SELF-ASSESSMENT QUESTIONS

1. A 65-year-old man presents with unexplained acute kidney injury (AKI). A kidney biopsy shows the presence of diffuse inflammatory infiltrates within the interstitium, leading to the conclusion that the AKI is a result of acute interstitial nephritis (AIN). He has a recent history of treatment with a nonsteroidal antiinflammatory drug (NSAID) and a proton pump inhibitor (PPI) for osteoarthritis. Which *one* of the following statements is correct?
   - **A.** Both nonsteroidal antiinflammatory drugs (NSAIDs) and proton pump inhibitors (PPIs) are among the classes of drugs most commonly responsible for AIN.
   - **B.** Only very few cases of AIN have been attributed to treatment with a PPI, and the AIN was most likely induced by treatment with an NSAID.
   - **C.** Only very few cases of AIN have been attributed to treatment with an NSAID, and the AIN was most likely induced by treatment with a PPI.
   - **D.** Only very few cases of AIN have been attributed to treatment with a PPI or an NSAID, and the AIN is unlikely to have been induced by treatment with an NSAID or a PPI.
2. A 75-year-old woman presents with AKI associated with mild proteinuria (albumin-to-creatinine ratio 500 mg/g), microscopic hematuria, and pyuria. This AKI developed while she was being treated with a fluoroquinolone, and her treating physician suspects that the AKI was caused by AIN induced by the fluoroquinolone. Which *one* of the following statements is correct?
   - **A.** The patient should be tested for eosinophiluria. If less than 1% of urinary white blood cells are eosinophils, the diagnosis of AIN can almost certainly be ruled out.
   - **B.** The patient should undergo a renal gallium scan. If there is no renal uptake, the diagnosis of AIN can almost certainly be ruled out.
   - **C.** The presence of an elevated ratio of albumin to creatinine is sufficient to rule out the diagnosis of drug-induced AIN in a patient who previously did not have albuminuria and who has not been treated with an NSAID.
   - **D.** A renal biopsy is the only test that can be performed to reliably rule out or confirm the diagnosis of AIN.
3. A 30-year-old woman develops AKI while being treated with penicillin. A renal biopsy shows diffuse interstitial infiltrates, confirming the diagnosis of AIN. Her serum creatinine has been stable at 3.0 mg/dl for the last 5 days. Which *one* of the following statements is correct?
   - **A.** The prognosis for drug-induced AIN is excellent, and full recovery should be expected within 6 weeks after removal of the inciting agent.
   - **B.** The prognosis for drug-induced AIN is excellent in patients who do not have granulomas on renal biopsy, and full recovery should be expected.
   - **C.** The prognosis for drug-induced AIN is excellent in patients who do not require dialysis, and full recovery should be expected if serum creatinine does not continue to rise.
   - **D.** The course of drug-induced AIN is not always benign, and it leads to chronic kidney disease in at least 40% of cases.

Primary Vesicoureteral Reflux and Reflux Nephropathy

Ranjiv Mathews, Tej K. Mattoo

DEFINITION

Vesicoureteral reflux (VUR) is a congenital or acquired abnormality in which there is retrograde flow of urine from the bladder to the kidneys. VUR may be primary (congenital) and can be associated with various syndromes, or secondary, such as from increased bladder pressure resulting from obstructive uropathy or neurogenic bladder. This chapter discusses primary VUR.

VUR may be suggested by fetal ultrasound in pregnancy (in which intermittent renal pelvic dilation is observed) or after urinary tract infection (UTI) in childhood. Prenatal renal injury in the form of dysplasia has been noted with high-grade VUR. The presence of VUR increases the risk for postnatal upper UTI, and the two together can cause renal injury leading to scarring of the kidney termed *reflux nephropathy* (RN). RN may manifest as hypertension, preeclampsia, chronic kidney disease (CKD), and even end-stage renal disease (ESRD). Some patients present with proteinuria as a result of secondary focal segmental glomerulosclerosis (FSGS).

Traditional management includes prompt treatment of UTI and long-term antimicrobial prophylaxis until the resolution of VUR. Surgical correction of the VUR may be recommended in those with high-grade VUR who have recurrent UTI in spite of antimicrobial prophylaxis or who are noncompliant with medical management. Debate persists as to whether surgery is superior to medical management; most studies have concluded that long-term outcomes are similar.

CLASSIFICATION

VUR is classified by radiologic evaluation on voiding cystourethrography (VCU) into five grades as defined by the International Reflux Study in Children (Fig. 61.1 and Table 61.1).[1] Grade I is reflux into the ureter; grade II is reflux into the renal pelvis without any dilation of the calyces; grade III is reflux to the renal pelvis with mild dilation of the renal pelvis; grade IV is reflux to the renal pelvis with greater dilation of the renal pelvis; and grade V is reflux to the renal pelvis with ureteral and pelvic dilation. An example of grade V reflux is shown in Fig. 61.2.

Grading of VUR is used to predict the outcomes of children with VUR. Because VUR may resolve spontaneously, grading is used to standardize management strategies as well as compare clinical outcomes between institutions. Although it is widely used, the classification system is not perfect; differences between grade III and grade IV are not always obvious. The degree of reflux may be modified by how aggressively the bladder is filled during VCU. Ureteral dilation also may be present without calyceal dilation, leading to difficulties with grading.

EPIDEMIOLOGY

VUR is often first suggested by dilation of the fetal kidney during ultrasound examination. VUR is suspected when the fetal renal pelvis is more than 5 mm in anteroposterior diameter; a diameter of more than 10 mm is suggestive of high-grade VUR. In neonates who had evidence of fetal dilation, as many as 13% to 22% will have VUR on VCU. Indeed, it is estimated that 1% to 2% of neonates have VUR, with a higher frequency in boys and premature infants.[2] The incidence of renal dysplasia is also greater in male infants with VUR.[3] Most cases of grades I to III VUR will spontaneously resolve within the patient's first year of life, whereas grades IV and V are more likely to persist. Spontaneous resolution of VUR is greater in male infants, even for those with higher grades of VUR (grades IV and V).

VUR is also diagnosed in 30% to 40% of children presenting with UTI, predominantly in girls. VUR is both less common and less severe in African American children.[4,5] Only about one third as many African American as White girls with UTI have VUR, and no significant differences in age or mode of presentation exist between the two races.

RN is responsible for 5% to 10% of ESRD in pediatric and adult patients.[6,7] In the Chronic Kidney Disease in Children (CKiD) study, among children with estimated glomerular filtration rate (eGFR) of 30 to 90 ml/min/1.73 m^2, RN was the underlying cause for CKD in 14.8% of the patients.

ETIOLOGY AND PATHOGENESIS

Primary VUR is a congenital anomaly of the ureterovesical junction caused by shortening of the intravesical submucosal length of the ureter, leading to an incompetent valve (Fig. 61.3). The formation of the ureteral bud from the mesonephric duct signals the initial development of the metanephric kidney, the final stage of renal development. The ureteral bud interacts with the mesenchyme to give rise to the metanephric kidney. As the mesonephric duct is gradually absorbed into the enlarging urogenital sinus (the precursor of the developing bladder), the location of the ureteral bud plays a role in the eventual location of the ureteral meatus within the bladder. If the ureteral bud reaches the urogenital sinus too early because of the absorption pattern of the mesonephric duct, it is eventually located more laterally and proximally in the bladder. This location is associated with the development of reflux because there is reduction in the intravesical submucosal length of the ureter.

The ureterovesical junction is designed to prevent free reflux of urine from the bladder to the kidney. The ureters pass into the bladder

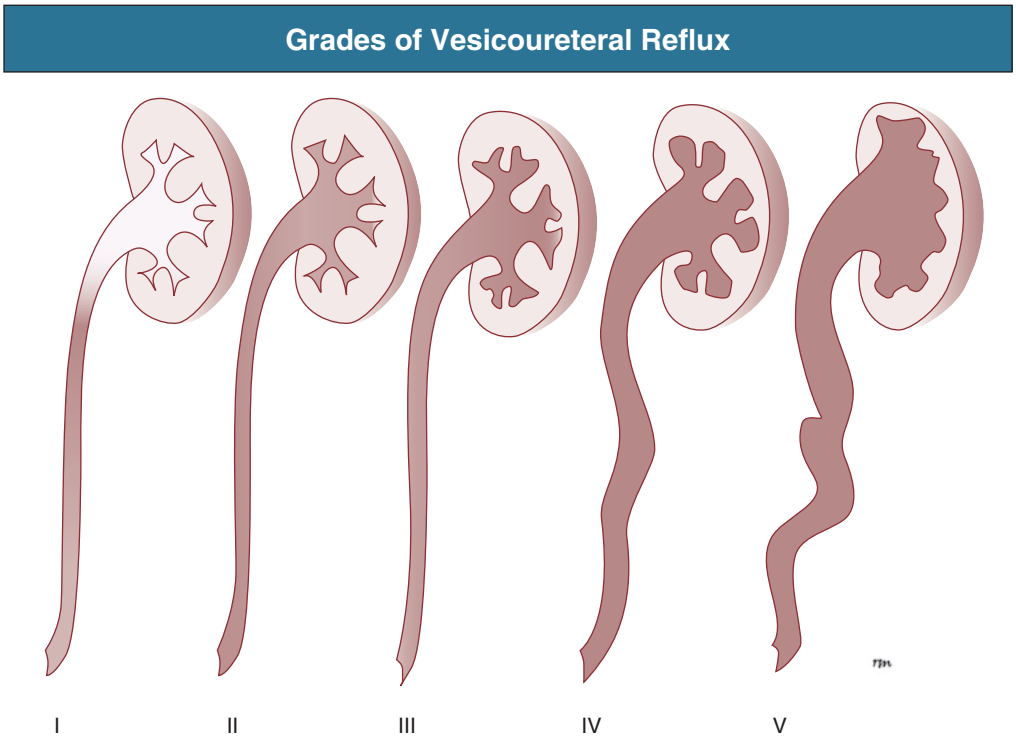

Fig. 61.1 Grades of vesicoureteral reflux.

TABLE 61.1 Classification of Vesicoureteral Reflux

Grade	Degree of VUR
I	Ureter only
II	Reflux into ureter, pelvis, and calyces with no dilation and with normal calyceal fornices
III	Mild or moderate dilation and/or tortuosity of the ureter and mild or moderate dilation of the pelvis; no or slight blunting of the fornices
IV	Moderate dilation and/or tortuosity of the ureter and moderate dilation of the pelvis and calyces; complete obliteration of the pelvis and calyces; complete obliteration of the sharp angles of the fornices but maintenance of the papillary impressions in the majority of the calyces (see Fig. 63.7C)
V	Gross dilation and tortuosity of the ureter, pelvis, and calyces; the papillary impressions are no longer visible in the majority of calyces (see Fig. 63.2)

Classification of vesicoureteral reflux according to the international reflux study in children.
VUR, Vesicoureteral reflux.

through the detrusor in an oblique path. The distal end of the ureter is located submucosally within the bladder. The length of the submucosal ureter is critical in the prevention of VUR. The muscles of the ureter extend into the trigone of the bladder and mesh with the fibers from the opposite ureter. This intermingling of fibers helps anchor the ureters into the trigone of the bladder. The distal submucosal segment is compressed against the muscular bladder wall with bladder filling, acting as an additional mechanism to prevent reflux. Because urine is propelled antegrade down the ureter, the tone of the ureter and the meatus in the bladder also help prevent reflux.

Multiple genes are involved in the development of VUR. *PAX2* (necessary for ureteral budding in mice), glial-derived neurotrophic factor *(GDNF)*, angiotensin II type 2 receptor, and uroplakin 3 (which is a component of tight junctions in uroepithelial cells) have been implicated in the development of VUR in mice; however, their role in human VUR remains controversial.[8,9] Neither autonomic innervation nor histology of the ureterovesical junction differs between patients with VUR and controls.[10]

TABLE 61.2 Types of Renal Damage Associated With Vesicoureteral Reflux

	Congenital	Acquired
Time of occurrence	Often prenatal	Postnatal, sometimes in adulthood
Previous urinary infection	Not usually	Usually
Gender	Usually boys	Usually girls (particularly after infancy)
Grade of VUR	Usually grades IV and V	Grades IV and V less common
Renal scarring	Often present	Present in minority*
Associated bladder dysfunction	Hypercontractile bladder common	Less commonly, high-capacity bladder with incomplete voiding

Modified from reference 11, with permission.
*Depends on unilateral versus bilateral involvement and the severity of renal involvement.

Reflux Nephropathy

RN is thought to result from one of two processes (Table 61.2).[11] Prenatal renal injury has been postulated to be secondary to the "water-hammer" effect of high-grade reflux and occurs in the absence of infection. This typically causes renal dysplasia. This form of renal scarring, which is also called *congenital RN*, is more commonly noted in infants with high-grade VUR, with a greater predominance of males. The second mechanism for development of renal injury is the combination of VUR and repeated UTI (so-called acquired RN). In these children, who are more commonly female, the combination of upper tract infection and reflux leads to renal inflammation and permanent scarring. Scarring tends to be more commonly located at the upper and lower poles of the kidney because of the anatomy of the renal papillae in these regions.

The risk for renal damage is greatest in presence of high-grade VUR.[12] The recently concluded Randomized Intervention for Vesicoureteral Reflux (RIVUR) trial also documented that the risk for new renal scarring is higher in relatively older children and not in younger children as reported in the literature previously.[12] One possible explanation for previously reported higher incidence of renal scarring in younger children could be a lower threshold for diagnosing and investigating younger children with UTI compared with the older children.

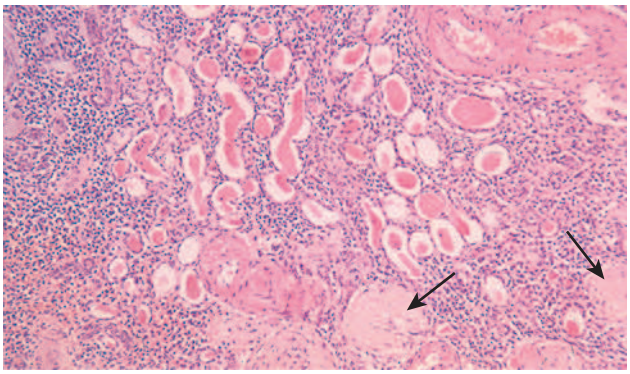

Fig. 61.4 Histologic changes in reflux nephropathy. Sclerosed glomeruli *(arrows),* chronic inflammatory cell infiltration, and atrophic tubules with eosinophilic casts are present. (Hematoxylin-eosin; original magnification ×40.)

RN is diagnosed by using technetium-99m (^{99m}Tc)-labeled dimercaptosuccinic acid (DMSA) renal scanning that demonstrates defects in the renal outline.[13] As noted previously, high-grade prenatal reflux can lead to renal injury in the absence of infection. Unfortunately, renal scarring secondary to UTI is indistinguishable by DMSA renal scan from that caused by prenatal renal dysplasia. In addition, renal injury can be noted after febrile UTI in the absence of identified VUR. Renal scarring as shown by ^{99m}Tc DMSA scan correlates more closely with the severity of VUR than with a history of UTI.[14]

PATHOLOGY

The process of renal scarring may take several years; in one study, the mean time from discovery of VUR to the appearance of a renal scar was 6.1 years.[15] Injury is seen more at the renal poles and is associated with clubbed calyces with medullary and cortical damage. The injury results from the local inflammatory response that may persist with chronic inflammation, tubular injury, local fibroblast activation, and interstitial collagen deposition (Fig. 61.4).[16] The loss of nephrons is associated with hyperfiltration and hypertension that result in proteinuria and progressive loss of renal function. This also can lead to the development of FSGS (Fig. 61.5).

CLINICAL MANIFESTATIONS

Presentation of Vesicoureteral Reflux

The three most common presentations are during follow-up for antenatal hydronephrosis, after a diagnosis of UTI, and on screening of siblings of a patient with VUR (Box 61.1).

Reflux Identified Secondary to Antenatal Hydronephrosis

Diagnosis of VUR may be suspected in utero with unilateral or bilateral hydronephrosis and confirmed at birth with VCU. There is a higher incidence of male infants diagnosed with VUR after identification of antenatal hydronephrosis.[17] Spontaneous resolution of the VUR occurs more commonly in boys with lower grades and unilateral reflux; infection rates are also lower in this cohort.[18] Female infants are more likely to have lower grades of VUR and are also less likely to develop renal

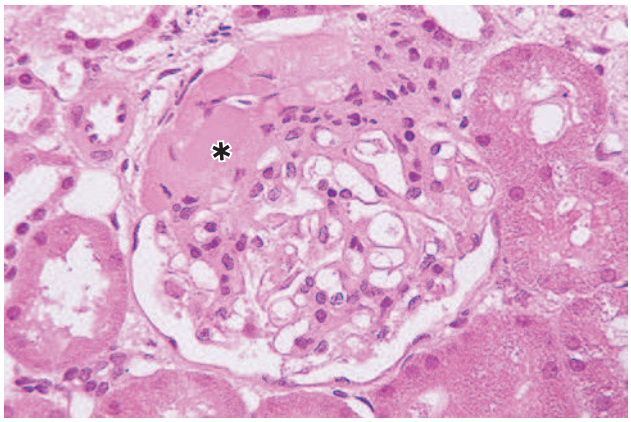

Fig. 61.5 Focal segmental glomerulosclerosis (FSGS) in reflux nephropathy. Light microscopy of a glomerulus from a patient with reflux nephropathy shows FSGS with the scarred area marked by an asterisk (*). (Hematoxylin-eosin; original magnification ×400.)

BOX 61.1 Clinical Presentations of Vesicoureteral Reflux

- Complicated urinary tract infection: Usually acute pyelonephritis in infants and children
- Asymptomatic
  - Detected by fetal ultrasound
  - Detected in the workup of members of an affected family
  - Detected in pregnant women with urinary tract infection
  - Detected during workup of kidney stones in children
  - Detected during assessment of other urologic congenital abnormalities

damage compared with newborn boys. Reflux in newborn boys may be a result of elevated bladder pressures secondary to posterior urethral valves or dyssynergia of the urethral sphincter; the latter improves with time, leading to higher potential for spontaneous resolution of even higher grades of VUR.[19,20]

Reflux Identified After a Urinary Tract Infection

VUR is most commonly found after UTI, particularly in a young child. The prevalence of VUR is higher in younger patients and decreases with age (Table 61.3). In neonates and toddlers, UTI may manifest as failure to thrive as opposed to typical symptoms of dysuria and frequency. VUR is more common in patients with complicated or upper tract UTI. Because VUR may potentiate the effect of UTI in children, the recommendations for evaluation of UTI have included ultrasound and VCU after resolution of the first UTI in both boys and girls. Indeed, neither the National Institute for Health and Care Excellence (NICE) nor the American Academy of Pediatrics (AAP) recommend routine voiding cystourethrogram (VCUG) in children with first febrile UTI.[21] The recent AAP guidelines suggested limiting the use of VCU to children identified as having complex UTIs or abnormalities on ultrasound. Our recommendations are therefore to begin with an ultrasound of the kidneys and bladder and performing a VCUG particularly if the ultrasound is abnormal (Fig. 61.6).

Most children diagnosed with VUR after a UTI are younger than 7 years. UTI in these patients may be associated with modifiable host factors, such as bladder and bowel dysfunction (BBD) in children. BBD is typically identified in toilet-trained children with urinary urgency, frequency, and/or incontinence in conjunction with constipation and is felt to be secondary to long-standing urine holding patterns. BBD is associated with development of UTIs that may be potentiated by the

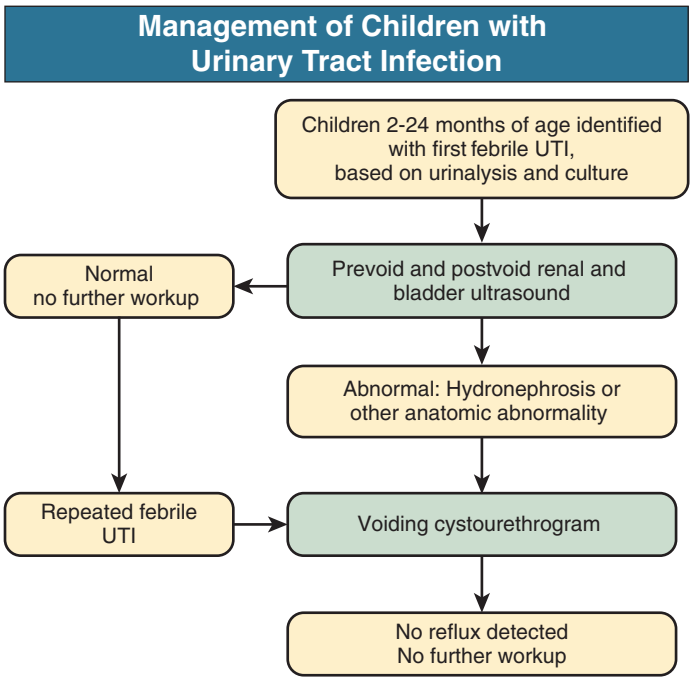

Fig. 61.6 American Academy of Pediatrics algorithm for evaluation of young children with diagnosed urinary tract infection (UTI).

TABLE 61.3 Prevalence of Vesicoureteral Reflux in Patients With Urinary Tract Infection, According to Age

Age	Percentage With VUR
2-3 days	57
3-6 days	51
2-6 months	60
7-12 months	35
1-4 years	50
5-9 years	35
10-14 years	14
14 years	10
Adult	5

VUR, Vesicoureteral reflux.

presence of VUR. For example, toilet-trained children with VUR identified after a UTI have a 43% incidence of dysfunctional voiding.[22]

Vesicoureteral Reflux in a Sibling

Approximately one third of siblings of an index patient with VUR also have VUR.[23] There is a slightly higher incidence of VUR in female siblings of female index patients; 75% of children with VUR identified by evaluating siblings are asymptomatic. The incidence of renal damage is also lower in the siblings diagnosed with reflux compared with the index patient with VUR.[24] For example, UTI with progression of scar was noted in only 5% of siblings with VUR observed for 3 to 7 years, and most of those with grades I and II VUR had spontaneous resolution.[24] The more "benign" course of sibling reflux compared with reflux identified after a UTI has led many to suggest limiting the testing of siblings. At this time, we recommend evaluating younger siblings (younger

than 2 years) of index children with VUR using ultrasound to identify renal abnormalities and reserve testing in older siblings to those who present with a UTI or other symptoms.

Presentation of Vesicoureteral Reflux in Women During Pregnancy

VUR also may first manifest in women during pregnancy, when it can be associated with asymptomatic bacteriuria or symptomatic UTI, hypertension, preeclampsia, low-birth-weight babies, or miscarriage. VUR is present in approximately 5% of women with UTI in pregnancy and 4% to 5% of women with preeclampsia. VUR can be distinguished from the normal ureteral dilation that occurs in pregnancy, which preferentially affects the midportion of the ureter, and lack of involvement of the renal parenchyma.

Other Presentations

An increased risk for renal calculi has been reported in children with VUR. Recurrent infections with urease-splitting organisms can lead to staghorn calculi. VUR or RN also may be discovered in adults after recurrent lower or upper UTI; indeed, about 5% of sexually active women with UTI have VUR.

Reflux Nephropathy

Renal scarring can occur in patients with VUR and can be seen in those with or without proven UTI. This scarring is called RN.[25,26] Young children are particularly at risk for renal scarring. Renal scarring is more common with febrile UTI in children, and in those younger than 5 years, as many as 75% develop acute pyelonephritis and renal scarring. Renal cortical defects (by DMSA scanning) are present in 45% of children with febrile UTI and VUR compared with 24% with UTI without VUR.[26] In a large prospective study of a population-based cohort of 1221 children aged 0 to 15 years with symptomatic UTI, scarring during initial evaluation was even higher, occurring in 86% of the boys and 30% of the girls. Girls had significantly more recurrences of febrile UTIs and acquired renal scarring than boys.[27]

The clinical manifestations of RN are varied and may include complicated UTI, hypertension, proteinuria, and various manifestations of CKD (Box 61.2).

Hypertension

Hypertension occurs in 10% to 30% of children and young adults with RN,[27,28] and according to one study, hypertension may take 8 years to develop from the time of diagnosis.[15] The exact cause of hypertension resulting from renal scarring is not known, but it is thought to be caused by impaired sodium excretion resulting from the renal injury and loss of renal function. Hypertension is relatively uncommon in children with VUR, with an estimated probability of 2%, 6%, and 15% at 10, 15, and 21 years of age, respectively. However, hypertension increases in proportion to the degree of renal injury.[29] Renal scarring (noted by DMSA scans) was reported in 20% of newly diagnosed hypertension in children and adolescents.

BOX 61.2 Clinical Presentations of Reflux Nephropathy

- Complicated urinary infection: Usually acute pyelonephritis in infants and children
- Hypertension: May be accelerated
- During pregnancy: Urinary infection, hypertension, preeclampsia
- Proteinuria
- Chronic renal impairment
- Urinary calculi
- Asymptomatic
  - Detected in the workup of members of an affected family
  - Detected by fetal ultrasound
  - Detected during assessment of other urologic congenital abnormalities

Proteinuria

Patients also may present with mild to moderate or (rarely) nephrotic-range proteinuria. Severe or nephrotic proteinuria may suggest a histologic diagnosis of secondary FSGS, which can be confirmed by renal biopsy if kidney size is normal and diagnosis is uncertain (see Fig. 61.5).[30] Proteinuria is commonly associated with hypertension and renal dysfunction. CKD progression often occurs gradually over 5 to 10 years.

End-Stage Renal Disease

According to the North American Pediatric Renal Transplant Cooperative Study annual report of 2008, 3.5% of the 6491 children on dialysis had RN, which makes it the fourth most common cause of ESRD in children after FSGS; renal aplasia, hypoplasia, or dysplasia; and obstructive uropathy.[31,32] The number of children with RN who present with ESRD as adults is not clear. According to one study of 123 adults with VUR diagnosed in childhood, the eGFR in those with nondilating VUR averaged 75 ml/1.73 m^2 and that in the dilating group was 72 ml/1.73 m^2; four patients (9%) in the nondilating group and 13 (17%) in the dilating group had an eGFR below 60 ml/1.73 m^2.[31]

Diagnosis of Vesicoureteral Reflux and Reflux Nephropathy

An algorithm for diagnosis of VUR after the discovery of UTI as recommended by AAP, is shown in Fig. 61.6. However, this is not followed universally by all practitioners, partly because of other published guidelines and recent evidence on the usefulness of antimicrobial prophylaxis in VUR as reported by the RIVUR study.[33] An example of the various tests in a child with UTI and VUR is shown in Fig. 61.7.

Renal Ultrasound

Ultrasound is the initial modality for the evaluation of postnatal hydronephrosis and UTI in children. Ultrasound is also used in siblings of children with VUR to determine whether renal dilation suggestive of high-grade reflux is present. Whereas ultrasound can suggest the possibility of high-grade VUR, it is less sensitive for diagnosis of acute pyelonephritis. In patients with acute pyelonephritis, abnormalities compatible with the diagnosis were reported in 20% to 69% by ultrasound compared with 40% to 92% by DMSA scintigraphy.[34] Nonetheless, ultrasound may be useful in detection of renal abscess and abnormalities of the perinephric space. Renal ultrasound is not diagnostic for VUR and is not a sensitive method for diagnosis of renal scars.

Voiding Cystourethrography

Voiding cystourethrography (VCU) is the primary diagnostic modality for identification of VUR. It requires catheterization. The grading of VUR is based on radiographic appearance by VCU (see Fig. 61.1). In children with UTI, VCU should be performed as soon as the child has completed antibiotic therapy.

The results of VCU can be affected by size, type, and position of the catheter; rate of bladder filling; height of the column of contrast media; state of hydration of the patient; and volume, temperature, and concentration of the contrast medium.

Nuclear cystography has been used to reduce the radiation exposure for children during follow-up of VUR. Nuclear cystography, although more sensitive, does not permit specific grading of VUR or reveal other anatomic defects, such as ureterocele and diverticulum. Therefore it is typically not the primary study performed for identification of VUR,

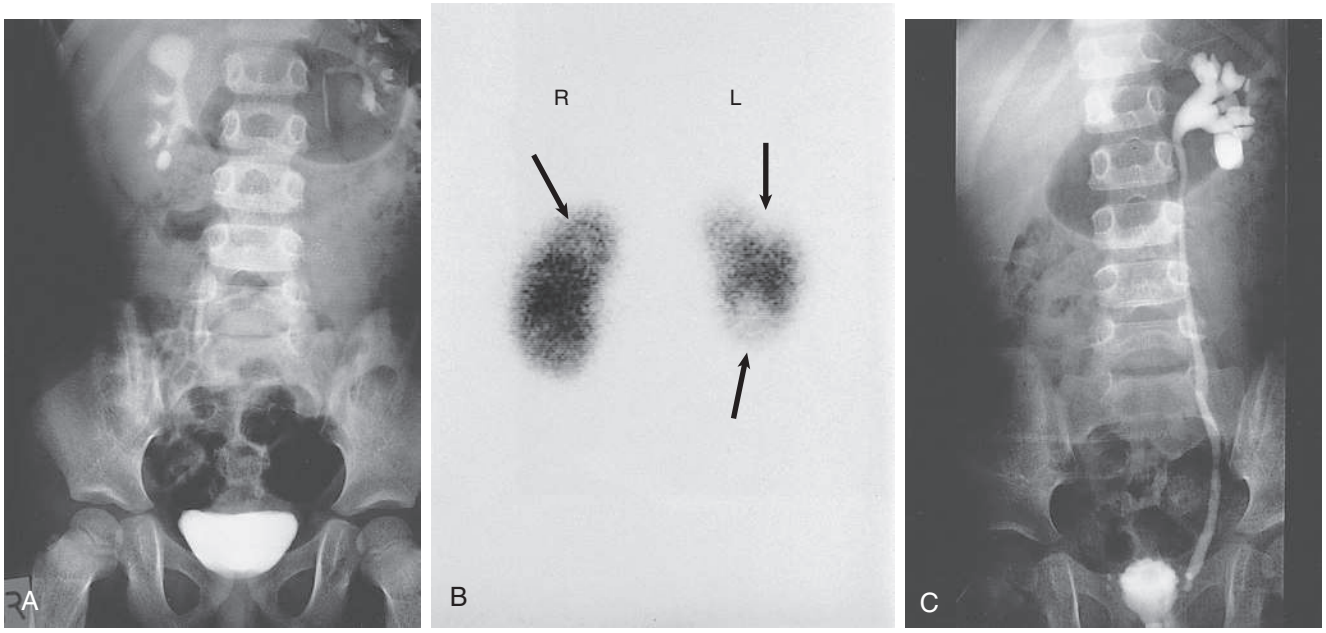

Fig. 61.7 Investigation of reflux nephropathy. Investigation of a 3-year-old child with urinary tract infection. (A) Intravenous urogram showing calyceal diverticulum in the upper pole of the right kidney and renal scarring in the upper pole and, probably, the lower pole of the left kidney. (B) DMSA scintigraphy (posterior view) demonstrating upper and lower pole scarring *(arrows)* in the left kidney and scarring of the right upper kidney in association with the calyceal diverticulum *(arrowhead)*. (C) Voiding cystourethrogram showing grade IV vesicoureteral reflux on the left.

but it is useful in determining improvement or resolution of reflux during follow-up or after surgical correction.

DMSA Renal Scintigraphy

DMSA scintigraphy is currently the gold standard for diagnosis of acute pyelonephritis and renal scarring with a high rate of sensitivity. Single-photon emission computed tomography (SPECT) DMSA scintigraphy is superior to planar imaging for detection of renal cortical damage.[35-37] The sensitivity of DMSA scintigraphy in experimentally induced acute pyelonephritis in a pig model was reported to be 92% when correlated with histologic findings.[37] By use of standardized criteria for its interpretation, high levels of intraobserver and interobserver agreement were reported.[38]

An abnormal DMSA scan during a febrile UTI allows the identification of children with renal inflammation who are at risk for development of renal scars. For acute pyelonephritis, DMSA scintigraphy can be performed within 2 to 4 weeks after the onset of UTI symptoms, but is not encouraged because it usually does not change clinical management. Some have suggested the use of DMSA scanning as an initial modality to identify children with abnormalities that may suggest the need for evaluation for VUR. DMSA scintigraphy to identify renal scarring should be performed 6 months after acute infection to allow reversible lesions to resolve.[39,40]

Dysplasia secondary to congenital reflux will appear similar to renal scarring after postnatal infections. In a child presenting with VUR, obtaining a baseline DMSA renal scan allows identification of renal dysplasia and scarring, which can then be observed over time.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) can be used for the diagnosis of renal scars because it discriminates swelling from scarring, both of which would be interpreted by DMSA scintigraphy as renal scarring. MRI may diagnose other coexisting conditions, such as nephrolithiasis,[40,41] which is not diagnosed by DMSA scintigraphy. Newer imaging methods that show promise in diagnosis of renal scarring include dynamic contrast-enhanced MRI and MRI using a gadolinium-enhanced short tau inversion recovery (STIR) sequence. However, routine use of MRI is less practical because of limited availability, especially for infants, need for prolonged sedation, and high cost. Gadolinium is also contraindicated in the presence of significant renal impairment (glomerular filtration rate <30 ml/min/1.73 m^2).

Proteinuria as a Marker for Reflux Nephropathy

Proteinuria predicts CKD progression due to RN.[42] Persistent albuminuria is helpful in diagnosis of glomerular damage at a very early stage.[43] Albuminuria increases with increasing severity of VUR and renal scarring.[44] In children with bilateral VUR with renal scarring and normal creatinine clearance, mild albuminuria was detected in 54% of the cases.[45] Evaluation for albuminuria offers the possibility of early intervention, such as the use of angiotensin-converting enzyme (ACE) inhibitors, aimed at retarding CKD progression. Proteinuria, when it is severe, is usually associated with FSGS.

NATURAL HISTORY OF VESICOURETERAL REFLUX AND REFLUX NEPHROPATHY

Primary VUR, especially grades I to III, generally improves with time, likely the result of growth and lengthening of the submucosal segment of the ureter. Spontaneous resolution of VUR is more common with non-White race, lower grades of reflux, absence of renal damage, and lack of voiding dysfunction. Resolution of VUR occurs more slowly in children with bilateral VUR in most but not all studies. In one study of children younger than 5 years with grades I to III VUR, the resolution rate of left unilateral VUR was better than for right VUR.[46] In another study, the mean time until spontaneous resolution in Black children was 15 months versus 21 months in White children.[47]

BBD, Bladder/bowel dysfunction; *CAP,* continuous antibiotic prophylaxis; *possible surgery,* injectable materials or reimplantation for lower grades and reimplantation for higher grades.

Increasing age at presentation and bilateral VUR decrease the probability of resolution, and bilateral grade IV or grade V VUR has a particularly low potential for spontaneous resolution.[48]

The natural history of VUR in adults has been reported in few studies. In one study of adults (mean age of 24 years) with gross VUR diagnosed in infancy, proteinuria and CKD were present in 3 of the 13 patients with unilateral RN and 2 of the 4 patients with bilateral RN.[49] In another study of 127 adults (mean age of 41 years) with VUR diagnosed during childhood, 35% had unilateral renal scarring, 24% had bilateral renal scarring, 24% had albuminuria, and 11% had hypertension. Of the patients with bilateral renal scars, 83% had reduced GFR.[50] An increased frequency of UTI and abnormal voiding patterns has been noted in adults with VUR. UTIs may be more common in adults who have had surgical management of VUR.

TREATMENT

The management of VUR has been based on the premise that VUR predisposes to the development of recurrent UTI and renal parenchymal injury, but also has the potential for spontaneous resolution. Various treatment strategies have been used with the ultimate objective of preventing renal injury. The two main treatment modalities are long-term antimicrobial prophylaxis and surgical correction. Surgical correction of VUR was common until antimicrobial prophylaxis for childhood UTI was introduced in 1975.[51] Many subsequent studies have reported no significant differences in outcome with medical management of VUR versus surgical treatment in the prevention of renal injury. For example, in the International Reflux Study in Children (n = 306 patients), no significant difference in outcome was found between medical and surgical management in terms of the development of new renal lesions or the progression of established renal scars, although there was a lower incidence of pyelonephritis in the surgical arm.[52] Long-term follow-up of this cohort for a period of 5 years in the European arm of the study also indicated no difference in outcomes.[53]

The 2010 American Urological Association guidelines reviewed seven treatment modalities used to manage VUR in children: intermittent antibiotic therapy; bladder training; continuous antibiotic prophylaxis; antibiotic prophylaxis and bladder training; antibiotic prophylaxis, anticholinergics, and bladder training; open surgical repair; and endoscopic repair. The key outcome measures were resolution of VUR, risk for pyelonephritis and scarring, and complications of medical versus surgical management. The study panel's recommendations are shown in Table 61.4. Antibiotic prophylaxis is recommended for all grades of VUR in children younger than 1 year because of a very high rate of spontaneous resolution. For children 1 to 5 years old, the study panel recommended antibiotic prophylaxis for all grades of VUR, with surgical options in grades III to V if VUR is bilateral or renal scarring is present. For children older than 6 years, the study panel recommended antibiotic prophylaxis for grades I and II (unilateral or bilateral) and unilateral grades III and IV, with surgical options if renal scarring is present, and surgical repair for bilateral grades III and IV and unilateral or bilateral grade V with or without scarring because the VUR has the lowest possibility of spontaneous resolution.[48]

Medical Management

Medical management involves long-term antimicrobial prophylaxis, appropriate management of BBD, if present, and follow-up renal imaging to assess the resolution of VUR and the potential development of renal injury. The antimicrobial agents most appropriate for prophylaxis include trimethoprim-sulfamethoxazole, trimethoprim alone, nitrofurantoin, and cephalexin. Follow-up of patients with VUR and UTI requires rapid evaluation (within 72 hours of the onset of fever) to allow early detection and prompt treatment of UTI. The timing of follow-up VCU is not well defined, but studies have suggested time intervals of 12 to 24 months. The treatment of bladder and bowel dysfunction may include the use of laxatives and timed frequent voiding every 2 to 3 hours. Pelvic floor exercises, behavioral modification, or anticholinergic medication may be required. A combined conservative medical and computer game–assisted pelvic floor muscle retraining decreases the incidence of breakthrough UTI and facilitate VUR resolution in children with BBD and VUR. Treatment of constipation by dietary measures, behavioral therapy, and laxatives helps reduce UTI recurrence and resolve enuresis and uninhibited bladder contractions.

Antibiotic Prophylaxis Versus Surveillance Only

Some studies challenge the benefit of long-term antimicrobial prophylaxis in the prevention of renal injury in patients with VUR. Concerns have been raised regarding the potential risks for long-term antibiotic use, including the possibility of development of resistance or allergy.

In the last few years, six prospective randomized trials evaluated the role of antimicrobial prophylaxis in the prevention of recurrent UTI and renal scarring in children. Altogether 1435 patients were randomized,

TABLE 61.5 Surgical Techniques for Vesicoureteral Reflux

Technique	Success Rates (%)	Pros	Cons
Open reimplantation	95	High success rates Limited requirement for follow-up VCU Reduction in hospital stays	Surgical incision Hospitalization required Catheters needed during postoperative management Need for pain control
Endoscopic injection Dextranomer and hyaluronidase (Deflux)	70-80	Reasonable success rates Outpatient management Minimal pain	Expensive Lower success rates Need for repeated procedures Need for follow-up VCU
Laparoscopic or robotic reimplantation	70-90	Reasonable success rates Small incisions Less discomfort	Lower success rates Requires hospitalization Need for follow-up VCU Long procedure Expensive equipment Significant surgical learning curve

VCU, Voiding cystourethrography.

including 961 (67%) female patients. Four studies[14,54-56] reported no benefit with antimicrobial prophylaxis in children with or without VUR. One study[57] reported a decrease of 6 percentage points (95% confidence interval [CI] 1-13) in the number of UTIs with prophylaxis compared with placebo. The Swedish reflux trial[57-59] demonstrated that the rate of UTI recurrence in girls was higher than in boys, and that this rate can be decreased with antibiotic prophylaxis and endoscopic procedure. None of the five studies showed any difference in the rate of renal scarring with or without prophylaxis.

The results of the recently concluded RIVUR trial, which randomized 600 children with VUR to prophylaxis or surveillance, demonstrated a 50% reduction in the incidence of recurrent UTIs with the use of daily prophylaxis. The impact on renal scarring was difficult to determine because few children enrolled in the study had scarring at entry and fewer still developed scarring over the short 24-month follow-up.

None of these studies showed any difference in the rate of renal scarring with or without prophylaxis. This stems from the fact that none of these studies were designed with renal scarring as the primary study end-point and the duration of follow-up was not long enough.

Hypertension and Proteinuria

Appropriate management of hypertension and proteinuria includes the use of ACE inhibitors or angiotensin receptor blockers (ARBs) as in other renal diseases (see Chapter 80). Combinations of ACE inhibitors and ARBs may provide additional lowering of proteinuria.[60] However, it is not known whether this antiproteinuric effect slows the progression of the renal disease. Historically, some patients also occasionally had their scarred kidney removed to help control hypertension, provided the contralateral kidney was healthy. However, this is exceptionally rare these days because of the availability of many potent antihypertensive agents.

Surgical Management

Surgical management of VUR is now reserved for patients in whom medical management with antimicrobial prophylaxis has failed to prevent UTIs. Current indications for surgical management of VUR are recurrent infections despite compliance with a prophylactic antibiotic regimen, worsening of renal scars, as judged by DMSA scanning, and failure to comply with prophylaxis. The recent introduction of minimally invasive surgery for VUR management has made some clinicians reconsider surgical correction as a potential first-line therapy. Immediate correction could potentially offset the need for antibiotic prophylaxis in children. Although most surgical techniques have high success rates for the correction of reflux and have been shown to reduce the risk of pyelonephritis, lower UTIs have been shown to occur in almost 20% of children that have had successful surgical management and no definitive impact on prevention of renal scarring.[61] A review of surgical techniques is presented in Table 61.5.

SELF-ASSESSMENT QUESTIONS

1. Which *one* of the following is correct about urinary tract infections (UTIs) in pediatric patients?
   A. They are more common in younger children.
   B. Girls are at a higher risk than boys.
   C. Vesicoureteral reflux (VUR) increases the risk for UTI.
   D. Constipation increases the risk for UTI.
   E. All of the above.
2. Which of the following imaging modalities is commonly used for the diagnosis of vesicoureteral reflux?
   A. Ultrasound
   B. Voiding cystourethrogram
   C. DMSA renal scan
   D. Magnetic resonance imaging
   E. Computed tomography scan
3. Complications of reflux nephropathy include:
   A. Hypertension
   B. Proteinuria
   C. Progressive renal failure
   D. Pregnancy-related complications
   E. All of the above

Chronic Interstitial Nephritis

Tetsuhiro Tanaka, Masaomi Nangaku

DEFINITION

Chronic interstitial nephritis is a histologic entity characterized by progressive scarring of the tubulointerstitium, with tubular atrophy, macrophage and lymphocytic infiltration, and interstitial fibrosis. Because the degree of tubular damage accompanying interstitial nephritis is variable, the term *tubulointerstitial nephritis* is used interchangeably with *interstitial nephritis. Tubulitis* refers to infiltration of the tubular epithelium by leukocytes, usually lymphocytes.

There are many primary as well as secondary causes of chronic interstitial nephritis (Box 62.1). Tubulointerstitial injury is clinically important because it is a better predictor than the degree of glomerular injury of present and future renal function. Although any glomerular disease can injure the tubulointerstitium secondarily through mechanisms involving the direct effects of proteinuria and ischemia, in this chapter we discuss only primary chronic interstitial nephritis.

PATHOGENESIS

The tubulointerstitium can be injured by toxins (e.g., heavy metals), drugs (e.g., analgesics), crystals (e.g., calcium phosphate, uric acid), infections, obstruction, immunologic mechanisms, and ischemia. Regardless of the initiating mechanism, however, the tubulointerstitial response shows little variation. Tubular injury results in the release of chemotactic substances and the expression of leukocyte adhesion molecules that attract inflammatory cells into the interstitium. Tubular cells express human leukocyte antigens, serve as antigen-presenting cells, and secrete complement components and vasoactive mediators, all of which may further stimulate or attract macrophages and T cells. Growth factors released by tubular cells and macrophages, such as platelet-derived growth factor and transforming growth factor β, may stimulate fibroblast proliferation and activation, leading to matrix accumulation.[1] The source of fibroblasts in renal interstitial fibrosis remains controversial but may include an intrinsic fibroblast (perivascular Gli1-positive progenitors) population, migration of circulating fibrocytes from perivascular areas, and phenotypic transition of pericytes into fibroblasts.[2] Over time, a loss of peritubular capillaries and decreased oxygen diffusion caused by expansion of the interstitium render the kidney hypoxic, and progressive apoptosis leads to local hypocellularity and fibrosis.[2] Renal function can become severely decreased, and renal replacement therapy may be required.

EPIDEMIOLOGY

Whereas chronic interstitial nephritis occurs with progressive renal disease of all causes, primary chronic interstitial nephritis is not a common cause of end-stage renal disease (ESRD); reports range from 42% in Scotland to 3% to 4% in China and the United States.[3-5] This variability in incidence may relate to differences in how diagnoses are made, exposure to causal factors, and treatment modalities such as the choice of antibiotics and the indication for pain killers.

In several regions of the world, marked increases in the incidence of chronic interstitial nephritis have been reported. These include Sri Lanka, some coastal areas of Central America, and the Balkan region in Europe (see Chapters 63 and 76).

PATHOLOGY

The pathologic features of chronic interstitial nephritis are nonspecific. They include tubular cell atrophy or dilation; interstitial fibrosis that is composed of interstitial (types I and II) collagens; and mononuclear cell infiltration with macrophages, T cells, and occasionally other cell types (neutrophils, eosinophils, and plasma cells). Tubular lumina vary in diameter but may show marked dilation, with homogeneous casts producing a thyroid-like appearance, hence the term *thyroidization.*

Some forms of chronic interstitial nephritis are associated with granulomatous lesions. Whereas a noncaseating granulomatous pattern is typical of sarcoidosis, interstitial granulomatous reactions also occur in response to infection of the kidney by mycobacteria (Fig. 62.1), fungi, or bacteria; certain drugs (including rifampin, sulfonamides, proton pump inhibitors [PPIs], and narcotics); and oxalate or uric acid crystal deposition.[6] Interstitial granulomatous reactions have been noted in renal malacoplakia (Chapter 51), granulomatosis with polyangitis (Wegener granulomatosis), heroin abuse, and after jejunoileal bypass surgery. The etiology for granulomatous interstitial nephritis remains obscure in 10% of cases.

CLINICAL MANIFESTATIONS

The impaired renal function is often insidious, and the early manifestations of the disease are those of tubular dysfunction, which may go undetected (Box 62.2).[7] Diagnosis is often made incidentally on routine laboratory screening or during evaluation of hypertension, in association with reduced glomerular filtration rate (GFR). Proteinuria is commonly less than 1 g/day. Urinalysis may show only occasional white blood cells and, rarely, white blood cell casts. Hematuria is uncommon. Anemia may occur relatively early because of dysfunction or loss of renal erythropoietin-producing cells in the interstitium.

The tubular dysfunction is often generalized, but some conditions may manifest with proximal tubular defects, including aminoaciduria, phosphaturia, proximal renal tubular acidosis (RTA), or, rarely, complete Fanconi syndrome (see Chapter 48). Distal tubular defects can

BOX 62.1 Major Causes of Chronic Interstitial Nephritis*

Diseases in Which the Kidneys Are Macroscopically Normal

- Drugs and toxins (e.g., aristolochic acid, lithium, cyclosporine, tacrolimus, indinavir, cisplatin, proton pump inhibitors)
- Metabolic (hyperuricemia, hypokalemia, hypercalcemia, hyperoxaluria, cystinosis)
- Heavy metals (lead, cadmium, arsenic, mercury, gold, uranium)
- Radiation
- Balkan nephropathy
- Mesoamerican nephropathy
- Immune-mediated conditions (systemic lupus erythematosus, Sjögren syndrome, sarcoidosis, granulomatosis with polyangitis [Wegener granulomatosis], other vasculitides)
- Vascular diseases (atherosclerotic kidney disease) (see Chapter 41)
  - Transplantation (chronic transplant rejection)
  - Hematologic disturbances (multiple myeloma, light-chain deposition disease, lymphoma, sickle cell disease, paroxysmal nocturnal hemoglobinuria) (see Chapters 49 and 64)
  - Progressive glomerular disease of all causes (glomerulonephritides, diabetes, hypertension)
  - Idiopathic

Diseases in Which the Kidneys Are Macroscopically Abnormal

- Analgesic nephropathy
- Chronic obstruction (see Chapters 58)
- Hereditary (nephronophthisis, medullary cystic kidney disease, familial juvenile hyperuricemic nephropathy, autosomal dominant polycystic kidney disease, autosomal recessive polycystic kidney disease)
- Infection (chronic pyelonephritis, malacoplakia, xanthogranulomatous pyelonephritis; see Chapter 51)

*Kidneys of any clinical entity can be shrunken at end stage. Some diseases categorized as macroscopically normal can in later stages result in macroscopically abnormal kidneys. For example, kidneys of sickle cell nephropathy are macroscopically normal unless papillary necrosis is present.

BOX 62.2 Functional Manifestations of Chronic Interstitial Nephritis

- Deterioration of glomerular filtration rate with insidious onset
- Tubular proteinuria mainly composed of low molecular weight protein (generally <1 g/day)
- Inactive urinary sediment
- Anemia of chronic kidney disease at a relatively early stage
- Proximal tubular dysfunction (aminoaciduria, phosphaturia, proximal renal tubular acidosis, Fanconi syndrome)
- Distal tubular dysfunction (type IV renal tubular acidosis)
- Medullary dysfunction (concentrating defects)
- Salt-wasting syndrome
- Salt-sensitive hypertension

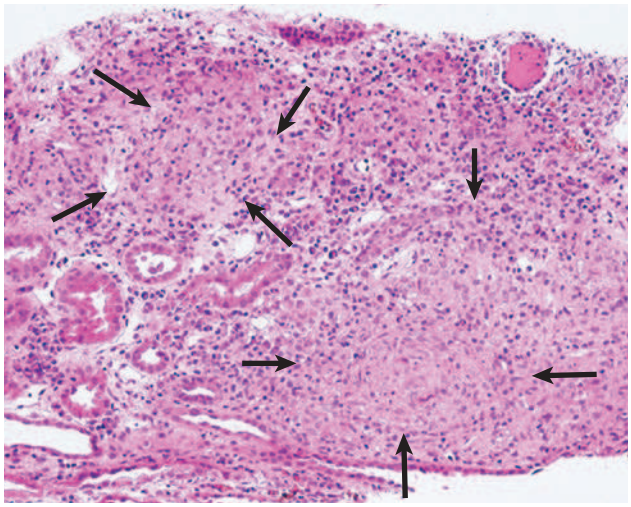

Fig. 62.1 Renal tuberculosis. Noncaseating granulomas with epithelioid cells in miliary tuberculosis (*arrows* show the peripheries of the granulomas). Although the typical pathologic change is granuloma with caseous necrosis with Langerhans-type giant cells, these atypical granulomas can be observed in tuberculosis and should be differentiated from sarcoidosis. (Hematoxylin-eosin [HE] stain.) (Courtesy Dr. Noriko Uesugi, Ibaraki, Japan.)

be associated with distal RTA (type 1 or type 4) (see Chapter 12). Concentrating defects (increased urinary frequency and nocturia) can be a sign of medullary dysfunction and may be severe enough to result in nephrogenic diabetes insipidus. Some patients develop a salt-wasting syndrome. Others, particularly with microvascular disease, may have a relative inability to excrete salt with resultant salt-sensitive hypertension.[8]

Clues to the causes of tubulointerstitial nephritis by history and physical examination are shown in Table 62.1.[9]

TREATMENT

Treatment includes identification and elimination of any exogenous agents (drugs, heavy metals), metabolic causes (hypercalcemia), or conditions (obstruction, infection) potentially causing the chronic interstitial lesion. In addition to classic drugs and toxins, a growing list of medications (e.g., PPIs) is now being linked to the risk for developing chronic kidney disease (CKD), which emphasizes a need to consider the risk and benefit of any drug carefully, particularly in patients with progressive course. Specific treatments may be required for an underlying cause of chronic interstitial nephritis, such as corticosteroids for sarcoidosis. General measures include control of blood pressure. Most clinicians favor the use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs), which reduce glomerular and systemic pressures, decrease proteinuria, and increase renal blood flow. However, the role of ACE inhibitors and ARBs is less clear when blood pressure is normal or when there are excessive solute losses (such as salt-wasting). Specific therapies for each clinical entity are discussed later.

DRUG-INDUCED CHRONIC INTERSTITIAL NEPHRITIS

Several drugs and herbs can cause chronic interstitial nephritis. Cyclosporine- and tacrolimus-induced nephropathy are discussed in Chapter 101; aristolochic acid as a cause of aristolochic acid–associated nephropathy (formerly known as *Chinese herbs nephropathy*) is discussed in Chapter 76.

TABLE 62.1 Clues to Causes of Tubulointerstitial Nephritis by History and Physical Examination

Feature	Symptom, Sign, or Historical Clue	Potential Diagnosis
Occupational history	Exposure to heavy metals (e.g., batteries, alloys)	Lead or cadmium nephropathy
Alcohol	History of moonshine ingestion	Lead nephropathy
Social history	Country of origin	Balkan nephropathy
Past history	Systemic lupus erythematosus	Disease-associated chronic interstitial nephritis
	Sjögren syndrome	
	Sarcoidosis	
	Inflammatory bowel disease	
	Autoimmune pancreatitis	
	Chronic pain syndrome	Analgesic nephropathy
	Gouty attack	Lead nephropathy
Medication	Prescribed	Drug-induced chronic interstitial nephritis
	Over-the-counter (NSAIDs, PPIs)	Analgesic nephropathy
	Herbal	Aristolochic acid–associated nephropathy
	Indinavir	Crystal nephropathy
Physical examination	Dry eyes	Sjögren syndrome
	Uveitis	TINU syndrome
Laboratory examination	Hyperuricemia	Chronic uric acid nephropathy
	Hypokalemia	Hypokalemic nephropathy
	Hypercalcemia	Hypercalcemic nephropathy
	High serum IgG4 levels	IgG4-related sclerosing disease
Radiologic examination	Decreased volume, bumpy contours, and papillary calcification on CT	Analgesic nephropathy
	Microcysts on MRI or ultrasound	Lithium nephropathy
	Nephrocalcinosis on CT	Hypercalcemic nephropathy

Modified from reference 10.
CT, Computed tomography; *IgG,* immunoglobulin G; *MRI,* magnetic resonance imaging; *NSAIDs,* nonsteroidal antiinflammatory drugs; *PPIs,* proton pump inhibitors; *TINU,* tubulointerstitial nephritis and uveitis.

Lithium Nephropathy

Definition and Epidemiology

Lithium is commonly used in the treatment of bipolar disorder. Complications of lithium treatment include nephrogenic diabetes insipidus, acute lithium intoxication, and chronic lithium nephrotoxicity. A meta-analysis of the data of 14 studies involving 1172 patients receiving chronic lithium therapy showed that the prevalence of reduced GFR was 15%.[10]

Pathogenesis

Diabetes insipidus results from accumulation of lithium in the collecting tubular cells after entry into these cells through sodium channels in the luminal membrane. Lithium blocks vasopressin-induced reabsorption by inhibiting adenylate cyclase activity, and hence cyclic adenosine monophosphate production, and also by decreasing the apical membrane expression of aquaporin 2, the collecting tubule water channel. Chronic lithium-induced interstitial nephritis may occur, possibly because of inositol depletion and inhibition of cell proliferation.

Pathology

Biopsies show focal chronic interstitial nephritis with interstitial fibrosis, tubular atrophy, and glomerulosclerosis. Whereas similar histologic changes have been reported in psychiatric patients without a history of lithium therapy, patients with lithium exposure often show microcystic changes in the distal tubule; interstitial inflammation and vascular changes are relatively minor. The degree of interstitial fibrosis is related to the duration of administration and cumulative dose.

Clinical Manifestations

Lithium-associated diabetes insipidus. The most common presentation of lithium-induced nephrotoxicity is nephrogenic diabetes insipidus, characterized by resistance to vasopressin, polyuria, and polydipsia. Impaired renal concentrating ability is found in about 50% of patients, and polyuria resulting from nephrogenic diabetes insipidus occurs in about 20% of patients chronically treated with lithium.

Lithium is also rarely a cause of hypercalcemia, which could potentially exaggerate the tubular concentrating defect and contribute to the development of chronic interstitial nephritis in lithium-treated patients. Nephrogenic diabetes insipidus in lithium treatment may be associated with distal RTA, although this partial functional defect is virtually never of clinical importance.

Chronic lithium nephropathy. In a retrospective analysis of data from Oxford University Hospitals, UK, the presence of lithium in serum was associated with an increased risk for stage 3 CKD (hazard ratio 1.93), with women younger than 60 years and those with lithium concentrations higher than median at increased risk.[11] Nephrogenic diabetes insipidus induced by lithium may persist despite the cessation of treatment, indicating irreversible renal damage.

In one study, the mean serum creatinine concentration of patients with biopsy-proven chronic lithium nephrotoxicity was 2.8 mg/dl (247 µmol/l) at the time of biopsy, and 42% of patients had proteinuria greater than 1 g/day.[12] After renal biopsy, all but one patient discontinued treatment with lithium, but seven patients nevertheless progressed to ESRD. A study of 74 lithium-treated patients in France showed that lithium-induced nephropathy developed slowly over several decades,

with an average latency between the start of therapy and ESRD of 20 years.[11]

Magnetic resonance imaging, in particular the half-Fourier acquisition single-short turbo spin-echo T2-weighted sequence, without the use of gadolinium, or ultrasound may help in detection of the characteristic microcysts in the kidney.[13]

Treatment

After other potential causes of polyuria and polydipsia have been excluded, particularly psychogenic polydipsia, the first step to consider is a reduction in lithium dosage. The potassium-sparing diuretic amiloride improves the polyuria and also blocks lithium uptake through sodium channels in the collecting duct. Thiazide diuretics should be avoided because they increase the risk for acute lithium intoxication because of the resultant volume contraction and an increase in sodium and lithium reabsorption in the proximal tubule.

Patients undergoing long-term lithium treatment should have renal function (serum creatinine and estimated GFR [eGFR]) and 24-hour urine volume measured yearly. Lithium has a narrow therapeutic index, so levels should be monitored and maintained between 0.6 and 1.25 mmol/l. The severity of chronic lithium intoxication correlates directly with the serum lithium concentration and may be categorized as mild (1.5 to 2.0 mmol/l), moderate (2.0 to 2.5 mmol/l), or severe (>2.5 mmol/l). Once-daily regimens are less toxic than multiple daily administration schedules, perhaps because of the possibility of renal tubular regeneration with a once-daily administration schedule.[14] Prevention of volume depletion is also important.

Because progressive renal injury with reduced GFR in patients without prior acute lithium intoxication is relatively unusual, raised serum creatinine concentration initially should be treated by a dose reduction. If serum creatinine is persistently elevated, a renal biopsy should be considered, although the findings rarely mandate the complete cessation of lithium treatment. At all times, the risk for discontinuation in a patient with a severe unipolar or bipolar affective disorder needs to be balanced with the relatively low risk for progressive renal injury.

Analgesic Nephropathy

Definition and Epidemiology

Analgesic nephropathy resulted from the abuse of analgesics, commonly mixtures containing phenacetin, aspirin, and caffeine, that were available as over-the-counter preparations in Europe and Australia. It is now extremely rare; indeed, some doubt that new cases are still presenting, after restrictions in compound analgesic sales.[15] A large study in the United States showed no association between use of current analgesic preparations and increased risk for chronic renal dysfunction,[16] although it does increase the risk for acute kidney injury (see Chapter 66).

Pathogenesis and Pathology

The primary injury in analgesic nephropathy is medullary ischemia caused by toxic concentrations of phenacetin metabolites combined with relative medullary hypoxia, aggravated by inhibition of vasodilatory prostaglandin synthesis and glutathione (an antioxidant) levels. The main pathologic consequence is papillary necrosis, with secondary tubular atrophy, interstitial fibrosis, and a mononuclear cellular infiltrate (Fig. 62.2).

Clinical Manifestations

Analgesic nephropathy is five to seven times more common in women than in men. Renal manifestations are nonspecific and consist of slowly progressive CKD with impaired urine concentrating ability, urinary acidification defects, and impaired sodium conservation. Patients may present with hypertension, reflecting the use of nonsteroidal antiinflammatory drugs (NSAIDs) and degree of renal parenchymal injury. Urinalysis shows sterile pyuria and mild proteinuria. Patients with analgesic nephropathy are at increased risk for transitional cell carcinoma of the uroepithelium. Recent prospective analysis of the Nurses' Health Study and the Health Professionals Follow-up Study also showed association of regular use of nonaspirin NSAIDs with an increased renal cell carcinoma risk, whereas aspirin and acetaminophen use were not.[17]

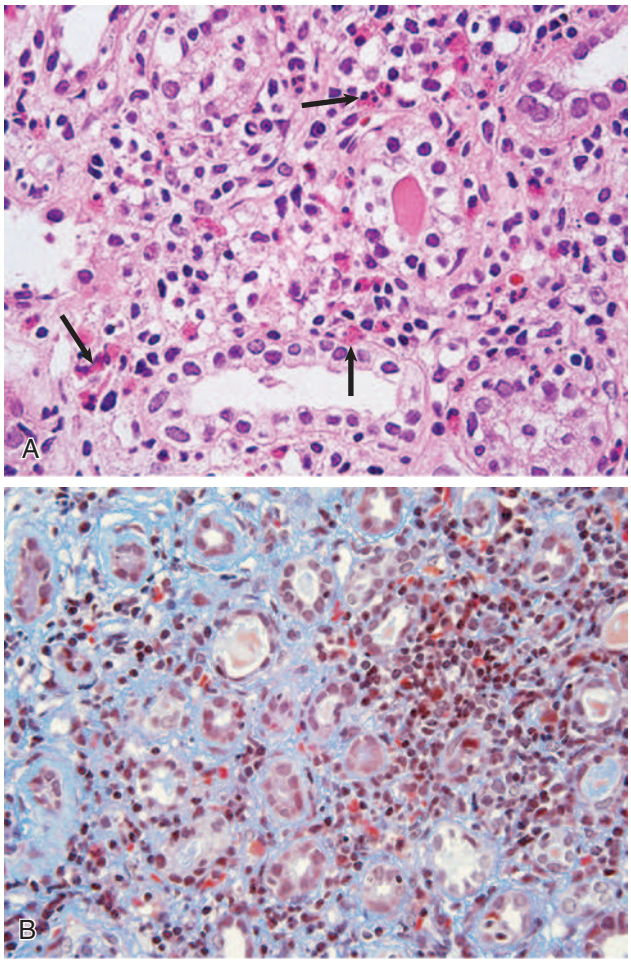

Fig. 62.2 Histologic changes in analgesic nephropathy. (A) Interstitial nephritis in a patient with analgesic nephropathy associated with marked mononuclear cellular infiltrate including eosinophils *(arrows).* (HE stain; original magnification ×600.) (B) Analgesic nephropathy with interstitial fibrosis and inflammatory cell infiltration. (Masson trichrome stain; original magnification ×400.) (Courtesy Drs. Akira Shimizu and Hideki Takano, Nippon Medical School, Tokyo.)

Diagnosis

Papillary necrosis is present histologically in almost all patients, but it can be detected radiologically only if part or all of the papilla has sloughed. Papillary necrosis is not pathognomonic of analgesic nephropathy; it is also seen in diabetic nephropathy (particularly during an episode of acute pyelonephritis), sickle cell nephropathy, urinary tract obstruction, and renal tuberculosis. Non–contrast-enhanced computed tomography (CT) demonstrates a decrease in renal mass with either bumpy contours or papillary calcifications (Fig. 62.3; see also Chapter 52).[18]

Treatment

Management consists of stopping or at least reducing the intake of analgesic medications. Because of the increased incidence of uroepithelial

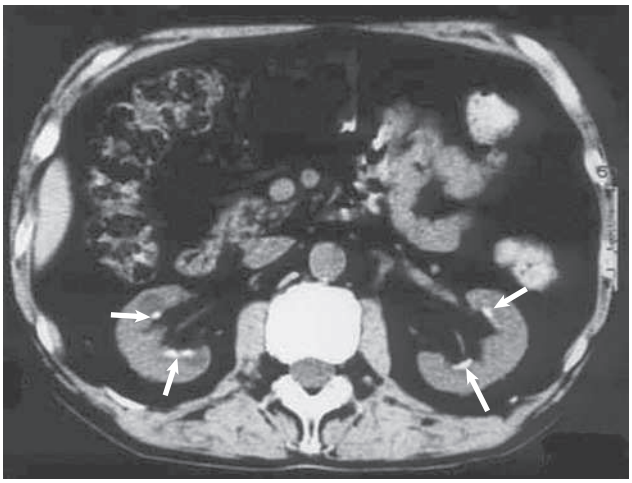

Fig. 62.3 Papillary calcifications in analgesic nephropathy. Non–contrast-enhanced CT scan of a patient with long-time analgesic abuse shows thinning of the renal parenchyma and typical papillary calcifications *(arrows).* (Courtesy Dr. Yoshifumi Ubara, Toranomon Hospital, Tokyo.)

tumors, close follow-up including regular urinalysis is necessary. New hematuria requires early referral for urologic evaluation, which includes urinary cytology, cystoscopy, and CT scan. It will be most prudent to perform yearly urinary cytologic examination at least several years after cessation of analgesics.

Analgesic nephropathy associated with over-the-counter medicines is also discussed in Chapter 76.

CHRONIC INTERSTITIAL NEPHRITIS CAUSED BY METABOLIC DISORDERS

Metabolic disorders that cause interstitial nephritis are discussed here. Hyperoxaluria is described in Chapter 57 and cystinosis in Chapter 48.

Chronic Uric Acid Nephropathy

Definition and Epidemiology

Historically, chronic interstitial nephritis associated with chronic hyperuricemia was called *gouty nephropathy* and was ascribed to the medullary deposition of crystals with surrounding inflammation and fibrosis. Later this concept was challenged, and the renal disease associated with gout was thought to be secondary to coexistent hypertension, vascular disease, or aging-associated renal injury. In addition, independent of intrarenal crystal deposition, recent epidemiologic studies document that an elevated serum uric acid is a risk factor for de novo development of CKD.[19] These increases in risk remain significant even after adjustment for eGFR, proteinuria, age, and components of the metabolic syndrome. These studies suggest that chronic hyperuricemia may be a risk factor for the development of CKD and progression of established CKD.[20]

Pathogenesis

Chronic gout and severe hyperuricemia can be associated with the deposition of uric acid crystals in the renal medulla (Fig. 62.4). However, independent of crystal deposition, experimental studies indicate that hyperuricemia causes chronic renal injury by activating the renin-angiotensin system and inducing oxidative stress, resulting in glomerular hypertension and impaired renal autoregulation.[21] Although uric acid can function as an antioxidant in the extracellular environment, within the cell uric acid has prooxidant effects and can lead to endothelial and mitochondrial dysfunction.

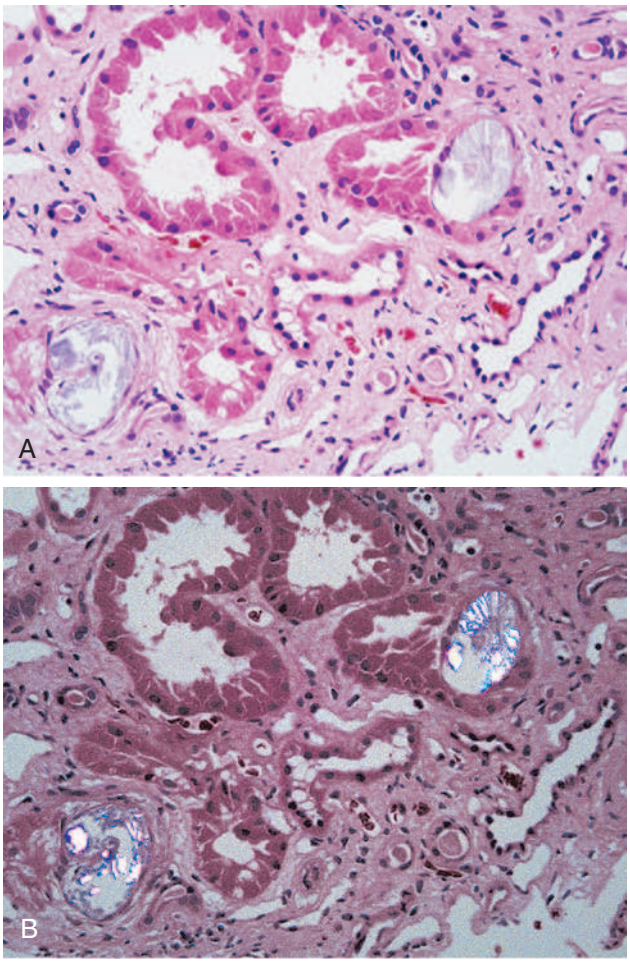

Fig. 62.4 Chronic uric acid nephropathy. (A) Large collections of elongated or fragmented uric acid crystals are present in association with atrophic tubules. (HE stain; original magnification ×400.) (B) The crystalline masses are refractile under polarized light. (Courtesy Drs. Akira Shimizu and Hideki Takano, Nippon Medical School, Tokyo.)

Pathology

Renal functional abnormalities are observed in 30% to 50% of patients who have had gout for many years, and histologic changes are observed in more than 90%.[22] The most consistent histologic findings are arteriolosclerosis, focal or global glomerulosclerosis, and chronic tubulointerstitial disease. Uric acid crystals also can be occasionally found within tubules and in the interstitium (see Fig. 62.4), especially in the outer medulla, and on rare occasions medullary renal tophi can be found on gross anatomic dissection. Experimental studies question whether the uric acid crystals themselves are responsible for the renal functional abnormalities.

