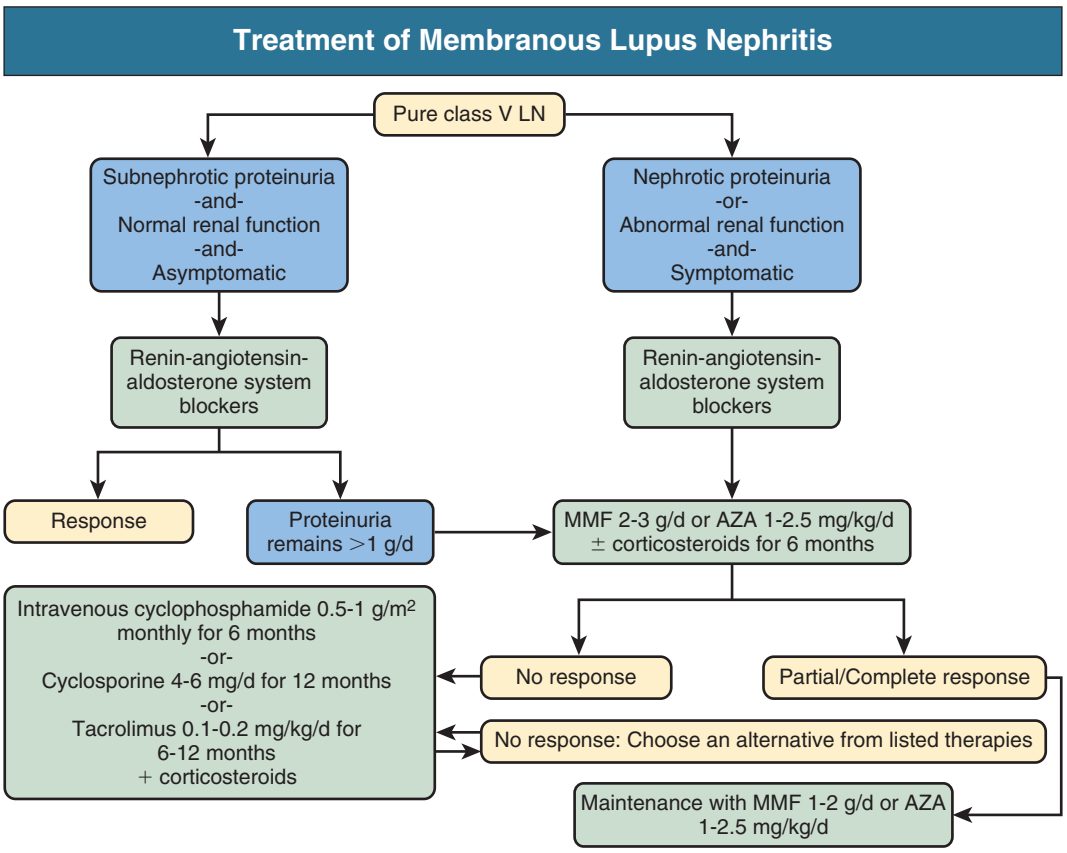

Fig. 26.10 Treatment of membranous lupus nephritis. *AZA,* Azathioprine; *MMF,* mycophenolate mofetil.

guidelines suggest renoprotective and antiproteinuric therapies for patients with subnephrotic proteinuria and no renal impairment, with immunosuppression reserved for patients with nephrotic syndrome and/or renal impairment.[48] The only small RCT in patients with class V LN compared cyclophosphamide or cyclosporine to corticosteroids alone.[76] The patients studied had preserved kidney function and a mean proteinuria of almost 6 g/day. Complete and partial remissions were more frequent in the cyclophosphamide and cyclosporine-treated patients. Cyclosporine induced remission more rapidly than the other drugs, but LN relapses were fewer in the cyclophosphamide group. Two trials of MMF versus cyclophosphamide as initial therapy of LN included 84 patients with pure membranous nephropathy among the 510 patients enrolled.[77] Remissions, relapses, and courses were similar in the class V patients treated with MMF and cyclophosphamide. Azathioprine plus corticosteroids also has been successful in patients with membranous LN, but these studies have been observational or retrospective.[78]

Long-Term Monitoring of Lupus Nephritis Patients

The relapse (flare) rate for LN ranges from 35% to 60%, depending on the population studied, the criteria for relapse, and the maintenance therapy used,[78-80] suggesting that LN patients in remission be closely followed. We recommend quarterly monitoring (including blood pressure, kidney function, proteinuria, urinary sediment, serum C3 and C4) with anti-dsDNA measured at least biannually.[50] Although changes in serology alone do not warrant therapeutic action, they may serve as an early warning that autoimmune activity is increasing and patients should be watched even more closely for flare.

Repeat kidney biopsies should be considered during long-term management of LN.[66] At LN flare, a repeat biopsy should be considered if a change in histologic class is suspected. Patients with proliferative LN tend to remain proliferative at flare, but patients with class II and V not infrequently develop a proliferative component. Evaluation of persistent proteinuria and declining kidney function in LN also may benefit from a repeat biopsy. Several studies have shown considerable discordance between histologic activity and clinical activity. Persistent proteinuria may be due to persistent inflammatory disease activity and require further immunosuppression or may be due to chronic damage and nephron loss, in which immunosuppression will not be beneficial. When considering reduction or withdrawal of maintenance therapy a repeat biopsy may help because even patients with sustained clinical inactivity still may have histologic activity.[66]

ANTIPHOSPHOLIPID ANTIBODY SYNDROME, ATHEROSCLEROSIS, AND PREGNANCY IN LUPUS NEPHRITIS

Intrarenal thrombosis caused by the antiphospholipid antibody syndrome is found in 30% of patients with SLE and may occur in the presence or absence of LN (see Chapter 28). The mainstay of treatment for antiphospholipid nephropathy has been anticoagulation plus chloroquine or hydroxychloroquine, although immunosuppressive agents also have been used.

Patients with lupus have increased risk for atherosclerotic complications and greater atherosclerotic plaque burden compared with age-matched controls, and these factors contribute to morbidity and mortality in SLE.[74] The risk for heart attack in a young woman with SLE is 50 times greater than that of a healthy woman, and even older women with SLE have 2.5 to 4 times the risk for myocardial infarction of age-matched controls. After adjustment for all traditional cardiovascular risk factors, patients with SLE have a 7- to 10-fold higher risk for nonfatal and a 17-fold higher risk for fatal myocardial infarctions. Chronic kidney disease, a frequent outcome of LN, is also a cardiovascular risk factor. Reduction of atherosclerotic risk should focus on blood pressure control (goal of 130/80 mm Hg), use of statins and hydroxychloroquine to correct lipid abnormalities,[81] and reduction of inflammatory disease activity.

The effects of SLE and LN on pregnancy and fetal outcomes, and the effects of pregnancy on LN activity, are discussed in Chapter 43.

END-STAGE RENAL DISEASE AND RENAL TRANSPLANTATION

Although approximately 10% of all lupus patients develop ESRD, the overall proportion of patients with ESRD attributable to lupus is 1% to 2%.[3,82] Patients of African ancestry are at higher risk for ESRD. Extrarenal lupus is often quiescent by the time patients reach ESRD, but those with active extrarenal disease may require immunosuppression while receiving renal replacement therapy. It has been suggested that patients with LN defer transplantation for 3 to 6 months to allow SLE to become inactive; however, recent data suggest that there is an increased risk for allograft failure if LN patients wait more than 3 months before transplantation.[83] Interestingly, the correlation between longer wait times and increased allograft failure was not seen in African American patients. Survival of lupus patients on dialysis or after kidney transplantation is similar to those of patients with other renal diseases.[82] Thrombotic events are increased in LN recipients, especially if they are positive for antiphospholipid antibody, but this does not appear to correlate to a diminished allograft survival.[82] Recurrent LN after kidney transplantation is rare, occurring in only about 1% of patients.[84]

SELF-ASSESSMENT QUESTIONS

1. A 21-year-old African American woman presents for initial therapy of lupus nephritis (LN). She was diagnosed with systemic lupus erythromatosus (SLE) 1 year ago, when she was found to have alopecia, malar rash, and arthralgias with antinuclear antibodies (ANA) and double-stranded DNA (dsDNS) antibodies. At that time, urine sediment was unremarkable, serum creatinine was 0.6 mg/dl, and she had no proteinuria. She was treated with low-dose corticosteroids and hydroxychloroquine, with resolution of her symptoms. Over the past month, she noticed foamy urine and mild ankle swelling. Evaluation showed blood on her urine dipstick, 24-hour urine with 4 g protein, serum creatinine of 1 mg/dl, and a rising dsDNA titer with both C3 and C4 now newly decreased. A kidney biopsy revealed ISN class IVA lupus nephritis, with 25% cellular crescents and areas of glomerular capillary necrosis. The patient is young and may want children in the future. Considering options for initial therapy for this patient's lupus nephritis, which of the following statements is correct?
   A. She should be treated with intravenous rituximab for initial therapy.
   B. She should be treated with high-dose corticosteroids and azathioprine for initial therapy.
   C. Mycophenolate mofetil (MMF) or cyclophosphamide is an appropriate choice. Ovarian protection or cryopreservation of eggs should be considered if cyclophosphamide is to be used.
   D. She should not receive MMF because she wants to get pregnant in the future.
2. A 24-year-old African American female has been treated for the last 6 months with MMF (2 to 3 g/day) and a tapering dose of corticosteroids for active focal proliferative lupus nephritis (ISN class IIIA). Her initial proteinuria decreased from 3.4 g daily to 1.2 g daily, urine sediment is inactive, and serum creatinine decreased from 1.6 to 0.9 mg/dl over the 6 months of therapy while anti-dsDNA titer declined and serum complement values returned to normal. What is the optimal therapy for this patient at this time?
   A. Continue the current dose of MMF for an additional 6 months and then taper slowly over 1 year.
   B. Given the persistent proteinuria, change to intravenous cyclophosphamide at 500 mg every 2 weeks for 6 doses and then administer azathioprine at 2 mg/kg daily.
   C. Reduce the MMF to 1000 mg bid and plan to continue for 3 years unless otherwise indicated.
   D. Change to azathioprine at 2 mg/kg/day, and plan to continue for 4 years unless otherwise indicated.
3. A 32-year-old White woman with a history of LN in the past wants to become pregnant and is concerned about flares during the pregnancy. In considering medications that have been used successfully in SLE patients during pregnancy, you discuss use of which of the following medications?
   A. Corticosteroids
   B. Intravenous cyclophosphamide, but not oral cyclophosphamide
   C. Rituximab
   D. Mycophenolate mofetil
4. A 28-year-old White female patient presents with nephrotic syndrome and is found to have class V membranous lupus on renal biopsy. Based on randomized controlled trials, which of the following medications has *not* been shown to be effective in treating this pattern of lupus nephritis?
   A. Intravenous cyclophosphamide
   B. Intravenous rituximab
   C. Oral cyclosporine
   D. Oral MMF

Renal Amyloidosis and Glomerular Diseases With Monoclonal Immunoglobulin Deposition

Pierre Ronco, Pierre Aucouturier, Bruno Moulin

The glomerular capillaries are a favorite site for the deposition of abnormal, misfolded, or aggregated proteins. In most patients, the resulting diseases are caused by a monoclonal immunoglobulin or subunit thereof and can be classified into two categories by electron microscopy (EM) (Table 27.1). The first category includes diseases with fibril formation, mainly amyloidosis, and diseases with microtubule formation, including cryoglobulinemic glomerulonephritis (see Chapter 21) and immunotactoid glomerulonephritis (GN). The second disease category is characterized by nonorganized electron-dense granular deposits. These deposits are localized along basement membranes in most tissues, especially in the kidney, and define a disease termed *monoclonal immunoglobulin deposition disease* (MIDD). In other rare cases, termed *proliferative glomerulonephritis with monoclonal immunoglobulin deposition* (PGNMID), monotypic immune complex–like deposits are observed.

RENAL AMYLOIDOSIS

General Characteristics of Amyloidosis

Definition

Amyloidosis is a generic term for a family of diseases defined by morphologic criteria. The diseases are characterized by the deposition in extracellular spaces of a proteinaceous material. Amyloid deposits are composed of a felt-like array of 7.5- to 10-nm-wide rigid, linear, nonbranching, aggregated fibrils of indefinite length. One amyloid fibril is made of two twisted 3-nm-wide filaments, each displaying the typical "cross-β"structure, where antiparallel β-sheets are perpendicular to the filament axis.

Amyloid Precursor–Based Classification

Amyloidoses are classified according to the nature of the precursor protein that composes the main component of fibrils[1] (Table 27.2). The amyloidogenic propensity is related to the ability of this precursor to form intermolecular β-sheets, and is enhanced by overproduction or impaired clearance of the precursor.

Renal amyloidoses mostly include immunoglobulin light-chain (AL) and systemic secondary (AA) amyloidoses. Other precursors, such as transthyretin, fibrinogen, apolipoprotein A-I, and lysozyme, are responsible for rare familial cases.

Other Components of All Amyloid Fibrils

Glycosaminoglycans (GAGs) are found tightly associated with amyloid fibrils extracted from involved tissues. GAGs are polysaccharide chains made of repeating hyaluronic acid–hexosamine units normally linked to a protein core, thus forming proteoglycans. Proteoglycans, mostly of the heparan sulfate type, appear to induce and stabilize the β-pleated amyloid structure.

Another constituent of all amyloid deposits is serum amyloid P component (SAP). SAP is resistant to proteolytic digestion, and coating of amyloid fibrils with SAP could result in their protection from catabolism. The high affinity of SAP toward amyloid has been exploited for scintigraphy with [^{123}I]-SAP. CPHPC (R-1-[6-[R-2-carboxy-pyrrolidin-1-yl]-6-oxo-hexanoyl] pyrrolidine-2-carboxylic acid) is a proline-derived small compound that specifically binds to SAP and allows rapid decreases in serum SAP levels. The combination of CPHPC with an anti-SAP antibody targets amyloid deposits and enables their elimination by recruiting phagocytic cells in a mouse model of AA amyloidosis.[2] A phase-1 human clinical trial in 15 patients using CPHPC followed by infusion of an anti-SAP antibody confirmed their potential in clearing amyloid deposits.[3]

General Mechanisms of Fibrillogenesis

Amyloidogenesis involves a nucleation-dependent polymerization process. Formation of an ordered nucleus is the initial and thermodynamically limiting step, followed by addition of monomers and elongation of the fibrils. Fibrillogenesis may involve several mechanisms of processing of the amyloid precursor, including partial proteolysis and conformational modifications. Macrophages seem to favor AA amyloidosis through C-terminal proteolysis of the precursor SAA and may be involved in other steps of the pathogenesis. In AL amyloidosis, the variable domain of the light chain (V_L) seems to be the main component of the fibrils. Light chains are internalized at caveolae of mesangial cells followed by trafficking to the lysosomal compartment where fibrils are formed.[4]

Pathology

On light microscopy, the deposits are extracellular, eosinophilic, and metachromatic, inducing a change in the color of dyes. After Congo red staining, the deposits appear faintly red (Fig. 27.1A) and show characteristic apple-green birefringence under polarized light (see Fig. 27.1B). Metachromasia is also observed with crystal violet, which stains the deposits red.

The earliest lesions are located in the mesangium (see Fig. 27.1A), along the glomerular basement membrane (GBM), and in the blood vessels. Mesangial deposits may be sparse or more diffuse, sometimes featuring a lobular distribution. Amyloid deposits also may infiltrate the GBM or may be localized on both of its sides, forming spikes. Advanced amyloid typically produces a nonproliferative, noninflammatory glomerulopathy with marked enlargement of the kidney. When glomeruli become massively sclerotic, the deposits may be difficult to demonstrate by Congo red staining. In this case, EM may be helpful; EM is also helpful in the very early stages in nephrotic patients (Fig. 27.2).

Except for fibrinogen amyloidosis, the media of the blood vessels is prominently involved at early stages. Vascular involvement may

predominate and occasionally occurs alone, particularly in AL amyloidosis. Deposits also may affect the tubules and interstitium.

Given the diversity of amyloidosis types, immunohistology should be routinely performed (see Fig. 27.1C). Immunohistology with antibodies specific for immunoglobulin chains may be difficult to interpret, because of the absence or inaccessibility of light-chain epitopes. Alternative techniques such as immuno-EM[5] and mass spectrometry–based proteomic analysis of deposits after laser microdissection or extraction from the whole sample, at highly specialized centers, can correctly classify more than 99% of patients with systemic amyloidosis.[6] A genetic cause should be sought by DNA sequencing in all patients with amyloidosis in whom confirmation of the amyloid precursor cannot be obtained by other techniques.[7]

Immunoglobulin-Associated Amyloidosis (AL Amyloidosis)

Free immunoglobulin subunits, mostly light chains, secreted by a single clone of B cells, are the cause of the most frequent and severe amyloidosis affecting the kidney. The involvement of an immunoglobulin heavy chain (AH and AHL amyloidosis) is rare.[8]

Pathogenesis

Determinant factors are borne by the precursor light chain, as demonstrated by transfer into experimental animals. Studies on the mechanisms of AL amyloidogenesis are made particularly difficult by the unique structural heterogeneity of the precursor. There is a striking overrepresentation of the lambda (λ) isotype, which is twofold to fourfold more common than the kappa (κ) isotype. A rarely expressed homology family of light-chain variable regions, the $V_{\lambda VI}$ variability subgroup, is found only in amyloid-associated monoclonal immunoglobulin light chains.

Amyloidogenicity is associated with physicochemical features that include low-molecular-mass light-chain fragments in the urine, abnormal disulfide bonding of light chains, and low isoelectric point (pI). An analysis of almost 200 light-chain sequences identified 12 positions in κ chains and 12 in λ chains where certain residues were associated with amyloidosis. Because of their high dimerization constant, light chains from patients with AL amyloidosis may display antibody-like binding properties toward extracellular structures that could favor a nucleation process.

The tropism of organ involvement is influenced both by the germline gene used for the light-chain variable region (V_L) and by somatic mutations occurring in the secreting clone. Patients expressing a monoclonal light chain of the $V_{\lambda VI}$ subgroup are more likely to present with dominant renal involvement and less frequent cardiac and multisystem disease, whereas those expressing monoclonal κ light chains of the $V_{\kappa I}$ subgroup are more likely to have dominant hepatic involvement. In addition, organ-specific environmental factors are also involved.

Amyloid light chains may contribute directly to the pathogenesis, independently of extracellular fibril deposition. In the heart and the kidney at least, the infiltration alone does not correlate well with clinical

TABLE 27.2 Characteristics of the Common Types of Amyloidosis

manifestations. Light chains from amyloid patients incubated with mesangial cells induce a macrophage-like phenotype, whereas those from light-chain deposition disease patients induce a myofibroblast-like phenotype.

Epidemiology

The incidence of AL amyloidosis is 9 cases per 1 million population per year. Fewer than one in four patients with AL amyloidosis have an overt immunoproliferative disease, most frequently multiple myeloma. The apparent prevalence of myeloma depends on the diagnostic criteria used. Demographic characteristics of *primary* amyloidosis, that is, amyloidosis without overt immunoproliferative disease, which is now part of the new entity called *monoclonal gammopathy of renal significance* (MGRS), are not different from those of myeloma.[9] The median age at diagnosis is 64 years, with a slight predominance of male patients, and about 10% are less than 50 years old.[10] Conversely, amyloid deposits are found in approximately 10% of all patients with myeloma and in 20% of those with light chain only myeloma.

Clinical Manifestations

The clinical presentation of AL amyloidosis depends on the pattern and severity of organ involvement, and almost any organ system may be affected by amyloid deposits. Except for the combination of macroglossia and periorbital purpura, which is pathognomonic of AL amyloidosis and occurs in less than a third of cases, clinical features are rarely specific and mimic other more common conditions of the elderly, particularly weakness and weight loss (Table 27.3). Except for bone pain, the initial symptoms in patients with and without myeloma are similar. However, nephrotic syndrome, orthostatic hypotension, and peripheral neuropathy are more frequent in patients with AL amyloidosis without myeloma.

Kidneys are the organs most commonly involved in AL amyloidosis, with a high risk for progression to end-stage renal disease (ESRD). In a study of 145 patients with AL amyloidosis, 42% of the patients who presented with renal manifestations required renal replacement therapy versus 5% of those who did not.[11] Renal impairment (serum creatinine >1.2 mg/dl [106 μmol/l]) is found in nearly half of the patients, with full nephrotic syndrome in 68%. Rare forms of vascular limited AL amyloidosis present with renal impairment but little (<1 g/day) or no proteinuria. There is a poor correlation between the extent of amyloid deposits seen on a kidney biopsy specimen and the extent of proteinuria. Renal manifestations also may include renal tubular acidosis (mostly as a part of Fanconi syndrome; see Chapter 48) and nephrogenic diabetes insipidus (resulting from urinary concentration defect), when amyloid deposits occur around proximal tubules and the loops of Henle or collecting ducts, respectively.

Restrictive cardiomyopathy is found at presentation in up to one third of patients and causes death in about half. Infiltration of the ventricular walls and the septum may be recognized by echocardiography and cardiac magnetic resonance imaging, which has high specificity for diagnosis of cardiac amyloidosis. Amyloid may induce arrhythmias and sick sinus syndrome. Amyloid deposits in the coronary arteries may result in angina and myocardial infarction. Cardiac troponins and N-terminal pro–brain natriuretic peptide (NT-proBNP) are sensitive markers of myocardial dysfunction and powerful predictors of overall survival in patients with AL amyloidosis.

Involvement of the gastrointestinal (GI) tract is common and can cause motility disturbances, malabsorption, hemorrhage, or obstruction. Macroglossia may interfere with eating and obstruct airways (Fig. 27.3). Abnormalities of hepatic function are usually mild. Splenomegaly may be associated with spleen dysfunction, predisposing to fatal bacterial infections. Peripheral nerve involvement may result in a painful sensory polyneuropathy, followed by motor deficits. Autonomic neuropathy causing orthostatic hypotension (one of the more disabling complications of AL amyloidosis), lack of sweating, GI disturbances, bladder dysfunction, and impotence may occur alone or together with peripheral neuropathy. Skin involvement may take the form of purpura, characteristically around the eyes (Fig. 27.4), and ecchymoses, papules, nodules, and plaques, occurring usually on the face and upper trunk. AL amyloidosis may infiltrate articular structures and mimic rheumatoid or an asymmetric seronegative synovitis. Infiltration of the shoulders may produce severe pain and swelling (shoulder pad sign). A rare but

Fig. 27.3 Macroglossia in patient with AL amyloidosis. (Courtesy Dr. S. Aractingi, Paris.)

potentially serious manifestation of AL amyloidosis is an acquired bleeding diathesis that may be associated with deficiency of factor X or factor IX or with increased fibrinolysis. It should be screened by prothrombin time and activated partial thromboplastin time before any biopsy of a deep organ. Widespread vascular deposits also may be responsible for bleeding.

A monoclonal immunoglobulin is found in the serum or the urine in almost 90% of patients. Immunochemical techniques combined with serum free light-chain (FLC) assays detect an abnormal result in 99% of patients.[12] The λ isotype is twice as frequent as the κ, contrasting with the 1:2 ratio of λ to κ observed in myeloma alone. Abnormal serum FLC may precede by many years the clinical onset of AL amyloidosis.

Renal AH and AHL amyloidosis account for 7.3% of cases of renal immunoglobulin-related amyloidosis and affect older patients with a median age at biopsy of 63 years.[8] Compared with patients with renal AL amyloidosis, those with renal AH and AHL amyloidosis present with less cardiac involvement, probably explaining their better survival. Renal biopsy is needed to diagnose renal AH/AHL because other sites usually are not affected. Most of the patients with renal AH/AHL amyloidosis have a circulating intact monoclonal immunoglobulin.

Immunoglobulin M (IgM)-related amyloidosis is a relatively uncommon variant of immunoglobulin-related amyloidosis, accounting for 6% of AL amyloidosis patients. It is characterized by less cardiac involvement but more frequent lymph nodes and neuropathic involvement. Non-Hodgkin lymphoma is the predominant underlying clonal disorder found in 54% of the patients, but plasma cell infiltration is still reported in 6% of the cases. Up to 74% of patients have an abnormal FLC ratio. Independent factors that have an impact on survival are Mayo stage according to revised classification including cardiac biomarkers (NT-proBNP and troponin),[13] age older than 67 years, neuropathy (peripheral and autonomic nervous system), and liver involvement, leading to a new staging system for IgM AL amyloidosis.[14]

Diagnosis

Diagnostic procedures in AL amyloidosis follow a stepwise approach to confirm the presence of amyloid deposition and identify the type of fibril and then assess the underlying plasma cell/B cell clone and evaluate the extent and severity of organ involvement. Because the disease is diagnosed more than 1 year after the onset of symptoms in almost 40% of cases, AL amyloidosis should be considered in any patient who presents with nephrotic-range proteinuria with or without renal impairment, nondilated cardiomyopathy, peripheral neuropathy, hepatomegaly, or autonomic neuropathy (Fig. 27.5). Particular vigilance should be

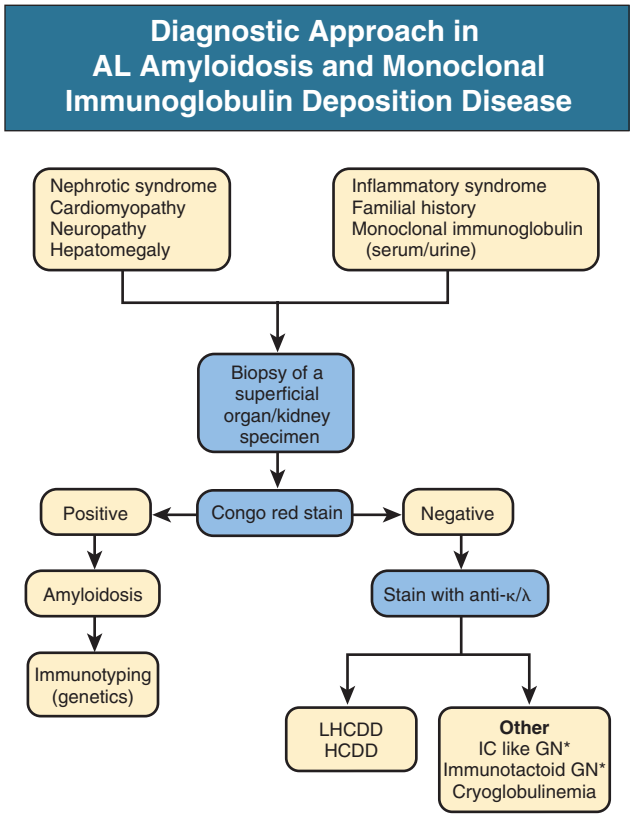

Fig. 27.5 Algorithm of diagnostic procedures in light-chain (AL) amyloidosis and monoclonal immunoglobulin deposition disease (MIDD). *No extrarenal manifestation. *GN,* Glomerulonephritis; *HCDD,* heavy- chain deposition disease; *IC,* immune complex; *LHCDD,* light- and heavy-chain deposition disease.

maintained in patients with multiple myeloma or monoclonal gammopathy of undetermined significance (MGUS), especially of the λ isotype.

All patients require immunofixation of serum and urine in an attempt to demonstrate the presence of a monoclonal light chain and quantitation of serum FLC. In most cases, the absolute difference between serum levels of free κ and λ (dFLC) will be a key parameter for the follow-up. In patients with chronic kidney disease (CKD), both types of polyclonal FLC increase with decreasing GFR, and one should look at the κ/λ ratio. A bone marrow specimen may be important at diagnosis because 10% of patients will not have a demonstrable monoclonal light chain by immunofixation, and a clone of plasma cells detected in the bone marrow by immunohistochemistry is a strong evidence of AL amyloidosis.

Biopsy of an affected organ is usually diagnostic, but less invasive alternatives should be preferred first. Biopsies of salivary glands or of subcutaneous abdominal fat yield positive results in 80% to 90% of cases. Rectal biopsy is diagnostic in more than 80%, provided the biopsy specimen contains submucosal vessels. Bone marrow biopsy specimens should be stained with Congo red for the presence of amyloid, and involvement of the bone marrow (observed in about 50% of patients) is strongly suggestive of the AL type.

It is not always easy to be certain that amyloidosis is of the AL type because immunohistochemical staining for immunoglobulin light chains may not be diagnostic,[15] and the presence of a monoclonal component is strong but not conclusive evidence. Caution is especially required when patients have an entire monoclonal immunoglobulin in the serum without evidence of FLC in the serum and urine. In those cases,

hereditary forms of amyloidosis should be considered because they may produce clinical syndromes indistinguishable from AL and may coexist with MGUS.[7] In cases of doubt, DNA analysis and amyloid fibril sequencing by mass spectrometry are necessary.

Several criteria have been established to define organ involvement. Particularly, elevation of NT-proBNP and cardiac troponin (cTnT) are markers of myocardial dysfunction in AL amyloidosis that strongly correlate with prognosis and are therefore used for the risk assessment staging according to the Mayo risk stratification systems.[13] However, a limitation of the NT-proBNP based staging system is the influence of renal failure on the concentration of this biomarker that can be partly overcome by using brain natriuretic peptide (BNP) in patients with an eGFR less than 30 ml/min/1.73 m^2.[16] Patients presenting with a standard Mayo Clinic stage III and very high concentrations of NT-proBNP (>8500 ng/l) or systolic hypotension (<100 mm Hg) have a poor prognosis, most of them dying within a few weeks from diagnosis.[17] At variance with cardiac involvement, the effect of kidney involvement on survival is not major but may limit the access to effective treatments. A recent staging system for renal involvement is used to predict the risk for dialysis and relies on the measurement of eGFR and proteinuria.[18] Proteinuria greater than 5 g/24 h and eGFR less than 50 ml/min/1.73 m^2 are predictive of a high risk for progression to dialysis, respectively 60% and 85% at 3 years.

Treatment and Outcome

Treatment of systemic AL amyloidosis relies mainly on chemotherapy to suppress the underlying clonal plasma cell. Consensus criteria to define hematologic and organ responses to treatment have been validated to identify early refractory patients.[19] These criteria should be assessed at least every 2 cycles or 3 months. "Partial response" is defined by a 50% or greater reduction in the difference between serum levels of free κ and λ (dFLC), "very good partial response" by a dFLC below 40 mg/l, and "complete response" by the absence of a detectable monoclonal immunoglobulin with normal serum FLC and κ/λ ratio (in the absence of renal impairment). Because organ response is highly correlated with the hematologic response and is predictive of overall survival, the treatment aim is to achieve at least a very good partial response. In the responders, gradual regression of AL amyloid deposits is possible. Clinical improvement does not parallel regression of amyloid load. Scintigraphy after injection of [^{123}I]-SAP component may be helpful for monitoring the extent of systemic amyloidosis, but this imaging technique is not readily available.

Patients with AL amyloidosis can be classified as at low, intermediate, or high risk. Only low-risk patients are potential candidates for high-dose melphalan followed by autologous stem cell transplantation (ASCT). These patients represent about 15% to 20% of all cases and are characterized by age younger than 65 years; an excellent performance status; levels of NT-proBNP and cTnT lower than 5000 ng/ml and 0.06 ng/ml, respectively; preserved renal function; and the absence of autonomic neuropathy or amyloid-related GI bleeding. The other patients, and more particularly those with cardiac cTnT levels higher than 0.06 ng/ml or NT-proBNP levels higher than 5000 ng/l, should not be considered candidates for ASCT because of unacceptable transplant-related mortality. Most patients are at intermediate risk (ineligible for ASCT, stages I to IIIa) and are treated with combination chemotherapy regimens, such as melphalan-dexamethasone (MDex), cyclophosphamide-bortezomib-dexamethasone (CyBorD), bortezomib-melphalan-dexamethasone (BMDex), or cyclophosphamide-thalidomide-dexamethasone (CTD).[20] Most of the studies evaluating these regimens are retrospective and not randomized, limiting the comparison of their efficacy and making selection of the best treatment difficult. Immune-modulatory drugs such as thalidomide, lenalidomide, and pomalidomide are used as rescue treatment for patients refractory to first-line regimens or those who relapse but cannot repeat front-line therapy. High-risk patients (stage IIIb) should be treated with low-dose chemotherapy under very close monitoring because of the risk to destabilize organ function with high doses of dexamethasone and bortezomib. Bortezomib may be preferred because of its rapidity of action.

Supportive therapy is aimed at sustaining organ function with specific modalities such as salt restriction and diuretics for edema, adequate nutritional support, octreotide to control diarrhea, pacemaker implantation in patients with recurrent arrhythmic syncope, fitted elastic leotards and midodrine for hypotension, or gabapentin or pregabalin for neuropathic pain. Angiotensin-converting enzyme inhibitors are generally poorly tolerated because of hypotension.

Except for those with advanced cardiac disease who may benefit from urgent heart transplantation, survival of patients with AL amyloidosis has improved in the last decade, with 4-year overall survival ranging from 40% to 60%. In patients eligible for ASCT, the hematologic response rate exceeds 70% (with 35% of complete response) and the overall median survival is 7.6 years.[21] About half of these patients in complete response are projected to be alive at 14 years, raising the hope that they might be cured. Intermediate-risk patients treated with MDex have comparable results to that observed with ASCT, with hematologic response rate of 76% (31% of patients obtaining complete response) and a median overall survival of 7.3 years. The use of bortezomib is associated with higher hematologic response rate but fails to demonstrate an overall survival advantage.

Emerging therapies are flourishing and include daratumumab, a monoclonal antibody that targets plasma cell antigen CD38, passive immunotherapies with antibodies directed against conformational epitopes of both light chains or against human AL amyloid deposits with the aim of fostering their reabsorption, stabilizers of λ dimers, and small compounds that activate the unfolded protein response.[22]

DIALYSIS AND TRANSPLANTATION

Most studies of the clinical course and outcome of dialysis patients include both AL and AA amyloidosis. Patient survival is about 70% at 1 year and decreases to 30% to 44% at 5 to 6 years. Median survival is shorter in patients with AL amyloidosis (26 to 39 months) than with AA amyloidosis; sepsis and cardiac deaths are the main causes of mortality.[23] Cardiac amyloid is the most important predictor of mortality in dialysis patients with AL amyloidosis.[23]

The management of patients with AL amyloid on hemodialysis is often complicated by persistent hypotension, GI hemorrhage, chronic diarrhea, and difficulties in the creation and maintenance of vascular access. Survival of AL and AA amyloidosis patients treated with peritoneal dialysis (PD) is similar to that of patients receiving hemodialysis.

Kidney transplantation is limited by the severity of heart involvement and the recurrence of deposits in the transplanted kidney. It may be offered to select patients who have achieved persistent hematologic remission, at least for 1 year. When solid-organ transplantation is considered (heart, liver, kidney), it should be preceded or followed by chemotherapy to avoid systemic progression and amyloid recurrence on the transplanted organ.[24] Patient survival was 9 years in those who had achieved at least a partial clonal response after kidney transplantation, versus 5 years in those who had no response.[25]

Inflammatory (Secondary) Amyloidosis (AA Amyloidosis)

Epidemiology

AA amyloidosis develops in 5% of patients with sustained elevation of serum amyloid A protein (SAA). Patients at risk are those with a long

duration of chronic inflammatory disease (median 17 years), high magnitude of acute-phase SAA response, homozygosity for SAA1 genotype, familial Mediterranean fever (FMF) trait (heterozygosity for variant pyrin), or other family history of AA amyloidosis.[26]

An important epidemiologic aspect of AA amyloidosis is the changing spectrum of underlying disease. Pyogenic and granulomatous infections, especially tuberculosis, account for far fewer cases (now only 15%) than previously.[26] In these patients, antibiotic treatment efficiently prevents AA amyloidosis by suppressing its cause. In contrast, the relative proportion of chronic inflammatory arthritis has increased by 60%.[26] However, it may be expected that effective disease-modifying treatments of these conditions will induce a decline in the incidence of AA amyloidosis. AA amyloidosis can be observed in a variety of other diseases, such as inflammatory bowel disease, non-ANCA systemic vasculitis, neoplasia, and immunodeficiency states. Hereditary AA amyloidoses associated with familial recurrent fever syndromes account for an increasing proportion of cases, about 10% in recent series.

Clinical Manifestations

Table 27.4 provides clinical features of AA amyloidosis.[26] The main target organ is the kidney, which is affected in almost all patients with AA amyloidosis. Presentation may be acute with nephrotic syndrome or very insidious. Proteinuria is absent in about 5% of cases. GI disturbances (e.g., diarrhea, constipation, malabsorption) and hepatosplenomegaly are the next most common manifestations. In contrast to AL amyloidosis, congestive heart failure (CHF), peripheral neuropathy, macroglossia, and carpal tunnel syndrome occur infrequently.

TABLE 27.4 Characteristics at Presentation of 374 Patients With Systemic Secondary (AA) Amyloidosis

Age, yr (range)	50 (9-87)

Diagnosis

Because only half of the patients in whom amyloid was found on renal tissue at autopsy are reported to have proteinuria before death, some recommend a systematic search for amyloidosis in patients with active, long-lasting inflammatory arthritis, even in the absence of proteinuria and CKD. The identification of even asymptomatic amyloid deposits should prompt more effective control of inflammation. Although findings on kidney biopsy are positive in almost 100% of symptomatic patients, less invasive biopsy procedures should be attempted first. Biopsies of accessory salivary glands and abdominal fat yield positive results in more than 80% of patients. Immunohistochemical staining using antibodies to SAA is required to confirm that Congo red–positive amyloid deposits are of the AA type. SAP scintigraphy shows that bones are not affected (unlike AL amyloidosis).

Natural History and Treatment

Average survival time of patients with AA amyloidosis is 133 months, much longer than with AL amyloidosis.[26] Main causes of death are infections and dialysis-related complications but not cardiac complications. Amyloid load and clinical outcome relate to circulating concentrations of SAA. The relative risk for death among patients with an SAA concentration below 4 mg/l is almost 18 times lower than in those with an SAA concentration of 155 mg/l or greater. Even a very modest elevation in the SAA concentration of 4 to 9 mg/l is associated with a risk for death increased by a factor of 4. These data emphasize the importance of vigorous treatment of the underlying inflammatory disease. SAA (preferable to C-reactive protein) serum levels should be monitored monthly and maintained at a target value of less than 4 mg/l.[26]

Amyloid deposits regress in 60% of patients who have a median SAA concentration below 10 mg/l, and survival in these patients is superior to survival when amyloid deposits do not regress. Other factors associated with increased mortality are older age and ESRD.

Eprodisate, a member of a newer class of compounds interfering with interactions between amyloidogenic proteins and GAGs, thus inhibiting polymerization of amyloid fibrils, slowed decline of renal function in patients with AA amyloidosis.[27] However, eprodisate had no beneficial effect on proteinuria, ESRD, amyloid content of abdominal fat, or mortality risk. The combination of CPHPC and anti-SAP antibody, as well as new biologics, are currently under evaluation.[22] Emphasis should remain on treatment of the underlying inflammatory disorder.

Most patients receiving renal transplantation in AA amyloidosis are those with rheumatic diseases. Amyloid deposits recur in about 10% of the grafts. Infections and cardiovascular events are the main causes of early death and require careful management.[28]

Familial Mediterranean Fever and Other Hereditary Recurrent Fever Syndromes

FMF represents a particular type of AA amyloidosis and is the most frequent cause of familial amyloidosis. FMF is usually transmitted as an autosomal recessive disorder and occurs most often in Sephardic Jews and Armenians. It is caused by mutations of the *MEFV* gene encoding a protein called pyrin, or marenostrin. Clinically, there are two independent phenotypes. In the first, brief episodic, febrile attacks of peritonitis, pleuritis, or synovitis occur in childhood or adolescence and precede the renal manifestations. In the second phenotype, renal symptoms precede and may long be the only manifestation of the disease. The attacks are accompanied by dramatic elevations of acute phase reactants, including SAA. Amyloid deposits are responsible for severe renal lesions with prominent glomerular involvement, leading to ESRD at a young age, and for early death.

Colchicine can prevent the development of proteinuria, may occasionally reverse nephrotic syndrome, and may prevent eGFR decline in patients with non-nephrotic proteinuria. It is less effective in preventing progression in patients with nephrotic syndrome or renal impairment. The minimum daily dose of colchicine for prevention of amyloidosis is 1 mg, and patients with clinical evidence of amyloidotic kidney disease should receive daily doses of 1.5 to 2 mg. However, about 10% of patients are unresponsive to colchicine and others are intolerant. Interleukin-1 receptor (IL-1R) antagonists are second-line agents in those patients.

The recent identification of genes responsible for syndromes of periodic fever with amyloidosis has led to a molecular diagnosis of hereditary AA amyloidosis. These syndromes include TNF-α receptor–associated periodic fever syndrome, Muckle-Wells syndrome, and familial cold autoinflammatory syndrome. Only a few cases of systemic AA amyloidosis have been reported in the hyperimmunoglobulinemia D with periodic fever syndrome. Most of these conditions can be controlled by means of anti–IL-1 or anti-TNF-α agents.

MONOCLONAL IMMUNOGLOBULIN DEPOSITION DISEASE

History and Definition

It was known from the late 1950s that nonamyloidotic forms of glomerular disease "resembling the lesion of diabetic glomerulosclerosis" could occur in multiple myeloma. Subsequently, monoclonal light chains were detected in these lesions.[29]

In clinical and pathologic terms, light-chain, light- and heavy-chain, and heavy-chain deposition disease (LCDD, LHCDD, and HCDD, respectively) are similar and therefore may be referred to as monoclonal immunoglobulin deposition disease (MIDD). These forms differ from amyloidosis in that the deposits lack affinity for Congo red and do not have a fibrillar organization. The distinction also relates to different molecular mechanisms of amyloid, which implicates one-dimensional elongation of a pseudocrystalline structure, and MIDD, which rather involves a one-step precipitation of immunoglobulin chains.

Epidemiology

MIDD is a rare disease that may occur in a wide range of ages (<30 to >90 years), with a male preponderance.[30] In MIDD, only 60 patients with HCDD have been described thus far[31] but the disease most likely remains underdiagnosed. MIDD is the second most frequent glomerulopathy in plasma cell dyscrasias, found in about 5% of patients with multiple myeloma at autopsy, approximately half the incidence of AL amyloidosis.[32] Conversely, the prevalence of multiple myeloma is higher than in patients with AL amyloidosis, being found in approximately 50% of patients with LCDD or LHCDD and 20% of those with HCDD. MIDD occasionally may occur with Waldenström macroglobulinemia, chronic lymphocytic leukemia, and non-Hodgkin lymphoma. The remaining patients can be classified as having MGRS.[9]

Pathogenesis

The pathogenesis of MIDD involves the kidney deposition of monoclonal immunoglobulin subunits inducing a dramatic accumulation of extracellular matrix. However, light-chain deposition does not mean pathogenicity and singular properties of light chains or heavy chains are most likely required for completion of the pathogenetic process that leads to kidney fibrosis. The same light chain can form granular aggregates or amyloid fibrils, depending on the environment, and different, partially folded intermediates of the light chain may be responsible for amorphous or fibrillar aggregation pathways.

HCDD also may be associated with unique heavy chains. A deletion of the first constant domain C_H1 was found in deposited or circulating heavy chains in patients with γ-HCDD.[31,33] In the blood, the deleted heavy chain either was associated with light chains or circulated in small amounts as a free unassembled subunit. It is likely that the C_H1 deletion facilitates the secretion of free heavy chains that are rapidly cleared from the circulation by organ deposition.[34] Partial or complete deletion of the variable V_H domain in heavy-chain disease without HC deposition suggests that this domain is required for tissue precipitation in HCDD.

A striking feature of light-chain deposition disease (LCDD) and HCDD is extracellular matrix accumulation. Nodules are made of normal matrix constituents. In cultured mesangial cells, LCDD light chains enhance the production of tenascin-C and profibrotic cytokines, such as transforming growth factor β and platelet-derived growth factor. It has been suggested that light chains bind an as-yet unidentified common caveolae-associated receptor on mesangial cells and induce their phenotypic transformation into myofibroblasts with increased synthesis of extracellular matrix constituents and reduced secretion of matrix metalloproteinases.

Clinical Manifestations

MIDD is a systemic disease with immunoglobulin-chain deposition in a variety of organs, although visceral immunoglobin-chain deposits may be totally asymptomatic. MIDD typically presents in the sixth decade.

Renal Manifestations

Renal involvement is an almost constant feature of MIDD, and renal symptoms, mostly proteinuria and CKD, often dominate the clinical presentation.[35] In 18% to 53% of patients with LCDD, albuminuria is associated with nephrotic syndrome. In about one fourth, however, albuminuria is less than 1 g/day and these patients have clinical features suggesting tubulointerstitial disease.[36] Hematuria is more common than would be expected for a nephropathy in which cell proliferation is usually modest. Patients with HCDD appear to have a higher prevalence of hypertension, hematuria, and nephrotic-range proteinuria, reaching 70% at diagnosis, associated with nodular glomerulosclerosis.[31]

The high prevalence of greater than 80%, early appearance, and severity of CKD are other salient features of MIDD. In most cases, GFR declines rapidly, which is a main reason for referral. CKD occurs with comparable frequency in patients with either low or high protein excretion and may manifest in the form of subacute tubulointerstitial nephritis or rapidly progressive glomerulonephritis (RPGN), respectively.

Extrarenal Manifestations

Liver and cardiac manifestations occur in about 25% of patients with LCDD and LHCDD. Liver deposits are constant. They are either discrete and confined to the sinusoids and basement membranes of biliary ductules without associated parenchymal lesions or massive with marked dilation and multiple ruptures of sinusoids, resembling peliosis. Hepatomegaly with mild alterations of liver function test results is the most common symptom, but patients also may develop life-threatening hepatic insufficiency and portal hypertension.

Cardiac involvement may be responsible for cardiomegaly and severe heart failure. Arrhythmias, conduction disturbances, and CHF are seen, with diastolic dysfunction and reduction in myocardial compliance similar to that found in cardiac amyloidosis.

Deposits may occur along the nerve fibers and in the choroid plexus, as well as in the lymph nodes, bone marrow, spleen, pancreas, thyroid gland, submandibular glands, adrenal glands, GI tract, abdominal vessels, lungs, and skin. They may be responsible for peripheral neuropathy

(B) Staining of mesangial nodules and tubular basement membranes with anti-κ antibody. (Immunofluorescence; ×312.) (C) Electron micrograph showing a layer of dense granular deposits *(arrow)* under the endothelium along the glomerular basement membrane. (×2500.) (Courtesy Dr. Béatrice Mougenot, Paris.)

(20% of the reported cases), GI disturbances, pulmonary nodules, amyloid-like arthropathy, and sicca syndrome. Extrarenal deposits seem to be less common in patients with HCDD.

Pathology

Light Microscopy

Tubular lesions are characterized by the deposition of a refractile, eosinophilic, periodic acid–Schiff (PAS)-positive, ribbon-like material along the outer part of the tubular basement membranes. The deposits predominate around the distal tubules, the loops of Henle, and, in some instances, the collecting ducts, whose epithelium is flattened and atrophied. Typical myeloma casts are only occasionally seen in pure forms of MIDD. In advanced stages, a marked interstitial fibrosis including refractile deposits is frequently associated with tubular lesions.

Glomerular lesions are heterogeneous. Nodular glomerulosclerosisis is found in about two thirds of patients with LCDD (Fig. 27.6A), and in almost all patients with HCDD, being a characteristic feature of this disease. Mesangial nodules are composed of PAS-positive, membrane-like material and are often accompanied by mild mesangial hypercellularity. Lesions resemble diabetic nodular glomerulosclerosis, with distinctive characteristics; the distribution of the nodules is fairly regular in a given glomerulus, the nodules are often poorly argyrophilic, and exudative lesions (e.g., fibrin caps and extensive hyalinosis of efferent arterioles) are not observed. In occasional cases with prominent endocapillary cellularity and mesangial interposition, the glomerular features mimic membranoproliferative glomerulonephritis (MPGN). Crescents are very uncommon except in α-HCDD.[31] Milder forms of LCDD show increased mesangial matrix or cells and modest GBM thickening, with abnormal brightness and rigidity. Glomerular lesions may be detectable only by immunostaining or ultrastructural examination in early stages.

Arteries, arterioles, and peritubular capillaries all may contain PAS-positive deposits in close contact with their basement membrane. Deposits do not show the staining characteristics of amyloid, but Congo red–positive amyloid deposits co-occur in approximately 10% of patients.[35]

Immunohistology

Immunohistology is central in the diagnosis of the various forms of MIDD. A criterion required for the diagnosis of MIDD is monotypic light-chain (mainly κ; Fig. 27.6B) or heavy-chain fixation along tubular basement membranes. The tubular deposits stain strongly and predominate along the loops of Henle and the distal tubules, but also often are detected along the proximal tubules. In contrast, glomerular immunohistology patterns display marked heterogeneity. In patients with nodular glomerulosclerosis, deposits of monotypic immunoglobulin chains are usually found along the peripheral GBM and to a lesser extent in the nodules themselves (see Fig. 27.6B). A linear staining usually decorates the Bowman capsule. Deposits are common in vascular walls and interstitium.

In patients with HCDD, immunohistology with anti–light-chain antibodies is negative despite typical nodular glomerulosclerosis. Monotypic deposits of γ, α, or μ chains may be identified. Any γ subclass may be observed. If immunofluorescence fails to detect light chains or γ-, α-, or μ heavy chains, IgD HCDD should be suspected and may require the use of laser microdissection and mass spectrometry.[37] Analysis of the kidney biopsy specimen with monoclonal antibodies specific for the constant domains of the γ heavy chain allowed identification of a deletion of the C_H1 domain in all tested cases. In most cases of γ1 or γ3 HCDD, complement components including C1 could be demonstrated in a granular or pseudolinear pattern. Complement deposits are often associated with signs of complement activation in serum.

Eculizumab treatment of dense deposit disease was shown to induce an HCDD-like pathology, although the clinical significance of this is not completely known.[38]

Electron Microscopy

The most characteristic ultrastructural features on EM are finely to coarsely granular electron-dense deposits along the outer (interstitial) aspect of the tubular basement membranes. In the glomerulus, the deposits are predominantly in a subendothelial position along the GBM and are located mainly along and in the lamina rara interna (see Fig. 27.6C). Deposits also can be found in mesangial nodules, the Bowman capsule, and the wall of small arteries between the myocytes.

Diagnosis

The diagnosis of MIDD must be suspected in any patient with nephrotic syndrome or rapidly progressive tubulointerstitial nephritis or with echocardiographic findings indicating diastolic dysfunction and the presence of a monoclonal immunoglobulin component in the serum or the urine (see Fig. 27.5). Sensitive techniques such as immunofixation fail to identify a monoclonal immunoglobulin component in 10% to 20% of patients with MIDD, although the serum FLC ratio is consistently abnormal.[30] The kidney biopsy thus plays an essential role in the diagnosis of MIDD and the associated dysproteinemia.

The diagnosis of plasma cell dyscrasia relies on bone marrow aspiration and bone marrow biopsy with cell morphologic evaluation and,

if necessary, immunophenotyping with anti-κ and anti-λ antisera to demonstrate monoclonality.

Treatment and Outcome

The outcome of MIDD remains uncertain, mainly because extrarenal deposits of light chains can be totally asymptomatic or cause severe organ damage leading to death. As in AL amyloidosis, treatment of patients with MIDD should be aimed at reducing immunoglobulin production.[39] Monitoring of light-chain production should rely on serum FLC assay, particularly when a blood or urine monoclonal component cannot be detected by conventional methods.

Most patients treated with high-dose melphalan and stem cell transplant achieve a hematologic and organ response with very low treatment-related mortality.[39] However, the role of stem cell transplantation is now challenged by highly effective new drugs, such as bortezomib. In 49 patients treated with a combination of bortezomib and dexamethasone, with or without cyclophosphamide, the overall hematologic response rate was 91% after a median follow-up of 54 months and a renal response rate was achieved in 26 patients, with a 35% increase in median eGFR and an 86% decrease in median 24-hour proteinuria.[40] To reduce the risk for disease recurrence in the graft, only patients who achieve a complete hematologic response should be candidates for renal transplantation.[41]

The outcome of patients with MIDD has improved with a reduction in the rate of ESRD and mortality, respectively, at 20% and 10%.[40] Such improvement is explained by earlier diagnosis and more potent chemotherapeutic regimens. Predictors of renal survival include a lower initial serum creatinine level and post-treatment difference between involved and uninvolved serum-FLCs under 40 mg/l (defining a very good partial hematologic response). Several variables have been independently associated with worse patient survival: older age, associated multiple myeloma, extrarenal LC deposition, and lytic bone lesions.[30] Nodular mesangial lesions and light-chain deposits may be reversible after effective chemotherapy.

Renal Diseases Associated With Monoclonal Immunoglobulin Deposition Disease

Myeloma cast nephropathy is found in about a third of patients with MIDD.[35] Clinical features and outcomes of MIDD and minimal change disease (MCN) more closely resemble those in MCN than pure MIDD. Nodular glomerulopathy is uncommon (<10%), some ribbon-like tubular basement membranes are seen in less than half the patients, and a third of the patients do not have granular dense deposits on EM. Renal and patient survival is significantly worse.

Amyloid deposits are found in one or more organs in about 7% of LCDD patients. Because amyloid deposits are focal, their true incidence may be greatly underestimated. It is possible that the coexisting diseases are induced by different variant clones.

NONAMYLOID FIBRILLARY AND IMMUNOTACTOID GLOMERULOPATHIES

Fibrillary and immunotactoid glomerulopathies are characterized, respectively, by fibrillar and microtubular deposits in the mesangium and the glomerular capillary loops (Table 27.5). These deposits do not have an amyloid-like cross-β structure and are readily distinguishable from amyloid on EM by the larger thickness of fibrils and lack of Congo red staining.

Epidemiology

The incidence of glomerulopathy with nonamyloid deposition of fibrillar or microtubular material in a nontransplant adult biopsy population is estimated at around 1%. It is most likely underestimated because of the insufficient attention given to atypical reactions with histochemical amyloid stains and the frequent lack of immune-ultrastructural studies. Only immunotactoid glomerulopathy has a significant association with underlying dysproteinemia, whereas fibrillary glomerulonephritis (FGN) has a wide spectrum of etiologies.[43] At variance with immunotactoid

TABLE 27.5 Immunologic and Clinical Characteristics of Fibrillary and Immunotactoid Glomerulopathies

Characteristics	Amyloidosis (AL Type)	Fibrillary Glomerulopathy	Immunotactoid Glomerulopathy
Congo red staining	Yes	No	No
Composition	Fibrils	Fibrils	Microtubules
Fibril or microtubule size	8-15 nm	12-22 nm	>30 nm*
Organization in tissues	Random (β-pleated sheet)	Random	Parallel arrays
Immunoglobulin deposition	Monoclonal LC (mostly λ)	Usually polyclonal (mostly IgG4), occasionally monoclonal (IgG1, IgG4)	Usually monoclonal (IgGκ or IgGλ)
Glomerular lesions	Deposits spreading from mesangium	MPGN, CGN, MP	Atypical MN, MPGN
Renal presentation	Severe NS, absence of hypertension and hematuria	NS with hematuria, hypertension; RPGN	NS with microhematuria and hypertension
Extrarenal manifestations (fibrillar deposits)	Systemic deposition disease	Pulmonary hemorrhage	Microtubular inclusions in leukemic lymphocytes
Association with LPD	Yes (myeloma)	Uncommon	Common (CLL, NHL, MGUS)
Treatment	Melphalan + dexamethasone; intensive therapy with blood stem cell autograft	Corticosteroids ± cyclophosphamide (crescentic GN)	Treatment of the associated LPD

*Mean diameter of the substructures did not differ between fibrillary glomerulonephritis (15.8 ± 3.5 nm) and immunotactoid glomerulopathy (15.2 ± 7.3 nm) in the series of Bridoux and colleagues.[42]

CGN, Crescentic glomerulonephritis; *CLL,* chronic lymphocytic leukemia; *GN,* glomerulonephritis; *LC,* light chain; *LPD,* lymphoproliferative disorder; *MGUS,* monoclonal gammopathy of undetermined significance; *MN,* membranous nephropathy; *MP,* mesangial proliferation; *MPGN,* membranoproliferative glomerulonephritis; *NHL,* non-Hodgkin lymphoma; *NS,* nephrotic syndrome; *RPGN,* rapidly progressive glomerulonephritis.

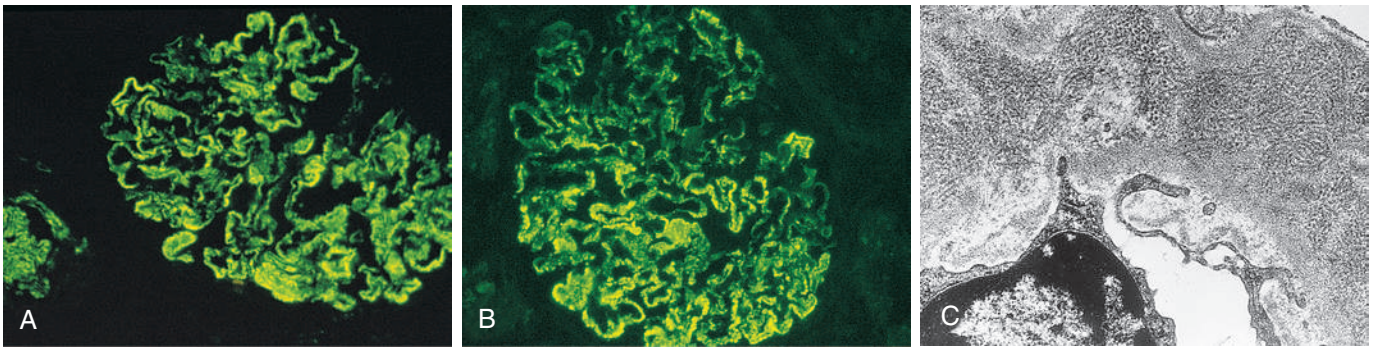

Fig. 27.7 Immunotactoid glomerulopathy. Atypical membranous nephropathy showing exclusive staining of the deposits with (A) anti-γ antibodies, and (B) anti-κ antibodies. (Immunofluorescence; ×312.) (C) Electron micrograph of glomerular basement membrane shows microtubular structure of the subepithelial deposits. (Uranyl acetate and lead citrate; ×20,000.) (Courtesy Dr. Béatrice Mougenot, Paris.)

glomerulopathy in which immunoglobulin deposits are usually monoclonal (IgGκ or IgGλ), those described in FGN are usually polyclonal (mostly IgG4).[42] Hematologic malignancy can be present in up to 38% of patients with immunotactoid glomerulopathy, including chronic lymphocytic leukemia in 19%, lymphoplasmacytic lymphoma in 13%, and multiple myeloma in 13%.[44]

Clinical Manifestations

The characteristics of fibrillary and immunotactoid glomerulopathies are described in Table 27.5 in comparison to AL amyloidosis. Patients with immunotactoid and fibrillary glomerulopathies have a mean age of 55 to 60 years (extreme: 19 to 86 years). They usually present with nephrotic syndrome, microscopic hematuria, and mild to severe CKD. Recent series show no significant difference at presentation between patients with immunotactoid and fibrillary glomerulopathy in serum creatinine level, incidence of nephrotic syndrome, microscopic hematuria, hypertension, or CKD. Extrarenal manifestations are uncommon and may involve the lung, skin, and peripheral nervous system.

Pathology

Immunotactoid Glomerulopathy

Renal biopsy shows membranous nephropathy (often associated with segmental mesangial proliferation; Fig. 27.7) or lobular MPGN. Granular deposits of IgG and C3 are observed along capillary basement membranes and in mesangial areas.[44] On EM, the distinguishing morphologic features of immunotactoid glomerulopathy are organized deposits of large, thick-walled microtubules (typically greater than 30 nm in diameter), at times arranged in parallel arrays (see Fig. 27.7C). Intracytoplasmic crystal-like immunoglobulin inclusions can be found in circulating B-lymphocytes of patients with CLL and related lymphoma.[42]

Fibrillary Glomerulopathy

Mesangial proliferation and aspects of MPGN are predominantly reported in series of fibrillary glomerulopathy. Glomerular crescents are present in about 30% of the biopsy specimens. Immunofluorescence studies mainly show IgG deposits mostly of the IgG4 subclass with a predominant mesangial localization. Monotypic deposits containing mostly IgGκ are detected in no more than 15% of patients.[45] On EM, fibrils are randomly arranged and their diameter varies between 12 and 22 nm. The fibril size alone is not sufficient to distinguish nonamyloidotic FGN from amyloid.[42]

One of the most abundant proteins by mass spectrometry is DnaJ heat shock protein family B member 9 (DNAJB9). It remains to be determined whether this protein serves as an autoantigen or whether it accumulates in fibrils because of still unknown unusual physicochemical properties.[42a, 42b, 42c]

Diagnosis

Diagnosis of immunotactoid and fibrillary glomerulopathies relies on EM, which must be performed in patients with atypical membranous nephropathy or MPGN, as well as in those with monotypic deposits in glomeruli. Diagnosis also relies on the detection by immunohistochemistry in glomeruli of DNAJB9 which seems to be a specific marker for fibrillary glomerulopathy (Nasr S, Vrana JA, Dasari S, et al, Kidney int Reports, 2018, accepted). All renal biopsy specimens should be routinely examined with anti-κ and anti-λ light-chain antibodies. In patients with immunotactoid glomerulopathy, lymphoproliferative disease should be sought. Association of immunotactoid and fibrillary glomerulopathy with hepatitis C virus or HIV infection also has been reported.

Outcome and Treatment

Patients with fibrillary glomerulopathy usually respond poorly to corticosteroids and cytotoxic drugs, with an incidence of ESRD of about 50%.[42,44,45] Several reports suggest that they may respond to rituximab.[45] The prognosis of immunotactoid glomerulopathy appears to be better than that of FGN. Therapy directed against the underlying hematologic malignancy usually leads to remission of the nephrotic syndrome.[42,45] Renal transplantation has been performed in a few patients. Disease recurred in several, especially in those with a persistent monoclonal gammopathy.

GLOMERULAR LESIONS ASSOCIATED WITH WALDENSTRÖM MACROGLOBULINEMIA AND OTHER MONOCLONAL IMMUNOGLOBULIN M-SECRETING B CELL LYMPHOPROLIFERATIVE DISORDERS

Symptomatic renal disease is much less common in patients with Waldenström macroglobulinemia than in those with multiple myeloma. Glomerulonephritis with intracapillary thrombi of aggregated IgM (intracapillary monoclonal deposit disease, ICMDD) is the most characteristic entity, which also may occur with other IgM-secreting monoclonal proliferations.[46] On immunohistology, thrombi and deposits stain with anti-μ and with anti-κ. The deposits are electron dense and granular without microtubular organization. Some of these patients have strong activation of the classic complement pathway with or without cryoglobulinemia. The frequency of ICMDD has decreased over time mostly because of improved treatment of Waldenström macroglobulinemia, whereas AL amyloidosis, cryoglobulinemic glomerulonephritis, and MPGN are increasingly encountered.[47] Lymphomatous infiltration of the renal interstitium is present in half of the cases.

Treatment should target the IgM-secreting clone. Renal manifestations usually improve with chemotherapy including rituximab.[47,48]

OTHER TYPES OF GLOMERULONEPHRITIS

In some patients, glomerular deposition of monoclonal IgG can produce a proliferative GN that mimics immune complex GN on light and EM.[49] Proper recognition of this entity, now termed *proliferative glomerulonephritis with monoclonal immunoglobulin deposits* (PGNMID), requires confirmation of monoisotypy by immunostaining for the γ heavy-chain subclasses. The IgG3κ isotype is strikingly overrepresented in PGNMID deposits. Tissue fixation of complement was observed in 90% of cases, and hypocomplementemia was found in 40% of the patients, all of whom had either IgG1 or IgG3 deposits. Clinical presentation included CKD in 80%, proteinuria in 100%, nephrotic syndrome in 44%, and microhematuria in 60%. Minute amounts of a monoclonal serum protein with the same heavy- and light-chain isotype as that of the glomerular deposits was identified in 50% of cases. Only one patient had multiple myeloma at presentation, and none developed hematologic malignancy over the course of follow-up. Proliferative GN with monoclonal IgG deposits may recur in the allograft.

A monoclonal IgM also can be found in PGNMID with an MPGN pattern. Few cases of "proliferative" GN with monoclonal immunoglobulin deposits with a membranous pattern have been reported. The majority of these patients have IgG1 deposits instead of IgG3.[50] A circulating monoclonal IgG could be detected in only one fourth of these patients.

Because PGNMID is a newly described entity and most patients have no overt malignancy, optimal treatment remains to be established. Every effort should be made to identify the type of clonal proliferation (plasmacytic or lymphocytic), which has an impact on the choice of therapy and the expected response.[51] Cyclophosphamide and bortezomib in association with dexamethasone are the drugs of choice in patients with bone marrow plasma cell infiltration or without detectable cell clone, whereas rituximab-based therapy is recommended in patients with a lymphocytic cell clone.

An increasing number of cases of C3 glomerulonephritis (C3GN) and monoclonal gammopathy have been reported. This association is encountered in about 60% of patients with C3GN above 60 years of age.[52] Such association may be related to complement activation through an autoantibody activity of the monoclonal IgG against a complement alternative pathway regulatory protein. In some cases of C3GN, masked monoisotypic IgGκ deposits may be demonstrated on antigen retrieval by pronase digestion.

SELF-ASSESSMENT QUESTIONS

1. Does AL (light-chain) amyloidosis involve the heart?
   - **A.** A contraindication to cardiac transplantation
   - **B.** Less common than in AA amyloidosis
   - **C.** Primarily responsible for valve dysfunction
   - **D.** A contraindication to hemodialysis
   - **E.** Best evaluated by assessment of brain natriuretic peptide (BNP) in patients with glomerular filtration rate (GFR) <30 ml/min/1.73 m^2
2. Does monoclonal immunoglobulin deposition disease (MIDD) involve the kidney?
   - **A.** A contraindication to kidney transplantation
   - **B.** Characterized by crescent formation
   - **C.** Frequently responsible for nondiabetic glomerulosclerosis
   - **D.** Characterized by microtubular deposits
   - **E.** Caused by deposition of cryoglobulin
3. Which of the following is the key investigation for the diagnosis of immunotactoid glomerulopathy?
   - **A.** Immunofixation of serum proteins
   - **B.** Immunofixation of urinary proteins
   - **C.** Bone marrow aspiration
   - **D.** Immunofluorescence examination of kidney biopsy sample
   - **E.** Electron microscopy
4. Which of the following is the most common clinical sign or symptom caused by MIDD?
   - **A.** Renal failure
   - **B.** Hematuria
   - **C.** Hypertension
   - **D.** Jaundice
   - **E.** Heart failure

Rare Glomerular Disorders

Richard J. Glassock

This chapter describes several rather uncommon, often rare, disorders or clinical syndromes that have glomerular disease as a major part of the clinical manifestations and tend to affect mainly adults. These disorders are not necessarily related to each other, and each must be recognized and differentiated from other, far more common, glomerular disorders to determine whether a familial disorder is present, to estimate the prognosis to plan appropriate therapy, or to determine the risk for a recurrence in the transplanted kidney. In addition, the chapter describes the primary and secondary antiphospholipid antibody syndromes in detail.

MESANGIAL PROLIFERATIVE GLOMERULONEPHRITIS WITHOUT IgA DEPOSITS

Mesangial proliferative glomerulonephritis (MesPGN) encompasses a heterogeneous collection of disorders having diverse clinical features and a largely unknown etiology and pathogenesis. The common feature of these disorders is a histologic pattern of glomerular injury on light microscopy characterized by diffuse mesangial proliferation[1-4] (Fig. 28.1). Thus MesPGN is noted for a diffuse and global increase in mesangial cells, often accompanied by an increase in mesangial matrix. Other cells (e.g., neutrophils and monocytes) also may contribute to the hypercellularity. Thus MesPGN is a glomerular lesion, *not a specific disease entity.*

For the purpose of this discussion, other forms of cellular proliferation that occur within the mesangial zones but are more focally and segmentally distributed are not included. These focal and segmental forms of proliferative glomerulonephritis (GN), often accompanied by areas of segmental necrosis of the glomerular tufts and very localized crescents, may accompany the evolution of pure MesPGN, but they often signify the presence of systemic disease, including systemic lupus, IgA-vasculitis (Henoch-Schönlein purpura) and IgA nephropathy, infective endocarditis, microscopic polyangiitis, granulomatous polyangiitis, Goodpasture disease, rheumatoid vasculitis, and mixed connective tissue disease. On occasion, focal and segmental proliferative GN is discovered in the absence of any recognizable multisystem disease process and in the absence of IgA deposits (i.e., idiopathic focal and segmental proliferative GN). Such patients have a clinical presentation, course, and response to treatment that are similar to those described for pure MesPGN, but they are not discussed further in this section.