Clinical Manifestations

Patients with chronic uric acid nephropathy present with hypertension with mildly impaired renal function, mild proteinuria, unremarkable urinary sediment, and minor tubular dysfunction (usually impairment of urine concentrating ability manifested as isosthenuria). Uric acid nephropathy should particularly be considered if there is a disproportionate elevation in serum uric acid in relation to the degree of renal impairment (Table 62.2).[23]

Diagnosis

The most important differential diagnosis for chronic uric acid nephropathy is chronic lead nephropathy. Familial juvenile hyperuricemic

TABLE 62.2 Serum Creatinine and Uric Acid Levels in Chronic Kidney Disease

SERUM CREATININE		SERUM URIC ACID	
mg/dl	µmol/l	mg/dl	µmol/l
<1.5	<132	9	536
1.5-2.0	132-176	10	595
>2.0	>176	12	714

Serum uric acid levels are increased with decreased renal function, but if uric acid levels are especially high for the level of creatinine, then chronic urate nephropathy should be considered. Shown are threshold levels of uric acid for which higher levels should increase the suspicion for chronic urate nephropathy.
Modified from reference 22.

nephropathy is a rare autosomal dominant disease that mimics chronic gouty nephropathy but manifests in adolescence or during early childhood (see Chapter 48).

Treatment

It remains controversial whether lowering uric acid can improve kidney disease in patients with gout or hyperuricemia. One randomized trial demonstrated that allopurinol therapy is associated with preservation of eGFR in CKD, although the treatment did not show any effects on the defined study end-point, which was ESRD.[24] Withdrawal of allopurinol from patients with stable CKD has resulted in worsening of hypertension and acceleration of kidney dysfunction, especially in patients who were not on ACE inhibitors.[25] Lowering uric acid in patients with asymptomatic hyperuricemia is also associated with an increase in eGFR.[26] There also have been reports that lowering uric acid may reduce the risk for cardiovascular disease in patients with CKD.[24,27] However, to date all studies have involved small numbers of patients and more definitive studies are required before treatment of hyperuricemia with uric acid–lowering therapy can be recommended routinely.

One reason for caution is the accumulation of xanthine in renal failure, which will be aggravated by the xanthine oxidase inhibitor allopurinol. When precipitated in the kidney, xanthine can cause acute kidney injury. To minimize this complication, it is recommended to initiate allopurinol at a dose of 50 to 100 mg/day, increasing to 200 or 300 mg/day after several weeks as tolerated. Another adverse effect of allopurinol use is a hypersensitivity reaction (Stevens-Johnson–like syndrome) that may be more common in patients with reduced eGFR. The newer xanthine oxidase inhibitor febuxostat does not require modification of dose at lower eGFR and appears to be less frequently associated with hypersensitivity or nephrotoxicity, but there are some studies that suggest that its use may be associated with greater cardiovascular mortality than that observed with allopurinol.

Hypokalemic Nephropathy

Definition and Epidemiology

Hypokalemia, if persistent for prolonged periods, can induce renal cysts, chronic interstitial nephritis, and progressive loss of renal function, known as *hypokalemic nephropathy,* which can be inherited or acquired. Hypokalemic nephropathy occurs in 15% to 20% of individuals with anorexia nervosa.[28]

Pathology

The characteristic finding is vacuolation of the renal tubules as a result of dilation of cisternae of the endoplasmic reticulum and basal folding, which is usually limited to the proximal tubular segments (Fig. 62.5).

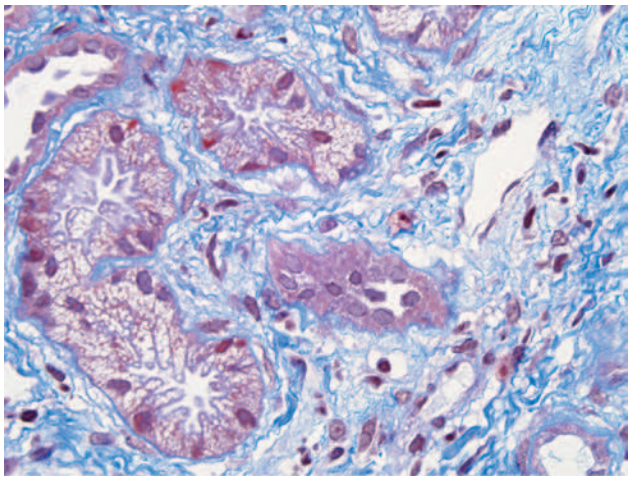

Fig. 62.5 Hypokalemic nephropathy. Vacuolization of the renal tubules is observed in association with interstitial fibrosis in a patient with hypokalemic nephropathy. (Masson trichrome stain; original magnification ×400.) (Courtesy Drs. Akira Shimizu and Hideki Takano, Nippon Medical School, Tokyo.)

This abnormality generally requires at least 1 month to develop and is reversible with potassium supplementation. More prolonged hypokalemia can lead to more severe changes, predominantly in the renal medulla, including interstitial fibrosis, tubular atrophy, and cyst formation. There is experimental evidence that hypokalemic injury may be caused by hypokalemia-induced renal vasoconstriction with ischemia. Local ammonia production stimulated by hypokalemia also may lead to intrarenal complement activation that may contribute to the renal injury. Furthermore, the associated intracellular acidosis can stimulate cell proliferation, which may account for the occasional development of cysts in hypokalemic patients.

Clinical Manifestations

Impaired urine concentration, manifesting with nocturia, polyuria, and polydipsia, may occur, particularly when serum potassium concentration is consistently below 3.0 mmol/l for months or years. The average duration of hypokalemia reported in patients with chronic hypokalemic nephropathy is 3.5 to 9 years. The renal defect is associated with decreased collecting tubule responsiveness to vasopressin, possibly because of decreased expression of aquaporin 2.

Diagnosis

Although degenerative changes in proximal tubular cells are a consistent but nonspecific finding in hypokalemic nephropathy, a particularly characteristic finding is vacuolar changes in the proximal tubules (see Fig. 62.5). Similar vacuolization of the convoluted tubules is observed in ethylene glycol poisoning.

Treatment

Hypokalemia usually can be treated with oral potassium supplements. The treatment of hypokalemia is discussed in Chapter 9. Coarse cytoplasmic vacuoles may persist for some time after normalization of serum potassium values.

Hypercalcemic Nephropathy

Definition and Epidemiology

Hypercalcemia can cause transient and reversible renal vasoconstriction with a decrement in renal function as well as chronic interstitial nephritis secondary to tubular cell necrosis and intratubular obstruction. In addition, hypoparathyroidism (especially after surgical treatment of

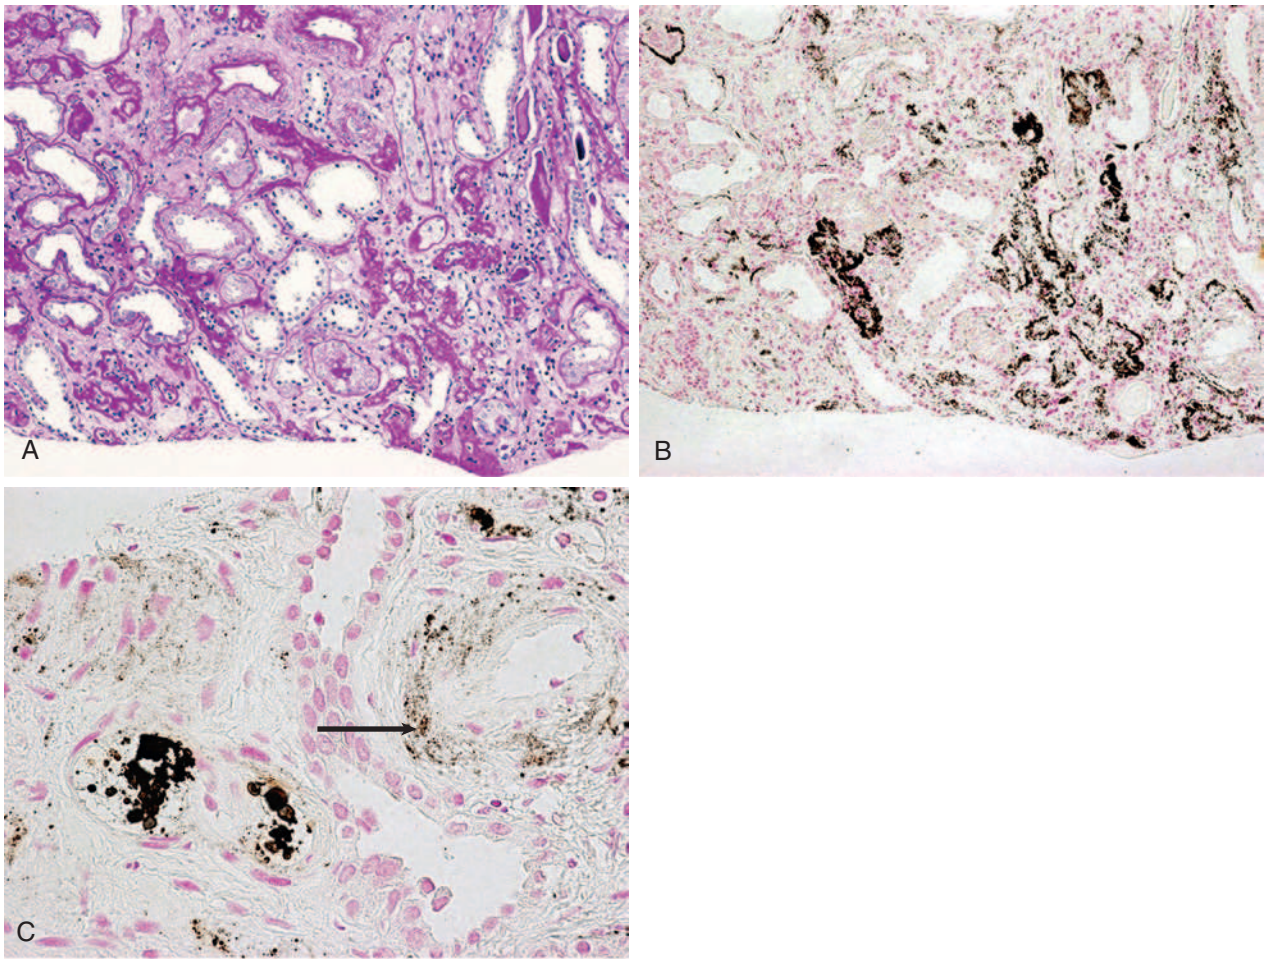

Fig. 62.6 Hypercalcemic nephropathy caused by sarcoidosis. (A) Marked tubular atrophy and interstitial fibrosis with mild lymphocytic infiltrate. (B) Dense calcium deposits are seen in the thickened basement membrane of the atrophic tubules and in the fibrotic area of interstitium (serial section of A). (C) Intraluminal calcium plaque in the atrophic tubules. Granular calcium deposits are observed in the arterial wall *(arrow).* (*A,* Periodic acid–Schiff stain; *B* and *C,* von Kossa stain.) (Courtesy Dr. Noriko Uesugi, Ibaraki, Japan.)

hyperparathyroidism) can result in marked hypercalciuria and a similar syndrome in the absence of hypercalcemia.

Pathology

Focal degeneration and necrosis of the tubular epithelium, primarily in the medulla, where calcium is concentrated, develop soon with persistent hypercalcemia. Although focal degenerative and necrotic lesions of the tubular epithelium can be observed with acute hypercalcemia, the most distinctive histologic feature of long-standing hypercalcemia is calcific deposits in the interstitium (nephrocalcinosis; Fig. 62.6). Deposition begins in the medullary tubules, followed by deposition in the cortical proximal and distal tubules and within the interstitial space, and secondarily leads to mononuclear cell infiltration and tubular necrosis.

Clinical Manifestations

Macroscopic nephrocalcinosis is often detected on radiography or ultrasound. A defect in urinary concentration is the most notable tubular dysfunction and manifests as polyuria and polydipsia. The mechanism is incompletely understood, but the impairment relates both to a reduction in medullary solute content and to interference with the cellular response to vasopressin. Reversible impairment of eGFR can result from either acute or chronic hypercalcemia by decreased renal blood flow. Irreversible, advanced CKD is a rare consequence of long-standing hypercalcemia and is almost invariably associated with calcium crystal deposition in the interstitium of the kidney.

CHRONIC INTERSTITIAL NEPHRITIS CAUSED BY HEREDITARY DISEASES OF THE KIDNEY

Nephronophthisis (NPHP) and medullary cystic kidney disease (MCKD) (or the NPHP-MCKD complex) are hereditary diseases associated with renal cysts at the corticomedullary junction. Karyomegalic interstitial nephritis is a hereditary form of chronic tubulointerstitial nephritis histologically characterized by nuclear enlargement with irregular outlines, hyperchromatic aspect, and prominent nucleoli. These disorders are described in detail in Chapters 45 and 48.

CHRONIC INTERSTITIAL NEPHRITIS ASSOCIATED WITH HEAVY METAL EXPOSURE

Lead Nephropathy

Definition and Epidemiology

Acute lead intoxication is rare but may manifest with abdominal pain, encephalopathy, hemolytic anemia, peripheral neuropathy, and proximal tubular dysfunction (Fanconi syndrome). In contrast, chronic low-level exposure to lead is associated with CKD, often with hyperuricemia.

Because lead has a biological half-life of several decades, both intermittent acute poisoning and low-level environmental exposure result in chronic cumulative lead poisoning.

Although some epidemiologic studies have suggested that low-level exposure may be associated with CKD or hypertension,[29-31] data indicating that lead causes CKD leading to ESRD are relatively sparse.[32] It should be noted, however, that there may be regional differences on this issue and a closer look will be needed to obtain an epidemiologic heatmap. The pathogenesis of the renal disease may be related to the accumulation of reabsorbed lead in the proximal tubule cells, effects of chronic lead exposure on the vasculature, or lead-induced hyperuricemia. Additional well-controlled longitudinal studies with adequate exposure and effect variables are awaited to confirm that lead exposure causes deterioration of renal function and eventual ESRD.

Pathology

The kidneys are granular and contracted. The characteristic morphology is chronic interstitial nephritis demonstrating nonspecific tubular atrophy, interstitial fibrosis, and a paucity of inflammatory cells. The earliest histologic finding is proximal tubular injury, with intranuclear inclusion bodies composed of a lead-protein complex. Glomerular scarring can be observed as a secondary event, and arteries and arterioles demonstrate medial thickening and luminal narrowing, probably related to hypertension. Immunofluorescence studies are noncontributory.

Clinical Manifestations

Chronic lead nephropathy is usually identified when a source of high exposure is known (occupational hazard or consumption of illicitly distilled spirits [moonshine]). Hyperuricemia is common because of impaired uric acid excretion. Urine sediment is benign, and urinary protein excretion is less than 2 g/day. Hypertension is almost always present, and in the absence of appropriate testing or a careful exposure history, lead nephropathy is often misdiagnosed as hypertensive kidney disease. Gouty arthritis ("saturnine gout") affects about half of patients. Patients with chronic lead intoxication may occasionally manifest other signs, including peripheral motor neuropathies, anemia with basophilic stippling, and perivascular cerebellar calcifications.

Diagnosis

Lead nephropathy may be underdiagnosed because no simple diagnostic blood test is available. Lead nephropathy is easily confused with chronic uric acid nephropathy, in which uric acid deposits (tophi) may form in the renal interstitium. All patients with hyperuricemia and renal impairment should have a history of occupational lead exposure excluded. The blood lead concentration is an insensitive measure of cumulative body stores. A clinical diagnosis of lead nephropathy is based on a history of exposure, evidence of renal dysfunction, and an abnormal calcium disodium edetate ($CaNa_2$ EDTA) lead chelation test. The association with gout and CKD is strong enough to merit lead chelation testing in patients with CKD who have gout and risk for lead exposure. $CaNa_2$ EDTA is administered (2 doses of 0.5 g in 250 ml 5% dextrose given 12 hours apart), and urine is collected for 3 days because urinary excretion is slower when eGFR is reduced. Normal urinary lead levels are less than 650 μg/3 days. X-ray fluorescence, which provokes the emission of fluorescent photons from the target area, is an alternative method that detects increased bone lead levels, which are also a reflection of cumulative lead exposure. Although x-ray fluorescence measurements allow a rapid, noninvasive estimation of lead in bone, detection equipment is available at only a small number of centers.

Treatment

Treatment involves infusions of $CaNa_2$ EDTA together with removal of the source of lead. The likelihood of a satisfactory response to $CaNa_2$ EDTA is influenced by the degree of interstitial fibrosis that has already occurred.

In industrial and occupational settings, such as in foundry workers and individuals working with lead-based paints and glazes, preventive measures to minimize exposure and low-level absorption are essential. Some studies in children show success with the oral chelating agent succimer (Chemet). Chelation therapy may slow progressive CKD, even in patients with mild lead intoxication.[33] However, chelation therapy has not been widely used because of adverse drug effects and concerns about the effects of remobilized lead. It is generally not indicated for adults with blood lead concentrations of less than 45 μg/dl. Because of a lack of controlled clinical trials demonstrating efficacy of chelation and concerns about potential side effects, recommendations for treatment with chelating agents are empiric and decisions to use chelation therapy for lead intoxication can be controversial.

Other Heavy Metal–induced Nephropathies

Cadmium is a metal with a wide variety of industrial uses, including the manufacture of glass, metal alloys, and electrical equipment. Cadmium is preferentially concentrated in the kidney, principally in the proximal tubule, in the form of a cadmium-metallothionein complex that has a biological half-life of about 10 years. Cadmium contamination may be an important contributor to the high risk for chronic interstitial nephritis in some agricultural communities in the developing world. A major outbreak of cadmium toxicity occurred in Japan as a result of industrial contamination. The disease was called *itai-itai,* or "ouch-ouch," because bone pain was the major clinical manifestation. Other manifestations included proximal tubular dysfunction (Fanconi syndrome), hyperphosphaturia, and vitamin D–resistant rickets with osteomalacia. The mechanism by which cadmium elicits chronic inflammation and fibrosis in the kidney is relatively unstudied. The diagnosis is suggested by a history of occupational exposure, increased urinary β_2-microglobulin, and increased urinary cadmium levels (>7 μg of cadmium per gram creatinine). Once manifested, renal injury tends to be progressive, even if exposure is discontinued. Chelation has not been effective in humans, and prevention is the only effective treatment.

Arsenic, used as a poison gas in World War I, is present in insecticides, weed killers, wallpaper, and paints. Chronic arsenic toxicity from inorganic arsenic most commonly manifests as sensory and motor neuropathies, distal extremity hyperkeratosis, palmar desquamation, diarrhea and nausea, Aldrich-Mees lines (white bands on the nails), and anemia. In rare cases, it may cause renal disease, manifested by proximal RTA and chronic interstitial fibrosis. Diagnosis is made by demonstration of an elevated urinary inorganic arsenic level.

Mercury is found in alloy plants, mirror plants, and some batteries, and mercury intoxication usually occurs as a result of accidental exposure to mercury vapor. Mercury has been shown to induce membranous nephropathy (MN) in experimental animals and has been reported with the use of mercury-containing skin-lightening creams.[34] Neither elemental mercury nor the mercurous salt (Hg_2Cl_2) produces sustained renal tubular injury, but mercury dichloride ($HgCl_2$) may produce acute tubular necrosis and subsequent chronic interstitial nephritis in laboratory animals. However, a report of endemic methyl mercury poisoning in Japan revealed a clinical picture dominated by neurologic sequelae; renal disease in these patients was surprisingly benign, consisting only of tubular proteinuria without changes in serum creatinine.

RADIATION NEPHRITIS

Definition and Epidemiology

Although radiation nephritis was relatively common decades ago, the incidence has decreased considerably because recognition of

radiation-induced renal damage has altered protocols for the administration of therapeutic radiation. In general, direct exposure of the kidney to 20 to 30 Gy (1 Gy = 100 rad) over 5 weeks or less will produce radiation nephritis.

Pathology

In general, vascular and glomerular lesions of thrombotic microangiopathy may predominate. The initial target of ionizing radiation within the kidney appears to be endothelial cells, leading to endothelial cell swelling. Electron microscopy reveals a split appearance of the capillary wall caused by the mesangial interposition and widening of the subendothelial space by a nondescript fluffy material. These features are shared by hemolytic uremic syndrome and thrombotic thrombocytopenic purpura, suggesting a common pathogenic mechanism originating from endothelial injury. However, tubulointerstitial changes are also usually present. Vascular occlusion leads to tubular atrophy, and severe disease is characterized by progressive interstitial fibrosis and the presence of interstitial inflammatory cells.

Clinical Manifestations

Hypertension is commonly observed. Progression to a chronic form of radiation nephritis may occur if resolution of acute radiation nephritis is incomplete. These patients present with proteinuria, progressive CKD, and eventual development of ESRD several years after irradiation in the absence of an acute phase.

Treatment

Prevention is the best approach; risk can be minimized by shielding the kidneys or fractioning the total-body irradiation into several small doses over several days. No specific treatment is available for established radiation nephritis. The general approach is control of hypertension and supportive treatment of CKD.

INTERSTITIAL NEPHRITIS MEDIATED BY IMMUNOLOGIC MECHANISMS

Sjögren Syndrome

Definition and Epidemiology

Sjögren syndrome may be associated with chronic interstitial nephritis. The reported prevalence of renal involvement in Sjögren syndrome varies from 2% to 67%, principally owing to different definitions between studies. Recent analysis of 130 patients with primary Sjögren syndrome in China showed an 80% incidence of biopsy-proven chronic interstitial nephritis.[35]

Pathology

The lesion is characterized histologically by infiltration of lymphocytes and plasmacytes in the interstitium with tubular cell injury and, rarely, granuloma formation. This progresses to tubular atrophy and interstitial fibrosis over time. Immunofluorescence reveals granular deposits of immunoglobulin G (IgG) and C3 along the tubular basement membrane (TBM).

Clinical Manifestations

The clinical and biochemical manifestations of interstitial nephritis may be the presenting or only features of Sjögren syndrome. Serum creatinine concentration is generally only mildly elevated in association with a bland urine sediment and abnormalities in tubular function, including Fanconi syndrome, distal RTA, hypokalemia, and nephrogenic diabetes insipidus. Sjögren syndrome is one of the most common causes of acquired distal (type 1) RTA in adults, and the hypokalemia may be marked, resulting in a clinical presentation of severe weakness. Hypokalemia may occur in the absence of RTA, resulting from salt wasting and secondary hyperaldosteronism.

Treatment

Treatment with corticosteroids at the stage of cellular infiltration is frequently beneficial for protecting renal function. Although the renal disease has a slow and protracted course and CKD develops over time, progression to ESRD is rare.

Sarcoidosis

Definition and Epidemiology

Histologic evidence of interstitial nephritis with noncaseating granulomas is common in patients with sarcoidosis, but the frequency of clinically significant disease is low.[36] It may manifest as either acute interstitial nephritis or chronic interstitial nephritis.

Pathogenesis and Pathology

Renal biopsy reveals normal glomeruli; interstitial infiltration, mostly with mononuclear cells; tubular injury; and, with more chronic disease, interstitial fibrosis. Whereas the classic finding is noncaseating granulomas in the interstitium, they are uncommon and nonspecific. An analysis of 18 patients with granulomatous interstitial nephritis showed that in 5 the disorder was associated with sarcoidosis; in 2, tubulointerstitial nephritis and uveitis; in 2, medication; and in 9, the condition was idiopathic.[37] Immunofluorescence and electron microscopic studies typically show no immune deposits.

Recent studies suggest that renal sarcoidosis may reflect an impaired immune response to certain bacteria, especially *Propionibacterium acnes.* Confirmatory studies are needed, and it is not known if antibiotic treatment aimed at *P. acnes* provides any benefit.

Clinical Manifestations

Most affected patients have clear evidence of diffuse active sarcoidosis, although some present with an isolated elevation in serum creatinine and only minimal extrarenal manifestations. The urinalysis may be normal or show only sterile pyuria or mild proteinuria.

In addition, hypercalcemia induced by increased production of calcitriol (1,25-dihydroxyvitamin D_3) by activated mononuclear cells (particularly macrophages) in the lung and lymph nodes occasionally results in renal problems (see the previous discussion of hypercalcemic nephropathy).

The serum ACE level is used best not as a primary diagnostic tool but as a marker of disease activity and response to therapy. A normal serum ACE level does not exclude renal sarcoidosis.

Treatment

Corticosteroid therapy tends to improve renal function, although recovery is often incomplete. Limited data are available concerning the optimal protocol for corticosteroid therapy, but initial dose is usually predniso(ol) one 0.5 to 1 mg/kg/day, which is followed by a slow taper. Rapid tapering of corticosteroids can result in relapse.

Systemic Lupus Erythematosus

Definition and Epidemiology

Interstitial nephritis with immune complexes is defined by granular deposits of immunoglobulins and complement in the TBM, interstitium, or both. Systemic lupus erythematosus is the most common reason for this type of interstitial nephritis (Fig. 62.7), and interstitial involvement is present in half of kidney biopsy specimens in lupus. Tubulitis serves as an independent predictive factor for eGFR decline in lupus nephritis.[38] Rarely, tubulointerstitial immune complex disease may be the only manifestation of lupus nephritis.

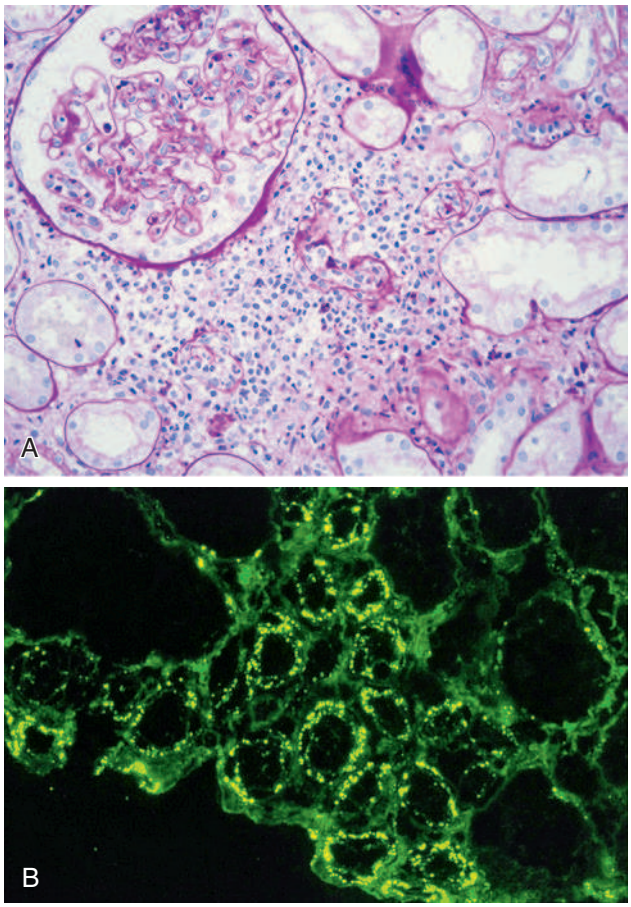

Fig. 62.7 Chronic interstitial nephritis in systemic lupus. (A) Interstitial nephritis observed in patients with systemic lupus erythematosus. (Periodic acid–Schiff stain; original magnification ×400.) B, Immunofluorescence study of the same patient revealed deposition of immunoglobulin G in the interstitium, in tubular cells, and along the tubular basement membrane. (Courtesy Drs. Akira Shimizu and Hideki Takano, Nippon Medical School, Tokyo.)

Clinical Manifestations

The presentation may be as acute or chronic interstitial nephritis. The possibility of interstitial involvement (without glomerular disease) is suggested by a rising serum creatinine concentration and a bland urine sediment. Interstitial involvement may be accompanied by signs of tubular dysfunction, such as distal RTA (type 1 or type 4); by isolated hyperkalemia resulting from impaired distal potassium secretion; or by hypokalemia resulting from salt wasting. The potentiating effects of sodium wasting on potassium secretion include an increase in sodium delivery to the potassium secretory site in the collecting tubules and associated volume depletion with subsequent stimulation of aldosterone secretion.

Treatment

Corticosteroid therapy is usually effective in suppressing tubular dysfunction and preserving renal function.

Inflammatory Bowel Disease

Although the most frequent renal complications of Crohn disease are calcium oxalate stones and renal amyloidosis, interstitial nephritis has been reported in patients treated for chronic inflammatory bowel disease. Aminosalicylates (5-aminosalicylic acid, mesalazine, and sulfasalazine) are responsible for most of these cases, but nephrotoxicity of these agents is very uncommon (mean rate only 0.3% per patient-year).[39] The median time for development of renal injury after commencing aminosalicylates is 3 years.[40] There is no clear relationship between aminosalicylate dose and the risk for nephrotoxicity, suggesting that this is an idiosyncratic response. Some patients have been reported to have biopsy-proven interstitial nephritis before the diagnosis of Crohn disease.

Aminosalicylates should be withdrawn when renal impairment develops in a patient with inflammatory bowel disease; if this does not result in a fall in serum creatinine, renal biopsy should be considered. Only one third of cases recover completely after drug withdrawal.[40] Corticosteroids are recommended when renal function does not respond to drug withdrawal.

IgG4-Related Kidney Disease

Definition and Epidemiology

On the basis of histologic and immunohistochemical examination of various organs of patients with autoimmune pancreatitis, a novel clinicopathologic entity of IgG4-related sclerosing disease has been proposed.[41] This is a systemic disease that is characterized by extensive IgG4-positive plasma cells and T-lymphocyte infiltration of various organs (Fig. 62.8). Initial reports of IgG4-related sclerosing disease came from Japan, but it has now been described in Europe and the United States and is considered to be a worldwide entity.

Pathogenesis

Whether IgG4 is pathogenic or is a "bystander" remains unknown. IgG4 does not activate the classical complement pathway effectively. However, immune complex formation may play a pathogenic role, raising the possibility of complement fixation via the lectin pathway or activation of the classical pathway of complement by some unknown mechanism.

Pathology

The most common pattern of involvement by IgG4-related kidney disease is tubulointerstitial nephritis with dense infiltration of IgG4-positive mononuclear cells. Distinctive features of the tubulointerstitial nephritis include (1) well-demarcated borders between involved and uninvolved areas; (2) involvement of the cortex and deep medulla, often extending beyond the renal capsule; (3) interstitial inflammatory cells comprising predominantly plasma cells and lymphocytes, with a high prevalence of IgG4-positive cells often admixed with fibrosis; (4) peculiar features of interstitial fibrosis called *storiform fibrosis* or *bird's-eye* pattern; and (5) deposits visible by light microscopy and immunofluorescence in the TBM, Bowman capsule, and interstitium.[42] Recent pathologic analysis revealed perivascular inflammation or fibrosis of medium- and small-sized vessels as a newly identified pathologic feature of IgG4-related kidney disease and proposed the term *interstitial fibrosclerosis* because storiform fibrosis contains mainly nonfibrillar collagens.[43] Immunofluorescence shows granular TBM staining for IgG accompanied by C3 of lesser staining intensity. MN also has been described as a manifestation of IgG4-related kidney disease.[44]

Clinical Manifestations

Clinical manifestations are observed in various organs, with presentations including sclerosing cholangitis, cholecystitis, sialadenitis, and retroperitoneal fibrosis. IgG4-related tubulointerstitial nephritis can be mass forming, similar to IgG4-related inflammatory lesions in other organs. Of patients with IgG4-related disease, 80% are reported to have had radiographic renal abnormalities: bilateral and multiple small low-attenuation lesions, a mass, or bilateral renal enlargement.[45] Whereas most IgG4-related sclerosing disease is associated with autoimmune

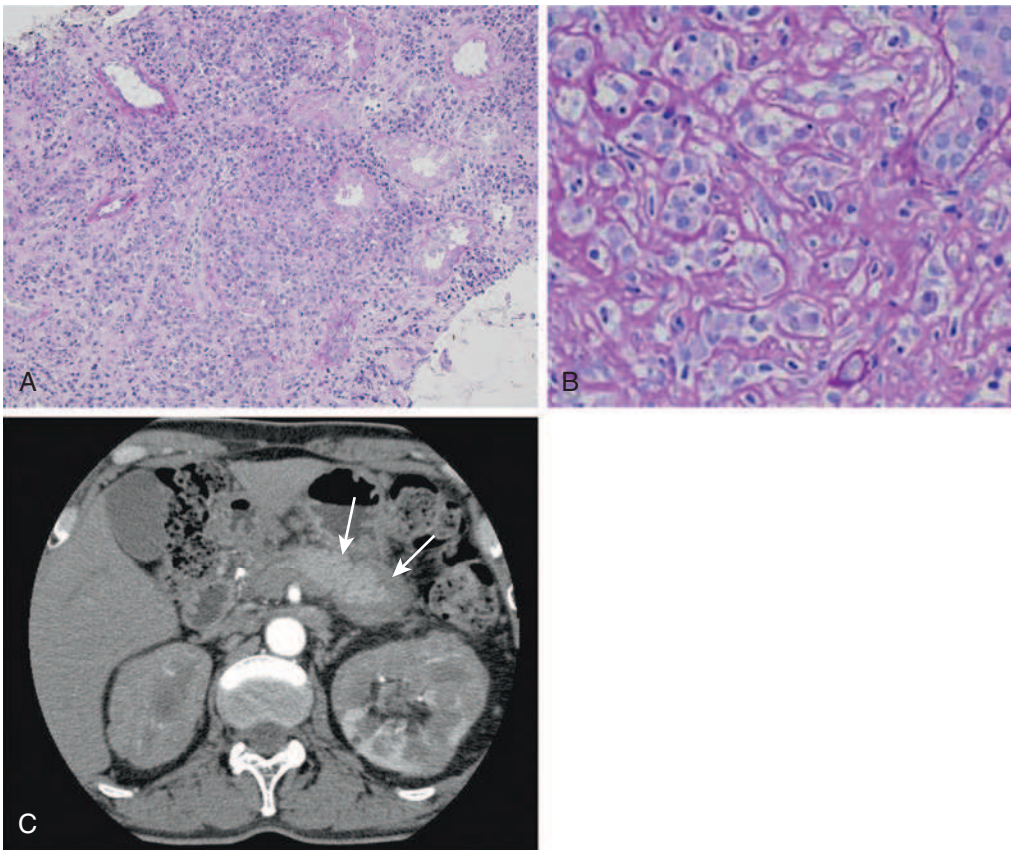

Fig. 62.8 Chronic interstitial nephritis in IgG4-related sclerosing disease. (A) Interstitial nephritis with numerous mononuclear cell infiltrates observed in a patient with autoimmune pancreatitis. Many of these cells are positive for IgG4 in typical cases. (Periodic acid–Schiff stain; original magnification ×200.) (B) Small nests of swollen plasma cells or individual plasma cells are encircled by collagenous tissue. The features resemble a maple wood grain pattern called *bird's eye*. Plasma cells look like birds' eyes in the wood, whereas fibrotic tissues correspond to branches of the wood. (C) CT scan of the patient revealed pancreatic swelling *(arrows)*. (**A** and **C,** courtesy Dr. Hiroshi Nishi, University of Tokyo, Tokyo. **B,** from reference 42.)

pancreatitis, cases without pancreatic involvement have been described. The disease occurs predominantly in older men. Serum IgG4 levels are raised, and IgG4-positive cells are found in the interstitium. According to a recent meta-analysis, a cut-off value of serum IgG4 ranging from 135 to 144 mg/dl confers a sensitivity of 87% and a specificity of 83%.[46] However, the finding of an elevated serum IgG4 is not specific, because this may occur in 5% of the normal population. The patients often show hypocomplementemia and eosinophilia. Recently proposed diagnostic criteria are shown in Table 62.3.

Treatment

The response to corticosteroids is generally favorable, but relapse is common. The protocol has not been established, but a starting dose of approximately 40 mg/day may be prudent. There is no correlation between histologic pattern and response to therapy, and even patients with extensive fibrosis on biopsy have shown a response to corticosteroid therapy.

Other Forms of Immune-Mediated Interstitial Nephritis

Primary anti-TBM nephritis is an extremely rare form of interstitial nephritis that usually is acute and characterized by linear deposits of immunoglobulins, commonly IgG, and complement in the TBM, together with tubular interstitial inflammation and anti-TBM antibodies in the serum. Anti-TBM antibodies, usually IgG, may be found in 50% to 70% of patients with anti–glomerular basement membrane nephritis and occasionally in patients with MN, systemic lupus, IgA nephropathy, minimal change disease, and malignant hypertension.

OBSTRUCTIVE UROPATHY

Complete or partial urinary tract obstruction is accompanied by pathologic changes in both the tubulointerstitium and glomeruli consisting of interstitial fibrosis, tubular atrophy, and occasionally focal glomerular sclerosis. Details are discussed in Chapter 58.

VASCULAR DISEASES

Ischemia resulting from intrarenal vascular involvement causes tubular atrophy, interstitial fibrosis, and cellular infiltration. This is further discussed in Chapter 41. Chronic ischemia in the tubulointerstitial compartment also plays a crucial role in the progression of a variety of glomerular and tubulointerstitial diseases.[2]

INFECTION-ASSOCIATED CHRONIC INTERSTITIAL NEPHRITIS

Although a variety of bacterial and viral infections can be associated with acute interstitial nephritis (see Chapter 60), chronic interstitial

TABLE 62.3 Diagnostic Criteria for IgG4-Related Tubulointerstitial Nephritis

Histology	Plasma cell–rich tubulointerstitial nephritis with >10 IgG4-positive plasma cells per high-power field in the most concentrated field*
	Tubular basement membrane immune complex deposits by immunofluorescence, immunohistochemistry, and/or electron microscopy†
Imaging	Small peripheral low-attenuation cortical nodules, round or wedge-shaped lesions, or diffuse patchy involvement
	Diffuse marked enlargement of kidneys
Serology	Elevated serum IgG4 or total IgG level
Other organ involvement	Includes autoimmune pancreatitis, sclerosing cholangitis, inflammatory masses in any organ, sialadenitis, inflammatory aortic aneurysm, lung involvement, retroperitoneal fibrosis

Diagnostic criteria for IgG4-related tubulointerstitial nephritis (TIN). diagnosis of IgG4 TIN requires the histologic feature of plasma cell–rich TIN with increased IgG4-positive plasma cells and at least one. Other feature from the categories of imaging, serology, or other organ involvement.
From reference 45.
*Mandatory criterion.
†Supportive criterion, present in >80% of cases.

nephritis secondary to infectious agents appears to be rare. Insidious *Mycobacterium tuberculosis* infection can cause chronic granulomatous tubulointerstitial nephritis.[47] Chronic bacterial infections can result in xanthogranulomatous pyelonephritis or renal malacoplakia (see Chapter 51).

SELF-ASSESSMENT QUESTIONS

1. A 29-year-old woman was admitted to the hospital because of anorexia, binge eating, and self-induced vomiting. On admission, her body mass index was 12.2 and she presented with nocturia and polyuria. The serum potassium level was 2.8 mEq/l. Which *one* of the following do you expect as the pathologic change of the renal biopsy specimen of this patient?
   A. Calcific deposits in the interstitium
   B. Vacuolation of the renal tubules
   C. Noncaseating granulomas
   D. Infiltration of IgG4-positive mononuclear cells
   E. Acellular interstitial nephritis with intranuclear inclusion bodies in the proximal tubules
2. IgG4-related tubulointerstitial nephritis is an emerging clinicopathologic entity that is a part of the systemic disease characterized by infiltration of IgG4-positive plasma cells in various organs. Which *one* of the following is *most* likely to be associated with this disease?
   A. Uroepithelial carcinoma
   B. Inflammatory bowel disease
   C. Cerebral aneurysm
   D. Autoimmune pancreatitis
   E. Angiokeratoma
3. A 58-year-old woman with a 30-year history of bipolar affective illness was admitted to hospital because of thirst, polyuria, and weight loss. Lithium had been prescribed for the preceding 18 years. On admission, she presented with hypernatremic dehydration. Which *one* of the following represents the *best* next step to diagnose the characteristic morphologic changes in the kidney?
   A. Non–contrast-enhanced magnetic resonance imaging
   B. Blood oxygen level–dependent magnetic resonance imaging (MRI)
   C. Non–contrast-enhanced computed tomography
   D. Scintigraphy
   E. Intravenous urography

Endemic Nephropathies

Ramón Garcia-Trabanino, Richard J. Johnson

Localized epidemics of chronic kidney disease (CKD) have been reported in various parts of the world and are known as *endemic nephropathies*. The word *endemic* is used in a lay rather than epidemiologic sense, to emphasize the regionally confined nature of such nephropathies. By definition, these nephropathies are distinct from CKD of usual causes and tend to manifest insidiously. Although both aging and metabolic syndrome are also associated with the insidious reduction in estimated glomerular filtration rate (eGFR), endemic nephropathies are distinguished by earlier onset, fewer classic risk factors, and more rapid progression to end-stage renal disease (ESRD).

There have been some spectacular examples in which the cause of endemic nephropathy has been identified. For example, in the 1920s there was a dramatic increased frequency of CKD in children and young adults in Queensland, Australia, that was shown to be due to lead poisoning, such as from exposure to paints. The children presented with either Fanconi syndrome from acute lead intoxication or CKD and hypertension associated with chronic lead intoxication. Likewise, an epidemic of CKD resulting from chronic interstitial nephritis and associated with Fanconi syndrome with hypophosphatemia and osteomalacia was discovered in the Toyama prefecture of Japan in the 1950s and 1960s and was shown to be caused by cadmium poisoning. A factory was found to be dumping cadmium into the Jinzu River, leading to contamination of the rice and soybeans. The disease was called *itai-itai* ("ouch-ouch") by the locals due to the severe joint pains, and manifested over decades, especially among the older women. For more information on nephropathies associated with heavy metals see Chapter 64. Finally, Balkan endemic nephropathy is another example in which the cause, the herb *Aristolochia clematis* contaminating wheat, has been identified. *Aristolochia* is also the cause of Chinese herbs nephropathy that was related to an epidemic of chronic tubulointerstitial disease first identified in individuals taking Chinese herbs for weight loss in the early 1980s. Diseases caused by *Aristolochia* (*Aristolochia*-associated nephropathy) are discussed in Chapter 78.

MESOAMERICAN NEPHROPATHY

Definition and Epidemiology

Mesoamerican nephropathy was first described in 2002 when physicians from reference Hospital Rosales in San Salvador noted a large number of young agricultural workers from the Bajo Lempa region presenting with CKD of unknown cause and a distinct epidemiologic pattern.[1] Subsequently, the disease was found to be endemic mainly along the Pacific coast, particularly involving Guatemala, Nicaragua, El Salvador, and Costa Rica (Fig. 63.1). Most of those affected are young men between ages 20 and 60 who are working manually in the fields, but there is evidence that women and even children are also at increased risk. Although manual work in the sugarcane fields carries the highest risk, the disease also has been reported among banana and cotton farmers, miners, construction and transportation workers, and others. Review of historical records suggest the disease has been present since the early 1970s but has increased progressively over recent decades, especially in men (Fig. 63.2).[2] In some areas, such as in Chichigalpa, Nicaragua, the prevalence of CKD (defined as eGFR <60 ml/min/1.73 m^2) approaches 40% of men between the ages of 20 to 40.[3] Although the true extent of the epidemic is veiled by the lack of comprehensive renal registries in the afflicted countries, this contrasts with an overall prevalence of 8.3% for all adults and with less than 0.4% for males ages 20 to 40 in the United States.

Pathogenesis

Although there have been rare reports linking the disease with carbamate pesticides or methyl parathion, most studies have been negative and there are no identified associations with aristolochic acid and heavy metals. One common risk factor is heat stress and recurrent dehydration, leading some to suggest it might be a type of heat stress nephropathy.[4,5] Heat stress is well known to cause acute kidney injury from a variety of mechanisms, including heat stroke and rhabdomyolysis, but the concept of a chronic kidney injury occurring from heat stroke is new. Consistent with this possibility, however, is the observation that Mesoamerican nephropathy is much more common in sugarcane workers who work at low altitude where it is warmer than at higher altitudes, despite similar working conditions and pesticide exposure. Experimentally, recurrent heat stress and dehydration also have been shown to induce CKD in animals because of hyperosmolarity-induced activation of the polyol-fructose and vasopressin pathways,[6] and the renal injury is amplified if animals are rehydrated with sugary (fructose-containing) beverages as opposed to water.[7] Heat stress also may result in subclinical rhabdomyolysis, uric acid overproduction, and supersaturation of urine resulting in intermittent uric acid crystalluria.[8] Leptospirosis, an infection that affects the kidney and is spread by rats, also has been proposed as a causal or potentiating factor.

Pathology

Few renal biopsies have been performed, often in patients who already have advanced CKD. The primary finding is chronic tubulointerstitial fibrosis with variable degrees of glomerulosclerosis (Fig. 63.3).[9] Immune deposits are absent. There remains debate over whether the glomerular changes are secondary to chronic disease or represent a primary glomerular injury. Potential mechanisms of glomerular injury include glomerular ischemia (the findings of shrinkage of the

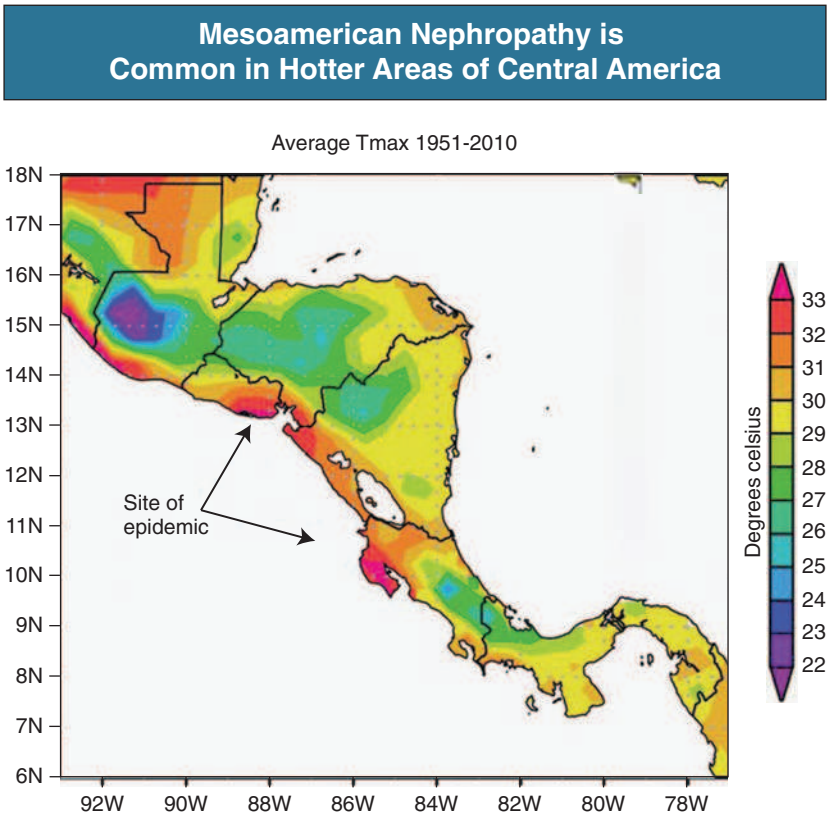

Fig. 63.1 Mesoamerican nephropathy. The major areas where Mesoamerican nephropathy has been observed along the Pacific Coast, especially involving the Guanacaste region of Costa Rica, the Bajo Lempa region of El Salvador, and the Chinandega Region of Nicaragua. These are also the hottest areas in Central America. (With permission from reference 13.)

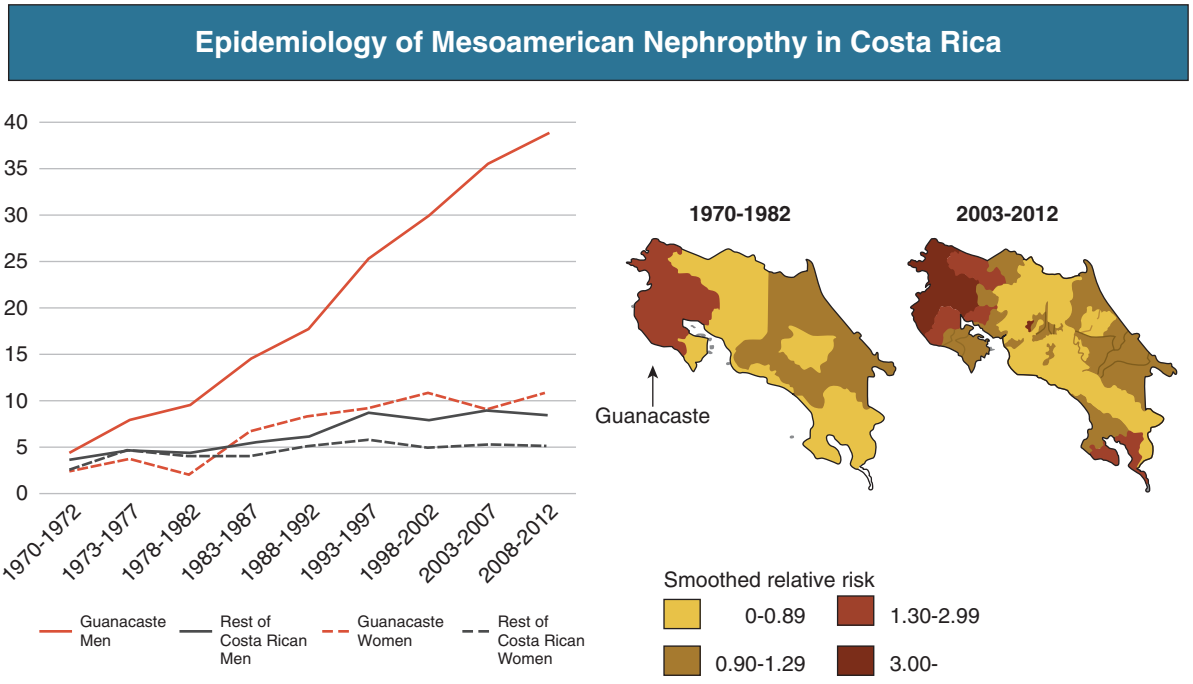

Fig. 63.2 Prevalence of CKD in Guanacaste, Costa Rica. Mesoamerican nephropathy was first noted in the 1970s in Guanacaste Region of Costa Rica. Shown is the increasing prevalence of chronic kidney disease in the Guanacaste Region of Costa Rica in men compared with the rest of Costa Rica. (With permission from reference 2.)

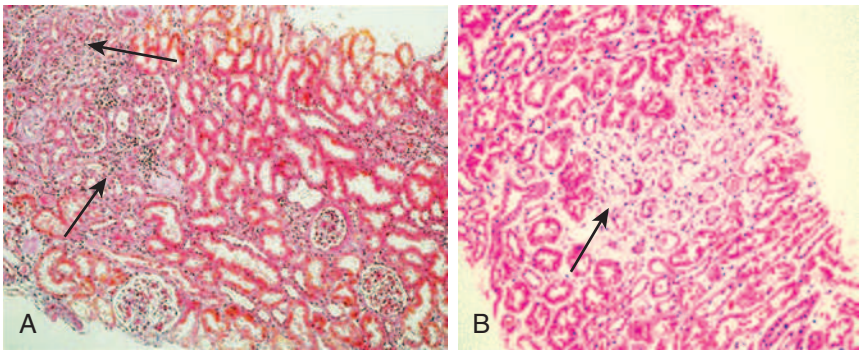

Fig. 63.3 Renal pathology in endemic nephropathy. Mesoamerican nephropathy is characterized by chronic tubulointerstitial fibrosis with localized inflammation *(arrows)*. Other findings include glomerular ischemia and variable glomerulosclerosis. Renal vascular disease is usually mild. Sri Lankan nephropathy (see Fig. 63.3B, hematoxylin and eosin stain) also has a similar histologic appearance with the tubulointerstitial fibrosis with some pockets of inflammatory cells. (**A,** Courtesy Dr. Annika Wernerson, Karolinska Institute Sweden. **B,** With permission from reference 14 [both 40× magnification].)

TABLE 63.1 Characteristics of Patients With Mesoamerican Nephropathy

No evidence for common causes of chronic kidney disease	Absence of diabetes (blood glucose <125 mg/dl or 7 mmol/l) BP normal or only slightly high Minimal evidence for GN (no RBC casts, urine protein <2 g/day) No evidence for obstruction (ultrasound) No evidence for polycystic kidney disease (ultrasound)
Clinical presentation	Asymptomatic rise in serum creatinine Minimal albuminuria Frequent hyperuricemia Serum potassium level often lower than expected Biopsy usually shows chronic tubulointerstitial disease and variable glomerulosclerosis (often performed late in disease)

BP, Blood pressure; *GN,* glomerulonephritis, *RBC,* red blood cell.

glomerular tuft and wrinkling of the basement membrane support this). In addition, hyperuricemia, which is commonly elevated in this disease, has been found experimentally to cause glomerular hypertension, and vasopressin induces hyperfiltration in addition to the effects on tubular injury.

Clinical Manifestations

Affected individuals are commonly manual workers, such as sugarcane cutters (Table 63.1). In early stages, some patients present with muscle weakness related to hypokalemia or aseptic dysuria possibly related to uric acid crystalluria. Other patients are asymptomatic but are identified when an elevated serum creatinine is found during health screening. Blood pressure is normal or only slightly elevated, and urine sediment shows low-grade (<1 g/day) proteinuria with occasional red cells and leukocytes. Serum sodium and potassium are often low early in the disease and appear to be associated with increased urinary losses; similarly, elevated magnesium and phosphate losses in the urine are also common, suggesting a tubular defect.[10] Serum uric acid is also elevated, often with levels greater than 9 mg/dl, typically 2 mg/dl higher than expected for the eGFR.[11]

Diagnosis, Treatment, and Prognosis

Diagnosis is made on clinical grounds and is based on living in the endemic area and presenting with CKD without clear cause (Fig. 63.4). The presence of hypokalemia and/or hyperuricemia aids diagnosis. Renal biopsies are generally not performed. Empiric treatment includes counseling on hydration and need for rest in shaded areas, avoidance of nonsteroidal antiinflammatory drugs (NSAIDs), and cessation of smoking. Given experimental data that rehydration with sugary beverages (>6% to 8%) markedly worsens renal injury,[7] avoidance of soft drinks or sugary beverages as hydration drinks is recommended. Although the therapy has not been proven, some local nephrologists (including the primary author) are treating subjects with low-dose angiotensin-converting enzyme inhibitors (especially if they are no longer working and at risk for dehydration) and with allopurinol and bicarbonate when serum uric acid levels are very elevated (>9 mg/dl) to reduce the formation of urine urate crystals and improve the aseptic dysuria. Treatment is empiric and controlled trials are needed. Dialysis is rarely available because of poverty and lack of insurance, and prognosis is guarded. It has been estimated that over 20,000 individuals have died to date.

SRI LANKAN NEPHROPATHY

Reports of an epidemic of CKD in the North Central Province of Sri Lanka began in the late 1980s. Today there over 100,000 individuals affected with the disease, with an ongoing mortality of 5000 per year.[12] Typically, affected individuals are males between the ages of 20 and 60 who are working in the rice paddies under extremely hot conditions. Women also may develop the disease. The clinical presentation is also similar to that of Mesoamerican nephropathy, with low-grade proteinuria and an asymptomatic elevation in serum creatinine or with late presentation in ESRD (see Table 63.1). Hyperuricemia is also common.[13] Renal biopsies early in the disease show chronic tubulointerstitial fibrosis, while later biopsies also show increasing glomerulosclerosis (see Fig. 63.3).[14] Many patients are very poor and have little access to medical care; thus treatment tends to be supportive and dialysis is only rarely provided.[12,15]

For decades the primary hypothesis has been that Sri Lankan nephropathy is due to a toxin, either an agrochemical or pesticide, or possibly heavy metal exposure such as cadmium or arsenic. Nevertheless, levels of heavy metals in the drinking water are within acceptable ranges,[16] and similarly it has been difficult to incriminate any specific agrochemical such as glyphosate.[12] However, those who drink local

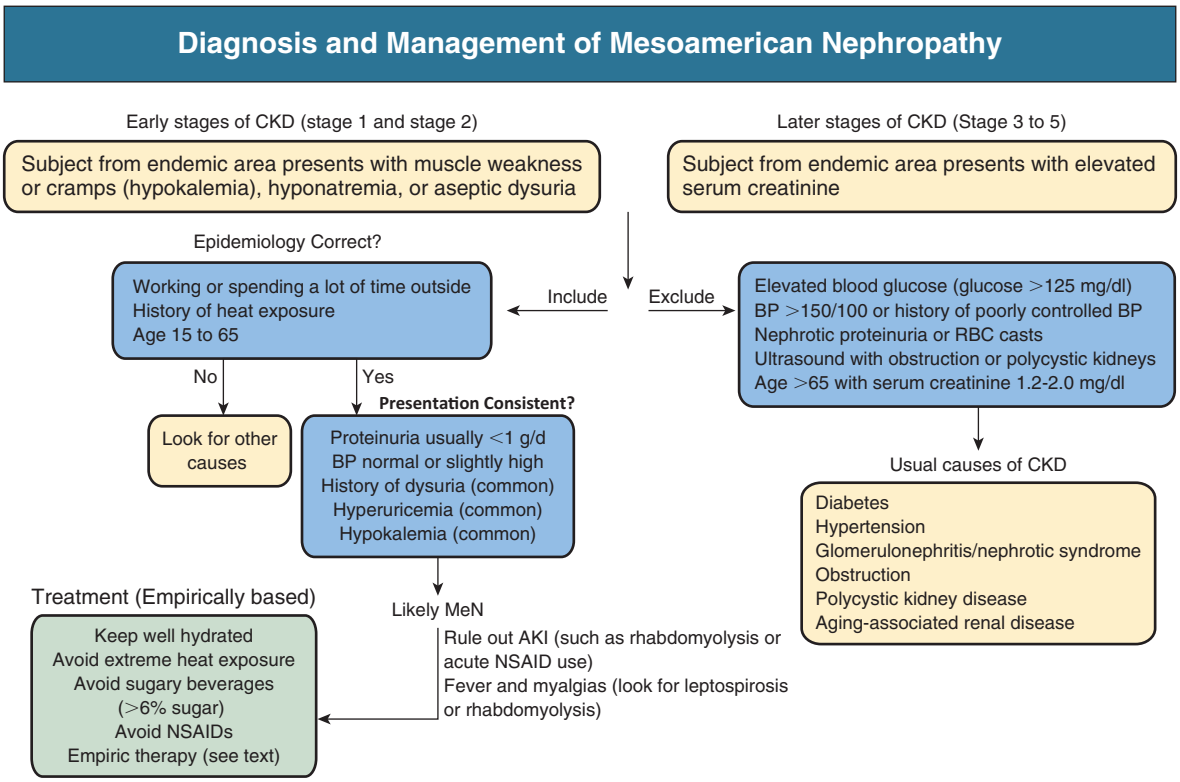

Fig. 63.4 Diagnosis and management of Mesoamerican nephropathy (MeN). *AKI,* Acute kidney injury; *BP,* blood pressure; *CKD,* chronic kidney disease; *NSAID,* nonsteroidal antiinflammatory disease; *RBC,* red blood cell.

well water are at higher risk for CKD, suggesting the presence of some unidentified toxin.[17] Importantly, the risk for CKD was also increased in those highly exposed to the sun, those who worked more than 6 hours per day, and those who drank less than 3 l/day liquids.[17] Noteworthy, because many workers believe the well water contains toxins, it seems likely that those who drink well water might be the same subjects who were limiting their water intake. Thus these studies also raise the question whether heat stress and recurrent dehydration may be involved in this disease as well.[13]

OTHER ENDEMIC NEPHROPATHIES

An epidemic of CKD has been reported in the Uddanam region of Andhra Pradesh in southern India and may have been present since the early 1990s.[18] Uddanam nephropathy is observed primarily in males working in the agricultural fields where the primary crops are cashews, coconuts, and rice. Similar to the other epidemics, the patients present with minimal proteinuria and elevated serum creatinine and have chronic tubulointerstitial disease on renal biopsy.[19] Hyperuricemia is also common in this condition. Indeed, to date there are no distinguishing features among the various epidemics, and many authorities believe the disease may have similar etiologies worldwide.

Other similar epidemics are also emerging. This includes an epidemic among manual workers near Tierra Blanca in the Veracruz region of Mexico, where heat stress also has been a major risk factor.[20] There are also early reports that similar epidemics may be manifesting in northeastern Thailand, Egypt, and Sudan.

POTENTIAL ROLE OF CLIMATE CHANGE AND GLOBAL WARMING

The similarity between the various epidemics has placed special emphasis on the role of heat stress and dehydration in CKD. Indeed, studies have shown that the sites where epidemics of CKD are reported are frequently in areas that are extremely hot, especially between the equator and the Tropic of Cancer. It also remains possible that global warming has a role in accelerating the epidemics. Although mean temperatures have increased only 0.8 degrees centigrade in the last 50 years, the frequency of extreme heat events (exceeding the 99th percentile) has increased by nearly 75%.[21] It is interesting that the sites where reports are emerging of epidemic CKD in India correlate with areas of increased extreme heat events such as heat waves (Fig. 63.5). This has led to the hypothesis that these epidemics may represent a type of heat stress nephropathy. If true, the increase in frequency being observed is likely related to increasing world temperatures. The heat stress hypothesis is currently being tested and yet needs to be confirmed. Other factors could include better reporting and the possibility that rehydration with sugary beverages could be accelerating the renal injury.[7] It also remains possible that toxins may be contributing to the various epidemics, or may be acting in synergy with heat stress to cause CKD, as suggested by the presence of some Fanconi-like features in Mesoamerican nephropathy and other locales.

The causes of Mesoamerican and Sri Lanka nephropathy are still unknown. Strong renal registries need to be in place to determine the severity of the epidemics. Genetic and environmental studies need to

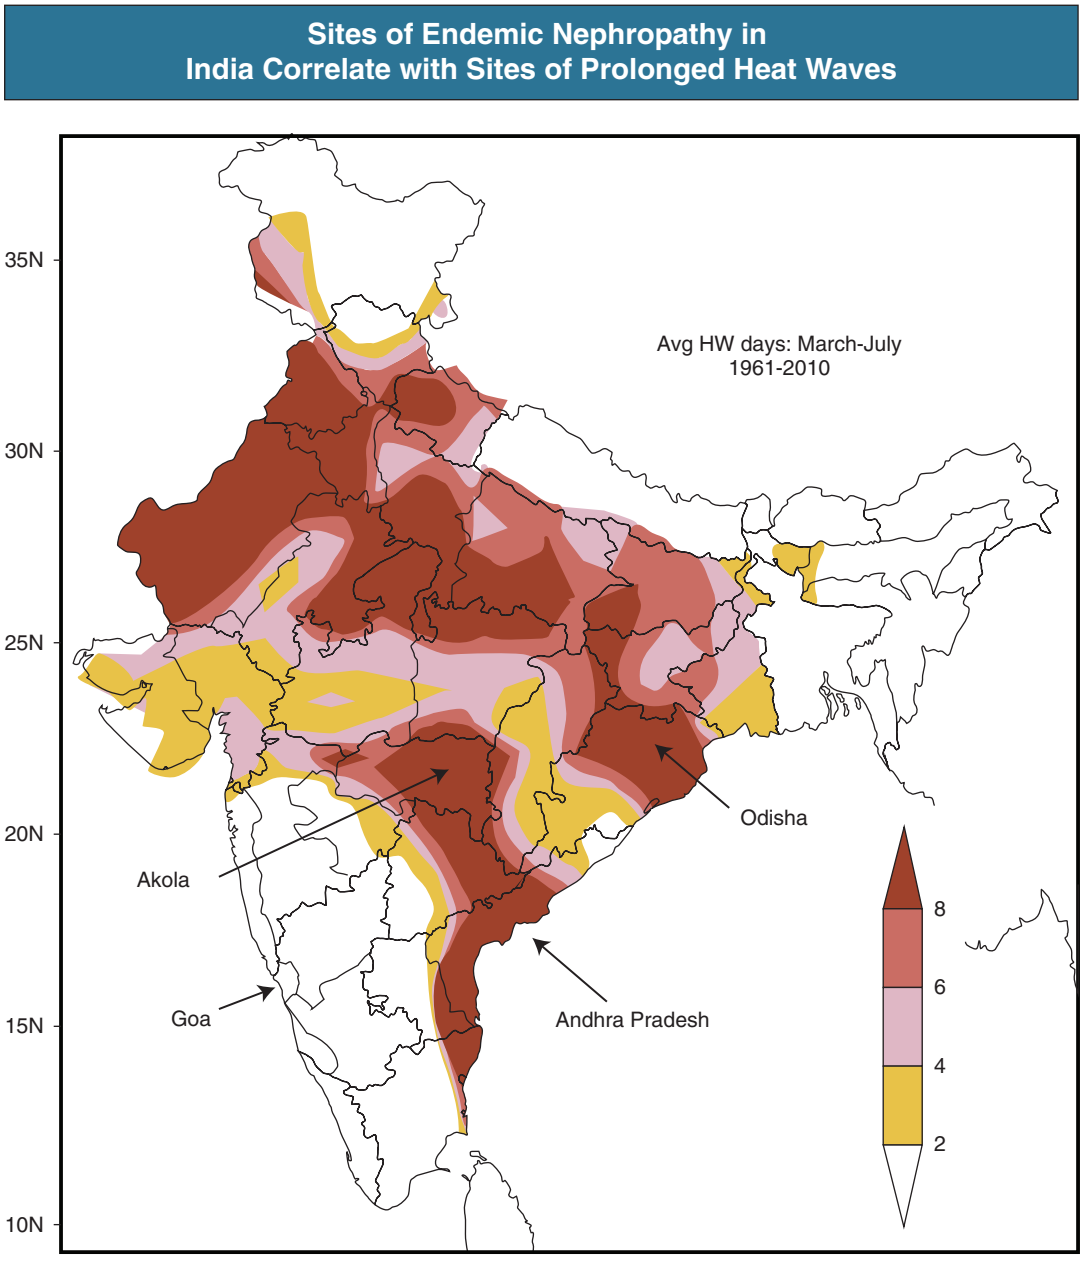

Fig. 63.5 Reported sites in India with increased frequency of chronic kidney disease (CKD) correlate with sites of prolonged heat waves. Shown is the average number of heat wave days between March and July (hottest time of the year) in India, based on the number of heat wave days over the 50-year period. Heat wave is usually defined as sustained temperatures of > 40 degrees C or an increase of 5–6 degrees C over the normal maximal temperature of that region. Andhra Pradesh (including the Uddanam region) has had some of the longest heat waves, with one recorded at 35 days. Other suspected sites of CKD of unknown etiology include the Akola district of Maharashtra, the central Odisha region and Goa. *HW,* heat wave. (Data originally from reference 22; reproduced from reference 13.)

be conducted as well. Given the linkage with heat stress and climate, there is also a need to determine whether similar epidemics are occurring in other hot regions where there are similar working conditions. The most successful research approach to these disorders will require strenghtening of local renal registries, controlled trials of current diagnosis and management protocols, and a multidisciplinary approach with contributions from nephrologists, epidemiologists, public health specialists, and agriculturalists.

SELF-ASSESSMENT QUESTIONS

1. Endemic nephropathies refer to:
   - **A.** Regions where chronic kidney disease (CKD) of any cause is highly prevalent
   - **B.** Regions with a high prevalence of CKD that is unrelated to common causes such as hypertension and diabetes
   - **C.** Ethnic groups with high susceptibility to CKD
   - **D.** Ethnic groups with high prevalence of CKD
   - **E.** Regions with high prevalence of patients undergoing renal replacement therapy
2. Which statement best describes Mesoamerican nephropathy?
   - **A.** A type of CKD of undetermined cause highly prevalent in the Pacific coast of Central America
   - **B.** A type of CKD caused by exposure to aristolochic acid
   - **C.** A type of CKD related to exposure to cadmium
   - **D.** A type of CKD often seen in Mesoamerican Maya ethnicity patients
   - **E.** A type of CKD that locals call *itai-itai*
3. Which of the following are similarities between Sri Lankan endemic nephropathy and Mesoamerican endemic nephropathy?
   - **A.** Highly symptomatic, predominantly glomerular damage with proteinuria, young patients from hot regions
   - **B.** Mostly asymptomatic, predominantly tubulointerstitial damage with low proteinuria, young workers from hot regions
   - **C.** Fanconi-like syndrome with high mortality rates and exposure to lead
   - **D** Fanconi-like syndrome with high mortality rates and exposure to heat stress
   - **E.** Highly symptomatic, predominantly tubulointerstitial damage with proteinuria, elderly patients
4. The idea of a potential role of climate change and global warming is suspected in emerging endemic nephropathies because of which of the following?
   - **A.** Most emerging endemic regions correlate with areas of increased extreme heat.
   - **B.** CKD is much more common in workers in warmer areas despite similar working conditions.
   - **C.** Patients are exposed to extreme heat stress and dehydration. Dehydration may be fueled by the fear of water contamination.
   - **D.** Most emerging endemic regions are comprised between the equator and the Tropic of Cancer.
   - **E.** All of the above.