In "pure" MesPGN, the peripheral capillary walls are thin and delicate, without obvious deposits, reduplication, focal disruptions, or cellular necrosis. The visceral and parietal epithelial cells, although occasionally enlarged, have not undergone proliferation. Crescents and segmental sclerosis should be absent in the pure form of the disorder. In addition, large deposits staining with periodic acid–Schiff (PAS) or fuchsin in the mesangium should be absent, because these deposits suggest IgA nephropathy (see Chapter 23), lupus nephritis (LN; see Chapter 26), or C3 glomerulonephritis (see Chapter 22), which may commonly manifest as a mesangial proliferative lesion. Postinfectious glomerulonephritis (as a result of streptococcal or nonstreptococcal microbial infections) also may cause a lesion of MesPGN. The tubulointerstitium and vasculature are usually normal, unless reduced renal function or hypertension is present or the patient is of advanced age.

On immunofluorescence (IF) microscopy, a wide variety of patterns of immunoglobulin and complement deposition are observed (Table 28.1). Most often, diffuse and global IgM and C3 deposits are found scattered throughout the mesangium in a granular pattern (so-called IgM nephropathy, see later discussion), but isolated C3, C1q, or even IgG deposits may also be seen.[5-7] If IgA is the predominant immunoglobulin deposited, the diagnosis is IgA nephropathy. In some cases, no immunoglobulin deposits are found. Prominent C3 deposition in the absence of immunoglobulin deposition should suggest C3 glomerulopathy (see Chapter 22).[7] Extensive C1q deposits, with or without immunoglobulin deposits should suggest C1q nephropathy (see later discussion).[8] On electron microscopy (EM), the number of mesangial cells is increased, with an occasional leukocyte. The amount of mesangial matrix is frequently but not invariably diffusely increased. Electron-dense deposits within the mesangium often can be seen. Very large mesangial or paramesangial electron-dense deposits suggest IgA nephropathy even if IF microscopy is not available. Subendothelial, intramembranous, or subepithelial deposits are not seen. If present, these suggest a postinfectious etiology or an underlying disease such as LN or C3 glomerulopathy. Deposits of multiple immunoglobulin classes identified by immunohistology and large numbers of tubuloreticular inclusions on EM suggest underlying LN.

The clinical presentation of MesPGN is quite varied, although persistent or recurring microscopic or macroscopic hematuria with mild proteinuria is most common. It commonly affects young adults,[1,2] with a slight male predominance. Nephrotic syndrome with heavy proteinuria is a less frequent initial presentation but is seen more often in association with diffuse mesangial IgM deposits (IgM nephropathy; see later discussion),[3] C1q deposits (C1q nephropathy)[4] or C3 glomerulonephritis.[5] Pure MesPGN is a rather uncommon lesion (<5%) in patients diagnosed with idiopathic nephrotic syndrome. In some countries, such as India and China, MesPGN is found in 10% to 15% of renal biopsy samples, but the frequency is much less in well-developed countries. Lesions of MesPGN have been observed in acute parvovirus B19 disease and in association with Castleman disease.

Renal function and blood pressure are usually normal, at least initially. Serologic studies are generally unrewarding. Serum C3 and C4

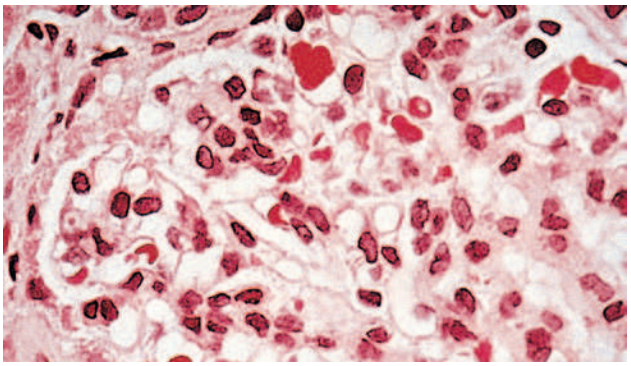

Fig. 28.1 Pure mesangial proliferative glomerulonephritis (MesPGN). Note the increase in mesangial cellularity, the delicate peripheral capillary walls, and the absence of sclerosis or parietal epithelial cell proliferation. TABLE 28.1 Immunofluorescence Microscopy Patterns in Mesangial Proliferative Glomerulonephritis

Pattern	Associated Disorders
Predominantly mesangial IgA deposits (± IgM, C3)	IgA nephropathy
Predominantly mesangial IgG deposits (± IgM, C1q, C3)	Often associated with lupus nephritis
Predominantly mesangial IgM deposits (± C3)	IgM nephropathy
Mesangial C1q deposits (± IgG, IgM, C3)	C1q nephropathy
Isolated mesangial C3 deposits	Often associated with resolving poststreptococcal GN or C3 GN
Negative for immunoglobulin or complement deposits	Idiopathic MesPGN

GN, Glomerulonephritis; *IgA, Immunoglobulin; MesPGN,* Mesangial proliferative glomerulonephritis.

complement components and hemolytic complement activity (CH50) are typically normal. A low C3 and normal C4 level suggests C3 glomerulopathy or poststreptococcal GN. Antinuclear antibody (ANA), antineutrophil cytoplasmic autoantibody (ANCA), anti–glomerular basement membrane (anti-GBM) autoantibody, and cryoimmunoglobulins are negative. Nevertheless, these studies should be performed in most patients to exclude known causes. MesPGN also can be found in resolving postinfectious (poststreptococcal) GN, often with isolated C3 deposits with scanty, subendothelial or subepithelial (hump-like) deposits on EM. Urinary protein biomarkers may help determine prognosis.[6] MesPGN also can be seen in non-poststreptococcal GN.

The prognosis of non-IgA MesPGN is quite variable depending on the underlying IF findings (see later discussion of IgM and C1q nephropathy), but it is often benign. The 30-year renal survival has been estimated to be 50%.[2] Severe and persistent nephrotic syndrome is a sign of a poor prognosis, particularly in males.[2] Patients with nephrotic syndrome may evolve to typical focal and segmental glomerulosclerosis over time.

The treatment of pure MesPGN, unaccompanied by other underlying diseases or lesions such as systemic lupus erythematosus (SLE), minimal change disease (MCD) lesion, or IgA nephropathy, is not well defined.[1,2] No randomized controlled trials (RCTs) have been performed because of the uncommon nature of the disorder. The prognosis for patients with isolated hematuria or hematuria combined with mild proteinuria (<500 mg/day) is generally benign, and thus no treatment other than management of hypertension is needed, unless a distinct change in the course is observed. Repeat renal biopsy may be indicated in such circumstances. For patients with nephrotic syndrome (with or without impaired renal function), a more aggressive approach is often recommended, especially in the presence of diffuse IgM deposits, as discussed later (IgM nephropathy), because many such patients will eventually progress to focal segmental glomerulosclerosis (FSGS). Even in the absence of RCTs, an initial course of corticosteroid therapy may be justified in most patients with nephrotic-range proteinuria, such as prednisone, 60 mg/day or 120 mg every other day for 2 to 3 months, followed by lowered doses on alternate-day regimen for 2 to 3 additional months. About 30% to 50% of these patients experience a decrease in proteinuria to subnephrotic levels, and complete remissions may occur. Relapses of proteinuria are common when steroids are tapered or discontinued. Such relapsing, partially corticosteroid-responsive patients might benefit from the addition of cyclophosphamide, chlorambucil, cyclosporine, mycophenolate mofetil (MMF), or rituximab to the regimen, although information on the efficacy and safety of these agents in pure MesPGN is limited.

Patients with persistent treatment-unresponsive nephrotic syndrome will almost invariably progress to ESRD, accompanied by a conversion to a lesion of FSGS over several years. Whereas transplantation is not contraindicated, patients who do progress to ESRD rapidly and develop superimposed FSGS may have a high risk for recurrence of proteinuria and FSGS in the transplanted kidney (see Chapters 18 and 108).

Immunoglobulin M Nephropathy

IgM nephropathy is characterized by diffuse and generalized glomerular deposits of IgM often accompanied by C3.[3,7] Mesangial electron-dense deposits are also observed. On light microscopy, a picture of pure MesPGN is usually observed, sometimes with superimposed FSGS.[7] Crescentic disease is very uncommon but may occur. A consensus definition of IgM nephropathy proposed (1) dominant mesangial staining for IgM by IF, (2) mesangial electron-dense deposits by EM, and (3) absence of any identifiable systemic disease.[7] Patients with only IgM deposits by IF but MCD by light microscopy and EM do not have IgM nephropathy, according to this definition. Patients may present with recurring macrohematuria and proteinuria, the latter in the nephrotic range in as many as 40% to 50% of patients.[7] Middle-aged adults are most commonly affected, and there is a slight male predominance.[7]

Glomerulosclerosis (but not the extent of mesangial proliferation), persisting nephrotic syndrome, and a poor response to corticosteroids or immunosuppressive therapy are often seen and connote a poor prognosis. As many as 80% of patients with IgM nephropathy and nephrotic syndrome will eventually progress to typical FSGS and, if unresponsive to corticosteroids, will slowly develop chronic kidney disease (CKD) and end-stage renal disease (ESRD). Patients with IgM deposition accompanying MesPGN but without nephrotic syndrome tend to have a benign course.

Treatment of IgM nephropathy with nephrotic syndrome is highly uncertain, although steroid therapy may be associated with a complete or partial remission in as many as 50% of patients. Anecdotal reports of success with rituximab have appeared. The etiology and pathogenesis are unknown, but IgM deposition itself is believed to be an important pathogenic factor acting to augment complement-mediated injury.

C1q Nephropathy

C1q nephropathy is characterized by IF microscopy showing diffuse marked deposition of C1q, often accompanied by IgG, IgM, or both.[4,8] C3 deposits are observed much less frequently. These immunopathologic

BOX 28.1 Rheumatic Diseases Associated with Glomerular Lesions

Glomerulonephritis With Rheumatic Disease

- Systemic lupus erythematosus (SLE; see Chapter 26)
- Rheumatoid arthritis
- Mixed connective tissue disease
- Rheumatic fever
- Ankylosing spondylitis
- Reiter syndrome
- Dermatomyositis/polymyositis
- Scleroderma
- Relapsing polychondritis
- Systemic or renal-limited polyangiitis (see Chapter 25)

BOX 28.2 Renal Disease in Rheumatoid Arthritis

Glomerular Lesions That May Be Direct Complications of the Disease

- Membranous nephropathy (MN)
- MesPGN (± IgA or IgM deposits)
- Diffuse proliferative GN
- Necrotizing and crescentic GN (rheumatoid vasculitis)
- Amyloidosis (AA type)

Glomerular Lesions Associated With Agents Used in Treatment of Rheumatoid Arthritis

- Gold: MN, MCD, acute tubular necrosis
- Penicillamine: MN, crescentic GN, MCD
- NSAIDs: Acute tubulointerstitial nephritis (TIN) with MCD, acute tubular necrosis, MCD without TIN
- Cyclosporine: Chronic vasculopathy and TIN, focal and segmental glomerulosclerosis (?)
- Azathioprine/6-mercaptopurine: TIN
- Pamidronate: Focal segmental glomerulosclerosis
- TNF-α inhibitors: Lupus-like lesions, crescentic GN

MCD, Minimal change disease; *MesPGN,* mesangial proliferative glomerulonephritis; *NSAIDs,* nonsteroidal antiinflammatory agents; *TIN,* tubulointerstitial nephritis.

features resemble those seen in LN; however, these patients have none of the clinical features of SLE and usually do not develop SLE even after prolonged follow-up. Anti-C1q vasculitis (also known as hypocomplementemic urticarial vasculitis or McDuffie syndrome) can resemble C1q nephropathy, although urticarial lesions and systemic symptoms are more common in anti-C1q vasculitis. These patients also have low levels of serum C1q and elevated anti-C1q auto-antibodies,

The light microscopic lesions of C1q nephropathy are heterogeneous. In addition to MesPGN, other morphologic lesions, including MCD and FSGS, are typically observed by light microscopy. Electron-dense deposits are seen in mesangium, subepithelial, and subendothelial locations as well. Nephrotic-range proteinuria occurs, often with hematuria. Males predominate and African Americans are often affected. Serum C3 components, ANA, and anti–double-stranded DNA (anti-dsDNA) antibodies are consistently normal or negative. The response to treatment is poor, and progression to ESRD may occur, particularly when nephrotic syndrome is present and FSGS lesions are seen by light microscopy. Anecdotal reports of success with immunosuppressive agents, including rituximab, have appeared. Patients with C1q deposits and MCD appear to respond well to conventional steroid therapy.

Mesangial Proliferative Glomerulonephritis Associated With Minimal Change Disease

MesPGN also may be a part of the spectrum of MCD-FSGS lesions (see Chapters 17 to 19). Distinct mesangial hypercellularity superimposed on a lesion of MCD (diffuse foot process effacement seen on EM) may point to a greater likelihood for corticosteroid unresponsiveness and an eventual evolution to the FSGS lesion.

GLOMERULONEPHRITIS WITH RHEUMATIC DISEASE

Several collagen vascular diseases other than SLE may be complicated by GN[9] (Box 28.1), including rheumatoid arthritis (RA), mixed connective tissue disease, polymyositis and dermatomyositis, acute rheumatic fever, scleroderma, and relapsing polychondritis. IgA nephropathy also may be seen in association with the seronegative spondyloarthropathies. Toxic or hypersensitivity reactions to nonsteroidal antiinflammatory drugs (NSAIDs) can contribute to glomerular disease.[10]

Rheumatoid Arthritis

A wide variety of glomerular, tubulointerstitial, and vascular lesions of the kidney may complicate RA (Box 28.2).[9] Clinical abnormalities, including abnormal urinalysis (hematuria, leukocyturia, proteinuria), and reduced renal function are common in patients with severe or long-standing disease RA. Membranous nephropathy (MN) (see Chapter 20) is the most common glomerular lesion, possibly because of the underlying disease itself or in the past as a result of therapy (parenteral or oral gold or penicillamine). The presence of human leukocyte antigen (HLA)-DR3 increases the risk for development of MN in a patient with RA. The lesion is not associated with anti–phospholipase A_2 receptor (anti-PLA_2R) autoantibodies.

MN that is associated with RA but not due to medication exposure has a course that is similar to that of the idiopathic disease, although spontaneous remissions are less likely to occur. By comparison, MN associated with drugs used to treat RA is most likely to remit after discontinuance of the drug therapy. Of patients with RA with drug-induced MN, 60% to 80% will remit within 1 year of stopping treatment.

Secondary (AA) amyloidosis (see Chapter 27) is found in 5% to 20% of patients with RA undergoing renal biopsy. Nephrotic syndrome and progressive renal failure are common.

NSAIDs also may produce tubulointerstitial nephritis, MCD, or both simultaneously (see also Chapters 17 and 60). A severe, necrotizing polyangiitis may complicate the course of long-standing RA (rheumatoid vasculitis). These patients may have profound reduction in C3 levels, striking elevation of rheumatoid factors, and marked polyclonal hypergammaglobulinemia. Renal involvement in rheumatoid vasculitis is now relatively uncommon for poorly understood reasons. The use of TNF-α inhibitors for treatment of RA can evoke a picture resembling LN (see Chapter 26).

Mixed Connective Tissue Disease

Mixed connective tissue disease is characterized by features that overlap with those of SLE, scleroderma, and polymyositis. Typically, the serum of such patients contains high-titer autoantibodies to extractable nuclear antigens (ribonucleoprotein-extractable nuclear antigen, U1 ribonucleoprotein antigen). Low titers of anti-dsDNA antibody also may be found. Renal disease, originally thought to be quite rare, is found in 10% to 50% of patients, most frequently MN and MesPGN. Treatment with steroids is generally effective, but some patients exhibit progressive

CKD. Patients with severe GN may respond to treatment regimens similar to those used in the treatment of LN (see Chapter 26).

Polymyositis and Dermatomyositis

The related collagen vascular diseases polymyositis and dermatomyositis are characterized by inflammatory lesions in muscle and variable skin lesions and often include Raynaud phenomenon. On occasion, patients have proteinuria and hematuria secondary to MesPGN with IgM deposits. Acute kidney injury (AKI) may rarely supervene when severe muscle injury and myoglobinuria are present. Treatment with steroids may ameliorate the renal manifestations and improve the muscle and skin manifestations.

Acute Rheumatic Fever

Acute rheumatic fever secondary to a pharyngeal (but not cutaneous) infection with a rheumatogenic strain of group A β-hemolytic streptococci is seldom accompanied by renal disease (see Chapter 55). Poststreptococcal GN and acute rheumatic fever almost never coexist because of the distinct difference between nephritogenic and rheumatogenic strains of streptococci. In addition, cutaneous streptococcal infections are never associated with acute rheumatic fever sequelae. Nevertheless, on rare occasions, MesPGN has been associated with acute rheumatic fever. MesPGN usually manifests with hematuria with scant proteinuria and often resolves with appropriate treatment and control of acute rheumatic fever.

Ankylosing Spondylitis and Reiter Syndrome (Seronegative Spondyloarthropathies)

The seronegative spondyloarthropathies and oligoarticular arthropathies may be associated with mesangial IgA deposition or MesPGN in some patients. Clinical manifestations are usually mild and nonprogressive. AA amyloidosis may complicate long-standing ankylosing spondylitis.

Scleroderma (Systemic Sclerosis)

Scleroderma is a heterogeneous disorder of unknown etiology characterized by uncontrolled expansion of connective tissue in the skin and other visceral organs,[11] as well as vascular thickening and narrowing. Clinical manifestations vary from increased connective tissue in localized patches of skin (morphea) to diffuse and generalized disease (systemic sclerosis). The latter leads to thickening of the skin of the face and hands, telangiectasia, Raynaud phenomenon, tendon friction rubs, and sclerodactyly. A characteristic pattern of blood vessel abnormalities is seen in the nail beds. Visceral involvement causes interstitial pulmonary fibrosis, loss of esophageal and other gastrointestinal motility, restrictive cardiomyopathy, and renal disease. Limited forms of the disease (CREST syndrome: calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia) occur but are seldom associated with renal disease. The disorder is more frequent in females, with an onset usually in young adults. Approximately 90% of patients will have a speckled pattern of fluorescent ANA, and 30% will have detectable antibody to topoisomerase I (Scl-70). Anticentromere antibody is strongly associated with the CREST syndrome. Anti–NA polymerase III, antitopoisomerase, and anticentromere antibodies are associated with more systemic and renal involvement and a poor prognosis. Rarely, the visceral abnormalities occur without cutaneous lesions (systemic sclerosis *sine* scleroderma).

Renal involvement in scleroderma ranges from low-grade proteinuria and slight impairment of glomerular filtration rate, to a more marked reduction in renal blood flow leading to a greatly elevated filtration fraction secondary to mild MesPGN, to severe AKI.[12,13] The last is referred to as scleroderma renal crisis (SRC) and consists of severe (hyperreninemic) hypertension, encephalopathy, systolic and diastolic congestive heart failure, and AKI. Rare cases of SCR may be seen without cutaneous features and even with relatively normal blood pressure. These patients are often positive for anti RNA polymerase II antibody, and complement activation can be observed.[14] There is often an accompanying microangiopathic hemolytic anemia with schistocytes and elevated serum lactate dehydrogenase. AKI results from primary involvement of the arcuate and interlobular arteries (Fig. 28.2). It may be superimposed on lesions of hypertensive emergencies (e.g., fibrinoid necrosis of the afferent arterioles) and ischemic glomerular changes (e.g., wrinkling of the capillary wall and thickening of the basal lamina).

The prognosis of patients with SRC has remarkably improved with the use of angiotensin-converting enzyme (ACE) inhibitors.[12,13] In one study, ACE inhibitor treatment was associated with better patient survival at 1 year (75% vs. 15%) and with significant preservation or recovery

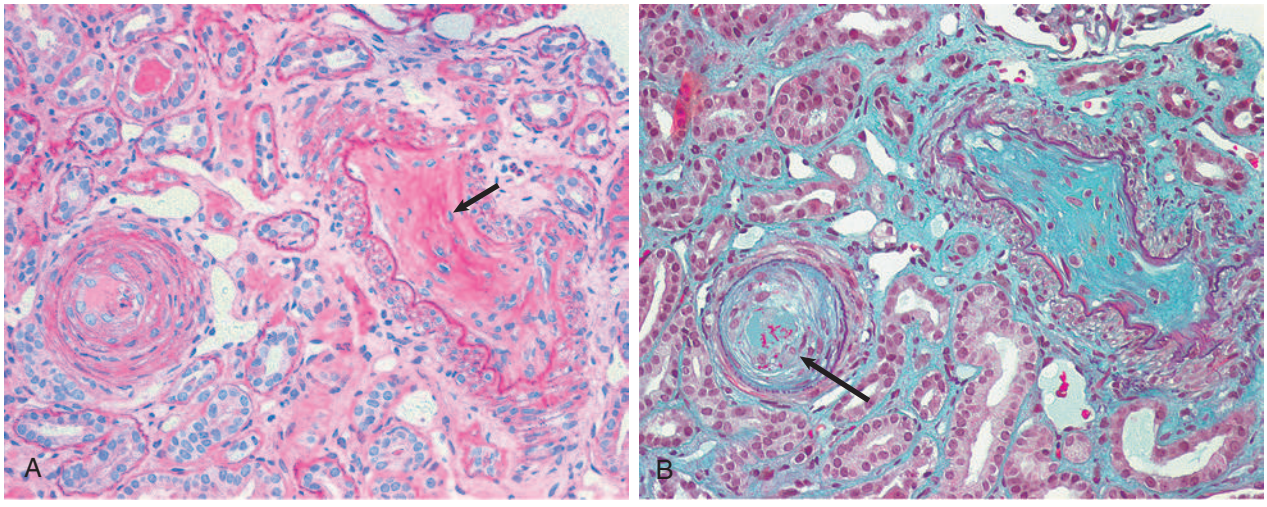

Fig. 28.2 Scleroderma. (A) Two interlobular arteries, one transversely and one tangentially cut, show a pronounced subendothelial thickening with weakly periodic acid–Schiff–positive mucinous material and myofibroblasts *(arrow)*. (B) Fragmented erythrocytes (schistocytes) can be seen in the Goldner elastica stain in *red (arrow)*. The process is limited to the intima because the lamina elastica interna is preserved. Surrounding tubules are collapsed and have atrophic epithelia secondary to postarteriolar ischemia. (Courtesy H. J. Groene, Heidelberg, Germany.)

of renal function.[14] Captopril is the preferred agent for treatment, largely because it is the agent with widest experience in this condition.[14] Delayed recovery of renal function is common in patients requiring dialysis support. ACE inhibitor treatment should continue during dialysis therapy. Transplantation may be a reasonable treatment option, but disease in other visceral organs may limit life expectancy. Various biologic agents, including TGF-α inhibitors, anti-CD20 (rituximab), interleukin 6 (IL6) monoclonal antibodies, eculizumab, and tyrosine kinase inhibitors are undergoing evaluation as therapies for scleroderma or SRC.[15,16]

Relapsing Polychondritis

Polychondritis is a chronic relapsing disorder characterized by destructive inflammation of cartilage (ear, nose, trachea, costal cartilage). It may be associated with crescentic GN, MesPGN, or MN.[17] Cartilage lesions may lead to deformities (saddle nose, floppy ears, tracheal collapse or stenosis), and the renal disease may be severe and progressive. Aggressive management of progressive disease with corticosteroids and cytotoxic agents (e.g., cyclophosphamide) is indicated to control both the systemic and renal manifestations. TNF-α antagonists are useful therapeutic agents in relapsing polychondritis. Tocilizumab or abatacept also can be used as third-line agents.

ANTIPHOSPHOLIPID ANTIBODY SYNDROME

The antiphospholipid antibody syndrome (aPLA syndrome) is a prothrombotic disorder characterized by venous and arterial thrombosis and by the presence of circulating autoantibodies to phospholipid-protein complexes, including those of the coagulation cascade.[18,19] The syndrome was first recognized by Hughes in 1983,[18] and has protean manifestations ranging from migraine headaches to multiple thrombosis and multiorgan failure (catastrophic aPLA syndrome; CAPS).[18,19] Thrombotic episodes occur at a frequency of about 7.5 per 100 patient years for 5 years after the first thrombotic event and often can be the presenting feature.[20] Neurologic symptoms and signs are common, including transient cerebral ischemic attacks (TIAs), strokes, migraine headaches, seizures, myelitis, and balance and sensory disturbances (often resembling multiple sclerosis).[18,19] Cardiovascular problems, such as pulmonary hypertension, premature atheromatous disease, renal artery stenosis, and myocardial infarction, are common.[18,19] Livedo reticularis is an important diagnostic clue (Fig. 28.3). Adrenal infarction or hepatic venous thrombosis may lead to acute adrenal insufficiency or Budd-Chiari syndrome, respectively. Visual loss, visual field defects, anosmia, aseptic bone necrosis, fracture, spinal claudication, and autonomic dystrophy are other, less well-described complications. Pulmonary hemorrhage or fibrosing alveolitis can be a presenting feature.[21] Repeated pregnancy loss is common.

The kidneys are frequently involved with a form of thrombotic microangiopathy (TMA; see also Chapter 29).[22,23] CAPS is a rare but often fatal form of the aPLA syndrome frequently associated with SLE or infections. It involves many organ systems, including the brain, kidneys, heart, and lungs.[24]

The aPLA syndrome may occur without known systemic disease or may accompany SLE (see also Chapter 26). The presence of aPLA syndrome in SLE confers a much worse prognosis and greater risk for neuropsychiatric and cardiovascular complications. The aPLA syndrome (primary or SLE related) always should be suspected whenever a history of migraine headache, TIA or stroke, multiple pregnancy loss, or arterial or venous thrombosis is identified or a family history of autoimmune disease is elicited. The criteria for the definite diagnosis of aPLA syndrome include the presence of at least both one clinical criterion plus one laboratory criterion[25]: *Clinical*—(1) thrombosis (arterial or venous) or (2) spontaneous abortions or stillbirths. *Laboratory* (two or more occasions at least 6 to 12 weeks apart)[25]—(1) Lupus anticoagulant, (2) anticardiolipin antibody, or (3) anti–β_2 glycoprotein I antibody. The pathogenic antibodies in aPLA syndrome appear to be primarily directed to the domain I of β_2-glycoprotein I.[26] Antibodies to prothrombin, thrombin, or phosphotidylserine may be predictive of severe thrombophilia and/or pregnancy loss.

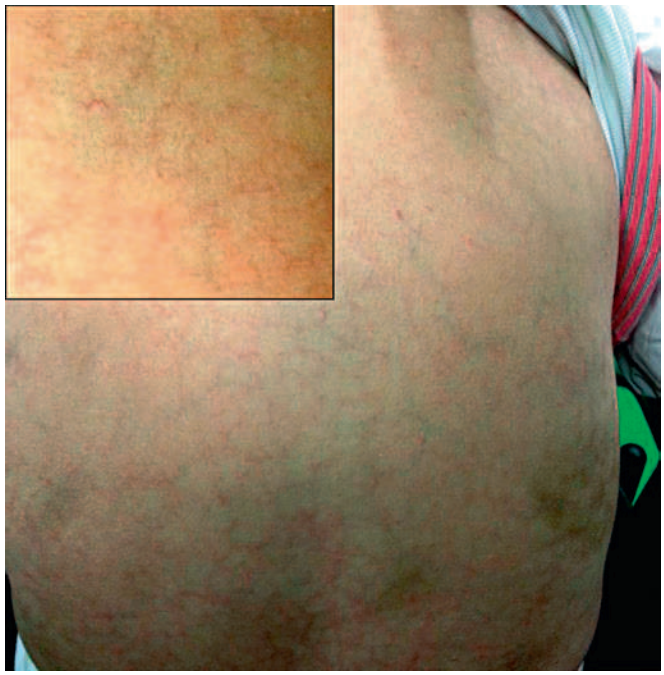

Fig. 28.3 Livedo reticularis in patient with antiphospholipid antibody syndrome. Note reticulated skin changes (*insert,* higher magnification) on the patient's back, in addition to some hematomas related to her warfarin therapy. (Courtesy J. Floege, Aachen, Germany.)

The pathogenesis of aPLA is probably multifactorial.[27] The thrombotic state seems to involve generation of reactive oxygen species leading to alterations in β_2-glycoprotein I function, impaired function of endothelial nitric oxide synthase, activation of prothrombotic receptors by autoantibodies, increased expression/activation of tissue factor, increased modified forms of prothrombotic factor XI, disruption of annexin A5 shield, and antibody-mediated activation of C3 and/or C5.[27] There is a prominent involvement of the mammalian target of rapamycin complex (mTORC) in aPLA syndrome.[28] Transplanted patients with aPLA syndrome who receive the mTORC inhibitor sirolimus for prevention of allograft rejection have a lower risk for recurrence of vascular lesions. However, mTORC inhibition in primary or secondary aPLA syndrome has not yet been tested in randomized trials.

Laboratory testing usually reveals an autoantibody to phospholipids (anticardiolipin, anti–β_2-glycoprotein 1, or prothrombin), but "antibody-negative" aPLA syndrome has been described.[24,26] False-positive test results for syphilis and a lupus anticoagulant are common. A prolonged prothrombin or partial thromboplastin time that does not correct when plasma is diluted 1:1 with normal plasma is found in such circumstances. Antiphospholipid antibodies may cross-react with platelet factor 4–heparin complex and thus may be associated with a false positive for antibody in heparin-induced thrombocytopenia. Mild thrombocytopenia is common (platelet counts about 100,000/mm^3, but usually not less than 80,000/mm^3). Thrombocytopenia may be an in vitro phenomenon related to the effect of the aPLA antibody on platelet membrane biology. Lymphocytopenia is common in patients with SLE and aPLA syndrome.

A mild hemolytic anemia (Coombs negative or positive) may coexist, giving rise to confusion with thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, and Evans syndrome. A frank microangiopathic hemolytic anemia is relatively uncommon. Patients with aPLA syndrome and reduced ADAMTS13 activity may be at higher risk for thrombotic events.[29] Anti-C1q autoantibodies are found frequently in primary aPLA syndrome and might contribute to abnormal complement activation, particularly in severe refractory cases.

In primary aPLA syndrome, overt renal manifestations are generally mild and are frequently absent. Nephrotic syndrome is relatively rare. In aPLA syndrome associated with SLE, the renal manifestations are determined largely by the severity of the underlying glomerular lesions, but the coexistence of aPLA syndrome contributes to a worse prognosis and extrarenal manifestations (neurologic, cardiovascular, osseous, ophthalmologic, pulmonary, hepatic, visceral, and obstetric) (see also Chapter 26). A strong association of aPLA with alveolar hemorrhage exists in SLE.[21]

The therapy for primary aPLA syndrome and that accompanying SLE is controversial.[30] Immunosuppressive agents, such as steroids or cytotoxic agents, even when they are used to control SLE, have yielded disappointing results. Symptomatic patients are best treated with anticoagulation. Aspirin (or clopidogrel) can be used routinely in mild cases. Combinations of aspirin and low-dose warfarin might be effective, but the risk for bleeding is increased. Vitamin K antagonism is the mainstay of treatment in severe cases, with the international normalized ratio (INR) adjusted to a level depending on symptoms; INR between 2.0 and 3.5 may be required. Low-molecular-weight heparin (subcutaneous or intravenous) is the treatment of choice for pregnancy complicated by aPLA syndrome and is also useful in alleviating migraine headache. Aspirin therapy in pregnancy with an aPLA-like syndrome does not appear to be effective. Long-term use of hydroxychloroquine can be beneficial in patients with primary aPLA syndrome without evidence of SLE.[31] Direct-acting oral anticoagulants (e.g., rivaroxaban, apixaban, dabigatran) may be equivalent or superior to warfarin, but it is premature to make any recommendations.[32]

Sirolimus, an inhibitor of mTORC, has been suggested for treatment of aPLA syndrome,[27] but mTORC inhibitors also can increase the risk for thrombosis in susceptible individuals. High-dose intravenous IgG (IVIG) can have dramatic beneficial effects, especially in acutely evolving disease associated with SLE. Combinations of plasma exchange and intravenous immunoglobulin seem to be beneficial in high-risk pregnancy with aPLA syndrome,[33] and plasma exchange alone can be helpful in CAPS.[34]

The benefits of immunomodulating agents such as rituximab have not been adequately evaluated in aPLA syndrome, but preliminary reports are encouraging when used alone or with plasma exchange. In severe, life-threatening disease, combinations of rituximab and plasma exchange should be seriously considered. Intensive plasma exchange (plus immunosuppression) has been used in other circumstances, such as in aPLA syndrome associated with SLE, with variable degrees of success. Monoclonal antibodies to C5 (eculizumab) or to CD20 (rituximab) also have been used to treat CAPS with some success.[35,36]

Novel therapeutic approaches to the aPLA syndrome, such as coenzyme Q10, statins, *N*-acetylcysteine, phosphodiesterase inhibitors, and factor XI inhibitors have not yet been thoroughly tested for safety and efficacy.

OTHER UNCOMMON GLOMERULAR DISORDERS

Lipoprotein Glomerulopathy

Lipoprotein glomerulopathy is apparently caused by an abnormality in lipoprotein metabolism.[37,38] It is characterized by extensive deposits of apolipoproteins A, B, and E in the glomeruli (mostly apo E), leading to greatly expanded capillaries filled with a pale-staining, PAS-negative, mesh-like substance having the appearance of lipid thrombi (Fig. 28.4), also described as "foam cells." These cells also may be seen in crystal-storing histiocytosis, macrophage activation syndrome, TMA, and lecithin–cholesterol acyltransferase deficiency (see later discussion).[39] IF stains for APO E are strongly positive, but immunoglobulins and complement are absent.[37,38] Clinically, there may be heavy proteinuria with nephrotic syndrome. Apo B and E levels are increased in plasma in association with a type III hyperlipoproteinemia. Apo E usually shows a heterozygous E2/E3 or E2/E4 phenotype, but homozygosity for Apo E2 or E3 also has been observed. Homozygous Apo E2 is also seen in familial type III hyperlipoproteinemia. Decreased low-density lipoprotein (LDL) receptor binding and increased heparin affinity may explain some of the pathogenetic processes in lipoprotein glomerulopathy. The disease may be associated with psoriasis and hypertensive emergencies (formerly called malignant hypertension) accompanied by TMA. Otherwise, there are no distinctive clinical features. Familial cases have strongly suggested a hereditary abnormality. The characteristics of Chinese patients with familial lipoprotein glomerulopathy secondary to the *APOE* Kyoto mutation have been described. Lipoprotein glomerulopathy may recur in the renal transplant.

Treatment with bezafibrate or fenofibrate may be effective and is the initial treatment of choice.[40] About three quarters of patients with

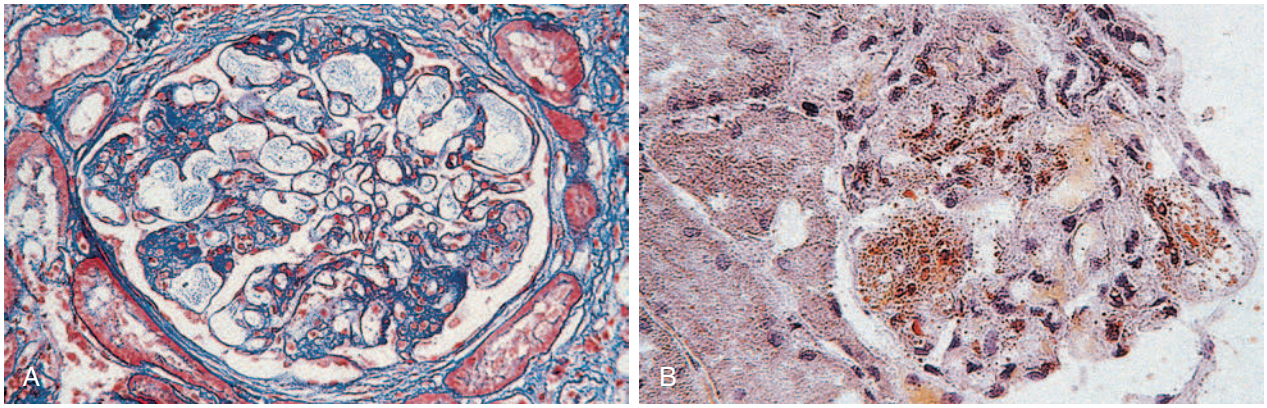

Fig. 28.4 Lipoprotein glomerulopathy. (A) Dilated capillary lumina containing a pale, trichrome-stained, mesh-like or granular substance. (×260.) (B) The granules stain positively with oil red O and antilipoprotein E antisera. (×260.) (Modified from Churg J, Berstein J, Glassock R. *Renal Disease: Classification and Atlas of Glomerular Disease.* New York: Igaku-Shoin; 1995.)

nephrotic syndrome treated with fibrates will achieve a complete or partial remission. Treatment with heparin-induced extracorporeal lipoprotein precipitation–apheresis systems (HELP-apheresis) also can achieve a complete remission in some patients.[41]

Lecithin–Cholesterol Acyltransferase Deficiency

Lecithin–cholesterol acyltransferase (LCAT) deficiency is an autosomal recessive disorder associated with a very low high-density lipoprotein (HDL) cholesterol but a remarkably variable and often low frequency of cardiovascular disease in carriers[42,43] (see also Chapter 19). The clinical characteristics include corneal opacities (misty deposits, also known as "fish eye"), splenomegaly, normocytic normochromic anemia (with target cells), low HDL and α-lipoprotein levels, and elevated LDL levels. Fish eye disease also can exist without anemia, splenomegaly, or renal disease. It is likely that the accumulation in plasma of a cholesterol-rich multilamellar particle called lipoprotein-X is pathogenic in the kidneys.[44]

Proteinuria, including nephrotic syndrome, as well as hypertension and progressive renal failure, are the main renal manifestations. On light microscopy, the glomeruli have foam cells, intimal hyperplasia, and thickening of the GBM with effacement of the foot processes (Fig. 28.5). Progressive renal failure is the rule; however, it has an often slow and insidious onset and is usually first detected in the fourth decade of life. Treatment is generally ineffective, but theoretically, an inhibitor of hepatic acyl coenzyme A–cholesterol acyltransferase activity might be of benefit. The disease can recur in the renal allograft and sequential kidney-liver transplantation might be curative.[45]

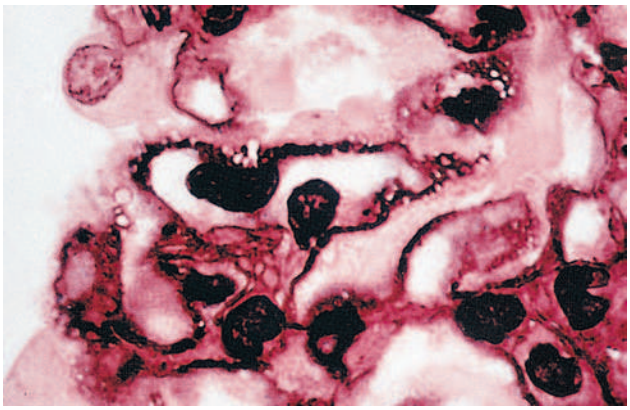

Fig. 28.5 Lecithin–cholesterol acyltransferase deficiency. Note the irregular, thickened glomerular capillary walls containing clear vacuoles, which are characteristic of the LCAT lesion. (Periodic acid–Schiff reaction, ×1000.) (Modified from Churg J, Berstein J, Glassock R. *Renal Disease: Classification and Atlas of Glomerular Disease.* New York: Igaku-Shoin; 1995.)

Collagen III Glomerulopathy

Collagen III glomerulopathy, also known as collagenofibrotic glomerulopathy, is an autosomal recessive systemic disorder with prominent renal manifestations that may be a *forme fruste* of nail-patella syndrome (see Chapter 46) because the glomerular abnormalities are similar.[46] Nevertheless, patients with collagen III glomerulopathy lack the typical skeletal abnormalities observed in the nail-patella syndrome. Mutations of the *LMX1B* gene are believed to be causative.[47] Clinically, patients present with proteinuria and slowly progressive renal failure. Patients may be of any age, and males predominate. Marked elevation of serum hyaluronan concentration might be a diagnostic biomarker.

On light microscopy the glomeruli are enlarged, with a marked expansion of the mesangial matrix by material weakly positive for PAS reaction (Fig. 28.6). Immunohistology is usually negative, but rarely will show "full-house" immunoglobulin and complement deposition. Antisera to collagen type III strongly react with the glomerular deposits. EM shows bundles of spirally arranged and frayed fibrillar deposits (Congo red negative) with periodicity characteristic of collagen. Similar deposits may be found in the spleen, liver, myocardium, and thyroid in fatal cases. No treatment is known to be effective, and there are no data yet on recurrent disease after renal transplantation.

Fibronectin Glomerulopathy

Fibronectin glomerulopathy is a rare, autosomal dominant, nonamyloid, fibrillary glomerular disease with onset usually in early adolescence with proteinuria, microhematuria, hypertension, distal (type 4), renal tubular acidosis, and slowly progressive renal failure.[48] The gene *(FN1)* responsible for the disorder maps to chromosome 2q32.[49] Most patients reach ESRD between the second and sixth decades of life. The renal pathology usually reveals enlarged, hyperlobular, and normocellular glomeruli with a homogeneous or fibrillary material (on PAS staining) in the mesangium and subendothelial area. EM shows randomly oriented fibrils (12 to 16 nm wide and 120 to 170 nm long). IF is negative for antibody and complement components but will stain brightly with use of an antifibronectin antibody. The pathogenesis of the disease is unknown. Mice knocked out for uteroglobin develop a similar lesion,

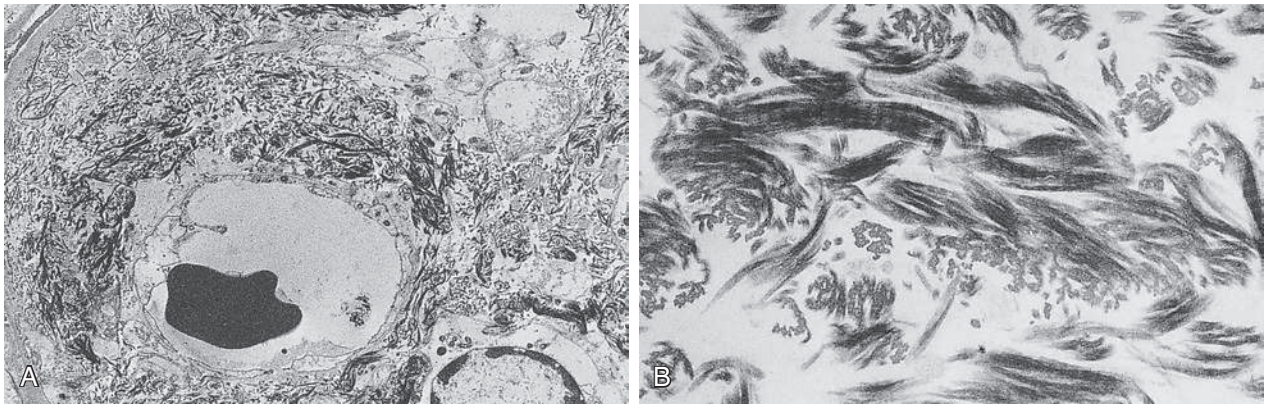

Fig. 28.6 Electron microscopy of collagen III (collagenofibrotic) glomerulopathy. (A) Fine fibrils occur in the mesangial and subendothelial areas. (×3000.) (B) These fibrils are randomly oriented with typical periodicity and average 30 nm in diameter. The fibrils are strongly positive for periodic acid–Schiff reaction with anti–collagen type III antibodies. (×15,000.) (Modified from Churg J, Berstein J, Glassock R. *Renal Disease: Classification and Atlas of Glomerular Disease.* New York: Igaku-Shoin; 1995.)

but studies in humans have not documented any linkage to genes for uteroglobin or fibronectin. The differential diagnosis includes other disorders associated with fibril deposition (see Chapter 27). There is no known effective treatment of fibronectin glomerulopathy. The disease can recur in renal allografts.

Nephropathic Cystinosis

Late-onset adult cystinosis, a variant of typical pediatric cystinosis with mutations in the cystinosin gene *(CTNS)*, results in a milder phenotype.[50] Cystinosin deficiency results in podocyte damage and proteinuria.[51] Patients with cystinosis also may present with glomerular disease during the teenage years. Nephrotic syndrome may occur. The glomerular lesions resemble FSGS except that cystine crystals are found in glomerular and tubular epithelial cells. Patients with cystinosis tend to have blond hair, photophobia, hypothyroidism, corneal deposits, rickets, and Fanconi syndrome with tubular proteinuria, or nephrogenic diabetes insipidus (see also Chapter 48). The treatment of choice is long-term cysteamine administration.[52]

Miscellaneous Storage Diseases Rarely Associated With Glomerular Lesions

Diseases associated with storage of abdominal lipids or carbohydrates in tissue may rarely provoke glomerular lesions, usually in infants and children. These include Hurler syndrome (type I mucopolysaccharidoses), von Gierke disease (glycogen storage disease), Gaucher disease, Refsum disease, nephrosialidosis, and I cell disease (mucolipidosis type II). Juvenile malabsorption of vitamin B_{12} with megaloblastic anemia (Imerslund syndrome; cubulin deficiency) can be associated with prolonged glomerular proteinuria (albuminuria), but progressive renal disease does not develop. Asphyxiating thoracic dystrophy (Jeune syndrome) is associated with glomerular, tubular, and interstitial abnormalities. Hereditary osteolysis causing arthralgias and deformities of wrists and ankles can be accompanied by chronic GN. The nail-patella syndrome and Fabry disease are discussed in Chapter 46.

Idiopathic (Nondiabetic) Nodular Glomerulosclerosis

An intercapillary nodular expansion of the mesangium encroaching on the glomerular capillary lumina, that is, the Kimmelstiel-Wilson lesion, is most commonly associated with diabetes mellitus and proliferative diabetic retinopathy (see Chapter 30). A small group of patients has been described in whom a similar lesion is seen in the absence of any overt features of diabetes mellitus or disordered glucose metabolism or other known causes of a similar lesion, such as κ light-chain deposition disease (see Chapter 27), chronic TMA, monoclonal immunoglobulin deposition disease (MIDD), fibrillary GN, and fibronectin glomerulopathy. Thus idiopathic nodular glomerulosclerosis is a diagnosis of exclusion.

The first examples of this new disorder were recognized in 1989.[53] Although some of these patients may have had intermittent manifestation of diabetes or only mild abnormalities of glucose homeostasis, such as an abnormal glucose tolerance test result, most have not had features diagnostic of diabetes. Recent marked weight loss with remission of glycemic abnormalities can mask the prior presence of type 2 diabetes and give rise to diagnostic confusion.

The clinical features are nonspecific and nondiagnostic. Patients with idiopathic nodular glomerulosclerosis are usually older (average age ~70 years) and female. Nephrotic syndrome is a common presentation. A heavy smoking history, obesity, and long-standing hypertension are frequent, but the pathogenic role of these abnormalities is uncertain.[54] It is possible that the long-term consequences of cigarette smoking and intermittent TMA are pathogenetically important.[54]

The pathology includes typical nodular glomerulosclerosis with thickening of the GBM and varying degrees of arteriolo-nephrosclerosis and hyalinosis identical to the diabetes-associated Kimmelstiel-Wilson lesions. No electron-dense or organized deposits are seen on EM. The GBM and tubular basement membrane may stain with IgG and albumin on IF. Neovascularization can be seen within the nodules. Some cases may resemble the lesions of chronic TMA.

The prognosis is poor and relates to the persistence of nephrotic-range proteinuria. Most patients with idiopathic nodular glomerulosclerosis will progress to ESRD, sometimes quite rapidly. The 50% renal survival in those who continue to smoke heavily is about 1 year after diagnosis. There is no known effective therapy other than angiotensin inhibition to reduce the proteinuria and smoking cessation where relevant.

Macrophage Activation Syndrome

The macrophage activation syndrome (MAS; also known as the hematophagocytic syndrome [HPS] or hematophagocytic lymphohistiocytosis [HLH]) is an uncommon disorder characterized by massive infiltration of the bone marrow by activated macrophages often accompanied by pancytopenia, fever, rash, coagulopathy, liver function abnormalities, adenopathy, hepatosplenomegaly, erythrophagocytosis, and TMA.[55] Primary MAS is seen in children with inherited dysfunction of the immune response, particularly natural killer (NK) cells. Secondary MAS in adults can be triggered by infections (particularly viral infections), autoimmune disease (SLE and Still disease) and neoplasia. Excessive production of cytokines (TNF-α and IL-1, -4, -6, -8, -10), extreme hyperferritinemia, marked hyper-triglyceridemia, and hypo-fibrinogenemia are common findings that often lead to the correct diagnosis. The erythrocyte sedimentation rate may be low.

Renal manifestations include AKI and nephrotic syndrome. Post-transplant MAS also can occur. When nephrotic syndrome or TMA is evident the underlying lesion is often collapsing FSGS.[56]

Treatment is difficult, and the mortality rate of MAS is high. Treatment consists of removal of the triggering agent (if possible). High-dose steroids, calcineurin inhibiting agents, IVIG, anti–TNF-α agents, anti–IL-1 receptor, and anti–IL-6 monoclonal antibodies, rituximab, and plasma exchange have been used with varying degrees of success.[57]

DRESS Syndrome

DRESS syndrome (drug reaction with eosinophilia and systemic symptoms) is an uncommon manifestation of severe drug hypersensitivity characterized by extensive mucocutaneous rashes, fever, lymphadenopathy, hepatitis, eosinophilia, and atypical lymphocytosis with multisystem organ injury.[58] Reactions to aromatic anticonvulsants, such as phenytoin and carbamazepine, are a common cause. AKI and proteinuria due to glomerular damage can be seen. Untreated, the DRESS syndrome can be fatal. For severe cases, parenteral and oral steroids are indicated.[59]

Kimura Disease

Kimura disease (or angiolymphoid hyperplasia with eosinophilia [ALHE]) is a rare disorder characterized by nonmalignant masses in the head and neck, lymphadenopathy, marked eosinophilia, elevation of serum IgE, and immune thrombocytopenia, mostly in subjects of Asian ancestry.[60] Renal involvement with nephrotic syndrome due to MN, FSGS (tip lesion variant), or MesPGN is common. Steroid therapy is successful in most cases.

SELF-ASSESSMENT QUESTIONS

1. A 42-year-old man is discovered to have proteinuria, impaired renal function (serum creatinine 2.3 mg/dl), and normocytic normochromic anemia (hemoglobin [Hb] 8.2 g/dl). The physical examination shows hypertension (150/98 mm Hg), mild obesity (body mass index 31 kg/m^2), bilateral corneal opacities, and 1+ edema. The albumin is 3.2 g/dl, total cholesterol is 120 mg/dl, low-density lipoprotein cholesterol is 80 mg/dl, high-density lipoprotein cholesterol is 15 mg/dl, and triglycerides is 200 mg/dl. Serum C3 is normal. A fasting blood sugar is 120 mg/dl. Urinary total protein excretion is 4.6 g/day. Which of the following is the *most* likely diagnosis?
   A. Alport syndrome
   B. Adult-onset cystinosis
   C. Lecithin–cholesterol acyltransferase deficiency
   D. C3 glomerulopathy
   E. Obesity-related glomerulopathy
2. Which of the following can be an effective for treatment of lipoprotein glomerulopathy?
   A. Cyclosporine
   B. Bezafibrate
   C. Atorvastatin
   D. Corticosteroids
   E. Plasma infusions
3. A 65-year-old woman is found to have nephrotic syndrome, and renal biopsy shows membranous nephropathy. Serum C3 is normal, and antinuclear antibody (ANA) is 1:80. Anti-dsDNA is negative. Immunofluorescence staining of the biopsy reveals extensive deposits of immunoglobin G4 (IgG4) and weak deposits of IgG1 and IgG3. Serologic studies for hepatitis B are negative. Which of the following is the *most* likely diagnosis?
   A. Membranous lupus nephritis
   B. Membranous nephropathy secondary to cancer
   C. Idiopathic (primary) membranous nephropathy
   D. Membranous nephropathy secondary to hepatitis C infection
4. A 46-year-old woman complains of frequent "migraine" headaches. She is found to be anemic (Hb 9.8 g/dl), and serum creatinine is elevated to 1.6 mg/dl. Her blood pressure is 156/94 mm Hg. Urinalysis reveals 2+ protein and a trace of blood. The serum C3 and C4 are normal, and ANA is negative. She takes an NSAID for headache. She has had three miscarriages and is presently amenorrheic. Her physical examination is otherwise unremarkable. There are no localizing neurologic findings. Which of the following tests would be *most* appropriate as a next step in the diagnostic evaluation of this patient?
   A. Anti-dsDNA autoantibody
   B. Magnetic resonance imaging of the brain
   C. Serum iron and iron-binding capacity
   D. Antiphospholipid antibody test
   E. Serum protein electrophoresis

Thrombotic Microangiopathies, Including Hemolytic Uremic Syndrome

Marina Noris, Piero L. Ruggenenti, Giuseppe Remuzzi

DEFINITIONS

Thrombotic microangiopathy (TMA) is a lesion of arteriolar and capillary vessel wall thickening with intraluminal platelet thrombosis and a partial or complete obstruction of the vessel lumina. Laboratory features of thrombocytopenia and microangiopathic hemolytic anemia are almost invariably present. Depending on whether renal or brain lesions prevail, two pathologically indistinguishable but somehow clinically different entities have been described: hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP). Because HUS can involve extrarenal manifestations and TTP may be associated with severe renal disease, the two can be difficult to distinguish on clinical grounds.[1] In comparison to HUS, TTP is associated with more severe thrombocytopenia and less severe acute kidney injury (AKI),[2] but changes in platelet count and kidney function largely overlap in HUS and TTP and there are no cut-off values that discriminate the two syndromes. However, newly identified pathophysiologic mechanisms have allowed for the differentiation of the two syndromes on a pathogenetic basis and have paved the way to specific diagnosis and treatment (Table 29.1 and Fig. 29.1).

The term HUS was introduced in 1955 by Gasser and coworkers in their description of an acute fatal syndrome in children characterized by hemolytic anemia, thrombocytopenia, and severe AKI. HUS occurs most frequently in children under the age of 5 years (incidence 5 to 6 per 100,000 children per year compared with an overall incidence of 0.5 to 1 per 100,000 per year). Over 90% of cases are associated with infection by Shiga-like toxin (Stx) producing *Escherichia coli* (STEC). STEC-HUS occurs primarily in children, except in epidemics, when it may occur in patients with a wider range of ages. For example, from May 2011 until July 2011, several European Countries, particularly Northern Germany, experienced one of the largest STEC-HUS outbreaks ever reported with 3816 patients suffering from *E. coli* O104:H4 infection, with 845 cases. Almost 90% of affected patients were adults and, compared with previous STEC epidemics, there was a higher prevalence of affected women.[3] *Streptococcus pneumoniae* causes a distinctive form of HUS accounting for 40% of childhood cases not associated with Stx-producing bacteria.[4] Approximately 10% of HUS cases are classified as atypical, caused neither by Stx-producing bacteria (STEC or *Shigella dysenteriae*) nor by *Streptococcus*.[5] Atypical HUS is less common than STEC-HUS, with an annual incidence of 0.5 to 2 per million per year. It can occur at any age and is a very severe disease. Before the introduction of complement inhibition therapy, 50% of patients with atypical HUS progressed to end-stage renal disease (ESRD) and 25% died in the acute phase.[4,5] Neurologic symptoms and fever can occur in 30% of patients. Pulmonary, cardiac, and gastrointestinal (GI) manifestations also can occur.

TTP was first described in 1925 by Moschcowitz in a 16-year-old female patient with fever, hemolytic anemia, bleeding, AKI, neurologic involvement, and a fulminant clinical course. Pathologic changes were characterized by widespread hyaline thrombosis of small vessels. TTP is a rare disease, with an incidence of approximately 2 to 4 cases per 1 million per year. TTP can affect any age group and classically presents with the pentad of thrombocytopenia, microangiopathic hemolytic anemia, fever, and neurologic and renal dysfunction. Neurologic symptoms are seen in over 90% of patients. Central nervous system (CNS) involvement mainly represents thrombo-occlusive disease of the gray matter, and clinical features include headache, cranial nerve palsies, confusion, stupor, and coma. Up to half of patients who present with neurologic involvement may be left with sequelae. Chronic kidney disease (CKD) may occur. One group has reported 25% of patients with creatinine clearance less than 40 ml/min on long-term follow-up. Cardiac involvement may be common in TTP.[6]

LABORATORY SIGNS

Laboratory features of thrombocytopenia and microangiopathic hemolytic anemia are almost invariably present in patients with TMA lesions.[5] Thrombocytopenia is due to platelet consumption by platelet-rich thrombi in the microcirculation of several organs. Thrombocytopenia may be severe, but is usually less so in patients with predominant renal involvement.[2,7] Giant platelets in the peripheral smear, reduced platelet survival time, or both are consistent with peripheral consumption. In children with STEC-HUS, the duration of thrombocytopenia is variable and does not correlate with the course of renal disease. Microangiopathic hemolysis is likely caused by the passage of blood through the damaged capillaries and arterioles occluded by thrombi, but other explanations also have been suggested.[8] Hemoglobin levels are low (<10 g/dl in >90% of patients). Reticulocyte counts are uniformly elevated. The peripheral smear reveals increased schistocyte numbers, with polychromasia and often nucleated red blood cells (RBCs). Detection of fragmented erythrocytes is crucial to confirm the microangiopathic nature of the hemolytic anemia—provided that valvular heart disease and other anatomic artery abnormalities that may cause erythrocyte fragmentation are excluded. Other indicators of intravascular hemolysis include elevated lactate dehydrogenase (LDH), increased indirect bilirubin, and low haptoglobin level.[5] The Coombs test is negative. Serum C3 levels may be low during the acute phase of the disease in STEC-HUS and atypical HUS, but also in TTP. Moderate leukocytosis may accompany

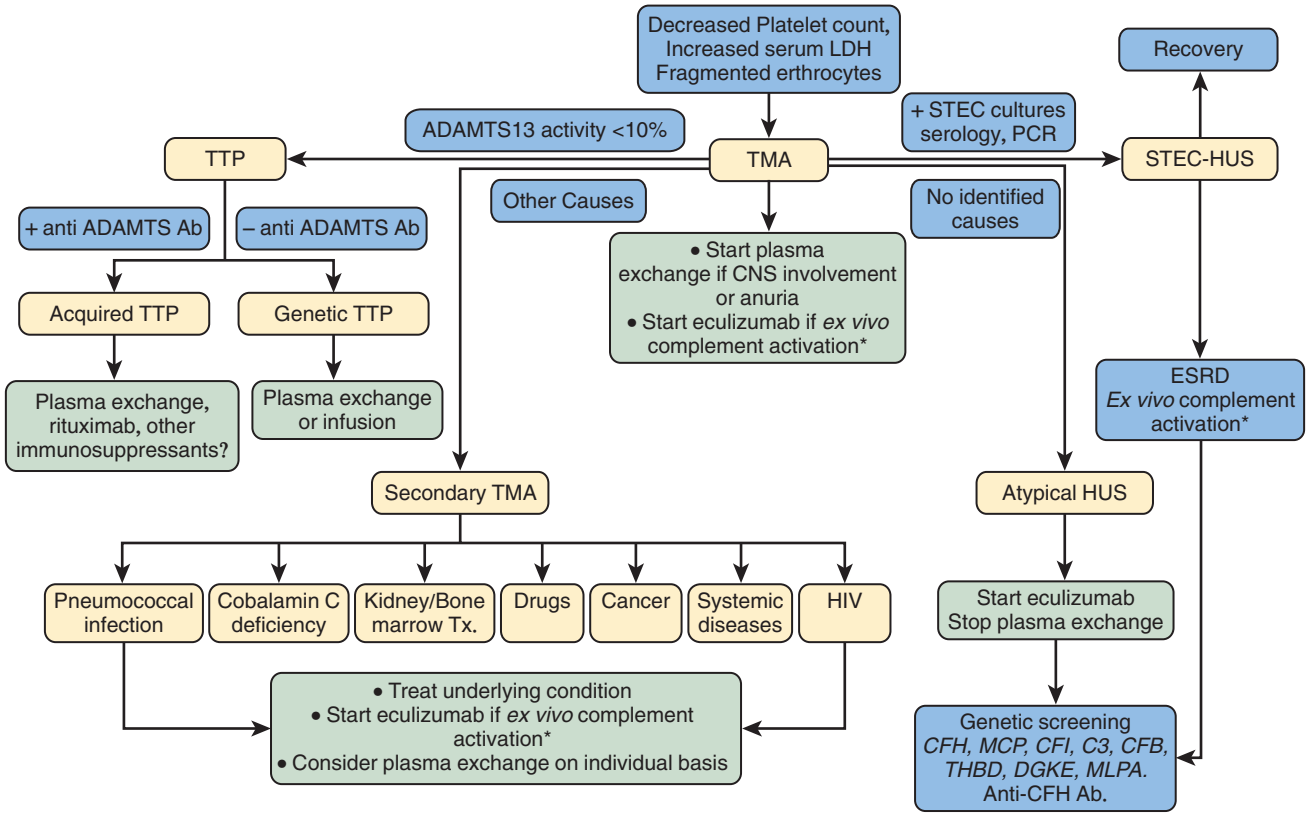

Fig. 29.1 Investigation, diagnosis, and management of thrombotic microangiopathies. *Ab,* Antibody; *CNS,* central nervous system; *HIV,* human immunodeficiency virus; *LDH,* lactate dehydrogenase; *STEC-HUS,* Shiga toxin–producing *Escherichia coli*–associated hemolytic uremic syndrome; *TMA,* thrombotic microangiopathy; *TPP,* thrombotic thrombocytopenic purpura; *Tx,* transplantation. *The authors recommend empirical treatment with ecluzimab in particular if there is evidence for in vivo complement activation (and ideally ex vivo complement activation if such diagnostic testing is available). This latter testing involves evaluating for serum induced complement deposition on cultured endothelial cells and is done only in a few specialized centers.[29]

the hemolytic anemia. Bone marrow biopsy usually shows erythroid hyperplasia and an increased number of megakaryocytes. Prothrombin time, partial thromboplastin time, fibrinogen level, and coagulation factors are normal, thus differentiating TMA from disseminated intravascular coagulation. Mild fibrinolysis with minimal elevation in fibrin degradation products, however, may be observed. Evidence of renal involvement is present in all patients with HUS (by definition) and in about 25% of patients with TTP.[1,9,10] STEC-HUS in 90% of cases is preceded by diarrhea, often bloody.

PATHOLOGY

The histologic lesions of TMA consist of widening of the subendothelial space and microvascular thrombosis. Electron microscopy best identifies the characteristic lesions of swelling and detachment of the endothelial cells from the basement membrane and the accumulation of fluffy material in the subendothelium, intraluminal platelet thrombi, and partial or complete obstruction of vessel lumina (Figs. 29.2 and 29.3).[11] These lesions are similar to those seen in other renal diseases such as scleroderma, malignant nephrosclerosis, chronic transplant rejection, and calcineurin inhibitor nephrotoxicity. In HUS, microthrombi are present primarily in the kidneys, whereas in TTP they mainly involve the brain. In children, particularly in those younger than 2 years of age, and in those with STEC-HUS, the glomerular injury predominates (Fig. 29.4).[11]

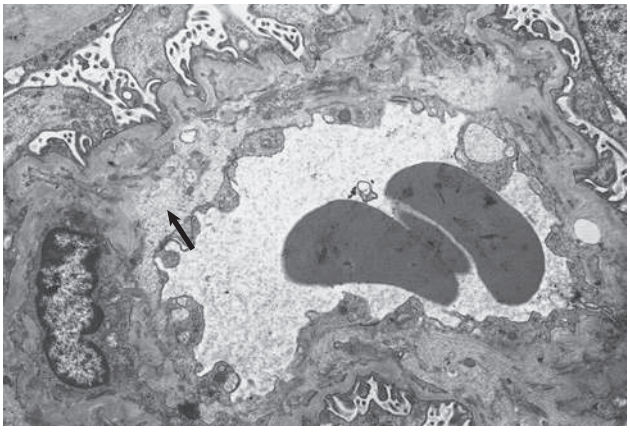

Fig. 29.2 Electron micrograph of a glomerular capillary in hemolytic-uremic syndrome. The endothelium is detached from the glomerular basement membrane (GBM); the subendothelial space is widened and occupied by electron-lucent fluffy material and cell debris *(arrow).* Beneath the endothelium is a thin layer of newly formed GBM.

TABLE 29.1 Classification of Hemolytic Uremic Syndrome and Thrombotic Thrombocytopenic Purpura According to Underlying Etiology

Clinical Presentation	Etiology
Hemolytic Uremic Syndrome	
Stx associated	Infections by Shiga toxin-producing bacteria
Neuraminidase associated	Infections by *Streptococcus pneumoniae*
Atypical	
Familial	*Mutations: CFH,* 40%-45%; *CFI,* 5%-10%; *C3,* 8%-10%; *MCP,* 7%-15%; *THBD,* 9%; *CFB,* 1%-2% *CFH/CFHR* hybrid genes: 5%; *DGKE:* 10% of patients under 1 yr of age
Sporadic	
Idiopathic	*Mutations: CFH,* 15%-20%; *CFI,* 3%-6%; *C3,* 4%-6%; *MCP,* 6%-10%; *THBD,* 2%; *CFB,* <1%; *CFH/CFHR* hybrid genes: 3%. *Anti-CFH antibodies:* 6%-10%
Pregnancy associated	*Mutations: CFH,* 40%-50%; *CFI,* 10-20%; *MCP,* 10%; *C3,* 14%
HELLP syndrome	*Mutations: CFH,* 10%; *CFI,* 20%; *MCP,* 10%
Transplantation (*de novo* aHUS)	*Mutations: CFH,* 15%; *CFI,* 16%
Thrombotic Thrombocytopenic Purpura	
Congenital	Homozygous or compound heterozygous mutations in *ADAMTS13* gene
Acquired	Anti-ADAMTS13 autoantibodies
Other TMAs	
Cobalamin C deficiency	Mutations in *MMACHC*
Drug induced	Ticlopidine and clopidogrel: Anti-ADAMTS13 antibodies. Other drugs: Unknown
BM/HSC transplantation	Unknown, rarely low ADAMTS13 levels
Malignancies	Unknown, rarely low ADAMTS13 levels
HIV	HIV virus, rarely low ADAMTS13 levels
SLE, APS, and other systemic diseases	Depends on the specific underlying diseases

aHUS, Atypical hemolytic uremic syndrome; *APS,* antiphospholipid syndrome; *HELLP,* hemolytic anemia, elevated liver enzymes; and low platelet count; *HIV,* human immunodeficiency virus; *BM/HSC,* bone marrow/hematopoietic stem cell; *SLE,* systemic lupus erythematosus.

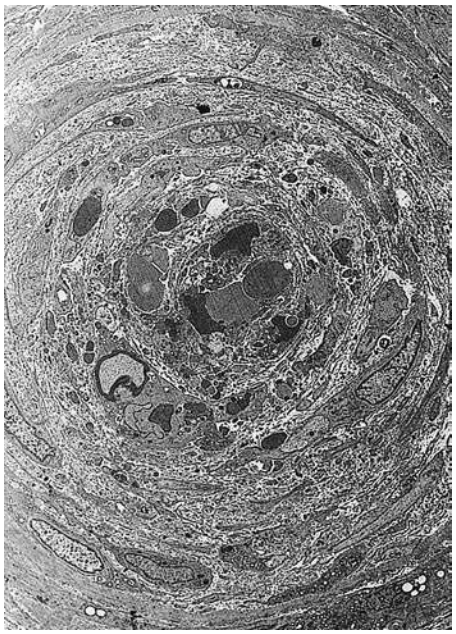

Fig. 29.3 Electron micrograph of a renal arteriole in hemolytic uremic syndrome. The vascular lumen is completely occluded by thrombi. There is marked intimal edema with consequent separation of myointimal cells.

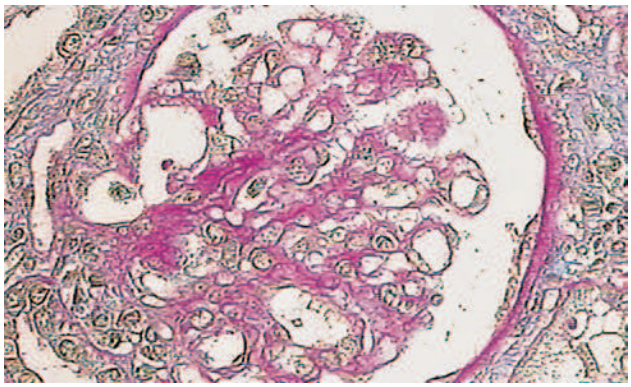

Fig. 29.4 Glomerulus from a patient with STEC-associated hemolytic uremic syndrome. A marked thickening of the glomerular capillary wall occurs with many double contours.