Myeloma and the Kidney

Ashley B. Irish

Myeloma is an uncommon malignancy; for example, it accounts for 1% to 2% of total and 10% to 15% of hematologic malignancies in the United States. African Americans have twice the incidence of Whites, and males predominate over females. It is a disease of older people with the median age of diagnosis greater than 65 years.[1] Myeloma is characterized by a neoplastic proliferation of plasma cell clones producing monoclonal immunoglobulin, which in 95% of cases, includes an excess of the light chain (LC) component, which can be nephrotoxic. Various causes and manifestations of acute kidney injury (AKI) are possible in myeloma (Table 64.1) but the major risk is myeloma cast nephropathy (MCN), which is a medical emergency that requires prompt diagnosis and intervention to avoid irreversible renal failure. Other monoclonal B cell–derived kidney disorders have been collectively described as monoclonal gammopathy of renal significance (MGRS) and differ from myeloma because they do not depend on expansion of the clonal mass for their nephrotoxicity and usually lack the additional features characteristic of myeloma such as bone disease.[2]

ETIOLOGY AND PATHOGENESIS OF MYELOMA

Plasma cells derive from mature uncommitted B cells and after antigen stimulus undergo heavy-chain class switching from μ (immunoglobulin M [IgM]) expression to α, δ, ε, γ. Whole immunoglobulin production requires the intracellular assembly of two heavy chains and two LCs, either kappa (κ) or lambda (λ), to derive whole IgG, IgA, IgD, and IgE. Normally LCs are excreted in slight excess, with a κ/λ ratio of approximately 2 : 1. In myeloma a clone of cells secretes excessive quantities of a specific immunoglobulin and/or LCs (the paraprotein or M-protein). All myelomas (whole immunoglobulin or LC only) arise from a preclinical phase of monoclonal gammopathy (MGUS) into a clinical or symptomatic phase as a consequence of somatic mutations. Mutations have important implications for prognosis and treatment and are incorporated into diagnostic and prognostic stratification tools.[3,4] Myeloma remains an incurable disease because of multiple subclones, which engender resistance to chemotherapy and account for the natural history of remission and relapse over time. Both deregulation of cell cycling and impaired apoptosis account for their progressive and dysfunctional accumulation within the bone marrow and occasionally other organs. Plasma cells express little surface immunoglobulin and are recognized by surface expression of CD38 and CD138; they normally reside only in the bone marrow. In myeloma, unrestrained plasma cell growth is supported by a complex milieu of autocrine and paracrine cytokines, especially interleukin-6 (IL-6). These cytokines are secreted from stromal cells, endothelial cells, and/or osteoclasts and maintain myeloma cell growth, survival, and migration; they also contribute to local organ dysfunction, such as bone resorption, fracture and anemia.[5]

ETIOLOGY AND PATHOGENESIS OF RENAL DISEASE IN MYELOMA

Free light chains (FLCs) circulate as monomers (predominantly κ ≅ 25 kDa) and dimers (predominantly λ ≅ 50 kDa) with a very short half-life (2-6 hours) because of free glomerular filtration, whereas the much larger whole immunoglobulin circulates intact for several weeks. The filtered FLC is reabsorbed in the proximal tubule cell (PTC) by receptor-mediated endocytosis after binding with the glycoprotein receptor cubilin[6] (Fig. 64.1). LCs in excess can induce an inhibitory effect on endocytosis in vitro and are associated with lysosomal overload and rupture, releasing enzymatic contents into the cytosol, manifest histologically by crystallization, vacuolation, and desquamation of the PTC. Endocytosis of LCs induces the release of the proinflammatory cytokines IL-6, IL-8, and monocyte chemoattractant protein-1 (MCP-1) by activation of nuclear factor κB (NF-κB) in the PTC.[7] Inhibition of proximal tubule uptake of LCs by silencing the megalin/cubilin genes with small interfering RNAs prevents proximal tubular toxicity.[8] This suggests that LC overload induces factors promoting interstitial injury and fibrosis, as described in other proteinuric states. Less common manifestations of PTC injury include the Fanconi syndrome, which is invariably associated with specific variant kappa LCs and often with pathologic evidence of crystalline inclusions.[9]

Injury to the PTC allows escape or overflow of LC to the distal nephron, where it can interact with the Tamm-Horsfall protein (THP) secreted by the cells of the thick ascending loop of Henle. Variations in the specificity of the binding region of different LCs modify the affinity of the LC for binding with THP, which could in part explain the variable nephrotoxicity of LCs.[10] This specificity of the individual LC for THP was illustrated by the finding that the intraperitoneal installation of LCs isolated from humans with specific renal LC-associated disease induces the same renal injury in animals.[11] Inhibition of binding of the LC to THP prevents cast formation.[12] Not all LCs are associated with tubular injury, and neither the amount nor type of urinary LCs correlates with the severity of cast formation. Nevertheless, in general, the higher the urinary excretion of LCs, the greater is the risk for renal failure and reduced response to chemotherapy.[13-15] In addition to LC-specific factors, tubular solute composition and tubular flow rates modulate the risk for cast formation. In animals, urinary acidification, furosemide, and urinary sodium and calcium concentrations may affect the tendency to increased binding or aggregation of LCs with THP, whereas colchicine may reduce this tendency in animals but not in humans.[16,17] The formation and passage of casts distally can occlude the tubule and allow intratubular obstruction, with rupture and even backflow of contents (Fig. 64.2).

TABLE 64.1 Etiology of Renal Injury and Clinical Manifestations in Myeloma

		Cause	Manifestation
Prerenal	Volume depletion	Hypercalcemia	Polyuria and polydipsia
		Gastrointestinal losses (nausea and vomiting)	Hypotension
		Sepsis	Fever
	Hemodynamic	Hemodynamic from NSAIDs	Oliguria, hyperkalemia
	Other	Hyperviscosity (IgA, IgG3)	Mental state alterations
		Hyperuricemia	Tumor lysis
Renal		Proximal tubular injury from light chains, uric acid, distal tubular injury from casts	Fanconi syndrome Tubular proteinuria Crystalluria
		Glomerular disease (LCDD, amyloid)	Nephrotic proteinuria Hematuria, active sediment
Postrenal		Calculi	Colic

IgA, Immunoglobulin; *LCDD,* light chain deposition disease; *NSAIDs,* nonsteroidal antiinflammatory drugs.

EPIDEMIOLOGY

Most myeloma manifests de novo, although around 1% evolves from patients with a known MGUS each year. In patients with newly diagnosed myeloma, the prevalence of IgG, IgA, IgD, and FLC-only myeloma was 52%, 21%, 2%, and 16%, respectively.[13] IgM and IgE myeloma are extremely uncommon. Approximately 70% of patients with myeloma also have a urinary M-protein. At the time of diagnosis, up to 50% of patients have evidence of impaired renal function judged by increased serum creatinine, around 25% presenting with serum creatinine greater than 2 mg/dl (177 µmol/l).[13,14] In unselected series, 2% to 10% of patients present with severe renal failure requiring dialysis, this figure is higher in series reported from renal units. In contrast to the general distribution of M-protein types in myeloma, LC and IgD myeloma are particularly associated with the risk for renal disease, being present in nearly 50% of patients with severe renal disease requiring dialysis.[18]

CLINICAL PRESENTATION

Most patients present with constitutional symptoms (fatigue, weight loss) and skeletal pain, especially back pain. Renal impairment is common and has a variety of causes (see Fig. 64.1). In a smaller proportion of patients, renal failure is the presenting manifestation of myeloma and these patients often have more advanced disease with high morbidity/mortality.[18] Renal findings are nonspecific, typically normal-size kidneys and bland urine. Urinary protein excretion may be increased because of the presence of LCs (Bence Jones protein). Urinary dipstick, or albumin measurement, may indicate only small amounts of protein because they measure albumin only. Significantly increased levels of urinary albumin are suggestive of amyloidosis or other monoclonal kidney disorders, which affect the glomerulus (see Chapter 27). Normal or elevated ionized calcium, a decreased serum anion gap, lytic bone lesions on x-ray, hypogammaglobulinemia, reductions in levels of other immunoglobulin classes (immunoparesis), significant cytopenias, or blood film changes (plasma cells and/or leukoerythroblastic film) are suggestive of myeloma. Clinical and laboratory findings that may distinguish MCN from other monoclonal B cell disorders affecting the kidney are listed in (Table 64.2).

PATHOLOGY

Histologic examination of the kidney in myeloma and AKI has diagnostic and prognostic utility, although it is not always required.[19,20] The introduction of the serum (FLC) ratio as a rapid diagnostic tool has reduced the requirement for biopsy for diagnosis. MCN is the most common histologic finding, occurring in 30% to 50% of patients; however, a diverse range of diseases have been reported depending on the indication for biopsy (Table 64.3). MCN is characterized by many distal tubular casts, which are strongly eosinophilic and consist of the monoclonal LC and laminated THP, which often appear fractured after fixation. Casts promote local inflammation with giant cell formation.[21,22] In 30% of cases, cast formation may not be prominent despite extensive tubulointerstitial injury[23] (Box 64.1 and Fig. 64.3). Glomeruli are usually spared unless there is associated LC deposition disease or amyloidosis.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The International Myeloma Working Group (2014) diagnostic criteria for symptomatic myeloma require one or more myeloma-defining events in addition to bone marrow clonally restricted plasma cells of 10% or greater or biopsy-proven plasmacytoma. A myeloma-defining event is a CRAB event (hypercalcemia, renal failure, anemia or lytic bone lesions) or one of three biomarkers: clonal bone marrow plasma cells greater than 60%, serum FLC ratio of 100 or greater (involved to uninvolved LC *and* the involved LC absolute value >100 mg/l), or more than one focal bone lesion on magnetic resonance imaging. To meet the criteria

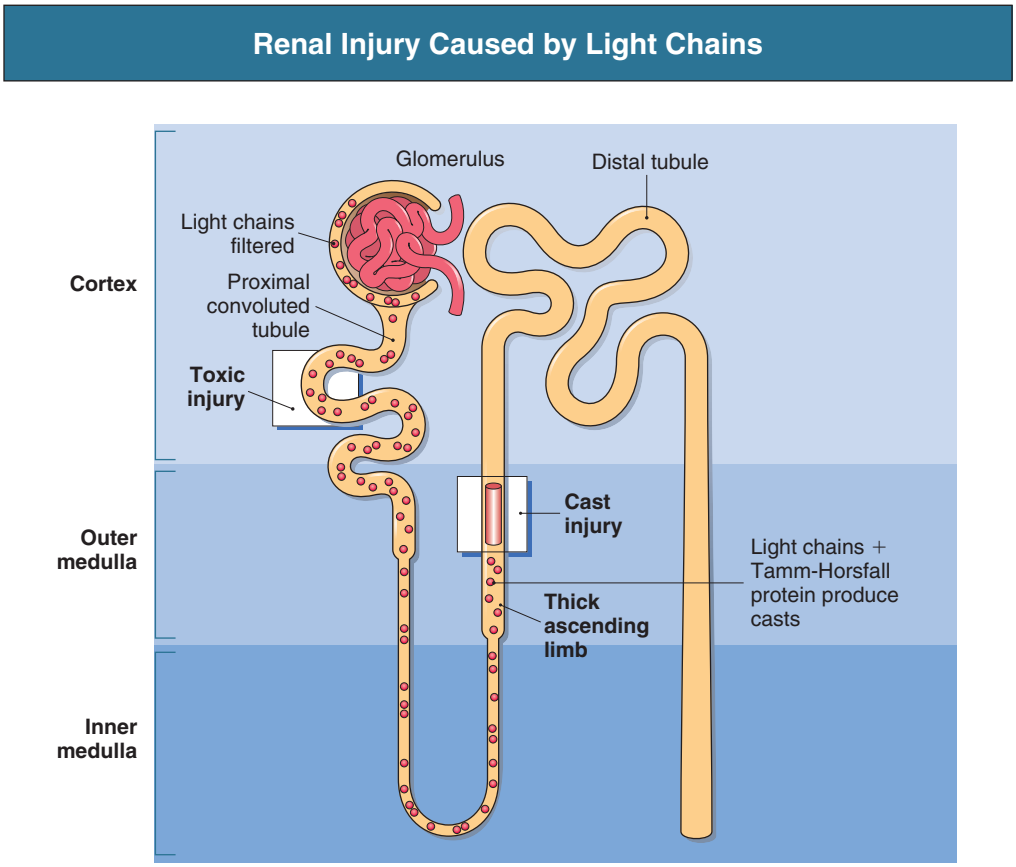

Fig. 64.2 Renal injury caused by light chains. Sites *(white boxes)* where light chains injure the tubule. In the proximal tubule, there is direct tubular cytotoxicity. In the distal tubule, there is cast injury.

for renal failure as a myeloma-defining event, a reduction in estimated glomerular filtration rate (eGFR) less than 40 ml/min/1.73 m^2, and a histologic diagnosis of cast nephropathy (or presumptive diagnosis based on a serum involved FLC of typically >1500 mg/l) is necessary to distinguish this from other paraprotein-defined renal diseases.[3] About 97% of patients with a diagnosis of myeloma have a detectable intact whole immunoglobulin and/or a free LC by serum protein electrophoresis (SEP) and immunofixation (IFE). The quantity of the M-protein is estimated from the SEP and may be used both for diagnosis and to monitor response to therapy. Urinary LC (Bence Jones protein) is determined from a concentrated sample, but despite this LC may be below the level of detection by IFE. The specific quantitative FLC assay (which measure only LC not bound to whole immunoglobulin in serum) is significantly more sensitive than SEP and IFE alone and is an automated assay that allows rapid diagnosis.[24,25] An abnormal monoclonal FLC increases the specific LC fraction and may suppress the other LC, which alters the normal ratio of FLC (0.26-1.65 κ/λ) to reflect the oversecretion of the abnormal LC clone (<0.26 for λ FLC clone, >1.65 for κ clone). The normal serum levels of FLC are very low (7 to 13 mg/l), but in patients with impaired renal function, accumulation of both (kappa and lambda) FLCs occurs as a result of reduced excretion, and because lambda free light chains tend to circulate as dimers, their clearance is reduced more than the monomeric kappa FLC. The use of an extended reference range of 0.37 to 3.1 improves diagnostic sensitivity for myeloma to 99% with 100% specificity in the presence of renal failure.[26] In patients with renal failure and biopsy-proven cast nephropathy, the ratios are highly abnormal and the absolute increase in the affected LC is on the order of 100 to 200 times normal with values usually greater than 1000 mg/l at presentation[26] (Fig. 64.4). Measurement of serum FLC has significant advantages over SEP and IFE and is now incorporated into international clinical guidelines for the diagnosis and management of myeloma.

Diagnostic difficulties can arise when elderly patients who are evaluated for newly diagnosed renal impairment have an M-protein on routine SEP. Approximately 3% of the population over 70 years of age will have a serum M-protein, most consistent with MGUS. A diagnosis of MGUS is more likely if the serum level of the M-protein is low (<3 g/dl), there is absent or very low urinary LC (<1 g/24 hours), and a normal FLC ratio with the absence of end organ injury (no lytic lesions, <10% plasma cells on bone marrow aspirate).[27] This distinction is important because most patients with MGUS will die of an unrelated disease, and only 1% a year progress to myeloma.[28] The majority of renal disease in patients with MGUS is unrelated to the M-protein.[29] However, it is now recognized that the spectrum of paraprotein and LC disorders associated with specific renal diseases histologically noted on biopsy is extensive and heterogeneous, but most are not associated with the malignant clonal expansion characteristic of myeloma. These disorders are now described as MGRS.[2] Evidence supportive of alternative causes of the renal disease (most commonly diabetes or vascular disease), along with a period of observation, may clarify the significance of the M-protein, although renal and/or bone marrow biopsy is often required when diagnostic uncertainty persists.

NATURAL HISTORY

Most patients with renal impairment at presentation will show resolution of these predominantly functional changes with therapeutic measures that include withdrawal of nephrotoxins, rehydration, treatment of

TABLE 64.2 Differentiating Features of Myeloma Kidney and Other Monoclonal Immune Deposition Diseases

	Myeloma Kidney	Other MIDDs
Proteinuria	<3 g/l	>3 g/l
Hematuria	Rare	LCDD, occasional Amyloidosis, rare
Hypercalcemia	Common	Absent
Hypertension	Uncommon	LCDD, common Amyloidosis, uncommon
Cytopenias	Anemia very common Leukopenia and thrombocytopenia, occasional	Uncommon
Immunoparesis*	Very common	Uncommon
Lytic bone lesions	Very common	Absent
Renal impairment	Common	Common
Associated whole immunoglobulin	IgA, IgD, IgG	None
Type of light chain	Either	Amyloid λ > κ, LCDD κ > λ
Serum light chain elevation	>500 mg/l	<500 mg/l

IgA, Immunoglobulin A; *LCDD,* light chain deposition disease; *MIDDs,* monoclonal immune deposition disease.

TABLE 64.3 Renal Pathology in Patients With Myeloma

Histologic Finding	Prevalence (%)
Myeloma kidney (myeloma cast nephropathy)	30-50
Interstitial nephritis/fibrosis without cast nephropathy	20-30
Amyloidosis	10
Light chain deposition disease	5
Acute tubular necrosis	10
Other (urate nephropathy, tubular crystals, hypercalcemia, focal segmental glomerulosclerosis)	5

From references 19, 20, 53, and 54.

BOX 64.1 Histologic Features of Myeloma Cast Nephropathy

- Many eosinophilic, often fractured casts (medullary portion of the distal nephron predominantly)
- Intratubular and interstitial macrophages and giant cells in response to casts
- Interstitial inflammation, fibrosis, tubular atrophy, crystalline inclusions
- Minimal glomerular abnormality
- Minimal or no vascular changes

hypercalcemia, treatment of sepsis, and reduction in LC load with chemotherapy. Response to treatment with improvement in renal function is associated with improved clinical outcomes.[30] Reversibility occurs more frequently with lesser degrees of initial renal impairment, lower LC excretion and presentation with hypercalcemia. Although renal function improves in the majority of patients, approximately 10% of patients presenting with renal impairment at diagnosis may require dialysis. Before the introduction of modern chemotherapy strategies, patients requiring dialysis had reported rates of recovery of renal function as low as 5% to 15%. However, the introduction of specific LC reduction strategies has increased renal recovery in up to 80% of patients if a significant reduction in the FLC level is achieved by day 21, with improvement in renal function and independence from dialysis being associated with improved patient outcomes.[31,32]

TREATMENT

There are three key issues in the management of MCN. The first is to suspect and diagnose myeloma in the differential diagnosis of AKI. The inclusion of serum FLC measurement for routine evaluation of otherwise unexplained AKI in the appropriate clinical circumstances is essential. This is because renal injury in myeloma is directly related to FLC excess and the increased sensitivity and specificity of FLC measurement, along with its rapid availability, may implicate or refute myeloma as a likely diagnostic possibility days in advance of standard tests (SPE/IFE) or renal biopsy. Early diagnosis is crucial to allow implementation of the second strategy, which is to prevent or reverse oliguria by rapid identification and management of possible contributing factors to renal impairment, which are present in around 50% of patients. Hypercalcemia, sepsis, and nonsteroidal antiinflammatory agents (NSAIDs) are the most common precipitants. Intravenous volume expansion is helpful to increase glomerular filtration, reduce single-nephron LC concentration, and increase tubular flow. The use of furosemide to promote diuresis should be avoided because it may favor cast formation. There is no clinical evidence of the superiority of volume expansion with sodium bicarbonate over sodium chloride, although prevention of urinary acidification is in theory desirable and in severe renal failure may be necessary for management of metabolic acidosis. The maintenance of a high fluid intake (3 liters/day) with water after initial volume correction and restoration of urine output with intravenous crystalloid is recommended to maintain high urine flow rates.

The third key requirement is the rapid reduction of FLC in the serum by chemotherapy. The immediate commencement of high-dose dexamethasone 40 mg/day is recommended, because plasma cells are highly responsive to corticosteroids, which induce rapid apoptosis and lowering of LC concentration. The addition of newer chemotherapy strategies (see later discussion) with high immediate LC lowering effects in combination with corticosteroids is critical to achieving a rapid response.[33] The routine addition of plasma exchange to conventional treatment did not improve either recovery from renal failure or patient survival.[34] The large volume of distribution of LC (which freely cross cell membranes) is not well suited to plasma exchange, and its role is controversial.[35,36] The use of a Polyflux dialysis membrane (HCO1100, Gambro) with a high cut-off of molecular weight up to 50 kDa, in conjunction with chemotherapy, was shown to be associated with a reversal of renal failure associated with the rapid reduction in circulating FLC in patients with cast nephropathy.[32,37,38] The benefit and role of high cut-off dialysis is still controversial and two small controlled trials did not confirm an independent benefit when combined with bortezomib chemotherapy.[38a,38b] A suggested algorithm for management of myeloma with AKI is shown in Fig. 64.5.

Chemotherapy

Although myeloma is incurable, chemotherapy will induce clinical improvement by control of the underlying disease in most patients. Bortezomib, a reversible proteasome inhibitor whose clearance is independent of renal function, has been successfully and safely used in

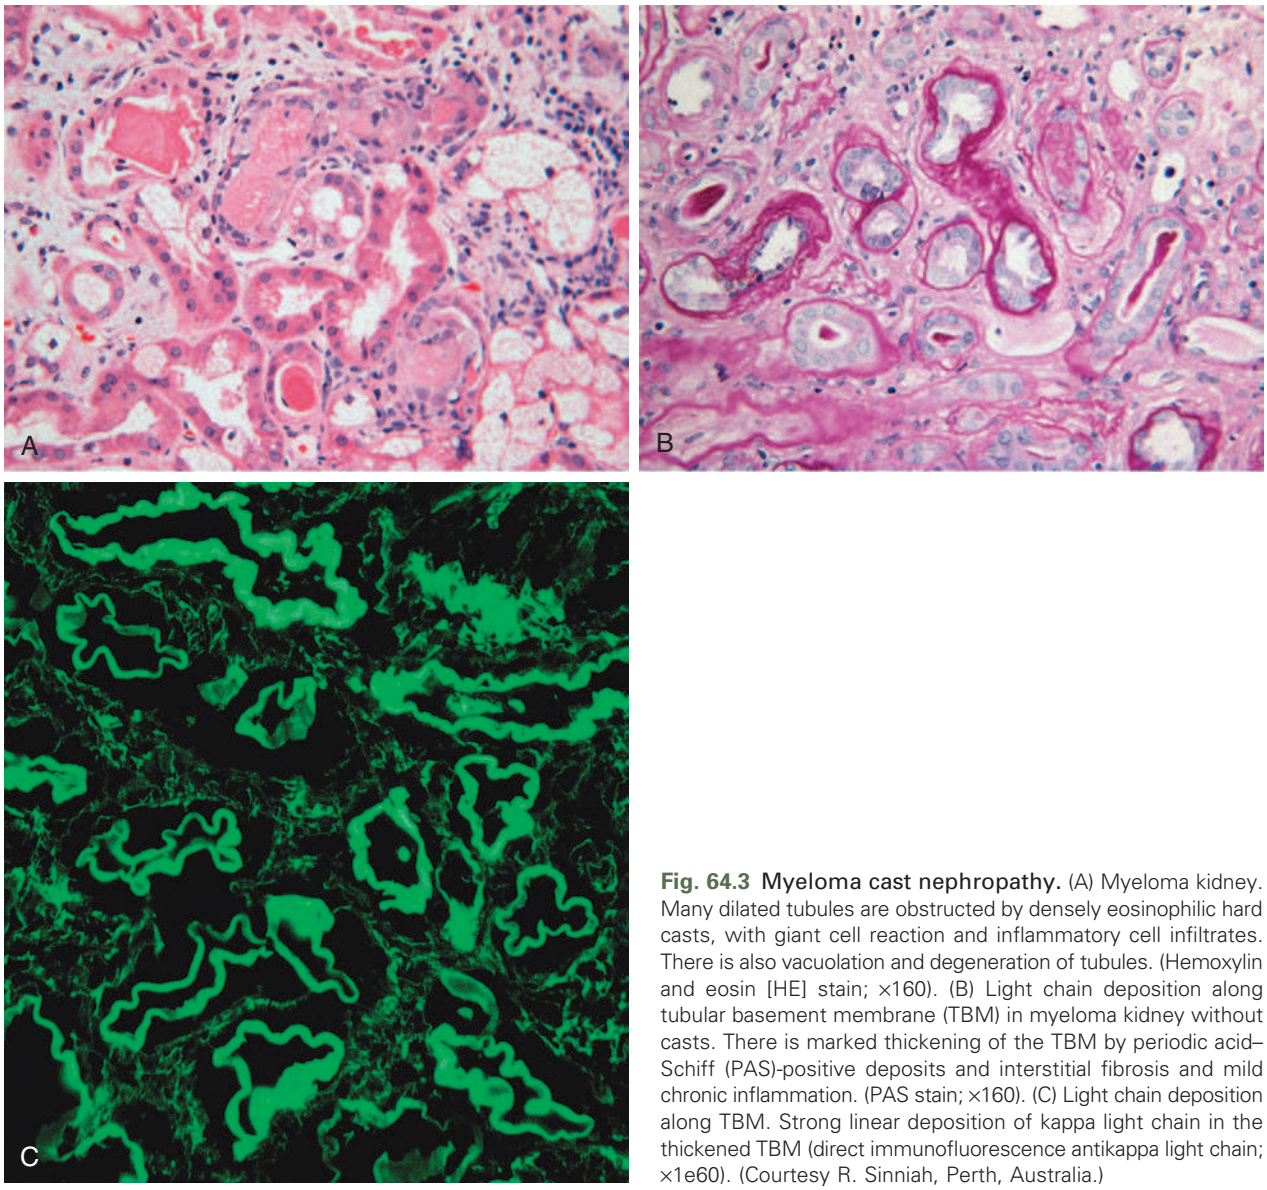

Fig. 64.3 Myeloma cast nephropathy. (A) Myeloma kidney. Many dilated tubules are obstructed by densely eosinophilic hard casts, with giant cell reaction and inflammatory cell infiltrates. There is also vacuolation and degeneration of tubules. (Hemoxylin and eosin [HE] stain; ×160). (B) Light chain deposition along tubular basement membrane (TBM) in myeloma kidney without casts. There is marked thickening of the TBM by periodic acid–Schiff (PAS)-positive deposits and interstitial fibrosis and mild chronic inflammation. (PAS stain; ×160). (C) Light chain deposition along TBM. Strong linear deposition of kappa light chain in the thickened TBM (direct immunofluorescence antikappa light chain; ×1e60). (Courtesy R. Sinniah, Perth, Australia.)

patients with severe degrees of renal failure and myeloma without significant toxicity and is the agent of choice for rapid reduction of LCs in combination with dexamethasone.[33] Bortezomib lowers the LC load by direct effects on plasma cells and also may protect renal proximal tubular cells by inhibiting activation of IL6 and NF-κB induced by LC endocytosis.[39] Immunomodulatory drugs such as thalidomide, lenalidomide, and pomalidomide are frequently used as consolidation/maintenance therapy or for relapsed disease in conjunction with dexamethasone. Agents used for management of myeloma in patients with AKI are summarized in Table 64.4. Autologous stem cell transplantation (ASCT) significantly extends survival and is now the treatment of choice for eligible patients.[33] Patients on dialysis are suitable for ASCT, although increased morbidity and mortality is recognized and are associated with renal recovery and freedom from dialysis.[40-42] For patients unsuited for ASCT, chemotherapy selection depends on comorbidity, and melphalan/prednisolone or dexamethasone/thalidomide may be useful. Close multidisciplinary management and discussion with hematology and oncology staff is required to individualize decision making because of the continuous advances in this area.

Infection and progression of disease remain the major impediments to survival, especially within the higher risk ESRD group. Median survival in recent ESRD series with conventional chemotherapy before ASCT was only 4 to 8 months; however, survival of up to 7 years is reported in selected cases of ESRD managed with ASCT and overall patient survival has improved with the advent of newer treatment strategies.[43] The improved overall management of myeloma with prolonged survival of patients will increase the referral of patients with relapsed and treatment-refractory disease presenting with MCN. The management of this patient group is challenging and must be individualized based on overall prognosis and potential for salvage chemotherapy and likelihood of benefit from dialysis.

Adjunctive Therapies

Patients with CKD/ESRD and myeloma respond to erythropoiesis-stimulating agents, and these should be used along with other hematopoietic agents, including granulocyte colony-stimulating factor (G-CSF) as required, although early in the disease frequent transfusion may be necessary.[44] Intravenous bisphosphonates rapidly correct hypercalcemia

TABLE 64.4 Chemotherapeutic Drugs Used in Myeloma and Renal Failure

Class	Agent	Route of Administration	Dose Reduction for CrCl <30 ml/min/1.73 m^2	Side Effects
Corticosteroids	Dexamethasone, Prednisone	PO/IV	None	Standard
Alkylating agents	Melphalan	PO/IV	Yes	Bone marrow suppression, infection
	Cyclophosphamide	PO/IV	No	
Immunomodulatory drugs	Thalidomide	Oral	No	Neuropathy, venous thrombosis, hyperkalemia, cytopenias
	Lenalidomide	Oral	Yes	
	Pomalidomide	Oral	Uncertain	
Proteasome inhibitors	Bortezomib	IV/SC	None	Neuropathy and cytopenias
	Carfilzomib	IV	No	
	Ixazomib	PO	Suggested	

CrCl, Creatinine clearance; *IV,* intravenously; *PO,* orally.

and are preferred to furosemide (which may aggravate tubular LC injury) and in the longer term reduce bone fracture.[45] However, there are several reports of toxicity (acute tubular necrosis, proteinuria) with full dose and/or rapid infusion of pamidronate and zoledronic acid; the use of reduced doses (pamidronate 30 to 60 mg, zoledronic acid 4 mg) and slower infusion rates are recommended.[46,47] Alternatively, bisphosphonates could be avoided in patients with an eGFR less than 30 ml/min/1.73 m^2 by using denosumab to manage hypercalcemia.[48] Replacement of profound immunoglobulin deficiency with regular intravenous immunoglobulin (IVIG) has been proven to reduce infectious complications in stable treated myeloma patients but is not widely adopted although recommended.[49] Caution is required to avoid further AKI because of the hyperosmolarity of IVIG, because renal impairment and diabetes represent known risk factors for this complication.[50]

DIALYSIS AND TRANSPLANTATION

Where renal replacement therapy is required long-term, both hemodialysis and peritoneal dialysis have been successfully used and there are no data to indicate that outcome is influenced by dialysis modality.

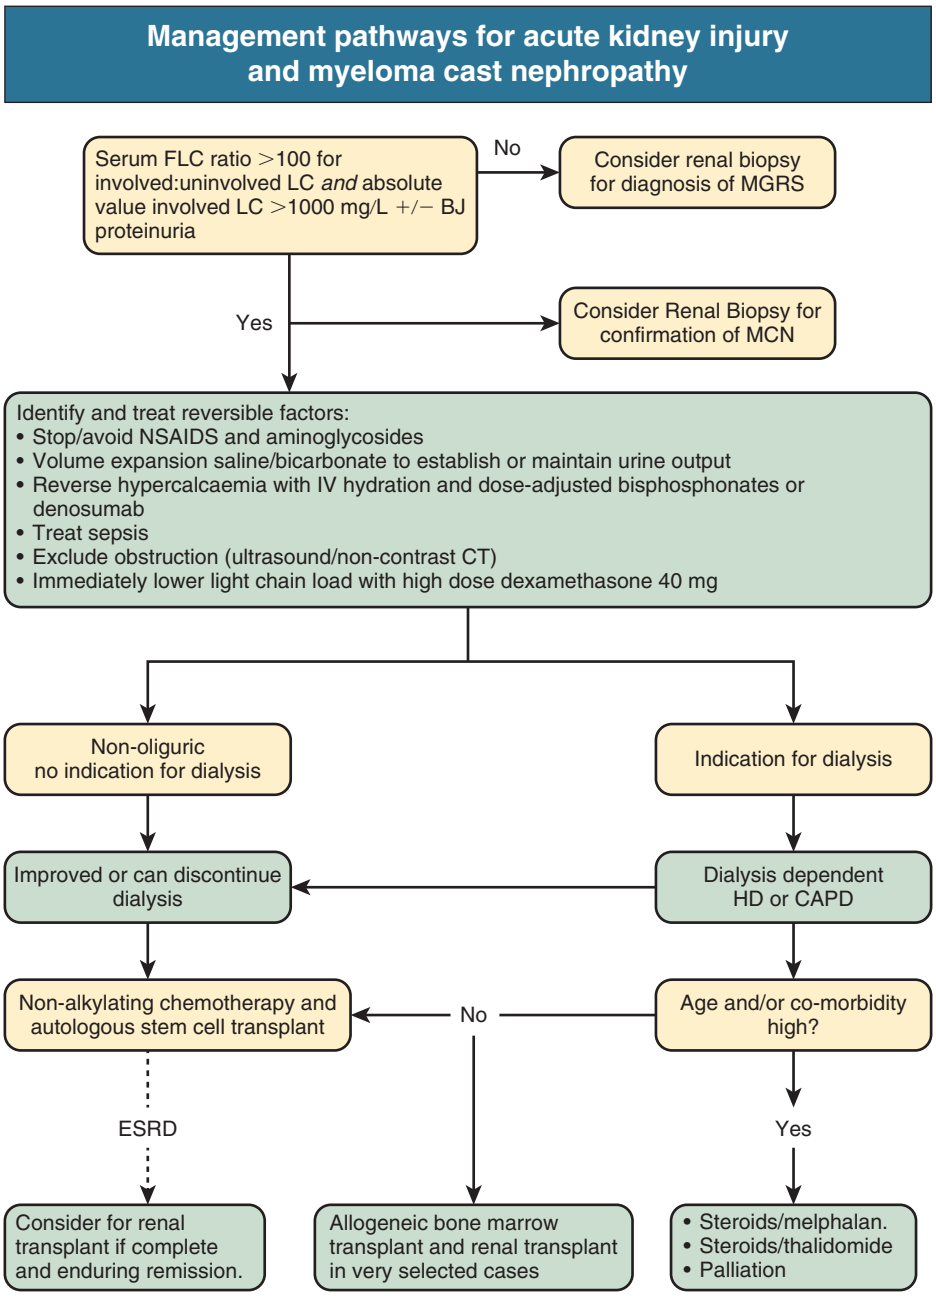

Fig. 64.5 Management pathways for acute kidney injury and multiple myeloma. *BJ,* Bence Jones; *CAPD,* continuous ambulatory peritoneal dialysis; *CT,* computed tomography; *ESRD,* end-stage renal disease; *FLC,* free light chain; *HD,* hemodialysis; *IV,* intravenous; *LC,* light chain; *MCN,* myeloma cast nephropathy; *MGRS,* monoclonal gammopathy of renal significance; *NSAIDs,* nonsteroidal antiinflammatory drugs.

Choice of long-term therapy requires individual assessment of patient circumstances. Aggressive measures to reduce the risk for systemic infection (antibiotic catheter locking solutions; mupirocin at exit sites; IVIG replacement) should be routinely considered because initially central venous catheters are often required for dialysis, plasma exchange, and chemotherapy. The timing of arteriovenous fistula placement requires an individualized risk assessment because it may be several months before irreversibility of renal failure or a response to chemotherapy is proven. Renal transplantation has a high risk for disease recurrence in the allograft and patient mortality, and given the incurability of the disease has rarely been appropriate.[51] Allogeneic bone marrow and renal allograft transplant have been reported, demonstrating the ability to induce allograft tolerance in haploidentical pairs.[52] This treatment is limited in availability and is not suitable for the majority of patients. The use of renal transplant after successful induction therapy and ASCT is unknown but may be suitable for younger patients when disease remission by standard criteria and normalization of the serum FLC ratio is achieved.

SELF-ASSESSMENT QUESTIONS

1. Kidney injury in patients with myeloma is most usually due to an excess of which of the following?
   A. Calcium
   B. Uric acid
   C. Light chains
   D. Immunoglobulins
   E. β_2-Microglobulin
2. What is the most common histologic lesion noted in patients with acute kidney injury and myeloma?
   A. Amyloidosis
   B. Light chain deposition disease (LCDD)
   C. Cast nephropathy
   D. Urate nephropathy
   E. Tubular crystals
3. In addition to corticosteroids, which therapy should be commenced urgently for the management of myeloma cast nephropathy?
   A. Vincristine
   B. Adriamycin
   C. Melphalan
   D. Cyclophosphamide
   E. Bortezomib
4. A 72-year-old man has a 3-month history of back pain and is managed with nonsteroidal antiinflammatory agents. He presents with anemia, hypercalcemia, and acute kidney injury. You suspect myeloma. What is the most appropriate investigation to rapidly confirm the diagnosis?
   A. Urine Bence Jones protein
   B. Serum protein electrophoresis
   C. Serum immunoglobulins
   D. Serum free light chains
   E. Renal biopsy

Onconephrology
Kidney Disease in Cancer Patients

Ala Abudayyeh, Mark A. Perazella

CANCER AND KIDNEY DISEASE

Malignant diseases are commonly associated with acute and chronic kidney disease (Box 65.1), which in turn increase morbidity and mortality in cancer patients.[1-3] Rapid advancements in oncology over the past two decades have turned many previously fatal cancers into chronic diseases. This relates mainly to recognition of gene mutations in various malignancies that are prime targets of anticancer therapies and using drugs to leverage the immune system for killing tumor cells. Cancer therapy with tried and true chemotherapeutic agents as well as targeted agents, immunotherapies, cytotoxic T cell therapies, and stem cell transplantation underpins this transition. However, these positives come with a price, including acute and chronic kidney disease. Nephrologists have been inundated with information on the nephrotoxicity of new drugs as well as the need to manage chronic kidney disease (CKD) in cancer survivors. An increased knowledge gap for many clinicians providing kidney care for these patients and the need for targeted education in this area has fueled the birth of onconephrology, an area of subspecialization within nephrology.

ACUTE KIDNEY INJURY

Acute kidney injury (AKI) is a common complication in cancer patients, particularly in those who are hospitalized or admitted to the intensive care unit (ICU). In these settings, AKI is associated with increased lengths of stay and higher costs. The 1-year risk for AKI as defined by RIFLE. *Risk* in a large Danish study of incident cancer patients was 17.5%.[1] The 1-year risk for more severe AKI, defined as the *Injury* and *Failure* categories, was 8.8% and 4.5%, respectively. Moreover, the 5-year risks for the *Risk, Injury,* and *Failure* AKI categories were even higher, at 27%, 14.6%, and 7.6%, respectively. AKI incidence was highest in patients with renal cell cancer, liver cancer, multiple myeloma, and leukemia. Among 9613 cancer patients with any AKI stage, 5.1% required renal replacement therapy (RRT) within 1 year of AKI onset. Unsurprisingly, older patients were most heavily represented in this analysis. In patients admitted to a comprehensive cancer center, AKI was 12%, nearly threefold higher than most noncancer settings, and was associated with worse clinical outcomes.[4] AKI developed in 55% of these cancer patients after being in the hospital for at least 48 hours.[4]

Critically ill cancer patients are at even higher risk to develop AKI than critically ill patients without cancer. Of 288 patients admitted to a cancer-focused ICU from 2006 to 2008, 54.1% developed AKI.[5] RIFLE *Risk* category occurred in 33.3% of patients, and the *Injury* and *Failure* categories each developed in 10.4% of patients. In addition to an increased risk for AKI, critically ill cancer patients have a higher incidence of RRT-requiring AKI compared with patients without cancer. Depending on AKI definition employed and underlying case-mix, 13% to 42% of critically ill patients with cancer may develop AKI and 8% to 60% require RRT.[6] Those with hematologic malignancies, myeloma, and septic shock are at highest risk to develop AKI.

Causes of hospital-acquired AKI in cancer patients include prerenal, intrarenal, and postrenal AKI (see Chapter 69). Risk factors for AKI in cancer patients includes typical comorbidities such as underlying diabetes mellitus and CKD, as well as exposure to radiocontrast, chemotherapy, and antibiotics.[4] It is therefore critical to identify at-risk cancer patients to allow prophylactic measures. This will allow clinicians to avert AKI and improve clinical outcomes for this fragile group.[4]

Prerenal Acute Kidney Injury

Nearly one third of AKI in cancer patients is prerenal and results from volume depletion from chemotherapy-induced nausea, vomiting, and diarrhea; chemotherapy-associated hypoalbuminemia contributes to the reduction in effective plasma volume and to compromised renal perfusion. Extracellular volume depletion as a result of third-spacing, as in malignant ascites or pleural effusion, or insensible losses from neutropenic fever also can lead to prerenal AKI. Abdominal compartment syndrome from tense ascites can lead to AKI from renal underperfusion.

Intrarenal Acute Kidney Injury

Intrarenal AKI is one of the most common forms of renal injury in cancer patients. The cause is often multifactorial (Chapter 69). Several chemotherapeutic agents and other nephrotoxic medications commonly used in cancer patients may cause toxic acute tubular necrosis (ATN).

BOX 65.1 Kidney Disease Associated With Common Cancers and Cancer Treatments

Leukemia

Common: Acute kidney injury (AKI) from sepsis, volume depletion, drug toxicity

Rare: Infiltrative disease, glomerulonephritis (GN), AKI from tumor lysis syndrome (TLS) and leukostasis

Multiple Myeloma

Common: Cast nephropathy, AKI from volume depletion and drug toxicity

Rare: Amyloidosis, light chain deposition disease (LCDD), Fanconi syndrome, AKI from hypercalcemia, C3 glomerulopathy, proliferative GN with monoclonal immunoglobulin deposits (PGNMIgD)

Lymphoma

Common: AKI from TLS and volume depletion

Rare: Obstructive uropathy, infiltrative disease, minimal change disease (Hodgkin's), membranoproliferative GN (non-Hodgkin's lymphoma)

Renal Cell Carcinoma

Common: Anti–vascular endothelial growth factor toxicity, postnephrectomy chronic kidney disease

Rare: Obstructive uropathy, membranous GN

Lung and Head and Neck Cancer

Common: Platinum toxicity

Rare: Syndrome of inappropriate antidiuretic, membranous GN

Genitourinary and Gynecologic Cancers

Common: Obstructive uropathy

Rare: Platinum toxicity

Kidney Disease in Commonly Used Cancer Treatments

Common: AKI, tubulopathy and CKD from chemotherapeutic agents (e.g., cisplatin, ifosfamide, methotrexate), complications of conditioning regimen and hemopoietic stem cell transplantation, and from toxicities of targeted anticancer therapies (includes proteinuria, thrombotic microangiopathy [TMA] and hypertension)

Rare: Radiation nephritis, TMA, GN.

Obstructive Uropathy

Common: Genitourinary and gynecologic cancers

Rare: Lymphoma

Cancer patients with sepsis are also at risk to develop severe ischemic ATN.[7] High and repetitive doses of chemotherapy, concurrent with other nephrotoxic agents, may increase AKI risk. Drug-induced acute interstitial nephritis (AIN) is a common cause of AKI in cancer patients, and exposure to the new immunotherapies and targeted therapies is increasing the prevalence of AIN.[8]

Postrenal Acute Kidney Injury

Genitourinary cancers may cause urinary tract obstruction and postrenal AKI. Cancers commonly associated with urinary tract obstruction are bladder, prostate, cervix, and ovary. Among these, pelvic irradiation or urogenital surgery procedures for cancer is more likely to cause urinary obstruction. Cervical and ovarian cancers with metastatic spread involving the ureters or bladder are associated with postrenal AKI. In hematopoietic stem cell transplantation (HSCT) recipients with BK infection, ureteral obstruction is a common cause of renal impairment and bulky retroperitoneal adenopathy associated with lymphomas may cause obstruction.

CHRONIC KIDNEY DISEASE

CKD is also a complication of many cancers and their therapy, and like AKI, is also associated with increased morbidity and mortality. Preexisting CKD from underlying comorbidities is highly prevalent in patients with various types of malignancy. Additionally, CKD may develop after multiple episodes of AKI, after nephrectomy for renal cancer, and from nephrotoxic medications that cause glomerulosclerosis and tubulointerstitial fibrosis. The Renal Insufficiency and Anticancer Medications (IRMA)-1 and -2 studies observed that 52.9% (IRMA-1) and 50.2% (IRMA-2) of patients with active malignancy had an estimated glomerular filtration rate (eGFR) less than 90 ml/min/1.73 m^2, respectively.[9] In this group, the prevalence of stage 3 CKD was 12% (IRMA-1) and 11.8% (IRMA-2), whereas stage 4 CKD was rare in these two studies (0.9% and 0.7%, respectively). In an Australian cohort with various cancers (n = 4077), an eGFR less than 60 ml/min/1.73 m^2 was observed in 30% of patients and 8.3% had an eGFR less than 45 ml/min/1.73 m^2.[10] In a cohort of Chinese patients with cancer, stage 3 CKD was noted in 12.8% (1051 of 8223) of patients.[11] The relatively common occurrence of CKD in many cancer patients has been confirmed in other studies.

The relationship between kidney disease and cancer appears to be bidirectional. Although there is an increase in CKD prevalence in cancer patients, both CKD and end-stage renal disease (ESRD) are risk factors for development of a number of malignancies[1] (see Chapter 88). In a retrospective cohort study of more than 1 million adults, lower eGFR was associated with an increased risk for renal cancer after adjustment for time-updated confounders. In addition, the adjusted hazard ratio was 2.28 (95% confidence interval [CI], 1.78-2.92) for eGFR less than 30 ml/min/1.73 m^2.[12] In patients with ESRD on dialysis, there is an increased risk for renal parenchymal cancer in patients with acquired renal cystic disease.

MORTALITY IN CANCER PATIENTS WITH KIDNEY DISEASE

The increased mortality associated with cancer-related AKI and CKD is related to a number of factors. AKI occurrence may require cessation of effective chemotherapeutic regimens, allowing unhindered tumor growth. Preexisting CKD may limit use of chemotherapeutic agents or promote underdosing of curative anticancer regimens. CKD and AKI may alter the bioavailability and/or safety profile of some anticancer drugs leading to use of suboptimal therapies. In addition, CKD and ESRD may impair immune surveillance, allowing cancers to grow and metastasize, especially when combined with insufficient drug dosing. It is also possible that anticancer agent nephrotoxicity is associated with worsening of preexisting CKD, which leads to increased all-cause mortality unrelated to cancer.

IMPORTANT MALIGNANCIES ASSOCIATED WITH KIDNEY DISEASE

Multiple Myeloma and Amyloidosis

Renal involvement occurs in about 50% of patients with myeloma but varies depending on the myeloma type[13] (see Chapter 64). Monoclonal light chain (LC) overproduction is commonly associated with kidney injury, with as many as 50% of patients requiring dialysis.[14] The LC type is also important; cast nephropathy and renal amyloidosis are common with lambda LCs, whereas severe proximal tubular injury causing Fanconi syndrome and LC deposition disease are common with kappa LCs. Cast nephropathy has been diagnosed in 41% of patients with myeloma and kidney disease.[15] Primary systemic (AL) amyloidosis

in patients with LC disease is another infrequent manifestation of myeloma (see Chapter 27). When amyloidosis complicates myeloma, it carries a grave prognosis. Renomegaly, gross proteinuria, and amyloid deposition are hallmarks of renal amyloidosis, and, based on autopsy studies, occurs in about 5% to 10% of patients with myeloma.[16]

Leukemia and Lymphoma

Various forms of kidney disease occur in patients with lymphoma and leukemia. Those admitted to an ICU had an AKI hazard ratio of 2.23 for AKI, compared with otherwise comparable patients without ICU admission.[17] In 200 patients with newly diagnosed high-grade lymphoma and leukemia, the incidence of RIFLE AKI was 68.5%, with 50% requiring RRT.[18] Possible causes of AKI in patients with leukemia and lymphoma include prerenal processes,[19] intrarenal causes such as ATN (especially from sepsis and nephrotoxic medications),[20] or postrenal causes such as mechanical obstruction from lymphadenopathy or retroperitoneal fibrosis.[21] Patients with leukemia or lymphoma commonly develop infiltrative disease of the kidney.[22] Most often, renal infiltration is asymptomatic or subclinical as noted in autopsy studies in which 34% of patients were found to have lymphomatous infiltration of the kidneys.[22] Leukemic or lymphoma cell infiltration is suggested by renomegaly on imaging (Fig. 65.1A), and urinalysis shows bland urine sediment and tubular proteinuria.[23] When AKI does occur, it is thought to be due to tubular compression and increased interstitial pressure from the massive malignant cell infiltration (see Fig. 65.1B).[24] Overproduction of lysozyme, which is a freely filtered cationic protein reabsorbed in the proximal tubule, may cause ATN and/or proximal tubular injury with full-blown Fanconi syndrome.[25] Intrarenal leukostasis may cause AKI in patients with acute myeloid leukemia (white blood cells >100,000 cells). Renal leukostasis is associated with reduced renal perfusion, blast aggregation within the renal microvasculature, and endothelial damage triggered by soluble cytokines. Emergent treatment with cytoreductive chemotherapy and leukopheresis is generally required.[26]

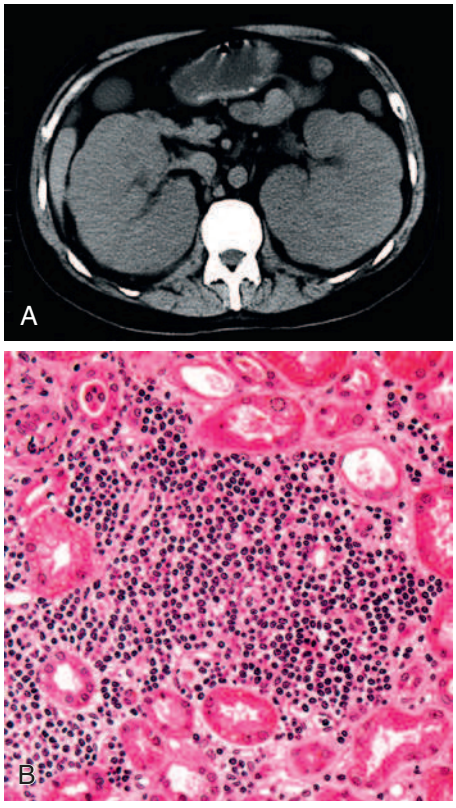

Fig. 65.1 (A) CT scan demonstrating renomegaly from lymphomatous infiltration of the kidneys. (B) Renal biopsy demonstrating low-grade B cell lymphoma cells within the renal parenchyma (Hematoxylin and eosin stain; ×400.)

ANTICANCER DRUGS AND KIDNEY DISEASE

Chemotherapeutic Agents

Oncologists generally assess kidney function before initiation of chemotherapeutic agents. Nevertheless chemotherapy-related nephrotoxicity has become an important area for the nephrologist. Understanding renal metabolism and excretion of these drugs is critical in ensuring efficacy while also avoiding toxicity. Nephrotoxicity associated with the more common chemotherapeutic drugs includes AKI primarily from ATN and AIN, as well as other metabolic perturbations (Table 65.1). However, emergence of targeted therapies and immunotherapies has been associated with an increase in various nephrotoxicities (Table 65.2).[27]

Immunotherapies

Immune Checkpoint Inhibitors

Leveraging the immune system to destroy cancer cells has become an attractive strategy for several different malignancies. Immune checkpoint inhibitors (ICIs) impair the checkpoints that function to suppress adaptive immune response and prevent autoimmunity. T cells possess surface receptors, such as programmed death-1 protein (PD-1) and cytotoxic T lymphocyte–associated antigen-4 (CTLA-4), which bind to their ligands on antigen-presenting cells, leading to T cell exhaustion. This normally prevents the development of autoimmunity. Tumor survival may be enhanced in malignancies that overexpress ligands that bind these inhibitory T cell receptors, thereby decreasing activated T cell infiltration into the tumor microenvironment and inhibiting antitumor T cell responses. To combat this, monoclonal antibody drugs that block ligand binding to PD-1 and CTLA-4 receptors were designed to facilitate T cell rescue and restore antitumor immunity. Ipilimumab, a fully human, immunoglobulin G1 (IgG)1 monoclonal antibody blocking CTLA-4; nivolumab, a fully human IgG4 antibody blocking the PD-1 receptor; and pembrolizumab, a humanized monoclonal IgG4-κ isotype antibody against PD-1, are the ICIs available in clinical practice. However, blocking immune checkpoints risks development of pathologic autoimmunity and end-organ injury, such as AIN. Twenty-six cases of AIN, some with granulomatous changes, have been described with the use of PD-1 receptor blockers.[8] Although some patients develop rash and eosinophilia, AKI is the only consistent clinical manifestation. A small number of cases have required RRT, but most respond to drug discontinuation and steroid therapy.

Interferon Therapy

Treatment with interferon (IFN) is associated with proteinuria secondary to glomerular injury that is primarily a podocytopathy.[28] Minimal change disease (MCD) was first described, but more recent reports describe collapsing and noncollapsing focal segmental glomerulosclerosis (FSGS). Nephrotic-range proteinuria and AKI are observed within weeks of commencing IFN therapy. Although proteinuria declines with IFN discontinuation, complete resolution is more common with MCD than with FSGS. Steroids are associated with complete remission in fewer than one third of patients with FSGS. IFN-related glomerular injury may be due to direct binding of IFN to podocyte receptors and alteration of normal cellular proliferation. Macrophage activation and skewing of the cytokine profile toward IL-6 and IL-13, which are possible permeability factors in MCD and FSGS, are also possible.

TABLE 65.1 Commonly Used Cancer Therapies Associated With Renal Toxicity

Tubular Injury	Glomerular Injury	Renal Vascular Injury
Acute Tubular Injury Platinums, zoledronate, ifosfamide, mithramycin, pentostatin, imatinib, diaziquone, pemetrexed, zoledronate	**Focal Segmental Glomerulosclerosis** Interferon (IFN) Pamidronate, tyrosine kinase inhibitors	**Thrombotic Microangiopathy** Bevacizumab (anti-VEGF monoclonal antibody)
Tubular Syndromes ***Renal Tubular Acidosis*** Ifosfamide, amphotericin, calcineurin inhibitors	***Minimal Change Disease*** IFN, pamidronate	**Tyrosine Kinase Inhibitors** Sorafenib, sunitinib, imatinib
Fanconi Syndrome Cisplatin, ifosfamide, azacitidine, diaziquone, imatinib, pemetrexed	***Proteinuria*** Sorafenib, sunitinib, vatalanib, axitinib	**Other Agents** Gemcitabine, mitomycin C, interferon-α, calcineurin inhibitors
Salt Wasting Cisplatin, azacitidine		
Magnesium Wasting Cetuximab, cisplatin, panitumumab		
Nephrogenic Diabetes Insipidus Cisplatin, ifosfamide, pemetrexed		
Acute Interstitial Nephritis Sorafenib, sunitinib, checkpoint inhibitors		
Crystalline Nephropathy Methotrexate, acyclovir, sulfa-based drugs		
Syndrome of Inappropriate Antidiuretic Hormone Cyclophosphamide, vincristine		

Targeted Therapies

Antiangiogenesis Therapy

The discovery that vascular endothelial growth factor (VEGF) is an important mediator of tumor growth and angiogenesis led to the development of drugs targeting this pathway for cancer therapy. However, VEGF is also an essential growth factor to maintain glomerular endothelial health. VEGF is secreted by podocytes and traverses the basement membrane, where it binds to VEGF receptors on endothelial cells and maintains glomerular endothelial cell integrity and filtration barrier function (Fig. 65.2). Anti-VEGF drugs (e.g., the monoclonal antibody bevacizumab) and drugs that inhibit tyrosine kinase (e.g., sunitinib) both block VEGF function. This leads to glomerular endothelial cell dysfunction and filtration barrier disruption, resulting in proteinuria, thrombotic microangiopathy, hypertension, and AKI.[29] Mild and asymptomatic proteinuria is common, and heavy proteinuria occurs in less than 10% of subjects.[30] Hypertension or aggravation of preexisting hypertension is common. The reported incidence varies between 17% and 80%.[31] Development of hypertension reflects efficacy of VEGF blockade therapy, perhaps explaining why bevacizumab-induced hypertension correlates with clinical outcomes.[32] Hypertension is managed with standard antihypertensive medications, although the use of angiotensin-converting enzyme inhibitors/angiotensin receptor blockers is preferable in patients with proteinuria. Renal side effects that develop with anti-VEGF therapy may require dose reduction or drug discontinuation.[30]

B-RAF Inhibitors

Malignant melanoma frequently has a B-RAF V600 mutation that can be effectively targeted by the selective B-RAF inhibitors vemurafenib and dabrafenib. Although effective anticancer agents, these drugs produce nephrotoxicity. A GFR decline at 1 and 3 months of therapy occurred in 15 of 16 patients, which was complicated by persistent kidney injury after 8 months of follow-up. Eight patients developed AKI after vemurafenib with ATN seen in 1 patient. AKI that was clinically suggestive of AIN was observed in 4 patients treated with vemurafenib with 3 of 4 patients recovering kidney function after drug discontinuation, although no biopsy data were available. Nearly 60% of 74 patients treated with vemurafenib developed AKI, primarily Kidney Disease: Improving Global Outcomes (KDIGO) stage 1, within 3 months of drug exposure.[33] Kidney biopsy revealed tubulointerstitial injury in 2 patients. Kidney function recovered within 3 months of B-RAF discontinuation. AKI and metabolic disturbances from B-RAF inhibitors have been described in the U.S. Food and Drug Administration Adverse Events Reporting System.[34] Although the mechanism of kidney injury is unknown, these drugs may interfere with the downstream MAPK pathway, increasing susceptibility to ischemic tubular injury.

Anaplastic Lymphoma Kinase Inhibitors

Anaplastic lymphoma kinase 1 (ALK-1) is a member of the insulin receptor tyrosine kinase family, for which small molecule inhibitors include crizotinib and ceritinib. Crizotinib is an effective agent for treatment of advanced ALK-positive non–small cell lung cancer and appears to be associated with two major issues, AKI and an increased risk for the development and progression of renal cysts.[35] In addition, this agent is also associated with development of peripheral edema and, rarely, electrolyte disorders. Crizotinib is associated with true and pseudo-AKI, the latter due to drug-induced reduced tubular creatinine secretion.

TABLE 65.2 Renal Toxicities Associated With Targeted Therapies

Drug Class	Renal Excretion	Most Frequent Renal Adverse Events	EVIDENCE FOR DOSE REDUCTION IN CKD		
			Mild/ Moderate*	Severe†	Dialysis
VEGF/VEGF-R–Targeting Agents					
Bevacizumab	No	Hypertension, proteinuria	No	No	No
Aflibercept	No	Hypertension, proteinuria	No	No	No
Sunitinib	16%	Hypertension, proteinuria	No	No	No
Pazopanib	<4%	Hypertension, proteinuria	No	No	No
Axitinib	23%	Hypertension, (proteinuria)	No	No	No
Other Multikinase Inhibitors					
Sorafenib	19%	Hypertension, proteinuria, hypophosphatemia	No	No	No
Regorafenib	19%	Hypertension, proteinuria, electrolyte disorders	No	No	No
Vandetanib	25%	Hypertension, proteinuria, AKI	No	Yes	No
Imatinib	13%	More renoprotective effects, AKI described	No	No	No
Mtor Inhibitors					
Everolimus	2%	Proteinuria, AKI, electrolyte disorders	No	No; suspend if AKI	No
Temsirolimus	4.6%	Proteinuria, AKI, electrolyte disorders	No	No; suspend if AKI	No
eGFR Inhibitors					
Gefitinib	<4%	Electrolyte disorders	No	No	No
Erlotinib	<9%	Electrolyte disorders	No	No	No
Afatinib	<5%	Electrolyte disorders	No	No	No
Cetuximab	No	Hypomagnesemia, other electrolyte disorders	No	No	No
Panitumumab	No	Hypomagnesemia, other electrolyte disorders	No	No	No
B-Raf Inhibitors ± MEK Inhibitors					
Vemurafenib	1%	AKI (tubular necrosis?)	No	No	Possible (risk for arrhythmia)
Dabrafenib	23%	Hypophosphatemia, (granulomatous nephritis?)	No	No	No
Trametinib	<20%	Hypertension, hyponatremia (with dabrafenib)	No	No	No
ERBB2-Targeting Agents					
Trastuzumab	No	Hypertension, AKI (with cisplatin)	No	No	No
Pertuzumab	No	No issues	No	No	No
Lapatinib	2%	No issues	No	No	No
Trastuzumab emtansine	<5%	Hypokalemia	No	No	No
Antibodies Against CTLA-4					
Ipilimumab	No	Autoimmune nephritis, (potential drug reaction with eosinophilia and systemic symptom syndrome)	No	No	No
Other Agents					
Crizotinib	No	Reduction of eGFR (tubular necrosis?), renal cysts	Possible, with caution	Possible, with caution	No
Catumaxomab	No	No issues	No	No	No

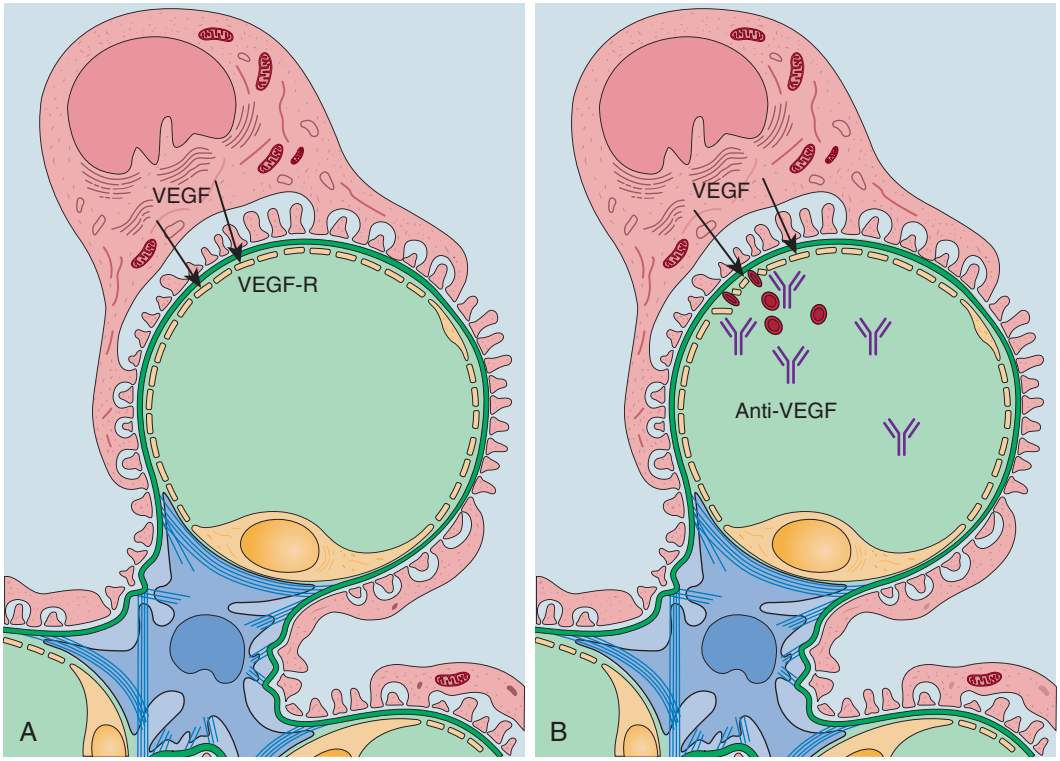

Fig. 65.2 Anti–vascular endothelial growth factor *(VEGF)* therapy and thrombotic microangiopathy. (A) Under normal circumstances, VEGF is produced constitutively by the podocyte and crosses the glomerular basement membrane to bind VEGF receptors *(VEGF-R)* on the endothelial cells, where it maintains endothelial health and integrity. (B) When *anti-VEGF* antibody is administered, the antibody binds to the VEGF and blocks binding to the endothelial cell, resulting in endothelial cell injury and thrombotic microangiopathy.

METABOLIC COMPLICATIONS

Tumor Lysis Syndrome

High-grade lymphomas, acute leukemias, and other rapidly proliferating tumors are prone to tumor lysis syndrome (TLS). Among these, patients with Burkitt lymphoma are particularly at risk. Volume depletion, hypotension, large primary or metastatic tumor load, preexisting CKD, and concurrent exposure to potential nephrotoxic agents are common risk factors for TLS-induced AKI. Cell lysis leads to hyperuricemia, hyperkalemia, hyperphosphatemia, and acidosis causing AKI, primarily from urate crystal deposition in the tubules. Hyperuricemia may also play a role in TLS-associated AKI independent of crystals, possibly as a result of inflammation and endothelial dysfunction.[36] Myocardial deposition of calcium-phosphate crystals may contribute to the development of life-threatening arrhythmias. TLS prevention in high-risk patients involves hydration to maintain a high urine output (>100 ml/h) and allopurinol or rasburicase to reduce hyperuricemia. Rasburicase, which degrades uric acid to water-soluble allantoin, more effectively lowers uric acid levels but has not been shown to be superior to allopurinol for prevention of TLS-associated AKI.[37] Early dialysis should be considered when progressive AKI develops in patients with TLS who will be unable to handle the excessive cellular contents (e.g., potassium, phosphate) to prevent life-threatening electrolyte abnormalities. Furthermore, accumulation of tumor lysis products can aggravate renal injury. In patients with severe TLS and oliguric AKI, continuous RRT (CRRT) may be required to control hyperkalemia and persistent hyperphosphatemia (Fig. 65.3).

Common Electrolyte Disorders

Although electrolyte abnormalities are common in cancer patients, factitious laboratory findings may occur. Paraproteins, especially IgM, may cause assay interferences with several tests that are mostly due to their physical interferences with reagents, reactions, or both.[38] Pseudohyperkalemia secondary to in vitro release of potassium from cells may occur in patients with acute leukemia, chronic lymphocytic leukemia, and chronic myeloproliferative disorders. When factitious values are suspected, careful collection and prompt analysis of repeat samples are required.

Hyponatremia is the most common electrolyte abnormality and affects nearly 50% of hospitalized cancer patients.[39,40] Hyponatremia is frequently due to the syndrome of inappropriate antidiuretic hormone (SIADH), which occurs with many malignancies, including lung cancers, head and neck cancers, and some hematologic cancers.[41] Nausea, pain, and analgesics such as morphine and its derivatives, antidepressants, and several chemotherapeutic agents may cause hyponatremia either by increasing arginine vasopressin secretion or enhancing its effect. Although SIADH is common, one third of cancer cases develop hyponatremia from volume depletion (Chapter 70), which is responsive to normal saline repletion. Treatment with fluid restriction is difficult in cancer patients with SIADH, especially in subjects receiving chemotherapy or HSCT, because these procedures require high intravenous fluid intake. Oral sodium chloride (titrated to target sodium correction) and loop diuretics are sometimes effective in those not receiving large intravenous fluid volumes, whereas V2-receptor antagonists may be an option to correct hyponatremia in such patients.[41] Hypernatremia is much less frequent compared with hyponatremia (3% vs. 47%) but is

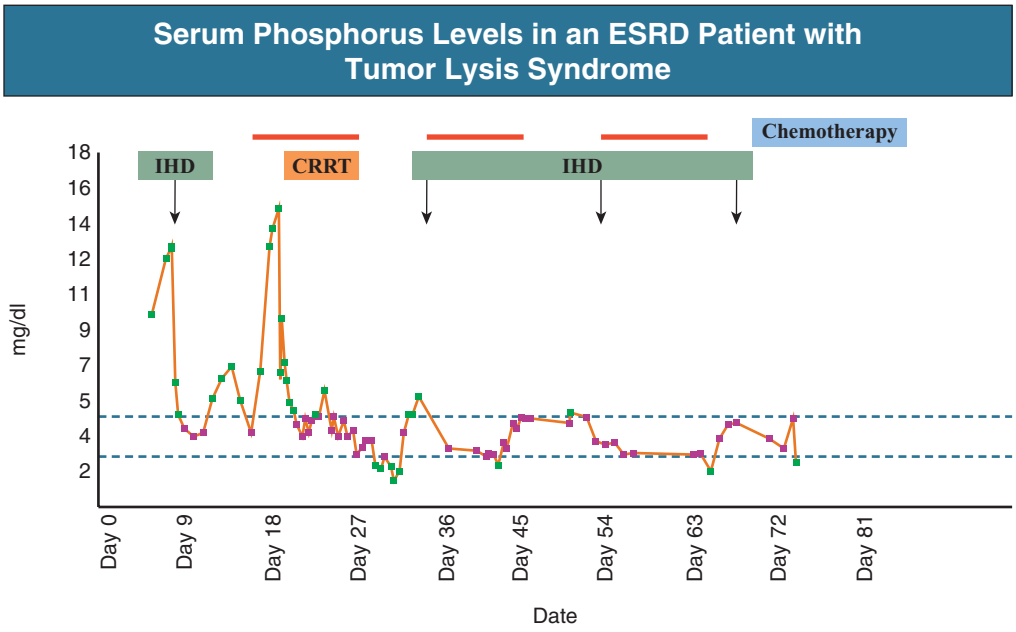

Fig. 65.3 Serum phosphorous levels in a patient with end-stage renal disease (ESRD) with tumor lysis syndrome being treated with continuous renal replacement therapy *(CRRT)* or intermittent hemodialysis *(IH)* *(arrows)*.

associated with higher mortality and longer hospital stays.[42] Most hypernatremia occurs in the hospital and is observed primarily in critically ill leukemia and HSCT patients who are receiving loop diuretics.

Other common electrolyte abnormalities in cancer patients, especially those who are receiving chemotherapy, include hypokalemia, hypomagnesemia, and hypophosphatemia. Nausea/vomiting, diarrhea, and poor nutrition from chemotherapy account for many of these abnormalities. However, severe abnormalities are usually due to drug-induced Fanconi syndrome. Ifosfamide and cisplatin are the most common agents, but kappa LC myeloma also can cause this syndrome. Cetuximab causes hypomagnesemia that occasionally can be severe. In health, epidermal growth factor (EGF) binds its receptor (EGFR) and stimulates distal tubular magnesium reabsorption. Cetuximab (EGFR antibody) competes with EGF for its receptor, thereby inhibiting normal reabsorption of luminal magnesium and causing hypermagnesiuria.

Hypercalcemia is common in patients with advanced cancer with bone metastasis and heralds a poor prognosis. Hypercalcemia is frequently associated with multiple myeloma and can be the presenting feature. Several mechanisms may underlie tumoral hypercalcemia such as elevated parathyroid hormone (PTH)-related peptide (PTHrP) levels associated with lung cancer, ectopic vitamin D in certain lymphomas, or tumor resorption of bones as in advanced cancer (Chapter 10). Treatment of hypercalcemia mandates vigorous intravenous fluid administration (Box 65.2). Although corticosteroids (for myeloma and vitamin D–related hypercalcemia) and calcitonin are useful, persistent hypercalcemia often requires bisphosphonate therapy for long-term control. Rarely, hemodialysis with low calcium dialysate alone is sufficient to control severe hypercalcemia in symptomatic patients. Use of bisphosphonates, especially zoledronate and pamidronate, can be complicated by AKI and collapsing FSGS, respectively. Ibandronate may be a less nephrotoxic option.[43]

BOX 65.2 Management of Cancer-Related Hypercalcemia

1. General measures: Intravenous fluids followed by loop diuretics if hypervolemia.
2. Administer calcitonin (4 IU/kg SQ every 6 to 12 hours based on calcium response), corticosteroids (prednisone 20 to 40 mg/day PO depending on cause) or both for acute and short-term calcium control.
3. If patient severely symptomatic and with reduced urine output and impaired renal function, consider dialysis with low bath calcium.
4. Start bisphosphonates (pamidronate 30 to 90 mg IV over 2 to 4 hours depending on GFR; zoledronate 4 mg IV over 15 minutes, dose adjusted for GFR, contraindicated for GFR <30 ml/min) for longer term hypercalcemia control (adjust for renal dysfunction).
5. Treat the underlying malignancy.
6. For bone resorption–associated hypercalcemia: Humanized anti-RANKL antibody (denosumab 60 to 120 mg SQ) maybe more effective than bisphosphonates (under evaluation)
7. For PTHrP-related hypercalcemia: Humanized monoclonal antibody against human PTHrP may be more effective than bisphosphonates (under evaluation)

GFR, Glomerular filtration rage; *IU,* international units; *IV,* intravenously; *PO,* orally; *PTHrP,* parathyroid hormone–related protein; *RANKL,* receptor activator of nuclear factor kappa-B ligand; *SQ,* subcutaneously.