Thrombi and leukocyte infiltration are common in the early phases and usually resolve after 2 to 3 weeks. Patchy cortical necrosis may be present in severe cases; crescent formation is uncommon. In idiopathic and familial forms and in adults, the injury mostly involves arteries and arterioles, with thrombosis and intimal thickening (see Figs. 29.3 and 29.5), secondary glomerular ischemia, and retraction of the glomerular tuft (Fig. 29.6). Focal segmental glomerulosclerosis may be a long-term sequela of acute HUS and is usually seen in children with long-lasting hypertension and progressive loss of renal function.

The typical pathologic changes of TTP are the thrombi that occlude capillaries and arterioles in many organs and tissues. These thrombi consist of fibrin and platelets, and their distribution is widespread. They are most commonly detected in kidneys, pancreas, heart, adrenals, and brain. Compared with HUS, pathologic changes of TTP are more extensively distributed, probably reflecting the more systemic nature of the disease.

MECHANISMS, CLINICAL FEATURES, AND MANAGEMENT OF SPECIFIC FORMS OF THROMBOTIC MICROANGIOPATHY

Shiga Toxin–Producing *Escherichia coli*–Associated Hemolytic Uremic Syndrome

Mechanisms

Shiga toxin–producing *E. coli*–associated hemolytic uremic syndrome (STEC-HUS) may follow GI infections by certain strains of *E. coli* or *S. dysenteriae* that produce powerful exotoxins (Shiga toxins or Stxs)[12] (see Fig. 29.1 and Table 29.1). Most patients present with bloody diarrhea that may still be present or resolved at the time of presentation of HUS. Multiple strains of *E. coli* (mostly serotype 0157:H7, but also about 200 other serotypes, with the predominance of serogroups 026,

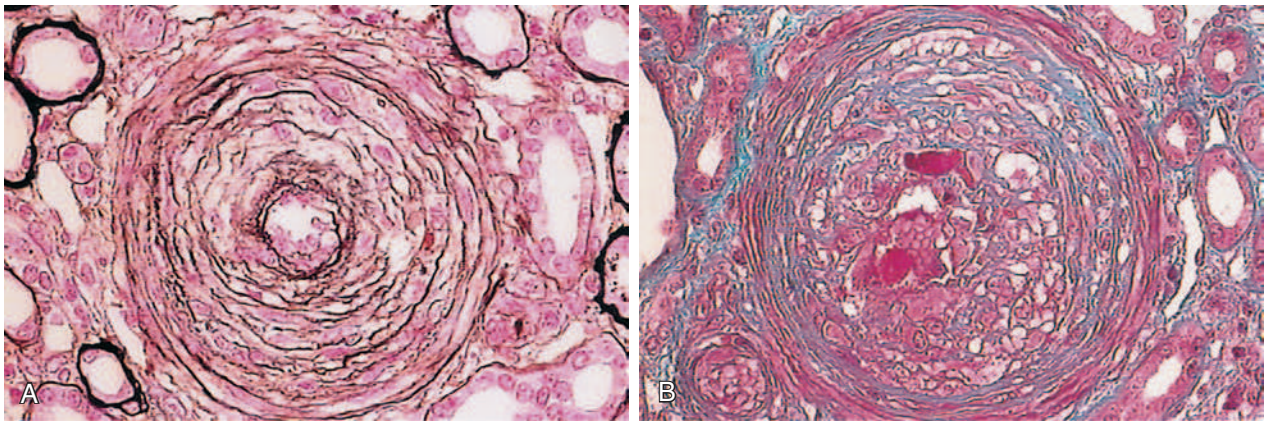

Fig. 29.5 Interlobular artery in a case of hemolytic-uremic syndrome with severe vascular involvement. (A) The vascular lumen is almost completely occluded. Changes include myointimal proliferation and reduplication of the lamina elastica. (B) Thrombotic material and erythrocytes can be seen in the lumen and within the vascular wall.

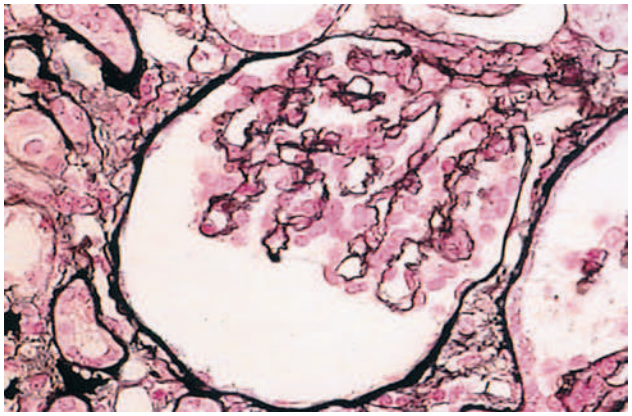

Fig. 29.6 Glomerulus from a patient with atypical hemolytic uremic syndrome with predominant vascular involvement. Severe ischemic changes have occurred. Note the shrinkage of the glomerular tuft and marked thickening and wrinkling of the capillary wall.

0103, 0117, 091, 0145, 0128, 0111, and 0146) isolated from human cases with diarrhea were found to produce Stxs (STEC). The natural reservoir of STEC is the GI tract of ruminants (mainly cattle). Most STEC-infected cattle remain free of disease because they lack vascular Stx receptors. Undercooked ground beef, meat patties, raw vegetables, fruit, milk, and recreational or drinking water contaminated by ruminants' excreta, have been implicated in the transmission of STEC.

E. coli 0157:H7 and other STECs have been responsible for multiple outbreaks throughout the world, becoming a public health problem in both developed and developing countries.[12] The very large HUS outbreak in Germany in 2011 was caused by ingestion of sprouts contaminated by an unusual STEC strain, O104:H4.[3] The chain of transmission appeared to have started in Egypt with fecal contamination of fenugreek seeds. It has been suggested that the higher prevalence of women in this outbreak reflects a gender-specific dietary preference.[3] Because no O104:H4 strains were detected in cattle feces collected in the outbreak area, infected ruminants are unlikely the cause of the O104:H4 STEC outbreak.

After food or water is ingested, the toxin is released into the gut and may cause watery or, most often, bloody diarrhea because of a direct effect on the intestinal mucosa. STEC closely adheres to the GI mucosa, causing destruction of brush border villi. Stxs are transported to the intracellular space of GI cells via transcellular pathways and are then translocated into the circulation. Free Stxs have not been detected in the sera of HUS patients, but Stx binds to neutrophils that serve as Stx carriers from the intestine to the kidney and other target organs. It has been proposed that other human blood cells (erythrocytes, platelets, and monocytes) also bind Stx, but the data are controversial.[13]

In the kidney, Stxs bind mainly to specific Gb3 receptors on glomerular endothelial cells but also to podocytes, mesangial cells, and proximal tubules. After binding to cell receptors, the toxin is internalized and inhibits protein synthesis. Treatment of endothelial cells with sublethal doses of Stx, exerting minimal influence on protein synthesis, increased mRNA and protein expression of chemokines and cell adhesion molecules. By altering endothelial cell adhesion properties and metabolism, Stxs favor leukocyte-dependent inflammation and induce loss of thromboresistance in endothelial cells, leading to microvascular thrombosis.

Evidence is also emerging that complement activation at the renal endothelial level may contribute to microangiopathic lesions in STEC-HUS. Low serum levels of C3 were reported in children with STEC-HUS since the 1980s. High serum levels of complement activation products Bb and C5b-9 were measured in children with STEC-HUS, indicating complement activation via the alternative pathway. Stxs might directly contribute to complement activation, as documented by C3 deposition on endothelial cell lines exposed to Stx and then perfused with human serum.[14] Stx-induced complement depostion was associated with loss of endothelial thromboresistance. In a murine model of HUS induced by Stx/lipopolysaccharide (LPS), factor B–deficient mice that cannot activate the alternative pathway of complement, exhibited less thrombocytopenia and were protected against glomerular abnormalities and renal function impairment.[14]

In vitro, tubular epithelial and mesangial cells are as susceptible to the cytotoxic effects of Stxs as endothelial cells. The tubular damage caused by Stx can lead to a reduction in the renal water handling capacity. Stxs inhibit water absorption across human renal tubular epithelial cell monolayers, which may contribute to the early events underlying renal dysfunction in STEC-HUS.

Diagnosis

Diagnosis depends on the detection of *E. coli* O157:H7 and other STECs and their products in stool cultures (see Fig. 29.1). When infection with STEC is suspected, physicians should ensure that stool specimens are collected promptly and specifically cultured for STEC.[12] Unlike most

other *E. coli*, serotype O157:H7 does not ferment sorbitol rapidly and thus forms colorless colonies on sorbitol containing MacConkey agar (SMAC). The use of SMAC provides a simple, inexpensive, and generally reliable method of screening stools for *E. coli* O157. The polymerase chain reaction is increasingly being used to detect Stx-encoding genes using DNA directly isolated from stool specimens, providing same-day results.[13] Convalescent-phase serum samples can be assayed for antibodies to O157 or other specific strain-derived LPS; however, the results may be biased by false-positive results due to antibodies preformed during antecedent STEC exposure.[12]

Clinical Course

After exposure to STEC, 38% to 61% of individuals develop hemorrhagic colitis and 3% to 9% (in sporadic infections) to 20% (in epidemic forms) progress to overt HUS (Fig. 29.7).[12,13]

STEC-induced hemorrhagic colitis not complicated by HUS is self-limiting and is not associated with an increased long-term risk for renal dysfunction. STEC-HUS is characterized by prodromal diarrhea followed by AKI. The average interval between *E. coli* exposure and illness is 3 days. Illness typically begins with abdominal cramps and nonbloody diarrhea; diarrhea may become hemorrhagic in 70% of cases usually within 1 or 2 days.[12] Vomiting occurs in 30% to 60% of cases and fever in 30%. Leukocyte count is usually elevated. HUS is usually diagnosed 6 to 10 days after the onset of diarrhea. Seventy-percent of patients who develop HUS require RBC transfusions, 40% to 50% need dialysis for an average duration of 10 days, and the remainder has milder renal involvement without the need for dialysis.[12,15] About 25% of patients with STEC-HUS have neurologic involvement, including lethargy, apnea, cortical blindness, hemiparesis, stroke, seizures, and coma. Rare complications include pancreatitis, diabetes mellitus, myocardial ischemia, and pleural and pericardial effusions. Still, 1% to 2% of patients die during the acute phase.

More than 90% of childhood cases of STEC-HUS fully recover from the acute disease. However a meta-analysis of 49 published studies (3476 patients, including children and adults) describing the long-term prognosis of patients who survived an episode of STEC-HUS, reported death or permanent ESRD in 12% and GFR below 80 ml/min/1.73 m^2 in 25%.[15]

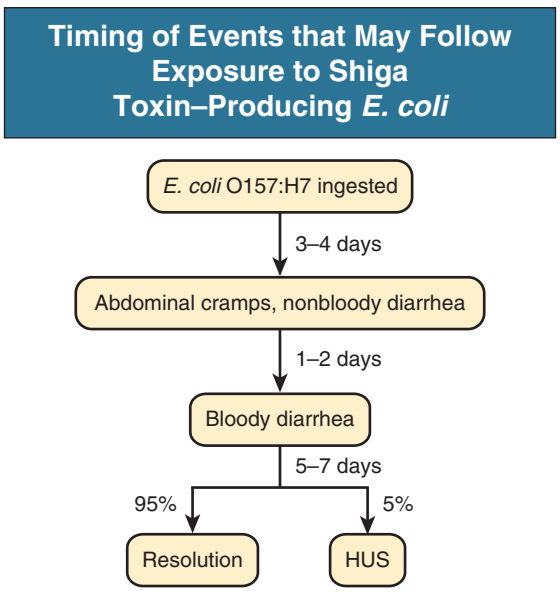

Fig. 29.7 Timing of events that may follow exposure to Shiga-toxin producing *E. coli*. *HUS,* Hemolytic uremic syndrome.

Disease presentation and outcome were particularly severe during the STEC O104:H4 German outbreak, in which 53 of the 855 HUS cases died.[3] Compared with previous STEC epidemics there was a higher incidence of dialysis-dependent AKI (20% vs. 6%) and death (6% vs. 1%).[3] Nearly half of the patients presented with neurologic symptoms and 20% suffered seizures. The severe clinical phenotype was explained by the lack of previous immunity to this novel STEC strain and its exceptional virulence.[3] *E. coli* O104:H4 not only produces the same Stx as STEC enterohemorrhagic strains but also has 93% of the genomic sequence of enteroaggregative *E. coli* strains, defined by their "stacked-brick" pattern of adhesion to host cells, which form fimbriae that facilitate adhesion to the intestinal wall. The evolution of *E. coli* O104:H4 is likely the result of the acquisition by an enteroaggregative strain of *E. coli* of a Stx-encoding phage from an enterohemorrhagic strain of *STEC*. The combination of these two virulence factors would lead to increased gut colonization and thus the release of increased quantities of toxin into the circulation. Whereas enterohemorrhagic *E. coli* are found in the GI tract of ruminants, enteroaggregative *E. coli* appear to have their reservoir in humans. This might explain why the *E. coli* O104:H4 strain has acquired new resistances to antibiotics most commonly used in human disease.

Therapy

Typical pediatric STEC-HUS treatment relies on supportive management of anemia, renal failure, hypertension, and electrolyte and water imbalance (see Fig. 29.1). Intravenous isotonic volume expansion as soon as an *E. coli* O157:H7 infection is suspected, even before culture results are available, may limit the severity of AKI and the need for renal replacement therapy.[16] Up to 80% of patients receive packed RBCs for symptomatic anemia. Heparin and antithrombotic agents may increase the risk for bleeding and should be avoided. Patients with severe STEC-HUS require careful monitoring, including urine output, weight, volume status, cardiovascular/respiratory function, and early signs of CNS or other organ involvement. Bowel rest is important for the enterohemorrhagic colitis associated with STEC-HUS. Antimotility agents should be avoided because they may prolong the persistence of *E. coli* in the intestinal lumen and therefore increase patient exposure to its toxin.

The use of antibiotics should be restricted to the very few patients presenting with bacteremia because, at least in children with gastroenteritis, they may increase the risk for HUS 17-fold.[17] A possible explanation is that antibiotic-induced injury to the bacterial membrane might favor the acute release of large amounts of preformed toxin. Alternatively, antibiotic therapy might give *E. coli* O157:H7 a selective advantage if these organisms are not as readily eliminated from the bowel as the normal intestinal flora. Moreover, several antimicrobial drugs, particularly the quinolones, trimethoprim, and furazolidone, are potent inducers of the expression of the Stx gene. Azithromycin may be an interesting exception because its use appeared to have some benefit on the duration of bacterial shedding in adult patients from the German O104:H4 epidemic.[18] In contrast to STEC-HUS, hemorrhagic colitis and HUS caused by *S. dysenteriae* should be treated with antibiotics because treatment shortens the duration of diarrhea, decreases the incidence of complications, and reduces the risk for transmission by shortening the duration of bacterial shedding.

Careful blood pressure control and renin-angiotensin system blockade may be beneficial in the long term for patients who develop CKD after an episode of STEC-HUS.[4]

Among newer treatments for Stx-HUS, new Stx-neutralizing monoclonal antibodies are under preclinical development. Other potential therapeutics under development are designed to limit Stx receptor expression or to prevent toxin binding, trafficking, or activity within the cells.[19]

TABLE 29.2 Specific Therapies Used in Hemolytic Uremic Syndrome and Thrombotic Thrombocytopenic Purpura, Dosing, and Efficacy

Therapy	Dosing	Efficacy
Immunosuppressives		
Prednisone Prednisolone	200 mg tapered to 60 mg/day then 5 mg reduction per wk 200 mg, tapered to 60 mg/day, then 5 mg reduction per wk	Probably effective in addition to plasma exchange in patients with TTP and anti-ADAMST13 autoantibodies or in aHUS with anti–factor H autoantibodies and in forms associated with autoimmune diseases. Lack of evidence from controlled trials in immune-mediated HUS or TTP.
Immunoglobulins	400 mg/kg/day	
CD20 cell depleting (Rituximab)	375 mg/m^2/wk up to CD20 depletion	Effective in treatment or prevention of TTP associated with immune-mediated ADAMTS 13 deficiency resistant to, or relapsing after, immunosuppressive therapy.
Fresh frozen plasma		
Exchange	1-2 plasma volumes/day	First-line therapy for aHUS and TTP.
Infusion	20-30 ml/kg followed by 10-20 ml/kg/day	Unproven efficacy in childhood STEC-HUS.
Cryosupernatant	See plasma infusion/exchanges.	To be considered if plasma exchange not available.
Solvent-detergent treated plasma	See plasma infusion/exchanges.	To replace whole plasma in case of plasma resistance or sensitization. To limit the risk for infections.
Liver-kidney transplant	Perioperative plasma infusion/exchange and eculizumab	To prevent CFH-associated HUS recurrence post-transplant. About 20% mortality risk.
Complement inhibition (Eculizumab)	900 mg wkly for the first 4 wk 1200 mg every 14 days up to 6 mo	Reported efficacy in aHUS

aHUS, Atypical hemolytic uremic syndrome; *CFH,* complement factor H; *STEC-HUS,* Shiga toxin–producing *Escherichia coli*–associated hemolytic uremic syndrome; *TTP,* thrombotic thrombocytopenic purpura.

The efficacy of specific treatments in adult patients is difficult to evaluate because most information is derived from uncontrolled series that may include atypical HUS cases. No prospective, randomized trials demonstrate whether plasma infusion or exchange are superior to supportive treatment alone (Table 29.2). However, comparative analyses of two large series of patients treated[20] or not treated[21] with plasma suggest that plasma therapy may dramatically decrease overall mortality of STEC 0157:H7–associated HUS. Plasma exchange should therefore be considered in adult patients with severe AKI and CNS involvement.

Kidney transplantation is safe for children who progress to ESRD. Recurrence rates range from 0% to 10%, and graft survival at 10 years is even better than in children with other causes of ESRD.

Evidence that uncontrolled complement activation may contribute to microangiopathic lesions of STEC-HUS[14] led to complement inhibitor therapy with the anti-C5 monoclonal antibody eculizumab in three children with severe STEC-HUS who fully recovered.[22] Eculizumab therapy in the STEC O104:H4 outbreak in Germany led to no significant difference in outcome between patients who received eculizumab together with plasma exchange and those who received plasma exchange alone.[23] However, these data were retrospectively collected. Moreover, patients given eculizumab were also the most severely ill. Whether eculizumab is a useful adjunct to treating the most severe forms of STEC-HUS needs to be clarified by randomized controlled trials.

Hemolytic Uremia Syndrome Associated With *Streptococcus pneumoniae*

Mechanisms

This is a rare (see Fig. 29.1 and Table 29.1) but potentially fatal disease that may complicate pneumonia or, less frequently, meningitis caused by *S. pneumoniae.*[24] Neuraminidase produced by *S. pneumoniae* cleaves N-acetylneuraminic acid from the glycoproteins on the cell membrane of erythrocytes, platelets, and glomerular cells; this exposes the normally hidden Thomsen-Friedenreich antigen (T antigen), which can then react with anti-T IgM antibodies naturally present in human serum. This reaction occurs more frequently in infants and children and causes polyagglutination of RBCs in vitro, so the Coombs test is positive, unlike in other forms of HUS. T-antigen exposure on RBCs is detected using the lectin *Hypogaea*. The finding of severe consumption of complement components in serum during the acute phase and the identification of complement-related gene mutations in a few patients suggests a role for complement dysregulation in this form of HUS.[25]

Clinical Course and Therapy

Patients, usually younger than 2 years, present with a severe illness, including respiratory distress, neurologic involvement, and coma. The acute mortality rate is about 25%. The outcome depends strongly on the effectiveness of antibiotic therapy. In theory, plasma infusion or exchange is contraindicated because adult plasma contains antibodies against the T antigen that may accelerate polyagglutination and hemolysis. Thus patients should be treated with only antibiotics and washed RBCs. In some cases, however, plasma therapy, occasionally in combination with steroids, has been associated with recovery.

Atypical Hemolytic Uremic Syndrome

Atypical HUS (aHUS) has several mechanisms, mainly associated with genetically determined complement dysregulation (see Fig. 29.1 and Table 29.1).[5,26] aHUS is usually sporadic, and fewer than 20% of cases are familial. Although some are in siblings, suggesting autosomal recessive transmission, others occur across two or three generations, indicating an autosomal dominant mode. Incomplete penetrance of the disease in mutation carriers is a common feature that confounds the interpretation of inheritance. Indeed, many sporadic cases of aHUS inherited the genetic defect from an unaffected parent.[27]

Various precipitants of aHUS have been described in complement gene mutation carriers, including nonenteric bacterial and viral infections,[5] immunotherapeutic agents (e.g., cyclosporine, tacrolimus), malignant hypertension, transplantation, and pregnancy.[5] De novo post-transplant HUS has been reported in patients receiving renal

transplants or other organs, due to calcineurin inhibitors or humoral rejection. It occurs in 5% to 10% of renal transplant patients who receive cyclosporine and in approximately 1% of those given tacrolimus. In 20% of female patients, aHUS manifests during pregnancy; the disease tends to occur at term or postpartum, within 3 months of delivery in most cases.[4] Pregnancy-associated increased concentrations of procoagulant factor, decreased fibrinolytic activity, and reduced expression of endothelial thrombomodulin may be predisposing factors. A severe form of pregnancy-associated TMA is the HELLP syndrome, in which microangiopathic hemolysis and liver injury accompany hypertension and renal dysfunction. About 50% of atypical HUS cases show no clear trigger (see Table 29.1).

Mechanisms

aHUS is linked to genetically determined dysregulation of the alternative pathway of complement (see Fig. 29.1 and Table 29.1).[5,26] Reduced serum levels of C3 with normal C4 in aHUS patients were reported in about 50% of patients with aHUS.[28] Low C3 reflects complement activation, as documented by high levels of activated products and C3 deposits in glomeruli and other kidney vessels. The complement system is part of innate immunity and consists of several plasma- and membrane-bound proteins protecting against invading organisms. Three activation pathways (Fig. 29.8)—classic, lectin, and alternative pathways—produce protease complexes, termed C3 and C5 convertases, that cleave C3 and C5, respectively, eventually leading to the membrane attack complex (MAC or C5b-9) that causes cell lysis. The alternative pathway (Fig. 29.9) is initiated spontaneously in plasma by C3 hydrolysis responsible for deposition of a low amount of C3b onto all plasma-exposed surfaces. On bacterial surfaces, C3b leads to phagocytosis by neutrophils and macrophages. Without regulation, a small initiating stimulus is quickly amplified to a self-harming response until complement components are depleted. On host cells, such a dangerous cascade is controlled by membrane-anchored and fluid-phase regulators (see Fig. 29.9). They both favor the cleavage of C3b to inactive iC3b by the plasma serine protease factor I (CFI, cofactor activity) and dissociate the C3 and C5 convertases (decay acceleration activity). Foreign targets and injured cells that either lack membrane-bound regulators or cannot bind soluble regulators are attacked by complement.

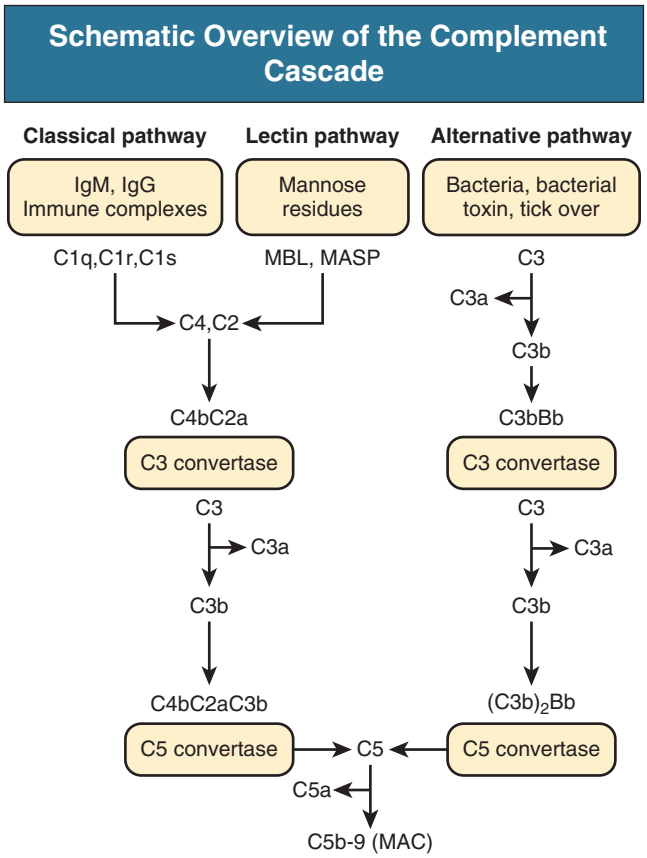

Fig. 29.8 Schematic overview of the complement cascade illustrating the three activation pathways (classical, lectin and alternative) and the membrane attack complex. *MBL,* membrane binding lectin; *MASP,* mannose-associated serine protease; *MAC,* membrane attack complex.

The C3 convertases of the classic/lectin pathways are formed by C2 and C4 fragments, whereas the alternative pathway convertase requires cleavage of C3 only (see Fig. 29.9). Thus low serum C3 levels in aHUS with normal C4 indicated selective alternative pathway activation.[28]

Several genetic abnormalities in members of the alternative pathway of complement have been described in aHUS, which account for about 60% of cases (see Table 29.1). Functional studies revealed that aHUS-associated mutations mainly result in complement activation that is restricted on the cell surface—which explains the normal circulating complement profile in about half of patients—and proceeds until the formation of C5b-9.[29]

Complement factor H. Complement factor H (CFH) regulates the alternative pathway both in the fluid phase and on the cell surface by acting as a cofactor for CFI and enhancing dissociation of C3 convertase (see Fig. 29.9). Over 120 *CFH* mutations (http://www.FH-HUS.org) have been identified in aHUS patients (mutation frequency about 30%).[30] These mutations most commonly are associated with normal CFH levels, but instead result in a protein that is unable to bind to and regulate complement on endothelial cells and platelets.[31] A high degree of sequence identity between *CFH* and the genes *CFHR1-5* for five factor H–related proteins (CFHR) located in tandem to *CFH* may predispose to gene conversions and genomic rearrangements.[32] Hybrid *CFH/CFHR1* and *CFH/CFHR3* genes, coding abnormal FH proteins in which the carboxy-terminal domains that mediate complement regulation on cell surface are substituted for those of FHR1 or by the entire FHR3 have been reported in 3% to 5% of patients with aHUS. The resulting gene products are hybrid FH molecules with decreased complement regulatory activity on endothelial surfaces.[32] Additional forms of *CFH/CFHRs* hybrid genes have been recently described.[33]

Anti-CFH inhibitory antibodies have been reported in 5% to 10% of aHUS patients and around 25% to 50% of pediatric cases.[34] Analogous to *CFH* genetic defects, these autoantibodies predominantly target the C-terminal end, thereby impairing complement regulation on host cell surfaces. The development of CFH autoantibodies in aHUS has a genetic predisposition, being strongly associated with the homozygous deletion of the *CFHR1* and *CFHR3* genes.[34]

Membrane cofactor protein. MCP is a transmembrane complement regulator widely expressed on all cells apart from erythrocytes. MCP serves as a cofactor for CFI to cleave C3b and C4b (see Fig. 29.9). *MCP* mutations account for 8% to 10% aHUS cases.[30] Most are heterozygous (http://www.FH-HUS.org). The majority cluster in critical extracellular modules for regulation. Expression on blood leukocytes was reduced for about 75% of mutants. Others have low C3b-binding capability and decreased cofactor activity.[30]

Complement factor I. CFI is a plasma serine protease that regulates the three complement pathways by cleaving C3b and C4b in the presence of cofactor proteins (see Figs. 29.8 and 29.9). *CFI* mutations affect 4% to 8% of patients.[30,35] All mutations are heterozygous, 80% cluster in the serine-protease domain. Approximately 50% of mutants are not

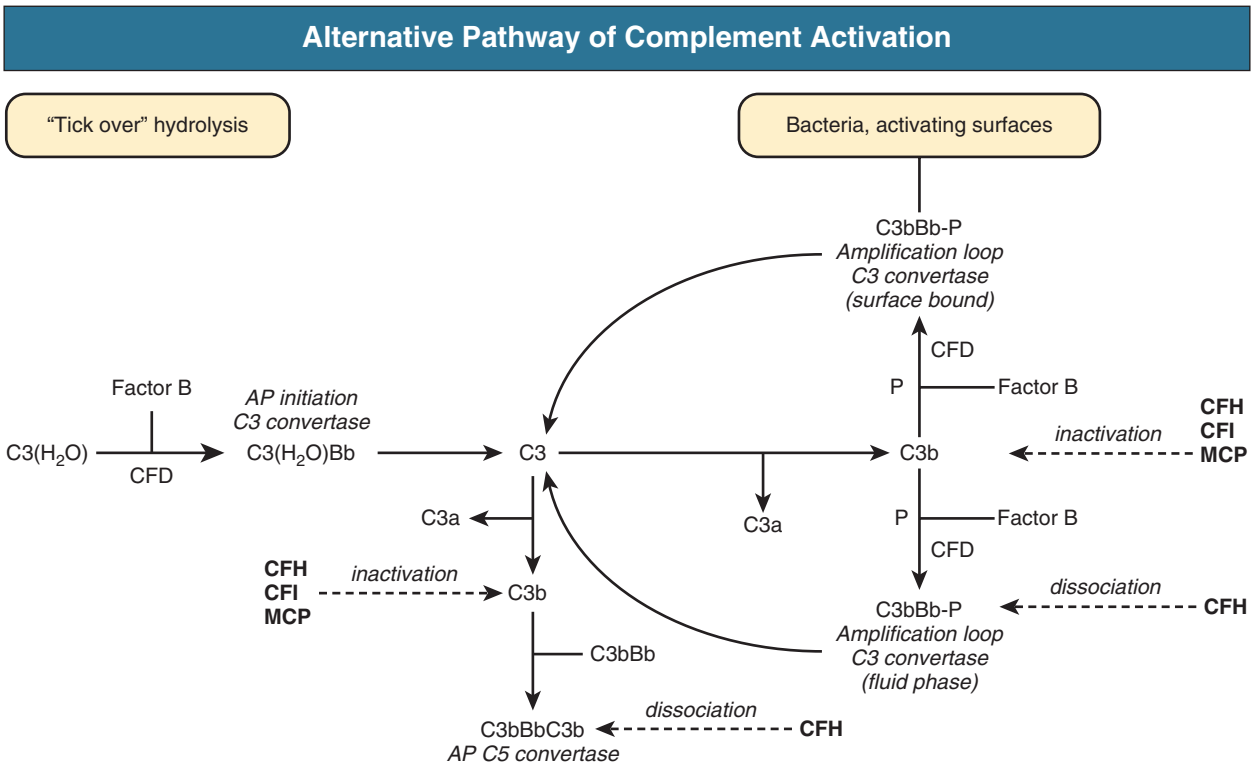

Fig. 29.9 Alternative pathway of complement activation. The alternative pathway *(AP)* is continuously activated in plasma by low-grade hydrolysis of C3. The latter binds factor B, to form a $C3(H_2O)B$ complex. Factor D *(CFD)* cleaves factor B to form the AP initiation C3 convertase that cleaves C3 to C3b. The activation is then amplified by the covalent binding of a small amount of C3b to hydroxyl groups on cell-surface carbohydrates and proteins of target cells such as bacterial cells. This C3b binds factor B, to form the amplification loop C3 convertase C3bBb. C3 convertase enzymes cleave many molecules of C3, resulting in a positive feedback amplification loop. C3b also binds to the C3 convertase forming the C5 convertase enzyme $C3b_2Bb$. The AP is highly regulated as to prevent nonspecific damage to host cells and limit the deposition of complement to the surface of pathogens. This fine regulation occurs through a number of membrane-anchored and fluid phase regulators. *CFH,* Complement factor H (acts as cofactor for factor I for C3b cleavage and favors the decay of the C3 convertase of the AP); *CFI,* complement factor I (degrades C3b and C4b); *CR1,* complement receptor 1 (has decay accelerating activity as well as cofactor activity for factor I–mediated cleavage of C3b and C4b); *DAF,* decay accelerating factor (destabilizes the C3 and C5 convertases of the classic and alternative pathways); *MCP,* membrane cofactor protein (binds C3b and C4b and has cofactor activity for both the classic and alternative pathways).

secreted; however, some mutants are secreted but have impaired proteolytic activity.[30,35]

Complement factor B and C3. Gain-of-function mutations can affect genes encoding the alternative pathway C3 convertase components, CFB and C3.[36,37] *CFB* mutations are rare (1% to 2%).[37] CFB mutants have excess C3b affinity and form a hyperactive C3 convertase resistant to dissociation.[37] About 4% to 8% of aHUS patients have heterozygous mutations in *C3,* usually with low C3 levels.[36] Most mutations reduce C3b binding to complement regulators, severely impairing its inactivation and result in increased C3 deposition on endothelial cells.[36]

Thrombomodulin. Heterozygous mutations in the gene *THBD* encoding thrombomodulin, an endothelial surface anticoagulant protein that also modulates complement on cell surfaces, have been found in 3% to 4% of patients with aHUS.[38] Cells expressing *THBD* variants inactivate C3b less efficiently.[38]

Determinants of disease penetrance. Two other factors are thought to determine the development of aHUS. First, in most patients there is a trigger, most frequently infection and pregnancy.[39] Second, a further genetic variant (modifier) can increase the risk for developing the disease. This can be an additional mutation in one of the aforementioned genes; it is now recognized that approximately 10% of aHUS patients will have mutations in more than one gene.[40] Common genetic risk variants (single-nucleotide polymorphisms [SNPs] and haplotype blocks) in *CFH, MCP,* and *CFHR1* have been shown to act as susceptibility factors for the development of aHUS.[40]

Diacylglycerol kinase ε. Homozygous or compound heterozygous mutations in *DGKE,* encoding the intracellular protein diacylglycerol kinase ε, have been recently associated with infantile recessive aHUS.[41] Mutation carriers presented with aHUS before 1 year of age (see Table 29.1), with hypertension, hematuria, and severe proteinuria, often in nephrotic range. *DGKE* is expressed in endothelium, platelets, and podocytes, is involved in terminating diacylglycerol signaling, and is not directly linked to complement. *DGKE* silencing in endothelial cells induced a proinflammatory and prothrombotic phenotype.