CANCER-RELATED GLOMERULONEPHRITIS

Cancer-related glomerulonephritis is a relatively rare but important entity in patients with certain malignancies. Proteinuria or nephrotic syndrome, rarely, can be the manifesting feature of cancer. Membranous nephropathy (MN) (Chapter 20) is the most common glomerular pathology associated with solid tumors. In the largest series of 240 patients with biopsy-proven MN, a cancer diagnosis was noted in 10%.[44] Common cancers associated with MN are lung, gastric, colon, and renal carcinomas, but several other solid tumors, such as prostate and breast cancer, are also linked (Table 65.3). In Hodgkin disease, the most common lesion is MCD (Chapter 17), possibly related to tumor-related T cell dysfunction. Chronic lymphocytic leukemia is commonly associated with membranoproliferative glomerulonephritis (Chapter 21), especially

in the presence of cryoglobulinemia. HSCT is associated with membranous nephropathy, and, rarely, MCD can be a manifestation of chronic graft-versus-host disease (GVHD).[45] Use of IFN-α, anti-VEGF therapies, and bisphosphonates in cancer therapy are associated with various glomerular diseases and thrombotic microangiopathy.[46]

TABLE 65.4 Causes of Acute Kidney Injury and Other Kidney Disease in Relation to the Timing of Hemopoietic Stem Cell Transplantation

Before and hours after HSCT	Tumor lysis syndrome from conditioning regimen (rare) Systemic toxicity from conditioning regimen (e.g., volume depletion [common]) DMSO toxicity from hemolysis, acidosis, and pigment nephropathy (rare)
Days to weeks after HSCT	Prerenal AKI from volume depletion, AKI from neutropenic-sepsis and drug toxicity (common) AKI related to engraftment syndrome (rare)
Weeks to months after HSCT	AKI from sepsis, volume depletion, drug and radiocontrast toxicity (common) AKI from sinusoidal obstruction syndrome of the liver, graft-versus-host disease (GVHD), thrombotic microangiopathy, and BK virus nephropathy (rare)
Months to years after HSCT	CKD from previous AKIs, continuous use of calcineurin inhibitors especially with GVHD, and from preexisting cancer, such as myeloma (common)

AKI, Acute kidney injury; *CKD,* chronic kidney disease; *DMSO,* dimethyl sulfoxide; *GVHD,* graft-versus-host disease; *HSCT,* hemopoietic stem cell transplantation.

HEMATOPOIETIC STEM CELL TRANSPLANTATION

Among the types of HSCT (see Chapter 111), the myeloablative allogeneic form requires higher doses of irradiation, chemotherapy, or a combination and carries the highest risk for developing AKI (up to 70%). AKI can have multiple causes in HSCT recipients and is associated with poor clinical outcomes in patients receiving any form of HSCT.[47] In addition to usual causes of AKI (volume depletion, intravenous contrast, sepsis, and drug toxicity), there are several specific renal syndromes that should be suspected based on the length of time since they developed after HSCT (Table 65.4).

CANCER THERAPY IN CHRONIC KIDNEY DISEASE AND END-STAGE RENAL DISEASE

Impaired kidney function complicates the selection and administration of chemotherapy and may lead to unduly high doses and drug accumulation.[48] Careful dosing and dialysis timing are critical because overdosing can aggravate systemic toxicities, whereas underdosing can lead to ineffective cancer treatment. Common risk factors for chemotherapy-induced nephrotoxicity include volume depletion, hypoalbuminemia, metabolic derangements, older age, presence of diabetes and other comorbid conditions, underlying AKI or CKD, presence of sepsis, and concomitant use of other potential nephrotoxins. Therefore optimizing kidney function in those with CKD before chemotherapy (correcting volume status, renal adjustment of chemotherapeutic doses, removing potential nephrotoxic agents, addressing tumor lysis early) can reduce risk for AKI and chemotoxicity. Moreover, administration of platinum compounds requires dose adjustments and timing with dialysis. Other commonly used agents for cancer treatment that need dose adjustment for GFR and dialysis are melphalan, methotrexate, pemetrexed, capecitabine, hydroxyurea, fludarabine, etoposide, irinotecan, and

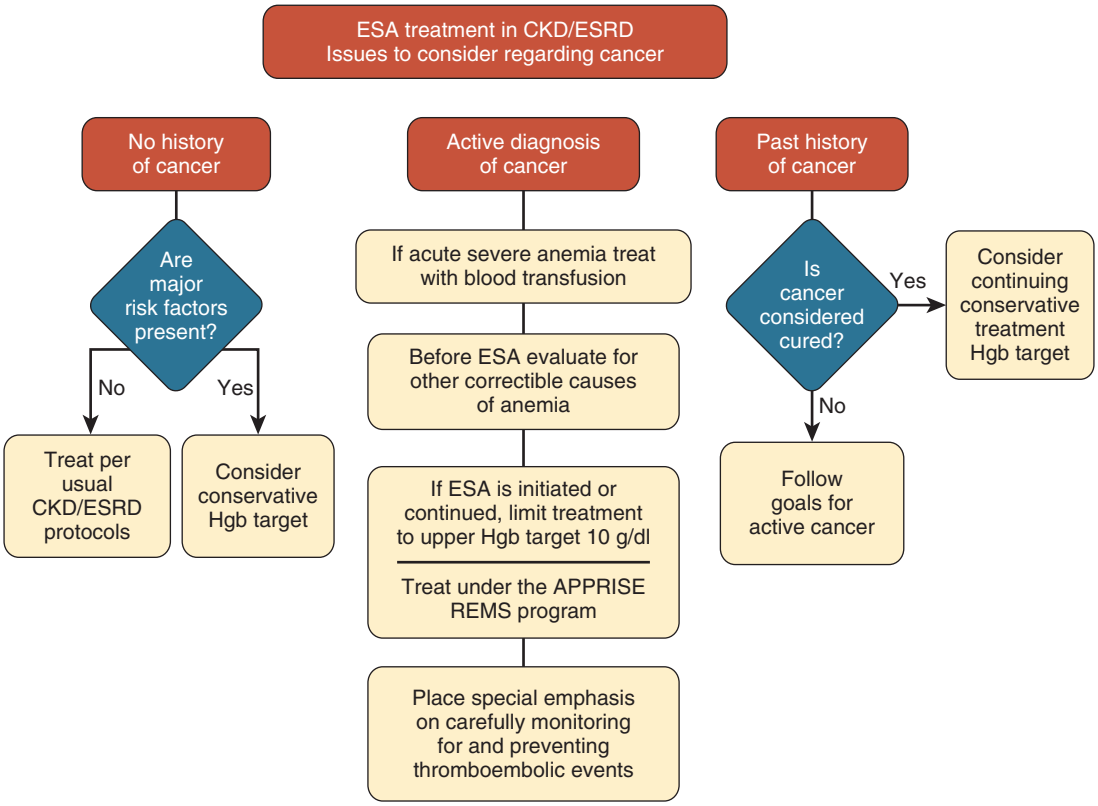

Fig. 65.4 Recommended approach to erythropoietin-stimulating agent *(ESA)* use in cancer patients with anemia and chronic kidney disease *(CKD)*/end-stage renal disease *(ESRD)*. *APPRISE,* Assisting Providers and cancer Patients with Risk information for the Safe use of ESAs; *Hgb,* hemoglobin; *REMS,* risk evaluation and mitigation strategy.

lenalidomide.[49] Tumor lysis developing in CKD/ESRD patients can be particularly challenging because the reduced ability to eliminate the tumor products can be life-threatening. In this situation, institution of daily dialysis or CRRT may become necessary. Moreover, in CKD/ESRD patients on active cancer treatment, erythropoietin (EPO) should be used judiciously because higher doses may be associated with poorer cancer outcomes.[50] A suggested approach is noted in Fig. 65.4.[51]

SELF-ASSESSMENT QUESTIONS

1. Which one of the following statements is *true* regarding patients with cancer and acute kidney Injury (AKI)?
   - **A.** AKI incidence in cancer patients has been reported the highest in lung cancer, adrenal cancer, and breast cancer.
   - **B.** AKI develops in 5% of patients hospitalized in the first 48 hours.
   - **C.** AKI in cancer patients had similar clinical outcomes compared with cancer patients without AKI.
   - **D.** Critically ill cancer patients have an increased incidence of AKI requiring renal replacement therapy (RRT) compared with AKI patients without cancer.
2. A 55-year-old man with a history of metastatic melanoma is admitted with acute kidney injury (serum creatinine at 5.3 mg/dl) after therapy with ipilimumab and pembrolizumab. At this time, which *one* of the following treatments should be ordered?
   - **A.** Glucocorticoids
   - **B.** Plasma exchange
   - **C.** Eculizumab
   - **D.** Supportive therapy with possible dialysis
   - **E.** Cyclophosphamide
3. A 65-year-old man presented with abdominal fullness and weight loss. A computed tomography scan of the chest and abdomen demonstrated a 12-cm soft tissue mass in the midabdomen with mild bilateral hydronephrosis. Pathologic analysis of tissue obtained by percutaneous biopsy of the mass revealed large B cell lymphoma. The patient was admitted for initiation of chemotherapy. Laboratory test results revealed the following: sodium 135 mEq/l, potassium 5.6 mEq/l, chloride 104 mEq/l, bicarbonate 15 mEq/l, blood urea nitrogen 79 mg/dl, creatinine 4.0 mg/dl (baseline 1.0 mg/dl), calcium 6.0 mg/dl, phosphorus 7.3 mg/dl, and uric acid 10.0 mg/dl. Urinalysis showed specific gravity of 1.020, pH 5.0, and a negative dipstick examination. Urine output decreased to 10 to 15 ml/h. At this point before chemotherapy, which of the following is the most important intervention at this time?
   - **A.** 2 grams intravenous calcium gluconate, 10 units intravenous insulin, and 1 ampule of D50
   - **B.** Urine alkalinization with intravenous sodium bicarbonate
   - **C.** Hemodialysis
   - **D.** Percutaneous nephrostomy tube placement
   - **E.** Intravenous fluid challenge (1 liter) with normal saline
4. Which of the following statements concerning hyponatremia in cancer patients is *most* correct?
   - **A.** Hyponatremia in cancer patients is not a complication of cisplatin therapy.
   - **B.** Hyponatremia in cancer patients had increased hospital length of stay and 90-day mortality.
   - **C.** Hyponatremia in cancer patients is less common than in the general population.
   - **D.** Hyponatremia in cancer patients is not associated with pain and nausea.

Pathophysiology and Etiology of Acute Kidney Injury

Leah Haseley, J. Ashley Jefferson

DEFINITION

Acute kidney injury (AKI) is denoted by an abrupt decline in glomerular filtration rate (GFR) sufficient to decrease the elimination of nitrogenous waste products and other uremic toxins. This has traditionally been referred to as *acute renal failure,* but in recent years, this has been replaced with the term *acute kidney injury* and standardized definitions of AKI have been developed (see Table 68.1).[1] Staging criteria have been developed based on the magnitude of the rise in serum creatinine and changes in the volume of urine output over 1 week.[1]

ETIOLOGY OVERVIEW

Although AKI is defined by reduced GFR, the underlying cause of the renal impairment is most frequently tubular and vascular factors. AKI can be caused by a broad range of etiologies, and the differential diagnosis must be considered in a systematic fashion. The traditional paradigm divides AKI into prerenal, renal, and postrenal causes. Prerenal causes may be hypovolemia or a decreased effective arterial volume. Postrenal renal failure is usually due to obstruction. Intrinsic renal causes of AKI should be considered under the different anatomic components of the kidney (vascular supply, glomerular, tubular, and interstitial disease; Fig. 66.1). Major extrarenal artery or venous occlusion must be considered in the differential diagnosis (see Chapter 38). Similarly, disorders of the small intrarenal vasculature can result in AKI (e.g., vasculitis, thrombotic microangiopathy, malignant hypertension, eclampsia, postpartum states, disseminated intravascular coagulation [DIC], scleroderma; see Chapters 25, 29, 37, 42, and 62). All forms of acute glomerulonephritis (GN) can manifest as AKI, as can acute inflammation and space-occupying processes of the renal interstitium (e.g., drug-induced, infectious, and autoimmune disorders, leukemia, lymphoma, sarcoidosis).

Among inpatients, prerenal azotemia and acute tubular necrosis (ATN) account for the majority of AKI cases[2] (Fig. 66.2), often in the setting of AKI superimposed on chronic kidney disease (CKD), so-called "acute-on-chronic kidney disease." The term *acute tubular necrosis,* although commonly used, is a misnomer because the alterations are not limited to the tubular structures and true cellular necrosis in human ATN is often minimal. ATN should be reserved for cases of AKI in which a renal biopsy (if performed) shows the characteristic changes of tubular cell injury (Fig. 66.3) or for patients with findings of tubular injury (such as renal tubular epithelial cells in the urine sediment) in an appropriate clinical setting. There are also significant geographical differences in the causes of AKI with the spectrum of causes in tropical countries described in Chapter 67.

PATHOPHYSIOLOGY AND ETIOLOGY OF PRERENAL ACUTE KIDNEY INJURY

Impaired renal perfusion with a resultant fall in glomerular capillary filtration pressure is a common cause of AKI. In this setting, tubular function is typically normal, renal reabsorption of sodium and water is increased, and consequently the urine exhibits low sodium concentration (<20 mmol/l) and high osmolality (>500 mOsm/kg), presuming a diuretic has not been administered. A marked reduction in renal perfusion may overwhelm autoregulation and precipitate an acute fall in GFR. With lesser degrees of renal hypoperfusion, glomerular filtration pressures and GFR are maintained by afferent arteriolar vasodilation (mediated by vasodilatory eicosanoids) and efferent arteriolar vasoconstriction (mediated by angiotensin II [Ang II]). In this setting, AKI may be precipitated by agents that impair afferent arteriolar dilation (nonsteroidal antiinflammatory drugs [NSAIDs]) or efferent vasoconstriction (angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers [ARBs]).

Prerenal AKI is often secondary to extracellular fluid volume depletion as a result of gastrointestinal losses (diarrhea, vomiting, prolonged nasogastric drainage), renal losses (diuretics, osmotic diuresis in hyperglycemia), dermal losses (burns, extensive sweating), or sequestration of fluid, sometimes known as *third-spacing* (e.g., acute pancreatitis, muscle trauma). Renal perfusion may be impaired in the setting of normal or increased extracellular fluid, when cardiac output is reduced (heart failure), or when there is systemic arterial vasodilation with redistribution of cardiac output to extrarenal vascular beds (e.g., sepsis, liver cirrhosis) (see Chapters 7, 72, and 73). An unusual cause of prerenal AKI is the infusion of large quantities of osmotically active substances such as mannitol, dextran, or protein, which can increase the glomerular oncotic pressure enough to exceed the capillary hydrostatic pressure stopping filtration.

Prerenal AKI can be corrected if the extrarenal factors causing the renal hypoperfusion are rapidly reversed. Failure to restore renal blood flow (RBF) during the functional prerenal stage will ultimately lead to tubular cell injury.

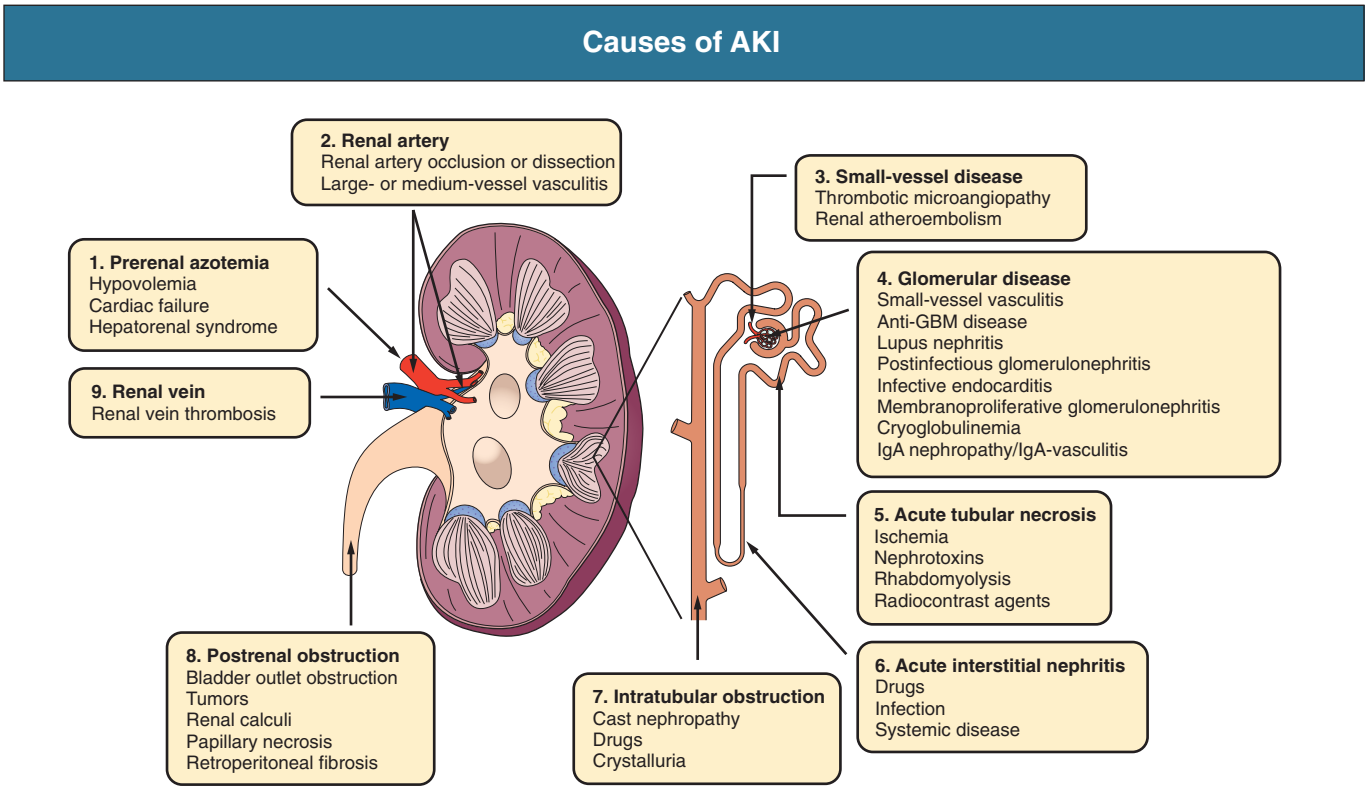

Fig. 66.1 Causes of acute kidney injury *(AKI).* AKI is classified into prerenal, renal, and postrenal causes. Renal causes of AKI should be considered under the different anatomic components of the kidney (vascular supply, glomerular, tubular, and interstitial disease). *GBM,* Glomerular basement membrane; *IgA,* immunoglobulin A.

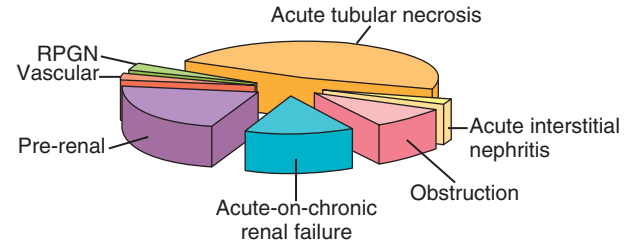

Fig. 66.2 Causes of acute kidney injury in the hospital setting. Madrid Acute Renal Failure Study (1996). *RPGN,* Rapidly progressive glomerulonephritis.

PATHOPHYSIOLOGY AND ETIOLOGY OF POSTRENAL ACUTE KIDNEY INJURY

Obstruction must be excluded in any patient with AKI because prompt intervention can result in improvement or complete recovery of renal function (see Chapter 58). Obstruction of the extrarenal collecting system at any level (renal pelvis, ureters, bladder, or urethra) can increase intratubular pressure, which opposes glomerular filtration pressure and decreases GFR. Obstructive nephropathy is more common in older men with prostatic disease, in patients with a single kidney, and in those with intraabdominal or pelvic cancer. Ureteral obstruction without hydronephrosis can occur with retroperitoneal fibrosis. All types of renal obstruction are also associated with inflammation and fibrosis and can result in permanent injury if the obstruction is prolonged. Nevertheless, most causes of obstructive nephropathy are amenable to therapy, and the prognosis is often good if treatment or intervention is early (Chapter 58).

PATHOPHYSIOLOGY OF ACUTE TUBULAR NECROSIS

ATN commonly occurs in patients with trauma, vascular and cardiac surgery, severe burns, pancreatitis, sepsis, and chronic liver disease. ATN is responsible for most cases of hospital-acquired AKI and is usually the result of ischemic or nephrotoxic injury or a combination of both. In the intensive care unit, two thirds of cases of AKI are due to the combination of impaired renal perfusion, sepsis, and nephrotoxic agents. The importance of combined injurious mechanisms is also highlighted by animal studies, in which severe and prolonged hypotension (<50 mm Hg for 2 to 3 hours in rats) or a single nephrotoxic agent may not cause ATN. Fever may exacerbate ATN by increasing the renal tubular metabolic rate, thereby increasing adenosine triphosphate (ATP) consumption. In renal artery occlusion in the rat, renal ischemia for 40 minutes resulted in minimal renal injury at 32° C, but marked renal injury at 39.4° C.

The typical course of uncomplicated ATN is recovery over 2 to 3 weeks; however, superimposed renal insults or multiple comorbidities often alter this pattern. For example, episodes of hypotension induced by hemodialysis may lead to additional ischemic lesions, potentially prolonging renal functional recovery.

Histology

The typical features of ATN include vacuolization and loss of brush border in proximal tubular cells. Sloughing of tubular cells into the

lumen leads to cast obstruction, manifested by tubular dilation. Interstitial edema can produce widely spaced tubules, and a mild leukocyte infiltration may be present (see Fig. 66.3). Despite the term *acute tubular "necrosis,"* frankly necrotic cells are uncommon on renal biopsy and histologic evidence of injury frequently only involves 10% to 15% of the tubules despite marked functional impairment. This implies that additional factors such as vasoconstriction and tubular obstruction are important in the loss of GFR.

Site of Tubular Injury in Acute Tubular Necrosis

Tubular damage is usually due to a combination of ischemic injury resulting in depletion of cellular ATP and direct tubular epithelial cell injury by nephrotoxins. The S3 segment of the proximal tubule and the medullary thick ascending limb (mTAL) are particularly vulnerable to hypoxic injury (Fig. 66.4) for several reasons:

1. *Blood supply:* Most blood flow to the kidney is directed to the renal cortex for glomerular filtration, where tissue P_{O_2} is 50 to 100 mm Hg. By contrast, the outer medulla and medullary rays are watershed areas receiving their blood supply from vasa rectae. Countercurrent oxygen exchange occurs, leading to a progressive fall in P_{O_2} from cortex to medulla. This results in medullary cells living on the "brink of hypoxia" (P_{O_2} as low as 10 to 15 mm Hg). The S3 segments of proximal tubule cells and distal mTALs are thus exposed to chronic borderline oxygen deprivation.
2. *High tubular energy requirements:* The cells of the S3 region and mTAL have high metabolic activity because of sodium reabsorption driven by basolateral membrane Na^+,K^+-ATPase. Blocking sodium reabsorption in the mTAL with loop diuretics raises the medullary tissue P_{O_2} from about 15 to 35 mm Hg. The low GFR in AKI may be renoprotective by diminishing sodium filtration and hence limiting the need for ATP-dependent sodium reabsorption. The drop in GFR in this setting has been called *acute renal success*!
3. *Glycolytic ability of tubular cells:* Proximal tubular cells have minimal glycolytic machinery and rely almost solely on oxidative phosphorylation for the generation of ATP. In contrast, mTAL cells have a large glycolytic capacity and are more resistant to hypoxic or ischemic insults.

Hemodynamic Factors in the Development of Acute Tubular Necrosis

Impaired Renal Autoregulation

Autoregulation between systolic blood pressures of 80 and 150 mm Hg allows maintenance of RBF, glomerular pressures, and GFR in a stable range. Below 80 mm Hg, this autoregulation fails, and ischemic injury

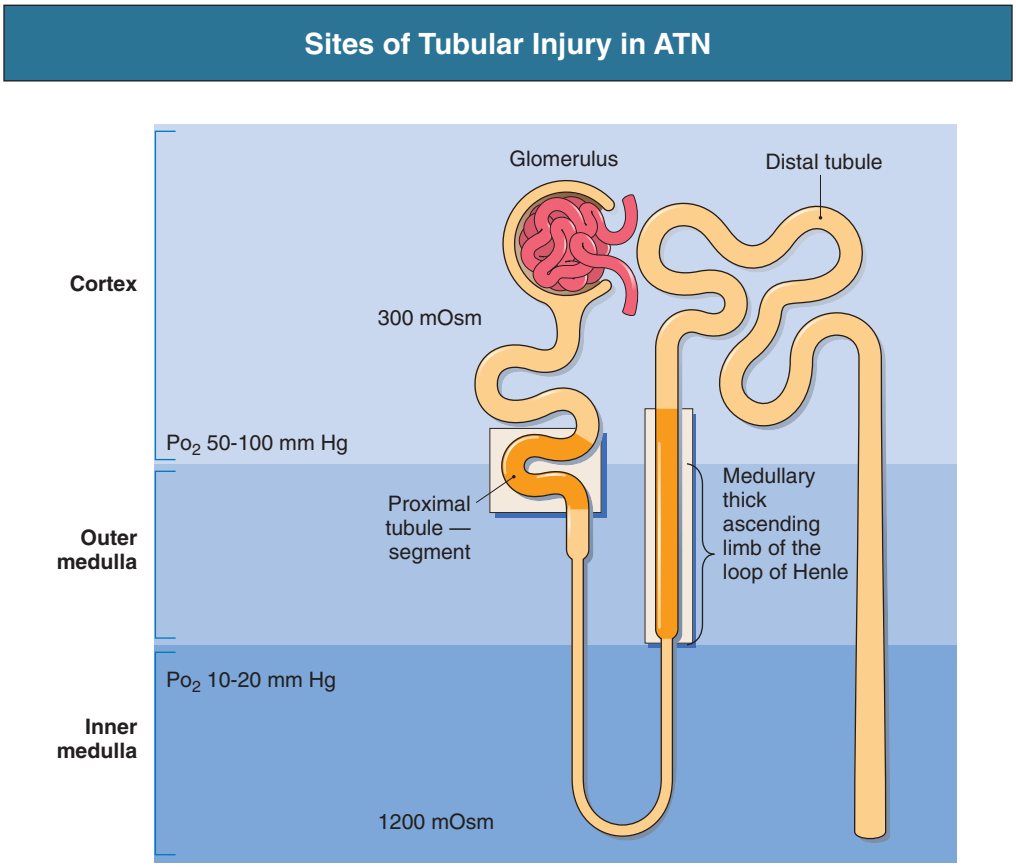

Fig. 66.4 Sites of tubular injury in acute tubular necrosis (ATN). The S3 segment of the proximal tubule and the medullary thick ascending limb are particularly vulnerable to ischemic injury because of the combination of borderline oxygen supply and high metabolic demands.

may result. In certain conditions, such as aging or CKD, autoregulation is impaired and ischemic injury may occur more easily with reductions in perfusion pressure. In settings of low renal perfusion (e.g., volume depletion, left ventricular failure, renal artery stenosis), GFR depend on autoregulation mediated by vasodilatory prostaglandins acting on the afferent arteriole Ang II-mediated efferent arteriolar vasoconstriction to maintain glomerular pressure. Any interference with these mechanisms (e.g., administration of ACE inhibitors or NSAIDs) may produce a precipitous fall in GFR.

Intrarenal Vasoconstriction

In established ATN, RBF is decreased by 30% to 50%. Indeed in AKI, rather than the normal autoregulatory renal vasodilation that occurs in response to decreased perfusion pressure, there is evidence of renal vasoconstriction. Vasoconstrictors implicated in this response include Ang II, endothelin-1, adenosine, thromboxane A_2, prostaglandin H_2, leukotrienes C_4 and D_4, sympathetic nerve stimulation (Fig. 66.5), and tubuloglomerular feedback (TGF). Some of these vascular abnormalities may be mediated by increased cytosolic calcium content in afferent arterioles as a result of ischemia.

Tubuloglomerular Feedback

The role of TGF (see Chapter 2) in the setting of AKI may be partly beneficial because the resultant decrease in GFR limits sodium delivery to damaged tubules. This in turn leads to reduced ATP-dependent tubular reabsorption of sodium, which protects against intracellular ATP depletion and thus renal injury. Adenosine A1 receptor knockout mice, with absent TGF, have augmented AKI after ischemia reperfusion.

Endothelial Cell Injury and the Development of Acute Tubular Necrosis

AKI is not limited to the tubular cell, and endothelial cell injury occurs partly as a result of acute renal ischemia and oxidant injury.[3] Endothelial injury is characterized by cell swelling, upregulation of adhesion molecules (with recruitment of inflammatory neutrophils and monocytes), and impaired vasodilation (decreased endothelial nitric oxide synthase and vasodilatory prostaglandins) and may mediate some of the impaired autoregulation and intrarenal vasoconstriction described earlier. Endothelial injury within the peritubular capillaries (vasa rectae) may produce congestion in the outer medulla, exacerbating interstitial edema and worsening hypoxic injury to the S3 segment of the proximal tubule and the TAL of Henle.

Tubular Epithelial Cell Injury and the Development of Acute Tubular Necrosis

The tubular cell may be injured because of ischemia (depletion of cellular energy stores [ATP]), or from direct cytotoxic injury. After acute renal ischemia, tubular cell injury also may result from the restoration of RBF (reperfusion injury). Mediators of tubular cell injury include reactive oxygen species (ROS), intracellular calcium influx, nitric oxide, phospholipase A2, complement, and cell-mediated cytotoxicity.[3] Mitochondrial injury can be caused by ROS, depletion of antioxidants, and increased intracellular calcium. Disruption of mitochondrial function exacerbates cellular injury as a result of disrupted energy metabolism and release of proapoptotic proteins. Autophagy is a mechanism by which cells degrade self-proteins and is a central part of the cellular

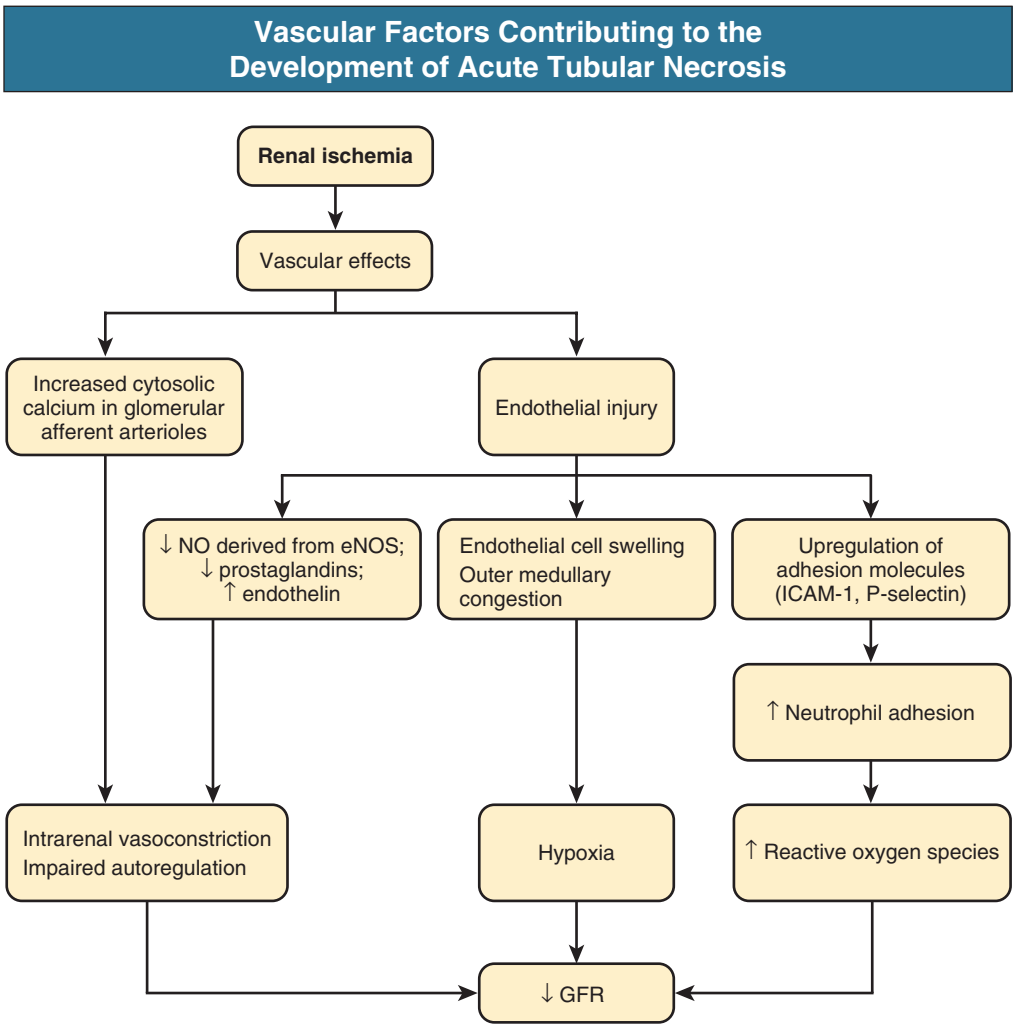

Fig. 66.5 Vascular factors contributing to the development of acute tubular necrosis. Renal vasoconstriction and endothelial injury promote renal ischemia and tubular injury. *eNOS,* endothelial nitric oxide synthase; *GFR,* glomerular filtration rate; *ICAM-1,* intercellular adhesion molecule 1; *NO,* nitric oxide.

response to stress and injury. Experimental work has shown that autophagy is important for removal of damaged mitochondria and the recovery of tubular epithelial cells from ischemic injury. ROS may be derived from local sources (including xanthine oxidase and cyclooxygenases secondary to mitochondrial injury) or from infiltrating leukocytes. In models of ischemic ATN, a variety of methods that inhibit ROS protect against renal injury. Hypoxia inducible factor and downstream mediators such as heme oxygenase 1 may protect cells against ischemic injury.[4]

Factors that affect the integrity and function of the renal tubular epithelial cells and contribute to the reduction in GFR include the following (Fig. 66.6):

1. *Cell death:* Despite the term *acute tubular necrosis,* only few tubular cells undergo cell death and mostly by apoptosis rather than necrosis. Indeed, in animal models, renal injury is ameliorated using caspase inhibitors and p53 inhibitors that decrease apoptosis.[5]
2. *Disruption of actin cytoskeleton:* A characteristic feature of sublethally injured cells is the disruption of the actin cytoskeleton. Activation of the cysteine protease calpain (partly as a result of increased intracellular calcium) can degrade actin-binding proteins such as spectrin and ankyrin. This leads to abnormal translocation of Na^+,K^+-ATPase and other proteins from the basolateral membrane to the cytoplasm or apical membranes. In the proximal tubular cell, this loss of polarity results in impaired proximal reabsorption of filtrate with resultant increased distal sodium chloride delivery, which activates TGF.
3. *Cast obstruction:* Tubular cells are attached to the tubular basement membrane (TBM) by α3β1 integrins, which recognize RGD (arginine-glycine-aspartate) sequences in matrix proteins. Disruption of the actin cytoskeleton results in movement of integrins from basolateral positions to the apical membrane, leading to impaired cell matrix adhesion and cell detachment. Many of these detached cells are still viable and can be cultured from urine of patients with ATN. Sloughed proximal tubular cells can bind to RGD sequences in Tamm-Horsfall protein, resulting in cast formation and intratubular obstruction. In models of ischemic AKI, the elevation in tubular pressures may be inhibited by synthetic RGD peptides mitigating the obstructive process.
4. *Backleak:* The loss of adhesion molecules (E-cadherin) and tight junction proteins (ZO-1, occludin) weakens junctions between cells, allowing filtrate to leak back into the renal interstitium. Although this does not alter the actual GFR at the level of the glomerulus, the net effect is a reduction in the measured GFR. Earlier dextran sieving experiments suggest only a modest effect of backleak on the decrement of GFR in AKI (about 10%); however, in the renal allograft

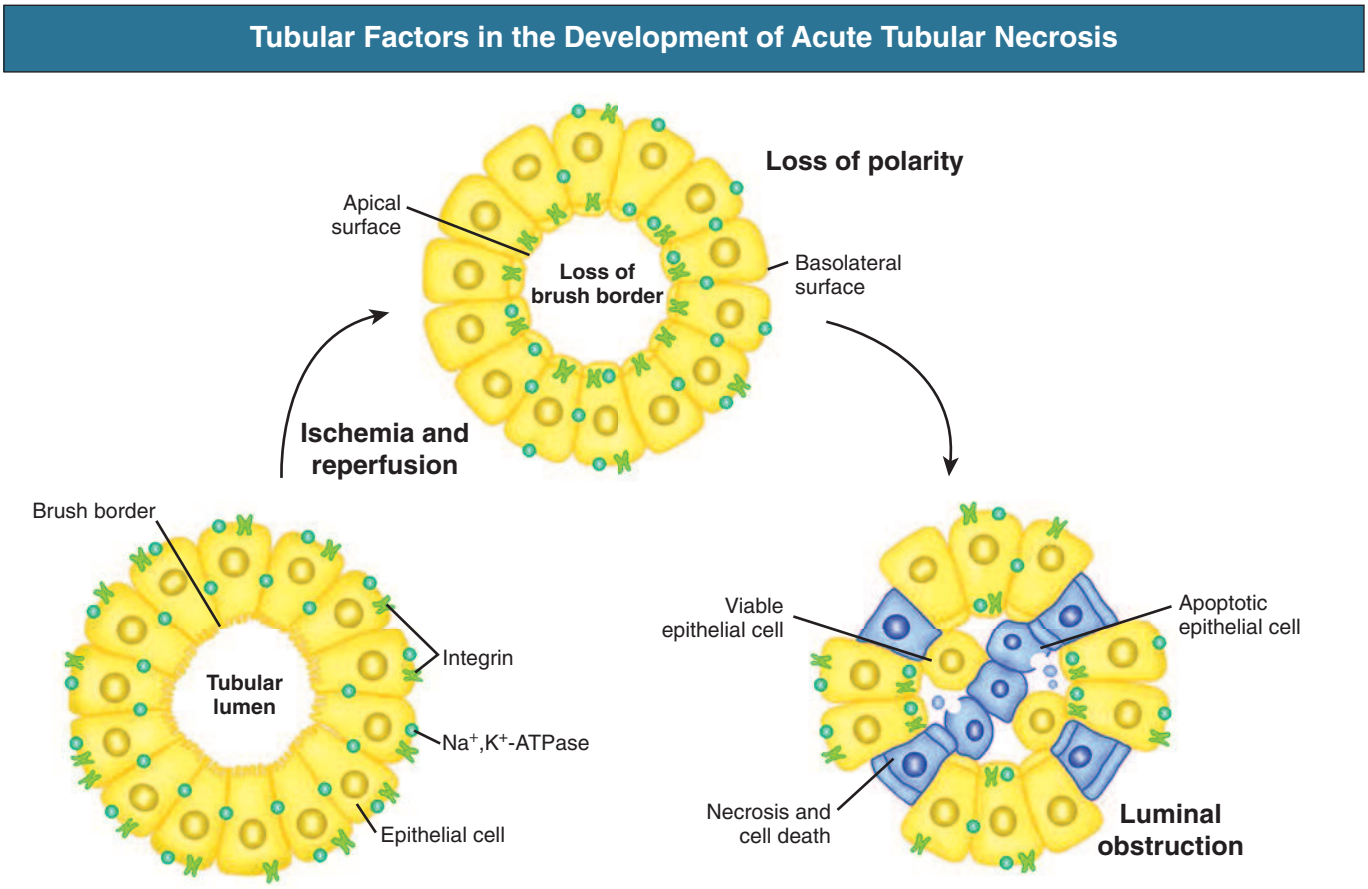

Fig. 66.6 Tubular factors in the development of acute tubular necrosis. Loss of cell polarity results in weakening of cell-to-cell and cell matrix adhesion resulting in cast obstruction and backleak of tubular fluid. (Modified from reference 40.)

with severe ATN, backleak has been calculated to account for up to 50% of the GFR reduction.

Inflammatory Factors in the Development of Acute Tubular Necrosis

Although ischemia causes direct renal cytotoxicity, tissue inflammation during reperfusion also contributes to renal injury and may cause some of the systemic effects of AKI. Components of both the innate and the adaptive immune systems contribute to the pathogenesis of ATN.[6] The innate immune system is activated by cellular injury and certain pattern recognition molecules. Toll-like receptor 2 (TLR2) and TLR4 are upregulated within the ischemic kidney, activated by molecules released from injured cells, and induce renal epithelial cells to produce chemokines. The complement system is also activated within the tubulointerstitium after ischemia/reperfusion, predominantly by the alternative pathway. It can directly induce nearby epithelial cells to produce proinflammatory cytokines (e.g., tumor necrosis factor-α [TNF-α], interleukin-6 [IL-6], IL-1β) and chemokines (such as MCP-1, IL-8, RANTES [regulated on activation, normal T cell expressed and secreted]) that promote the infiltration of leukocytes and are also directly vasoactive.

A network of dendritic cells extends throughout the renal interstitium, which help shape the inflammatory response within the kidney after ischemia/reperfusion, likely through their interactions with other inflammatory cell types. Neutrophils and mononuclear cells are seen in peritubular capillaries. Neutrophil activation and the release of proteases and ROS can exacerbate injury. By contrast, neutrophil depletion or the inhibition or genetic deletion of neutrophil adhesion molecules (ICAM-1) ameliorates injury in ischemic ATN. Monocytes infiltrate the kidney after reperfusion and differentiate into the M1 (proinflammatory) type, exacerbating renal injury after ischemia. These macrophages may later convert to an M2 (reparative) phenotype. Cells of the adaptive immune system, including T and B lymphocytes, also contribute to renal injury in models of ATN, and their depletion ameliorates injury. It is not known whether these responses are antigen specific. Furthermore, some B cell and T cell subsets, such as T regulatory cells, help limit renal injury.

AKI may have systemic effects on other organ systems.[7] The injured kidney may prime and activate leukocytes, which produce proinflammatory cytokines that can mediate remote organ injury (Fig. 66.7). The lungs may be particularly vulnerable from the combined effects of volume overload, increased vascular permeability, and proinflammatory environment. These distant organ effects may partly account for the increased mortality in patients with AKI (Chapter 69).

Recovery Phase

Recovery from ATN requires the restoration of tubular cell number and coverage of denuded TBM. A marked increase in cell proliferation occurs in recovering human ATN (see Fig. 66.3). The restoration of tubular cell number is due to the dedifferentiation and proliferation of surviving tubular cells rather than from a mesenchymal stem cell source.[8] After tubular epithelial cell proliferation, the dedifferentiated cells must migrate to areas of denuded TBM, attach to the basement

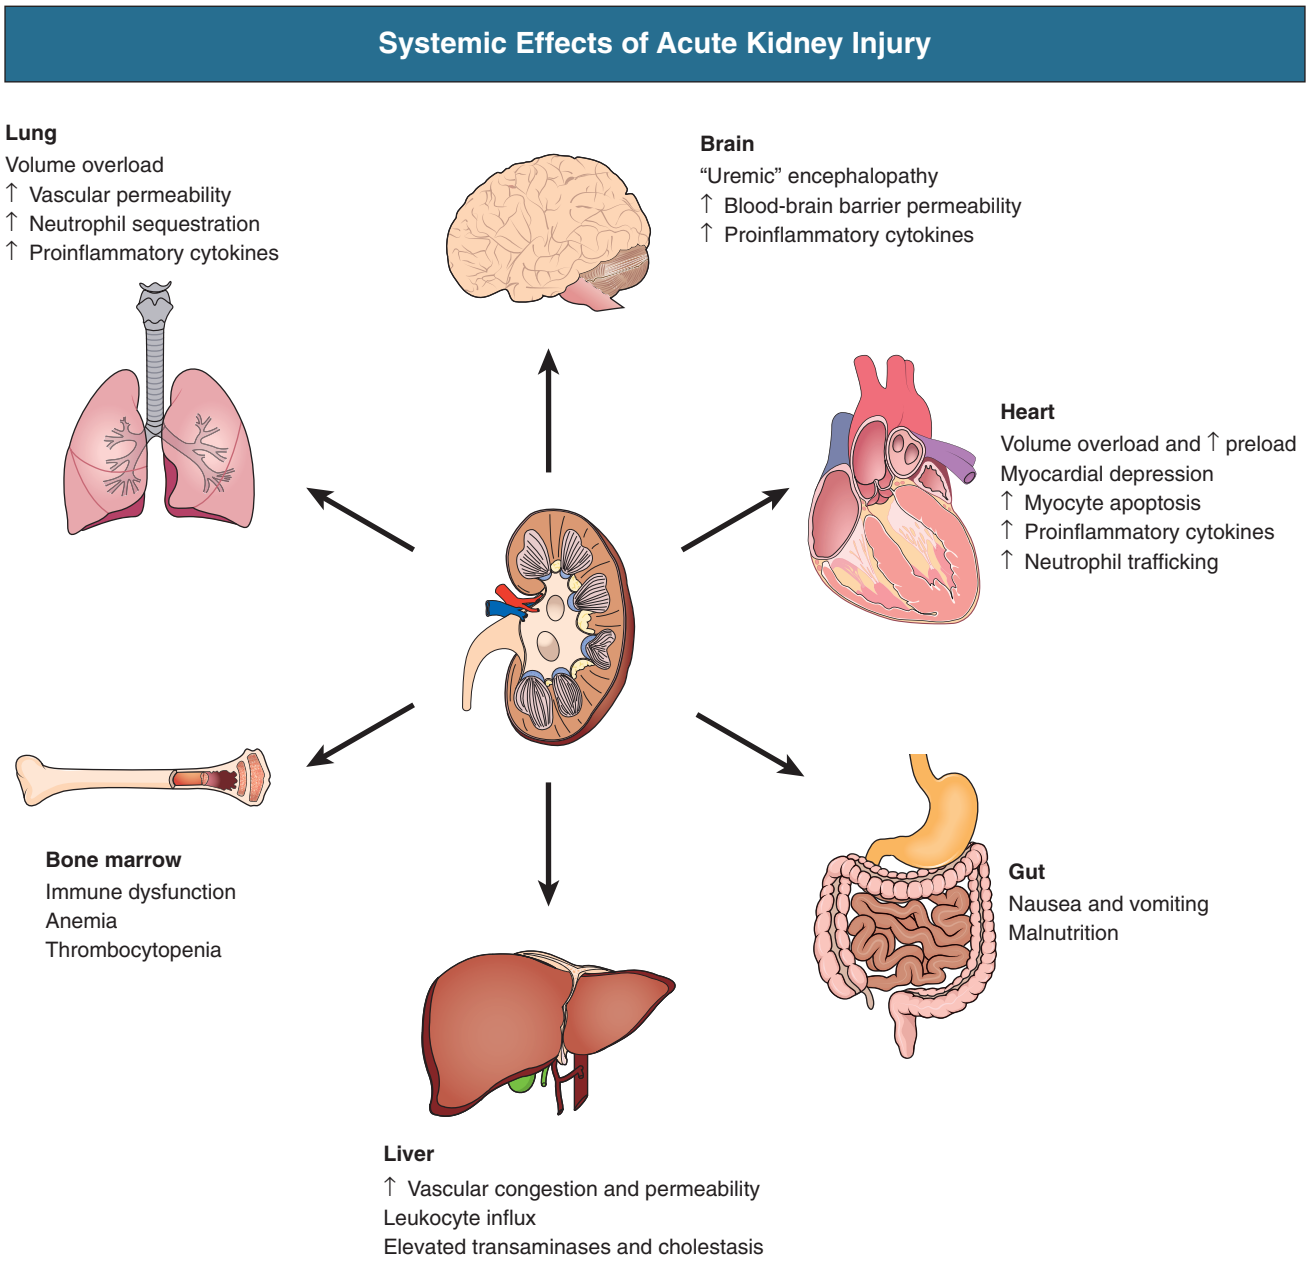

Fig. 66.7 Systemic effects of acute kidney injury (AKI). AKI may contribute to remote organ injury, partly because of abnormalities in inflammatory and immune function from renal tubular dysfunction. (Modified from reference 7.)

membrane, and differentiate into mature polar tubular epithelial cells. The early inflammatory infiltrates of neutrophils and M1 monocytes are replaced by M2 monocytes, which support epithelial cell repair, after which their numbers decline by migration or apoptosis. When the injury process is persistent or severe, maladaptive repair may occur leading to CKD.[9]

NEPHROTOXIC AGENTS AND MECHANISMS OF TOXICITY

The identification and avoidance of nephrotoxic agents in AKI is critical because AKI may be rapidly reversible on removal of the offending agent. The mechanisms of nephrotoxicity include alterations in renal hemodynamics, induction of direct tubular injury, generation of allergic reactions resulting in interstitial nephritis, and intratubular obstruction. The list is extensive, but the more common agents are presented in Fig. 66.8.

Nonsteroidal Antiinflammatory Drugs

NSAIDs commonly cause AKI in the community because of the large amounts of these drugs either prescribed or purchased over the counter. COX-2–specific NSAIDs have similar effects on renal function as the nonselective NSAIDs and thus are not safer with respect to AKI. NSAID-related AKI is most often due to a hemodynamically mediated reduction in GFR that occurs in patients who are particularly dependent on vasodilatory prostaglandins to maintain renal perfusion. These include elderly

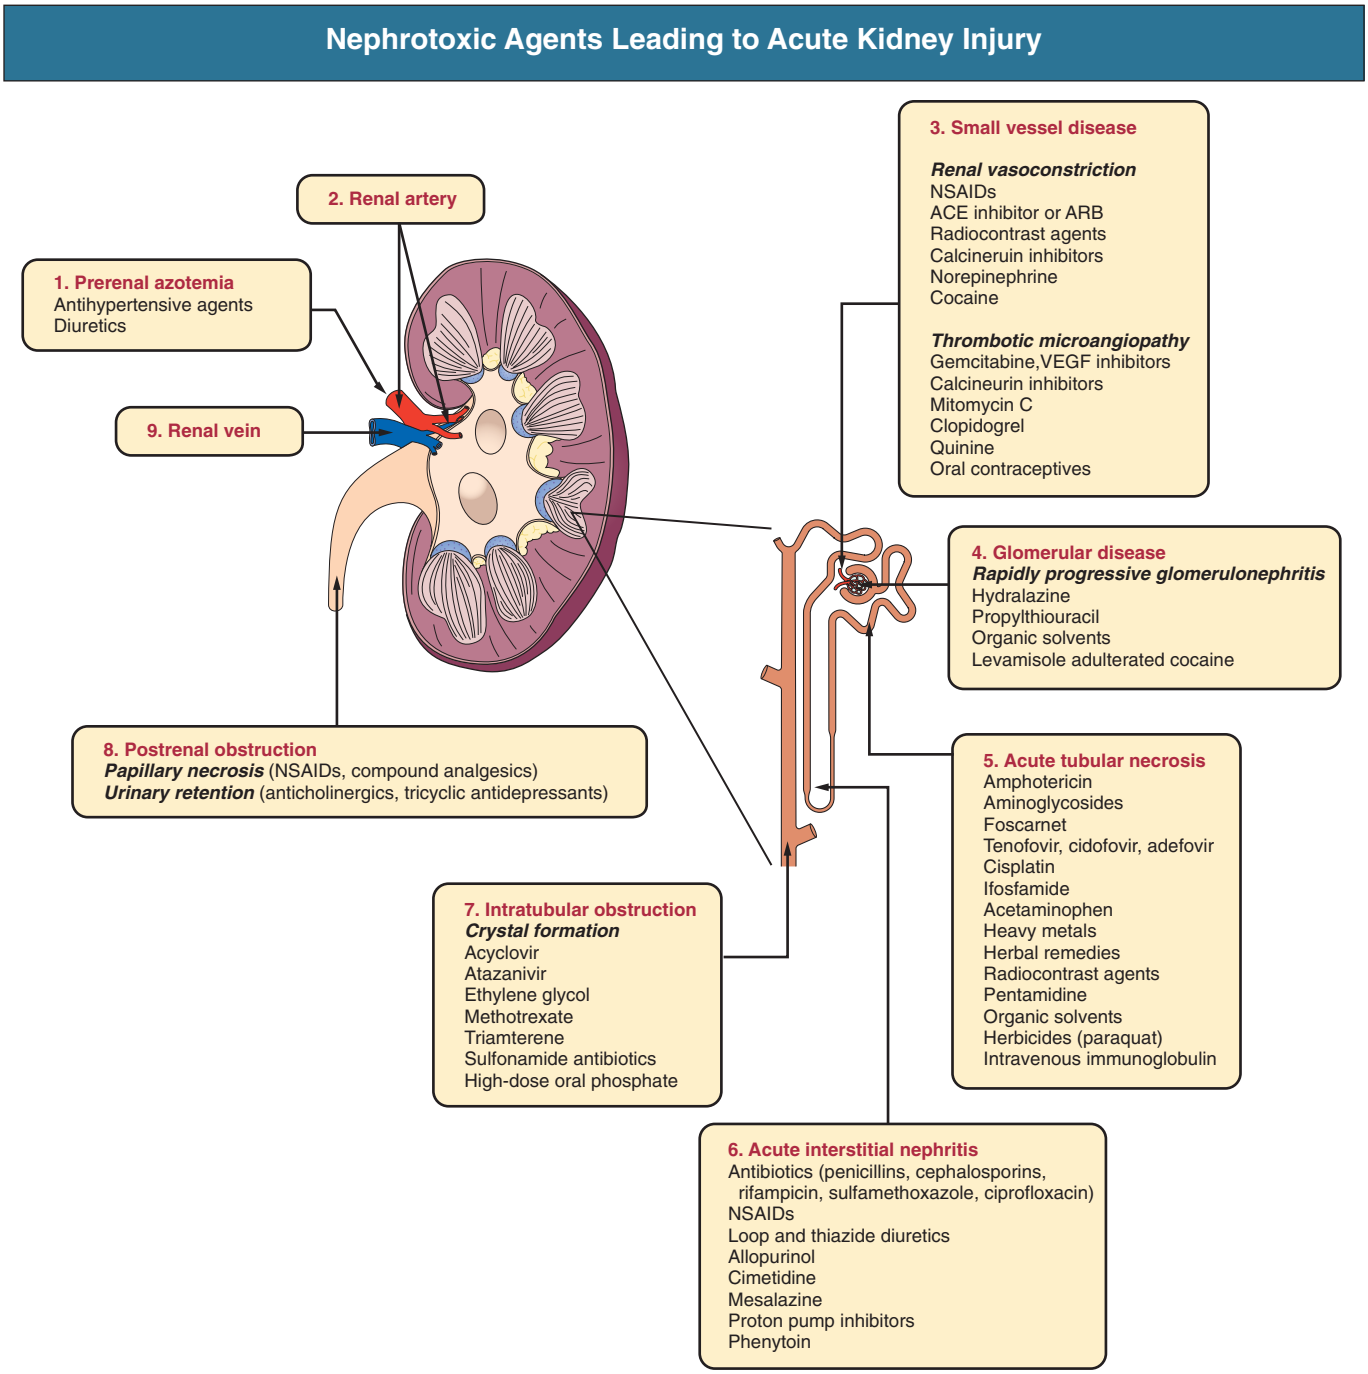

Fig. 66.8 Common nephrotoxic agents leading to acute kidney injury. *ACE,* Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *NSAIDs,* nonsteroidal antiinflammatory drugs.

patients with atherosclerotic disease, volume-depleted patients, and those in sodium-avid states such as cirrhosis, nephrotic syndrome, and congestive heart failure. This form of AKI is usually reversible in 2 to 7 days on discontinuation of the drug and rarely occurs in otherwise healthy individuals. Less frequently, NSAIDs induce ATN or even more rarely papillary necrosis. NSAIDs also may cause an acute interstitial nephritis, often with significant proteinuria (see Chapter 60). Other renal side effects of NSAIDs include fluid and electrolyte disturbances such as sodium retention exacerbating hypertension and congestive heart failure, hyponatremia, and hyperkalemia.

Acetaminophen (Paracetamol)

Isolated ATN with acetaminophen may occur in rare cases, but renal injury is more typically associated with acute hepatitis. Renal and liver toxicity usually occur when more than 15 g has been taken, but in alcoholics, normal doses may be toxic. Acetaminophen is conjugated in the liver and undergoes renal excretion. Less than 5% undergoes metabolism by cytochrome P-450 (CYP2E1) enzymes to form a toxic metabolite, *N*-acetyl imidoquinone, which is inactivated by the thiol group of glutathione. With high levels of acetaminophen, glutathione

becomes depleted, and *N*-acetyl imidoquinone can bind to thiol groups on intracellular proteins, resulting in cell injury. Because glutathione is a major intracellular antioxidant, its loss may predispose to oxidative injury of the tubular cells.

Clinically, acute hepatitis and ATN only begin once glutathione levels are depleted, and clinical manifestations usually present 3 to 4 days after ingestion. *N*-Acetylcysteine, which substitutes for glutathione by providing a free thiol group, can be protective if administered early.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

ACE inhibitors and ARBs may cause hemodynamically induced AKI in the setting of reduced renal perfusion by impairing compensatory vasoconstriction of the efferent arteriole. These drugs may directly impair renal perfusion by their antihypertensive effects. Patients in whom renal perfusion is compromised because of dehydration, renovascular disease, or functionally impaired autoregulation are at particular risk for developing AKI after initiation of therapy. Patients chronically treated with ACE inhibitors or ARBs have an increased risk for postoperative renal dysfunction, probably as a consequence of intraoperative hypotensive episodes.

Aminoglycosides

Aminoglycosides are excreted by glomerular filtration. Toxicity may occur if the dose is not adjusted to the GFR. Cationic amino groups (NH_3^+) on the drugs bind to anionic megalin on the brush border of proximal tubular epithelial cells, and the drugs are then internalized by endocytosis. Aminoglycosides accumulate in proximal tubular cell lysosomes and can reach 100 to 1000 times their serum concentration. The drug interferes with cellular energetics, impairs intracellular phospholipases, and induces oxidative stress.[10]

Nonoliguric AKI usually occurs after 5 to 10 days of treatment with gentamicin. Involvement of distal tubular segments may produce polyuria, potassium, and magnesium wasting. The risk for AKI correlates with the accumulation of gentamicin in proximal tubular cells and is related to the daily dose and duration of therapy. Prolonged accumulation in proximal tubular cells may allow development of AKI even after the drug has been discontinued. Additional risk factors for gentamicin toxicity include increasing age, preexisting renal disease, hypotension, concurrent liver disease, sepsis, and concurrent nephrotoxins. Simultaneous treatment with vancomycin can potentiate aminoglycoside nephrotoxicity. Aminoglycoside serum levels should be monitored to minimize nephrotoxicity. When possible, the drug should be administered in a single daily total dose, which leads to lower renal proximal tubular cell accumulation. Gentamicin, tobramycin, and netilmicin appear to have similar nephrotoxic effects. Amikacin, which has fewer amino groups per molecule, may be less nephrotoxic.

Vancomycin

Whether vancomycin is nephrotoxic is controversial.[11] Early formulations of the drug contained impurities that were thought to account for the renal injury. More recently, the recommendation for higher vancomycin trough levels to target resistant methicillin-resistant *Staphylococcus aureus* has led to recognition that vancomycin monotherapy can be nephrotoxic. Vancomycin is excreted primarily by glomerular filtration, but accumulation in proximal tubule cells via basolateral secretion is thought to underlie nephrotoxicity. Experimentally, high-dose vancomycin causes oxidative stress and triggers intrarenal apoptotic pathways. In humans, high trough levels of vancomycin have been associated with nephrotoxicity in a graded fashion, with an initial trough greater than 20 mcg/ml significantly increasing the odds of AKI. Additional risk factors for vancomycin nephrotoxicity include total dose greater than 4 g/day, long duration of therapy, concurrent nephrotoxin exposure, and critical illness. ATN is the predominant lesion seen in experimental models, but case reports of human biopsies have shown both interstitial nephritis and ATN. Vancomycin can cause a drug reaction with eosinophilia and systemic symptoms (drug-related eosinophilia with systemic symptoms [DRESS] syndrome) with inflammatory renal injury. Treatment is generally conservative. High-flux hemodialysis can be used for drug removal when levels are very high. Renal injury from vancomycin is generally reversible.

Amphotericin B

This polyene macrolide antibiotic binds to sterols in the cell membranes of both fungal walls (ergosterol) and mammalian (cholesterol) cell membranes, resulting in the formation of aqueous pores that increase membrane permeability. Within the renal tubular cell, the subsequent sodium influx leads to increased Na^+,K^+-ATPase activity and depletion of cellular energy stores.[12] Additionally, the standard amphotericin B formulation is suspended in the bile salt deoxycholate, which has a detergent effect on cell membranes. Nephrotoxicity relates to cumulative dosage, usually occurring after administration of 2 to 3 g.

Early signs of nephrotoxicity include a loss of urine-concentrating ability, followed by a decrease in GFR. Hypokalemia and hypomagnesemia secondary to distal tubular wasting are common. A distal renal tubular acidosis may be present as a result of proton backleak in the cortical collecting duct.

Prevention of nephrotoxicity requires the maintenance of high urine flow rates by saline loading during amphotericin administration. The more expensive liposomal amphotericin B preparations reduce the incidence of AKI by approximately 50%. Because amphotericin B binds more avidly to fungal ergosterol than to cholesterol, delivering the drug as a cholesterol liposome diminishes binding to tubular epithelial cell membranes without altering fungicidal activity. Additionally, liposomal preparations do not contain deoxycholate. Amphotericin B–induced AKI is usually reversible with discontinuation of the drug, although distal tubular injury as manifested by magnesium wasting may persist.

Antiviral Therapy

Acyclovir

Nephrotoxicity is typically seen after intravenous acyclovir administration and may be due to direct tubular cell toxicity and the formation of intratubular acyclovir crystals. The latter appear as birefringent needle-shaped crystals on urine microscopy. However, crystals also may be seen in non-AKI patients, and renal biopsy data suggest that acute interstitial nephritis may be the predominant mechanism of toxicity.

Oliguric AKI typically occurs within a few days of treatment and may be associated with abdominal or loin pain. High serum levels of acyclovir as a result of decreased renal clearance may produce neurologic toxicity. The AKI is usually mild and recovers on stopping the drug. Maintaining a high urine flow rate and avoiding intravenous bolus administration of acyclovir may be preventive.

Tenofovir

Tenofovir is a nucleoside reverse transcriptase inhibitor used to treat both HIV and hepatitis B infection. The prodrug, tenofovir disoproxil fumarate (TDF), is the most widely used therapy for HIV in the world. Tenofovir is secreted into proximal tubule cells via organic anion transporters, where it can interfere with mitochondrial DNA synthesis and upset the energy supply, resulting in characteristic enlarged, dysmorphic mitochondria. Manifestations of tenofovir nephrotoxicity include subclinical tubular defects (e.g., normoglycemic glycosuria), Fanconi syndrome, ATN, and CKD.[13] Renal manifestations can develop within weeks

of drug initiation or can occur after years, but reversibility is common. Risk factors include preexisting CKD, advanced age, low CD4 count, and total dose and duration of TDF use. Patients with HIV infection are at increased risk for a variety of renal diseases (see Chapter 56), and biopsy should be strongly considered when renal dysfunction does not improve after drug cessation or resistance patterns make tenofovir critical for patient care. Tenofovir alafenamide, a new formulation, concentrates in mononuclear cells, resulting in reduced drug delivery to the kidney. Early reports suggest a lower risk for nephrotoxicity with this agent.[14]

Atazanivir

Atazanvir is a protease inhibitor used in many HIV regimens. Atazanivir can cause urolithiasis and crystalline-induced renal injury, although at a much lower frequency than its predecessor indinavir. Risk factors for atazanivir stones include duration of therapy, history of nephrolithiasis, and hyperbilirubinemia. Renal biopsies have shown acute interstitial nephritis or a granulomatous interstitial nephritis in which atazanivir crystals were detectable in a giant cell reaction. Acute manifestations are largely reversible, but long-term use can lead to CKD.[15]

Other Antiviral Agents

Among antivirals used to treat HIV infection, both cobicistat and dolutegravir inhibit proximal tubular secretion of creatinine, causing a false elevation in serum creatinine that does not reflect an actual drop in GFR. A small rise in creatinine is considered acceptable and generally occurs within 2 weeks of starting these drugs. New direct-acting antivirals used to treat hepatitis C (e.g., ledipasvir, sofosbuvir) do not have significant nephrotoxicity. Adefovir, a second-line drug used to treat hepatitis B, was frequently nephrotoxic when prescribed at high doses, but current low-dose regimens appear safe for most patients. Foscarnet and cidofovir are well-recognized nephrotoxic antivirals.

Hypoglycemic Therapy: SGLT2 Inhibitors

Sodium glucose cotransporter type 2 (SGLT2) inhibitors have shown promise for reducing cardiovascular events and CKD in patients with diabetes, but may also predispose to AKI. There have been numerous recent reports of AKI associated with use of SGLT2 inhibitors, including canagliflozin, dapagliflozin, and empagliflozin. Most patients developed AKI within the first month of therapy, and it was not always reversible. Risk factors may include dehydration and use of NSAIDs. However, in a recent randomized controlled trial, the use of empagliflozin was associated with a lower incidence of AKI than placebo.[16]

Immunosuppressive Agents

Calcineurin Inhibitors

Cyclosporine and tacrolimus may cause AKI because of afferent arteriolar vasoconstriction, partly mediated by endothelin. This is usually reversible on dose reduction. Persistent injury may lead to chronic interstitial fibrosis in a striped pattern along medullary rays reflecting both the ischemic nature of the insult and the development of arteriolar hyalinosis. Associated clinical features include hypertension, hyperkalemia, hyperuricemia, and wasting of phosphorus and magnesium from tubular injury. Calcineurin inhibitors also cause reversible tubular dysfunction and are associated with the development of thrombotic microangiopathy, likely because of their effects on the endothelium (see Chapter 29).

Other Immunosuppressive Agents

The monoclonal anti-CD3 antibody (OKT3) or polyclonal antilymphocyte and antithymocyte preparations (ALG, ATG) may cause first-dose cytokine release syndrome and prerenal azotemia secondary to capillary leak. Intravenous immunoglobulin can cause AKI, which may be partly mediated by the high sucrose concentration in these products. Tubular uptake of sucrose may result in osmotic cell swelling and injury. Although it does not typically cause AKI, sirolimus delays the recovery from AKI in animal models and in kidney transplant patients with delayed graft function.

Ethylene Glycol

Ethylene glycol, found in antifreeze, is a cause of both deliberate and accidental overdose. It is rapidly metabolized by alcohol dehydrogenase to glycoaldehyde and glyoxylate, which are toxic to tubular cells. Further metabolism generates oxalic acid, which can precipitate, leading to intratubular obstruction.

The diagnosis is suggested by the presence of severe anion gap metabolic acidosis and elevated serum osmolal gap. Calcium oxalate crystals are often seen on urine microscopy (see Chapter 4, Fig. 4.7). Management includes inhibition of alcohol dehydrogenase with fomepizole or intravenous ethanol if this agent is not available. Although there is no specific ethylene glycol level above which extracorporeal removal is mandated, hemodialysis is the quickest way to remove both parent alcohol and toxic metabolites. Methanol intoxication may manifest with similar metabolic abnormalities, but rarely causes AKI (see Chapter 12).

Anticoagulation-Related Nephropathy

AKI has been described in patients taking warfarin who develop an acute rise in the international normalized ratio, usually to greater than 3. This occurs predominantly in patients with underlying CKD. AKI results from glomerular hematuria with obstruction of renal tubules by red blood cell casts. The direct thrombin inhibitor dabigatran can cause similar glomerular lesions when administered to rats, but human studies are lacking.[17]

Acute Phosphate Nephropathy

Oral sodium phosphate has been widely used as a bowel preparation for colonoscopy procedures, but recent cases of AKI have limited the use of this purgative.[18] AKI associated with oral sodium phosphate is believed to be caused by phosphaturia and acute calcium-phosphate deposition within the renal tubules. Risk factors for this condition include older age, volume depletion, and underlying CKD.

Drugs of Abuse

AKI is a common condition in those who abuse drugs and may be due to nephrotoxicity of the drug, coexistent viral infection (HIV, hepatitis C), sepsis, infective endocarditis, or rhabdomyolysis.[19]

Cocaine induces intense vasoconstriction, which may lead to AKI secondary to severe hypertension or rhabdomyolysis. Mechanisms for rhabdomyolysis include coma and pressure necrosis, vasospasm leading to ischemic muscle injury, and adrenergic stimulation with hyperpyrexia leading to increased cellular metabolism. Cocaine also may exert direct toxic effects on the myocyte.[20] The majority of cocaine entering the United States is contaminated by levamisole, an immunomodulator and antihelminthic agent. In humans, levamisole has been reported to cause an antineutrophil cytoplasmic antibody (ANCA)-positive vasculitis with a necrotizing crescentic GN and prominent skin lesions.

Other illicit drugs associated with AKI include opiates (coma-associated, pressure-induced rhabdomyolysis), phencyclidine (rhabdomyolysis secondary to hyperpyrexia and vasoconstriction), and methamphetamines (AKI secondary to rhabdomyolysis, acute interstitial nephritis, or acute necrotizing angiitis). Synthetic cannabinoids have been implicated as a cause of AKI, although the culprit component is unclear. When available, renal biopsy has shown ATN and more rarely AIN. In the majority of cases no other cause for AKI could be identified.[19]

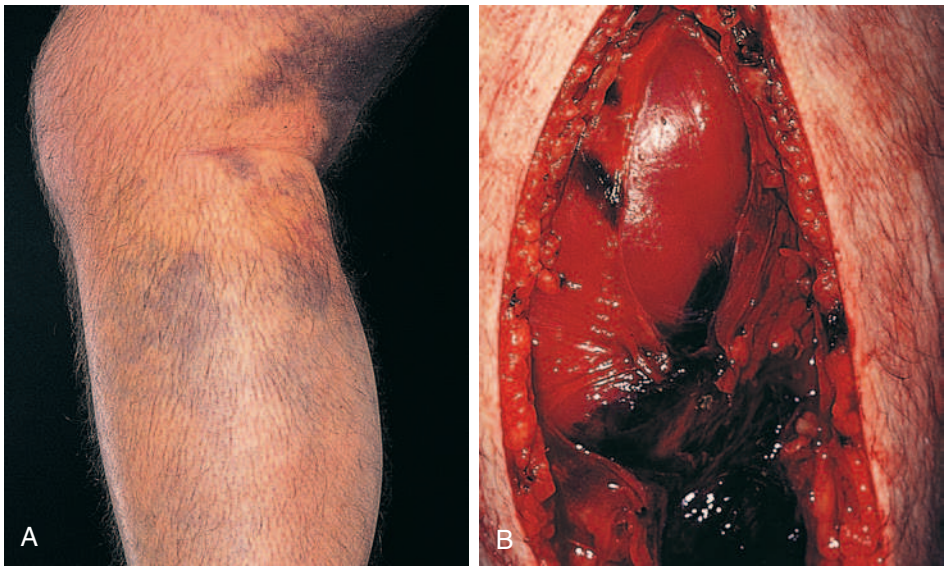

Fig. 66.9 Compartment syndrome. (A) Severe calf swelling secondary to anterior and posterior compartment syndromes after ischemia-reperfusion. (B) Appearance after emergency fasciotomy. Note edematous muscle and hematoma. (Courtesy M. J. Allen, FRCS.)

Occupational Toxins

Heavy Metals

Lead intoxication usually causes chronic nephropathy (see Chapter 62). Rarely, acute tubular injury occurs that may be associated with Fanconi syndrome. ATN also may occur in cadmium and mercury poisoning.

Organic Solvents

Organic solvents may cause acute tubular injury as a result of peroxidation of membrane lipids. Subacute renal failure secondary to anti–glomerular basement membrane (anti-GBM) antibody disease has been reported with exposure to halogenated hydrocarbons.

Herbal Remedies

Specific herbs used in traditional African medicine (e.g., Cape aloes, *Callilepis laureola*) are common causes of AKI in parts of Africa. Aristolochic acid (found in certain traditional Chinese medicines) can cause subacute renal failure (see Chapters 62 and 76).

Radiocontrast-Induced Nephropathy

AKI secondary to contrast nephrotoxicity typically occurs in patients with underlying renal impairment and is rarely seen in patients with preserved renal function. In hospitalized patients, it is often difficult to determine whether contrast computed tomography (CT) is the primary cause of AKI because imaging is often obtained in the setting of other potential renal insults (infection, antibiotics, etc.). Recent studies have questioned the link of intravenous contrast CT with nephrotoxicity, suggesting minimal risk for AKI when low or isoosmolar contrast is administered intravenously to patients with an eGFR greater than 30 ml/min.[21-23] Indeed, in these studies, the rates of AKI were similar among well-matched hospitalized patients who received noncontrast CT scans.

Intraarterial contrast administration, required for cardiac catheterization or renal angiography, is felt to pose a greater risk for AKI because these procedures often require larger doses of iodinated material that is then delivered to the renal arteries in a concentrated manner. Risk factors for the development of AKI from radiocontrast nephropathy include diabetic nephropathy, advanced age (>75 years), congestive heart failure, volume depletion, hyperuricemia, and high or repetitive doses of radiocontrast agents. Concurrent use of NSAIDs, ACE inhibitors, or diuretics may increase the risk.

Both renal ischemia and direct tubular epithelial cell toxicity are implicated in the pathogenesis of contrast nephrotoxicity. Typically, a biphasic hemodynamic response is seen. Initial vasodilation (lasting a few seconds to minutes) is followed by more prolonged renal vasoconstriction. The resultant medullary hypoxia may be exacerbated by low flow in the vasa recta as a result of a contrast-induced rise in blood viscosity. An osmotic diuresis, leading to increased sodium delivery to the mTAL, may result in increased oxygen consumption for sodium reabsorption. Uricosuria, as well as a hyperosmolar activation of the aldose reductase-fructokinase system in the kidney, has been proposed to play a role. Radiocontrast agents also cause direct tubular epithelial cell injury. Human studies have demonstrated low-molecular-weight proteinuria, suggestive of proximal tubular injury, partly mediated by ROS. The administration of antioxidants ameliorates contrast nephrotoxicity in animals.

OTHER SPECIFIC ETIOLOGIES OF ACUTE KIDNEY INJURY

Heme Pigment Nephropathy

Heme pigment nephropathy is a common cause of AKI and is usually secondary to the breakdown of muscle fibers (rhabdomyolysis), which release potentially nephrotoxic intracellular contents (particularly myoglobin) into the systemic circulation. Less commonly, heme pigment nephropathy may occur secondary to massive intravascular hemolysis. Prevention and therapy of heme pigment nephropathy are discussed in Chapter 70.

Causes of Rhabdomyolysis

Muscle trauma is the most common cause of rhabdomyolysis. The initial description was by Beall and colleagues[24] during the bombing of London in World War II. Other common causes of muscle injury include marked exercise, seizures, pressure necrosis secondary to coma, substance abuse, and limb ischemia (Fig. 66.9). In skeletal muscles confined to rigid compartments, cell swelling after injury may result in increased intracompartmental pressures that can impair local

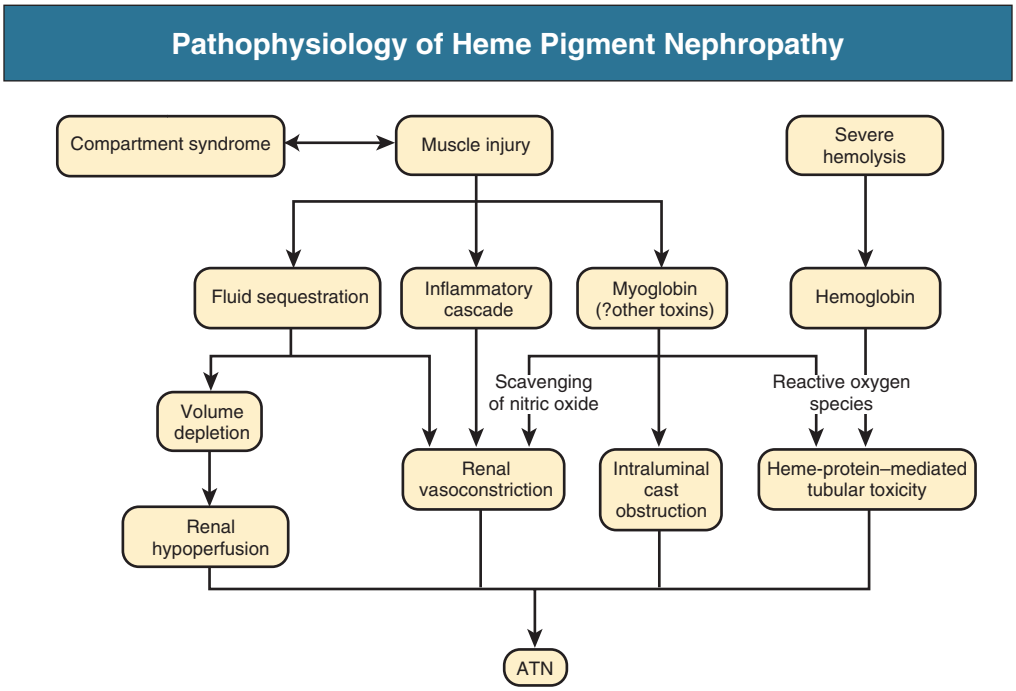

Fig. 66.10 Pathophysiology of heme pigment nephropathy. *ATN,* Acute tubular necrosis.

microvascular circulation and lead to compartment syndrome (Fig. 66.10). In the patient with alcohol abuse, rhabdomyolysis is often multifactorial. Contributing causes include pressure necrosis from coma ("found down"), direct myotoxicity from ethanol, seizures, and electrolyte abnormalities (hypokalemia and hypophosphatemia). Therapy with statins may be associated with rhabdomyolysis, especially when fibrates, cyclosporine, or erythromycin are used concurrently. Familial myopathies such as McArdle syndrome and carnitine palmitoyl transferase deficiency should be suspected in patients with recurrent episodes of rhabdomyolysis associated with muscle pain, positive family history, onset in childhood, and the absence of other identifiable causes. In developing countries, ingestion of hair dye containing paraphenylene diamine as a means of self-harm may cause AKI secondary to rhabdomyolysis. Snake and spider bites, bee stings, and venomous caterpillar bites may cause rhabdomyolysis (see Chapter 67).

Causes of Hemoglobinuria

Intravascular hemolysis results in circulating free hemoglobin. If the hemolysis is mild, the released hemoglobin is bound by circulating haptoglobin. With massive hemolysis, however, haptoglobin stores become exhausted. Hemoglobin (69 kDa) then dissociates into α-β dimers (34 kDa) that are small enough to be filtered, resulting in hemoglobinuria, hemoglobin cast formation, heme uptake by proximal tubular cells, ATN, and filtration failure. Causes of hemoglobinuric AKI include incompatible blood transfusion, autoimmune hemolytic anemia, malaria (blackwater fever), glucose-6-phosphate dehydrogenase deficiency, paroxysmal nocturnal hemoglobinuria, march hemoglobinuria, and toxins (dapsone, venoms).

Pathogenesis of Heme Pigment Nephropathy

The renal injury is due to a combination of factors, including volume depletion, renal vasoconstriction, direct heme-protein–mediated cytotoxicity, and intraluminal cast formation (Table 66.1).[25] Volume depletion is often prominent in patients with rhabdomyolysis owing to the sequestration of large amounts of fluid (up to 15 to 20 liters) in injured muscle. Volume depletion activates the sympathetic nervous system and renin-angiotensin system, resulting in renal vasoconstriction. This may be exacerbated by the scavenging of nitric oxide by circulating heme proteins.

Myoglobin (17 kDa) is freely filtered at the glomerulus and is toxic to tubular epithelial cells. The heme center of myoglobin may directly induce lipid peroxidation and renal injury, and liberated free iron catalyzes the formation of hydroxyl radical through the Fenton reaction, inducing free radical–mediated injury. Renoprotection has been demonstrated in animal models with free iron scavengers and various antioxidants. Finally, the precipitation of myoglobin with Tamm-Horsfall protein and sloughed proximal tubular cells may result in obstructing casts in the distal nephron, especially when tubular flow rates are low because of volume depletion. The binding of myoglobin to Tamm-Horsfall protein is enhanced in acidic urine.

TABLE 66.1 Causes of Rhabdomyolysis

Muscle injury/ischemia	Trauma; pressure necrosis, electric shock, burns, acute vascular disease
Myofiber exhaustion	Seizures, excessive exercise, heat exhaustion
Toxins	Alcohol, cocaine, heroin, amphetamines, ecstasy, phencyclidine, snake bite
Drugs	Statins, fibrates, zidovudine, neuroleptic malignant syndrome, azathioprine, theophylline, lithium, diuretics
Electrolyte disorders	Hypophosphatemia, hypokalemia, hyperosmolar states
Infections	Viral: Influenza, HIV, coxsackievirus, Epstein-Barr virus Bacterial: *Legionella, Francisella, Streptococcus pneumoniae, Salmonella, Staphylococcus aureus*
Familial	McArdle disease, carnitine palmitoyl transferase deficiency, malignant hyperthermia
Other	Hypothyroidism, polymyositis, dermatomyositis

Atheroembolic Renal Disease

This underrecognized condition occurs predominantly in older patients with atherosclerotic vascular disease (see also Chapter 38). It can occur spontaneously, but is most commonly precipitated by arteriography, vascular surgery, thrombolysis (streptokinase and tissue plasminogen activator), or anticoagulation. Destabilization of atherosclerotic plaques primarily in the aorta above the level of the renal arteries results in showers of cholesterol that lodge in small arteries in the kidneys (see Fig. 41.13) and the lower extremities (see Fig. 41.11). Characteristic needle-shaped clefts may be seen on renal or skin biopsy, denoting the localization of cholesterol plaques before dissolution with tissue fixation (Fig. 41.13). The cholesterol emboli produce a marked and progressive inflammatory reaction, resulting in occlusion of the involved vasculature.

Renal Artery or Vein Occlusion

AKI can be caused by bilateral renal artery occlusion or unilateral occlusion in the setting of a single functioning kidney (see also Chapter 38). Thrombosis or embolization (noncholesterol) of the renal artery or its intrarenal branches are more common in elderly patients. Atrial fibrillation is an important risk factor for renal emboli. Aortic dissection may progress to occlude the renal arteries. Renal vein thrombosis most commonly occurs in the setting of nephrotic syndrome and rarely may cause AKI if bilateral.

Acute Interstitial Nephritis

This is most commonly a drug-induced phenomenon and is an important differential diagnosis in AKI because removal of the offending agent can result in reversal of the condition. Less commonly, interstitial nephritis may be due to infection or immune-mediated diseases. Acute interstitial nephritis is discussed further in Chapter 60.

Thrombotic Microangiopathy

Thrombotic microangiopathy (TMA) constitutes a wide range of conditions that should be considered when a patient presents with AKI and thrombocytopenia, although the condition may occur in the absence of a low platelet count. All forms of TMA can manifest with AKI (see also Chapter 29).

Glomerular Disease

All types of glomerular disease may present with AKI, but it is more commonly seen with forms of acute GN such as postinfectious GN, ANCA-associated small-vessel vasculitis, anti-GBM disease, lupus nephritis, and IgA nephropathy. The term *rapidly progressive GN* has been used in this setting and is often associated with glomerular crescents on renal biopsy. Glomerular disease associated with the nephrotic syndrome is less likely to manifest as AKI, but AKI may occur secondary to volume depletion from diuretic use, superimposed ATN, renal vein thrombosis, or, rarely, from superimposed acute GN (e.g., anti-GBM disease in membranous nephropathy). Minimal change disease in adults is the most common nephrotic disorder associated with AKI. Glomerular disease is discussed further in Section IV.

SPECIFIC CLINICAL SITUATIONS

Determining the cause of AKI is often aided by recognizing common patterns of manifestation and determining the likely causes arising in each of these situations.

Acute Kidney Injury in the Patient With Sepsis

Sepsis accounts for up to 50% of cases of AKI in intensive care unit patients, and the presence of septic AKI is associated with mortality rates as high as 50% to 60% in those requiring renal replacement therapy.[26] In recent years, the traditional model of hypotension and vasoconstriction leading to ischemic ATN has been challenged by the finding that in early sepsis, RBF is often normal or even increased. Moreover, the severe drop in GFR observed with sepsis is out of proportion to the relatively mild degree of histologic injury seen on renal biopsies, and on autopsy only 22% of patients with sepsis-associated AKI had histologic features of ATN.[27]

The pathogenesis of sepsis-associated AKI is mediated by molecules released from pathogens (lipopolysaccharide, flagellin, lipoteichoic acid, DNA), or injured cells, which activate the innate immune system by binding to TLRs and other receptors on immune cells.[28,29] This leads to the activation of a wide range of cellular and humoral mediator systems, including the cytokine cascade (TNF-α, IL-1β, IL-6); the complement, coagulation, and fibrinolytic systems, increased oxidative stress, and the release of mediators such as eicosanoids, platelet-activating factor, endothelin-1, and nitric oxide. Renal endothelial cells can be damaged in the procoagulant milieu and upregulate their expression of adhesion molecules, further amplifying the immune response. Disruption of the renal microcirculation ensues, with local areas of cortical ischemia despite maintenance of normal renal arterial blood flow. Ligation of TLRs on tubular cells (TLR-4) leads to mitochondrial dysfunction, oxidative stress, and severe apoptosis, rather than necrosis. The mechanism for the abrupt GFR decline in early sepsis likely involves *efferent* arteriolar vasodilation. Therapies that promote efferent arteriolar vasoconstriction may be beneficial. In a sheep model of sepsis, infusion of Ang II improved mean arterial pressure and GFR despite a decrement in RBF. In human studies, treatment with arginine vasopressin, which constricts the efferent more than the afferent arteriole, was associated with reduced progression to the most severe category of AKI in patients with septic shock.[30] Sepsis may lead to multiorgan failure, and affected patients may have repeated episodes of AKI as a result of nephrotoxic drug exposure or hospital-acquired infections. Finally, maladaptive repair processes can lead to CKD after AKI in sepsis.

Acute Kidney Injury in the Trauma Patient

AKI significantly increases mortality among those with severe trauma.[31] Mechanisms for renal injury include rhabdomyolysis (earthquake victims, crush injuries, burns), ATN from hypovolemic shock, or abdominal compartment syndrome secondary to massive hemorrhage or aggressive hydration. Direct kidney injury may result from penetrating (gunshot, stab wound) or more commonly blunt trauma (fall, motor vehicle collision, assault, sports injury). Proper diagnosis of these injuries requires a contrast-enhanced CT with delayed imaging; otherwise, late extravasation from the renal pelvis or ureters may be missed. Management is generally conservative, but emergent nephrectomy may be required.

Acute Kidney Injury in the Postoperative Patient

Postoperative AKI is commonly due to perioperative hemodynamic instability, volume depletion, and/or nephrotoxin exposure.

After Cardiac Surgery

Risk factors for postoperative AKI include duration of cardiac bypass, preoperative renal function, hyperuricemia, age, diabetes, valvular surgery, blood transfusions, and poor cardiac function.[32] The surgery is often performed with the patient cooled to less than 30°C to protect cells against ischemic injury; however, systemic hypothermia may cause intravascular coagulation. Aortic instrumentation and cross-clamping may lead to renal atheroembolism. Cardiac bypass causes exposure of blood to a nonendothelialized surface, resulting in activation of

neutrophils, platelets, complement, and fibrinolytic systems. Significant hemolysis may occur, potentially resulting in hemoglobinuria. Perioperative myocardial infarction or left ventricular dysfunction may impair renal perfusion postoperatively, although the low cardiac output is often transient (myocardial stunning) and recovers within 24 to 48 hours. Atrial fibrillation is a common complication and may be associated with peripheral embolization. Off-pump coronary artery bypass operations may have a lower risk for AKI than surgeries involving cardiopulmonary bypass.

After Vascular Surgery

AKI is common after abdominal aortic aneurysm repair, but the risk appears to be lower in those undergoing endovascular versus open repair.[33] Mechanisms for AKI include ischemic ATN as a result of prolonged aortic cross-clamping, renal artery thromboembolism or dissection, and cholesterol atheroemboli. Additional complications specific to endovascular repair include contrast nephropathy and renal ischemia secondary to endograft malpositioning or migration. In patients with peripheral vascular disease, there is often ischemic renal disease, and preoperative reduction in eGFR is the strongest predictor of the risk for postoperative AKI.

Abdominal Compartment Syndrome

Markedly raised intraabdominal pressures (>20 mm Hg) may occur after trauma, after abdominal surgery, or secondary to massive fluid resuscitation and can cause AKI.[34] The mechanism remains unclear, but may be due to increased renal venous pressure and vascular resistance. Intraabdominal pressures are best estimated by measurement of intravesical (bladder) pressures. Efforts to reduce intraabdominal pressures, including paracentesis, nasogastric suction, ultrafiltration, or surgical decompression, may improve renal function.

Pulmonary-Renal Syndrome

The term *pulmonary-renal syndrome* usually describes the presence of pulmonary hemorrhage in a patient with acute GN. It can be caused by anti-GBM disease (Goodpasture syndrome), systemic vasculitis, or systemic lupus erythematosus (see Chapters 24 to 26). Given the fulminant course of the previously mentioned diseases, patients with pulmonary-renal syndrome require urgent evaluation, and specific testing for these diseases should be pursued. A similar clinical presentation may occur in patients with pulmonary infection and AKI or in the setting of pulmonary edema secondary to volume overload from AKI. Other conditions that may masquerade as a pulmonary renal syndrome are outlined in Table 66.2.

Acute Kidney Injury and Liver Disease

AKI is common in patients with cirrhosis. The differential diagnosis is typically among prerenal AKI, ATN, and hepatorenal syndrome. The pathophysiology of hepatorenal syndrome is discussed in Chapter 73. Assessment of intravascular volume status can be difficult, and a therapeutic trial of volume replacement is typically undertaken. Risk factors for AKI in this population include hypovolemia, gastrointestinal bleeding, and infection (particularly spontaneous bacterial peritonitis). It is important to note that severe malnutrition and decreased muscle mass may be masked by the presence of edema. In these settings, a "normal" creatinine can be deceptive and represent a significant loss of GFR. Rarely, the same etiologic agent may be responsible for both the liver and renal injury. This occurs with certain infections (e.g., leptospirosis, hantavirus) and nephrotoxic agents (Table 66.3). AKI secondary to bile cast nephropathy has been described in obstructive jaundice.

TABLE 66.2 Causes of Pulmonary-Renal Syndrome

Immunologic and drug induced	Anti–glomerular basement membrane disease (Goodpasture) Antineutrophil cytoplasmic antibody associated: Granulomatosis with polyangiitis Microscopic polyangiitis Churg-Strauss syndrome Immune complex disease: Lupus IgA-vasculitis Mixed cryoglobulinemia Rheumatoid vasculitis Drugs: Penicillamine Hydralazine Propylthiouracil
Infection	Severe bacterial pneumonia, postinfectious glomerulonephritis, *Legionella,* leptospirosis, hantavirus, infective endocarditis
Pulmonary edema and acute kidney injury	Volume overload in severe left ventricular failure
Multiorgan failure	Acute respiratory distress syndrome and acute kidney injury
Other	Paraquat poisoning; renal vein or inferior vena cava thrombosis with pulmonary emboli

TABLE 66.3 Causes of Acute Kidney Injury and Liver Disease

Prerenal azotemia	Diuretic use, gastrointestinal loss, large volume paracentesis, hypoalbuminemia
Hepatorenal syndrome	
Acute tubular necrosis	Hyperbilirubinemia (bile cast nephropathy), sepsis, gastrointestinal hemorrhage
Drugs	Acetaminophen (paracetamol), NSAIDs, tetracycline, rifampicin, isoniazid, anesthetic agents, sulfonamides, anticonvulsants (DRESS syndrome), allopurinol, methotrexate, aspirin (Reyes syndrome)
Infections	Hepatitis C and cryoglobulinemia, hepatitis B and polyarteritis nodosa, leptospirosis, hantavirus, Epstein-Barr virus, gram-negative sepsis, spontaneous bacterial peritonitis
Other	Papillary necrosis, inhalation of chlorinated hydrocarbons, mushroom poisoning *(Amanita phalloides),* carbon tetrachloride

DRESS, Drug rash with eosinophilia and systemic symptoms; *NSAIDs,* nonsteroidal antiinflammatory drugs.

Acute Kidney Injury in Heart Failure (Cardiorenal Syndrome)

The development of AKI in patients with decompensated heart failure is common and is associated with poor prognosis (see also Chapter 72). Reduced renal perfusion secondary to decreased cardiac output has long been considered the primary cause; however, there are

TABLE 66.4 Causes of Acute Kidney Injury in Patients With Cancer

Prerenal	Nausea and vomiting, hypercalcemia, cardiomyopathy secondary to chemotherapy
Vascular	Thrombotic microangiopathy (adenocarcinoma of stomach; cancer of the breast, prostate, lung, or pancreas; radiation nephropathy), renal vein thrombosis secondary to hypercoagulability, disseminated intravascular coagulation (acute promyelocytic leukemia)
Glomerular	Rapidly progressive glomerulonephritis
Acute tubular necrosis	Sepsis and antibiotic nephrotoxicity
Malignant infiltration	Lymphoma, acute lymphoblastic leukemia
Intraluminal obstruction	Tumor lysis syndrome, myeloma cast nephropathy
Postrenal obstruction	Transitional cell carcinoma ureters and bladder, prostatic obstruction, extrinsic ureteral compression (tumor, nodes, retroperitoneal fibrosis)
Chemotherapeutic agents	
Tubular toxicity	Cisplatin, ifosfamide, plicamycin (mithramycin), imatinib, pemetrexed, pentostatin, high-dose bisphosphonates
Thrombotic microangiopathy	Mitomycin C, gemcitabine, cisplatin, calcineurin inhibitors, anti-VEGF therapies
Other mechanisms	Capillary leak syndrome (IL-2 therapy), acute interstitial nephritis (interferon-α, checkpoint inhibitors), intraluminal obstruction (methotrexate)

IL-2, Interleukin-2; *VEGF,* vascular endothelial growth factor.

important contributions from right ventricular dysfunction leading to renal venous hypertension and activation of renin angiotensin and sympathetic nervous systems.[35]

Acute Kidney Injury in the Cancer Patient

Patients with cancer are prone to AKI because of the underlying malignancy and its treatment (see Chapter 65). In a large European population, the incidence of AKI was 18% in the year after cancer diagnosis, and AKI occurs commonly in critically ill cancer patients.[36] Prerenal azotemia is common in cancer patients because of the high frequency of vomiting and diarrhea, and urinary tract obstruction must always be ruled out (Table 66.4). More specific causes of intrarenal AKI are noted in the following sections.

Tumor Lysis Syndrome

Necrosis of tumor cells may release large amounts of nephrotoxic intracellular contents (uric acid, phosphate, xanthine) into the circulation. This usually occurs after treatment of lymphoma (particularly Burkitt) and leukemia, but may occur with solid tumors. Rarely, a spontaneous form of tumor lysis syndrome (TLS) occurs in patients with rapidly growing tumors that have outstripped their blood supply. AKI occurs when crystals of uric acid, calcium phosphate, and xanthine precipitate in the renal tubules causing obstruction and inflammation. Hyperuricemia may contribute to AKI by crystal-independent mechanisms, including renal vasoconstriction, and oxidative injury.[37] Risk factors for TLS include preexisting CKD, bulky and rapidly proliferating tumors, volume depletion, and acidic urine. The AKI is typically oligoanuric, and the condition should be suspected in patients with high lactate dehydrogenase levels suggestive of massive cell lysis. Markedly elevated phosphate and urate levels may be found. Hyperkalemia may be prominent and life threatening. Prevention and therapy of TLS are discussed in Chapter 70.

Hypercalcemia

Hypercalcemia is common in advanced cancer and may result from lytic bone metastases, overproduction of 1,25 dihydroxyvitamin D (predominantly lymphomas), or the production of parathyroid hormone–related peptide. Hypercalcemia causes nausea, vomiting, and polyuria, and AKI in this setting is often driven by volume depletion. Additional mechanisms for hypercalcemia-induced AKI include direct intrarenal vasoconstriction and intratubular obstruction.

Chemotherapeutic Agents

Cisplatin is commonly associated with nonoliguric AKI, and nephrotoxicity is the most common dose-limiting side effect of this drug.[38] Cisplatin accumulates in mitochondria, inhibiting oxidative phosphorylation and resulting in excessive reactive oxygen formation and impairment in ATP generation, leading to cell death. Tubular injury affects both the proximal and distal nephron and clinically may be associated with magnesium wasting, impaired urinary concentration, and, rarely, salt wasting with volume depletion. Prophylaxis against nephrotoxicity includes volume loading and reducing the dose when possible. Although renal impairment may persist after treatment, progressive decline in GFR is unusual. When combined with bleomycin and vinca alkaloids, cisplatin has been associated with thrombotic microangiopathy. The alternative agent carboplatin appears to be less nephrotoxic.

Ifosfamide is a cyclophosphamide analogue with a nephrotoxic metabolite, chloroacetaldehyde. AKI is usually mild, although proximal tubular dysfunction (Fanconi syndrome) and hypokalemia may be prominent and sometimes persistent.

High-dose methotrexate and its metabolites can precipitate within the tubular lumen and cause AKI. Risk factors for drug crystallization include acid urine, volume depletion, impaired GFR, and concurrent nephrotoxin exposure. Aggressive hydration and urinary alkalinization (pH >7.0) can reduce the risk for nephrotoxicity.

Gemcitabine is a nucleoside analogue that causes AKI primarily by damaging the renal endothelium. The most common manifestation is a thrombotic microangiopathy that develops 1 to 2 months after drug completion. AKI is often accompanied by new-onset hypertension or worsening of existing hypertension. Laboratory evidence of systemic hemolysis is common. AKI secondary to thrombotic microangiopathy may be caused by mitomycin and by drugs that inhibit VEGF pathways (e.g., bevacizumab, tyrosine kinase inhibitors).[39]

PD-1 (programmed cell death 1) receptor inhibitors, such as ipilimumab, nivolumab, and pembrolizumab have recently emerged as agents with an increased risk for AKI. Additional chemotherapeutic agents that may cause AKI are listed in Table 66.4.

SELF-ASSESSMENT QUESTIONS

1. Acute tubular injury predominantly affects which segments of the nephron?
   A. Proximal convoluted tubule and loop of Henle
   B. Proximal tubule and distal convoluted tubule
   C. Loop of Henle and distal convoluted tubule
   D. Distal convoluted tubule and collecting ducts
   E. All tubular segments of the nephron equally
2. What is the most likely mechanism by which nonsteroidal antiinflammatory drugs (NSAIDs) cause acute kidney injury (AKI) in a patient with systolic heart failure?
   A. Impaired efferent arteriole vasodilation
   B. Impaired efferent arteriole vasoconstriction
   C. Impaired tubuloglomerular feedback
   D. Impaired afferent arteriole vasodilation
   E. Impaired afferent arteriole vasoconstriction
3. Which of the following nephrotoxic agents causes AKI predominantly by the formation of intratubular crystals?
   A. Cisplatin
   B. Methotrexate
   C. Gentamicin
   D. Amphotericin
   E. Tacrolimus
4. How does tubular injury (acute tubular necrosis) cause a drop in glomerular filtration rate?

67

Acute Kidney Injury in the Tropics

Emmanuel A. Burdmann, Vivekanand Jha, Visith Sitprija

The tropics span the area on either side of the equator (approximately 23 degrees north to 23 degrees south). Approximately 40% of the world population lives in the tropics, and this proportion is expected to rise to 60% by 2060.[1] Tropical countries have high sociopolitical and economic heterogeneity. The same country may have poor underdeveloped areas that lack basic public health infrastructure and also wealthy regions with sophisticated health facilities.

Acute kidney injury (AKI) epidemiology in the tropics is heavily influenced by these dissimilarities. In large cities and tertiary hospitals, AKI patient characteristics are similar to those found in high-income countries in nontropical areas and the principal causes of AKI are ischemia, principally secondary to sepsis, and drug nephrotoxicity. In contrast, in remote small urban areas, in poor and vulnerable neighborhoods of large cities, and in rural zones, AKI is frequently community-acquired and affects previously healthy young individuals. Poverty, malnutrition, lack of sanitary infrastructure, deficient public health system, and uncontrolled urbanization are frequent problems that add significantly to the disease burden. In those settings, infectious diarrhea linked to unsafe drinking water and poor hygiene, tropical infectious diseases, envenomation by snakes or arthropods, use of natural medicines, and poor obstetric care are common causes of AKI. A strong seasonal variation in the incidence of AKI occurs in the tropics, with a spike during and immediately after the rainy seasons. Heavy precipitation leads to conditions favorable for survival of organisms causing or transmitting infectious diseases and forces venomous snakes out of their flooded burrows, making accidents more likely.[1,2] Although epidemiologic data for community-acquired AKI in tropical countries are limited, some authors showed a high frequency and high early mortality for these patients.[3,4] Access to renal replacement therapy (RRT) is frequently limited because of nonavailability or high costs.[3-5]

There is regional variability in the cause of AKI in the tropics. Malaria, leptospirosis, diarrheal diseases, and venomous snakebite are common causes in South Asia. Malaria, diarrheal diseases, obstetric accidents, and indigenous herbal remedies are frequent causes in Africa. Malaria, leptospirosis, dengue fever, animal envenomation, and obstetric complications are important causes in Latin America.[1-5] AKI associated with rhabdomyolysis and dehydration secondary to heat stroke and/or prolonged strenuous work in an unhealthy environment may occur.[6] The long-term morbidity, mortality, and economic weight of tropical disease–associated AKI are nearly unknown.

SNAKEBITE

Snakebite is a neglected public health occupational hazard. Economically deprived populations living in rural communities are affected disproportionately.[7] It has been suggested that there are 0.5 to 2 million cases of envenomation from snakebite (20,000 to 94,000 deaths) annually, with the highest burden in South and Southeast Asia, Latin America, and sub-Saharan Africa.[8] This is likely an underestimate because the data are based on hospital admissions.

Kidney injury may develop after bites by hematoxic or myotoxic snakes belonging to Viperidae and Elapidae families, such as Russell viper, saw-scaled viper, puff adder, rattlesnake, tiger snake, green pit viper, *Bothrops, Lachesis, Crotalus,* boomslang, gwardar, dugite, *Hypnale, Cryptophis,* and sea snakes. AKI is more frequent after Russell viper bites (Fig. 67.1) in Asia and *Bothrops* or *Crotalus* bites in Latin America.[1,2,9-11] The prevalence is higher in children, probably because of the higher venom dose in relation to the body size.[1,2]

Clinical and Laboratory Features

Clinical manifestations depend on the nature and injected dose of venom. Local pain, swelling, blistering, ecchymosis and tissue necrosis at the bite site, and coagulation abnormalities leading to bleeding diathesis are frequent in Russell viper and *Bothrops* bites (Figs. 67.2 and 67.3). Neurotoxicity (manifested by paralysis) and rhabdomyolysis (manifested by myalgia and cola-colored urine) may occur after sea snake and *Crotalus* bites.[1,2,9-12] Other uncommon clinical manifestations include myocardial injury and hypopituitarism.[13,14]

AKI develops within a few hours (snake venom concentrates in kidney minutes after the bite) to as late as 96 hours after the accident.[1,2,9-11] The AKI is usually oliguric and catabolic; rapid increases in serum creatinine and potassium are usual. Oliguria generally lasts for 1 to 2 weeks, and its persistence suggests the likelihood of acute cortical necrosis, which can be confirmed by renal biopsy or a contrast-enhanced computed tomography scan.[1,2,9-11] Proteinuria and hematuria have been described and may reflect differences in venom composition.[10] Although kidney function usually recovers, AKI-associated snakebite has been associated with chronic kidney disease (CKD) in both adults and children on long-term follow-up.[15,16] AKI after snakebite may aggravate renal dysfunction in agrochemical nephropathy.[17]

Laboratory investigation may disclose hemolysis (elevated free serum hemoglobin and lactate dehydrogenase and reduced haptoglobin), along with hypofibrinogenemia; reduced factors V, X, and XIIIA; protein C and antithrombin C; and elevated fibrin degradation products. Rhabdomyolysis may be indicated by raised creatinine phosphokinase, hyperphosphatemia, and hyperuricemia. Other findings include leukocytosis and elevated hematocrit as a result of hemoconcentration.[1,2,9-11]

Pathology

Grossly, the kidneys may have petechial hemorrhages. Acute tubular cell injury ranging from mild changes to overt tubular necrosis, with hyaline or pigment casts, variable degree of interstitial edema and

Fig. 67.1 Russell viper. This large snake is an important cause of venomous snakebite–induced acute kidney injury in Asia.

infiltration, and scattered hemorrhages, which usually are found on light microscopy. Mesangiolysis may occur (especially with *Crotalid* envenomation), and blood vessels may show fibrin thrombi. Electron microscopic findings include dense intracytoplasmic bodies representing degenerated organelles in the proximal tubules and electron-dense mesangial deposits. Less common findings are acute interstitial nephritis, necrotizing vasculitis, and proliferative and crescentic immune-complex glomerulonephritis (GN). Acute cortical necrosis is seen in about 20% to 25% of cases after Russell viper and *Echis carinatus* bites and has been described after *Bothrops* bites.[1,2,9-11]

Pathogenesis

Snake venom is a mixture of enzymes, toxins, peptides, carbohydrates, lipids, metals, biogenic amines, and nucleotides. Several factors are potentially involved in kidney injury, including direct tubular toxicity, hemodynamic instability, hemolysis, rhabdomyolysis, systemic inflammation, coagulation abnormalities causing glomerular deposition of microthrombi, oxidative stress, hyperuricemia, release of cytochrome c, and apoptosis of tubular epithelial cells.[1,2,9-11,18-21]

Management

The basic therapeutic approach is the same as that for AKI related to any cause (see Chapters 70 and 71). Key steps for reducing morbidity and mortality include early administration of specific monovalent antivenom, appropriate volume replacement, maintenance of adequate urine output, correction of electrolyte imbalance, administration of tetanus immunoglobulin, and treatment of infections.[1,2,9-11,18] Locally available polyvalent antivenom is effective against envenoming by multiple snakes or unknown snakes.[22] Nonavailability of antivenom in rural hospitals and poor infrastructure that hampers transportation to health centers delay administration of antivenom and contribute to high mortality.[1,2,9-11,23] Limited availability and the risk for side effects have encouraged the exploration of alternatives for antivenom therapies, but to date none have shown efficacy.[24]

ARTHROPODS

Bees

Hundreds of simultaneous bee stings causes a multifaceted clinical picture, comprising intravascular hemolysis; rhabdomyolysis; low platelet count; coagulation disorders and bleeding; cardiovascular, hepatic, and pulmonary injury; and severe AKI, with mortality up to 16%.[1,25,26] Similarly, AKI can follow multiple stings from wasps, yellow-jackets, or hornets.[26] The potential mechanisms include direct venom nephrotoxicity, intrarenal vasoconstriction, hemoglobinuria, myoglobinuria, hypotension, thrombotic microangiopathy,[27] and inflammatory and oxidative stress pathways activation.[28] Renal histologic examination usually shows acute tubular necrosis (ATN).[1,25,27] The high morbidity and lethality of massive bee attacks has prompted the development of equine serum antivenom, which was effective in protecting against rhabdomyolysis and hemolysis in mice.[29]

Caterpillars

Accidents with caterpillars of the genus *Lonomia* produce severe hemorrhagic disorders, characterized by both fibrinolytic and disseminated intravascular coagulation–like activity.[25] Severe and prolonged AKI, with some patients evolving to CKD, has been reported after *Lonomia obliqua* (Fig. 67.4) bites.[25,30,31] Availability of *Lonomia* antivenom has led to an apparent decrease in the number of severe cases in Brazil.[30] Early antivenom administration in rats prevented *Lonomia* venom–induced hemorrhagic manifestations and renal dysfunction.[32] The AKI involves glomerular deposition of fibrin, intravascular hemolysis, direct venom

Fig. 67.4 *Lonomia obliqua* caterpillars. Each hair works as a miniature hypodermic needle to inject the hemolymph, which contains powerful venom that is able to induce severe coagulation system changes. (Courtesy Elvino J. G. Barros, Porto Alegre, Brazil.)

nephrotoxicity, activation of the endothelial cell inflammatory pathway, increased renal expression of proteins involved in cell stress, heme-induced oxidative stress, coagulation, and complement system activation.[33] Kidney histologic findings include ATN, ischemia, and tubular atrophy.[31,33]

Loxosceles

Spiders of the genus *Loxosceles* (Fig. 67.5) can cause local necrosis at the bite site (Fig. 67.6), intravascular hemolysis, rhabdomyolysis, coagulation abnormalities, and AKI.[25] Even patients with mild cutaneous lesions may develop severe hemolysis and AKI, which is the main cause of death after these accidents. AKI pathogenesis has been related to massive intravascular hemolysis, renal vasoconstriction, direct nephrotoxicity, and rhabdomyolysis.[25,34] Renal histologic examination shows pigment-induced ATN.[34] Antivenom is likely the most effective therapy against AKI, but its use is frequently delayed because the bite goes unnoticed.

Scorpions

Scorpion venom causes autonomic overactivity and massive discharge of vasoactive substances and inflammatory cytokines.[35] The venom concentrates rapidly in kidney tissue. Scorpion venom–associated AKI is rare.[36,37] Mechanisms causing AKI are probably renal vasoconstriction, hemodynamic instability, rhabdomyolysis, systemic inflammation, and direct venom nephrotoxicity.[35-39] Renal histologic abnormalities include ATN, glomerular changes, interstitial infiltrates, thrombotic microangiopathy, and cortical necrosis.[35,36,38,39] A Mexican study suggests that scorpion envenomation can lead to CKD in children.[40]

NATURAL MEDICINE

Herbs and indigenous remedies are widely used in poor societies living in the tropics, and are an important cause of AKI, especially in sub-Saharan Africa. This is discussed in Chapter 76.

MALARIA

Five species of *Plasmodium* parasites (*falciparum, vivax, malariae, ovale,* and *knowlesi*) cause malaria. Globally, malaria afflicts over 200 million people annually, causing nearly 500,000 deaths, mostly in children with *P. falciparum.* The incidence of *P. knowlesi* infection is increasing in Southeast Asia, predominantly in Sarawak, Malaysia. The contribution of malaria as the cause of AKI among different geographical areas ranges from 2% to 39%. The frequency of AKI in *P. falciparum* malaria might reach 60%, and in *P. vivax* malaria varies from 10% to 19%.[41] Using Kidney Disease: Improving Global Outcomes (KDIGO) criteria, the frequency of malaria-associated AKI is higher than using the World Health Organization (WHO) criteria.[42] *P. malariae, P. knowlesi,* and *P. ovale*–induced AKI are less common. In this chapter, we focus on *P. falciparum* malaria–associated AKI.

Pathophysiology

The characteristics of the different species of parasite influence the pathogenesis and clinical manifestations of malaria. *P. vivax, P. ovale,* and *P. knowlesi* infect young erythrocytes, and *P. malariae* infects aging cells. *P. falciparum* infects erythrocytes of all ages, producing a higher number of merozoites (Fig. 67.7). Heavy parasitemia is therefore commonly observed in *P. falciparum* malaria, creating adverse effects on the microcirculation. *Plasmodium* parasites primarily infect erythrocytes, with secondary effects on the microcirculation and immune system. Parasitized erythrocytes play a major role in the pathophysiologic process of the disease through decreased erythrocyte deformability and sequestration, knobs and rosette formation, cytoadherence, and changes in membrane transport and permeability (Fig. 67.8). The presence of knobs on parasitized erythrocyte membranes and cytoadherence between parasitized erythrocytes and vascular endothelial cells are characteristic of *P. falciparum* malaria. Cytoadherence of mature *P. vivax* parasitized erythrocytes to vascular endothelial cells involves intercellular adhesion molecule-1, CD36, endothelial protein C receptor, platelet endothelial cell adhesion molecule, and chondroitin sulfate A receptors.[43] *P. vivax*–caused cytoadherence is lower than that of *P. falciparum*–infected erythrocytes. As in other infectious diseases, several proinflammatory cytokines (tumor necrosis factor, interleukins 1, 6, and 8, interferon-γ) and vasoactive mediators are released. The renin-angiotensin-aldosterone-system is also stimulated. Hemodynamic changes in malaria are similar to those of bacterial sepsis, including decreased systemic vascular resistance, hypervolemia, increased cardiac output, and increased renal vascular resistance. Because of increased vascular permeability, the initial hypervolemia is followed by hypovolemia and decreased cardiac output, with decreased renal blood flow and glomerular filtration rate (GFR). Increased blood viscosity, intravascular coagulation, hemolysis, rhabdomyolysis, jaundice, fever, lactic acidosis, complement activation, and reactive oxygen species further compromise renal blood flow. Activation of poly (ADP-ribose) polymerase by peroxynitrite and free radicals decreases oxygen utilization.

AKI in malaria is ischemic and hypoxic in origin and usually occurs with heavy parasitemia, intravascular coagulation, intravascular hemolysis,

Fig. 67.6 Local necrotic injury in the left leg of a female patient after *Loxosceles* bite. (A) At 4 days after the bite. (B) At 60 days after the bite. (C) At 3 months after the bite. (Courtesy Carlos A. C. Mendes, São José do Rio Preto, Brazil.)

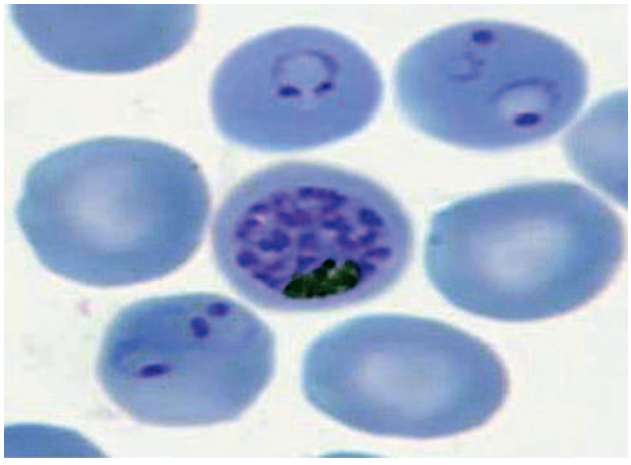

Fig. 67.7 Ring form and merozoites of *Plasmodium falciparum* in infected erythrocytes.

or rhabdomyolysis.[41] Immune responses in malaria involve Th1 and Th2 activation. Immune complex GN can occur (see Chapter 55). Tubular changes vary from cloudy swelling to tubular degeneration with tubulorrhexis in the patient with AKI (Fig. 67.9). Bile and hemoglobin casts and Tamm-Horsfall protein are present in the tubular lumen. Interstitial mononuclear infiltration and edema can occur. Thrombotic microangiopathy and cortical necrosis have been reported.[44,45] Malarial antigens are occasionally seen along the glomerular endothelium and medullary capillaries. Adhesion molecules and proinflammatory cytokines are overexpressed in the vascular endothelium and proximal tubules.[41]

Clinical Manifestations

Malarial AKI affects predominantly nonimmune adults, mostly infected by *P. falciparum*. Reports link *P. vivax* infection with acute respiratory distress syndrome (ARDS), severe AKI, and thrombotic microangiopathy.[44] Mixed *Plasmodium* infections and comorbidities related to sepsis are likely important contributing factors to AKI. Constitutional symptoms include fever, chills, headache, prostration, and occasionally jaundice. The urinalysis usually shows few erythrocytes, leukocytes, and granular casts and proteinuria, often less than 1 g/24 hours.

Hemoglobinuria happens in the patient with intravascular hemolysis, frequently associated with glucose-6 phosphate dehydrogenase deficiency. Rhabdomyolysis with myoglobinuria can be observed. Fluid and electrolyte changes are common in malaria.[41,46] Hyponatremia, usually asymptomatic, is observed in 67% of patients, is related to the severity of malaria, and resolves within a few days after antimalarial treatment. The causes of hyponatremia are multiple, including increased antidiuretic hormone with water retention, intracellular shift of sodium as a result of decreased Na^+,K^+-ATPase activity, and sodium depletion. Hypernatremia is uncommon, indicates hypothalamic lesions with diabetes insipidus, and is associated with unfavorable prognosis. Hypokalemia secondary to respiratory alkalosis occurs in 20% to 40% of patients with uncomplicated cases. Hyperkalemia is observed in patients with intravascular hemolysis, rhabdomyolysis, and/or AKI. Hypocalcemia with prolonged QTc interval occurs in 45% of severe malaria cases and resolves when infection is controlled.[46] Decreased activities of Na^+,K^+-ATPase, Ca^{2+}-ATPase, and parathyroid hormone are considered the main causes for hypocalcemia. Hypophosphatemia secondary to respiratory alkalosis is observed in 6% to 30% of the patients. Hypomagnesemia is seen in 30% of patients.[46] Downregulation of sodium channels on the apical membrane of alveolar epithelial cells and increased vascular permeability account for the development of pulmonary edema and ARDS.[47]

Malarial AKI is characterized by a rapid increase in SCr and is often associated with cholestatic jaundice. Risk factors for AKI include high parasitemia, deep jaundice, high liver enzyme values, thrombocytopenia, decreased diastolic blood pressure, retinopathy, and ARDS. Hemolytic uremic syndrome has been described. Severe acidosis-associated lactic acidemia, hypoglycemia, and central nervous system symptoms are observed in severe malaria. Malarial AKI with multiple organ involvement and papilledema carries an unfavorable prognosis. AKI duration ranges from 1 to several weeks and is oliguric in 60% of the patients. Quinine and artesunate are the antimalarial agents most commonly used. The first choice in malarial AKI is artesunate, because it has high efficacy and does not need adjustment for renal function. Early and frequent RRT (hemodialysis or peritoneal dialysis) is lifesaving.[41] Continuous venovenous hemofiltration yields good results in patients with multiorgan involvement, especially those with pulmonary edema or ARDS.[41] Exchange blood transfusion and erythrocytapheresis are adjunctive for the patient with heavy parasitemia.[48] The mortality rate of malarial AKI ranges from 10% to 50%. Kidney function may not recover completely in severe AKI, evolving to CKD in 7% of malaria-induced AKI.

LEPTOSPIROSIS

Leptospirosis, the world's most common zoonosis, is caused by *Leptospira* genus spirochetes. The WHO included leptospirosis as a reemerging infectious disease in both developed and developing areas, and cases have been increasingly reported in developed countries.[49] Wild and domestic mammals (rodents, dogs, pigs, cattle, horses) are the disease vectors. The infection is transmitted accidentally to humans through broken skin or mucosal membranes exposed to water or soil contaminated with organisms shed in the urine from the natural vectors.[1,2,50] Leptospirosis is a job-related threat for rodent exterminators, slaughterhouse workers, farmers, pet traders, veterinarians, garbage collectors, and sewer workers.[50]

Human leptospirosis is endemic in many tropical countries and usually reaches epidemic levels after heavy rainfall and flooding, or natural disasters, such as hurricanes or earthquakes. There is an annual global estimate of 1 million cases, with 58,900 fatalities, about half among young adult males.[51] A high seroprevalence of anti-*Leptospira* antibodies has been found in the general asymptomatic population in tropical countries, ranging from 18% to 33%. As many as 29% of wild small animals in the Peruvian Amazon were found to be infected by leptospiras.[1,2,50]

L. interrogans, the only parasitic species, is mobile, aerobic, and unstained by the Gram method. Its endotoxins primarily affect tubulointerstitial cells. The bacterial outer membrane contains lipopolysaccharide, cytotoxic glycolipoprotein (GLP), and lipoproteins (LipL), especially LipL 32, which is immunogenic. Because leptospiras have special tropism for the kidneys, the effect of GLPs on tubular Na^+,K^+-ATPase activity is potentially involved in the AKI cellular pathophysiology,[52] in the urinary concentrating defects, and in the paradoxical hypokalemia frequently seen in these patients.[1,2,50,52] Glycocalyx and endothelial injury caused by spirochete membrane proteins also may contribute to AKI.[53]

Kidney involvement is almost universal in leptospirosis, but becomes relevant in Weil disease, the most severe form of leptospirosis, which is characterized by multiorgan involvement, with diffuse alveolar hemorrhage, pulmonary edema, ARDS, or a combination of these features, accompanied by AKI and a high mortality rate.[50] Leptospirosis-associated AKI incidence of varies from less than 10% to more than 80%, and its

severity is associated with increasing mortality.[54,55] Oliguria, jaundice, arrhythmias, thrombocytopenia, elevated baseline SCr, and urinary neutrophil gelatinase–associated lipocalin (NGAL) levels have been associated with AKI development.[54,56] AKI is typically nonoliguric and associated with hypokalemia.[1,2,50] Tubular changes characterized by high urinary fractional excretion of sodium and potassium precede reduced GFR, which could explain the high frequency of hypokalemia.[50] Long-term follow-up of leptospirosis-associated AKI found late development of CKD and presence of tubular function abnormalities.[57-59]

Antibiotics of the penicillin group are considered the basis of treatment, but their efficacy remains unproven.[50,60] Treatment recommendations include a high RRT dose, conservative fluid intake, and approaches to minimize lung injury.[50]

HEMORRHAGIC FEVERS

Viral hemorrhagic fevers (VHFs) are caused by RNA viruses of four different families *(Flaviridiae, Arenaviridae, Bunyaviridae, Filoviridae)*. Dengue, Rift Valley fever, yellow fever, and Crimean-Congo virus can be acquired by bites from infected arthropods, by inhalation of infected rodent excreta particles (Lassa, Junin, Machupo, Hantaan virus), or through contact with contaminated material (Ebola virus). The clinical picture includes fever, malaise, increased vascular permeability, and coagulation abnormalities that may lead to bleeding. Dengue and yellow fever are the most prevalent forms of VHF in the tropical regions.[1,2,61]

Dengue Fever

Dengue is an acute febrile disease caused by an arbovirus transmitted primarily by mosquitoes, with usually a benign evolution. The main dengue vector is the female *Aedes aegypti* mosquito. Dengue is currently the most important urban arboviral disease. The number of yearly infections is estimated at 390 million.[62]

Several factors account for the rising incidence and widespread occurrence of dengue such as climate changes (global warming, intensity and duration of rain season, hurricanes), ecosystem modifications, demographic increases, uncontrolled urbanization, and human migration. There are four serotypes of antigenically related dengue *flavivirus* (DEN 1 to DEN4), but immunity to one does not confer enduring immunity to another. The introduction of a new serotype in a determinate area accounts for the occurrence of epidemics and the hemorrhagic fever dengue form, which is a more severe form of the disease that may be lethal.[63] A new serotype of dengue virus was recently discovered in Malaysia.[64]

Dengue virus infection may manifest as undifferentiated fever, dengue fever, dengue hemorrhagic fever (DHF), or dengue shock syndrome (DSS). Common clinical manifestations of dengue fever are high fever, myalgia, arthralgia, retroocular pain, headache, anorexia, nausea, vomiting, and a cutaneous rash similar to measles or rubella. DHF and DSS are severe forms of the disease, characterized by fever, hemorrhage, thrombocytopenia, and evidence of plasma leakage (increased hematocrit, pleural effusion, ascites, and hypoalbuminemia), mental disorientation, breath shortness, tachycardia, shock, and death.[63]

Kidney involvement in dengue includes AKI, proteinuria (sometimes nephrotic), GN (see Chapter 55), hemolytic uremic syndrome, and electrolyte abnormalities.[63,65] The frequency of dengue-associated AKI varies from 1% to approximately 30%, and its development and severity are related to poor prognosis.[63,66,67] Dengue-induced AKI is usually associated with shock, hemolysis, and/or rhabdomyolysis,[63,68] but may occur without any of these triggers, and is described in all forms of dengue.[63] Risk factors for AKI comprise increased hepatic enzymes, hypoalbuminemia, reduced serum bicarbonate, other simultaneous viral or bacterial infection, multiple organ dysfunction, use of inotropic or nephrotoxic drugs, increased age, obesity, dengue severity, rhabdomyolysis, presence of diabetes mellitus, and delayed hospitalization.[63,69]

There is no specific treatment for dengue fever. Therapy is mostly supportive, avoiding the use of aspirin and nonsteroidal antiinflammatory drugs.

Yellow Fever

Yellow fever is a noncontagious infectious disease that is endemic in tropical Africa, South America, and Panama. The yellow fever virus is part of the *Flavivirus* genus (Flaviviridae family).[61] Yellow fever is transmitted to humans by blood-eating insect bites, especially by the *Aedes* and *Haemagogus* genera. There are two cycles, termed *sylvatic* and *urban*. The sylvatic cycle affects sporadic individuals who get in contact with the vectors when performing economic or recreational activities in infested forests. The urban cycle is characterized by virus transmission through *A. aegypti* to individuals living in urban areas. The urban cycle was eliminated in the Americas from the 1940s to 1950s, but its resurgence was recently documented in Bolivia. The movement of viremic individuals to cities with high vector populations can potentially generate explosive urban epidemics affecting thousands of nonvaccinated people.[61] There is no evidence of yellow fever in Asia, despite an extensive presence of vectors.[70] It is possible that the hyperendemicity of dengue in Southwest Asia has afforded protection because of cross-reactive antibodies.

Yellow fever infection might be asymptomatic, cause moderate febrile disease, or be severe, causing hemorrhagic fever, liver failure, AKI, and death. Most patients (85%) fully recover after 3 to 4 days and become permanently immunized against the disease. About 20% develop the severe form, with mortality of up to 50%.[61] After 3 to 6 days of incubation, the clinical picture of yellow fever starts abruptly with high fever, chills, anorexia, myalgia, headache, vomiting, and bradycardia. Hemorrhagic manifestations may occur. There is then a remission period with symptom improvement, and mild cases do not have any further manifestation. In the severe forms fever recurs, followed by vomiting, epigastric pain, and jaundice, the so-called intoxication phase. There are large increases in transaminases and bilirubin, and leukopenia and ST segment abnormalities may develop. Hemorrhagic events associated with hepatic damage and consumptive coagulopathy can occur, such as hematemesis, melena, petechiae, bruises, mucosal bleeding, and metrorrhagia in women. Microcirculatory thrombosis, disseminated intravascular coagulation, tissue anoxia, oliguria, and shock may follow.[61]

Yellow fever–associated AKI occurs usually after 5 days of disease in the severe forms and may evolve to anuria and ATN, with increased mortality. In Africa, AKI is observed earlier, without jaundice or liver abnormalities, with higher mortality. AKI mechanisms are poorly understood. Renal ischemia, intravascular coagulation, shock, bilirubin-induced renal tubule cell toxicity, virus direct effect on renal tissue, and intense inflammatory cytokine discharge are likely mechanisms of AKI.[71,72]

Ebola Virus Disease

Ebola virus belongs to the Filoviridae family and has caused several outbreaks of Ebola virus disease (EVD) in Central and West Africa in the last several years, with high morbidity and mortality. The virus is transmitted from individual to individual through mucous membrane contact with contaminated body fluids or tissue. Like other VHFs, the initial clinical picture of EVD is unspecific (fever, weakness, arthralgias, muscle pain, headache). The disease evolves to anorexia, nausea and vomiting, abdominal pain, intense diarrhea, electrolyte unbalance, hemodynamic instability, and multisystem organ failure, including ARDS and AKI. In the most recent outbreak, critically ill patients treated early and adequately by experienced teams in well-provided tertiary health care settings experienced strikingly lower mortality. Some of them

developed anuric AKI and needed RRT. Because there is no effective Ebola virus–specific therapy, the big challenge is how to prevent and treat the complications of EVD, including AKI, in low-resources settings.[73-76]

Diagnosis and Clinical Evaluation of Acute Kidney Injury

Eric Judd, Paul W. Sanders, Anupam Agarwal

The term *acute renal failure* (ARF) describes the clinical syndrome in which an abrupt (hours to days) decrease in renal function leads to the accumulation of nitrogenous waste products and, commonly, a reduction in urine output. *Acute kidney injury* (AKI) has become the consensus term for ARF.[1-3] This change in terminology served to standardize a definition for the syndrome as well as incorporate knowledge that increases in serum creatinine as small as 0.3 mg/dl (27 µmol/l) are associated with increased morbidity and mortality.[4]

In 2012 the Kidney Disease: Improving Global Outcomes (KDIGO) guideline unified the definition of AKI and included stages of severity (Table 68.1). AKI has since been defined as an increase in serum creatinine of 0.3 mg/dl or more within 48 hours of observation or 1.5 times baseline or greater, which is known or presumed to have occurred within 7 days, or a reduction in urine volume below 0.5 ml/kg/h for 6 hours.[1] Subclassification of AKI based on disease severity as indicated by the level of increase in serum creatinine and reduction in urine output has been adopted as a three-stage classification by KDIGO. Increasing severity of AKI based on creatinine and urine output associates with increased risk for death.[1]

Mortality rates for patients with AKI in the intensive care unit (ICU) remain high, 17% in stage 1 and 28% in stage 2 to 3.[5,6] Even after adjusting for risk factors, odds ratios for mortality of such patients were: stage 1, 1.68 (0.89-3.17, confidence interval [CI] 95%); stage 2, 2.95 (1.38-6.88, CI 95%); and stage 3, 6.88 (3.88-12.23, CI 95%).[7] In a large population of hospitalized adults, AKI severity was directly associated with increased hospital mortality, lengthened hospital stay, and higher overall cost. The associations were present for changes in serum creatinine as low as 0.3 mg/dl.[4] Patients with AKI who survive hospitalization also have an increase in long-term mortality, with an adjusted relative risk for mortality of 1.4, which is amplified with increasing AKI stage.[8] Furthermore, AKI survivors are at increased risk for developing comorbidities, including chronic kidney disease (CKD).[9]

There are many different causes of AKI, and most are identified through clinical investigation. Globally, hypotension and volume contraction or dehydration accounted for 40% of AKI cases in both the hospital and nonhospital setting.[10] In higher income countries, hypotension and shock was the most common cause of AKI, whereas volume contraction or dehydration predominated in lower income countries. Nephrotoxic agents were implicated in up to a quarter of AKI events across all countries.[10] However, nephrotoxin administration may account for a larger proportion of hospital-acquired AKIs in older patients.[11,12] Kidney biopsy is rarely performed to establish the cause of AKI. In an observational study of 745 patients with AKI in the ICU, 3% (22 patients) underwent kidney biopsy, and, as expected, glomerulonephritis (GN) and acute interstitial nephritis (AIN) were each diagnosed in about a third of the biopsy specimens and about 23% showed only acute tubular necrosis (ATN).[6]

EARLY DETECTION OF ACUTE KIDNEY INJURY

The definition of AKI is based on increases in serum creatinine, yet when used as a marker of renal function, serum creatinine concentrations have multiple limitations. In addition to a steady-state balance of creatinine production and excretion being required for appropriate estimation of glomerular filtration rate (GFR), serum creatinine concentrations may not rise for subtle declines in GFR and are slow to rise for rapid falls in GFR. Furthermore, the generation of creatinine from muscle is reduced in sepsis-induced AKI, and serum creatinine concentrations may not increase proportionally to GFR decline.[13] A window of time exists in which kidney injury goes undetected until serum creatinine concentrations rise (8 to 48 hours) (Fig. 68.1).[14] Novel serum and urine biomarkers with potential as early indicators of AKI include tissue inhibitor of metalloproteinase 2 (TIMP-2), insulin-like growth factor–binding protein 7 (IGFBP7), hepcidin, kidney injury molecule 1 (KIM-1), neutrophil gelatinase–associated lipocalin (NGAL), cystatin C, interleukin-18 (IL-8), and others. They also may allow for improved prognostication and insight into the specific cause of AKI.

Fig. 68.2 depicts the continuum of kidney injury severity and a number of biomarkers. Serum cystatin C, a cysteine protease inhibitor that is freely filtered at the glomerulus and normally reabsorbed by proximal tubule cells, may be more sensitive than serum creatinine concentrations at detecting small reductions in GFR.[15] Urinary cystatin c has been shown to detect AKI in multiple clinical settings.[14]

The combination of urinary levels or IGFBP7 and TIMP- outperforms all other biomarkers in the early detection of AKI in critically ill patients.[16] Both proteins are expressed in tubular cells and have autocrine and paracrine effects that lead to G1 cell cycle arrest for short periods. In AKI, preventing or delaying tubular cell division may be a protective response to injury. The risk for stage 2 or 3 AKI correlated well with logarithmic values of [IGFBP7]*[TIMP-2] measured from a urine sample obtained within 12 hours of the diagnosis of AKI,[16] and their combined urinary levels correlated to clinician-adjudicated AKI better than KDIGO criteria.[17]

Assessing kidney function with a loop diuretic challenge (furosemide stress test) improves prediction of kidney outcomes compared with biomarker measurement. In patients with early AKI in the ICU, urinary responses to intravenous furosemide predicted the need for dialysis better than biomarker measurement alone.[18] Failure to produce more than 200 ml of urine within 2 hours of intravenous furosemide dosed

TABLE 68.1 Kidney Disease: Improving Global Outcomes Composite Staging of Acute Kidney Injury

Stage	Serum Creatinine	Urine Output
1	1.5-1.9 × baseline *Or* ≥0.3 mg/dl (≥26 μmol/l) increase	<0.5 ml/kg/h for 6-12 h
2	2.0-2.9 × baseline	<0.5 ml/kg/h for ≥12 h
3	3.0 × baseline *Or* Increase in serum creatinine to ≥4.0 mg/dl (≥352 μmol/l) *Or* Initiation of renal replacement therapy *Or* In patients younger than 18 yr, decrease in estimated glomerular filtration rate <35 ml/min/1.73 m^2	<0.3 ml/kg/h for ≥24 h *Or* Anuria for ≥12 h

From The Kidney Disease Improving Global Outcomes (KDIGO) Working Group. KDIGO clinical practice guideline for acute kidney injury. *Kidney Int Suppl.* 2012;2(1):1-138.

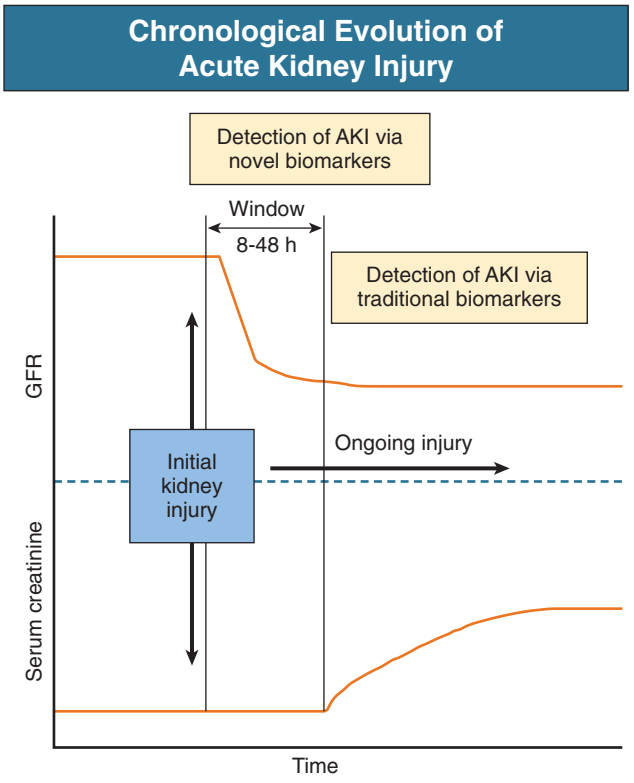

Fig. 68.1 Chronological evolution of acute kidney injury *(AKI). GFR,* Glomerular filtration rate. (Modified from reference 14.)

at 1 to 1.5 mg/kg strongly predicted both the need for dialysis and progression to AKI stage 3.[18]

KIM-1, a cell membrane glycoprotein upregulated in injured proximal tubular cells, can act as a nonmyeloid phosphatidylserine receptor that transforms epithelial cells into semiprofessional phagocytes.[19] The ectodomain of this membrane-associated molecule is shed into the urine of injured but not healthy kidneys. KIM-1 messenger ribonucleic acid (mRNA) levels may rise more than any other gene after kidney injury, and urinary levels are increased specifically with AKI resulting from ischemia or toxin exposure.[20,21]

NGAL, a protein produced by neutrophils, binds and traffics free iron.[20] It also mediates the tubular response to epidermal growth factor and is thereby involved in the progression of kidney disease.[22] Urinary NGAL levels are increased in the setting of tubular stress or injury, but not in prerenal disease.[23,24] A large number of studies correlated urinary NGAL levels to early detection of AKI.[14]

IL-18 is an inflammatory cytokine found in macrophages, monocytes, and proximal tubule cells. Urinary levels are upregulated in renal ischemic injury in multiple clinical settings.[14]

Biomarkers have the potential for detecting AKI early, identifying minor kidney injuries that do not raise serum creatinine concentrations, monitoring therapeutic benefits of novel treatment interventions, and specifying the cause of AKI. However, AKI frequently occurs unobserved in the community or is present at the time of recognition. Approximately 50% of patients admitted from the emergency department with septic shock have AKI on arrival to the ICU.[5] Even with early recognition of AKI, health care providers have not been able to alter its trajectory. The composite outcome of maximum change in serum creatinine level, need for dialysis, or death at 7 days did not change when primary providers were notified of AKI by an electronic alert system.[25] Nevertheless, biomarkers have potential to further understanding of AKI and remain an exciting tool on the horizon of clinical use for diagnosing, identifying a cause of, and predicting outcomes of AKI.