Diagnosis of Atypical Hemolytic Uremia Syndrome and Testing for Genetic Mutations

Differential diagnosis of aHUS requires exclusion of infections by STEC or neuroaminidase-producing *S. pneumoniae* of ADAMTS13 deficiency or autoantibodies against ADAMTS13 and systemic associated diseases

TABLE 29.3 Outcome of Atypical Hemolytic Uremic Syndrome According to the Associated Genetic Abnormality

Affected Gene	Affected Protein and Main Effect	Frequency in aHUS (%)	Rate of Remission With Plasma Exchange* (%)	5- to 10-Year Rate of Death or ESRD† (%)	Recurrence Rate After Kidney Transplant† (%)
CFH	Factor H (no binding to endothelium)	30	60 (dose and timing dependent)	70-80	60-70
CFHR1/3	Factor HR1, R3 (anti–factor H antibodies)	5-10	70-80 (combined with immunosuppression)	30-40	30
MCP	Membrane cofactor protein (no surface expression)	10-15	No indication to plasma exchange	<20	15-20
CFI	Factor I (low levels/low cofactor act)	4-10	30-40	60-70	70-80
CFB	Factor B (C3 convertase stabilization)	1-2	30	70	One case reported
C3	Complement C3 (resistance to C3b inactivation)	8-10	40-50	60	40-50
THBD	Thrombomodulin (reduced C3b inactivation)	4-5	60	60	One case reported

*Complete remission or hematologic remission with renal sequelae.
†The data are related to the period before the introduction of anticomplement therapy.

(see Fig. 29.1).[26] Full analysis of disease-associated genes and testing for anti-CFH antibodies is recommended for patients who progress to ESRD and are candidates for kidney transplantation. Reference laboratories in several countries are equipped for genetic and antibody testing. Although new sequencing techniques have reduced cost and time, a complete evaluation still requires several days. Treatment of acute episodes (plasma therapy or eculizumab when available, see later discussion) should be started very rapidly after clinical diagnosis, without waiting for results of genetic and anti-CFH antibody tests.

Clinical Course

Sixty percent of patients, irrespective of mutation type, are affected during childhood,[30] and almost all patients with anti-CFH antibodies developed the disease before 16 years of age.[42] Acute episodes manifest with severe hemolytic anemia, thrombocytopenia, and AKI. Extrarenal involvement (CNS or multivisceral) occurs in 20% of cases.[5,30,39] Short- and long-term outcomes vary according to the underlying complement abnormality (Table 29.3). Until a few years ago, 50% to 70% of patients with *CFH, CF, C3, CFB, or THBD* mutations and 40% of children with anti-CFH autoantibodies lost renal function, died during the presenting episode, or developed ESRD after relapses (see Table 29.3).[5,30] Chronic complement dysregulation may lead to atheroma-like lesions with cardiovascular complications and excess mortality. In *MCP*-mutation carriers, recurrences were frequent but long-term outcome was good and 80% of patients remained dialysis-free.[5,30] However, rare patients with *MCP* mutations had severe disease, immediate ESRD, intractable hypertension, and coma, possibly because of concurrent genetic abnormalities.[40]

Therapy

Fresh frozen plasma. Plasma therapy (plasma exchange, 1 to 2 plasma volumes/day; plasma infusion, 20 to 30 ml/kg/day) has been the gold standard of aHUS therapy since the 1980s and was essentially the only therapy available until 2011 (see Table 29.2). Consensus-based guidelines recommended that plasma therapy should be started within 24 hours of diagnosis and then continued until remission or a declaration of nonresponse.[5] Because CFH is a plasma protein, plasma infusion or exchange provides normal CFH to patients carrying *CFH* mutations.[30,39] Long-term treatment, however, may fail as a result of development of plasma resistance.[43] Heterozygous *CFH* mutation carriers usually have normal levels of CFH, half of which is dysfunctional. The beneficial effect of plasma is strongly dependent on the amount, frequency, and modality of administration, with plasma exchange being superior to plasma infusion by removal of mutant CFH that could antagonize the normal protein. Plasma exchange in association with immunosuppressive therapy (induction with corticosteroids and cyclophosphamide, and maintenance with azathioprine or mycophenolate mofetil), is recommended in patients with anti-CFH antibodies, to remove the inhibitory antibodies[26,34] and allowed long-term dialysis-free survival in 60% to 70% of patients.[34] Data on the effect of rituximab, an anti-CD20 antibody, in such circumstances are scanty and inconsistent: of five patients treated with rituximab alone or with plasma exchange, only two showed disappearance of anti-CFH antibodies.[34]

Patients with *CFI* mutations showed a partial response to plasma (see Table 29.3).[5,30,39] Thirty to forty percent of patients with *CFB* mutations and 50% of those with *C3* mutations responded to plasma infusion or exchange.[5,36,37] Possibly these patients need frequent large-volume plasma exchange to clear the hyper-functional mutant *CFB* and *C3*.[5] Because MCP is a cell-associated protein, effects of plasma are unlikely in patients with *MCP* mutations. Indeed 80% of patients with an *MCP* mutation underwent spontaneous remission independently of plasma treatment (see Table 29.3).[5,30,39]

Kidney transplantation The outcome of kidney transplantation in aHUS was poor because of the high frequency of disease recurrence. Disease recurred in 60% to 80% of transplanted patients with mutations in complement circulating proteins (CFH, CFI, CFB, and C3) and graft failure occurred in 80% to 90%[36,37,44] (see Table 29.3). The risk for post-transplant aHUS recurrence in patients with anti-CFH autoantibodies is not well known because available information is limited to 27 renal transplants in 21 patients.[34] Recurrence of HUS was documented in eight (30%) cases. A reduction in autoantibody levels with plasma exchange, steroids, and/or rituximab, enabled successful renal transplantation in few patients.[34]

The lowest incidence of recurrence was observed in patients with *MCP* and *DGKE* mutations.[41,44] *MCP* and *DGKE* are highly expressed in the kidney, and a graft that brings normal proteins corrects the defect. However, about 20% of patients with *MCP* mutations also carry a mutation in another complement gene. Such patients have a worse graft outcome with higher incidence of recurrences than patients with an isolated *MCP* mutation.[40]

Testing affected patients for mutations on all disease-associated genes should allow patients and clinicians to make informed decisions regarding listing for transplantation based on risk for recurrence.

Most studies have shown that plasma exchange therapy fails to prevent graft loss in patients with recurrent post-transplant HUS.[44] A preemptive plasma infusion or exchange strategy has been successful in preventing recurrent aHUS in renal transplant recipients, although aHUS recurred in some when plasma therapy was tapered.[45]

Living-related kidney donation is contraindicated given the high risk for recurrence, and it even may be risky to donors because unienephrectomy may precipitate aHUS if they are complement gene mutation carriers.

Complement inhibitors. The humanized anti-C5 monoclonal antibody eculizumab was approved in 2011 in the United States and Europe for the treatment of aHUS and has profoundly changed aHUS management. The efficacy and safety of eculizumab in inducing remission of acute episodes of aHUS and maintaining long-term remission, both in native kidneys and in the kidney grafts, was documented in two prospective clinical trials of primarily adult patients with plasma-dependent or plasma-resistant aHUS[46] and in a pediatric trial in 22 children, of whom 12 had no prior plasma treatment.[47] Eculizumab is now widely used as a first-line therapy for aHUS, provided that other causes of TMA are excluded (see Fig. 29.1).[26] The main concern with eculizumab is increased susceptibility to infection with encapsulated organisms, particularly *Neisseria* infections. For this reason, patients must receive meningococcal vaccination. Patients should receive vaccination against meningococcus, including type B; however, vaccination should not delay the start of eculizumab. Antibiotic prophylaxis is mandated during the first 2 weeks and is recommended for the overall treatment duration because not all serotypes are covered by vaccination.[26]

It is not clear how long eculizumab therapy should be extended, a relevant issue because of the very high cost of the drug. In addition, the risk for sensitization associated with chronic eculizumab exposure or with its deposition in tissue, and the recent report of hepatoxicity in pediatric patients,[48] suggest that careful tapering to withdrawal whenever possible, should be attempted, under tight control of disease and complement activity.[29]

Conceivably, chronic lifetime treatment with eculizumab at doses able to persistently block the complement cascade might be indicated to prevent disease recurrence in some cases. A retrospective study of aHUS patients who discontinued eculizumab in the French Registry showed no relapse in patients without identified complement gene mutations, whereas disease relapses occurred in 72% of patients with *CFH* mutations and 50% of those with *MCP* mutations.[49] However, whether and to what extent this applies to all patients with aHUS and complement abnormalities is unknown, and controlled clinical studies are required. Different clinical courses before eculizumab therapy, and different residual complement activity while on eculizumab therapy, should be taken into consideration when strategies of chronic eculizumab therapy or discontinuation are planned.

Liver-kidney transplant. In patients with *CFH* mutations combined liver-kidney transplant have been done with the rationale of correcting the genetic complement defect, thus preventing disease recurrence in the transplanted kidney (see Table 29.2). Liver transplantation, in contrast to eculizumab therapy, cures aHUS definitively without the need of specific therapies other than standard immunosuppression to prevent graft rejection. The short-term mortality risk associated with acute complement activation in the liver graft observed in initial attempts has been substantially reduced with prophylactic plasma exchange and perioperative eculizumab. Over 80% of patients with aHUS who received liver transplants to date with the previously described preparative regimen have had excellent long-term outcomes.[50,51] However, the risks for kidney and liver transplantation have limited the widespread dissemination of this option and a careful assessment of benefits in candidate patients is required.

Thrombotic Microangiopathy Associated With Cobalamin C Deficiency

A renal TMA can manifest in methylmalonic aciduria and homocystinuria caused by recessive mutations in the *MMACHC* gene, which result in deficiency of cobalamin C type (cblC), the most common genetic functional variant of cobalamin (vitamin B_{12}) (see Fig. 29.1 and Table 29.1). It is a rare condition, and only 36 cases of TMA associated with cblC defect have been reported. Pulmonary hypertension may accompany the disease. Diagnosis is facilitated by finding elevated plasma homocysteine and methylmalonic aciduria. TMA usually presents in early infancy, although adult onset has also been reported. Mortality is high if untreated, but metabolic therapy with hydroxycobalamin is very effective.

Thrombotic Thrombocytopenic Purpura

In the microvasculature of patients with TTP, systemic platelet thrombi develop, mainly formed by platelets and von Willebrand factor (VWF). VWF plays a major role in primary hemostasis, forming platelet plugs at sites of vascular injury under high shear stress. VWF is synthesized in vascular endothelial cells and megakaryocytes as a high-molecular-weight polymer[52] and stored in the Weibel-Palade bodies. On stimulation, VWF is secreted by endothelial cells as ultra-large (UL) multimers that form string-like structures attached to the endothelial cells, possibly through interaction with P-selectin. Under fluid shear stress, the UL-VWF strings are cleaved to generate the range of VWF multimer sizes that normally circulate in the blood.[53] The proteolytic cleavage of VWF multimers appears to be critical to prevent thrombosis in the microvasculature.

ADAMTS13 is the protease responsible for cleaving VWF, creating 140- and 176-kDa fragments (Fig. 29.10). It derives primarily from the stellate cells of the liver. ADAMTS13 is also expressed, albeit at lower levels, in other types of cells such as renal podocytes and tubular cells, vascular endothelial cells, and platelets. The plasma concentration of ADAMTS13 is approximately 1 μg/ml (5 nmol/l). The elimination half-life of ADAMTS13 is 1 to 2 days in the circulation.

Mechanisms

ADAMTS13 is severely deficient in patients with primary TTP leading to accumulation of UL-VWF multimers that are highly reactive with platelets.[54,55] Exposure of UL-VWF multimers and platelets to shear stress leads to platelet aggregation. The levels of shear stress necessary for inducing platelet aggregation is in the range found in normal arteriolar and capillary circulation. Therefore VWF and platelets have a propensity to form aggregates in normal arterioles and capillaries that need to be constantly regulated. By cleaving UL-VWF multimers before they are activated by shear stress to cause platelet aggregation, ADAMTS13 prevents spontaneous microvascular thrombosis in the normal circulation (see Fig. 29.10). The platelet aggregation observed in patients with TTP and ADAMTS13 deficiency is thus a direct consequence of the accumulation of UL-VWF multimers. Consequently, microvascular thrombi occur in almost all organ vessels,

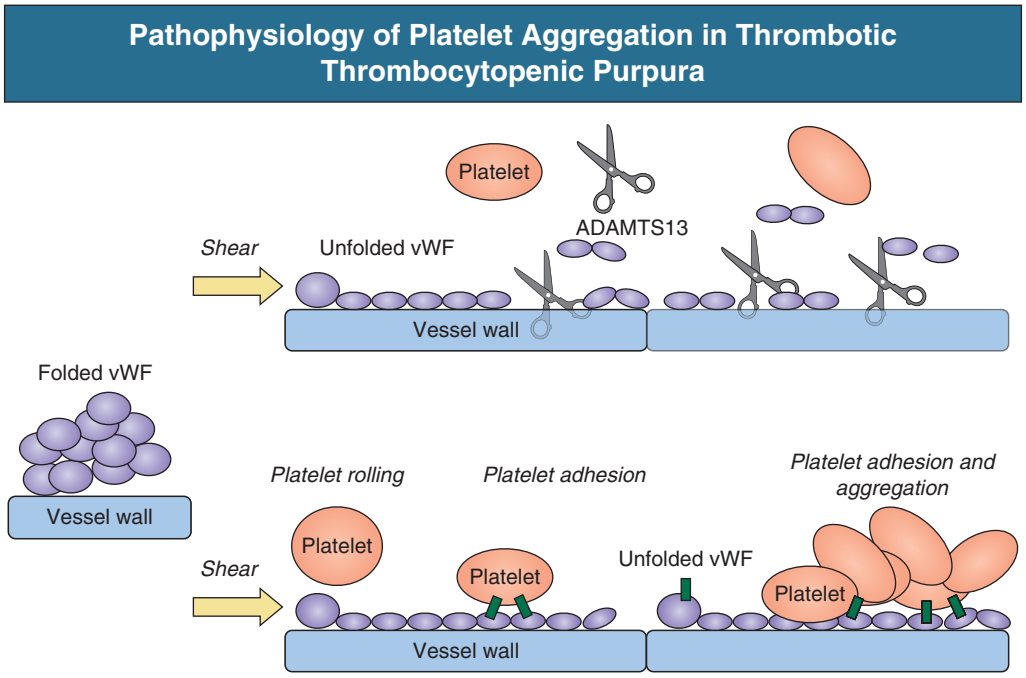

Fig. 29.10 The pathophysiology of platelet aggregation in thrombotic thrombocytopenic purpura. Von Willebrand factor *(VWF)* is synthesized and stored as ultra-large (UL) multimers in endothelial cells and megakaryocytes. On stimulation, UL-VWF multimers are secreted by endothelial cells into the circulation in a folded structure. On exposure to enhanced shear stress, UL multimers form string-like structures that adhere to endothelial cells. Normally, UL-VWF strings are cleaved by ADAMTS13 to generate VWF multimers from 500 kDa to 20 million Da and prevent thrombosis in the microvasculature *(upper panel).* When the ADAMTS13 proteolytic activity is defective because of the inhibitory effect of anti-ADAMTS13 autoantibodies or congenital defective synthesis of the protease, UL-VWF multimers accumulate and interact with activated platelets to facilitate platelet adhesion and aggregation, with thrombi formation and occlusion of the vascular lumen *(lower panel).*

resulting in diffuse organ ischemia and thrombocytopenia secondary to platelet consumption.

Two mechanisms for deficiency of the ADAMTS13 activity have been identified, an acquired deficiency secondary to the formation of anti-ADAMTS13 autoantibodies (acquired TTP) and a genetic deficiency resulting from homozygous or compound heterozygous mutations in *ADAMTS13* (genetic TTP) (see Fig. 29.1).

TTP associated with Anti-ADAMTS13 antibodies. This form accounts for the majority of acute primary cases (60% to 90%) and is characterized by severe functional deficiency of ADAMTS13 because of transient, specific autoantibodies that tend to disappear during remission (see Fig. 29.1 and Table 29.1).[55] Patients with TTP secondary to hematopoietic stem cell transplantation, malignancies, or HIV infection rarely have severe ADAMTS13 deficiency and inhibitory IgG antibodies.[56] Severe ADAMTS13 deficiency and ADAMTS13 inhibitory antibodies were detected in 80% to 90% of patients with ticlopidine-associated TTP and in a few patients with clopidogrel-induced TTP (see Table 29.1). The deficiency resolved after the drugs were discontinued. ADAMTS13 inhibitors have not been described in other drug-associated TTP. TTP diagnosed during pregnancy comprises approximately 7% of all TTP cases. Most of these cases have acquired ADAMTS13 deficiency, but pregnancy also has been reported as a triggering event in patients with genetic ADAMTS13 deficiency (see later discussion).

The pathogenicity of TTP-associated anti-ADAMTS13 autoantibodies is supported by the observation that they usually disappear from the circulation when remission is achieved by effective treatment and that this occurs in parallel with the normalization of ADAMTS13 activity.

TTP associated with genetic deficiency of ADAMTS13. This rare inherited form of TTP is associated with homozygous or compound heterozygous mutation in the *ADAMTS13* gene and accounts for about 5% of all of cases of TTP (see Table 29.1). The disease is inherited as a recessive trait in patients with and without a family history of TTP[57]; more than 120 *ADAMTS13* mutations have been identified.[58] Studies on secretion and activity of the mutated forms of *ADAMTS13* showed that most of these mutations led to impaired secretion of the protease from the cells, and when the mutated protein is secreted the proteolytic activity is greatly reduced.

Most patients are carriers of compound heterozygous mutations; only 20% of mutations have been observed in homozygous form.

Clinical Course

Compared with patients with less severe ADAMTS13 deficiency, severely deficient patients experience a higher proportion of therapy-induced remissions (82% to 88% vs. 20% to 75%) and lower mortality (8% to 18% vs. 18% to 80%).[56] The high mortality risk in non–severely deficient patients may be due to the higher proportion of secondary causes and death from underlying diseases, such as patients with hematologic malignancies.

Among patients who have a severe ADAMTS13 deficiency, patients with inhibitory antibodies experience a more severe manifestation of the disease, take a substantially longer time to achieve clinical remission and require a higher plasma volume than patients with genetic ADAMTS13 deficiency. In patients with inhibitory antibodies, a risk as high as 50% to develop relapses has been reported and undetectable ADAMTS13 activity and persistence of anti-ADAMTS13 inhibitors during remission predict recurrences.

TTP has been reported in 1 in every 1600 to 5000 patients treated with ticlopidine, and 11 cases have been reported during treatment with clopidogrel. The overall survival rate is 67% and is improved by early treatment withdrawal and plasma therapy.

Approximately 60% of patients with genetic deficiency of ADAMTS13 experience their first acute episode of disease in the neonatal period or during infancy, but a second group (10% to 20%) manifests the disease after the third decade of life. TTP recurrences occur in 80% of patients,[58] but their frequency varies widely. Whereas some patients with genetic ADAMTS13 deficiency depend on frequent chronic plasma infusions to prevent recurrences, other patients remain free of disease for long periods after plasma discontinuation. The type and location of *ADAMTS13* mutations may influence the age of onset of TTP and the penetrance of the disease in mutation carriers. Mutations resulting in very low residual ADAMTS13 activity (<1%) were associated with childhood onset, relapsing disease, and renal impairment.[10]

Environmental factors may contribute to induce full-blown manifestation of the disease. According to this "two hit model," deficiency of ADAMTS13 predisposes to microvascular thrombosis and TMA supervenes after a triggering event that activates microvascular endothelial cells and causes the secretion of UL-VWF multimers. Potential triggers of these phenomena are infections and pregnancy.

Therapy

Plasma is the cornerstone of therapy in an acute episode because it replaces defective protease activity. Plasma exchange, as compared with infusion, may offer the additional advantage of rapidly removing anti-ADAMTS13 antibodies, if present (see Table 29.2).[6]

Because of the potential for sudden clinical deterioration, treatment should be initiated as soon as possible after diagnosis. Treatment consists of a daily 1 to 2 plasma volume exchange until clinical symptoms have resolved and the platelet count is stably normal (≥150,000/μl). Fresh-frozen plasma and cryosupernatant plasma are considered equivalent because of comparable levels of ADAMTS13.

Corticosteroids (see Table 29.2) given in combination with plasma therapy may be beneficial in autoimmune forms of TTP by inhibiting the synthesis of anti-ADAMTS13 autoantibodies; plasma exchange will have only a temporary effect on the autoimmune basis of the disease, but additional immunosuppressive treatment may cause a more durable response. A recent randomized clinical trial found that caplacizumab, an anti-VWF humanized single-variable-domain immunoglobulin (nanobody), combined with plasma exchange was associated with a shorter time to normalization of the platelet count than was plasma exchange plus placebo in patients with acquired TTP.[59]

Prospective studies have successfully and safely used rituximab (see Table 29.2) in patients who failed to respond to standard daily plasma exchange and methylprednisolone and in patients with relapsed acute TTP who previously had antibodies to ADAMTS13. Treatment was associated with clinical remission, disappearance of anti-ADAMTS13 antibodies, and increase of ADAMTS13 activity to levels greater than 10%.[60] However, time to remission has been variable, from 1 to 4 weeks after the first dose. The duration of remission has ranged between 9 months and 4 years, with relapses reported in approximately 10%. Rituximab also has been used electively to prevent relapses in patients with autoantibodies and recurrent disease.[61] Longitudinal evaluation of ADAMTS13 activity and autoantibody levels may help monitor patient response to treatment. Re-treatment with rituximab should be considered when ADAMTS13 activity decreases and inhibitors reappear into the circulation, to prevent a relapse. The proteasome inhibitor bortezomib induces and maintains remission in patients with relapsed or refractory acquired TTP, but prospective trials are needed to determine the treatment schedule and the efficacy.[62]

In genetic forms of TTP, ADAMTS13 is constitutively lacking and can be replaced by plasma therapy. During acute episodes, patients often require plasma exchange to restore a stable clinical and laboratory state. Providing sufficient ADAMTS13 to achieve 5% normal enzymatic activity may be sufficient to degrade large VWF multimers—which may induce remission of the microangiopathic process—and this effect is sustained over time. Infused ADAMTS13 has a plasma half-life of 2 to 3 days in vivo, and although plasma levels fall below 5% within 3 to 7 days after plasma administration, the effect of plasma on platelet count and clinical parameters may last up to 3 weeks, suggesting that ADAMTS13 remains available, for example, on platelets and endothelial cells. Patients with genetic ADAMTS13 deficiency tend to relapse. Patients with frequent relapses, a severe clinical course with neurologic sequelae, renal insufficiency, and siblings who have died of TTP, should be put on regular prophylactic plasma infusions every 2 to 3 weeks, a regimen that has been shown to be effective in preventing episodes of acute TTP and maintaining the patients in good health for years.

Other Forms of Thrombotic Microangiopathies Associated With Systemic Diseases or Drugs

Antiphospholipid Syndrome, Scleroderma, and Hypertensive Emergencies

Plasma therapy always should be attempted in TMA that is associated with systemic diseases even though its efficacy is poorly defined (see Fig. 29.1 and Table 29.1). In antiphospholipid syndrome (see Chapter 28), oral anticoagulation remains the only treatment of proven efficacy to prevent and treat microvascular and macrovascular thrombosis, even if concomitant thrombocytopenia may increase the risk for bleeding. Preliminary reports suggest that rituximab may be efficacious, but further controlled studies are needed.[63]

Blood pressure control is fundamental in TMA associated with scleroderma crisis and hypertensive emergencies.

Human Immunodeficiency Virus

HUS and TTP are both possible complications of acquired immunodeficiency syndrome (AIDS) that may account for as many as 30% of hospitalized TMA patients where AIDS is epidemic (see Fig. 29.1 and Table 29.1). Plasma therapy is the only feasible approach in these forms, although the prognosis is poor.

Malignancy

Spontaneous TMA complicates almost 6% of cases of metastatic gastric carcinoma, which in turn accounts for about 50% of all malignant disease–associated TMA (see Fig. 29.1 and Table 29.1). The prognosis is extremely poor. Therapy is minimally effective.

Thrombotic Microangiopathy After Bone Marrow Transplantation

TMA complicates 10% to 40% of allogeneic bone marrow and hematopoietic stem cell transplants and is associated with high mortality[64] (see Fig. 29.1 and Table 29.1). The disease is multifactorial, with risk factors including immunosuppressive drugs, graft-versus-host disease, chemotherapy, radiation, and infections. Treatment remains controversial. Some evidence suggests that complement is activated and favorable outcomes with eculizumab have been described in a few cases, but prospective trials are needed to establish a consensus.

Drugs

TMA, more commonly resembling HUS, is described in 2% to 10% of cancer patients treated with mitomycin C[65] (see Fig. 29.1 and Table 29.1). Patients who develop mitomycin C–associated TMA are usually in remission from their malignancy. The fatality rate is about 70%;

patients surviving the acute phase often remain on chronic dialysis or die later of recurrence of the tumor or metastases. The possibility of preventing the disease by giving corticosteroids during mitomycin treatment has been suggested and needs to be confirmed. Plasma exchange is usually attempted, but its effectiveness is unproven. Quinine is one of the most common drugs associated with TMA.[65] It is generally used to treat muscle cramps but is also contained in beverages and nutrition health products (e.g., tonic water, herbal preparations). Quinine-dependent platelet, erythrocyte, granulocyte, lymphocyte, and endothelial antibodies may contribute to the pathogenesis. Severe renal impairment is frequent, and hemodialysis is required in most cases. High rates of death and CKD have been reported. Quinine cessation and plasma therapy should be initiated rapidly. TMA associated with interferon-α is characterized by predominant renal impairment. Recovery of the disease is common in cases of early discontinuation of the drug and prompt supportive therapy. However, kidney prognosis is usually poor, with ESRD reported in about 42% of cases.

SELF-ASSESSMENT QUESTIONS

1. Which are the common clinical features characterizing patients with thrombotic microangiopathies?
   - **A.** Thrombocytopenia, nonimmune hemolytic anemia, with or without neurologic and/or renal dysfunction
   - **B.** Diarrhea and renal dysfunction
   - **C.** Anemia, antiplatelet antibodies, and purpura
   - **D.** Disseminated intravascular coagulation
2. Which is the *most* common form of thrombotic microangiopathy?
   - **A.** Atypical hemolytic uremic syndrome
   - **B.** Shiga toxin *E. coli*–associated hemolytic uremic syndrome
   - **C.** Thrombotic thrombocytopenic purpura
   - **D.** Antiphospholipid syndrome
3. Which is the *most* common genetic abnormality associated with atypical hemolytic uremic syndrome (aHUS)?
   - **A.** *C3* mutations
   - **B.** *ADAMT13* mutations
   - **C.** *CFH* mutations
   - **D.** *CFTR* mutations
4. Which of the following is *not* indicated for treatment of aHUS?
   - **A.** Conservative therapy
   - **B.** Eculizumab
   - **C.** Plasma exchange
   - **D.** Antibiotics
5. For which of the following is there an indication for rituximab?
   - **A.** Thrombotic thrombocytopenic purpura (TTP) with congenital ADAMTS13 deficiency
   - **B.** Shiga-toxin producing *Escherichia coli*–associated HUS
   - **C.** TTP with anti-ADAMTS13 antibodies
   - **D.** aHUS-associated with *MCP* mutations

30

Pathogenesis, Clinical Manifestations, and Natural History of Diabetic Kidney Disease

Sydney Tang, Kumar Sharma

DEFINITIONS

Diabetic kidney disease (DKD) is the leading cause of end-stage renal disease (ESRD) in the developed world. It can develop in the course of both type 1 and type 2 diabetes and as a consequence of other forms of diabetes mellitus (DM). *Type 1 diabetes* is an autoimmune disease characterized by antibody-mediated and cell-mediated destruction of pancreatic islets. Type 1 diabetes may occur at any age but usually presents before the age of 30 years. *Type 2 diabetes* is characterized by a combination of insulin resistance and insulin deficiency. The *metabolic syndrome* (insulin resistance, visceral obesity, hypertension, hyperuricemia, and dyslipidemia) is often followed by type 2 diabetes. For a long period, insulin resistance is compensated by increased insulin secretion, but a gradual decline in pancreatic β-cell function finally culminates in hyperglycemia, and patients with type 2 diabetes may require treatment with insulin. Type 2 diabetes was typically a disease of elderly adults, but recently it is increasingly seen in younger adults, adolescents, and even children. Other types of DM include maturity-onset diabetes of the young, gestational diabetes, and diabetes secondary to various metabolic disorders or the result of corticosteroid or other immunomodulatory treatments.

PATHOGENESIS OF DIABETIC KIDNEY DISEASE

Genetic and Environmental Factors

The risk for development of DKD is equal in type 1 and type 2 diabetes, and only 30% to 40% of patients with type 1 or type 2 diabetes will ultimately develop nephropathy. The prevalence of nephropathy in diabetic patients varies among different racial and ethnic groups such that it is relatively increased in African Americans, Native Americans, Mexican Americans, Polynesians, Australian aborigines, and urbanized South Asian immigrants in the United Kingdom compared with Whites. Although barriers to care seem likely to account for some of these interpopulation differences, polygenetic factors likely also contribute.

Familial clustering of DKD has been reported in type 1 and type 2 diabetes and in White and non-White populations. In a person with type 1 diabetes who has a first-degree relative with diabetes and nephropathy, the risk for development of DKD is 83%. The frequency is only 17% if there is a first-degree relative with diabetes but without nephropathy.[1] In type 2 diabetes, familial clustering has been well documented in Pima Indians.[2] A familial determinant is also suggested by higher albumin excretion rates in offspring of patients with type 2 diabetes with nephropathy. The risk is particularly high in the offspring if the mother had been hyperglycemic during pregnancy, perhaps because this causes reduced formation of nephrons ("nephron underdosing") in the offspring.[3,4] Low birth weight and nephron underdosing are also associated with hypertension, metabolic syndrome, and perhaps DKD, although for DKD the data are somewhat controversial. Nephron underdosing[5] is believed to lead to compensatory glomerular hypertrophy and increased single-nephron glomerular filtration rate (GFR), thus aggravating glomerular injury in diabetes.

The risk for DKD does not show simple mendelian inheritance, and multiple genes are presumably involved. In patients with type 1 diabetes the estimate of heritability for nephropathy was 35%; however, replication studies did not identify any single genetic variances reaching whole genome levels of significance.[6] Nevertheless, single nucleotide polymorphisms in the engulfment and cell motility 1 *(ELMO1)* gene have been associated with risk for DKD in several ethnic groups with type 2 diabetes.[7-9] Gene polymorphisms also may contribute to familial clustering. A study suggested a predisposition to DKD caused by a polymorphism in the carnosinase gene, causing accumulation of carnosine with antioxidant properties.[10] A detrimental effect of the double-deletion polymorphism of the angiotensin-converting enzyme (ACE) genotype on disease progression[11] has not been uniformly confirmed.[12,13]

Environmental factors, especially diet, may be involved in the pathogenesis of diabetes and DKD. One of the strongest risk factors is the intake of soft drinks containing added sugars such as sucrose or high-fructose corn syrup. Fructose increases uric acid levels, a potent predictor for the development of type 2 diabetes as well as DKD, probably via uric acid inducing oxidative stress and endothelial dysfunction. Low birth weight may increase the risk for hypertension and diabetes later in life because it results in an elevation of uric acid that persists from birth throughout childhood. Smoking is a strong environmental risk factor for progression of DKD and may be related to hypoxia in the kidney. Recent studies also demonstrate important roles for sleep apnea, overall caloric intake, and the degree of exercise, although quantitative relationships have not been established.

Hemodynamic Changes

Hyperfiltration is common in early diabetes but can be corrected with good glycemic control. Increased GFR involves glucose-dependent effects causing afferent arteriolar dilation, mediated by a range of vasoactive mediators, including insulin-like growth factor 1 (IGF-1), transforming

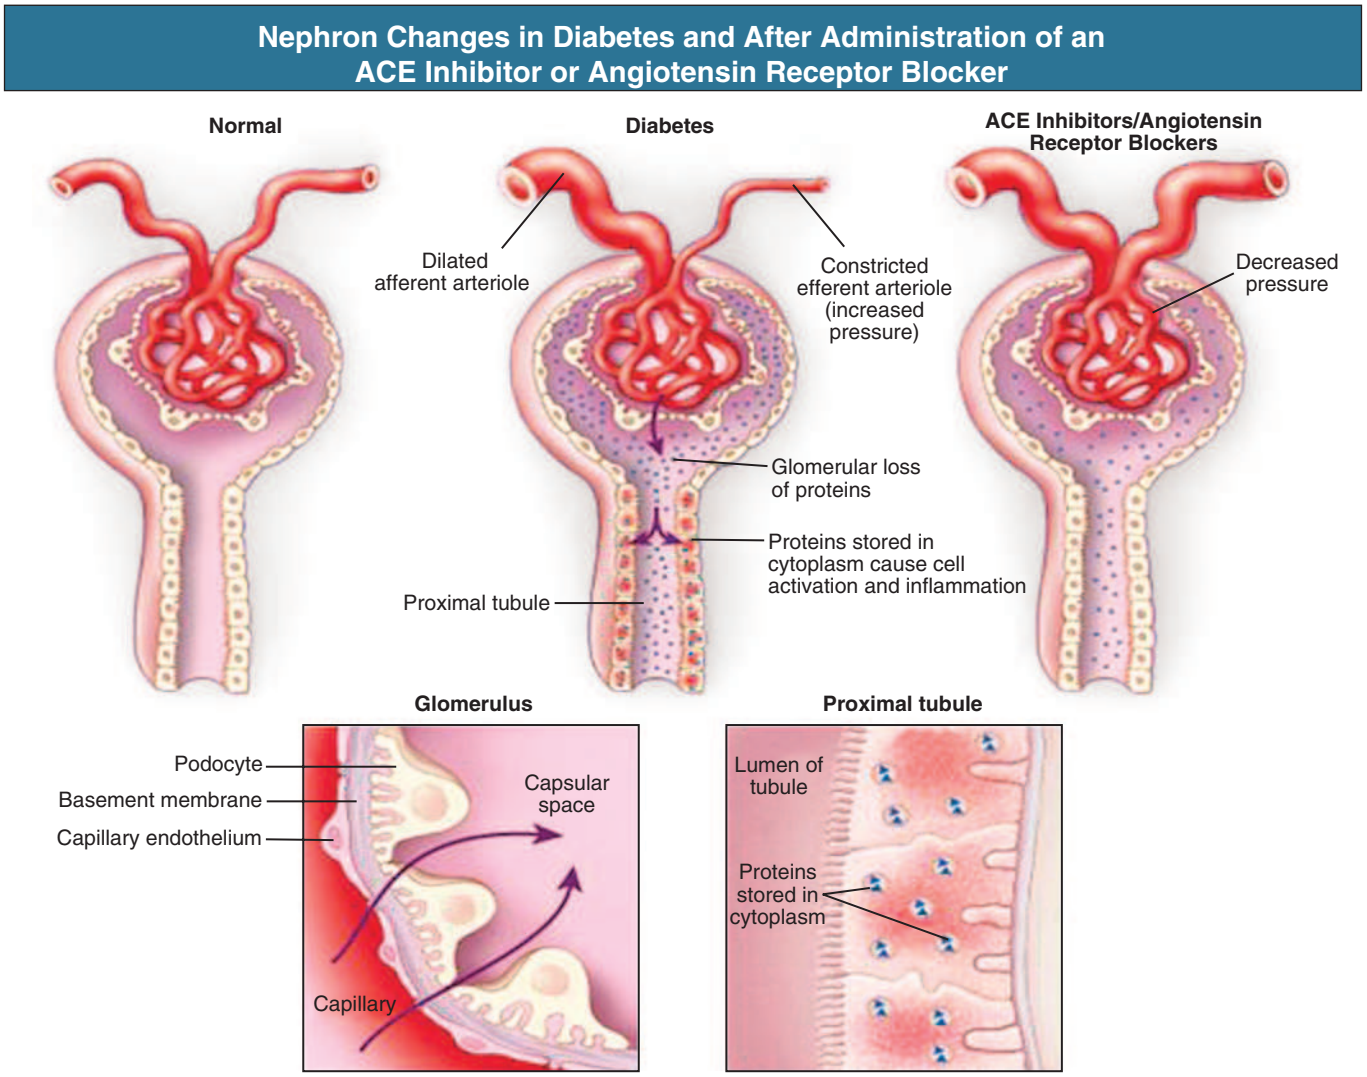

Fig. 30.1 Schematic comparison of normal nephron, nephron in diabetic kidney disease (DKD), and nephron in DKD after angiotensin-converting enzyme *(ACE)* inhibitor/angiotensin receptor blocker (ARB) administration. Note afferent vasodilation and efferent angiotensin II (Ang II)–mediated vasoconstriction in DKD causing glomerular hypertension, which is relieved by an ACE inhibitor and ARB therapy. Note also protein leakage into the filtrate and tubular loading, with endocytosed protein causing an inflammatory reaction that promotes interstitial fibrosis. This is reversed by ACE inhibitor/ARB treatment.

growth factor-β (TGF-β1), vascular endothelial growth factor (VEGF), nitric oxide (NO), prostaglandins, and glucagon (Fig. 30.1). Over time, development of vascular disease of the afferent arteriole may result in permanent alterations in renal autoregulation that favor glomerular hypertension. Renal injury in DKD is caused not only by hemodynamic disturbances (e.g., hyperfiltration, hyperperfusion) but also by disturbed glucose homeostasis, and the two pathways interact. For example, shear stress increases glucose transport into mesangial cells by upregulation of specific glucose transporters. Furthermore, shear stress and mechanical strain resulting from altered glomerular hemodynamics trigger autocrine and paracrine release of cytokines and growth factors in the glomerulus.