DIAGNOSTIC APPROACH TO ACUTE KIDNEY INJURY

The basic diagnostic approach to patients with AKI is to determine the cause (see Chapter 66). This process should start by excluding or correcting both prerenal and postrenal causes (Fig. 68.3). In hospitalized patients, determining the causative diagnosis often involves selecting the most probable cause among many choices.[26] Assessing daily urine volume can narrow the differential diagnosis, dividing AKI into oliguric (<500 ml) and nonoliguric causes. A careful history and physical examination and basic laboratory tests often suffice for diagnosis (Table 68.2).[26]

Acute Kidney Injury Versus Chronic Kidney Disease

On occasion, it can be difficult to determine whether a patient with renal failure has AKI or AKI superimposed on CKD. Knowledge of prior serum creatinine concentrations is required to determine the degree of potentially reversible AKI. Ultrasound evidence of small, scarred kidneys is consistent with CKD, but even advanced diabetic nephropathy, amyloidosis, HIV infection–related nephropathy, or polycystic kidney disease can present with normal or increased kidney size. The findings on presentation of normocytic anemia, hyperparathyroidism, peripheral neuropathy, and broad waxy casts in the urinary sediment suggest CKD. Patients with CKD are at high risk for the development of AKI.[27]

CLINICAL ASSESSMENT

The evaluation of a hospitalized patient with AKI should begin with a complete medical history and review of the hospital records. Once the prior serum creatinine concentration or other evidence of underlying kidney disease is established, the history should be directed toward the events preceding the AKI (see Fig. 68.3). These events may be part of a systemic disease process (e.g., sepsis, rhabdomyolysis), an inpatient event (e.g., surgery, nephrotoxic agent exposure), or an outpatient event

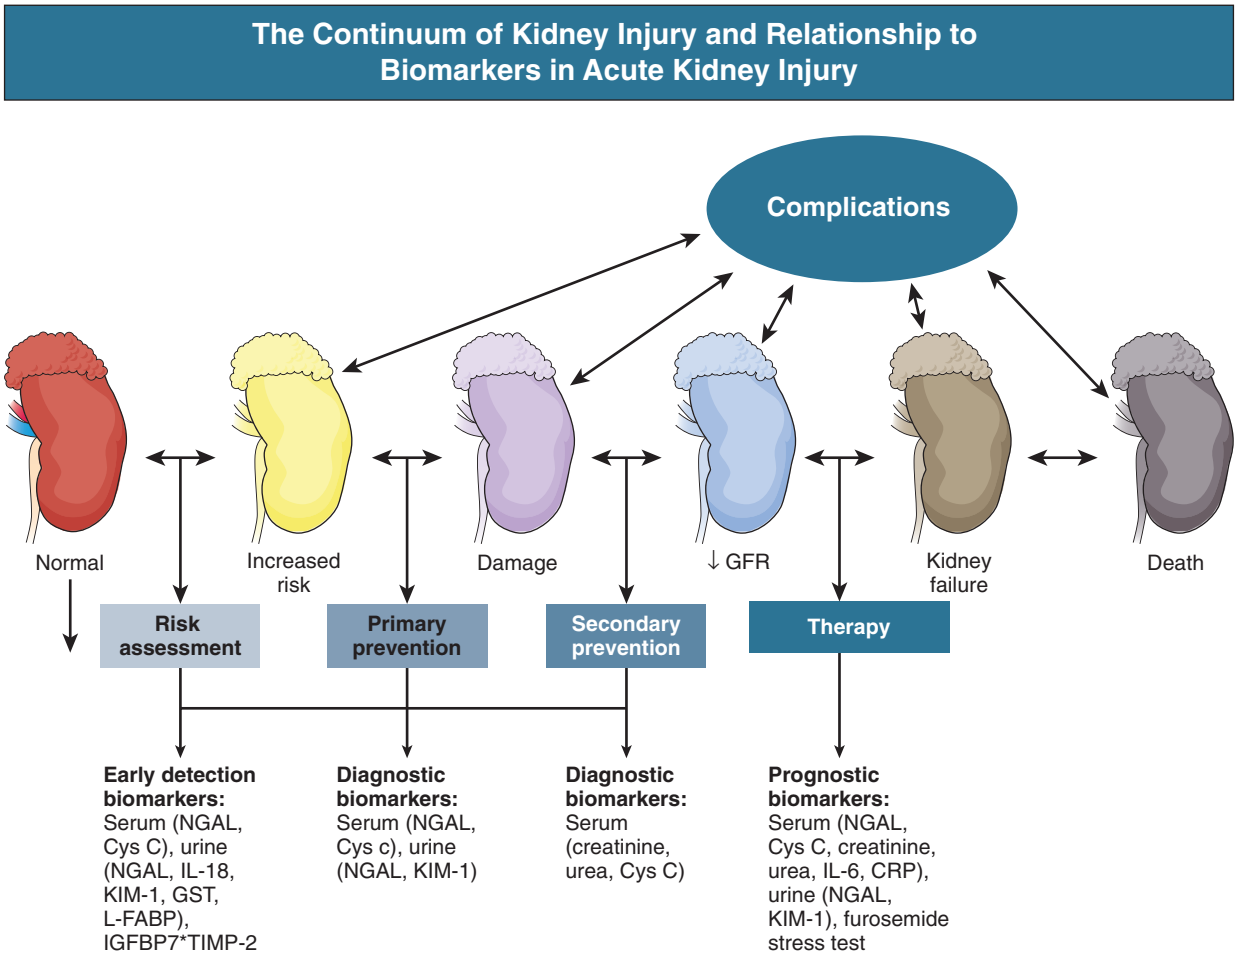

Fig. 68.2 Continuum of kidney injury and biomarkers of acute kidney injury (AKI). Injury begins before excretory function is lost (i.e., decreased glomerular filtration rate *[GFR]*) and can potentially be detected by the measurements of biomarkers. *CRP,* C-reactive protein; *Cys C,* cystatin c; *GFR,* glomerular filtration rate; *GST,* glutathione-*S*-transferase; TIMP-2, tissue inhibitor of metalloproteinase 2; IGFBP7, insulin-like growth factor-binding protein 7; *IL-6,* interleukin-6; *IL-18,* interleukin-18; *KIM-1,* kidney injury molecule 1; *L-FABP,* liver fatty acid–binding protein; *NGAL,* neutrophil gelatinase-associated lipocalin. (Modified from reference 23.)

(e.g., medication or drugs, volume contraction from diarrhea or vomiting). Particular attention should be paid to the medication record, looking for use of nonsteroidal antiinflammatory drugs (NSAIDs), renin-angiotensin-aldosterone antagonists, diuretics, antibiotics, proton pump inhibitors, Chinese herbs that contain aristolochic acid (see Chapter 62), or the use of a synthetic cannabinoid, a newly identified nephrotoxin.[28] In Africa and India the ingestion of hair dyes containing paraphenylenediamine may result in AKI. Clues to a postrenal cause (e.g., urinary hesitancy, frequent nocturia, pelvic or flank pain, overflow urinary incontinence, metastatic cancer) should be assessed early.

Physical examination may reveal reduced body weight, marked orthostatic decrease in blood pressure, an increase in pulse rate, and lack of jugular venous distention, all suggesting a reduction in extracellular fluid volume. Patients with prerenal AKI can appear volume overloaded in heart failure, cirrhosis, and nephrotic syndrome when effective arterial blood volume is reduced. In critically ill patients, hemodynamic measurement by right heart catheterization may be necessary to differentiate volume overload from noncardiogenic pulmonary infiltrates. Trends in daily intake and output volumes also assist in determining the extracellular fluid volume of the critically ill patient.

Examination of the abdomen may reveal a tender, distended bladder in a lower urinary tract obstruction, and, when this is present, sterile postvoid bladder catheterization should be performed. A distended, tense abdominal wall may represent ascites, aggressive intravenous fluid resuscitation, or recent abdominal surgery. Intraabdominal pressure can be measured in the ICU to distinguish AKI from abdominal compartment syndrome, defined as an intraabdominal pressure exceeding 20 mm Hg.[29]

Fever, skin rash, and arthralgias may be signs of systemic lupus erythematosus, vasculitis, endocarditis, or drug allergy with AIN. A history of recent aortic catheterization (e.g., cardiac catheterization) and the findings of livedo reticularis or a discolored toe are diagnostic clues for cholesterol or atheromatous emboli. Painless hematuria suggests acute GN or genitourinary malignancy, whereas painful hematuria is more consistent with obstruction.[26]

Electronic Health Record to Predict Acute Kidney Injury

Computer-based models have been used to develop AKI electronic alerts.[30,31] In one study, real-time alert of worsening of AKI by an AKI "sniffer" increased the timeliness of early therapeutic intervention.[32]

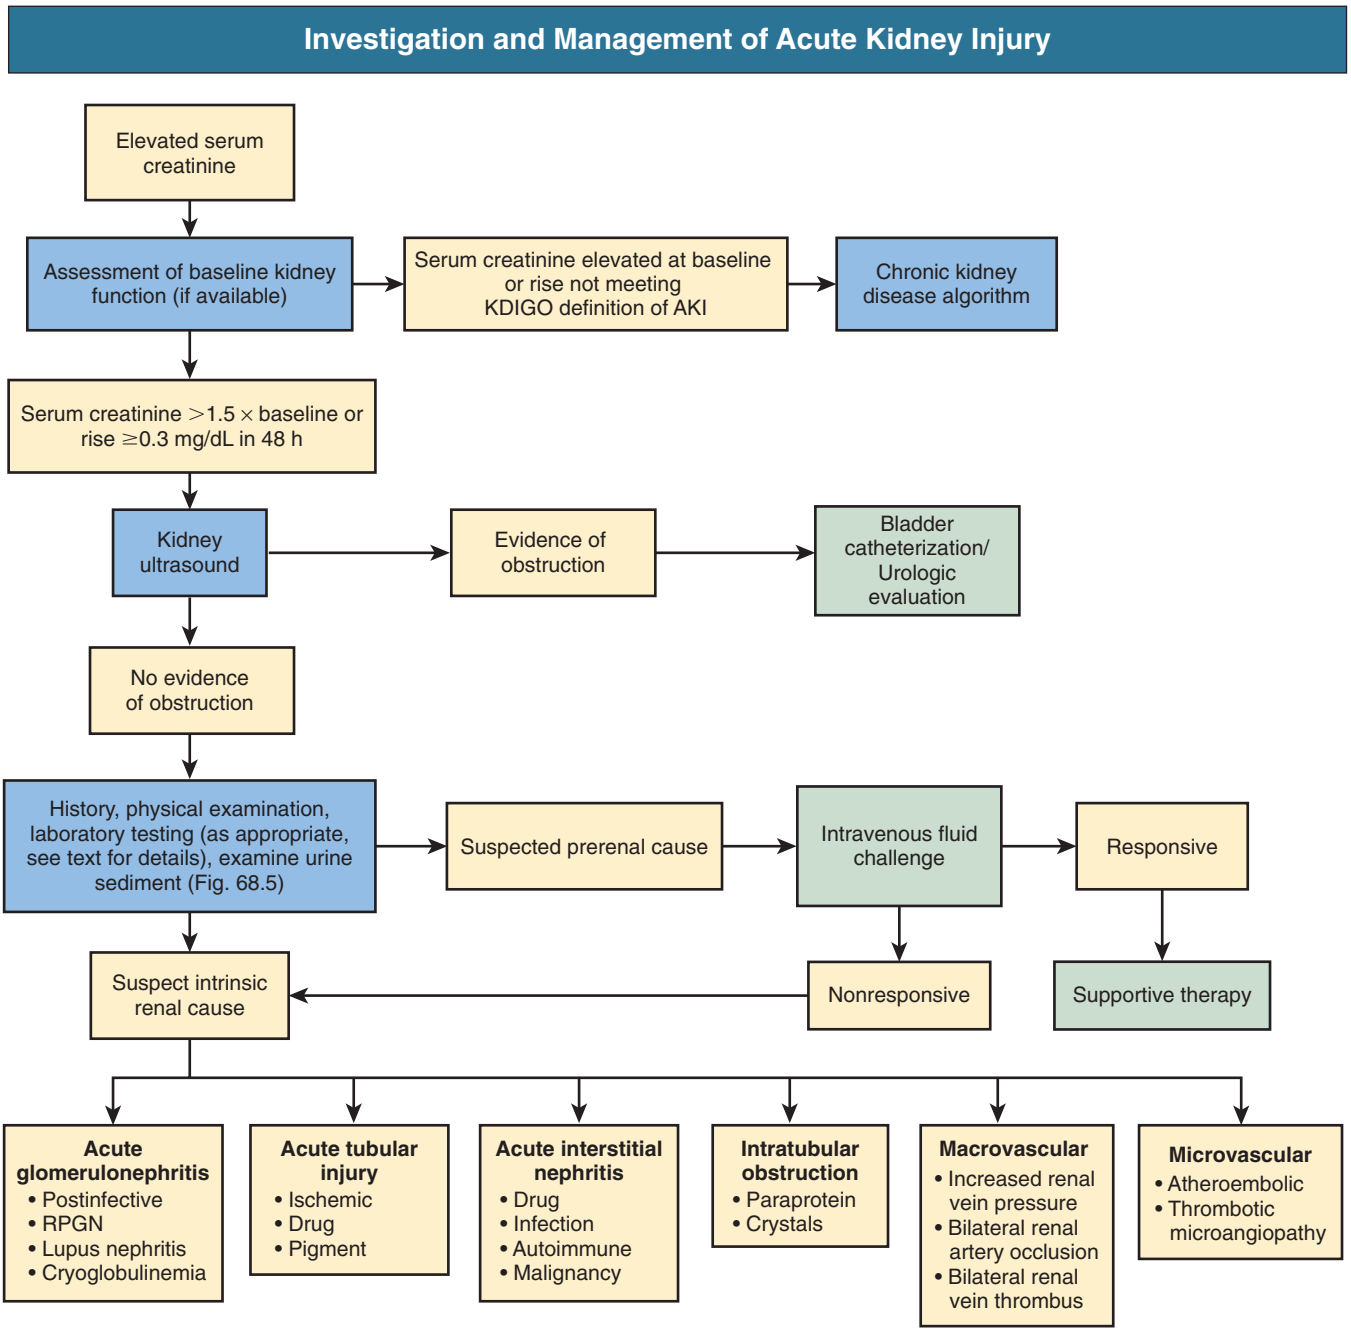

Fig. 68.3 Investigation and management of suspected acute kidney injury (AKI). The majority of AKI causes can be identified by reviewing the events that preceded the AKI. Evaluating for urinary obstruction early prevents the delay of urologic therapy, if needed; however, not all patients require a kidney ultrasound. If prerenal and postrenal causes have been excluded, the kidneys are normal size, and the diagnosis remains unclear, a kidney biopsy may be indicated. *AKI,* Acute kidney injury; *KDIGO,* Kidney Disease: Improving Global Outcomes; *RPGN,* rapidly progressive glomerulonephritis.

However, in a large randomized controlled study, an electronic alert system for AKI in hospitalized patients did not demonstrate any improvements in clinical outcomes and rather increased the use of health care resources.[25] Further studies are needed to further define the utility of such AKI alerts.

DIAGNOSTIC EVALUATION

Differentiating the two most common causes of AKI in hospitalized patients, prerenal AKI and ATN, may be difficult when both the effective arterial blood volume and the time course of the kidney injury are unknown.[33] Here the term *acute tubular injury* may more accurately describe the pathology involved in intrinsic AKI from ischemic or toxic insults.[34] Evaluation of urine volume, urinary sediment, and urinary indices (the last is useful only in patients with oliguria) is helpful in making the correct diagnosis (Table 68.3 and Fig. 68.3). Initial laboratory tests include a urinalysis, blood urea nitrogen (BUN), serum sodium, potassium, bicarbonate, and creatinine levels not only for the diagnosis but also for assessment of complications of AKI.[26]

TABLE 68.2 Differential Diagnosis by Pathophysiologic Classification of Acute Kidney Injury

Cause	Comments
Prerenal	**30%-60% of AKI**
Volume depletion	Renal losses, GI losses, hemorrhage
Decreased cardiac output	Right- or left-sided heart failure, cardiac tamponade
Systemic vasodilation	Sepsis, anaphylaxis, anesthetics
Afferent arteriolar vasoconstriction	NSAIDs, calcineurin inhibitors, radiocontrast, hepatorenal syndrome, hypercalcemia
Efferent arteriolar vasodilation	ACE inhibitors, ARBs
Intrinsic	**~40% of AKI**
Acute tubular injury	
Ischemic	
Nephrotoxic (drug)	Aminoglycosides, lithium, amphotericin, pentamidine, cisplatin, ifosfamide, radiocontrast
Nephrotoxic (pigment)	Rhabdomyolysis, intravascular hemolysis
Acute interstitial nephritis (AIN)	
Drug induced	Penicillins, cephalosporins, NSAIDs, PPIs, allopurinol, rifampin, sulfonamides
Infection related	Pyelonephritis, viral nephritides
Autoimmune diseases	Sjögren syndrome, sarcoidosis, SLE
Malignancy	Lymphoma, leukemia
Intratubular obstruction	
Paraprotein	Immunoglobulin light chains
Crystals	Acute phosphate nephropathy, tumor lysis syndrome, ethylene glycol, acyclovir, indinavir, methotrexate
Acute glomerulonephritis	Postinfectious, cryoglobulinemia, RPGN, SLE
Macrovascular	Increased renal vein pressure from increased intraabdominal pressure, bilateral renal vein thrombosis, bilateral renal artery emboli
Microvascular	Atheroembolic disease, HUS, TTP, scleroderma renal crisis, malignant hypertension
Postrenal (Obstruction)	**Approximately 10% of AKI**
Intrinsic	Bilateral ureteral stones, bladder outlet obstruction (prostatic enlargement or blood clot), neurogenic bladder
Extrinsic	Retroperitoneal fibrosis, metastatic cancer

ACE, Angiotensin-converting enzyme; *ARBs,* angiotensin receptor blockers; *GI,* gastrointestinal; *HUS,* hemolytic uremic syndrome; *NSAIDs,* nonsteroidal antiinflammatory drugs; *PPIs,* proton-pump inhibitors; *RPGN,* rapidly progressive glomerulonephritis; *SLE,* systemic lupus erythematosus; *TTP,* thrombotic thrombocytopenic purpura.

Results from initial laboratory testing may prompt further evaluation. For example, glycosuria occurring with a normal plasma glucose level offers evidence for proximal tubular dysfunction. The presence of amino acids and bicarbonate in the urine along with elevated urinary fractional excretion of phosphate and uric acid confirm Fanconi syndrome (see Chapter 48).

Ratio of Blood Urea Nitrogen to Creatinine

The ratio of BUN to creatinine in healthy individuals is 10 to 15:1 (when both are expressed in mg/dl or 40 to 60 when expressed in mmol/l). In prerenal AKI the ratio may be greater than 20:1 because of a disproportionate increase in urea reabsorption resulting from elevated serum vasopressin levels. However, upper gastrointestinal tract bleeding, impaired protein anabolism (e.g., systemic corticosteroid administration), increased catabolism (e.g., sepsis), and increased protein intake also can raise BUN levels. Furthermore, diminished urea production from decreased protein intake or underlying liver disease can prevent the expected rise in BUN by increased tubular reabsorption. Also, elevations in creatinine levels may exceed BUN levels in patients with creatinine release from muscle breakdown, as in rhabdomyolysis.

Urine Volume

In AKI, urine volume directly correlates with residual GFR.[35] Urine volume can indicate the severity of AKI and also provide important diagnostic information. Oliguric AKI (<500 ml/day) is typically associated with worse outcomes than AKI with preserved urine volume, especially with a positive fluid balance in the critical care setting.[36-39] Oliguria commonly occurs in AKI caused by ATN, although it can be seen in early prerenal AKI or AIN. Wide variations in daily urine output suggest obstruction. Anuria (urine output <100 ml/day) suggests obstruction or a bilateral acute vascular catastrophe (renal vein or renal artery occlusion), shock or rarely renal cortical necrosis, hemolytic uremic syndrome, or anti–glomerular basement membrane (GBM) antibody disease.[26]

Urinalysis and Urine Microscopy

In the setting of AKI, a dipstick urinalysis may reveal microhematuria or proteinuria but must be interpreted in conjunction with more specific tests such as a ratio of spot urinary protein or albumin to creatinine and urine microscopy. Dipstick urinalysis may not detect immunoglobulin free light chains (FLCs) or may be falsely positive for protein in the setting of radiographic contrast or alkaline urine. In conjunction with urine microscopy, the presence of urinary hemoglobin or myoglobin by dipstick can be further differentiated. Urine microscopy has been validated as a diagnostic and prognostic tool in hospitalized patients with AKI.[33] A fresh urine sample is centrifuged, and the sediment is examined for the presence of cells, casts, and crystals (Figs. 68.4 and 68.5) (see also Chapter 4). Urine microscopy in early prerenal AKI is typically normal with occasional hyaline casts. "Muddy brown" granular casts and renal tubular epithelial cells in the urine support ATN-related

TABLE 68.3 Clinical and Laboratory Variables in the Differential Diagnosis Between Prerenal and Renal Acute Kidney Injury

	Prerenal	Renal
History	Volume loss from GI, urinary, skin, or blood or reduced EABV (e.g., heart failure, pancreatitis)	Drugs or toxin exposure, hemodynamic change
Clinical presentation	Hypotension or volume depletion	No specific symptoms or signs
Laboratory studies		
BUN/S_{Cr}	>20	<20
Sediment	Normal to few hyaline casts	Muddy brown casts
U_{osm} (mmol/kg)	>500	<350
Proteinuria	None to trace	Mild to moderate
U_{Na} (mmol/l)	<20	>40
FE_{Na} (%)	<1	>1
FE_{Urea} (%)	<35	>35
Novel biomarkers	None	IGFBP7*TIMP-2, KIM-1, cystatin C, NGAL, CYR61, others

BUN, Blood urea nitrogen; *CYR61,* cysteine-rich protein 61; *FE_{Na},* fractional excretion of sodium; *FE_{Urea},* fractional excretion of urea; *GI,* gastrointestinal; EABV, effective arterial blood volume; IGFBP7*TIMP-2, insulin-like growth factor-binding protein 7 and tissue inhibitor of metalloproteinase 2; *KIM-1,* kidney injury molecule 1; *NGAL,* neutrophil gelatinase–associated lipocalin; *S_{Cr},* serum creatinine; *U_{Na},* urinary sodium; *U_{osm},* urinary osmolality.

AKI. In hospitalized patients with AKI, the presence of more than 10 granular casts per low-power field had a positive predictive value of 100% for a final diagnosis of ATN and a urine sediment score based on granular casts and renal tubular epithelial cells was directly associated with worsening AKI. Thus urine microscopy is useful both in distinguishing ATN-related AKI from prerenal AKI and in predicting the severity of AKI.[33]

Findings on urinalysis and urine microscopy (see Chapter 4) may suggest CKD (broad, waxy casts) but, more important, may be diagnostic clues to a rare cause of AKI. Proliferative GN may be characterized by considerable microhematuria and proteinuria by dipstick and an active urinary sediment consisting of red blood cells (RBCs) and RBC casts. In this setting the history and physical examination findings should be supported by serologic testing and a kidney biopsy, if the kidneys are normal in size. The presence of white blood cells (WBCs) in clumps and casts, in the absence of bacteria, suggests AIN.[26] Renal tubular epithelial cells, granular casts, RBCs, and, rarely, even RBC casts can occur in patients with AIN, whereas urinary eosinophils are no longer considered helpful in diagnosing AIN (see Chapter 60).[40] A urine sediment with abundant uric acid crystals accompanying high serum phosphorus levels in a patient undergoing chemotherapy may indicate tumor lysis syndrome (TLS).

Fractional Excretion of Sodium and Urea

The urine-serum concentrations of sodium in relation to the urine-serum concentrations of creatinine (fractional excretion of sodium [FE_{Na}]) has been used to approximate renal tubular function:

$$FE_{Na} = \frac{[U/S]_{Na}}{[U/S]_{Cr}} \times 100\%$$

where U = urine, S = serum, Na = sodium, and Cr = creatinine.

The basic premise is that renal tubular cells will reabsorb sodium in the prerenal setting, whereas tubules damaged by ATN will not.[41] FE_{Na} less than 1% is consistent with prerenal AKI, and FE_{Na} above 3% is typical of ATN. However, FE_{Na} may be less than 1% despite the presence of ATN in the setting of sepsis, hemoglobinuria or myoglobinuria, radiocontrast exposure, nonoliguria, heart failure, and advanced cirrhosis. Underlying CKD, diuretic use, recent intravenous fluid administration, glycosuria, bicarbonaturia, and salt-wasting disorders may be associated with elevated FE_{Na} despite the presence of prerenal AKI.[41] Therefore FE_{Na} has significant limitations in the setting of hospital-acquired AKI, yet may be helpful in differentiating prerenal AKI from ATN in specific patient populations with oliguria.

Urea reabsorption, primarily occurring in proximal tubules, is less affected by loop and thiazide diuretics, and the fractional excretion of urea (FE_{Urea}) may be an alternative to FE_{Na} in patients receiving diuretics. FE_{Urea} calculation is identical to that of FE_{Na}, and values less than 35% favor prerenal AKI over ATN.

Laboratory Evaluation of Acute Kidney Injury in Systemic Illnesses

In the presence of a systemic illness, additional laboratory evaluation may narrow the differential diagnosis of AKI. Serum complement levels of C3 and C4 are useful in differentiating causes of GN, particularly when a kidney biopsy is not feasible. Postinfectious GN, infective endocarditis, lupus nephritis, mixed cryoglobulinemia, and membranoproliferative GN are typically associated with low levels of serum C3 and/or C4 (see Chapter 21). Whereas, serum complement levels are normal in antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis, anti–glomerular basement antibody disease, and Henoch-Schönlein purpura (immunoglobulin A [IgA] vasculitis). Despite activation of the complement system in thrombotic microangiopathy (see Chapter 29), serum C3 and C4 can be maintained at normal levels through increased hepatic production.[42] Alternatively, when liver synthesis is impaired, low serum levels of C3 and/or C4 are less reliable in differentiating the type of acute GN.

In the right clinical setting, laboratory studies may support a specific cause of AKI. For example, AKI with thrombocytopenia, schistocytes on peripheral blood smear, and an elevated blood lactate dehydrogenase level would be consistent with thrombotic microangiopathy. However, these laboratory findings may be present in sepsis with disseminated intravascular coagulation (DIC). AKI in sepsis with DIC typically results from ATN or antibiotic-related AIN and not thrombotic microangiopathy.

In the appropriate clinical setting the following laboratory tests can help identify a cause: complete blood count, hemoglobin, serum albumin, creatine kinase, uric acid, phosphorus, urine myoglobin, HIV antibody, hepatitis C antibody, cryoglobulins, rheumatoid factor, hepatitis B virus studies, antinuclear antibody, anti–double-stranded DNA antibody, ANCA, anti-GBM antibody, and serum FLC.

Imaging Studies

Kidney imaging may not be necessary if a clear diagnosis of AKI exists (e.g., prerenal AKI or ATN). However, when the diagnosis is uncertain, and especially if urinary obstruction or renal vascular occlusion are suspected, imaging is indicated.[26] Renal ultrasound can identify urinary obstruction, polycystic kidney disease, and the size and number of kidneys. When Doppler flow is used, renal artery and veins can be assessed. High-resolution, noncontrast computed tomographic imaging

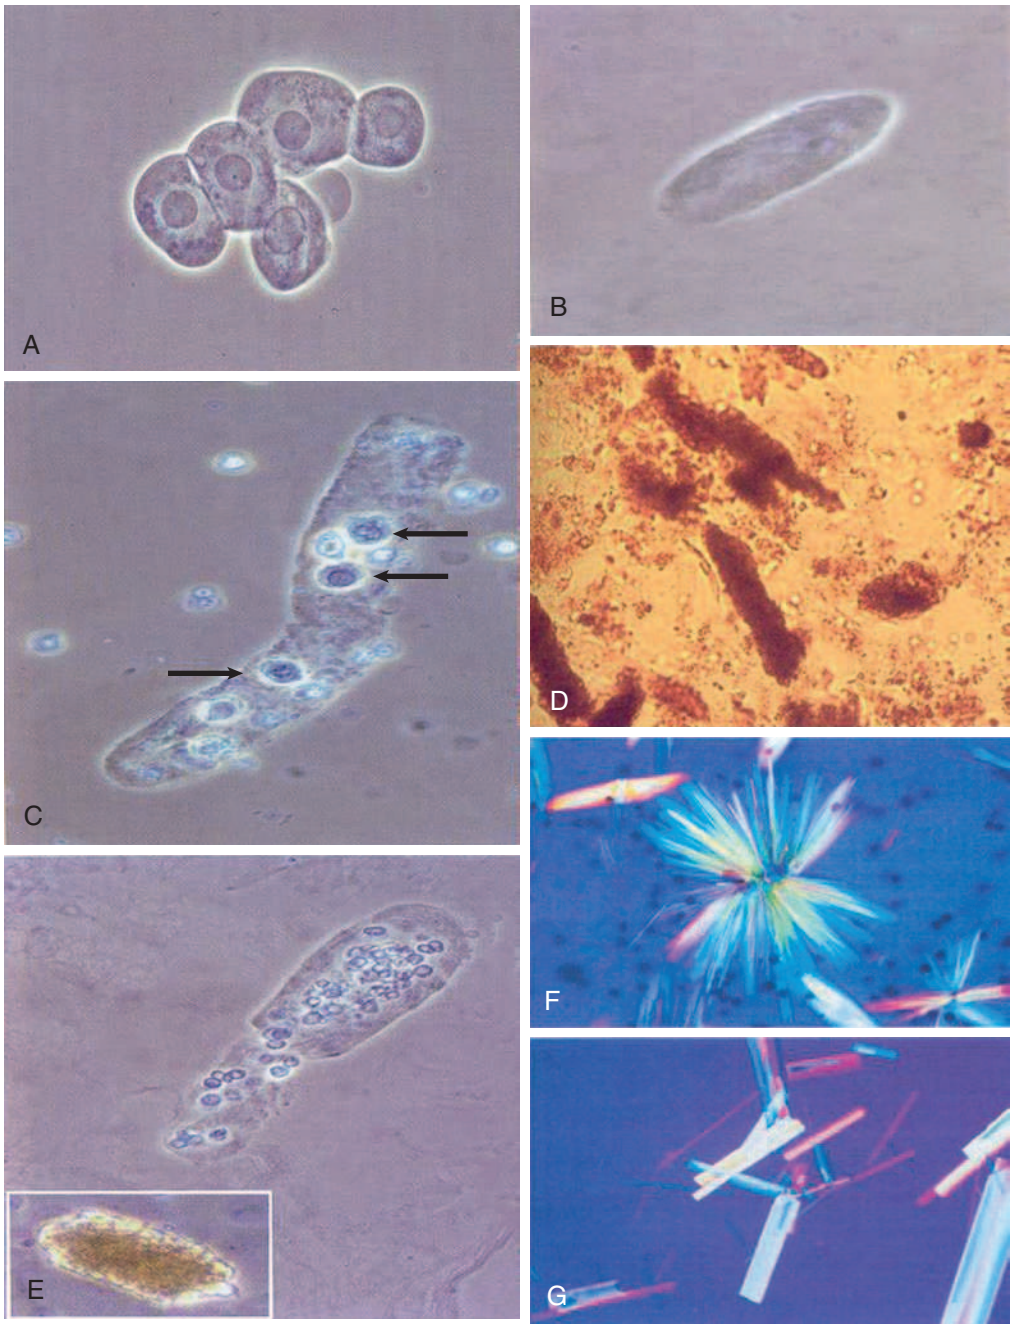

Fig. 68.4 Examples of urinary sediments seen in acute kidney injury (AKI). (A) Epithelial cell aggregate. (B) Hyaline cast as can be seen in prerenal AKI. (C) Epithelial cast as can be seen in early acute tubular necrosis (ATN, *arrows* indicate epithelial cells). (D) Muddy brown cast, typical of established ATN. (E) Erythrocyte cast as seen in glomerulonephritis and vasculitis. *Inset:* Hemoglobin cast. (F and G) Two forms of indinavir crystals.

is the preferred test for the detection of urinary tract calculi. Radionuclide renography may be used to estimate the renal plasma flow in a transplanted kidney with AKI but is increasingly replaced by Doppler ultrasound. Other radionuclide methods are less useful in AKI (e.g., tagged WBC scan for AIN). Magnetic resonance imaging without contrast is now recommended to evaluate renal arterial or venous thrombosis.[26]

Kidney Biopsy

Kidney biopsy is reserved for patients in whom prerenal and postrenal AKI have been excluded and the cause of intrinsic renal AKI remains unclear (see Fig. 68.3). Kidney biopsy is particularly useful when clinical assessment and laboratory investigations suggest diagnoses other than ischemic or nephrotoxic injury that may respond to disease-specific therapy (e.g., vasculitis, systemic lupus erythematosus, and AIN).

ACUTE KIDNEY INJURY IN SPECIFIC SETTINGS

Acute Tubular Necrosis

ATN is a clinical syndrome of abrupt and sustained decline in GFR that is triggered by an acute ischemic or nephrotoxic event and develops

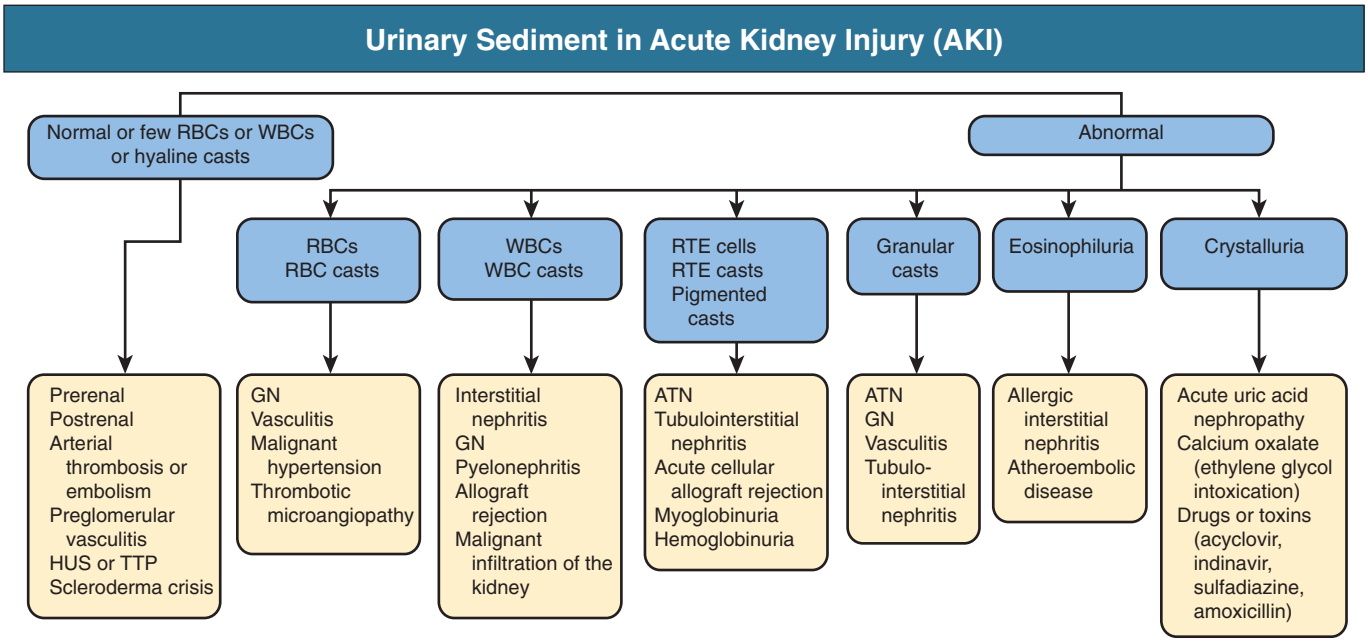

Fig. 68.5 Urinary sediment in acute kidney injury (AKI). *ATN,* Acute tubular necrosis; *GN,* glomerulonephritis; *HUS,* hemolytic uremic syndrome; *RBC,* red blood cell; *RTE,* renal tubular epithelial; *TTP,* thrombotic thrombocytopenic purpura; *WBC,* white blood cell.

within minutes to days after the insult.[26] Apart from kidney biopsy, no definitive test can diagnose ATN. The diagnosis is suggested by a history of recent hypotension, volume depletion, sepsis, or nephrotoxic exposure. Muddy brown, coarse, granular casts are present on urine microscopy in the majority of patients with ATN, particularly those who are oliguric.[26] Other laboratory findings consistent with the diagnosis of ATN are shown in Table 68.3.

The pathophysiology of ATN involves multiple pathways (see Chapter 66). Obstruction of flow within the tubule by cellular debris, disruptions of tubular cell polarity and cytoskeleton, loss of the lining epithelium with resulting backleak of glomerular filtrate into the renal interstitium, and afferent arteriolar constriction all may play pathophysiologic roles in ATN. ATN has been described as a (mal)adaptive response of the kidney—"trading away" GFR for the preservation of medullary oxygenation and tubular integrity.[34]

ATN after ischemia/reperfusion injury is usually most severe within the outer medulla of the kidney (see Chapter 66).[43] The typical histologic features of human proximal tubular injury include vacuolation, loss of brush border, disruption of the epithelial cells lining the tubule, and presence of intratubular casts. Necrosis of tubular cells is typically focal and may be missed in a biopsy specimen because most biopsies contain cortex and the outer medulla is not sampled adequately. Apoptosis of tubular cells is present in kidney biopsy specimens from humans with ATN, and evidence of cellular regeneration is often seen, most commonly in areas of greatest tubular cell loss. Regenerative changes and fresh epithelial injury are often observed in the same biopsy specimen, suggesting that recurrent episodes of tubular ischemia continue to occur during the maintenance phase of ATN. The morphologic appearance of the common forms of nephrotoxin-induced ATN is similar to that of ischemic ATN, with loss of microvasculature and immune cell infiltration. Correlations of morphologic findings to functional end-points have been difficult.

Acute Interstitial Nephritis

AIN is characterized by the presence of inflammatory infiltrates and edema within the interstitium, with an acute deterioration in GFR (see Chapter 60).[44] It is not an uncommon cause of AKI, accounting for 15% to 27% of renal biopsies performed because of AKI, yet AIN may be overlooked as a cause of AKI in settings in which ATN is common (e.g., sepsis). Drug use, in particular antimicrobials and NSAIDs, are the most common cause of AIN (see Table 68.2).[44]

The diagnosis of AIN generally requires kidney biopsy. The clinical presentation of drug-induced AIN is variable, with a mean delay between drug exposure and the appearance of renal manifestations of 10 days, although the latent period can be as short as 1 day with some antibiotics or as long as several months with NSAIDs.[44] In AIN the reported frequency of symptoms included arthralgias (45%), fever (36%), and skin rash (22%). In the same analysis, urinary findings included non-nephrotic proteinuria (93%), leukocyturia (82%), and microscopic hematuria (67%).[44] The classic clinical presentation of maculopapular rash, peripheral eosinophilia, and arthralgias may not be present in drug-induced AIN and is uncommon in infection-related or idiopathic AIN (see Table 68.2).

Acute Kidney Injury from Intratubular Obstruction

Several endogenous and exogenous molecules can precipitate in the tubular lumen to produce AKI, including uric acid, calcium phosphate, calcium oxalate, immunoglobulin FLCs, myoglobin, and medications (e.g., acyclovir, indinavir, methotrexate, sodium phosphate–containing cathartics, and sulfadiazine).[26] Medication-induced crystal nephropathy occurs more commonly when high doses of medication are combined with low tubular flow rates from volume contraction or underlying CKD.

Ethylene glycol ingestion from solvents and antifreeze may result in AKI from calcium oxalate crystal deposition. Patients with ethylene glycol poisoning typically have high anion gap metabolic acidosis because the ethylene glycol is metabolized into glycolic acid. The glycolic acid is converted to oxalic acid, which binds free calcium to form calcium oxalate crystals. Crystal deposition resulting in AKI typically manifests 48 to 72 hours after ingestion; oxalate crystals can be readily identified in the urine soon after exposure.

Intratubular obstruction from calcium phosphate and urate crystals contribute to AKI in TLS, which is characterized by a constellation of

metabolic derangements caused by massive and abrupt release of intracellular components in the blood after rapid lysis of malignant cells. It is typically seen after initiation of cytotoxic therapy for hematologic malignancies with large tumor burden or cell counts.[45] Clinical features of TLS result from the effects of the metabolic derangements. Nucleic acids released during cell lysis are metabolized to hypoxanthine and then xanthine, which is converted by xanthine oxidase to uric acid. With significant tumor lysis, severe hyperuricemia and intratubular obstruction from urate crystals may result. Hyperkalemia may induce cardiac arrhythmias, weakness, and paresthesias. Hyperphosphatemia initially produces muscle cramps and lethargy but also can promote nausea, vomiting, diarrhea, and seizure. Hypocalcemia, primarily caused by phosphorus binding, causes similar symptoms with muscle cramps, tetany, cardiac arrhythmias, and seizures.[45] Hyperkalemia and hypocalcemia associated with AKI in a patient receiving cytotoxic chemotherapy may be the only initial clues to the syndrome because blood uric acid and phosphate levels are not routinely monitored. Urine microscopy can assist in the diagnosis by revealing the presence of many urate crystals.

Rhabdomyolysis

Rhabdomyolysis is characterized by the leakage of muscle-cell contents, including myoglobin, electrolytes, creatine kinase, aldolase, lactate dehydrogenase, nucleic acids, and aspartate aminotransferase into the circulation.[46] AKI, occurring primarily in severe rhabdomyolysis, results from renal vasoconstriction, proximal tubular cell injury from oxidant stress, and intranephronal obstruction. Both myoglobin, a heme pigment protein that contains iron in the ferrous (Fe^{2+}) state, and uric acid have less nephrotoxicity in alkaline urine. Intravascular volume contraction and acidic urine promote distal tubule obstruction from myoglobin and uric acid precipitation.

Muscle injury leading to rhabdomyolysis frequently follows trauma (e.g., crush syndrome or prolonged immobilization), increased exertion (e.g., seizure, alcohol withdraw, strenuous exercise), genetic defects (e.g., disorders of glycolysis or gluconeogenesis, disorders of lipid metabolism, mitochondrial disorders), infections (e.g., influenza A and B), body temperature changes (e.g., heat stroke, neuroleptic malignant syndrome, hypothermia), and drug or toxin exposure (e.g., lipid-lowering drugs, alcohol, quetiapine, cocaine, heroin).[46]

Patients with acute rhabdomyolysis often present with muscle pain and reddish-brown urine. The presence of pigmented granular casts and the lack of RBCs on urine microscopy coupled with a blood-positive urinary dipstick are important diagnostic clues for rhabdomyolysis-related AKI. However, the diagnosis must be confirmed by elevated serum creatine kinase levels and the presence of urinary myoglobin.[26] A weak correlation exists between creatine kinase values and the incidence of AKI. The risk for AKI is lower when creatine kinase levels are less than 20,000 U/l. Rhabdomyolysis may contribute to AKI with creatinine kinase levels as low as 5000 U/l when coexisting conditions such as sepsis, intravascular volume contraction, and acidosis are present.[46]

Acute Kidney Injury in Myeloma

Monoclonal immunoglobulin FLCs are responsible for the majority of severe AKI in patients with myeloma. In such patients, monoclonal FLCs are overproduced, often with circulating levels hundreds times higher than normal.[47] Unlike most endogenously produced proteins, monoclonal FLCs have a strong propensity to cause tubular damage (see Chapter 27).[47] Some kappa monoclonal FLCs are cytotoxic and promote proximal tubular cell injury, with one mechanism resulting in a defect in sodium-coupled cotransport processes producing type II renal tubular acidosis, aminoaciduria, phosphaturia, and glycosuria (i.e., Fanconi syndrome).[48] A separate mechanism of FLC-mediated AKI is intratubular obstruction from precipitation of monoclonal FLCs in the distal nephron, that is, cast nephropathy.[26] Cast formation occurs under specific conditions mediated by the ionic composition of tubule fluid, tubule fluid flow rates, the concentration of Tamm-Horsfall glycoprotein and FLCs, the strength of the binding interaction between Tamm-Horsfall glycoprotein and FLC, and the presence of furosemide.[47] AKI attributed to cast nephropathy occurs in approximately one third of patients with multiple myeloma and AKI. Other causes of AKI include extrarenal obstruction (e.g., nephrolithiasis, amyloid deposition in the ureters), hypercalcemia, hyperviscosity syndrome, and non–myeloma-related causes (e.g., AIN or contrast-induced nephropathy [CIN]).[26]

Cast nephropathy should be considered, particularly in older patients with unexplained AKI. Predisposing conditions may include hypercalcemia, intravascular volume contraction, furosemide use, exposure to radiocontrast, and/or NSAID use. AKI may be the presenting event in patients with an undiagnosed plasma cell dyscrasia. Because FLC may not be detected on dipstick analysis, urinalysis in cast nephropathy will often show no or trace protein and the urinary sediment is typically bland. Assay of serum FLC levels is critical in assisting in the differential diagnosis of unexplained AKI (Chapter 64), but kidney biopsy may be needed to diagnose cast nephropathy. A low urinary albumin excretion (<10%) assessed with 24-hour urine electrophoresis was found useful in distinguishing cast nephropathy from ATN and less acute causes of kidney injury in multiple myeloma (e.g., amyloid light-chain [AL] amyloidosis and monoclonal immunoglobulin deposition disease).[49]

Contrast-Induced Nephropathy

Contrast-induced nephropathy (CIN), defined as AKI occurring shortly after exposure to intravenous radiocontrast, is an established cause of AKI. However, the incidence of CIN is low (<1%) in patients with normal renal function and no other risk factors for AKI.[26] Risk factors for CIN include CKD, diabetic nephropathy, advanced heart failure, states of reduced renal perfusion, high total dose of contrast, and concomitant exposure to other nephrotoxins. Data from animal models suggest that both renal vasoconstriction from direct effects of the contrast media and toxic injury of tubular cells (likely from activation of osmolality-sensitive aldose reductase in the proximal tubule) are the main factors in the pathophysiology of CIN.[50] Emerging data suggest a role for contrast-induced uricosuria in the pathogenesis of CIN.[51] The kidney injury likely occurs within minutes of contrast exposure; however, the detection of AKI is typically delayed by 24 to 48 hours after contrast exposure. The timing of AKI in relation to contrast exposure and the exclusion of other causes of AKI generally suffice for diagnosis. Urinalysis and urine sediment findings are typically consistent with ATN. Renal biopsy is generally not helpful in the setting of CIN because the expected findings of ATN are nonspecific, no CIN-specific treatment exists, and the renal injury is typically short lived.

SELF-ASSESSMENT QUESTIONS

1. A 20-year-old man with Marfan syndrome is admitted to the hospital for elective aortic valve replacement and endovascular repair of a distal (type B) thoracic aortic dissection. On postoperative day 4, his urine output decreases to 420 ml over a 24-hour period and the urine appears dark in his Foley catheter collection bag. He requires mechanical ventilation and pressor support, with a mean arterial blood pressure of 70 mm Hg. There is no rash visible on examination. Available laboratory data follow.

Preoperation Blood		Postoperation Day 4 Blood		Postoperation Day 4 Blood	
				Arterial Blood Gas	
Sodium	140 mEq/l	Sodium	141 mEq/l	pH	7.27
Potassium	4.0 mEq/l	Potassium	6.1 mEq/l	P_{CO_2}	31 mm Hg
Chloride	108 mEq/l	Chloride	106 mEq/l	P_{O_2}	97 mm Hg
Bicarbonate	24 mEq/l	Bicarbonate	14 mEq/l	HCO_3^-	14 mEq/l
Blood urea nitrogen (BUN)	12 mg/dl	BUN	24 mg/dl	Urinalysis	
Creatinine	0.6 mg/dl	Creatinine	4.4 mg/dl	Specific gravity	1.028
Glucose	100 mg/dl	Glucose	98 mg/dl	pH	6.0
		Calcium	5 mg/dl	Protein	Negative
		Phosphate	10.2 mg/dl	Blood	Positive
		Albumin	3.8 g/dl	Ketones	Negative
		Osmolality	294 mOsm/kg	Red blood cells	none
		Lactate	Normal		

What is the most appropriate next diagnostic test?

A. Serum creatine kinase level
B. Kidney ultrasound with Doppler
C. Kidney biopsy
D. Serum antineutrophil cytoplasmic antibody
E. Fractional excretion of urea

2. Which test result is most consistent with preserved renal tubular function in a person who is volume contracted and has healthy kidneys?

A. Urine osmolality of 300 mOsm/kg
B. Fractional excretion of urea of 45%
C. Blood urea nitrogen of 34 mg/dl
D. Spot urine sodium of 40 mEq/l
E. None of the above

3. A 72-year-old man is brought to the emergency department by his family because of worsening confusion throughout the day. One week ago the patient fell and fractured his distal radius, necessitating splinting and pain medication. His medical history was pertinent with chronic kidney disease stage 3 (baseline serum creatinine 1.4 mg/dl), long-standing hypertension, chronic obstructive pulmonary disease, osteopenia, and benign prostatic hypertrophy. Current medications included lisinopril 20 mg/day, amlodipine 5 mg/day, hydrochlorothiazide 25 mg/day, doxazosin 4 mg nightly, oxycodone 5 mg every 8 hours as needed for arm pain, vitamin D 2000 international units/day, and ipratropium bromide–albuterol inhaled 4 times per day. Arrival vital signs include blood pressure 176/92 mm Hg, pulse 114/min, respirations 18/min, weight 55 kg, and temperature 98.5° F. Physical examination revealed an agitated older man with flat neck veins, reduced air movement on chest auscultation, a large and tender abdomen, a right forearm cast, and trace lower extremity edema. No skin lesions were seen or palpated. Initial laboratory test results were as follows:

Blood tests: Sodium 138 mEq/l, potassium 5.2 mEq/l, chloride 110 mEq/l, bicarbonate 20 mEq/l, BUN 54 mg/dl, serum creatinine 2.6 mg/dl, leukocyte count 7500 cells/ml, hemoglobin 11.2 g/dl, platelet count 150,000 cells/µmol, alanine aminotransferase 28 U/l (normal 15-58 U/l), aspartate aminotransferase 36 U/l (normal 15-40 U/l), and prothrombin time 14 seconds. Urinalysis with microscopy: Specific gravity 1.010, no blood or protein, and a bland sediment with no casts and few cells. What is the most appropriate next diagnostic test?

A. Kidney ultrasound with Doppler
B. Peripheral blood smear
C. Renal biopsy
D. Postvoid bladder catheterization
E. None of the above

Epidemiology and Prognostic Impact of Acute Kidney Injury

Neesh Pannu, Marcello Tonelli

INCIDENCE OF ACUTE KIDNEY INJURY

The incidence of acute kidney injury (AKI) in unselected hospitalized patients is between 0.4% and 18%, depending on the definition used, and accounts for 1% to 4% of all hospital admissions.[2] Several large studies suggest that the incidence of AKI in hospitalized patients has increased by approximately 13% per year over the last three decades.[3] In these studies, incidence was identified by diagnostic codes that are highly specific for AKI (97%) but are relatively insensitive (35% sensitivity),[4] and thus these studies likely underestimate the true incidence. Less is known about community-acquired AKI; there is significant etiologic and geographical variation in the reported incidence and risk factors for AKI in the community settings. A recent study from Taiwan reports an incidence of 17.25 in 1000 admissions using serum creatinine–based criteria for AKI.[5] Similar increases have been observed in the incidence of severe AKI (requiring renal replacement therapy [RRT]) between 2000 and 2009 and a doubling in the number of deaths attributable to AKI (Fig. 69.1).[6] The increased incidence is likely related to increasing patient age and a higher burden of comorbidity, including a higher prevalence of chronic kidney disease (CKD). AKI survivors had prolonged hospital length of stay and a greater requirement for posthospitalization care,[7] thus incurring significantly higher health care costs.[8]

The incidence of AKI using consensus definitions based on serum creatinine and urine output (Table 69.1) has been best characterized in critically ill populations. Despite using standardized definitions for AKI, multicenter studies of critically ill patients have reported the incidence of AKI to be between 10% and 67%, likely reflecting differences in case-mix between health care systems and countries.[9]

RISK FACTORS FOR ACUTE KIDNEY INJURY

Risk factors for AKI have been determined in a variety of clinical settings including cardiac surgery, contrast-induced AKI, and critically ill populations; however, risk prediction models that accurately predict the occurrence of AKI have been elusive. Nonmodifiable risk factors common to all populations are presented in Box 69.1.

Age

Multiple studies have shown that AKI is more common in older individuals, and many have shown an independent association between AKI and older age.[10] In a community-based prospective study, the patients aged 80 to 89 years were 55 times more likely to develop AKI than adults younger than 50 years.[11] Possible explanations for this association include (1) structural and functional changes associated with age that lead to diminished nephron reserve and reduced capacity for renal autoregulation, (2) accumulation of comorbidity that increases susceptibility to AKI (vascular disease, diabetes, hypertension, CKD), and (3) increased exposure among older persons to medications and procedures that predispose to AKI.[10]

Reduced Estimated Glomerular Filtration Rate

Preexisting reduction in estimated glomerular filtration rate (eGFR) is a potent risk factor for AKI after exposure to radiocontrast,[12] major surgery, and medical illness,[13] although the pathophysiology underlying this association is poorly understood. It has been reported that the odds of developing dialysis requiring AKI are increased at lower baseline eGFR; the excess risk compared with normal eGFR was approximately twofold in patients with baseline eGFR 45 to 60 ml/min/1.73 m^2, but more than 40-fold for patients with baseline eGFR less than 15 ml/min/1.73 m^2.[14] These associations were confirmed in several recent systematic reviews that demonstrate strong independent associations between risk for AKI and lower baseline eGFR[15-17] (see Fig. 69.2). Although these analyses support a causal association between CKD and in-hospital AKI, little is known about how this association may be modified by the presence of one or more comorbidities such as heart failure or whether all causes of CKD confer similar risk for AKI.

Proteinuria

Proteinuria is also strongly associated with AKI risk. A case-control study of over 600,000 patients identified proteinuria as an independent predictor for AKI,[14] which was replicated in multiple settings, including after cardiac surgery in Taiwan and in general population studies from the United States and Canada[18-20] (Fig. 69.3).

Hyperuricemia

Two prospective randomized trials[20a,20b] also found allopurinol plus hydration to be superior to hydration alone in preventing AKI following radiocontrast administration. Nevertheless, uric acid can also be a biomarker for other risk factors (e.g. mild CKD, cancer) and while the two studies are interesting, more data is needed before this intervention is recommended. Several retrospective studies have observed a graded association between uric acid levels and AKI after cardiac revascularization, as well as in unselected hospitalized patients. A recent systematic review and meta-analysis (n = 13,084) of 18 studies evaluating the association between uric acid and risk for contrast-associated AKI also found that that the presence of hyperuricemia was independently associated with an increased risk for AKI (adjusted odds ratio [OR] 1.68, confidence interval [CI] 95% 1.38-2.04).[21,22]

Population Incidence of AKI Requiring Dialysis in the United States from 2000 to 2009

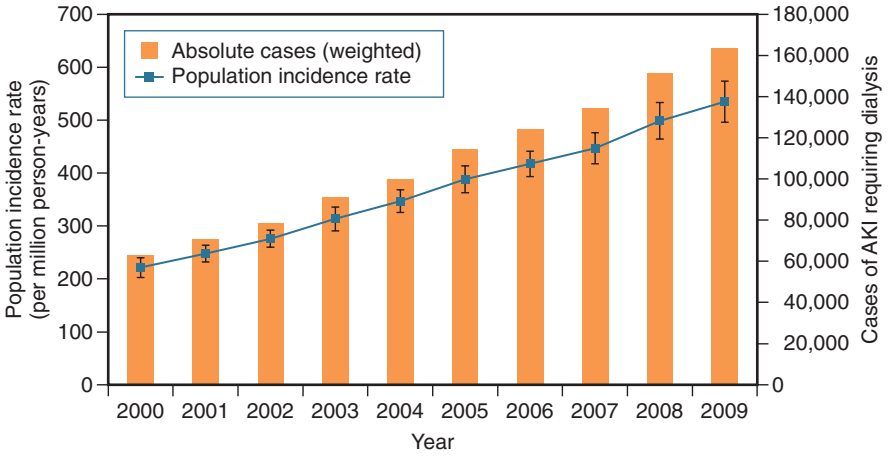

Fig. 69.1 Population incidence of patients with acute kidney injury *(AKI)* who require dialysis in the United States from 2000 to 2009 (absolute count and incidence rate per million person-years). Whiskers represent 95% confidence interval for incidence rates. The number of cases of AKI in which patients required dialysis increased from 63,000 in 2000 to almost 164,000 in 2009; the population incidence increased at 10% per year from 222 to 533 cases per million person-years. (From reference 6.)

BOX 69.1 Patient-Specific Risk Factors for Acute Kidney Injury

- Age
- Gender (male)
- Chronic kidney disease
- Proteinuria
- Diabetes
- Congestive heart failure
- Sepsis
- Volume depletion
- Chronic liver disease
- Hyperuricemia

BOX 69.2 Risk Factors for Chronic Kidney Disease After Acute Kidney Injury

- Age
- Baseline eGFR
- Congestive heart failure
- Hypertension
- Recurrent AKI
- Serum albumin during hospitalization
- Severity of AKI (AKI stage, requirement for dialysis)
- eGFR at hospital discharge

AKI, Acute kidney injury; *eGFR,* estimated glomerular filtration rate.

TABLE 69.1 Recent Consensus Definitions of Acute Kidney Injury

Definitions	Serum Creatinine Criteria	Urine Output Criteria
RIFLE (2003)	Increase in serum creatinine × 1.5 or decrease in GFR by 25% within 48 h	Urine volume <0.5 ml/kg/h × 6 h
AKIN (2007)	Increase in serum creatinine × 1.5 or by ≥0.3 mg/dl (≥26.5 μmol/l) within 48 h	Urine volume <0.5 ml/kg/h for 6 h
KDIGO (2012)	Increase in serum creatinine by ≥0.3 mg/dl (≥26.5 μmol/l) within 48 h Increase in serum creatinine to ≥1.5 times baseline, which is known or presumed to have occurred within the prior 7 days Severity staging after initial criteria met	Urine volume <0.5 ml/kg/h for 6 h

ASSOCIATION BETWEEN ACUTE KIDNEY INJURY AND ADVERSE OUTCOMES

AKI is associated with high costs and adverse clinical outcomes, including excess mortality, increased length of hospital stay, development and/or progression of CKD, and requirement for chronic dialysis in survivors (Box 69.2).

Mortality

Multiple observational studies demonstrate increased mortality among patients who develop AKI in hospital. In its most severe form (requirement for acute dialysis) AKI is associated with mortality ranging from 15% (AKI only) to 80% (AKI in critically ill patients).[23] However, comparing patients with AKI to those without AKI does not distinguish between the increased risk for death caused by kidney disease per se and the increased risk associated with the underlying illness that was sufficiently severe to result in AKI. Therefore there is uncertainty about whether the association between AKI and mortality is truly independent. Nonetheless, the development of AKI signifies a poor prognosis in individual patients.

Small changes in serum creatinine of as little as 25% above baseline are a significant predictor of all-cause short-term mortality.[24] A

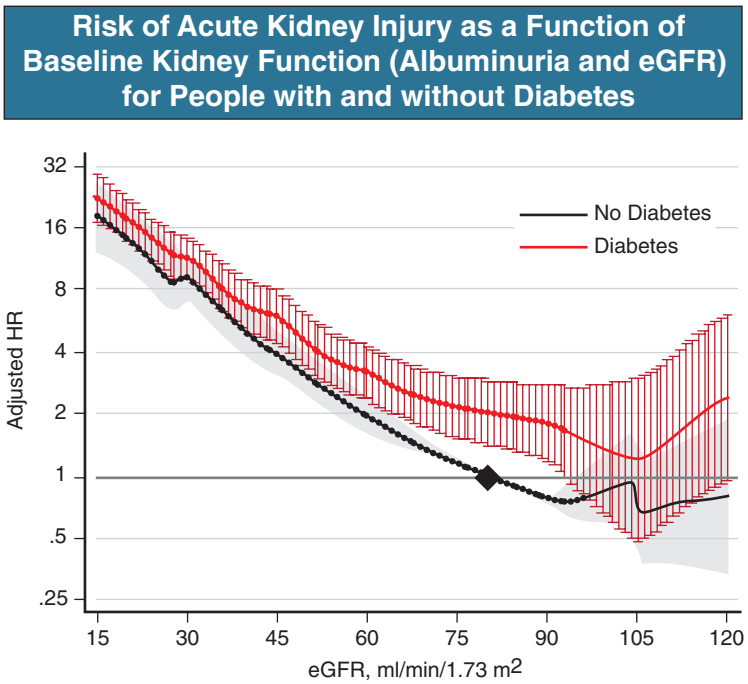

Fig. 69.2 Hazard ratio *(HR)* of acute kidney injury for people with and without diabetes according to baseline estimated glomerular filtration rate. *eGFR,* Estimated glomerular filtration rate.

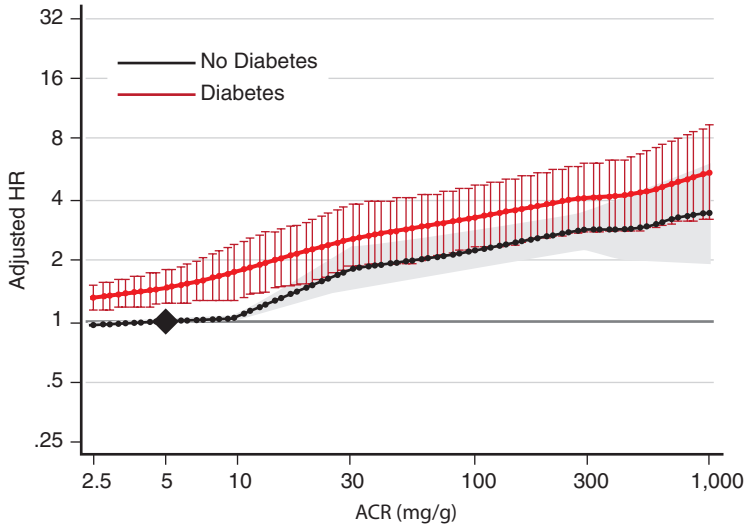

Fig. 69.3 Hazard ratio *(HR)* of acute kidney injury for people with and without diabetes according to the ratio of urine albumin to creatinine. *ACR,* Albumin:creatinine ratio.

meta-analysis of eight studies of hospitalized patients (most of whom were critically ill or had heart failure) confirmed a graded relationship between increasing severity of AKI and short-term mortality.[25] Most importantly, it confirmed that even mild forms of AKI are clinically relevant; an increase in serum creatinine of 0.3 mg/dl (26 µmol/l) was associated with a short-term relative risk for death of 2.3 (95% CI 1.8-3.0). After adjustment for comorbidities, the odds or hazards ratios for death associated with AKI ranged from 1.7 to 1.92. Similar findings were reported in several population-based studies of unselected hospitalized patients.[26]

The association between AKI and mortality is likely influenced by several factors, including the presence of underlying CKD, the duration and severity of AKI, and the degree of recovery of kidney function. A population-based study of hospitalized AKI patients in Canada found that the relation between AKI and in-hospital mortality was strongest in those with severe AKI and baseline eGFR greater than 60 ml/min/1.73 m^2 (adjusted hazard ratio [HR] 10.62, 95% CI 8.78-12.82).[26,27] The presence of CKD modifies this association; by comparison, in patients with a baseline eGFR less than 30 ml/min/1.73 m^2, the adjusted hazard ratio of in-hospital mortality was 4.71 (95% CI 3.61-6.15). An analysis of postoperative AKI comparing renal and survival outcomes in those with and without preexisting CKD (eGFR <45 ml/min/1.73 m^2) found a lower attributable mortality rate because of AKI (HR 1.26, 95% CI 1.09-1.78) when subjects with prior CKD but no AKI were used as the reference.[28]

Although the incidence of AKI continues to climb, there has been a corresponding improvement in survival. A recent analysis reported

a 19% decrease in mortality between 2000 and 2009 in patients who required acute dialysis. Whether this represents a trend toward earlier use of dialysis (rather than a true improvement in survival) requires further investigation.

Chronic Kidney Disease

Until recently it was accepted that AKI survivors generally recovered renal function and remained independent from dialysis. This assumption was supported by the findings of small cohort studies of predominantly critically ill patients. One recent study described long-term outcomes of 226 critically ill patients with previously normal eGFR who required acute dialysis for AKI and reported that 86% of survivors had "normal" kidney function at 5 years.[29]

However, an increasing number of recent studies have linked AKI survivorship to the development of CKD or end-stage renal disease (ESRD). For example, in one study AKI (defined using ICD-9 codes) was associated with an eightfold increase in the risk for ESRD compared with subjects without AKI or CKD.[30] A second cohort study evaluated the risk for progressive CKD after AKI in subjects with baseline eGFR greater than 45 ml/min/1.73 m^2,[31] and found that survivors of dialysis-dependent AKI had a 28-fold increased risk for developing stage 4 CKD (eGFR <30 ml/min/1.73 m^2) or greater, compared with those without AKI.[31]

Since then, multiple studies have demonstrated an association between AKI and initiation or progression of CKD and/or ESRD in a variety of clinical settings, including cardiac surgery, cardiac catheterization and in unselected hospitalized patients. A meta-analysis of 13 cohort studies reported that the hazard ratios for CKD and ESRD were 8.8 (95% CI 3.1, 25.5) and 3.1 (95% CI 1.9, 5.0) compared with subjects without AKI. National renal registry data from the United States shows that approximately 2% to 3% of patients with AKI requiring dialysis will fail to recover kidney function and/or progress to ESRD within 1 year.[32] Recurrent episodes of AKI further increase the risk for progressive CKD; each additional AKI event after the first episode appears to double the risk for progression to stage 4 CKD.

It is possible that the apparent association between AKI and CKD is confounded by age, frailty, and unmeasured comorbidity. Also, it is sometimes difficult to distinguish AKI from progressive CKD, and there is the possibility that the observed associations are due to misclassification. However, AKI also has been linked to the development of CKD in children, in whom these potential confounders are less likely.[33] A prospective single-center study of 126 critically ill pediatric AKI survivors who fully recovered kidney function reported that 10% of patients developed CKD (albumin-to-creatinine ratio ≥30 mg/g or eGFR less than 60 ml/min/1.73 m^2) over 3 years of follow-up.[34] Importantly, 38% of the cohort had mildly decreased eGFR (60 to 90 ml/min/1.73 m^2), 3.2% had hypertension, and 8.7% had hyperfiltration—all risk factors for future CKD. Given that the median age of these patients at the time of the AKI episode was 0.5 years, these numbers likely underestimate the long-term risk for CKD for these children. Similar findings were reported in a meta-analysis of outcomes after pediatric hemolytic uremic syndrome.[35]

Cardiovascular Risk

Contrast-induced nephropathy after cardiac catheterization is known to be associated with excess risk for subsequent cardiovascular events; however, there are conflicting data about whether AKI is associated with an increased risk for cardiovascular events in patients without preexisting cardiovascular disease. Several large retrospective cohort studies of patients undergoing both vascular and nonvascular major surgery have recently confirmed an association between postoperative AKI and cardiovascular mortality.[36,37] Further, a recent systematic review analyzed data from 25 cohort studies of patients (n = 254,408) with and without AKI and reported that AKI is associated with an 86% increased risk for cardiovascular mortality, a 38% increased risk for major adverse cardiovascular events and a 40% increased risk for heart failure.[38] The pathophysiology of this association remains unclear.

In summary, the development of AKI during hospitalization identifies a cohort of patients at high risk for adverse outcomes. Recognition of AKI therefore presents an opportunity to mitigate future risk through appropriate monitoring and implementation of evidence-based care for CKD. However, U.S. data suggest that only 5% of AKI survivors saw a nephrologist after hospital discharge,[32] and AKI survivors with CKD and proteinuria often do not receive treatment with angiotensin-converting enzyme inhibitors/angiotensin receptor blockers after discharge from hospital.[39] This treatment gap is undoubtedly larger in patients with AKI from lower income countries.

Health Care Costs

A single-center study of AKI in hospitalized patients demonstrated a direct relationship between severity of AKI and associated hospital length of stay and hospital costs.[24] When defined as a 0.3 mg/dl (26 µmol/l) increase in serum creatinine, AKI was associated with an incremental hospitalization cost of $4886 USD; a doubling of serum creatinine was associated with an incremental cost of $9000. Studies of specific populations of hospitalized patients support these findings; a recent study of the cost of AKI after cardiac surgery suggests that the average difference in postoperative costs ranges between $9000 and $14,000 depending on AKI severity. Postoperative AKI in noncardiac surgery is associated with an $11,308 increase in the median cost compared with patients who do not experience postoperative AKI.[40] In multivariable analysis, AKI was the most costly postoperative complication for these patients and resulted in the largest proportion of resource use compared with all other complications. Another study of 5875 surgical patients found severe AKI requiring RRT to be the second most costly postoperative complication, with an estimated mean increase in hospital expenditures of $28,359 compared with an uncomplicated postoperative course, and resulted in almost twice the excess cost compared with cardiac arrest.[41] However, none of these studies accounted for the impact of CKD on AKI and attendant costs, which is likely to be significant.

ACUTE KIDNEY INJURY AS A PUBLIC HEALTH ISSUE

Conservative population-based estimates of AKI incidence in hospitalized adults are in the range of 3000 per 100,000 person-years[42]; the majority of these patients will survive to hospital discharge. The incidence of stage 4 CKD or greater in AKI survivors is approximately 120 per 100,000 person-years[43] and the number of adults developing new CKD after AKI may be as high as 100,000 per year in the United States alone. Extrapolated to a global scale, AKI is likely responsible for hundreds of thousands of new CKD cases each year. Given this tremendous burden of morbidity and mortality, strategies that mitigate the progression of CKD after AKI should be a public health priority.

SELF-ASSESSMENT QUESTIONS

1. All of the following are risk factors for acute kidney disease (AKI) except:
   A. Age
   B. Chronic kidney disease
   C. Congestive heart failure
   D. Thyroid disorders
   E. Diabetes
2. The incidence of AKI in hospitalized patients has:
   A. Decreased by >10% annually over the last decade
   B. Decreased by 1% over the last decade
   C. Increased by >10% annually over the last decade
   D. Increased by 1% annually over the last decade
   E. Stayed the same
3. AKI is associated with:
   A. Higher health care costs
   B. Increased risk for CKD
   C. Increased risk for chronic dialysis
   D. All of the above
4. The incidence of stage 4 CKD (eGFR below 30 ml/min/1.73 m^2) or greater in AKI survivors is approximately:
   A. 1200 per 100,000 person-years
   B. 120 per 100,000 person-years
   C. 12 per 100,000 person-years
   D. 1.2 per 100,000 person-years

Prevention and Nondialytic Management of Acute Kidney Injury

Josée Bouchard, Etienne Macedo, Ravindra L. Mehta

Acute kidney injury (AKI) often results from a combination of insults. The most commonly associated causes are failure of renal autoregulation, direct nephrotoxicity, ischemia/reperfusion, and inflammatory states. AKI severity predicts adverse outcomes, including requirement for renal replacement therapy (RRT), length of hospital stay, and mortality. Studies using the Risk, Injury, Failure, Loss of kidney function, and End-stage kidney disease (RIFLE), Acute Kidney Injury Network (AKIN), and Kidney Disease Improving Outcomes (KDIGO) classification systems (see Chapter 68) have shown that even small changes in creatinine levels are associated with short-term and long-term mortality.[1,2] Furthermore, the distant effects of AKI contribute to dysfunction of other organs, such as the heart, lungs, brain, and liver.[3] Consequently, primary prevention and early diagnosis of AKI are of primary importance. Once AKI has been detected, efforts to attenuate the effects of injury and treatment of its consequences are necessary.

RISK ASSESSMENT

Considering the conceptual model of AKI illustrated in Fig. 70.1, the first step in preventing AKI is an adequate risk assessment. The initial care of patients at risk should focus on identification and, if possible, reversal of the risk factors. Several factors are associated with AKI (Box 70.1 and Table 70.1). Risk scores are also available to help predict AKI, most often in specific conditions (see Table 70.1). However, in most clinical settings, there are scarce data to evaluate the prevalence and potential impact of modifiable risk factors on AKI development and progression. The most common risk factor is chronic kidney disease (CKD), and thus adequate determination of baseline kidney function is fundamental. Because 40% to 50% of patients do not have a baseline renal function available, and the first creatinine measured in the hospital may be affected by the disease process occurring before hospital admission, CKD status is sometimes difficult to determine. More sensitive and specific biomarkers of cellular damage may help enable early risk assessment. For a further discussion of risk factors and scoring systems, see Chapters 68 and 69.

PRIMARY PREVENTIVE MEASURES

Optimizing Volume and Hemodynamic Status

To prevent AKI, adequate renal perfusion is required. Prompt resuscitation of patients with hypoperfusion was shown to improve outcomes more than a decade ago.[4] Adequate perfusion is ensured by optimizing volume status and maintaining hemodynamic status and cardiac output. Common reasons for fluid administration and/or vasopressors to prevent AKI include hypovolemia, hypotension, and sepsis. However, assessment of volume status can be challenging, particularly in patients in the intensive care unit (ICU). In addition, studies in ICU patients or patients undergoing surgery have shown that only about half of hemodynamically unstable patients respond to fluid administration. There are no guidelines for optimizing hemodynamic and fluid status for renal function preservation. Too often, the effect of fluid expansion on hemodynamic status and renal function is retrospective and evaluated by trial and error. However, dynamic measures such as the passive leg raising maneuver and the fluid bolus test coupled with real-time stroke volume monitoring can determine fluid responsiveness accurately.[5,6] Unfortunately, these are rarely performed even in ICUs. On the ward, volume status assessment and response to fluid administration most often relies on blood pressure, heart rate, oxygen saturation, central venous pressure, and urine output. These parameters are known to be not specific or sensitive, thus better, simple tools are urgently needed to assess volume status and fluid responsiveness outside ICUs. In emergency settings, point of care ultrasound can be useful. For example, a collapsing inferior vena cava at the end of expiration is suggestive of hypovolemia.

Four phases of fluid therapy have recently been conceptualized, including rescue, optimization, stabilization, and deescalation.[7] *Rescue* implies the "administration of fluid for immediate management of life-threatening conditions associated with impaired tissue perfusion." *Optimization* refers to the "adjustment of fluid type, rate, and amount based upon context to achieve optimization of tissue perfusion." Fluid boluses are used during the rescue phase, whereas fluid challenges are administered during the optimization phase. Fluid bolus in an adult typically includes the infusion of 500 ml of isotonic fluids over 15 minutes or less without close monitoring. Fluid challenge involves the administration of 250 ml or 3 ml/kg of isotonic fluids over 5 to 10 minutes with stroke volume (SV) reassessment. Some studies have defined fluid responders as an increase of 10% to 15% of SV or cardiac output after fluid challenge. These two phases are essential in preventing AKI secondary to hypoperfusion. *Stabilization* aims for achieving a neutral or slightly negative fluid balance to favor organ support, and *deescalation* is defined by the "minimization of fluid administration; mobilization of extra fluid to optimize fluid balance." In the stabilization and deescalation phases, clinicians should target a neutral and then a negative fluid balance if fluid overload is present. To obtain a neutral or negative fluid balance, fluid administration should be minimized and oral or intravenous diuretics or even ultrafiltration may be required depending on the clinical scenario and underlying kidney and cardiac function. Adverse outcomes associated with fluid overload include cardiopulmonary complications, delayed wound healing and kidney function recovery, and increased mortality.[8,9] A retrospective study has shown that elevated central venous pressure within the first 24 hours

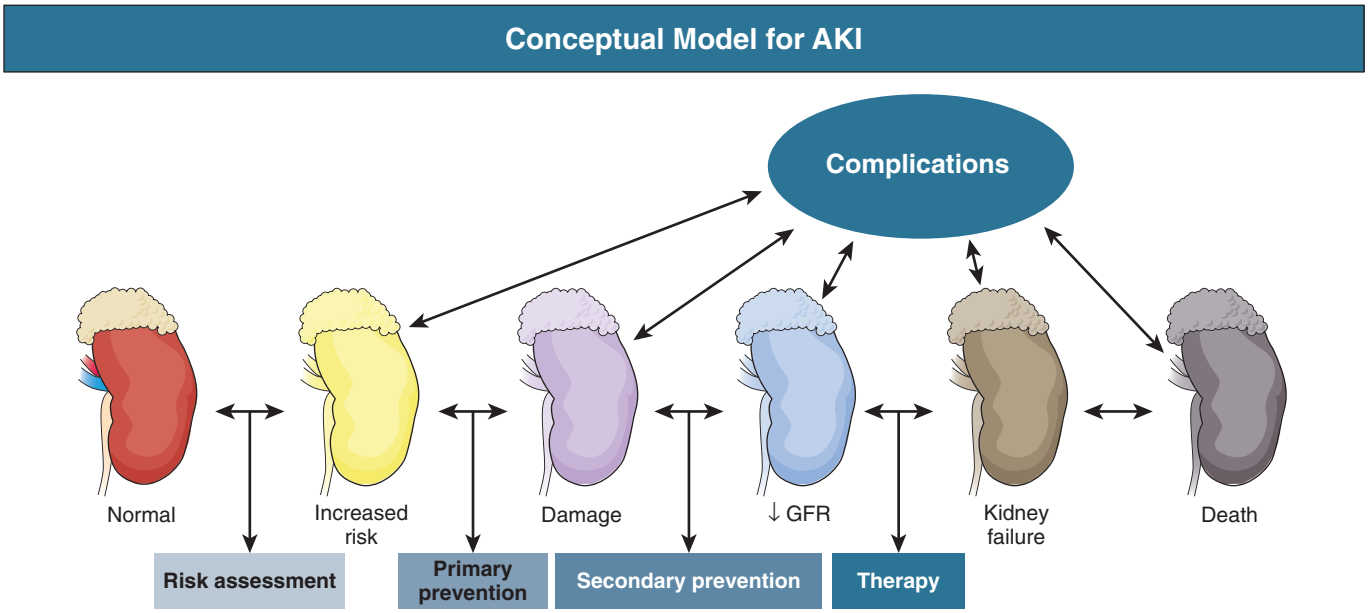

Fig. 70.1 Conceptual model for acute kidney injury (AKI). *GFR,* Glomerular filtration rate. (Modified from reference 48.)

BOX 70.1 Major Risk Factors for Acute Kidney Injury

Patient Factors
- Older age (>75 years)
- Diabetes
- Liver failure
- Chronic kidney disease
- Atherosclerosis
- Renal artery stenosis
- Hypertension
- Hypotension
- Hypercalcemia
- Hyperuricemia
- Sepsis
- Perioperative cardiac dysfunction
- Rhabdomyolysis
- Tumor lysis syndrome

Medications and Agents
- Nonsteroidal antiinflammatory drugs
- Cyclooxygenase-2 inhibitors
- Cyclosporine or tacrolimus
- Angiotensin-converting enzyme inhibitors
- Angiotensin receptor blockers
- Iodinated radiocontrast agent
- Hydroxyethyl starch (HES)
- Aminoglycosides
- Amphotericin

Procedures
- Cardiopulmonary bypass procedures
- Surgery involving aortic clamp
- Increased intraabdominal pressure
- Large arterial catheter placement with risk for atheroembolization
- Liver transplantation
- Kidney transplantation

of ICU admission was associated with AKI, suggesting a role of venous congestion in the development of AKI.[10]

There is controversy about the optimal fluid to use for resuscitation. The recent KDIGO AKI guidelines suggest that isotonic crystalloids should be used instead of synthetic (hydroxyethyl starch [HES]) and nonsynthetic (albumin) colloids for intracellular volume expansion in patients at risk or presenting with AKI, in the absence of hemorrhagic shock.[11] Large studies have clearly demonstrated that HES solutions increase the risk for AKI. A randomized controlled trial (RCT) in 7000 ICU patients has shown that even solutions with lower molecular weight such as 6% HES 130/0.4 increased the need for RRT compared with 0.9% sodium chloride (normal saline).[12] Another large RCT including 804 patients with severe sepsis has shown that 6% HES 130/0.4 is detrimental to kidney function and also survival compared with Ringer acetate.[13] The mechanism of HES-induced AKI may be due to proximal renal epithelial cell uptake of HES causing an acquired lysosomal storage disease. Therefore HES should be avoided in patients at risk for and with AKI.

For albumin, the Saline Versus Albumin Fluid Evaluation (SAFE) trial of 6997 critically ill patients found that fluid resuscitation with saline or albumin resulted in similar relative risks for death.[14] In addition, no significant differences were found in new single-organ and multiple-organ failure or days on RRT. Two subgroup analyses from this study showed that use of albumin may be deleterious in patients with traumatic brain injury and potentially beneficial in sepsis. Therefore the use of albumin can be considered when substantial amounts of crystalloids (e.g., 2 liters) are required to maintain adequate mean arterial pressure (MAP), especially in septic patients. However, its effect must be balanced against its potential risks; that is, it is possibly deleterious in patients with trauma and has low potential for transmission of infectious diseases.

The type of crystalloids used may influence renal outcomes. A study comparing renal artery flow velocity and renal cortical tissue perfusion showed a significant reduction in renal artery flow and cortical tissue perfusion with saline but not with the use of chloride-restrictive fluids. Indeed, greater chloride delivery to the macula densa may activate tubuloglomerular feedback, triggering renal vasoconstriction and reduced glomerular filtration rate (GFR). A large retrospective study showed that chloride-restrictive fluids (lactated solution with balanced buffer–chloride concentration of 98 mmol/l or chloride-poor 20% albumin-chloride concentration of 19 mmol/l) compared with chloride-rich intravenous fluids (0.9% saline, 4% succinylated gelatin solution, or 4% albumin solution) were associated with a significant decrease in AKI and RRT requirement.[15] A meta-analysis confirmed that high-chloride fluids significantly increased the risk for AKI.[16] However, the recent SPLIT trial, a large RCT including 2278 patients, failed to show differences in renal outcomes with the use of the same buffered crystalloid than the aforementioned study compared with 0.9% saline.[17] In this study, AKI was defined as a rise in serum creatinine level of at least twofold. Critiques of this study included the low severity of disease at baseline

TABLE 70.1 Specific Risk Factors for the Development of Acute Kidney Injury in Common Clinical Situations

Miscellaneous	Hemodynamic	Gastrointestinal and Endocrine
Postoperative (General)		
Age	Congestive heart failure	Cirrhosis/biliary surgery
Proteinuria	Aortic cross-clamping	Obstructive jaundice
Hypertension	Cardiac instability	Diabetes mellitus
Massive blood transfusion	Major vascular surgery	Hyperglycemia
	Infection/sepsis	
	Multiorgan failure	
Cardiac Surgery		
Female gender	ACE inhibitor therapy	Emergency surgery
COPD	Heart failure	Valve surgery only
Proteinuria	LV ejection fraction <35%	Previous cardiac surgery
Preoperative S_{Cr} >2.1 mg/dl	Preoperative IABP	Other cardiac surgery
Anemia	Hyperglycemia	Combination of CABG + valve surgery
Insulin-requiring diabetes	Hyperuricemia	Blood transfusion
Critically Ill		
High A-a gradient*	Age	
Low serum albumin	S_{Cr} >1.3 mg/dl	
Proteinuria	Serum bilirubin >1.5 mg/dl	
Hyperglycemia	Elevated CVP >8 cm	
High intraabdominal pressure	Hemodynamic instability	
Active cancer	Sepsis	
Iodinated Contrast Administration		
Age >75 yr	Volume of contrast >100 ml	
Heart failure	Intraarterial injection	
Diabetes mellitus	Systolic BP <80 mm Hg for >1 hr and need for inotropic support or IABP 24 hr after procedure	
S_{Cr} >1.5 mg/dl or eGFR <60 ml/min/1.73 m^2	Use of IABP	
History of pulmonary edema		
Anemia/blood loss (Hct: <39% for men; <36% for women)		
Hyperuricemia		
Nephrotoxic Antibiotics		
Volume depletion	Amphotericin	
Older age	Aminoglycosides	
Chronic kidney disease		
Duration of therapy >7 days		
Volume depletion		
Divided dose regimens		
Liver disease		

(Modified from Lameire N, Van Biesen W, Vanholder R. Epidemiology, clinical evaluation, and prevention of acute renal failure. In: Feehally J, Floege J, Johnson RJ, eds. Comprehensive Clinical Nephrology. Philadelphia: Mosby-Elsevier; 2007:771–785.)

*A-a gradient, alveolar-arterial oxygen gradient calculated with the sea level standard formula $(713 \times FiO_2) - (PcO_2/0.8) - PaO_2$, where FiO_2 is fractional inspired oxygen concentration, PaO_2 is arterial partial oxygen pressure, and PcO_2 is partial carbon dioxide pressure.

ACE, Angiotensin-converting enzyme; *CABG,* coronary arterial bypass graft; *COPD;* chronic obstructive pulmonary disease; *CVP,* central venous pressure; *Hct,* hematocrit; *IABP:* intraaortic balloon pump; *LV,* left ventricular; S_{Cr}, serum creatinine.

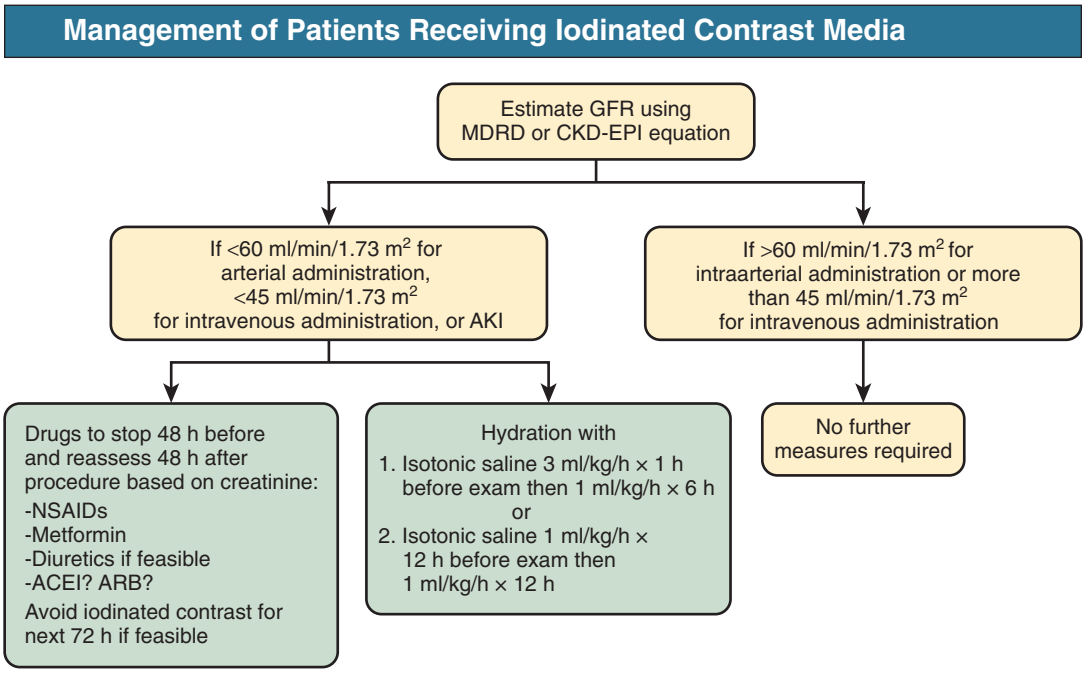

Fig. 70.2 Management of patients receiving iodinated contrast media. *ACEI,* Angiotensin-converting enzyme inhibitor; *AKI,* acute kidney injury; *ARB,* angiotensin receptor blocker; *CKD-EPI,* Chronic Kidney Disease Epidemiology Collaboration; *D5W,* 5% dextrose in water; *GFR,* glomerular filtration rate; *MDRD,* Modification of Diet in Renal Disease; *NSAIDs,* nonsteroidal antiinflammatory drugs.

and low volume of fluid administered (2.6 liters ± 2.1 to 3.0 liters in each group). In addition, the solution used contained acetate (which may cause myocardial toxicity) and gluconate (which may have other metabolic effects). In conclusion, the use of low-chloride solutions does not improve renal outcomes compared with normal saline in patients at low-moderate risk for AKI. Two large RCTs are ongoing to assess outcomes associated with different type of fluid solutions in high-risk populations. Currently, the choice of chloride-rich versus low-chloride solutions needs to be based on the patient's clinical condition, including electrolyte and acid-base balance, as well as availability and costs.

There is no consensus on how to use vasopressors to prevent AKI or avoid further deterioration of kidney function. According to international guidelines for sepsis management, after initial fluid resuscitation with 30 ml/kg of crystalloids and addition of albumin in patients requiring substantial amounts of crystalloids to maintain adequate MAP, vasopressors should be initiated targeting a MAP above 65 mm Hg.[18] In sepsis, norepinephrine is the first-choice vasopressor. With regard to the kidney, a recent RCT showed that vasopressin is equivalent or may be better than norepinephrine to improve kidney outcomes in patients with septic shock.[19] RRT was required in 25% of patients in the vasopressin group and in 35% of the norepinephrine group; however, rates of RRT were comparable among survivors from each group, and the overall mortality rate was also similar between groups.

Finally, inotropic agents such as dobutamine should be administered if myocardial dysfunction or ongoing signs of hypoperfusion are present. The optimal MAP values to prevent AKI need to be better delineated. One study has found that in hypertensive patients with septic shock, targeting MAP between 80 to 85 mm Hg instead of 65 to 70 mm Hg reduced the risk for AKI and RRT, whereas the risk for atrial fibrillation seemed to be heightened.[20] Therefore target MAP values may need to be individualized depending on age, hypertension status, and degree of peripheral artery and renovascular disease.

Prevention of Contrast-Induced Acute Kidney Injury

The concept of contrast-induced AKI (CI-AKI) has been recently questioned. However, physicians are less likely to prescribe contrast to patients with CKD and more likely to prescribe intravenous fluids if contrast is administered, which may affect results from observational studies.

The Prevention of CI-AKI Consensus Working Panel recommends that measures to reduce the AKI risk should be implemented in patients with a baseline estimated GFR (eGFR) below 60 ml/min/1.73 m^2. According to the KDIGO guidelines, this threshold could probably be lowered to 45 ml/min/1.73 m^2. For prevention of CI-AKI, patients at risk should receive intravenous hydration (Fig. 70.2). Hydration with isotonic saline is superior to half-isotonic (0.45%) saline.[21] An RCT compared isotonic saline with isotonic sodium bicarbonate (three 50-ml ampules of 1 mmol/ml sodium bicarbonate added to 850 ml of 5% dextrose) at 3 ml/kg/h for 1 hour before the procedure followed by 1 ml/kg/h for the 6 hours after the procedure. CI-AKI was significantly lower in the bicarbonate compared with the saline group (2% vs. 14%).[22] The superiority of bicarbonate was subsequently confirmed in some but not all RCTs. The rationale for isotonic bicarbonate was based on animal studies showing that bicarbonate is capable of scavenging reactive oxygen species, and the increased pH in the proximal tubule and the renal medulla associated with bicarbonate administration could reduce generation of superoxide. Most hydration studies with isotonic bicarbonate used shorter infusion protocols (7 hours) than those with isotonic saline (usually 12 to 24 hours), which is attractive for emergency procedures. However, there are risks for compounding errors with sodium bicarbonate that can lead to electrolyte disorders. The KDIGO AKI guidelines recommend either isotonic sodium chloride or sodium bicarbonate solutions in patients at risk for CI-AKI unless there are contraindications to volume expansion. However, the 2 × 2 factorial design (PRESERVE) trial aiming to compare the effectiveness of sodium bicarbonate with isotonic sodium chloride and oral *N*-acetylcysteine (NAC) with placebo

in 8680 high-risk patients scheduled to undergo coronary or noncoronary angiography recently showed no difference in terms of AKI or mortality between the use of sodium bicarbonate and isotonic sodium chloride. The use of NAC is discussed later in this chapter.

Iodinated contrast can be categorized according to osmolality into high-osmolar contrast medium (approximately 2000 mOsm/kg), low-osmolar contrast medium (600 to 800 mOsm/kg), and iso-osmolar contrast medium (290 mOsm/kg). Clinical studies suggest that the risk for nephrotoxicity increases with increasing osmolarity but the higher cost of iso-osmolar agents prevents their universal use. The KDIGO AKI guidelines recommend either iso-osmolar or low-osmolar iodinated contrast for patients at risk for CI-AKI.

The volume of contrast administered is also an independent predictor of CI-AKI and should be reduced as much as possible. Based on the volume of contrast given (V; ml) and the creatinine clearance (CrCl; ml/min), a V/CrCl ratio above 3.7 independently predicts CI-AKI. Administration of iodinated contrast more than once over 48 to 72 hours should be avoided. The drugs used for CI-AKI prevention are included in the section on pharmacologic approaches.

Prevention of Drug-Induced and Nephrotoxin-Induced Acute Kidney Injury

Drug-induced nephrotoxicity often can be predicted because it is more common in certain patient populations and clinical situations. Prevention involves the knowledge of mechanisms of renal injury, patient-related risk factors, and drug-related risk factors. The most important patient-related factors are older age (60 years or older), CKD, diabetes, heart failure, volume depletion, and sepsis. Preventive measures include correctly estimating the GFR before initiation of therapy, adjusting the dosage, monitoring renal function and drug dosage during therapy, and the administration of intravenous saline before exposure if possible. Alternative non-nephrotoxic drugs should be used, and nephrotoxic drug combinations should be avoided whenever feasible.

Amphotericin

Amphotericin-associated nephrotoxicity can occur in as many as one third of treated patients, and the risk for AKI increases with higher cumulative doses. Lipid formulations cause less nephrotoxicity compared with the standard formulation, and therefore amphotericin deoxycholate is preferred over conventional amphotericin; however, it is significantly more expensive. Recently alternative antifungal agents such as itraconazole, voriconazole, and caspofungin have been more commonly used in patients at high risk for AKI and should be used rather than conventional amphotericin.

Angiotensin-Converting Enzyme Inhibitors, Angiotensin Receptor Blockers

Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) cause vasodilation of the efferent glomerular arteriole, further reducing intraglomerular pressure already compromised by the blood pressure–lowering effect of these agents. After the initiation of an ACE inhibitor or ARB, if creatinine increases by more than 30%, bilateral renal artery stenosis, stenosis of the renal artery in a solitary kidney, diffuse intrarenal small-vessel disease, or generalized volume depletion should be suspected, and these drugs discontinued. It remains unclear whether withdrawing an ACE inhibitor or ARB before iodinated contrast administration is beneficial.

Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs (NSAIDs) should be avoided in CKD and intravascular volume depletion because they inhibit cyclooxygenase, which blocks prostaglandin-induced vasodilation of the afferent arteriole, potentially reducing GFR and renal blood flow. In critically ill patients, renal hypoperfusion caused by decreased effective circulating volume is relatively common and inhibition of prostaglandin-induced vasodilation may further compromise renal blood flow and exacerbate ischemic injury.

Aminoglycosides

AKI caused by aminoglycoside nephrotoxicity (AG-AKI) usually occurs 5 to 10 days after initiation of the treatment. AG-AKI is typically nonoliguric and associated with decreased urine concentrating ability and urinary magnesium wasting. A recent large population-based study in adults undergoing surgery receiving antibiotic prophylaxis found an association between one dose of gentamicin (4 mg/kg) and AKI that challenges the notion that AG-AKI only occurs after a few days of treatment.[23] Because of the toxicity of aminoglycosides, the KDIGO guidelines recommended against using them in patients with or at risk for AKI unless no other alternative is available. With multiple daily administration schedules, elevated aminoglycoside peak levels appear to correlate with nephrotoxicity. Because aminoglycoside uptake by proximal tubular cells is saturable, once-daily administration can decrease tubular cell toxicity. In the general population, extended intervals between doses maintains the target dose while decreasing the risk for nephrotoxicity compared with multiple daily doses; therefore, in patients with normal kidney function who are not at risk for AKI, aminoglycosides should be administered daily if possible.

Tumor Lysis Syndrome

Tumor lysis syndrome (TLS) is caused by uric acid and calcium-phosphate precipitation in the tubules. Identification of patients at high risk is fundamental to prevent AKI in this setting. The most common hematologic malignancies associated with TLS are aggressive lymphomas and acute lymphoblastic leukemia. The risk factors for TLS are related to patient (age, baseline renal function) and tumor characteristics (cell turnover rate, growth rate, extensive bone marrow involvement, tumor bulk, and chemosensitivity).[24] Baseline uric acid higher than 7.5 mg/dl, lactate dehydrogenase levels greater than 1500 U/l and white blood cells greater than 25×10^9/l are also risk factors. The diagnosis is based on two simultaneous laboratory abnormalities occurring within 3 days before or 7 days after chemotherapy: uric acid greater than 8 mg/dl, potassium greater than 6 mEq/l, phosphate above 4.5 mg/dl, calcium less than 7 mg/dl or any symptomatic hypocalcemia.

In patients at low risk for developing TLS, management includes hydration and close monitoring of volume status and renal function. The use of urine alkalinization to promote elimination of urate is not recommended because it can induce calcium phosphate deposition and therefore aggravate TLS. In patients at intermediate and high risk, aggressive hydration with isotonic saline 2 to 3 l/m^2 per day aiming for urine output between 80 to 100 ml/m^2/h should be initiated. In patients at intermediate risk with uric acid levels lower than 8 mg/dl, a xanthine oxidase inhibitor such as allopurinol also should be started 2 days before chemotherapy, whereas rasburicase should be used in patients with uric acid levels higher than 8 mg/dl. Rasburicase should not be used in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. For high-risk patients, a single dose of rasburicase (up to 0.2 mg/kg, although a lower dose is usually prescribed) is recommended, followed by close monitoring of uric acid levels. If uric acid normalizes, allopurinol treatment can be started. If urine output decreases despite adequate fluid administration, a loop diuretic should be added, and RRT will be required if oliguria persists.

Secondary prevention. After the renal insult has occurred, secondary preventive measures should be directed to avoid further injury, facilitate

repair and recovery, and prevent complications. The timeliness of interventions is crucial to their effectiveness. Various approaches have been applied but are best appreciated in the context of specific clinical scenarios.

Traumatic and Nontraumatic Rhabdomyolysis

The main step in preventing AKI after traumatic rhabdomyolysis and crush syndrome is early and aggressive fluid therapy.[25] Intravenous isotonic saline should be initiated even before the crushed limb is relieved to prevent precipitation of the pigment in the tubular lumen. Fluid should be administered aiming to target urine output of 200 to 300 ml/h. Fluid composition is controversial because no direct comparative trials have been performed. Recommendations to use sodium bicarbonate intend to maintain alkaline urine and decrease precipitation of myoglobin and arteriolar vasoconstriction. However, sodium bicarbonate also can precipitate calcium phosphate deposition and worsen hypocalcemia and should be avoided in severe hypocalcemia or metabolic alkalosis. On the other hand, large volumes of normal saline can cause hyperchloremic metabolic acidosis. Some experts use both normal saline and sodium bicarbonate. For example, if urine pH is less than 6.5, each liter of normal saline can be alternated with 850 ml of 5% dextrose plus 150 mmol of sodium bicarbonate. Mannitol has been suggested to be beneficial because of its diuretic, antioxidant, and vasodilatory properties. Mannitol could prevent renal tubular cast deposition, expand extracellular volume, and reduce intracompartmental pressure, muscle edema, and pain. However, mannitol may exacerbate heart failure and nephrotoxicity, requires close monitoring, and is contraindicated in oliguria, hypervolemia, hypertension, and heart failure. Mannitol can be considered if urine flow is higher than 20 ml/h at a rate of 5 g/h added to each liter of infusate not to exceed 1 to 2 g/kg/day. Muscle damage induces stretch-activated ion channels, allowing for influx of calcium into cells after reperfusion. The resultant hypocalcemia is usually asymptomatic but can lead to cardiac dysrhythmias. Hence, care must be taken to avoid sodium bicarbonate–induced hypocalcemia, which can trigger tetany, seizures, and cardiotoxicity and worsen muscle damage. During AKI recovery, hypercalcemia is frequent, mainly in patients who received calcium infusion, as a result of the mobilization of previously precipitated calcium. Thus hypocalcemia should be treated only if symptomatic.

In treating patients with rhabdomyolysis, it is important to consider when to stop fluid resuscitation. A general recommendation is to stop when creatine kinase levels decrease to less than 5000 U/l and myoglobinuria disappears, as shown by a negative urine dipstick for blood. However, the risk for fluid accumulation and compartmental expansion always should be evaluated. Frequent assessment of serum creatinine, uric acid, and creatine kinase also help the clinician determine the appropriate volume expansion. RRT should be considered in resistant hyperkalemia or metabolic acidosis, rapidly rising serum potassium, oliguria, anuria, or volume overload.

Hyperglycemia

It remains uncertain whether strict control of blood glucose reduces AKI incidence and mortality. In a large RCT in ICU patients, intensive glucose control (glucose of 81 to 108 mg/dl [4.5 to 6.0 mmol/l]) increased the risk for death at 90 days compared with conventional glucose control (<180 mg/dl [<10 mmol/l]). Intensive glucose control also increased the risk for severe hypoglycemia. There was no change in the incidence of AKI or use of RRT. Other studies have not found an increase in mortality with intensive glucose control. In summary, intensive glucose control in ICU patients increased the incidence of severe hypoglycemia and either increased or had no effect on mortality compared with blood glucose ranges of 140 to 180 mg/dl (7.8 to 10 mmol/l) and 180 to 200 mg/dl (10 to 11 mmol/l). We recommend maintaining glucose concentration in the range of 110 to 149 mg/dl (6.1 to 8.3 mmol/l).

Remote Ischemic Preconditioning

Remote ischemic preconditioning (RIPC) is performed by applying inflation of a blood pressure cuff for four or five short cycles in the upper or lower limb. RIPC aims to create brief ischemia and reperfusion in the arm or leg to provide protection in distant organs, such as heart, kidney, lung, and brain. The underlying mechanisms include activation of humoral factors, including adenosine, bradykinin, cannabinoids, in addition to subcellular modulators, nuclear factor-B and nitric oxide (NO). Two recent large RCTs in cardiac surgery found that RIPC does not confer a benefit over sham conditioning (placebo).[26,27] In one RCT, the combined outcome of MACE (major adverse cardiovascular events: death from cardiovascular causes, nonfatal myocardial infarction, coronary revascularization, or stroke) 12 months after randomization was similar in RPIC compared with sham procedure. In the other, no difference was found in death, myocardial infarction, stroke, or AKI at hospital discharge. Currently, the use of RIPC for preventing cardiac surgery and contrast-induced AKI is controversial because its beneficial effects may be conditioned by the use of propofol as an anesthetic.

Pharmacologic Approaches

Because of the multiple different causes of AKI, various pathways have been targeted in studies to prevent or alter the course of AKI. These pathways include inhibition of inflammatory mediators, enhancement of renal perfusion by blocking vasoconstrictor mechanisms and intensifying vasodilator mechanisms, attenuation of leukocyte infiltration, inhibition of the coagulation cascade, and administration of growth factors to accelerate renal recovery. Most of these preventive strategies were successful in animal models but did not translate into beneficial effects in patients. Only a few have shown benefits (Table 70.2).

N-Acetylcysteine

N-Acetylcysteine (NAC) is a tripeptide analogous to glutathione and is able to cross cellular membranes. NAC may reduce vasoconstriction and oxygen free radical generation after the administration of contrast material. Because an increased production of free radicals by the kidneys is partly responsible for their cellular damage in postischemic and nephrotoxic AKI, several clinical studies have attempted to use NAC to prevent AKI, mainly in CI-AKI and during cardiac surgery.

In the initial study, NAC at a dose of 600 mg orally twice daily the day before and the day of the procedure prevented AKI after iodinated contrast administration. However, numerous subsequent studies have shown conflicting results. The recent PRESERVE trial has shown that the use of NAC does not provide any benefit to prevent CI-AKI. Therefore, we no longer recommend using NAC to prevent CI-AKI.

Loop Diuretics and Natriuretics

Diuretics are often used to manage fluid in patients who develop AKI. Although nonoliguric AKI has been associated with better outcomes than oliguric AKI, diuretics have been shown to be ineffective in the prevention of AKI or for improving outcomes once AKI occurs. In addition, diuretics should be avoided when AKI is attributed to prerenal causes. Meta-analyses have confirmed that the use of diuretics to prevent AKI did not reduce in-hospital mortality or need for RRT.[29] An RCT including 94 patients undergoing high-risk cardiac surgery showed that prophylactic nesiritide (β-type natriuretic peptide) did not reduce RRT requirement or lengths of stay, although AKI rates were lower with nesiritide.[30] In opposition, a Japanese RCT including 303 patients with CKD who underwent coronary artery bypass graft (CABG) surgery

TABLE 70.2 Summary of Drugs Used in Prevention of Acute Kidney Injury

Drug	Level of Evidence	Results	Comments
Dopamine	RCTs	No effect on kidney function	
Fenoldopam	Small RCTs One meta-analysis	No effect on kidney function Beneficial effect on kidney function	Further studies required
Norepineprine vs. vasopressin	RCT in septic shock	Tendency toward less renal replacement therapy with vasopressin	Further studies required
Loop diuretics	RCTs and meta-analysis	No effect on kidney function	
Nesiritide	RCTs in cardiac surgery	Decreased incidence of AKI Controversial effect on renal replacement therapy requirement	Further studies required
N-Acetylcysteine	RCTs and meta-analysis	No effect in CI-AKI	
Statins	Retrospective studies: Perioperative period RCTs in CI-AKI	Beneficial effect on kidney function Possible beneficial effect on kidney function	Further studies required Patients not receiving statins who need this drug for other indications may reasonably receive statins before their angiography
Insulin	Meta-analyses	Controversial effect	KDIGO recommends to target blood glucose 110-149 mg/dl (6.1-8.3 mmol/l)
Calcium channel blockers	RCT in peri-transplant period	No effect on kidney function	Further studies required
Levosimendan	Meta-analysis in cardiac surgery	Beneficial effect on kidney function and need for renal replacement therapy	Further studies required
Adenosine antagonists	RCTs	Controversial effect on kidney function	Further studies required
Erythropoietin	RCTs in cardiac surgery, critically ill and CI-AKI	No effect on kidney function	
Small interfering RNA targeting p53	Animal models and phase 1	Beneficial effect on kidney function	Phase 2 trial just finished in cardiac surgery
THR-184*	Phase 2 RCT	No effect on kidney function	
Multipotent stem cells	Animal models	Beneficial effect on kidney function	Human studies required
Mesenchymal stem cells	Phase I clinical trials	Decreased incidence of AKI	Further studies required

CI-AKI, Contrast-induced acute kidney injury; *KDIGO,* Kidney Disease: Improving Global Outcomes (KDIGO); *PO,* by mouth; *RCTs,* randomized controlled trials; *RNA,* ribonucleic acid; *, a bone morphogenetic protein-7 agonist.

showed that human atrial natriuretic peptide (hANP, carperitide) decreased postoperative serum creatinine and need for dialysis,[31] although other studies using the same medication have shown increased mortality in patients with acute heart failure. Further studies are required.

Vasoactive Agents

Renal-dose dopamine 0.5 to 3 mcg/kg/min given as a renal vasodilator increases urine output, but several studies have confirmed that this drug does not affect AKI outcome or mortality.[32] Dopexamine, a synthetic dopamine analogue, is a dopamine type-1 and less potent dopamine type-2 receptor agonist. Small studies performed in patients undergoing liver transplant surgery have not found a beneficial effect of dopexamine in preventing AKI.

An RCT in 409 patients with septic shock showed that norepinephrine is equivalent to vasopressin in terms of kidney failure–free days.[19]

Fenoldopam is a pure dopamine type-1 receptor agonist with hemodynamic renal effects similar to those of low-dose dopamine, without systemic α- or β-adrenergic stimulation. In a meta-analysis, fenoldopam was shown to reduce the risk for AKI in postoperative or critically ill patients (odds ratio 0.43).[33] Intrarenal administration of fenoldopam allows the use of a substantial dose of fenoldopam mesylate while avoiding systemic adverse effects, such as hypotension. In a registry of 268 patients treated with intrarenal fenoldopam infused for at least 1 hour, the incidence of CI-AKI was less than 1%, compared with 27% based on historic rates in that population. Data from experimental models suggest that fenoldopam may have additional antiinflammatory effects. Currently, we do not recommend use of fenoldopam to prevent AKI because no high-quality data support use of this agent.

Statins

Although the pathogenesis of CI-AKI is not completely known, multiple mechanisms may be involved. Statins induce downregulation of angiotensin receptors, decrease endothelin synthesis, decrease inflammation, improve endothelial function by inhibiting nuclear factor (NF)-κB, decrease expression of endothelial adhesion molecules, increase NO bioavailability, attenuate production of reactive oxygen species, and protect against complement-mediated injury. Those mechanisms may be involved in CI-AKI. A number of observational publications and some but not all RCTs support the potential for renal protection with statin administration. The statin most commonly studied in this setting was rosuvastatin, at doses varying between 10 and 40 mg/day for 1 to 7 days after the procedure. Therapy should continue in patients who are already receiving a statin, and those who need statins for another indication such as myocardial infarction may receive statins before their angiography. It is currently unclear whether statins should be specifically initiated to prevent CI-AKI.

Statins also may reduce the risk for AKI after elective surgery. In a large retrospective study of 213,347 patients who underwent surgery, 32% received a statin before surgery.[34] AKI occurred in 1.9% of these patients. After multivariable adjustment, statin use was associated with

a decreased risk for AKI, need for RRT, and 30-day mortality. There was no difference between groups in dialysis requirement 90 to 120 days after surgery. Two other observational studies have found the same results. These findings need to be validated before clinical recommendations can be made regarding the use of statins to prevent perioperative AKI.

Calcium Channel Blockers

Calcium channel blockers (CCBs) have been shown to reverse the afferent arteriolar vasoconstriction induced by a variety of stimuli and also have an independent natriuretic effect. These drugs have been evaluated in the prevention of delayed graft function (DGF). A large multicenter RCT did not find any benefit on the incidence and severity of DGF. A systematic review did not find strong evidence for the routine use of CCBs to reduce the incidence of DGF after transplantation.

Adenosine Antagonists

Theophylline, a nonselective adenosine receptor antagonist, prevents adenosine-mediated vasoconstriction of the afferent arteriole. Adenosine is released in response to increased luminal chloride concentrations in the distal tubules as part of the tubuloglomerular feedback. Small studies have shown discordant results in the prevention of CI-AKI. A recent RCT adding theophylline to NAC showed reduced incidence of CI-AKI. A large meta-analysis found a significant reduction in CI-AKI with theophylline; however, beneficial effects were not observed in patients with baseline creatinine above 1.5 mg/dl (132 µmol/l).[35] There is insufficient evidence to recommend theophylline as a solo agent, and the KDIGO AKI guidelines do not suggest using theophylline to prevent CI-AKI.

Selective adenosine blocking agents, such as rolofylline, have been used in trials for prevention and treatment of cardiorenal syndrome. In a small double-blind RCT in decompensated heart failure with AKI, the coadministration of adenosine A_1 antagonist with furosemide increased diuresis and prevented further decrease in GFR.

Emerging Agents

Multipotent mesenchymal stem cells (MSCs) were shown to prevent ischemia/reperfusion–induced AKI in rats. A phase I clinical trial evaluated the feasibility and safety of suprarenal aorta infusion of allogeneic MSCs in patients undergoing on-pump cardiac surgery.[36] No adverse events were associated with the MSC infusion, and lengths of hospital stay and readmission rates were decreased by 40% compared with matched historical controls. Postoperative kidney function remained at baseline levels and no patients in the treatment group required hemodialysis (HD), whereas 20% of controls developed AKI. In addition, kidney function in the treatment group was stable for up to 16 months in patients with CKD, whereas matched controls showed progressive deterioration in kidney function.[36] The long-term safety of MSC is unknown.

In animal and preliminary human studies, therapeutic use of erythropoietin (EPO) seemed promising. EPO can prevent AKI and improve recovery through limitation of apoptosis, promotion of neovascularization, antiinflammatory action, and tissue regeneration. A clinical trial of preoperative EPO in patients who underwent elective CABG surgery showed a reduction in the incidence of AKI and improved postoperative renal function, but in another trial, different doses of recombinant EPO administered to patients after cardiac surgery did not result in a difference in urine NGAL between 48 hours and randomization compared with placebo, and the incidence of AKI was similar.[37] A recent meta-analysis demonstrated no benefit in administering EPO to reduce cardiac surgery-associated AKI.[38] In the ICU, a recent meta-analysis also failed to show renoprotective benefits of EPO.[39] Another RCT comparing the effect of EPO or placebo in preventing CI-AKI has not shown any benefit.[40]

A recent meta-analysis on the use of levosimendan, a calcium-sensitizing agent, has demonstrated reduced AKI after cardiac surgery, RRT requirement, and mortality.[41] Future studies are required to determine the dose effect of levosimendan, especially in patients with CKD.

In an animal model of AKI, animals treated with small interfering ribonucleic acid targeting p53 presented a significant decrease in creatinine levels 24 hours after ischemic injury, compared with those treated with a placebo. Because p53 has, among other activities, a tumor suppression function, one of the major drawbacks to the use of an inhibitor of p53 is its potential carcinogenic effect. A phase 2 trial has just been completed in patients undergoing cardiac surgery.

In a recent phase 2 RCT including 452 patients at risk for AKI undergoing cardiac surgery, THR-184, a peptide that activates the bone morphogenetic protein pathway, did not reduce AKI over the postoperative week (NCT01830920).

Summary

To prevent AKI, hypovolemia, hypotension, and sepsis should be quickly addressed. Isotonic fluids and vasopressors can be administered depending on the clinical scenario.

HES should definitively be avoided. Some experts also recommend avoiding a high volume of chloride-rich solutions in patients at high risk for AKI. Nephrotoxins should be avoided. For prevention of CI-AKI (see Fig. 70.2), patients with eGFR lower than 45 ml/min/1.73 m^2 receiving intraveinous contrast, or those with eGFR lower than 60 ml/min/1.73 m^2 receiving intraarterial contrast should receive intravenous hydration with isotonic saline. The benefit of statins and RIPC is controversial. To prevent TLS, patients at intermediate and high risk should receive aggressive hydration with isotonic saline. A xanthine oxidase inhibitor or rasburicase should be administered depending on the underlying risk. For rhabdomyolysis, normal saline is most often administered compared with sodium bicarbonate. Additional studies are required to assess whether fenoldopam, some vasopressors, nesiritide, levosimendan, and statins are beneficial to prevent AKI.

TREATMENT OF ACUTE KIDNEY INJURY

Once measures to prevent AKI have failed, a key question is whether AKI can be managed with nondialytic therapy alone or if RRT is necessary (see Chapter 71). Management of AKI in cardiac and liver failure is discussed in Chapters 72 and 73, respectively.

General Management

Appropriate management requires timely diagnosis of the clinical condition. Considerable effort and investment have been directed in the search for a more sensitive and specific biomarker to diagnose AKI. Initial management of AKI includes assessment of the cause and volume status. Adequate hemodynamic status should be maintained to ensure renal perfusion and avoid further kidney injury. In the injured kidney, autoregulation of blood flow, the mechanism responsible for maintaining a constant flow during fluctuations in BP, is lost. This loss increases the susceptibility to develop AKI after episodes of hypotension. Therefore fluid and vasoactive drug management is needed in both patients at risk for AKI and with AKI. In patients with AKI attributed to dehydration only, it is expected that the serum creatinine decreases after the administration of 1 to 3 liters of isotonic fluid over 24 to 48 hours, depending on the severity of the underlying condition. Of note, there is no standardized definition for AKI related to dehydration. As previously mentioned, the optimal MAP is unknown and probably needs to be individualized according to age, hypertension status, and degree

of peripheral artery and renovascular disease. Any potentially nephrotoxic agents should be avoided, including intravascular iodinated contrast. Gadolinium-based contrast agents should be avoided because of the risk for development of nephrogenic systemic fibrosis. If gadolinium-based contrast agents need to be used in AKI, patients should be informed about the risk for nephrogenic systemic fibrosis, and macrocyclic chelate (i.e., gadobutrol, gadoteridol or gadoterate meglumine) should be preferred over linear chelates. The lowest dosage possible should be administered and repeated exposures avoided. Antimicrobial agents such as aminoglycosides, amphotericin, acyclovir, and pentamidine should be avoided whenever possible, or their dose adjusted to prevent further insult. Any medications associated with AKI also should be avoided if possible.

Fluid and Electrolyte Management

Whereas early and vigorous resuscitation with crystalloid solutions and aggressive infection control can reduce the incidence of AKI (see earlier discussion), the role of fluid resuscitation in established AKI not attributed to dehydration is less clear. Volume status is one of the most difficult parameters to assess, and fluid resuscitation should target a predefined preload, SV, or cardiac output rather than a set MAP. Nevertheless, many clinical studies have emphasized the limitations of static measures such as central venous pressure, right atrial pressure, and pulmonary artery occlusion pressure in predicting volume expansion efficacy. Other bedside indicators of preload, such as the right ventricular end-diastolic volume (evaluated by thermodilution) and the left ventricular end-diastolic area (measured by echocardiography), are ineffective in differentiating volume responder from nonresponder patients. As previously discussed, two techniques have an acceptable degree of clinical accuracy to determine fluid responsiveness: the passive leg raising maneuver and the fluid bolus test coupled with real-time SV monitoring. In ICU patients receiving mechanical ventilation, respiratory changes in left ventricular SV also can predict fluid responsiveness. In hypovolemic patients, positive-pressure ventilation may induce a fall in the venous return and consequently in cardiac output. Based on the positive relationship between ventricular end-diastolic volume and SV, the expected hemodynamic response to volume expansion is an increase in right ventricular end-diastolic volume, left ventricular end-diastolic volume, SV, and cardiac output.

Volume expansion in ICU patients can frequently result in a relative increase in body weight of 10% to 15% or more, sometimes doubling the total body water in a short time. As previously highlighted, studies have demonstrated an association between fluid accumulation and mortality in AKI. A prospective multicenter observational study found fluid overload at AKI diagnosis, defined as an increase in body weight relative to baseline of more than 10%, was independently associated with increased mortality.[9] The risk for death was proportional to the magnitude and duration of fluid accumulation. However, the effect of fluid overload on renal recovery was inconsistent. A second analysis from the Fluids and Catheters Treatment Trial (FACTT) in AKI patients confirmed that in early AKI, positive fluid balance is strongly associated with mortality. The study showed a protective effect of furosemide on mortality, which disappeared after adjustment for fluid balance. Other studies have shown a deleterious effect of fluid overload on kidney function. In summary, results from observational studies suggest that a conservative fluid approach may be beneficial in terms of mortality and kidney recovery in patients with severe AKI. Fluid resuscitation should be guided, and, after the initial resuscitation period, treatment focus should focus on preventing further fluid overload, monitoring signs of fluid overload, and early removal of excess volume. However, RCTs are required to confirm these findings before any formal recommendation can be made.

Drugs to Promote Recovery From Acute Kidney Injury

See Table 70.3 for a summary of drugs used in treatment of AKI.

Loop Diuretics

Although loop diuretics are often prescribed in established AKI, a meta-analysis confirmed that they are not associated with reduced mortality or improved kidney recovery.[42] Other meta-analyses have shown that loop diuretics do not affect mortality, need for dialysis, or the number of dialysis sessions. Diuretics are ototoxic, and thus concomitant prescription of aminoglycosides and diuretics should be avoided because of an increased risk for ototoxicity. We suggest using diuretics to manage fluid overload as needed but not to treat AKI.

Natriuretics

Atrial natriuretic peptide (ANP) has been studied as a treatment for AKI in four RCTs. ANP was initially shown to reduce need for dialysis but not mortality. In the largest study published, ANP improved dialysis-free survival in the subgroup of oliguric patients only. Unfortunately, a subsequent trial including 222 oliguric patients did not confirm that ANP reduces mortality or dialysis-free survival.[43] A smaller more recent study showed that ANP decreased the probability of dialysis and improved

TABLE 70.3 Summary of Drugs Used in Treatment of Acute Kidney Injury

Drug	Level of Evidence	Results	Comments
Dopamine	RCTs	No effect on mortality or kidney function	
Fenoldopam	Small RCTs One meta-analysis	No effect on mortality or kidney function Beneficial effect on mortality and need for dialysis	Further studies required
Norepinephrine	Prospective observational studies	Possible beneficial effect on kidney function	Further studies required
Loop diuretics	RCTs and meta-analyses	No effect on kidney function	Further studies required
Atrial natriuretic peptide	RCTs	Possible beneficial effect on survival and kidney function	Further studies required
B-type natriuretic peptide	RCT in acute heart failure	No effect on kidney function	
Multipotent stem	Animal models and human studies	Beneficial effect on kidney function in animal models but no effect in one human study	Further studies required; ongoing study in cisplatin-induced AKI
Erythropoietin	Animal models and human studies	Controversial effect on kidney function	Further studies required
Alkaline phosphatase	Small RCT	Beneficial effect on kidney function in sepsis	Further studies required; ongoing phase 2 trial

RCTs, Randomized controlled trials.

dialysis-free survival.[44] Therefore larger studies are required to confirm the benefits of ANP in AKI. Nesiritide, a β-type natriuretic peptide, has been studied to treat heart failure. Nesiritide induces vasodilation and an indirect increase in cardiac output but has no inotropic effects and neutral effect on heart rate. In addition, it inhibits adverse neurohormonal activation and can result in natriuresis and diuresis in some individuals. However, in a large RCT in patients with acute heart failure, this drug did not decrease mortality or rehospitalization rates and had a nonsignificant effect on dyspnea.[45] Nesiritide did not adversely affect renal function, but it increased hypotension. Nesiritide also has been assessed in high-risk cardiovascular surgery, in which it reduced AKI rates in the immediate postoperative period but did not improve long-term survival. The KDIGO guidelines do not support the use of ANP or nesiritide to treat AKI.

Vasoactive Agents

Dopamine use to treat AKI is not recommended (see earlier discussion). Vasopressors often have been considered detrimental for organ perfusion. In septic shock, a small prospective study showed that norepinephrine improved serum creatinine and creatinine clearance when MAP was raised above 70 mm Hg. However, in another small RCT, increasing MAP from 65 to 85 mm Hg with norepinephrine did not improve renal function. No studies have compared the effect of different target MAPs to treat AKI.

In a meta-analysis, fenoldopam decreased the need for dialysis (7% vs. 10%) and in-hospital mortality (15% vs. 19%) in postoperative or ICU patients.[33] Several limitations were present in this meta-analysis, such as absence of an independent measure of GFR and standardized criteria for initiation of dialysis, heterogeneity of populations, AKI definitions, dosage, and duration of treatments. In addition, fenoldopam has hypotensive properties and may be more dangerous in the real world outside of RCTs. No single prospective study has shown that fenoldopam can reduce the need for dialysis. These results need to be confirmed with an adequately powered trial, and we do not suggest using fenoldopam to treat AKI in concordance with the KDIGO guidelines.

Specific therapy for patients with the hepatorenal syndrome includes the use of terlipressin in combination with octreotide (see Chapter 73). In countries such as the United States, where terlipressin is not available, a combination of midodrine, octreotide, and albumin infusions is often used. Norepinephrine also has been used in these settings with good response equivalent to that of terlipressin.

Other Agents

Other agents have been studied for treatment of established AKI. One promising therapy is MSCs. MSCs are multipotent cells with antiinflammatory and immunomodulatory properties proven to be beneficial in animal models of myocardial ischemia, sepsis, and AKI. In animal models, infusion of MSCs improved recovery of renal function in cisplatin-induced ischemia/reperfusion injury and glycerol-induced AKI. A dose-escalating phase I clinical trial was conducted to test the safety and preliminary efficacy of MSCs in patients at high risk for AKI.[36] An experimental study using a model of progressive mesangioproliferative nephritis evaluated the long-term effects of intrarenal, syngeneic MSC transplantation. Although rats in the MSC-treated group had lower proteinuria and better kidney function on day 60, 20% of the glomeruli of MSC-treated rats contained single or clusters of large adipocytes with pronounced surrounding fibrosis. Therefore the MSC benefit of maintaining kidney function in the short term needs to be balanced with a possible long-term effect of partial mal-differentiation of intraglomerular MSC into adipocytes and subsequent glomerular sclerosis. There is an ongoing study on the use of MSC to improve AKI after cisplatin administration (clinical trials.gov CIS/MSC08).

EPO might be beneficial to treat AKI, as shown in animal models. However, a recent animal model showed that although EPO had protective effects on renal function in AKI, the supraphysiologic dose needed for renoprotection contributed to fibrogenesis and stimulated CKD in the long term. A small randomized trial in elective CABG showed a beneficial effect of EPO on recovery after AKI.[46] However, in a larger retrospective study, the use of EPO was not associated with renal recovery. There is insufficient evidence to promote the use of EPO as a treatment for AKI.

In severe sepsis and septic shock, a small study has shown that the infusion of alkaline phosphatase improves kidney function, possibly through reduced NO metabolite production and attenuated tubular enzymuria. There is an ongoing international phase 2 study assessing the effect of recombinant alkaline phosphatase on renal and nonrenal outcomes in septic patients with AKI.

Another potential agent is the endogenous antioxidative enzyme heme oxygenase-1 (HO-1), a stress-inducible enzyme. HO-1 has important antiapoptotic and antiinflammatory functions, and the induction of HO-1 has been shown to be protective in several forms of injury, including AKI.

Summary

Dehydration, hypotension, and infections should be rapidly treated. Any potentially nephrotoxic agents should be avoided, including intravascular iodinated contrast. Gadolinium-based contrast agents should also be avoided. Fluid overload should be minimized, and depending on the clinical condition corrected once the patient is stabilized. No agent has been clearly shown to facilitate renal recovery. Several studies are ongoing to test the efficacy of new drugs to treat AKI in specific conditions.

TREATMENT OF ACUTE KIDNEY INJURY COMPLICATIONS

Fluid Overload

When fluid overload occurs in AKI, all intakes should be minimized and medical treatment should be attempted before dialysis initiation. In patients with positive fluid balance with large fluid intakes and inadequate urine output and in those presenting with symptomatic volume overload, loop diuretic therapy can be initiated with measures to optimize systemic and renal perfusion. Intravenous bolus doses of diuretics may be necessary to optimize the response, especially in patients with heart failure and nephrotic syndrome. If there is a response to an intravenous bolus, continuous infusion can be tried because it is less ototoxic. Natriuretic peptides inhibit sodium reabsorption in the nephron, resulting in net sodium excretion. There is currently no evidence to support the use of natriuretic peptides as an adjunctive treatment in AKI.

Morphine and nitrates can be used to alleviate the respiratory symptoms of pulmonary edema in urgent situations. Morphine can be administered intravenously at an initial dose of 2 to 4 mg over a 3-minute period and repeated at 5- to 15-minute intervals as needed. Nitrates are also commonly used. Nitroglycerin reduces left ventricular filling pressure through venodilation; an initial dose of 5 mcg of intravenous nitroglycerin per minute can be used. When fluid overload cannot be rapidly treated with medical management, positive-pressure ventilation may be initiated with or without endotracheal intubation and dialysis, depending on the clinical situation (see Chapter 72).

Potassium Disorders

Hyperkalemia, covered in detail in Chapter 9, is a frequent complication of AKI that may affect cardiac conduction and lead to bradycardia or

even asystole. If electrocardiographic changes are present, intravenous administration of calcium is urgently needed. Sources of potassium should be removed, including drugs with effect on potassium handling, such as β-adrenergic antagonists, potassium-sparing diuretics, ACE inhibitors, and ARBs.

The next step is to enhance the shift of potassium to the intracellular space by parenteral glucose and insulin infusions. Sodium bicarbonate also promotes shift of potassium and is most efficient when there is concomitant metabolic acidosis. It can be started if there is no concern regarding fluid overload. β-Adrenergic agonists given as aerosols are effective at very high doses but more likely to produce side effects and therefore are rarely prescribed to treat hyperkalemia.

Potassium excretion should be increased by the administration of saline, loop diuretics, and cation exchange resins such as sodium polystyrene sulfonate or calcium resins. The resins can be administered orally or rectally as a retention enema and are usually not effective after a single dose only. There is also a concern to promote intestinal necrosis when sodium polystyrene sulfonate is administered with sorbitol. Sodium polystyrene sulfonate should be avoided postoperatively until normal bowel function resumes and in patients with bowel obstruction or ileus. New agents, such as sodium zirconium cyclosilicate (ZS-9) and patiromer, have not yet been studied to treat acute hyperkalemia. If hyperkalemia is unresponsive to conservative measures, emergency HD is the treatment of choice. Continuous RRT (CRRT) can be used with higher volumes of replacement solution and/or dialysate and low or no potassium content if HD is unavailable. Because RRT initiation usually takes a few hours, medical management always should be used pending initiation of dialysis. Monitoring of potassium levels should continue after conservative or dialytic management to prevent and treat rebound hyperkalemia.

Sodium Disorders

Hyponatremia is more common in AKI associated with heart failure, liver failure, or diuretics. In these settings, water restriction to below the level of output is mandatory. Sodium restriction is usually necessary to treat fluid overload and edema. In patients with true volume depletion and prerenal AKI, isotonic saline needs to be administered to correct both disorders.

In patients with AKI and hypernatremia, treatment of the cause is necessary and water deficit should be estimated. Water should be administered orally or intravenously as dextrose in water to correct serum sodium concentration at a maximum rate of 8 to 10 mmol/l/day. Dialysis and CRRT may be required to optimally correct sodium disorders in AKI.

Calcium, Phosphorus, and Magnesium Disorders

Hyperphosphatemia and hypocalcemia are common in AKI. Hyperphosphatemia is usually caused by reduced excretion by the kidneys, and continuous release from rhabdomyolysis or TLS also can be contributive (see Chapters 10 and 66). As phosphorus levels increase, calcium levels decrease, resulting in hypocalcemia. Total calcium levels usually drop to 7 to 8 mg/dl (1.75 to 2.0 mmol/l). Other causes of hypocalcemia in AKI are skeletal resistance to parathyroid hormone (PTH) and low calcitriol production. Hypocalcemia is aggravated when bicarbonate is administered to correct acidosis. A high-calcium, high-phosphorus product could theoretically trigger tissue calcium deposition, which can cause cardiac arrhythmia. No RCT has evaluated the benefits of treating these disorders. However, because hyperphosphatemia caused by oral phosphorus-containing medications and TLS can cause AKI, severe hyperphosphatemia should be avoided to prevent further damage. Calcium-based phosphate binders and other phosphate binders can be used in this setting. If there is symptomatic hypocalcemia or hemodynamic instability, calcium gluconate infusion should be administered.

Hypercalcemia is rare in AKI and is usually seen in the recovery phase of rhabdomyolysis when calcium is released from calcium-containing complexes in muscle (see Chapters 10 and 66). In addition, when production of calcitriol is reestablished by the recovering kidney, an enhanced responsiveness to PTH can be seen. Hypercalcemia in this setting is rarely problematic and can be easily treated with medical management. Mild hypermagnesemia is frequent in AKI and usually does not have clinical consequences.

Acid-Base Disorders

In AKI, metabolic acidosis is the most common acid-base abnormality (see Chapter 12) because of reduced regeneration of bicarbonate and failure to excrete ammonium ions. Accumulation of phosphate and unexcreted unmeasured anions, such as sulfate, urate, hippurate, hydroxypropionate, furanpropionate, and oxalate, is contributory. Hypoalbuminemia can attenuate this acidification process, and it is exacerbated by lactic acidosis. Despite retention of unmeasured anions, the anion gap remains within normal in 50% of patients. Whereas metabolic acidosis is frequent, triple acid-base disturbances also can occur. The approach to acid-base disturbances in AKI needs to be adjusted according to the underlying causes.

There is controversy surrounding the optimal treatment of acute metabolic acidosis. When metabolic acidosis is simply a complication of AKI, sodium bicarbonate can be administered if the serum bicarbonate concentrations fall below 15 to 18 mmol/l. Volume overload can occur after the administration of bicarbonate. The administration of bicarbonate in shock with lactic acidosis is controversial, given the possibility of an increase in carbon dioxide generation, worsening of the intracellular acidosis, and volume overload. Rapid improvement in metabolic status may enhance hypocalcemia and lower cardiac output. Therefore in patients with lactic acidosis, most physicians restrict the administration of sodium bicarbonate to patients with severe metabolic acidosis (arterial pH <7.10 to 7.15) to maintain the pH above 7.15 to 7.20 until the primary process is reversed. Alternative forms of base treatment such as tris(hydroxymethyl)aminomethane (THAM) are not recommended in patients with AKI because THAM can cause hyperkalemia. Restriction of protein intake also has been suggested as a method of acidosis control because protein breakdown has been associated with worsening acidosis, as in CKD. However, protein restriction is not recommended in AKI.

Nutrition

Patients with AKI have an increased risk for protein-energy malnutrition because of poor nutrient intake and high catabolic rate. Nutritional assessment is difficult, especially in AKI patients with high metabolic demands. Subjective global assessment evaluates nutritional status, requires no additional laboratory testing, and is highly predictive of outcome.

Patients with AKI should receive a basic intake of 0.8 to 1.0 g of protein/kg/day if not catabolic and a total energy intake of 20 to 30 kcal/kg/day, as recommended in the KDIGO guidelines. In addition, in patients on RRT, 1.0 to 1.5 g of protein/kg/day should be administered up to 1.7 g/kg/day in CRRT and hypercatabolic patients. The enteral route should be favored if the gastrointestinal tract is functioning; parenteral nutrition should be prescribed only when the gastrointestinal tract cannot be used or when the enteral route is inadequate to reach nutrient intake goals.[47]

SELF-ASSESSMENT QUESTIONS

1. In a general population of critically ill patients, administering starches has proven to be:
   - **A.** Beneficial for kidney function (decrease in need for renal replacement therapy [RRT])
   - **B.** Beneficial for hypotension
   - **C** Detrimental for kidney function (increase in need for RRT)
   - **D.** Detrimental for hypotension
2. Which of the following drugs should be stopped, if feasible, 48 hours before iodinated contrast administration in patients with chronic kidney disease and a glomerular filtration rate below 45 ml/min/1.73 m^2?
   - **A.** Furosemide
   - **B.** Metformin
   - **C.** Nonsteroidal antiinflammatory drugs
   - **D.** Thiazide diuretics
   - **E.** All of the above
3. The measures to prevent AKI in patients with traumatic rhabdomyolysis include all of these statements, *except:*
   - **A.** Urine output should be maintained around 300 ml/h until creatine kinase (CK) levels are lower than 1000 U/l.
   - **B.** Urine output should be maintained around 300 ml/h until myoglobinuria disappears.
   - **C.** Mannitol is beneficial because of diuretic, antioxidant, and vasodilatory properties.
   - **D.** Mannitol can prevent renal tubular cast deposition, expand extracellular volume, and reduce intracompartmental pressure, muscle edema, and pain.
   - **E.** Monitoring of ionized calcium is important to avoid $NaHCO_3$-induced hypocalcemia (as a result of metabolic alkalosis).
4. Regarding fluid administration for critically ill patients at risk for AKI, all of the following sentences are true *except:*
   - **A.** Chloride-restrictive fluids (lactated solution, Plasma-Lyte 148, or chloride-poor 20% albumin) may be preferable to chloride-rich intravenous fluids (0.9% saline, 4% succinylated gelatin solution, or 4% albumin solution), although further studies are needed.
   - **B.** Volume expansion should be maintained after major vascular surgeries unless patients develop evidence of pulmonary congestion.
   - **C.** Guidelines on sepsis management mention that septic patients should receive initial fluid resuscitation with crystalloids at a minimum of 30 ml/kg.
   - **D.** Albumin should be considered in patients with sepsis who require substantial amounts of crystalloid to maintain adequate mean arterial pressure.
   - **E.** Fluid expansion should be stopped when patients are no longer fluid responsive.

Dialytic Management of Acute Kidney Injury and Intensive Care Unit Nephrology

Mark R. Marshall, Luis A. Juncos

Intensive care unit (ICU) nephrology focuses on abnormalities of fluid, electrolyte, and pH homeostasis in ICU patients and the prevention and management of functional renal impairment relative to physiologic demand. This chapter describes best practices for acute renal replacement therapy (ARRT) and strategies for avoiding common treatment-related complications. The chapter uses appropriate clinical practice guidelines as starting points for discussion and summarizes their recommendations (Box 71.1).[1-11]

When the Acute Kidney Injury Network (AKIN) criteria are applied, approximately 40% of ICU patients develop acute kidney injury (AKI), an independent risk factor for death. The nondialytic therapy of AKI is discussed in Chapter 70. Approximately 10% of ICU patients require ARRT, and mortality in this population is improving over time despite greater illness severity.[12] Death attributable to AKI arises from nonresolving infection, hemorrhage, or nonresolving shock, despite optimal care. These conditions therefore may be considered an "acute uremic syndrome" that is a possible target for modulation with ARRT, analogous to the traditional uremic syndrome observed in end-stage renal disease (ESRD).

ORGANIZATIONAL ASPECTS OF ACUTE RENAL REPLACEMENT THERAPY PROGRAMS

ICUs can be described as open (patient care remains under the attending physician of record), closed (patient care is transferred to an intensivist), or comanaged (an open ICU in which patients receive mandatory consultation from an intensivist). Most ICUs in Australia are closed, whereas those in the United States and Europe vary. When AKI and ARRT are considered, advantages of intensivist-based management include immediate availability of service and decreased fragmentation of care. This model of care is supported by ecologic studies suggesting better outcomes in closed ICUs. Alternatively, advantages of nephrology-based management include greater understanding of the dialysis process and underlying AKI. This model of care is supported by studies suggesting better outcomes in ICU patients with AKI with earlier referral to nephrology. These studies have irreconcilable differences that make consistent interpretation difficult. Clinical governance over ARRT is likely to remain contentious, although the clinical expertise of staff will always be more important than their specialty. Specific training in ICU nephrology and exposure to ARRT is inadequate in many critical care and nephrology training schemes and should be included as a core component.

In many regions, ICU nurses deliver all modalities of ARRT; in others, support from nephrology staff is required. As the usability of continuous renal replacement therapy (CRRT) and intermittent hemodialysis (HD) machines improve, it is likely that ICU expertise will grow in all modalities, provided in-service education and support are adequate.

OVERVIEW OF ACUTE RENAL REPLACEMENT THERAPIES

The main modalities of ARRT are intermittent HD and its variants, CRRT, and peritoneal dialysis (PD). Intermittent HD and CRRT are most popular, although utilization varies regionally. Recently intermittent HD has undergone resurgence through lower efficiency variants that are applied for longer periods, with lower ultrafiltration rate (UFR) and slower solute clearance, resulting in improved hemodynamic stability and larger dialysis dose. These variants are most commonly referred to as *sustained low-efficiency dialysis* (SLED). Collectively, however, they are best referred to with the umbrella term *prolonged intermittent renal replacement therapy* (PIRRT), a term more aligned to nomenclature endorsed by the Acute Dialysis Quality Initiative (www.adqi.net) (Fig. 71.1). *Acute PD* is mostly used in resource- constrained settings and is not considered further in this chapter.

Therapeutic goals for ARRT are not well defined. The usual minimum recommendation is to correct acidosis or hyperkalemia, refractory hypervolemia, and uremic features such as pericarditis or coma. Serum electrolyte concentrations should be maintained in the normal range. Dialysis dose should meet targets, which are discussed later. The process of ARRT itself should not jeopardize the patient by exacerbating hemodynamic instability, increasing end-organ damage, or delaying renal recovery.

Determining goals with respect to a patient's extracellular volume status is not straightforward. Assessment itself is difficult; physical signs are generally not informative. Measures of cardiac filling (e.g., by central venous pressure, pulmonary capillary wedge pressure, left ventricular diastolic dimensions) may be inaccurate surrogates for intravascular volume status, especially for patients with sepsis. An alternative approach is to test the effect of therapeutic maneuvers such as fluid challenge on measures of cardiac filling, stroke volume, and blood pressure (BP). Even after fluid status has been assessed, determining the correct therapeutic goal is difficult. Ongoing severe fluid depletion is undesirable, but so is severe fluid overload, which is strongly associated with increased mortality and poorer renal recovery. Patients with extracellular fluid excess in the absence of intravascular hypervolemia will benefit from fluid removal if they develop abdominal compartment syndrome, poor wound healing, or especially impairment of lung compliance and oxygenation. Increasingly, fluid status is defined by fluid accumulation: (total input – total output in liters) expressed as a percentage of premorbid or pre-ICU weight. No clinical trials have evaluated the impact

of different fluid accumulation thresholds, but strong observational evidence supports targeting less than 10% to 20% fluid accumulation and initiating or prescribing ARRT to keep fluid accumulation within this range.[13]

Variations of ARRT have been used to enhance removal of cytokines. Cytokines are medium and larger molecules that modulate the immune response. Their production becomes dysregulated during acute illness, and their clearance decreased during AKI, resulting in excessive levels that have cardiodepressant, vasodilatory, and immunosuppressive properties.[14] Consequently, there is interest in enhancing cytokine removal during acute illness or AKI, especially in high-cytokine states such as sepsis. Cytokines can be removed with high cut-off hemofilters (membranes with a molecular weight cut-off of 60 to 150 kDa), bioadsorption devices, coupled plasma filtration–adsorption, and high levels of convective clearance. However, some of these techniques will remove both proinflammatory and antiinflammatory cytokines, with an uncertain net effect on the overall inflammatory milieu. Others will remove beneficial circulating substances such as medications, including antibiotics. All of these techniques are experimental at present, supported by only observational studies and pilot clinical trials. Larger multicenter trials of high-volume hemofiltration and bioadsorption with polymyxin B have not shown clinical benefit, although more definitive studies are underway for polymyxin B and coupled plasma filtration–adsorption (ClinicalTrials.gov identifiers NCT01046669, NCT01639664). In general, progress in this area is hampered by a lack of biomarkers and/or clinical scores to trigger treatment decisions; it is not clear how to identify patients who might benefit from cytokine removal and when it should be applied.