DKD is also associated with tubular abnormalities; hyperfiltration increases the colloid osmotic pressure in postglomerular capillaries, facilitating reabsorption of sodium in the proximal tubule. Angiotensin II (Ang II) also appears to have a role, causing hypertrophic proximal tubular growth and increased sodium reabsorption.[14] Specific inhibition of the sodium-glucose cotransporter 2 (SGLT2) in proximal tubular cells is associated with reduced progression of diabetic kidney disease, emphasizing the role of tubuloglomerular feedback and glomerular hyperfiltration in DKD (see Chapter 31).[15]

Renal Hypertrophy and Mesangial Matrix Expansion

Renal growth occurs early after the onset of diabetes. Glomerular enlargement is associated with increased numbers of mesangial cells, mesangial cell hypertrophy, and increase of capillary loops, thus enhancing the filtration surface area. Renal tubular hypertrophy is primarily the result both tubular epithelial cell proliferation and hypertrophy.

Experimentally, avoidance of hyperglycemia prevents renal hypertrophy. Hyperglycemia causes hypertrophy by stimulating growth factors in the kidney, including IGF-1, epidermal growth factor (EGF), platelet-derived growth factor (PDGF), VEGF, TGF-β, and Ang II. Hyperglycemia also induces the expression of thrombospondin, a potent activator of latent TGF-β. Experimentally, neutralizing antibodies to TGF-β attenuated diabetes-related renal hypertrophy and extracellular matrix (ECM) accumulation and preserved renal function. However, a recent

study in diabetic patients did not show beneficial effects on serum creatinine or proteinuria.[16] Similarly, inhibition of VEGF prevented glomerular hypertrophy in models of DKD and reduced albuminuria.[17] Urine EGF levels are linked to progression of chronic kidney disease (CKD) of multiple etiologies, including diabetic kidney disease,[18] and such prognostic and efficacy biomarkers may guide future interventional studies.

The pathological hallmarks of DN are mesangial expansion, nodular diabetic glomerulosclerosis (the acellular Kimmelstiel-Wilson lesion), and diffuse glomerulosclerosis. Mesangiolysis likely plays a key role in cell loss and nodule formation. Increasing evidence suggests that local NO deficiency contributes to these histologic lesions, in particular nodule formation. Indeed, endothelial cell nitric oxide synthase (NOS)-deficient mice made diabetic represent one of the most promising models for DN.

Inflammation and Diabetic Kidney Disease

Inflammatory processes and immune cells are involved in the development and progression of DKD.[17] Glomerular and interstitial infiltration by monocytes/macrophages and activated T lymphocytes, as well as heightened Nlrp-3 inflammasome activation, are observed both in human and experimental DKD.[19] Chemokines and their receptors, in particular monocyte chemotactic protein-1 (MCP-1/CCL2), RANTES/CCL5, IL-6, and TNF receptors, as well as adhesion molecules (e.g., ICAM-1), seem to contribute to this (Fig. 30.2).[17,20] Interestingly, soluble

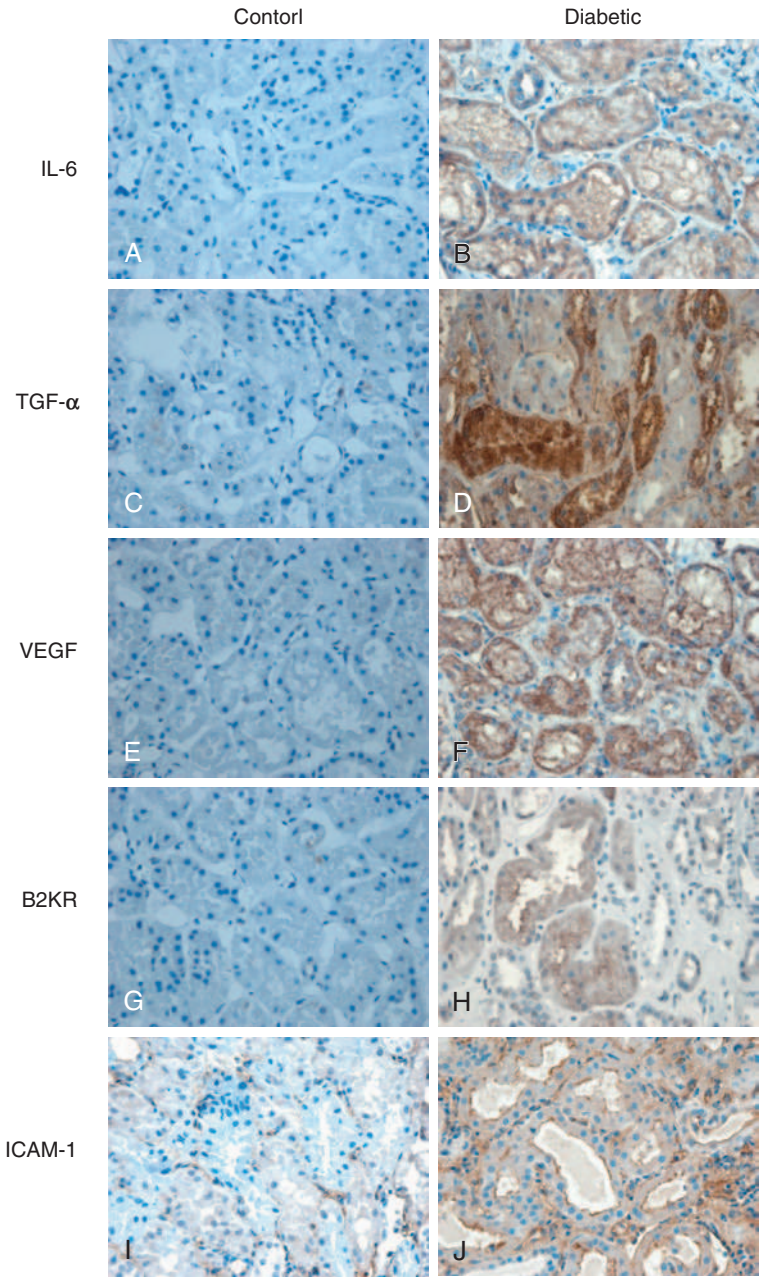

Fig. 30.2 Overexpression of inflammatory chemokines, adhesion molecules, and growth factors in the renal tubules of human diabetic kidney disease (DKD). (Left panels) DKD biopsies. (Right panels) Normal, nondiabetic kidney biopsies. *B2KR*, Bradykinin receptor 2; *ICAM*, intercellular adhesion molecule; *IL-6*, interleukin-6; *TGF*, transforming growth factor; *VEGF*, vascular endothelial growth factor. (Counterstained with hematoxylin-eosin stain; magnification, ×100. (From reference 20.)

TNF receptors appear to be a robust biomarker for progressive kidney disease in both type 1 and type 2 diabetes. Bardoxolone methyl, as an inducer of the KEAP1-Nrf2 pathway, exhibits antiinflammatory effects, but in a phase III clinical trial caused significantly more adverse effects and increased mortality (see Chapter 31). Another trial using the oral CCR2 inhibitor CCX140-B for 52 weeks yielded more promising results in reducing residual albuminuria in subjects with type 2 diabetes.[21]

Mechanisms Underlying Proteinuria

Widening of the glomerular basement membrane (GBM) is associated with accumulation of type IV collagen and net reduction in negatively charged heparin sulfate proteoglycan (see "Renal Pathology"). The expression of one permeability-controlling protein, nephrin, is abnormally low in DN.[17] The transcription of nephrin is suppressed by Ang II and restored by inhibitors of the renin-angiotensin system (RAS). In addition, in DN, apoptosis of podocytes is triggered by various factors, including Ang II and TGF-β, and adhesion of podocytes to the GBM is reduced by advanced glycation end-products (AGEs)-induced suppression of neuropilin-1. Podocyte loss also follows hyperglycemia-induced ROS generation, causing podocyte apoptosis or detachment. Migration of podocytes is also attenuated by the reduction of neuropilin-1, thereby preventing surviving podocytes from covering denuded areas of GBM, which promotes development of focal segmental glomerulosclerosis (FSGS).

Crosstalk between glomerular endothelial cells and podocytes involves activated protein C (APC). APC formation is regulated by endothelial thrombomodulin and is reduced in diabetic mice.[22] In DN, thrombomodulin-dependent APC formation inhibits podocyte apoptosis (Fig. 30.3).[23] In cultured podocytes, adipocyte-specific hormone adiponectin administration prevented high glucose–induced podocyte dysfunction. Endothelial cell dysfunction associated with altered fenestrations and glycocalyx may contribute to enhanced permeability. Adiponectin levels are low in patients with the metabolic syndrome or type 2 diabetes, which may contribute to development of albuminuria; however, once diabetes is established, elevated adiponectin levels correlate with faster progression of disease. In advanced stages of DN, albuminuria evolves into nonselective proteinuria with high-molecular-weight serum proteins escaping across the GBM with disrupted texture, gaps, and holes.

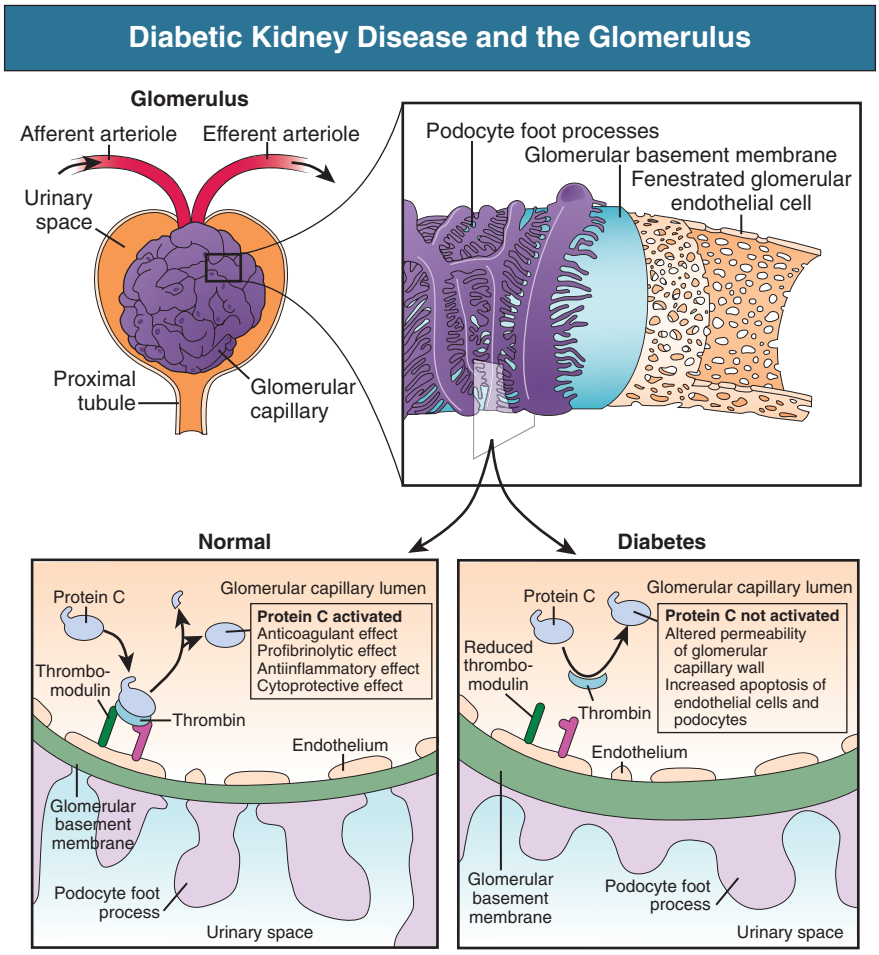

Fig. 30.3 Crosstalk between endothelial cells and podocytes involving protein C. Under physiologic conditions, protein C is activated by the binding of thrombin to its receptor, thrombomodulin, on glomerular endothelial cells. The formed complex catalyzes the conversion of protein C to its catalytically activated form, which has potent anticoagulant, profibrinolytic, antiinflammatory, and cytoprotective effects. In diabetic nephropathy, the production of activated protein C (APC) in the glomerulus is reduced because of suppression of thrombomodulin expression. Decreased functional activity of APC affects the permeability of the glomerular capillary wall and enhances apoptosis of glomerular endothelial cells and podocytes. (From reference 23.)

Tubular Changes

Although glomerulosclerosis is a cardinal feature of DKD, tubulointerstitial injury ultimately determines the rate of attrition of renal function. In vitro studies have demonstrated the pathogenic role of various diabetic substrates in promoting tubule hypertrophy, stimulating ECM production and inducing a proinflammatory and profibrotic phenotype in proximal tubular epithelial cells (PTECs), including high glucose, accumulation of glycated proteins, AGEs and their carbonyl intermediates, elevated intrarenal Ang II, oxidative stress, and hypertension-induced mechanical stress.[24] Another mechanism by which glucose may promote diabetic tubulopathy is by conversion through the polyol pathway to fructose, where it is degraded by local fructokinase to induce oxidative stress and local inflammation.

Glomerular cells, tubular epithelial cells, macrophages/lymphocytes, and fibroblasts/myofibroblasts all contribute to matrix accumulation along the glomerular and tubular basement membranes and within the interstitial space. In particular, matrix-producing myofibroblasts promote progression of fibrosis in DKD by facilitating deposition of interstitial ECM (Fig. 30.4).

Clinical studies showed that even mild anemia (hemoglobin level <12.5 g/dl for men, 11.5 g/dl for women) increases the risk for progression of DKD. Anemia presumably causes renal hypoxia. Moreover, hypoxia is exacerbated by the progressive hyalinosis of the afferent and efferent arterioles and loss of peritubular capillaries. In experimental chronic renal injury, hypoxia is an important factor aggravating interstitial fibrosis, partly by the induction of TGF-β and VEGF. The transition of tubular epithelial cells into fibroblasts is stimulated by cellular hypoxia.[26] The induction of growth factors and cytokines is mediated by hypoxia-inducible factor-1 (HIF-1), which can be amplified by Ang II. Whether early treatment of anemia with erythropoietin or HIF1 stabilizers delays DKD progression remains unproven.

Hyperglycemia and Diabetic Kidney Disease

Role of Glucose Control

Evidence of the role of tight glycemic control in retarding the development of DKD includes the following:

- In the Diabetes Control and Complications Trial (DCCT), there was a remarkable reduction in progression from normoalbuminuria to microalbuminuria and other microvascular complications, specifically retinopathy, in patients with type 1 diabetes with tight glycemic control.[27]
- Euglycemia that followed isolated pancreatic transplantation was associated with regression of diabetic glomerulosclerosis after 10 years.[28]
- In the United Kingdom Prospective Diabetes Study (UKPDS), reducing the hemoglobin A_{1c} (HbA_{1c}) level by approximately 0.9% in patients with type 2 diabetes reduced the risk for microvascular complications, including nephropathy.[29]
- In the ADVANCE study, intensive glucose control with a target HbA_{1c} level of 6.5% was associated with a long-term reduction in ESRD, without evidence of any increased risk for cardiovascular events or death.[30]
- In the EMPA-REG study, type 2 diabetics treated with empagliflozin with lower glycated hemoglobin levels had significant reduction in cardiovascular and renal events, though the protective effects of the SGLT2 inhibitor is likely beyond simply glycemic control.[15]

A unifying theory was that hyperglycemia leads to diabetic complications through an accumulation of mitochondrial superoxide production and oxidative sequelae.[31] However, in vivo studies do not show an increase in mitochondrial superoxide[32]; indeed there appears to be a consistent reduction in mitochondrial electron transport chain activity with diabetes. There is also a reduction of mitochondrial biogenesis in animal models as well as in patient biopsy samples. Stimulation of

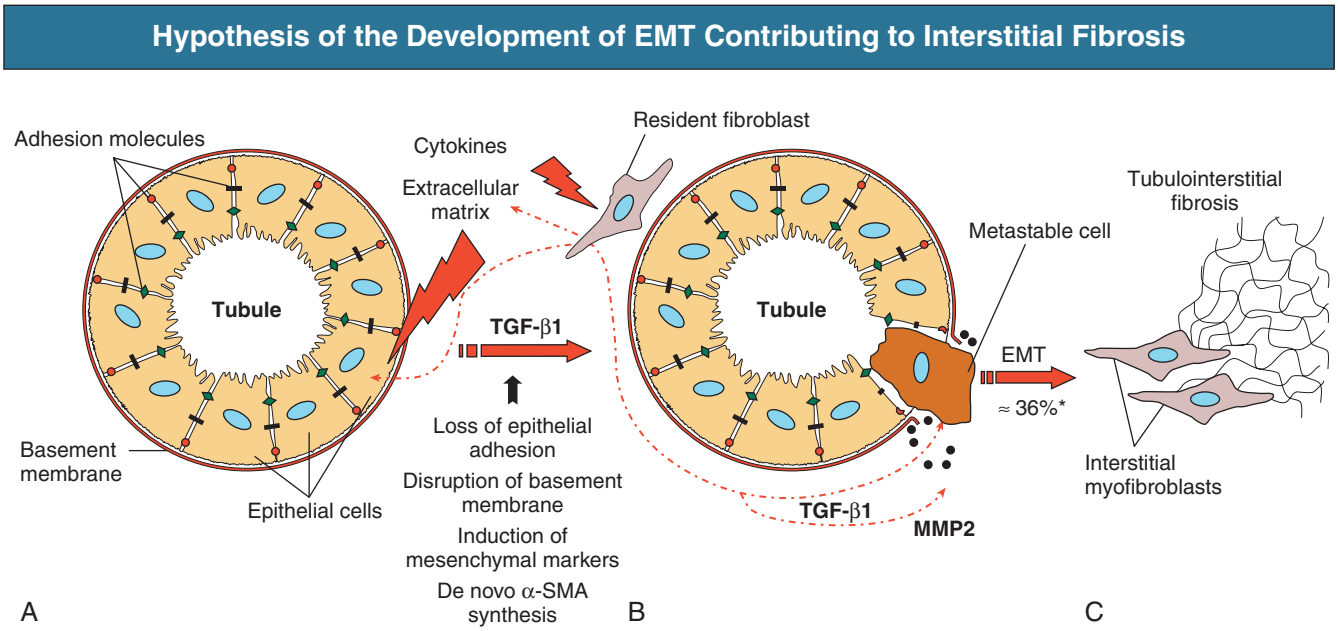

Fig. 30.4 Hypothesis of the development of epithelial-mesenchymal transition *(EMT)* contributing to interstitial fibrosis. Initiated by external stimuli (e.g., cytokines), tubular cells lose their cell-cell contacts (e.g., E-cadherin) (A) and start to express mesenchymal markers (e.g., α-SMA, vimentin) (B). After disruption of tubular basement membrane (by MMP2) metastable cells disengage themselves from cell connective and transdifferentiate to interstitial myofibroblasts that synthesize extracellular matrix and contribute to fibrosis (C). *MMP,* Matrix metalloproteinase; *SMA,* smooth muscle actin; *TGF,* transforming growth factor. *Up to 36% of all interstitial myofibroblasts in diabetic kidney disease are thought to derive from EMT. (Modified from reference 25.)

oxidative phosphorylation and mitochondrial biogenesis is associated with reduced inflammation and fibrosis in experimental models of diabetic kidney disease.

Protein kinase C pathway. Many of the adverse effects of hyperglycemia have been attributed to activation of protein kinase C (PKC), a family of serine-threonine kinases that regulate diverse vascular functions. The activity of PKC-β, especially the membrane-bound form, is increased in the retina, aorta, heart, and glomeruli of diabetic animals. In short- and long-term studies of diabetic rats, an orally effective PKC-β inhibitor reduced albuminuria and renal TGF-β overexpression, as well as ECM accumulation. PKC-α may represent an additional therapeutic target because albuminuria was virtually absent in diabetic PKC-α knockout mice.

Advanced glycation end products pathway. Chronic hyperglycemia can lead to nonenzymatic glycation of amino acids and proteins (Maillard or Browning reaction)[33] (Fig. 30.5). Over time, these products undergo rearrangement, including cross-linking, to become irreversible AGEs. Both circulating and tissue proteins, as well as lipids and nucleic acids, may thus be glycated. Although primarily observed in diabetes, AGEs also accumulate in aging and in renal failure.[33]

The concentration of AGEs is increased in the serum, glomeruli, and tubules of DN patients. AGEs bind to macrophages, mesangial cells, and tubular cells and mediate cellular actions, including expression of adhesion molecules, cell hypertrophy, ECM synthesis, epithelial-mesenchymal transition (EMT), and inhibition of NOS. AGEs injected in vivo induce albuminuria and glomerulosclerosis.[33] AGEs have profound effects on podocytes, including induction of hypertrophy, followed by apoptosis and suppression of nephrin synthesis. Among several binding sites, the most important is RAGE (receptor for AGE), which is present in tubular cells and podocytes. Ang II stimulates upregulation of RAGE on podocytes.[34] This effect is mediated by angiotensin-2 (AT_2) receptors not blocked by sartanes.[34] One of the actions of RAGE is activation of nuclear factor-κB (NF-κB). sRAGE, the soluble extracellular domain of RAGE, acts as a decoy receptor and experimentally ameliorates the renal lesions in diabetes.[33]

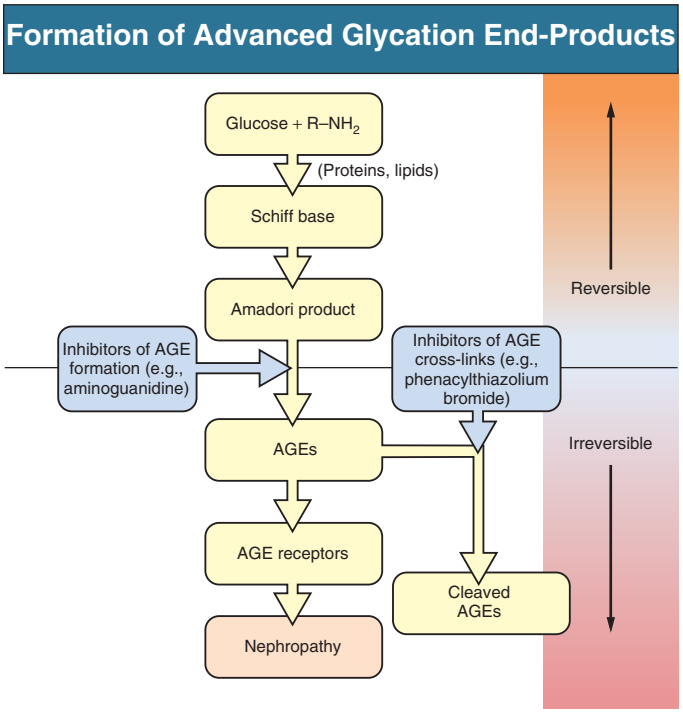

Fig. 30.5 Mechanism of formation of advanced glycation end-products *(AGEs)*.

Administration of aminoguanidine, an inhibitor of AGE formation, to diabetic animals reduces AGE deposition, mesangial matrix expansion, and albuminuria, but has inconsistent effects on GBM thickening. The clinical experience with aminoguanidine has been disappointing and riddled with side effects. Newer, more specific and potent agents include phenacylthiazolium bromide, which cleaves covalent AGE-derived protein cross-links, but so far there has not been any report of its utility in experimental DKD.

Polyol pathway. The polyol pathway involves the conversion of glucose to sorbitol and eventually fructose. The role of polyols in diabetic complications has been assessed with aldose reductase inhibitors such as sorbinil, tolrestat, and ponalrestat, which have shown promise in preventing diabetic cataracts. Aldose reductase inhibitors also blunt hyperfiltration in DKD and have a mild effect on reducing albuminuria. Overall, however, the experience with aldose reductase inhibitors in DKD has been disappointing and associated with hypersensitivity reactions and liver function abnormalities. More recent experimental studies have focused on blocking fructokinase, which is in the distal polyol pathway, with more promising results. Other studies with regulation of myoinositol in the proximal tubule of the kidney reproduced many of the features of tubulointerstitial disease and may be an important target for future intervention.

Hexosamine pathway. Although most of the intracellular glucose is metabolized by the glycolytic pathway, some fructose-6-phosphate is diverted into the hexosamine pathway, increasing the concentrations of *N*-acetylglucosamine. This glucosamine modifies certain transcription factors, such as Sp1 activity, by post-translational *O*-linked β-*N*-acetyl glucosaminylation (O-GlcNAc). In turn, Sp1 then leads to enhanced transcription of key mediators, such as TGF-β1 and plasminogen activator inhibitor 1. Glucosamine-mediated modification of the enzyme Akt/PKB reduces expression of endothelial NOS and promotes apoptosis of cells. The role of O-GlcNAc modification has been linked to diabetic cardiac effects, although interventions have not yet been assessed in clinical trials.

Adenosine monophosphate kinase. Recent studies suggest an alternative pathway that may contribute to DKD. The energy-sensing enzyme 5′-adenosine monophosphate kinase (AMPK) pathway may contribute to DKD. Inhibition of 5′-AMP-activated protein kinase in caloric-excess states has been linked to inflammation (NF-κB, nicotinamide adenine dinucleotide phosphate [NADPH] oxidase, MCP-1 stimulation), vascular dysfunction (eNOS inhibition), stimulation of hypertrophy (mammalian target of rapamycin complex [activation]), and profibrotic pathways (TGF-β signaling).[35-37] Stimulation of AMPK is beneficial in both type 1 and type 2 models of diabetic kidney disease. Fatty acid oxidation stimulated by the LKB1-AMPK-PGC1a pathway is also beneficial for both diabetic and nondiabetic kidney disease. Future studies with specific AMPK activators are eagerly awaited.

Kallikrein-kinin pathway. The effects of the plasma and tissue serine protease enzyme kallikrein are primarily through bradykinin (BK). In vitro, high glucose stimulates expression of renal tubular kallikrein (KLK1), and BK promotes proinflammatory and profibrotic responses in PTECs.[20,24] Blocking the BK_2 receptor in *db/db* mice reduced serum creatinine and albuminuria. Recombinant KLK1 stimulated the production of inflammatory cytokines in PTECs.[38] Pancreatic kallikrein administered systemically could ameliorate renal injury in both STZ-induced and *db/db* mice.[39] Nonetheless, the human tissue kallikrein-binding protein, kallistatin, has been shown to ameliorate tubulointerstitial injury and renal fibrosis in *db/db* mice via multiple mechanisms, including suppression of oxidative stress, TGF-β and NF-κB signaling and hemodynamic effects.[40] The discrepancy may be due to different experimental models.

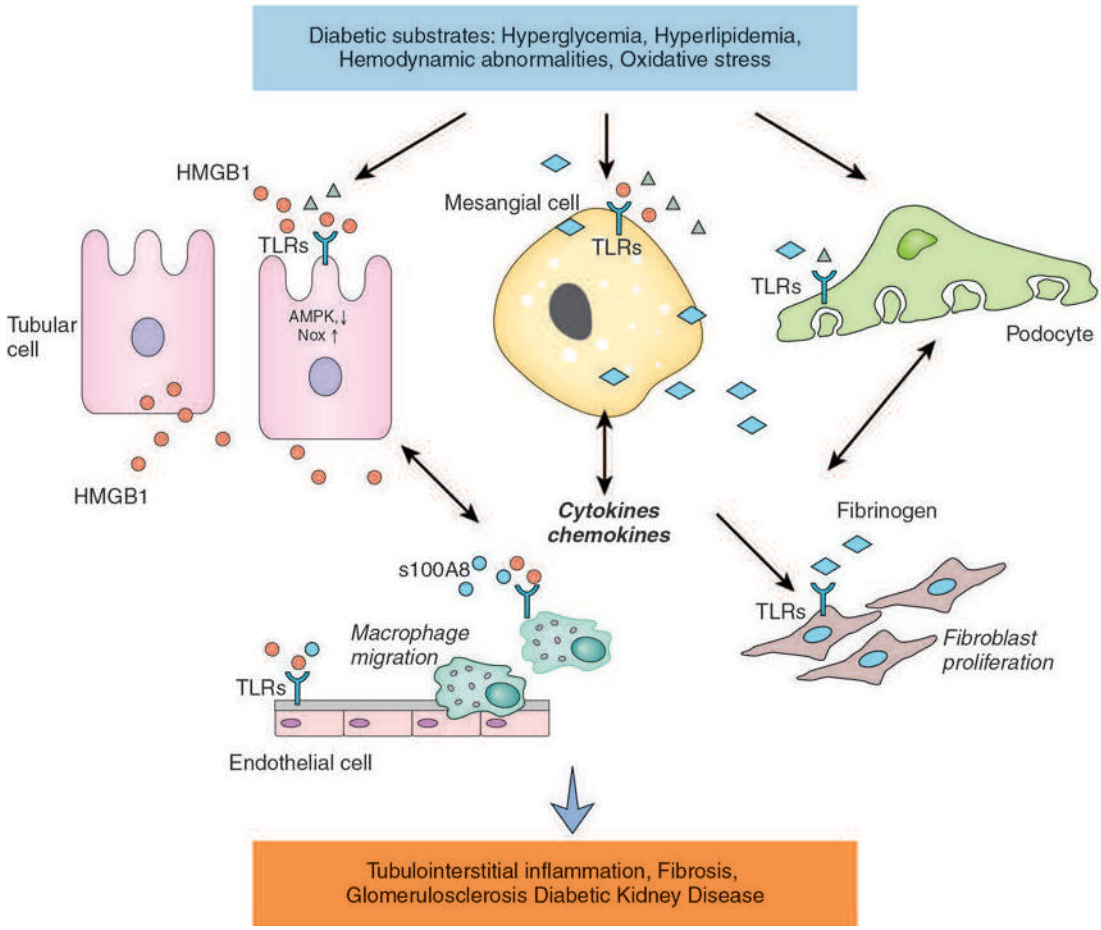

Fig. 30.6 Role of Toll-like receptors (TLRs) in diabetic kidney disease. TLRs in resident renal cells could recognize and respond to the metabolic stress of diabetes or endogenous ligands activated during the diabetic state, inducing downstream signaling events to propagate the synthesis proinflammatory cytokines and chemokines, which act as effectors to further facilitate macrophage recruitment and fibroblast proliferation, leading to a self-perpetuating cycle of renal inflammation and subsequent tubulointerstitial fibrosis and glomerulosclerosis. *HMGB1,* High-mobility group box-1 protein; *S100A8,* S100 calcium binding protein A8. (Modified from reference 42.)

Activation of innate immunity. Diabetes can be considered a metabolic danger signal that is effected via Toll-like receptors (TLRs), a conserved family of pattern recognition receptors that play a fundamental role in innate immunity. In particular, TLR-4 is overexpressed in the renal tubules of human diabetic nephropathy (DN) biopsies.[41,42] In vitro, silencing TLR-4 ameliorated high glucose–induced tubular cell inflammation. In experimental DKD, either systemic deletion or the application of a TLR-4 antagonist conferred renoprotection.[42] In addition, TLRs are also expressed in other resident renal cell types such as podocytes and mesangial cells, as well as infiltrating macrophages, that could act in concert to bring about an inflammatory phenotype observed in diabetic kidney disease (Fig. 30.6).

A key component of innate immunity includes the NADPH oxidase pathway, expressed primarily in the lysosomes of phagocytic cells, but also in the kidney. Enhanced Nox4 in podocytes may contribute to glomerular disease involving a pathway linking Nox to the citric acid cycle.[43]

Renin-Angiotensin-Aldosterone System and Diabetic Kidney Disease

Experimental and clinical studies in type 1 and type 2 diabetes suggest that ACE inhibitors or angiotensin receptor blockers (ARBs) retard progression of DKD (see Chapter 31). Although plasma renin activity is low in DKD, it is inappropriate in relation to increased extracellular volume and exchangeable sodium, suggesting activation of the RAS.[44] In experimental diabetes, sites of local RAS activation have been identified in glomeruli, renal vessels, and tubular cells.[44] High glucose concentration and AGEs stimulate angiotensinogen and renin expression in various renal cells, mainly through reactive oxygen species.[44] Proteinuria further activates the local RAS of tubular cells. Adipocytes are another source of Ang II in obese patients.

In patients with DKD, prorenin levels are elevated, possibly reflecting increased synthesis. Specific prorenin and renin receptors have been demonstrated in the kidney; ligand binding causes nonenzymatic activation of prorenin to yield renin activity and locally produced Ang II.[45] Moreover, prorenin and renin can directly bind to specific receptors on mesangial and tubular cells and induce proinflammatory and profibrogenic cytokines. Interestingly, 1,25-dihydroxyvitamin D_3 (calcitriol) suppresses the RAS. Thus, in diabetic patients with advancing CKD, decreasing calcitriol production further activates the RAS.

Ang II has many nonhemodynamic effects and mediates cell proliferation, hypertrophy, ECM expansion, and cytokine (TGF-β, VEGF) synthesis.[44] Therefore ACE inhibitors and ARBs presumably act by hemodynamic as well as nonhemodynamic actions.

Aldosterone accelerates progression in renal damage models independently of Ang II. In DKD, aldosterone escape has been linked to progression of proteinuria (see Chapter 31). Aldosterone synthesis is stimulated in DKD, and this steroid hormone stimulates the synthesis of other proinflammatory and profibrogenic cytokines (MCP-1, TGF-β).[46]

Other vasoactive agents may be involved in the pathogenesis of DKD, including alterations in systemic or intrarenal production of endothelin, NO, the kallikrein-kinin system, and natriuretic peptides. A randomized controlled clinical trial examining the efficacy of a selective endothelin-A receptor antagonist, the Study Of Diabetic Nephropathy with Atrasentan (SONAR) is currently under way.

Uric Acid and Fructose

As discussed earlier, an elevated uric acid level can predict the development of DKD as well as diabetic CKD, and pilot studies have reported an early benefit of allopurinol therapy on diabetic albuminuria.[47]

Uric acid is generated during the metabolism of fructose, when it appears to induce oxidative stress in mitochondria. In addition to dietary fructose from added sugars, there is increasing evidence that in diabetes, fructose is generated in the kidney, where it is metabolized to generate uric acid and oxidative stress that may mediate renal injury. Thus both dietary fructose and endogenous production of fructose may be involved in the development of diabetes and its complications.[48]

A phase III study (Preventing Early Renal Function Loss [PERL]) is ongoing to determine the role of allopurinol on uric acid levels and progression of DKD in patients with type 1 diabetes.

EPIDEMIOLOGY

In most Western countries, DKD has become the leading cause of ESRD. According to the U.S. Renal Data System (www.USRDS.org), in 2016, DKD was the most frequent primary diagnosis, with over 150 cases per 1 million population per year. In China, a large-scale hospital-based survey found that DKD exceeded glomerulonephritis (GN) as the most prevalent cause of ESRD since 2011.[49] The proportion of diabetics among patients with ESRD varies considerably among countries, but in many developed countries the figure currently stands between 40% and 60%. Classic features of DKD were observed in about 60% of diabetic patients (i.e., normal kidney size despite ESRD; proteinuria >1 g/2 h with or without retinopathy); 13% had an atypical presentation with ischemic nephropathy, and in 27% a known primary renal disease coexisted with diabetes. An important mode of presentation has become irreversible acute kidney injury (AKI), for example, after administration of nonsteroidal antiinflammatory drugs (NSAIDs), cardiac events, and septicemia. Many patients also lose the clinical manifestations of overt diabetes (e.g., hyperglycemia) because of CKD-associated weight loss, impaired renal gluconeogenesis, or increased insulin half-life in CKD.

Currently, with better treatment of hypertension and coronary heart disease, an increasing proportion of patients with type 2 diabetes survive to develop DKD and ESRD. The proportion of patients with type 1 and type 2 diabetes who develop proteinuria and elevated serum creatinine concentration is related to the duration of diabetes. Diabetes caused an estimated 4 million deaths worldwide in 2017, of which half occurred in patients below the age of 60 and more than half were caused by increased risks for cardiovascular and other diseases. There is a more rapid increase in the prevalence of type 2 diabetes in the developing world compared with the developed world. Indeed, 4 out of 5 people with diabetes live in low- and middle-income countries, and it has been projected that these countries will experience the greatest surge in diabetes over the next two decades (Fig. 30.7).[50] For example, the prevalence of diabetes is predicted to increase by 110% in Africa, 70% in Southeast

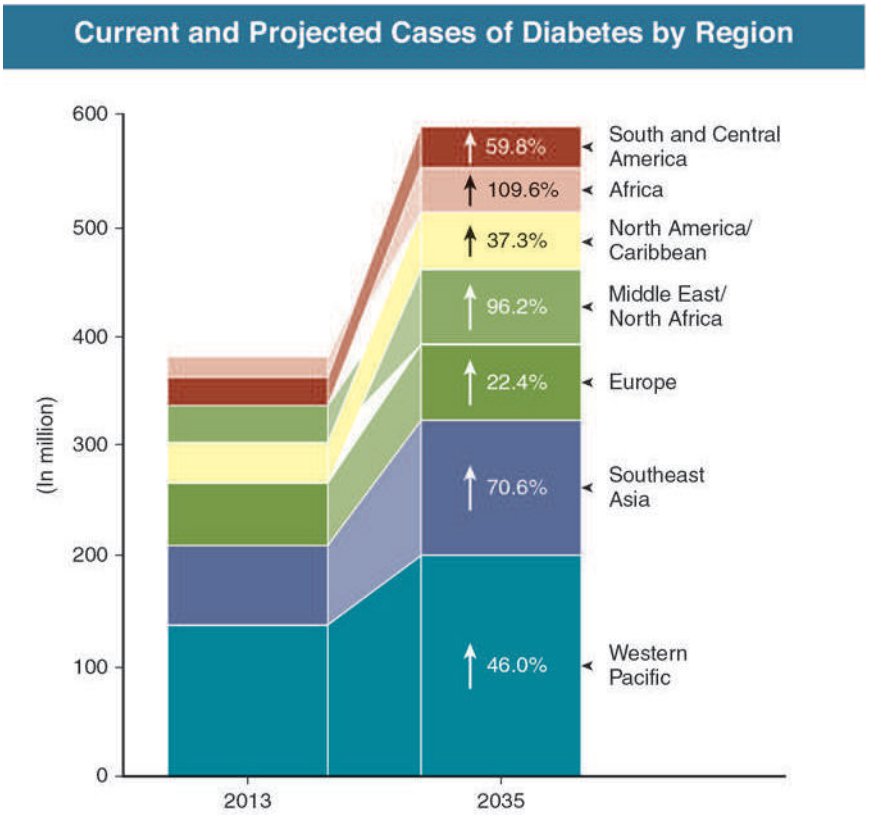

Fig. 30.7 Predicted increase in diabetes prevalence by geographical region over the next two decades. The rate of increase is greatest in the developing world. (Modified from reference 50.)

Asia, and 60% in South and Central America by 2035, versus 37% in North America and 22% in Europe. In Asia, high mortality from diabetes is most prominent in patients aged 50 to 60 years, which translates to a reduction in life expectancy of more than a decade. Up to 60% of Asian diabetic patients have elevated albuminuria, compared with 30% to 40% reported in Western diabetic populations in cross-sectional surveys.[51] Also, the incidence of diabetes-associated ESRD varies in Western countries, with very high numbers of patients in the United States. The reasons are complex and include genetic variability,[52] differences in lifestyle, and different national health care systems, with variable access to screening programs and early management for diabetes.[53]

CLINICAL MANIFESTATIONS AND NATURAL HISTORY

DKD is part of a generalized microvascular syndrome that is accompanied by macrovascular disease.

Obesity, Metabolic Syndrome, and Renal Disease

The metabolic syndrome—defined as having at least three of the five parameters of increased waist circumference, elevated triglycerides, decreased high-density lipoprotein, elevated blood pressure (BP), and elevated fasting blood glucose concentration—is increasingly being recognized not only as a major contributor to cardiovascular diseases but also as a negative influence on renal function[54,55] Obesity is often defined as body mass index greater than 30, although different values define obesity in other countries (e.g., India, Japan). Obese individuals have large kidneys and glomerulomegaly, with increased renal blood flow, increased filtration fraction, and glomerular hyperfiltration.[56] Obese patients have moderate increased albuminuria even in the absence of hypertension. The resemblance of obesity-related kidney disease to the early features of diabetic kidney disease is striking. In addition, sleep apnea, which is common in obese individuals, leading to hypoxic episodes, may contribute to kidney impairment. Visceral adipocytes are a potent source of deleterious factors[57] and could have an impact on renal function (Ang II, leptin, TNF-α). By contrast, the secretion and plasma concentration of adiponectin, an adipokine with cardiovascular protective, antidiabetic, and antiinflammatory properties, are markedly decreased in obesity and its related pathologies (see "Mechanisms Underlying Proteinuria"). Thus renal changes may occur years before the manifestation of type 2 diabetes during obesity and the development of the metabolic syndrome.

Evolution of Diabetic Kidney Disease

One of the earliest changes of renal function in in patients with type 1 as well as many with type 2 diabetes is an increase in GFR, or hyperfiltration, which is accompanied by an increase in renal size. The next observable change is the development of microalbuminuria (30 to 300 mg albumin/24 h; now often termed *moderately increased albuminuria*), which later progresses to macroalbuminuria (>300 mg albumin/24 h; now often termed *severely increased albuminuria*). Diabetic patients with persistent microalbuminuria are at greatly increased risk for development of overt DKD, which is heralded by the development of proteinuria (albuminuria >300 mg/24 h/day), on average 15 years after disease onset, with progressive increase in proteinuria and BP and development of progressive CKD. Williams[59] proposed a scheme of the natural history and pathophysiology of nephropathy typically observed in type 2 diabetes over a period of 20 years (Fig. 30.8).

Mogensen[58] proposed a scheme of the different stages of DKD that is largely valid in type 1 diabetes but less reliable in type 2 diabetes. In the latter, CKD may occur in the absence of albuminuria, possibly as a result of macrovascular disease. Of note, with improved management of glycemic control and BP control there is a growing population of patients with type 1 diabetes with normoalbuminuria that have progressive DKD.[59] In this cohort, progressive renal decline, not albuminuria, is the predominant clinical feature. The putative mechanisms that initiate and sustain progressive renal decline in type 1 diabetes are not well known. Whether the initial lesion of progressive renal decline is in the glomerulus, tubule, interstitium, or vasculature remains to be elucidated via clinical and epidemiologic studies, because a pure animal model of progressive renal decline with normoalbuminuria is lacking.

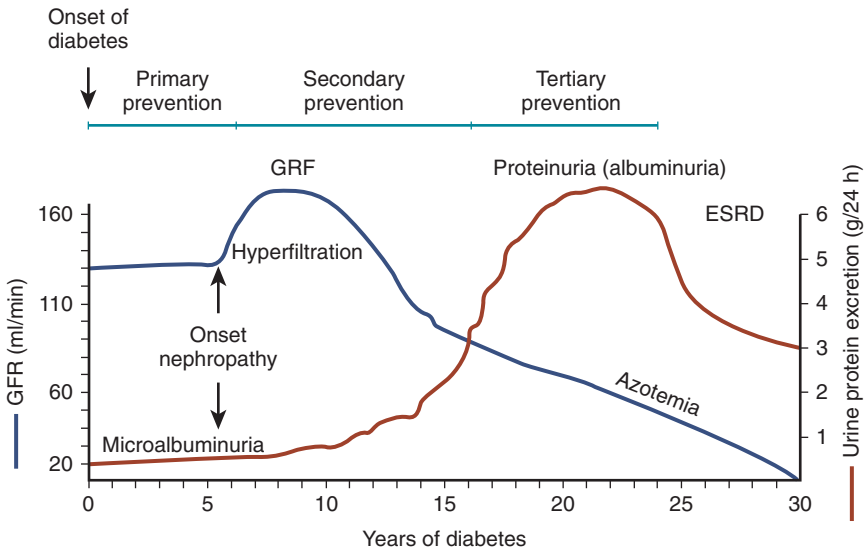

Fig. 30.8 Natural history of diabetic nephropathy (DN). Changes in glomerular filtration and proteinuria over time from the onset of diabetes. Proteinuria reduction is shown as a tertiary prevention. *ESRD,* end-stage renal disease; *GFR,* glomerular filtration rate. (From reference 59.)

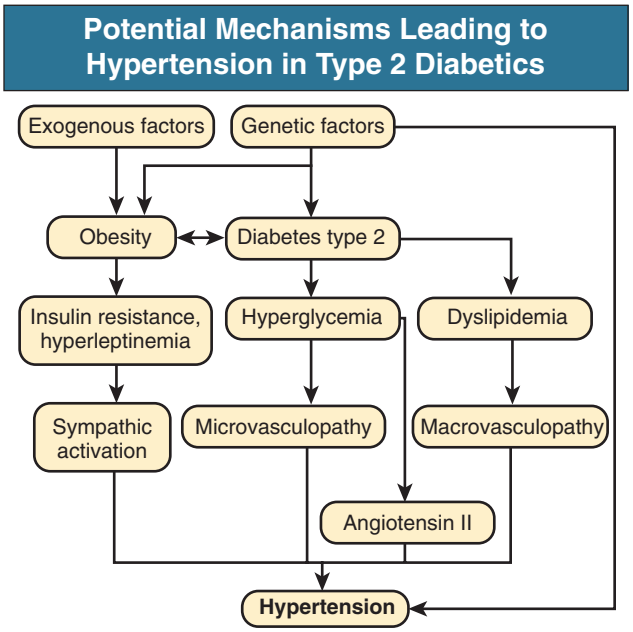

Fig. 30.9 Overview of potential mechanisms leading to hypertension in patients with type 2 diabetes. Genetic susceptibility factors for primary hypertension and diabetes may be clustered so that an individual patient may have a higher incidence of both diseases. Obesity and the metabolic syndrome lead to insulin resistance and hyperleptinemia associated with sympathetic nerve activation. Hyperglycemia directly activates the renin-angiotensin system and, in addition, through renal microvasculopathy stimulates development of hypertension. Dyslipidemia leads through macrovasculopathic alteration to stiffness of vessels and hypertension.

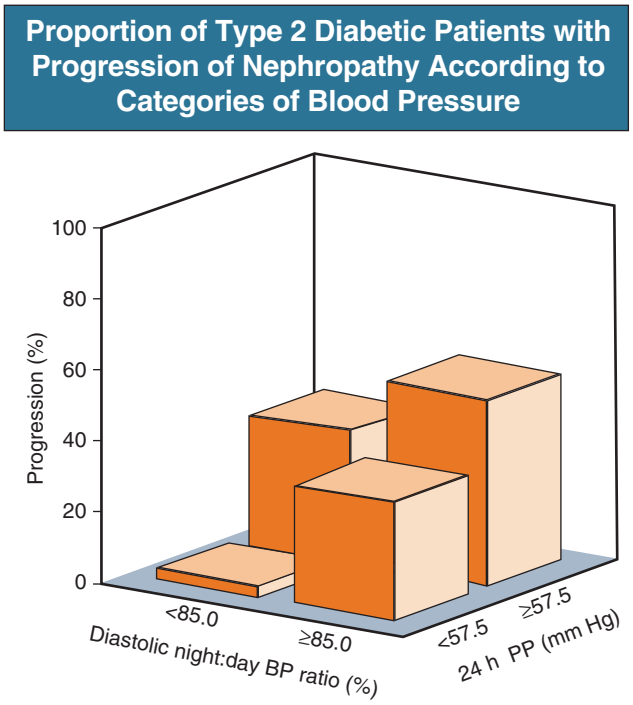

Fig. 30.10 Proportion of patients with type 2 diabetes with progression of nephropathy according to categories of blood pressure *(BP).* Progression risk according to categories of night to day diastolic BP (median value <85% or ≥85%) and 24-hour ambulatory pulse pressure *(PP)* (median value <57.5% or ≥57.5%). (From reference 64.)

Hypertension and Diabetic Kidney Disease

If hypertension develops in a patient with type 1 diabetes, it is almost always caused by renal parenchymal disease. At present, however, patients with type 1 diabetes survive longer, and a minority of elderly patients with type 1 develop primary hypertension with no evidence of nephropathy. In patients with type 2 diabetes, hypertension often precedes the onset of diabetes by many years as a feature of metabolic syndrome. At diagnosis of type 2 diabetes, an abnormal BP and an abnormal circadian BP profile are found in 80% of patients. Prediabetic hypertension increases the risk for onset and progression of DKD. If patients with type 2 diabetes ultimately develop nephropathy, the prevalence of hypertension further increases, with greater BP elevation, but the relationship between hypertension and nephropathy is generally much less than in type 1 diabetes. The pathogenesis of hypertension in type 2 diabetes is complex and involves RAS activation, direct sympathetic nerve activation, and macrovascular changes.[60] Furthermore, there is evidence that genetic factors defining primary hypertension as well as diabetes are clustered (Fig. 30.9).

In DKD, it has been well documented that the nocturnal BP decrease is frequently attenuated, or nondipping, which even precedes the onset of microalbuminuria.[60] Furthermore, the BP response to exercise tends to be exaggerated, even when the BP is normal under basal conditions. Stiffening of the aorta increases the peak systolic pressure and decreases the diastolic pressure, resulting in increased BP amplitude, which explains why isolated systolic hypertension is so common in patients with type 2 diabetes.[61] Low diastolic pressure increases the risk for coronary events because coronary perfusion occurs during diastole only.[62] Ambulatory pulse pressure and impaired nocturnal BP decline are independent predictors of nephropathy progression in patients with type 2 diabetes (Fig. 30.10). The increased prevalence of sleep apnea in DKD also contributes to hypertension.[63]

Associated Extrarenal Microvascular and Macrovascular Complications

Diabetic retinopathy is present in virtually all patients with type 1 diabetes and albuminuria from DN. In contrast, only 50% to 60% of proteinuric patients with type 2 diabetes have retinopathy.[66,67] Consequently, the absence of retinopathy does not exclude the diagnosis of DN in patients with type 2 diabetes.[67] In patients with DN, retinopathy tends to progress more rapidly so that yearly or half-yearly ophthalmologic examination is indicated.

Many patients with DN also have polyneuropathy. Sensory polyneuropathy is an important aspect of the diabetic foot. There is a strong inverse correlation between the incidence of diabetic foot and renal function. Motor and sensory neuropathy may cause areflexia, wasting, and sensory disturbances such as paresthesia, anesthesia, and impaired perception of vibration and pain, but the most vexing clinical problems are the results of autonomic polyneuropathy. Because cardiac innervation is defective, pain and angina are frequently absent when the patient has coronary heart disease and myocardial infarction. Further consequences of autonomic polyneuropathy are gastroparesis and diarrhea or constipation (see Chapter 86). These problems are caused by impaired intestinal innervation, often complicated by intestinal bacterial overgrowth because of stasis. Also, urogenital abnormalities are common, including erectile impotence and detrusor paresis with delayed and incomplete emptying of the bladder.

The major macrovascular complications associated with DKD are stroke, coronary heart disease, and peripheral vascular disease.[64,65] These complications occur up to five times more frequently in diabetic patients with than without DKD.

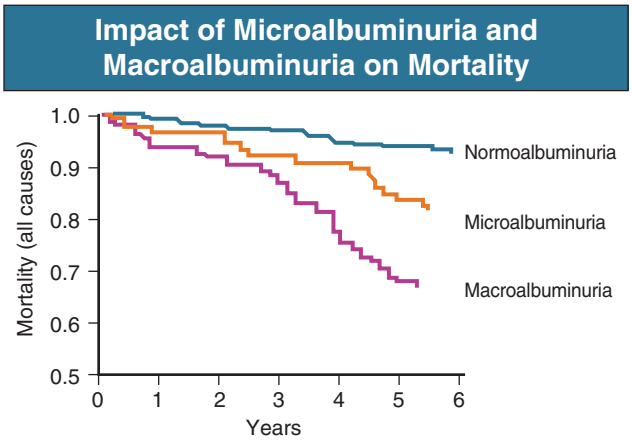

Fig. 30.11 Impact of microalbuminuria and macroalbuminuria on mortality. The impact of microalbuminuria and macroalbuminuria on mortality was evaluated prospectively in 328 White patients with non–insulin-dependent diabetes mellitus observed for 5 years. Microalbuminuria and macroalbuminuria led to a significant increase in total mortality compared with that in patients who remained normoalbuminuric. (From reference 68.)

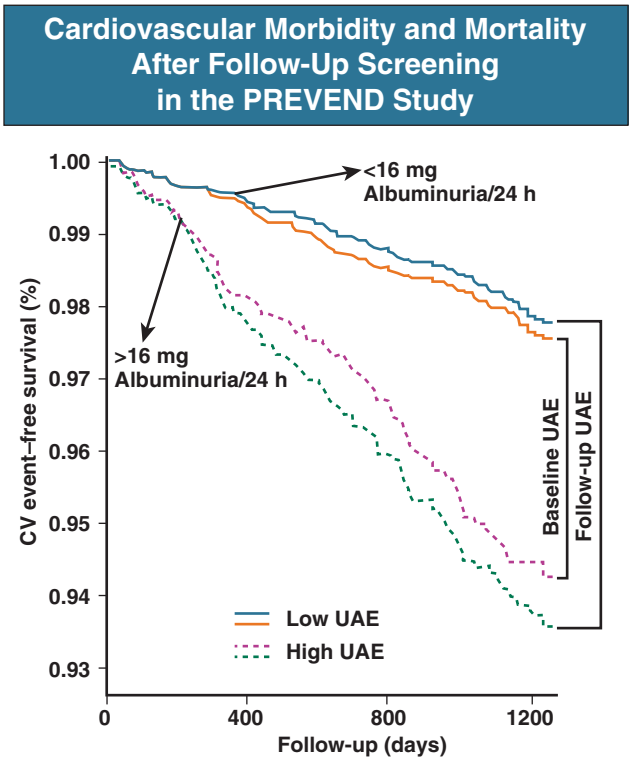

Fig. 30.12 Event-free survival for cardiovascular *(CV)* morbidity and mortality after follow-up screening in the PREVEND study. Individuals are stratified according to the presence of a high or low urinary albumin excretion *(UAE)*. High and low UAE are defined by either the UAE measurement from the baseline screening *(orange and violet lines)* of approximately 4.2 years before follow-up screening or the repeated UAE measurement at time of the follow-up screening *(blue and green lines)*. To allow comparison, the survival curves for the 6800 individuals with either the baseline or follow-up measurement of UAE are plotted in the same graph. A high UAE *(dashed lines)* is defined as a UAE ≥ 16.2 mg/24 h, being the 75th percentile of UAE with use of the UAE measurement of the baseline screening. (From reference 69.)

Survival in Patients With Diabetic Kidney Disease

The presence of DKD greatly increases mortality in patients with both type 1 and type 2 diabetes. Compared with the background population, mortality in patients with type 1 diabetes and no proteinuria is elevated only 2-fold to 3-fold; in contrast, it is increased 20-fold to 200-fold in patients with proteinuria.[68,69]

The major increase in risk starts when abnormal levels of albuminuria have developed (Fig. 30.11). An increased risk is found even in the upper normal range of albuminuria (Fig. 30.12). Urinary albumin excretion is a good predictor of cardiovascular events the first 5 years after measurement, but repeating the measurement several years later also detects progression, which is associated with increased cardiovascular risk.[69] The presence of albuminuria likely reflects generalized endothelial cell dysfunction, thus increasing the risk for atherosclerosis.[69] Albuminuria is also associated with many cardiovascular risk factors, such as elevated BP, dyslipoproteinemia, increased platelet aggregation, and increased C-reactive protein concentration. An added risk factor is presumably the association with autonomic polyneuropathy, which is a predictor of death from myocardial infarction or arrhythmia. A recent observation has been the predictive value of soluble TNFR1 or TNFR2 for progressive diabetic kidney disease in the type 1 and type 2 population.[70]

RENAL PATHOLOGY

After the onset of diabetes, kidney weight increases by an average of 15%. Renal size remains increased until overt nephropathy is established. Most patients with type 1 diabetes have a sustained increase in glomerular volume and glomerular capillary luminal volume. These changes are accompanied by hypertrophy of the interstitium.[71]

In patients with diabetes of more than 10 years duration, regardless of whether nephropathy is present, GBM thickening up to three times the normal range of 270 to 359 nm is an almost universal feature (Fig. 30.13). In advancing DKD, there is a consistent correlation between GBM thickness and fractional mesangial volumes with the urinary albumin excretion rate.

Nodular glomerular intercapillary lesions in advanced DKD were described in 1936 by Kimmelstiel and Wilson (Fig. 30.14C).[72] The nodules are located in the central regions of peripheral glomerular lobules as well-demarcated eosinophilic and periodic acid–Schiff-positive masses (see Fig. 30.14C and D). When they are not acellular, nodules contain pyknotic nuclei. It is suggested that nodules result from microaneurysmal dilation of the associated capillary followed by mesangiolysis and laminar organization of the mesangial debris with lysis of the center of the lobule. Foam cells often surround the nodules. These appearances, reported in only 10% to 50% of biopsy specimens in both type 1 and type 2 diabetes, are also seen in membranoproliferative glomerulonephritis (see Chapter 21), in amyloidosis and light-chain deposition disease (see Chapter 27), and specific stains and immunofluorescence findings, respectively, will clarify the diagnosis.

The diffuse glomerular lesion occurs more often than the nodular lesion, with an incidence of more than 90% in patients with type 1 diabetes longer than 10 years and an incidence of 25% to 50% in patients with type 2 diabetes. Diffuse glomerular lesions consist of an increase of mesangial matrix extending to involve the capillary loops (see Fig. 30.14B). In contrast to nodular lesions, which are of little functional significance, the degree of diffuse glomerulosclerosis correlates with the clinical manifestations of worsening renal function. Accumulation of mesangial matrix is the feature most consistently associated with progression.[73] In more severe disease, the capillary wall thickening and mesangial expansion lead to capillary narrowing (see Fig. 30.13B) and hyalinization, with accompanying periglomerular fibrosis.

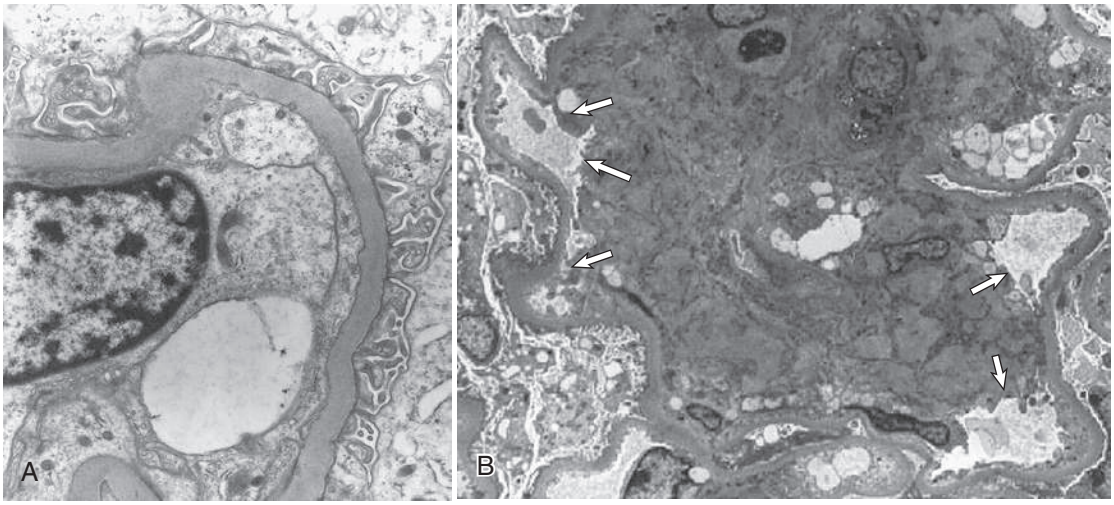

Fig. 30.13 Electron microscopy of structural changes in diabetic nephropathy. (A) Glomerular basement membranes are diffusely thickened. (B) The expanded mesangium encroaches on the capillary spaces *(arrows)*.

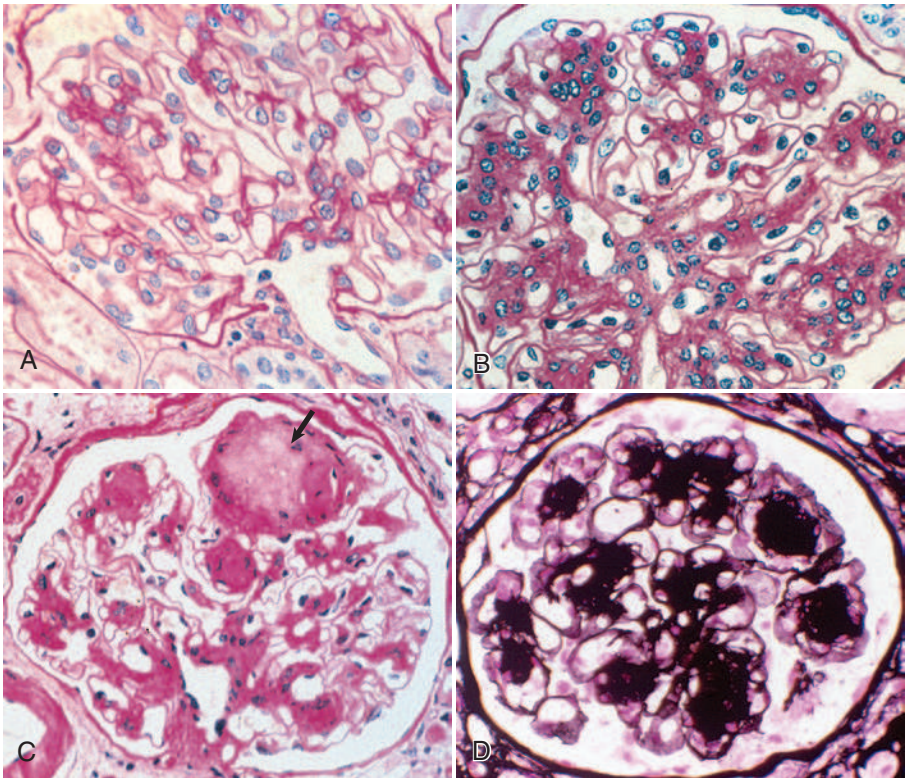

Fig. 30.14 Light microscopy of glomerular changes in diabetic kidney disease (DKD). (A) Normal glomerulus. (B) Diffuse glomerular lesion. Widespread mesangial expansion. (C) Nodular lesion as well as mesangial expansion. There is a typical Kimmelstiel-Wilson nodule at the top of the glomerulus *(arrow)*. (*A, B,* and *C,* Periodic acid–Schiff reaction). (D) Nodular lesion. Methenamine silver staining shows the marked nodular expansion of mesangial matrix.

Podocytes are involved early in the course of DKD in type 1 and type 2 DM (Fig. 30.15), and an increase in foot process width is already observed with only slight increases in albuminuria.[74,75] Longitudinal studies in DKD demonstrated a reduction in podocyte number that closely correlated with proteinuria.[74] Renal biopsy specimens from Pima Indians with type 2 diabetes showed a broadening in podocyte foot processes and a concomitant reduction in the number of podocytes per glomerulus.[76]

Arteriolar lesions are prominent in diabetes. Hyaline material progressively replaces the entire wall structure and involves both the afferent and efferent vessels, which is highly specific for diabetes.

A new classification of DN was introduced in 2007. This classification considers not only glomerular changes (Fig. 30.16) but also pathologic alterations of the tubulointerstitium and vasculature.[77] Immunohistologic examination is usually negative, but linear immunoglobulin G (IgG) can be seen occasionally because of passive trapping in the GBM (Fig. 30.17).

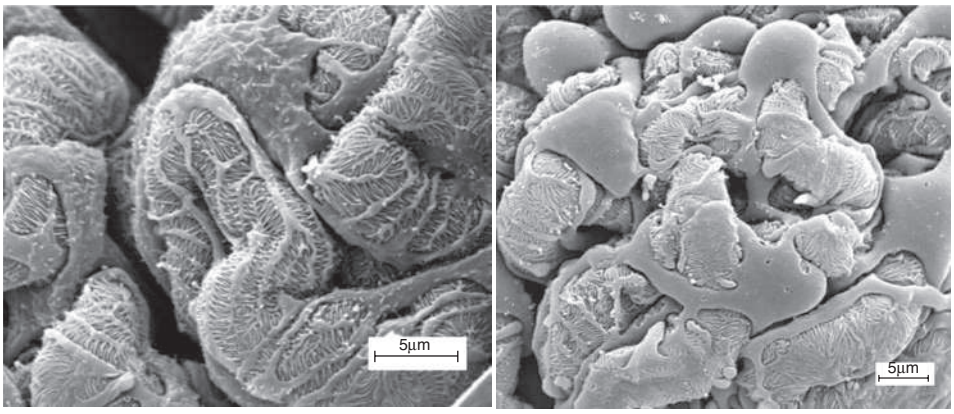

Fig. 30.15 Electron micrograph of external surface of glomerular tufts from rats after removal of the Bowman capsule by freeze-fracture. (Left) Normal rat kidney with podocyte cell body; the primary processes and terminal foot processes resting on the glomerular capillary basement membrane are clearly seen. (Right) In diabetic rat kidney, the decrease in the density of foot processes and the denuded glomerular capillary basement membrane are apparent. (From reference 75.)

Tubulointerstitial fibrosis and tubular atrophy may be the best pathologic correlates for the progressive decline in GFR. Tubulointerstitial fibrosis and renal arteriosclerosis are more prevalent in type 2 than type 1 diabetes. In fact, renal structure is heterogeneous in patients with type 2 diabetes; only a subset of patients with type 2 have typical diabetic glomerulopathy, whereas a substantial proportion have more advanced tubulointerstitial and vascular rather than glomerular lesions or have normal or near-normal renal structure.[77] Some patients with type 2 diabetes have a kidney appearance more suggestive of glomerular ischemia or tubulointerstitial disease.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of DKD is based on the detection of proteinuria. In addition, most patients also have hypertension and retinopathy. The main evaluation procedures in the patient with suspected DKD include the following:

- Measurement of urinary albumin or protein
- Measurement of serum creatinine concentration and estimation of GFR
- Measurement of BP
- Ophthalmologic examination

Measurement of Albuminuria or Proteinuria