Timing of ARRT initiation is controversial, and specific thresholds for starting are unknown. Proponents of early initiation argue that it is in the patients' interest to prevent rather than treat the acute uremic syndrome and recommend initiation once kidney injury or failure is present. However, ARRT does have potential for harm, including catheter-related infection, intradialytic hypotension, and electrolyte disturbances. Recently completed clinical trials have had discordant results, with an overall treatment effect of 0.74 (0.43 to 1.27) directionally favoring earlier initiation.[15] All have been underpowered, and the two largest included a substantial proportion of patients who might not be considered for ARRT in usual clinical practice. Again, larger and more definitive studies are underway (ClinicalTrials.gov Identifiers: NCT0168259, NCT02568722).

Currently, a reasonable approach can be distilled from existing guidelines (Fig. 71.2)[1,10,11]; as long as the ARRT is not clinically inappropriate (e.g., the prognosis is not futile), ARRT should be initiated for life-threatening hyperkalemia or acidosis refractory to medical treatment, uremic features such as pericarditis or coma and refractory hypervolemia causing end-organ complications (e.g., pulmonary edema). ARRT should be initiated if the burden of fluid and solute derangements is increasing and anticipated to result in complications,

rather than waiting for them. ARRT should probably be initiated earlier in patients who are less able to resolve fluid and solute derangements (e.g., advanced chronic kidney disease [CKD]), or to tolerate them (e.g., advanced chronic lung or heart disease).

INTERMITTENT ACUTE RENAL REPLACEMENT THERAPY

Techniques for Acute Intermittent Hemodialysis

Intermittent HD is categorized according to hemodialyzer membrane and mechanism of solute removal. High-flux membranes allow greater convective removal of middle and larger solutes, but limited clinical data do not show obvious advantages in the ICU setting. Biocompatibility is a membrane characteristic that includes a low capacity for activating complement and leukocytes. After complement activation, there is stasis of leukocytes in the lungs, renal parenchyma, and other organs and the release of products of leukocyte activation. Although studies have been inconsistent, the use of biocompatible membranes is recommended.

Hemodiafiltration (HDF) is usually performed in the ICU as a continuous modality. However, intermittent HDF also can be performed with use of sterile replacement fluid generated from ultrapure dialysate ("online"), which is infused directly into the extracorporeal blood circuit. Limited clinical data again do not show obvious advantages in an ICU setting.

Dialysate for intermittent ARRT can be delivered by either a batch or single-pass system. The latter uses concentrate and potable water that is purified by reverse osmosis in a central plant or portable unit. Most ICUs do not have a central plant, although this is increasingly common in units in which online HDF is performed. Water purity is important to avoid backfiltration of bacterial contaminants, specifically endotoxin, which could exacerbate cytokine-mediated injury. Reference standards for water purity in the ICU setting are the same as those for

the ESRD setting (www.iso.org; see Box 71.1 and Chapter 93). Online replacement fluid for HDF is sterilized with ultrafilters in the dialysate pathway and does not differ from commercial batch preparations in terms of microbial counts, endotoxin concentration, and cytokine-inducing activity. Some suggest sterile dialysate for all acute intermittent HD; however, data are insufficient data to support a strong recommendation.

Strategies to Reduce Intradialytic Hemodynamic Instability During Intermittent Hemodialysis

Hypotension is detrimental for end-organ function and recovery. The consequences of specifically intradialytic hypotension are not well studied in the critically ill AKI population; for instance, it is unclear whether it leads to myocardial stunning and cardiovascular morbidity as it does in the ESRD setting. However, fresh ischemic lesions in kidney biopsy specimens can be found in AKI patients on intermittent HD for longer than 3 weeks, and residual renal function often decreases immediately after treatments, suggesting that intradialytic hemodynamic stability is desirable. Axiomatically, the most effective measure to minimize intradialytic hypotension is increasing the frequency and treatment time of intermittent HD, thereby minimizing ultrafiltration targets, but other measures should also be considered.

Bicarbonate-buffered dialysate should be used. It is associated with less hypotension than acetate dialysate, which has a peripheral vasodilating and myocardial depressant effect. Importantly, online bicarbonate-buffered dialysate still contains between 3 to 5 mmol/l of acetate, for chemical stability. Although this small amount of acetate may not compromise stable maintenance HD patients, a clinical trial has shown increased acetemia, hypotension, and arrhythmia in critically ill patients treated with conventional bicarbonate-buffered dialysate compared with acetate-free dialysate.[16] This may contribute to greater intradialytic hypotension during intermittent HD compared with CRRT.

Hemodynamic stability is facilitated by sodium profiling during intermittent ARRT. Rapid reduction in serum osmolality promotes water movement into cells, reducing effective circulating volume. The default dialysate [Na^+] for intermittent HD and PIRRT in critically ill patients is approximately 145 mmol/l and avoids such fluid shifts. Sodium profiling further ameliorates this process by inducing water flux into the vascular compartment. A clinical trial showed that intermittent HD with sodium profiling (starting 160 mmol/l, reducing 140 mmol/l) combined with ultrafiltration profiling (50% of ultrafiltration volume removed in first third of treatment) improved hemodynamic stability.[17] Similar data exist for PIRRT. Profiling should not be used in patients with dysnatremias, in whom serum [Na^+] should be corrected slowly to minimize the risk for neurologic complications.

Online blood temperature and blood volume monitoring involves biofeedback systems that automatically adjust treatment operating parameters. Blood volume monitoring adjusts UFR and dialysate [Na^+] in response to a fall in circulating blood volume, and blood temperature monitoring maintains blood temperature at a target value by controlling thermal transfer to and from dialysate to avoid vasodilation and decreased vascular resistance. Although helpful in the ESRD setting, neither technique prevents intradialytic hypotension in the ICU setting.[18,19] The likely reasons pertain to different causes and compensatory mechanisms for hypotension in the two settings.

High-dialysate calcium (1.75 mmol/l) has been used to improve hemodynamic stability during intermittent HD in ESRD patients with cardiomyopathy. This technique is limited by the development of hypercalcemia and has not been studied in the ICU setting.

A number of studies have suggested less intradialytic hypotension during intermittent HDF than HD in the ESRD setting.[20] It is unlikely that is also the case in critically ill AKI patients, although definitive studies are yet to be conducted.

Extensive cumulative clinical experience shows that lower efficiency modalities of ARRT provide better hemodynamic stability because of slower fluid and solute removal. Meta-analyses show better preservation of BP and lower vasopressor requirements in those treated with CRRT rather than intermittent HD.[1,21] Some studies have shown comparable hemodynamic stability between CRRT and lower efficiency prescriptions of PIRRT,[22-24] and they are the first choice for hemodynamically unstable patients.[1]

Prolonged Intermittent Renal Replacement Therapy

PIRRT uses standard intermittent HD equipment, but with lower solute clearances and UFR maintained for prolonged periods.[25] One issue that hampers consistent interpretation of the PIRRT literature is the lack of treatment standardization and wide range of operating parameters. Treatment duration can vary from 6 to 18 hours and dialysate flow rate *(Qd)* from 100 to 300 ml/min. In either case, urea clearances are lower and higher than in intermittent HD and CRRT, respectively. This allows for the convenience of scheduled downtime, without compromising dialysis dose. With longer treatments, phosphate replacement is usually required at 0.1 to 0.2 mmol/kg and dietary protein should be supplemented by at least 0.2 g of protein/kg/day. A prescription algorithm is shown in Fig. 71.3.

Prescribed correctly, PIRRT provides a high dose of dialysis with minimal urea disequilibrium, excellent control of electrolytes, and good tolerance to ultrafiltration. PIRRT is usually delivered as a diffusive therapy, although there is increasing experience with combined diffusive and convective clearance.

Dosage of Intermittent Acute Renal Replacement Therapy

The relationship between small-solute clearance and outcomes of critically ill AKI patients is now established. A key study showed that delivered single-pool *Kt/V (spKt/V)* below 1.0 per intermittent HD treatment was associated with decreased survival in patients with intermediate illness severity, although the study did not relate outcomes to frequency of treatments.[26] Definitive clinical trials have shown a "ceiling effect" to small-solute clearance, above which survival becomes dose-independent,

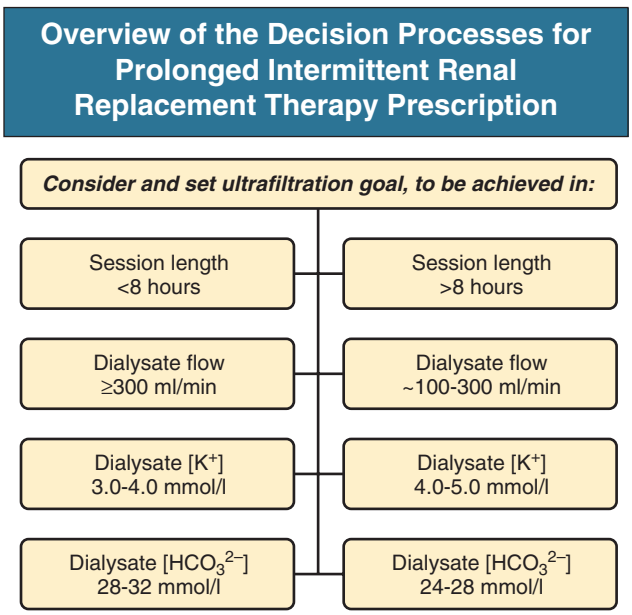

Fig. 71.3 Overview of the decision processes for prolonged intermittent renal replacement therapy prescription.

with no benefit with intermittent ARRT that delivers small-solute clearance greater than a *spKt/V* of 1.2 to 1.4 per treatment thrice weekly.[27,28]

The minimum recommended intermittent HD and PIRRT dose in ICU patients with AKI is delivered *spKt/V* of at least 1.3 per treatment at least thrice weekly.[1] Underdelivery of acute intermittent HD is common, and routine measurement of dose should be undertaken to guide appropriate adjustment of operating parameters as summarized in Box 71.2. If this dosage target cannot be achieved, treatment frequency should be increased. The required number of treatments per week can be established from the nomogram in Fig. 71.4, which expresses combinations of HD dose and frequency as a continuous small-solute clearance (corrected equivalent renal urea clearance [EKRc]). The target EKRc is a value of 13 ml/min or higher.[29,30] This framework can be used to interpret the Hannover Dialysis Outcome Study of PIRRT; patients treated with daily PIRRT to keep plasma urea at 11.3 ± 4 mmol/l (EKRc of 20 ml/min, assuming urea generation of 20 mg/min) had outcomes indistinguishable from those of patients treated to keep plasma urea at 19 ± 6 mmol/l (EKRc of 13 ml/min, equal to a *spKt/V* of 1.2-1.4 per treatment thrice weekly).[28]

BOX 71.2 Measures to Increase Intermittent Hemodialysis Dose

- **Maximize hemodialyzer surface area** (up to 2-2.2 m^2)
- **Maximize hemodialyzer porosity** (high flux)
- **Maximize blood flow rate** by:
  - Maximizing internal lumen diameter of catheter (up to 2.0-2.2 mm)
  - Titrating blood flow to maximum arterial and venous pressure (up to – and + 300-350 mm Hg, respectively)
  - Correcting position of catheter tip in SVC and IVC as appropriate
  - Use right-sided IJ and SC in preference to left-sided IJ and SC
- **Minimize access recirculation** by correcting position of catheter tip in superior or inferior vena cava as appropriate using internal jugular and subclavian, rather than femoral, catheters
- **Maximize dialysate flow** (up to 800-1000 ml/min)
- **Add postdilution HDF**
- **Optimize anticoagulation** to reduce hemodialyzer fiber bundle clotting
- **Optimize circulation** to reduce compartmental urea sequestration
- **Increased treatment frequency** (up to daily)
- **Increased treatment duration** (up to 6-8 hours, then consider PIRRT [SLED] or CRRT)

(Modified from reference 61).
CRRT, Continuous renal replacement therapy; *HDF,* hemodiafiltration; *IJ,* internal jugular; *IVC,* inferior vena cava; *PIRRT,* prolonged intermittent renal replacement therapy; *SC,* subclavian; *SLED,* sustained low-efficiency dialysis; *SVC,* superior vena cava.

CONTINUOUS RENAL REPLACEMENT THERAPY

CRRT involves the application of lower UFR and solute clearances for substantial periods every day. The lower UFR provides the best hemodynamic stability of any ARRT modality, and the longer treatment duration results in better and more consistent control of uremic solutes, especially for severely catabolic patients.

Interruptions to CRRT because of circuit clotting leads to a reduction in dose from downtime, as well as expense related to blood circuitry changes. Mean operating time for CRRT is reported to be between 17 and 22 h/day,[31] although a given session can be extended as long as 72 hours with rigorous application of protocols related to anticoagulation and catheter placement and positioning.

Techniques for Continuous Renal Replacement Therapy

The Acute Dialysis Quality Initiative (www.adqi.net) classification of CRRT is the standard and uses nomenclature based on the type of vascular access and the method of solute removal.

Venovenous (VV) denotes CRRT using a central venous catheter and mechanical blood pump. This provides reliable and rapid blood flow rate *(Qb)* of approximately 250 ml/min, but is more complex and costly and has the disadvantage of potential inadvertent disconnection of lines, resulting in hemorrhage or air embolism with continued pump operation; this risk is minimized by monitors and alarms.

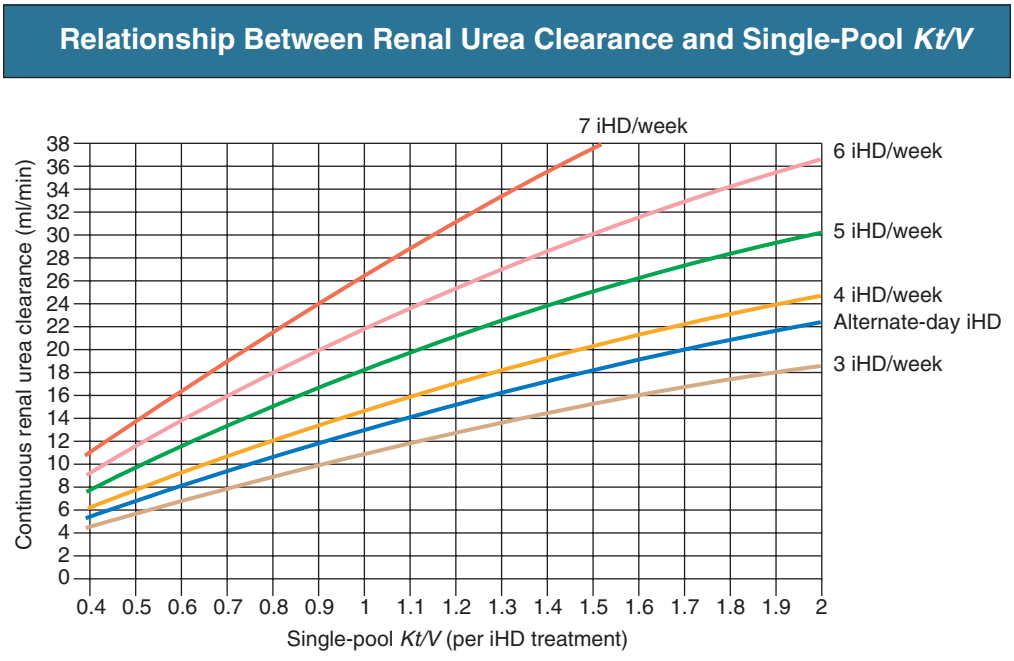

Fig. 71.4 Relationship between corrected continuous renal urea clearance and single-pool Kt/V (weekly urea clearance/volume of distribution of urea) per treatment for a frequency of three to seven treatments per week. *iHD,* Intermittent hemodialysis. (From reference 62.)

Arteriovenous (AV) denotes CRRT in which an arterial catheter allows blood to circulate by systemic BP. A venous catheter is placed for return. AV circuits are simple but involve arterial puncture, which can lead to distal embolization, hemorrhage, and vessel damage. A *Qb* of 90 to 150 ml/min is typical with mean arterial pressure above 80 mm Hg, although even then flow can be erratic, predisposing to clotting. This is largely an obsolete practice because of these issues.

Mechanisms of Solute Removal

Hemodialysis

Continuous HD provides diffusive small-solute transport. *Qb* and *Qd* during CRRT are usually comparatively low (~150 ml/min and ~2 l/h, respectively). Under these conditions, the ratio of dialysate urea nitrogen to blood urea nitrogen (DUN/BUN) is 1.0, indicating complete saturation. Urea clearance therefore equals *Qd* and is unaffected by *Qb* until *Qb* decreases to less than 50 ml/min.

With increasing *Qd,* there are decreasing gains in small-solute clearance as the DUN/BUN progressively decreases. Fig. 71.5 illustrates this principle.[32] The flattening of the curves indicates conditions in which increasing *Qb* does not enhance clearance. For instance, at a *Qb* of 200 ml/min, urea clearance will correspond to *Qd* at a rate of 2 l/h (or less) and will not increase with increased *Qb.*

Hemofiltration

Continuous hemofiltration (HF) provides convective small- and medium-solute transport. An important determinant of clearance is the site of fluid replacement, which can be infused either prefilter into the arterial blood-line (predilution) or postfilter into the venous blood-line (postdilution). The standard method is postdilution. However, higher UFR can lead to hemoconcentration in the hemofilter, increased resistance in the blood flow pathway, reductions in *Qb,* and ultimately clotting of the hemofilter. In practice, UFR should not exceed 30% of the plasma water flow rate (i.e., filtration fraction should be below 0.30). The problem can be ameliorated by increasing *Qb* to at least 200 to 250 ml/min or diluting the blood and clotting factors with replacement fluid before it reaches the hemofilter (predilution).

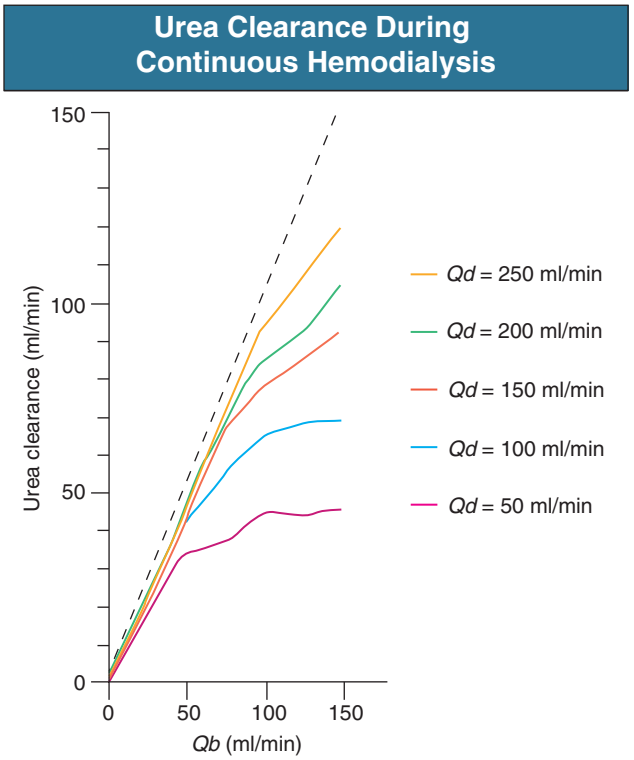

Fig. 71.5 Determinants of urea clearance during continuous hemodialysis. Relationship among urea clearance, *Qb* (blood flow), and *Qd* (dialysate flow) during continuous hemodialysis. The flattening of the urea clearance curves describes the conditions in which increases in *Qb* do not enhance clearance. (From reference 32.)

The disadvantage of predilution is that filtrate is generated from blood is diluted with replacement fluid, containing a lower concentration of uremic solutes. Small-solute clearance is reduced by approximately 15% at low UFR, although this increases to about 40% with a higher UFR.[33,34] Clearance of any given solute during continuous HF is calculated as follows:

$$K\ (\text{postdilution}) = UFR \times S \times 60 \,/\, \text{body weight}$$

$$K\ (\text{predilution}) = UFR \times S \times [Qbw(Qbw + Qr)] \times 60 \,/\, \text{body weight}$$

where *K* is clearance (mL/kg/hr), *S* is the sieving coefficient of the solute, *Qbw* is blood water flow rate (mL/min) equal to the product of *Qb* and (1 − hematocrit), and *Qr* is the replacement fluid rate (ml/min).

Hemodiafiltration

Continuous HDF refers to a combination of the preceding techniques. With large enough membranes, the small-solute clearances approach the sum of the individual techniques.[33]

Specific Techniques

CRRT techniques are shown in Fig. 71.6. The choice of technique depends on equipment availability, clinician expertise, prospects for vascular access, and whether the primary need is for fluid and/or solute removal. For isolated fluid removal, slow continuous ultrafiltration (SCUF) can be used. Given its minimal solute clearance (equal to the UFR at generally 4-5 ml/min), SCUF is primarily used for treatment of cardiorenal syndrome. Between HD and HF, the benefit of larger solute clearance is uncertain in this population, whereas those of small-solute clearance are more evident (see later). A meta-analysis comparing HD to HF showed no differences in patient survival or kidney recovery.[35]

Of note, the practice of treating lactic acidosis with CRRT should be discarded. The only effective treatment is addressing the cause of lactate formation (improving tissue oxygenation, removing dead gut, etc.); extracorporeal lactate clearance is 10-fold to 100-fold lower than plasma clearance through hepatic metabolism.

Dosage of Continuous Renal Replacement Therapy

CRRT dose is expressed as effluent volume flow rate per unit of premorbid or pre-ICU weight (ml/kg/h). The relationship between CRRT dose and mortality has now been established in several definitive clinical trials, the most important of which are the Acute Renal Failure Trial Network Study and the Randomised Evaluation of Normal versus Augmented Level of replacement therapy (RENAL) trial. As with intermittent HD, there appears to be a dose of CRRT (20 to 25 ml/kg/h) above which survival becomes dose-independent. In clinical practice, interruptions to CRRT will compromise prescribed dose, and to achieve delivered goals it is generally necessary to prescribe 25 to 30 ml/kg/h while minimizing downtime. Optimal CRRT dose appears to be related more to small-solute than larger solute clearance, and there are no specific guidelines for monitoring of larger solute clearance.

Technical Aspects of Continuous Renal Replacement Therapy

Equipment

Dedicated CRRT machines are commercially available that integrate blood pump, arterial and venous pressure monitors, an air detection

Continuous Renal Replacement Therapies				
	Slow continuous ultrafiltration	**Continuous hemofiltration**	**Continuous hemodialysis**	**Continuous hemodiafiltration**
				Arteriovenous (AV) or venovenous (VV)	AV or VV	AV or VV	AV or VV	AV or VV
Blood flow (ml/min)	50-100	50-200	50-200	50-200
Dialysate flow (ml/min)	–	–	10-20	10-20
Clearance (l/24 h)	–	12-36	14-36	20-40
Ultrafiltration rate (ml/min)	2-5	8-25	2-4	8-12
Blood filter	Highly permeable filter	Highly permeable filter	Low-permeability dialyzer with countercurrent flow through the dialyzer compartment	High-permeability dialyzer with countercurrent flow through the dialyzer compartment
Ultrafiltrate	Corresponds exactly to the patient's weight loss	Replaced in part or completely to achieve purification and volume control	Corresponds to patient's weight loss; solute clearance by diffusion	In excess of patient's weight loss; solute clearance by both diffusion and convection
Replacement fluid	None	Yes	None	Yes, to achieve fluid balance
Efficiency	Used only for fluid control in overhydrated states	Clearance for all solutes equals ultrafiltration	Limited to small molecules	Extends from small to large molecules

Fig. 71.6 Continuous renal replacement therapy modalities. The pump *(P)* is used only in venovenous modes. (Modified from reference 63.)

system, a method for removing air bubbles, and computerized volumetric or gravimetric systems to balance dialysate inflow/replacement fluid with dialysate outflow/filtrate.

Hemofilters

Specific devices for CRRT are usually referred to as hemofilters. However, conventional hemodialyzers can serve as hemofilters. For adequate UFR to be achieved, the surface area must be large (>1.5 m^2) for low-flux hemodialyzers, although it can be smaller for high-flux ones. Some CRRT machines use a specific hemofilter because of a dedicated cartridge system. Sieving coefficients of small solutes are maintained throughout the life of hemofilters only in the absence of fiber bundle clotting and membrane repolarization, and a progressive decrease in dialysate or ratio of filtrate urea nitrogen to BUN will be noted with prolonged treatments. Monitoring of this parameter is recommended by some to avoid the advent of total extracorporeal circuit clotting and wastage of blood, as well as compromise of CRRT dose from declining saturation of effluent; proponents recommend prophylactic change of hemofilter if this ratio falls to 0.6 or less.

There is keen interest in high cut-off hemofilters, as discussed previously, although albumin losses may prevent their prolonged use. There is also interest in hemofilters with adsorptive membranes, such as those based on polymethyl methacrylate and polyethyleneimine grafted polyacrylonitrile. These provide adequate small-solute clearance and cytokine adsorption. In both cases, studies are under way to determine safety and efficacy.

Replacement Fluids and Dialysate

CRRT requires sterile replacement fluid or dialysate for blood purification, with composition that is determined by the clinical requirements for acid-base control and electrolyte management. Fluids are available commercially, but can be prepared aseptically in hospital pharmacies, albeit at greater cost and potential for human error during compounding.

Buffer choice is between bicarbonate and lactate, the latter being metabolized in the liver to bicarbonate in a 1:1 ratio. Although many patients tolerate lactate solutions, bicarbonate solutions are superior in terms of acid-base control, hemodynamic stability, urea generation, cerebral dysfunction, and also possibly survival in patients with a history of cardiac failure. Overall, bicarbonate has become the buffer of choice and is preferred in patients with lactic acidosis and/or liver failure. If lactate-buffered fluids are used, the development of lactate intolerance (>5 mmol/l increase in serum lactate during CRRT) should trigger a switch to bicarbonate-based fluid. Bicarbonate concentrations in fluid are typically 25 to 35 mmol/l; concentrations in the lower part of this range are indicated during high-dose or prolonged CRRT and during regional citrate anticoagulation therapy to prevent metabolic alkalosis.

Glucose concentrations in fluids range from 0.1% in commercially prepared fluids to 1.5% to 4.25% in PD fluids adapted for use with CRRT. To avoid hyperglycemia, glucose intake should be less than 5 g/kg/day, with a glucose concentration in fluid of 100 to 180 mg/dl (5.5 to 10 mmol/l) to maintain zero glucose balance.

Intravenous phosphate supplementation is often required during CRRT and is usually administered separately because of the potential for precipitation with calcium and magnesium in dialysate or replacement fluid. This concern may be unjustified, and phosphate has been safely supplemented by injecting phosphate into these solutions. Importantly, phosphate oversupplementation carries a risk for nephropathy caused by calcium phosphate crystal formation. There are no evidence-based guidelines for phosphate supplementation in critically ill patients with AKI, and phosphate kinetics are notoriously complex and multicompartmental to model. In general, an approach involving careful monitoring is warranted, with redosing or adjustment according to response to therapy; 1 or 2 doses of 20 mmol infused over several hours each will safely correct hypophosphatemia in moderate hypophosphatemia (<0.65 mmol/l), even if there are ongoing losses (e.g., from CRRT). Axiomatically, the most logical approach is prevention. One practice is to use continuous infusions starting when phosphate levels are dropping and in the lower range of normal. In this approach, a starting dose of 30 mmol over 24 hours is adjusted to keep the levels between 0.8 to 1.1 mmol/l. There is increasing experience with commercial replacement solutions containing up to 1.2 mmol/l of phosphate. They are generally safe and effective, but should be avoided in those with severe metabolic acidosis in whom narrowing of strong ion differences has potential to worsen acidemia.

VASCULAR ACCESS

A prerequisite for all ARRT modalities is reliable vascular access characterized by low resistance to flow and minimal access recirculation. If the patient has an AV fistula or graft, this should be used for intermittent HD. Otherwise, access is usually via uncuffed untunneled (temporary) double-lumen polyurethane or silicone catheters in the internal jugular or femoral veins. The subclavian veins are used less frequently because of a higher incidence of procedural complications, venous stenosis, and thrombosis.

For CRRT and PIRRT, *Qb* less than 250 ml/min is usually sufficient. For acute intermittent HD, higher *Qb* is usually required to allow sufficient solute clearance within a clinically or logistically appropriate dialysis schedule. Flows can be safely increased until venous and arterial pressures are plus and minus 350 mm Hg, respectively, after which hemolysis can occur. Left-sided internal jugular and subclavian catheters provide flows that are more erratic and up to 100 ml/min lower than elsewhere. Femoral and right-sided internal jugular or subclavian catheters provide the best *Qb.*[36]

Overall access recirculation is approximately10% at *Qb* 250 to 350 ml/min and may increase to as much as 35% at higher *Qb.* Recirculation is least in internal jugular catheters and highest in femoral catheters less than 20 cm in length. For that reason, catheters in the femoral position should be at least 24 cm long. Up to half of acute intermittent HD treatments will require catheters to be used in reversed configuration, such that the original venous line is used for blood inflow (relative to dialyzer) and the original arterial line for outflow. In this configuration, access recirculation doubles to approximately 20% at 250 to 350 ml/min, resulting in a reduction in dialysis dose.[36] Recent advances in catheter design include the use of symmetric (nonstepped) bias-cut spiraled ports on their tips. Unlike catheters with stepped tips, this design results in minimal or acceptable access recirculation in both normal and reversed configuration. Overall, data support a recommendation for right-sided internal jugular catheters with bias-cut spiraled ports as the first choice for intermittent HD and PIRRT, with femoral and left-sided internal jugular catheters as the second and third choices, respectively.[1]

In the ICU setting, catheter-associated bloodstream infection is common and is associated with a mortality risk estimated at 10% to 50%. There is ongoing controversy around the risk for infection with different insertion sites, but on balance the internal jugular site is preferred, especially in those with a larger body mass index. However, it is likely that the way the catheter is handled is more important at preventing infection than the site in which it is inserted.

Low rates of infection require both adherence to specific clinical guidelines and grounding of activities within a formal quality improvement framework.[37] There is strong evidence that standardizing catheter insertion techniques to best practice results in a close to zero catheter-related infection rate.[38] The relevant interventional bundles are contained in position statements of the Institute for Healthcare Improvement (IHI) and the Centers for Disease Control and Prevention (CDC) Healthcare Infection Control Practices Advisory Committee (HICPAC).[3,4] The core elements appropriate for dialysis catheters are listed in Box 71.3.

Antibiotic- or antiseptic-impregnated lines are recommended by the CDC for patients whose catheters are expected to remain in place for longer than 5 days and those at high risk for infection (e.g., extensive burn injury, neutropenia, etc.). A potential downside of these impregnated lines is anaphylaxis. Topical antibiotic ointments are not recommended because of their potential to promote fungal infections and antimicrobial resistance. Catheter-restricted locking solutions are effective at reducing catheter-associated infections in chronic intermittent HD.[3,5] However, their safety and efficacy in the ICU setting is unresolved and warrants further study.

BOX 71.3 Best Practices to Minimize Catheter-Associated Bloodstream Infection

Insertion

- Hand hygiene and aseptic technique (including early replacement of catheters inserted in uncontrolled settings if adherence to these measures cannot be ensured)
- Maximum barrier precautions (hat, mask, sterile gloves, sterile gown, and full patient drape)
- Appropriate skin preparation (2% chlorhexidine in 70% alcohol)
- Avoidance of the femoral site for catheter placement, especially in obese patients
- Avoidance of catheter placement near open wounds

Maintenance

- Daily review of the need for the line, with prompt removal of unnecessary lines
- Appropriate dressing with sterile gauze or a sterile, transparent, semipermeable dressing
- Appropriate schedule for dressing changes according to condition and type of dressing
- Daily review of the catheter exit site by inspection or palpation with minimal disturbance to the dressing unless clinically indicated
- Appropriate skin preparation before ports are accessed
- Daily cleansing of patients with a 2% chlorhexidine wash
- Use of a sutureless securing device for catheter stabilization

ANTICOAGULATION IN ACUTE RENAL REPLACEMENT THERAPY

Most ICU patients can avoid any anticoagulation during intermittent HD because of short treatment duration. Only a minority can do so during PIRRT or CRRT. Most commonly, unfractionated heparin is used, keeping the activated partial thromboplastin time (APTT) in the

venous blood-line 1.5 to 2 times the control value and the systemic APTT below 50 seconds. This typically requires an initial bolus dose of approximately 2000 U and a maintenance infusion of approximately 500 U/h. Advantages of unfractionated heparin include low cost, relative safety, and ease of monitoring. Risks include bleeding, hyperkalemia, elevated hepatic transaminases, and heparin-induced thrombocytopenia (HIT) in 3% to 5% of patients.

Low-molecular-weight heparin (LMWH) is theoretically advantageous because of increased antithrombotic activity and decreased hemorrhagic risk. However, disadvantages include a prolonged half-life (approximately doubled in AKIN stage 3, with no significant clearance during ARRT), incomplete reversal with protamine, and limited availability of appropriate monitoring by serial anti–factor Xa determinations (recommended level 0.25 to 0.35 U/ml). Meta-analyses and the American College of Chest Physicians (ACCP) guidelines conclude that the use of LMWH is associated with major bleeding in patients with a creatinine clearance below 30 ml/min, and recommend either unfractionated heparin or a reduction in LMWH dose by 50% for such patients.[6,39] LMWH dosage is not interchangeable between different drugs. Most experience is with dalteparin administered as a single bolus of approximately 20 to 30 U/kg for intermittent HD, followed by an infusion of approximately 10 U/kg/h for PIRRT or CRRT. Overall, evidence does not support a recommendation of LMWH over unfractionated heparin in the critically ill AKI setting.

Other approaches to anticoagulation include direct thrombin inhibitors (e.g., argatroban), antithrombin-dependent factor Xa inhibitors (e.g., fondaparinux), and serine protease inhibitors (nafamostat mesilate). Argatroban does not cross-react with heparin antibodies and is the preferred approach for HIT because of its hepatic clearance (half-life ~35 minutes, no significant clearance during intermittent HD or PIRRT[40]) and ease of monitoring with APTT. It is administered as a 0.1 to 0.25 mg/kg bolus before intermittent HD or an infusion of 0.1 to 0.2 mg/kg/h during PIRRT, titrated according to APPT. Further management of HIT is provided in guidelines from the ACCP and the European Best Practice Guidelines.[6,8]

For those receiving systemic anticoagulation with heparin, the incidence of significant bleeding complications is up to 25% to 30%. A regional strategy mitigates this risk, and the preferred technique is regional citrate anticoagulation, which provides the lowest rates of hemorrhage and greatest prolongation of filter life. Regional citrate anticoagulation involves calcium chelation in the extracorporeal blood circuit with calcium reversal.

For intermittent HD and PIRRT, this involves an infusion of 4% trisodium citrate into the arterial blood-line, with zero- or low-calcium dialysate and an infusion of calcium chloride into the venous blood-line. A simpler approach has been described in which the citrate infusion is combined with normal calcium dialysate and no calcium infusion. The positive calcium flux through the hemodialyzer maintains calcium balance, and provides partial chelation of the undialyzed citrate.

For CRRT, regional citrate anticoagulation is performed with either 4% trisodium citrate or anticoagulant citrate dextrose A. For continuous HD, a prefilter infusion of between 3% to 7% of *Qb* is used, with a postfilter infusion of calcium chloride. This requires dialysate that is hyponatremic and devoid of alkali because citrate metabolizes to bicarbonate in the liver in a 1:3 ratio (Table 71.1). Frequent monitoring and titration of citrate dose have usually been advocated to keep the ionized calcium within a therapeutic range. Many centers now use a simplified fixed-dose anticoagulant citrate dextrose, a protocol that minimizes the need to measure postfilter calcium or adjust the citrate infusions. Major complications of regional citrate anticoagulation include systemic hypocalcemia and metabolic alkalosis from citrate toxicity.

There is increasing experience with commercial replacement solutions containing citrate as buffer; this chelates calcium in the blood without the need for a separate citrate infusion. This also allows for direct coupling of citrate and calcium infusions by CRRT machinery, such that a change in *Qb* leads to an automatic change in citrate delivery into the extracorporeal blood circuit and calcium infusion into the venous line (relative to dialyzer) or catheter. This does not obviate monitoring for systemic hypocalcemia and metabolic alkalosis, but is expected to be safer and will likely become the standard approach in the future.

TABLE 71.1 Comparison of Regional Citrate Anticoagulation Protocols

	Modality	Blood Flow (ml/min)	Replacement Fluid Composition (mmol/l)	Dialysis Fluid Composition (mmol/l)	Citrate Source
Mehta et al[53] (1990)	CAV-HD	52-125	Normal saline	Na 117, Cl 122.5, Mg 0.75, K 4, dextrose 2.5%	4% Trisodium citrate
Hoffmann et al[55] (1995)	CVV-HD	125	*Prefilter:* Normal saline + KCl 4, alternate with 0.45% saline + KCl 4 *Postfilter:* 0.45% saline + $MgSO_4$ + $CaCl_2$	—	4% Trisodium citrate
Palsson and Niles[54] (1999)	CVV-HD	180	Citrate 13.3, Na 140, Cl 101.5, Mg 0.75, dextrose 0.2%	—	Customized citrate solution
Tolwani et al.[56] (2001)	CVV-HD	125-150	—	Normal saline + $MgSO_4$ 1.0, KCl 3	4% Trisodium citrate

ACD-A, Anticoagulant citrate dextrose form A; *CAV-HD,* continuous arteriovenous hemodialysis; *CVV-HD,* continuous venovenous hemodialysis; *CVV-HDF,* continuous venovenous hemodiafiltration; *PD,* peritoneal dialysis. Number behind electrolytes are concentrations in mmol/l.

Regional heparin anticoagulation involves neutralization of heparin by infusion of protamine into the venous blood-line. It may be complicated by rebound bleeding, occurring when neutralization with protamine wears off faster than the anticoagulation from heparin. Furthermore, protamine may cause sudden hypotension, bradycardia, or anaphylactoid reactions.

Prostacyclin is an effective alternative anticoagulant. However, it is a vasodilator, causing a variable but occasionally marked decrease in BP. Moreover, there is a risk for worsening ventilation-perfusion mismatch and lactic acidosis in patients with multiorgan dysfunction and a risk for increasing intracranial pressure in patients with combined liver and kidney failure.

MODALITY CHOICE AND OUTCOMES IN ACUTE RENAL REPLACEMENT THERAPY

On the basis of current evidence, the use of one modality of ARRT over another is unlikely to translate to overall clinical benefit, if applied as an initial modality to all patients.[1,21] This does not mean the modalities are clinically equivalent. In comparative trials, 5% to 15% of patients treated initially with HD require a change to CRRT because of progressive hemodynamic instability or poor metabolic control.[41,42] The evidence can be summarized thus: the use of intermittent HD as initial modality results in the same outcomes as the use of CRRT as initial modality, as long as a switch is made in a timely manner as best practice and clinical indications dictate.

The relationship between modality choice and mortality is modified by clinical context. In those at risk for dialysis disequilibrium syndrome (e.g., those with raised intracranial pressure or abdominal compartment syndrome), solute disequilibrium should be minimized to avoid water influx into tissues; lower efficiency PIRRT and CRRT are more desirable for such patients.[20] For most, modality choice still depends mostly on the most clinically appropriate rate of solute and fluid removal.[1] Patients who are hemodynamically unstable, including those with cardiogenic shock, appear to have better organ recovery if they are treated with PIRRT and CRRT.[43] Other studies are examining modality selection and outcomes in acute lung injury, sepsis, and acute cardiac decompensation, although there are no definitive data as of yet.

The role of is PIRRT is difficult to determine, partly because of the lack of standardization with respect to prescription. In the older descriptions of PIRRT, the duration (12 to 18 hours) and other operating characteristics ($Qd \leq 100$ ml/min, $Qb \leq 200$ ml/min) were closer to those of CRRT, and treatment tolerance was excellent. Currently, the typical duration is 6 to 8 hours and Qd is usually 300 ml/min, and outcomes may not be as good as those with CRRT, especially in high-risk populations such as those with septic shock.[44] It is clear that PIRRT is not a homogenous modality. Practically, lower efficiency prescriptions (i.e., with lower UFR and slower solute removal) should be used for hemodynamically unstable patients and perhaps those with sepsis, as well as when it is imperative to avoid fresh ischemic injury, such as those with cardiovascular disease and CKD (see Fig. 71.3).

Outcomes other than survival are important for patients who survive critical illness and AKI. The risk for ESRD is increased several-fold after critical illness with AKI requiring ARRT, and this drives longer term risk for death that results in up to a third of 90-day survivors dying at 44 months. Therefore it is a high priority to optimize renal recovery, and observational studies suggest that this can be achieved by the more rigorous application of lower efficiency modalities to hemodynamically unstable patients and those with a low renal reserve, such as those with CKD. For quality of life and other patient-centered outcomes, it does not appear that the intensity or modality of ARRT is the main determinant, although more studies are needed.

CRRT is generally more expensive than intermittent HD or PIRRT. However, economic evaluations of ARRT are all limited by wide variation in ICU cost and reimbursement structures, and many do not consider longer term outcomes such as the development of ESRD. At present, economic evaluations comparing modalities needs to be conducted locally, with careful consideration of underlying assumptions about costs and outcomes.

ACUTE RENAL REPLACEMENT THERAPY DURING MECHANICAL CIRCULATORY SUPPORT

The two forms of mechanical circulatory support (MCS; Box 71.4)[45-47] that are most commonly encountered by ARRT providers are extracorporeal membrane oxygenation (ECMO) and ventricular assist devices (VADs). ECMO can be venovenous or venoarterial; deoxygenated blood is taken from a central vein and pumped through an oxygenator back into either a central vein or the arterial system, thereby providing respiratory or cardiorespiratory support, respectively.[48] VADs are devised to assist the left and/or right ventricles (LVAD and RVAD, respectively) in patients with refractory heart failure or cardiogenic shock. They are used as a bridge to recovery or transplantation or as destination therapy for patients ineligible for transplant. Early versions had pulsatile flow, but newer versions have continuous flow, an improved safety profile, and they now comprise 90% of implanted VADs in the United States. Another modality of respiratory support increasingly used is extracorporeal carbon dioxide removal ($ECCO_2R$). It removes carbon dioxide via a minimally invasive approach that requires lower blood flow and smaller cannulas than ECMO. Of particular interest for ARRT providers is respiratory dialysis, a form of $ECCO_2R$ that decarboxylates blood using a hemofiltration system linked to a gas exchange membrane.[49]

AKI is common in patients with circulatory and/or respiratory failure. If hypoperfusion is causing AKI, initiating MCS may improve renal function.[50] However, the incidence of intrinsic AKI (and the need for ARRT) is high because patients requiring MCS are sicker and MCS can

BOX 71.4 Select Types of Mechanical Circulatory Support Devices

- Intraaortic Balloon Pump

Neurohormonal Adaptation Devices
- Vagal Nerve Stimulation: *CardioFIT*

Continuous Aortic Flow Devices
- Continuous aortic flow augmentation: *Cancion CRS*
- Implantable augmented aortic flow pump: *Exeleras*
- Reitan catheter pump

Ventricular Assist Devices (VAD)*
- Left ventricular assist device (LVAD)
- Right ventricular assist device (RVAD)
- Biventricular assist device (BiVAD) or total artificial heart

Extracorporeal Membrane Oxygenation (ECMO)
- Venovenous ECMO: Provides respiratory support
- Venoarterial ECMO: Provides full cardiorespiratory support
- Extracorporeal carbon-dioxide removal ($ECCO_2R$)†
- Respiratory dialysis

*For a classification of VADs based on generation or type, see references 45 and 46.
†For list of available devices, see reference 49.

be complicated by periprocedural hypotension, inflammation, thromboembolism, and hemolysis. Although scant data are available regarding the use of ARRT during MCS, the general principles are similar to those for other ICU patients. However, prolonged or continuous ARRT modalities may be especially advantageous during MCS because they allow for more effective management of patients receiving large fluid volumes. Maintaining adequate volume balance facilitates weaning of MCS, whereas volume overload is associated with worse outcomes.[51]

Technical Aspects of Acute Renal Replacement Therapy During Mechanical Circulatory Support

Access Options and Techniques

Patients on MCS present several access options.[52] The first is through standard HD catheters (see Chapter 93), which have the advantage of maintaining the two circuits independent of each other. This is the preferred access for ARRT in patients with VADs. The risks are similar to those in other patients, but infections are an important cause of mortality.

The second option, which can be used in ECMO or RVADs, but not LVADs (thromboembolism risk), is to directly link the ARRT device to the MCS circuit. This is achieved by creating a shunt along the MCS circuit using two three-way taps, the placement of which depend on the type of ARRT. During inline RRT, the shunt is created between an arterial port (placed after the pump, where the pressure is positive) and a venous port (placed before the pump, where the pressure is negative). This pressure gradient drives blood flow through a hemofilter placed directly in line (Fig. 71.7A). The ultrafiltrate, dialysate, and/or replacement fluid rates are regulated by infusion pumps. This method is simple

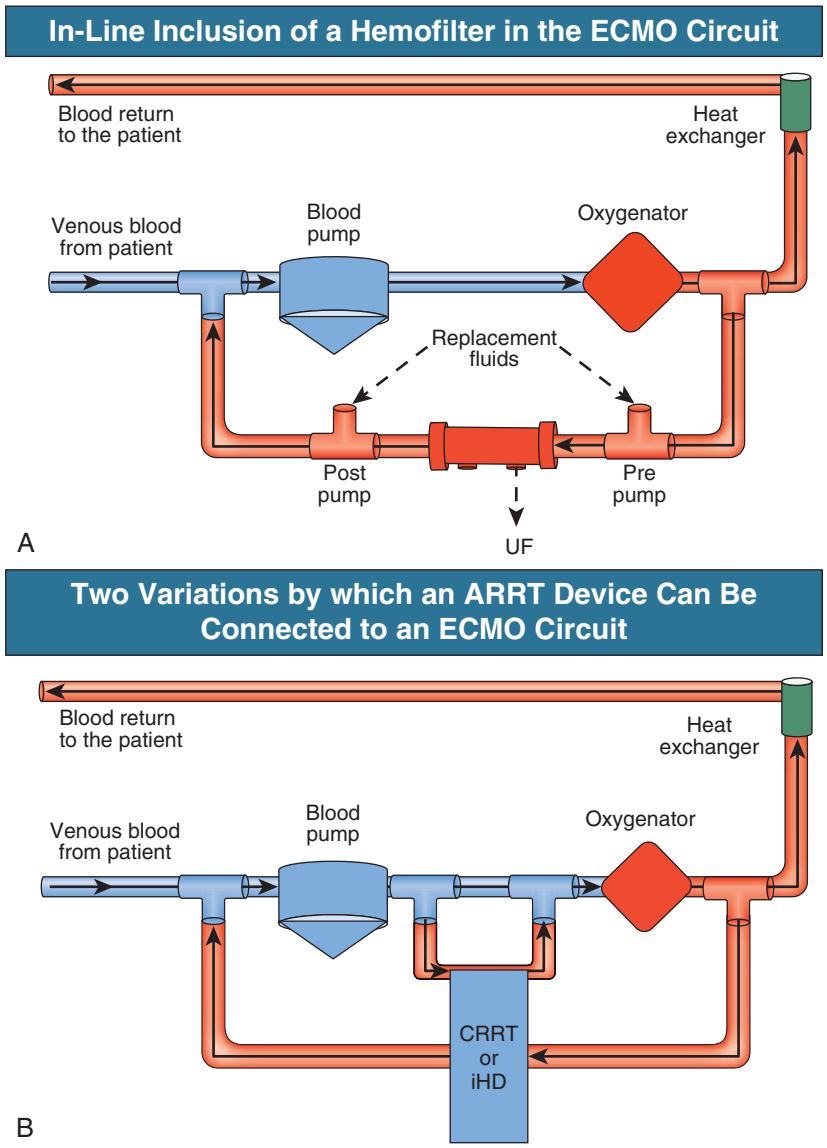

Fig. 71.7 Techniques used to incorporate acute renal replacement therapy *(AART)* into extracorporeal membrane oxygenation *(ECMO)* and ventricular assist device (VAD) circuits. (A) Inline inclusion of a hemofilter in the ECMO circuit. Note that inclusion into a right VAD (RVAD) circuit would be similar except simplified in that blood comes from the body to the pump and then goes back to the body without passing through an oxygenator. (B) Two variations by which an ARRT device can be connected to an ECMO circuit. Note that flow in the mechanical circulatory support circuit is high enough that recirculation is not a concern even when the arterial access port is distal to the venous return port. *CRRT,* Continuous renal replacement therapy; *iHD,* intermittent hemodialysis; *UF,* ultrafiltration.

TABLE 71.2 Special Considerations in Patients on Mechanical Circulatory Support Requiring Acute Renal Replacement Therapy

Monitoring Blood Pressure, Volume Status, and Mechanical Circulatory Support Function

Parameters Monitored During ARRT	Method/Affected Parameter	Target
Blood pressure	Terumo slow-deflating cuffs Doppler audible ultrasound Arterial line in critically ill patients	MAP 70-80 mm Hg Not to exceed 90 mm Hg
Volume status/preload	Central venous pressure Filling volumes (echocardiography) Pulsatility index Pump flow	Parameters vary with each device Contact the VAD coordinator for targets
Considerations and Complications of MCS/ARRT		
Volume Shifts/Hypovolemia/UF	***Hematologic Issues***	***Other***
Errors Hypotension Reduced pump filling (low-flow events) Suckdown events Chattering	Bleeding Thrombosis Hemolysis	Stroke Infection
Advanced Cardiac Life Support		
NO chest compressions (could dislodge the cannulae) Standard ACLS protocols are used VAD ejection is asynchronous with the underlying cardiac rhythm VAD patients tolerate arrhythmias and remain asymptomatic		

ACLS, Advanced Cardiac Life Support; *MAP,* Mean arterial pressure; *UF,* ultrafiltration; *VAD,* ventricular assist device.

and inexpensive, but the infusion pumps are relatively inaccurate and can thus be a source of error. Connecting an ARRT machine to the MCS circuit is achieved in a similar manner. However, because blood flow through the filter is achieved via the CRRT pump (rather than pressure gradients), a variety of access sites along the MCS can be used (see Fig. 71.7B). This setup uses commercially available ARRT machines that control the renal replacement therapy procedure and hence depends on the availability of appropriate equipment and properly trained staff.

Monitoring and Management of Key Acute Renal Replacement Therapy–Related Issues

The concurrent usage of continuous-flow MCS and ARRT creates challenges that are distinct from those in other critically ill patients (Table 71.2). Monitoring BP, volume status, and MCS function is particularly challenging and of fundamental importance.[52] BP needs to be adequately assessed and treated because continuous-flow MCS is vulnerable to changes in afterload; increases can reduce pump output. However, because these patients have minimal pulses, standard methods for measuring BP are unreliable. Thus specialized BP cuffs with low pulsatility modes or determining mean arterial pressure with Doppler ultrasonography are used (see Table 71.2).

The changes in intravascular volume during ARRT pose a particular risk for these patients because their MCS is dependent on preload. Volume status is best assessed by central venous pressure, echocardiogram, or the pulsatility index (a dimensionless value calculated in the Heartmate II from the magnitude of flow pulses averaged over 15-second intervals). Hypovolemia leads to left ventricular collapse with subsequent fall in MCS flow, pump overdrive, hypotension, and ventricular arrhythmias. This is corrected by gentle volume administration, as other causes of preload reduction (e.g., bleeding, sepsis) are considered. Decreasing the pump speed and treating arrhythmias usually should be performed only after consultation with appropriate MCS personnel.

DRUG DOSAGE IN ACUTE RENAL REPLACEMENT THERAPY

For patients undergoing CRRT, 20 liters of daily filtrate corresponds to a glomerular filtration rate of approximately 14 ml/min and the dose of drugs should be calculated accordingly. Any drug with a low therapeutic index that can be readily measured should be measured frequently early in the course of ARRT, until a stable pattern appears. One day of CRRT is in general comparable to one intermittent HD treatment with regard to drug removal.

SELF-ASSESSMENT QUESTIONS

1. Survival of critically ill patients who require acute renal replacement therapy (RRT) is improved through the routine application of which *one* of the following interventions?
   - **A.** The routine use of continuous rather than intermittent modalities
   - **B.** Pulsed high-volume continuous venovenous hemofiltration (CVVH) (effluent rate of 60-100 ml/kg/h) for those with sepsis
   - **C.** The routine use of daily rather than thrice-weekly treatment schedules for those receiving intermittent RRT modalities
   - **D.** Ensuring single-pool *Kt/V* of 1.3 or more for those receiving intermittent RRT modalities delivered on a thrice-weekly schedule
2. Which *one* of the following statements is true regarding central venous catheters for acute RRT in critically ill patients?
   - **A.** Catheter brand and design choice can and should be standardized between continuous and intermittent RRT modalities.
   - **B.** Catheters should be placed and used for intermittent hemodialysis (HD), rather than use of arteriovenous fistulas or prosthetic bridge grafts in patients who have them.
   - **C.** Access recirculation is reduced by characteristics of catheter design and site of placement.
   - **D.** Left-sided internal jugular catheters are routinely preferred to femoral ones.
3. Which of the following interventions is *not* recommended to reduce central venous catheter–associated bloodstream infection during RRT for critically ill patients?
   - **A.** A formal quality improvement framework and program for catheter insertion and maintenance
   - **B.** The routine use of topical antibiotic ointments at the exit site
   - **C.** Antibiotic- or antiseptic-impregnated catheters for patients at high risk for catheter-associated bloodstream infection
   - **D.** Routine placement of catheters in the internal jugular site
4. Which *one* of the following statements is true regarding anticoagulation for acute RRT in critically ill patients?
   - **A.** For those receiving systemic anticoagulation with heparin, the incidence of significant bleeding complications is 10%.
   - **B.** Argatroban is the preferred approach in those with heparin-induced thrombocytopenia.
   - **C.** Certain low-molecular-weight heparins are cleared significantly by acute RTT and therefore are preferable.
   - **D.** Complications from regional citrate anticoagulation are greater than those from systemic unfractionated heparin.
5. Which of the following interventions is useful to prevent intradialytic hypotension for critically ill patients receiving intermittent RRT modalities?
   - **A.** Combined sodium and ultrafiltration profiling
   - **B.** Blood temperature monitoring and biofeedback control
   - **C.** Circulating blood volume monitoring and biofeedback control
   - **D.** The use of hemodiafiltration rather than hemodialysis

Dialytic Management of Refractory Heart Failure

Edward A. Ross, Kevin Damman, Amir Kazory

Nephrologists are increasingly consulted regarding fluid management in patients with refractory heart failure (HF). Renal expertise extends beyond diuretics and electrolyte homeostasis and now includes recent advances in drug therapies, acute and chronic fluid removal by extracorporeal dialysis machines or isolated ultrafiltration (UF) devices, and peritoneal modalities.

DEFINITION AND SCOPE OF THE PROBLEM

HF and renal dysfunction may coexist, but each disease also can cause or exacerbate the other. Poor cardiac output results in reduced renal perfusion and potentially kidney ischemia and progressive chronic kidney disease (CKD).[1] Conversely, CKD may result in salt and water retention with subsequent venous congestion, hypertension, activation of the renin-angiotensin-aldosterone system (RAAS), and vascular calcification that cause cardiac dysfunction, accelerated atherosclerosis, and left ventricular hypertrophy and remodeling. These conditions may exacerbate HF, creating a vicious cycle of reduced cardiac output and kidney dysfunction.

Of the 100,000 patients in the Acute Decompensated Heart Failure National Registry (ADHERE), 57% had CKD stages 3 or 4, 7% were at stage 5, and only 9% had normal kidney function. In patients with HF who presented with CKD at the time of admission, there was greater use of diuretics and inotropes, less angiotensin-converting enzyme (ACE) inhibitor and angiotensin receptor blocker (ARB) administration, and a 5% higher in-hospital mortality rate.[2]

PATHOGENESIS

Fig. 72.1 illustrates the pathogenesis of refractory HF. The pathophysiology and treatment strategies for combined heart and kidney failure (cardiorenal syndrome)[3] highly depend on whether the HF occurs with reduced (HFrEF) versus HF with preserved ejection fraction (HFpEF). In the former, low cardiac output HF plays a key role resulting in worsening renal perfusion and function, activating the RAAS and sympathetic nervous system (SNS), leading to salt and water retention with a paradoxical further worsening of cardiac function. Central to this vicious cycle is tubuloglomerular feedback (TGF; Chapter 2), which is maladaptive in HF, especially when certain drugs (e.g., diuretics) alter tubular sodium delivery. Secondary (hyper)aldosteronism (resulting in increased sodium retention), increased systemic vascular resistance (putting more strain on the heart), and higher cardiac filling pressures may reduce cardiac output, as further increases in preload lead to lower stroke volume. This further activates the SNS, which worsens vasoconstriction, cardiac function, and renal perfusion. Excessive activation of both the RAAS and SNS has long been considered the hallmark of worsened HF. Other pathophysiologic mechanisms are discussed in the following paragraphs.

Venous Congestion

Right-sided congestion and renal venous hypertension also contribute to kidney dysfunction.[4] In this regard, HF is analogous to abdominal compartment syndrome, portal hypertension, or renal venous thrombosis; however, some of these conditions differ in whether there is extravascular versus intravascular hydrostatic pressure transmitted to the kidneys. Venous hypertension is thought to trigger neuromyogenic changes that decrease renal perfusion, raise kidney interstitial pressure, narrow the arterial-to-venous pressure gradient, lower renal blood flow and glomerular filtration rate (GFR), trigger maladaptive autoregulatory responses, and exacerbate neurohumoral pathways already problematic in HF. Furthermore, there is also a direct effect of higher renal venous pressure that transmits to the renal parenchyma. This higher pressure directly opposes glomerular filtration, causes collapsing of tubules, and may be the first trigger for tubulointerstitial fibrosis.[5] These mechanisms are consistent with a critical role of the adrenergic system in modulating venous tone and thus capacity. In that veins contain nearly 70% of the circulatory volume, changes to venous capacitance (and pressure) can decompensate or ameliorate HF, without changes to total body salt, fluid, or weight.[6] This variation in the venous reservoir volume reconciles how approximately a third of outpatients have HF decompensation with minimal change in weight and why approximately 15% of HF inpatients can symptomatically improve despite no weight loss. Changes in reservoir capacity also confound interpretation of simultaneous changes in volume by extracorporeal UF. Besides these hemodynamic effects, volume overload from either cardiac or renal dysfunction causes circumferential stretch of endothelial cells of the venous system, which can trigger the release of tumor necrosis factor and interleukin-6 (IL-6), potentially impairing myocardial contractility and renal function.[7,8]

Some studies report that kidney function in decompensated HF correlates better with right-sided pressures than the ejection fraction or cardiac index. In addition, elevated central venous pressures correlated with mortality and inversely with kidney function.[9,10]

Adenosine

Adenosine receptors maintain intrarenal vascular tone via multiple pathways, including A_1 receptors (which cause afferent arteriolar vasoconstriction) and A_2 receptors (which induce efferent vessel dilation). Actions of adenosine at the macula densa and mesangium depend on angiotensin, renin, nitric oxide, and prostaglandin levels. The great appeal of A1 receptor antagonists is that they also have beneficial direct vascular effects: vasodilating cortical arterioles, and thereby blocking

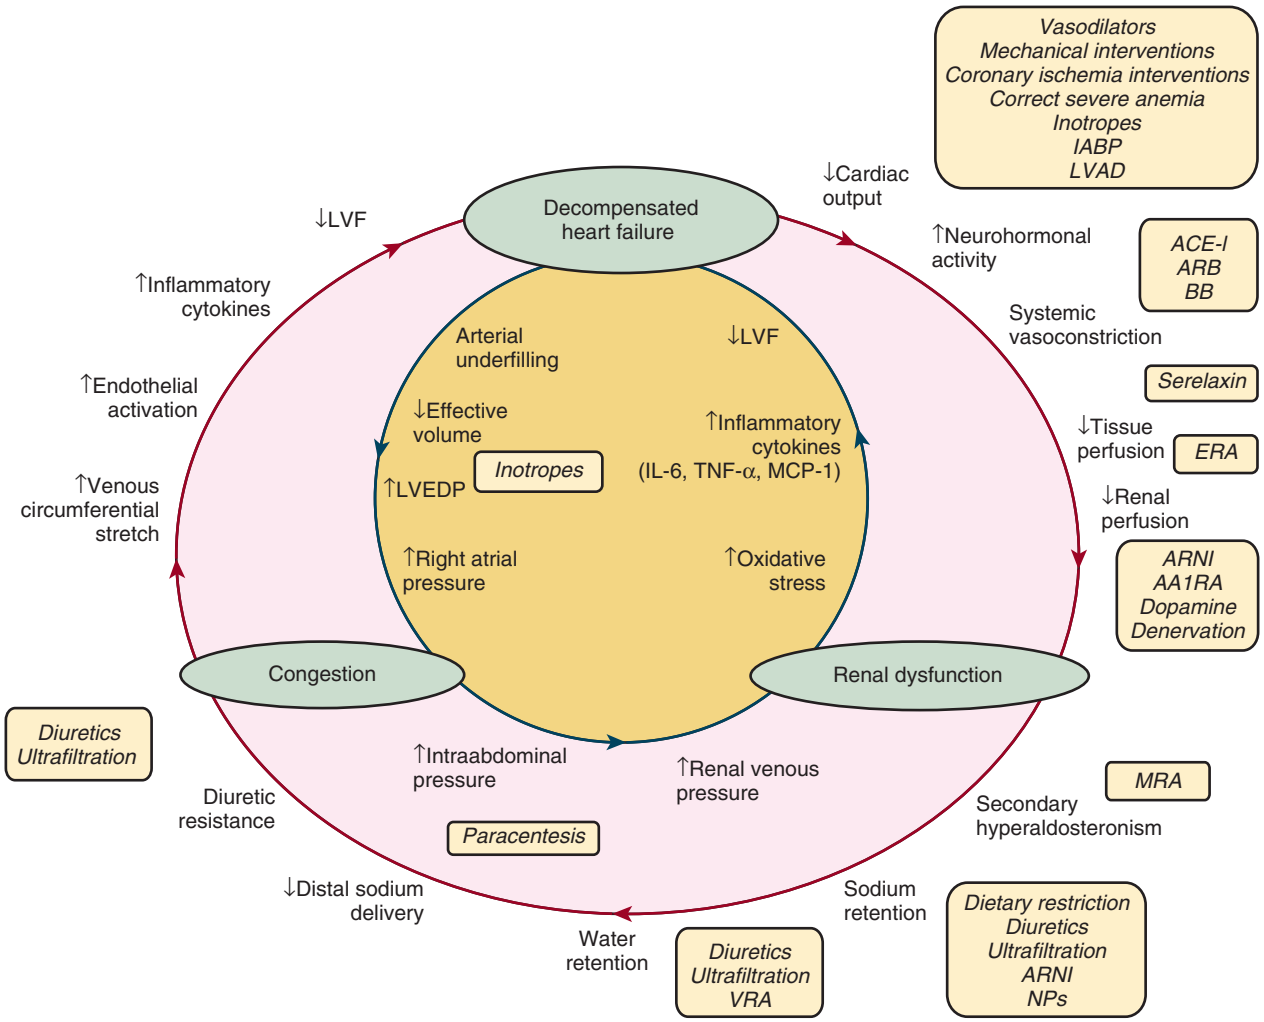

Fig. 72.1 Reciprocal pathophysiologic pathways linking heart failure, renal dysfunction, and congestion in cardiorenal syndrome. Decompensation of heart failure can lead to deterioration in renal function via exacerbated neurohormonal activity (i.e., low forward flow) or through fluid overload and renal venous congestion (i.e., high backward pressure). The impact of various pharmacologic and nonpharmacologic therapeutic options on the underlying pathophysiologic mechanisms is illustrated. *AA1RA,* Adenosine A_1 receptor antagonist; *ACE,* angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *ARNI,* angiotensin receptor neprilysin inhibitor; *BB,* β-blocker; *ERA,* endothelin receptor antagonist; *IABP,* intraaortic balloon pump; *IL-6,* interleukin-6; *LVAD,* left ventricular assist device; *LVEDP,* left ventricular end-diastolic pressure, *LVF,* left ventricular function; *MCP-1,* monocyte chemoattractant protein-1; *MRA,* mineralocorticoid receptor antagonist; *NPs,* natriuretic peptides; *TNF-α,* tumor necrosis factor-α; *VRA,* vasopressin receptor antagonist.

TGF so as to permit a continued diuresis in HF. In addition, there is a growing literature on the effects of adenosine on the myocardial fibrosis in animal ischemia-reperfusion models. Over-expression of the A1 receptor induces dilated cardiomyopathy and fibrosis.

Anemia

Anemia may be caused by chronic disease or coexistent CKD, or it may be the consequence of hemodilution by venous congestion. Relative EPO deficiency and resistance to EPO are among the pathologic phenomena that link the anemia of CKD with that of HF. The term *cardiorenal anemia syndrome* emphasizes this pharmacologically remediable aspect of HF.

Diuretic Resistance and Adverse Effects

Many patients with HF develop diuretic resistance, failing to have appropriate natriuresis despite escalating doses, with worsening neurohumoral mediator levels.[11] Indeed, morbidity and mortality in advanced HF increased up to fourfold with higher doses of diuretics,[12] and higher doses have been associated with worse GFR (despite equivalent fluid losses),[14] although differences in baseline characteristics likely contributed to these outcomes.[13] In the Diuretic Optimization Strategies Evaluation (DOSE) trial (see later), there was no difference in outcome in high- versus low-dose diuretic therapy, despite a higher incidence of (transient) worsening GFR in the high-dose diuretic group.[15]

TREATMENT

General Approach and Limitations

A pragmatic approach is to first address potentially treatable causes of HF such as valvular disease, conduction disorders and arrhythmias, pericardial effusion, or coronary ischemia (Box 72.1). The clinician approximates the volume of excess fluid and crafts a daily therapeutic

BOX 72.1 Treatment Modalities for Refractory Heart Failure

Traditional Treatment
- Diuretics: Loop diuretics, long-acting thiazides
- Digoxin
- ACE inhibitors and ARBs
- Mineralocorticoid receptor antagonists
- β-Blockers
- Vasodilators
- Blood transfusions

Pharmaceuticals
- Neprilysin inhibitor/ARB combination for HFrEF
- Inotropes: For example, milrinone, dobutamine*
- Synthetic natriuretic peptides*
- Aquaretics: Vasopressin antagonists*
- Erythropoiesis-stimulating agents*
- Adenosine receptor blockade*

Mechanical Treatment
- Biventricular pacing
- Ventricular assist devices

Ultrafiltration
- Peritoneal dialysis
- Manual (CAPD) and automated using a cycler (APD)
- Extracorporeal therapies
- Intermittent short-duration ultrafiltration
- Slow continuous ultrafiltration (SCUF)

*No clinical benefit established.
ACE, Angiotensin-converting enzyme; *APD,* automated peritoneal dialysis; *ARB,* angiotensin receptor blocker; *CAPD,* continuous ambulatory peritoneal dialysis; *HFrEF,* heart failure with reduced ejection fraction.

goal concurrent with reducing excess salt intake.[16] Medication-naïve patients then can be cautiously treated as described later, with serial monitoring because hypotension or renal dysfunction commonly limit the use of pharmaceuticals. Determining to what degree a particular patient may be able to tolerate drug-induced lower levels of blood pressure (e.g., from afterload-reducing agents) is clinically challenging. If there is marked sensitivity of the blood pressure or GFR to low doses of RAAS blockade, bilateral renal artery stenosis should be considered (see Chapter 41).

Pharmacologic Therapeutic Strategies

The pharmacologic management of HF is summarized in Box 72.1 and includes traditional approaches for arrhythmias (e.g., for atrial fibrillation) and afterload reduction, SNS, and RAAS blockade. Although diuretics remain the mainstay of treatment of congestion in HF, salt and water excretion in acute HF is often inadequate; registry data indicated that of patients admitted with acute HF, approximately 16% were discharged at a higher body weight.[17]

Diuretics

Despite the concerns described, most patients initially respond to intensified diuretic regimens, which may require increasing the dose or frequency of loop diuretics, coadministering a long-acting thiazide diuretic, or continuously infusing loop diuretic. In the DOSE study,[15] high versus low doses and continuous versus bolus infusion of loop diuretics were tested in acute HF, and no clinically relevant differences were no found in the regimens. For patients with up to 80 mg of oral furosemide equivalent dose as outpatient, an intravenous bolus of 40 mg furosemide followed by infusion of 5 mg/hour can be considered. For those with higher doses as outpatient, a bolus of 80 mg followed by 10 mg/hour infusion would be a reasonable start point. The dose would then need to be tailored according to the clinical and laboratory parameters such as serum creatinine, blood pressure, and urine output.

Loop diuretic efficiency, defined as urine output per diuretic dose, has been identified as an important prognostic indicator in decompensated HF, independent of the underlying kidney function. The most obvious explanation for this finding is that characteristics of more advanced cardiac and renal disease are contributing to decreased diuretic efficiency. However, one might speculate that the loop diuretic efficiency can be modulated by therapeutic interventions (e.g. addition of thiazide diuretics) and wonder if such strategies would improve outcomes. While there have been successful attempts for rapid and reliable prediction of poor natriuretic response in patients treated for acute decompensated HF, future large scale trials are needed to confirm the results of these preliminary studies.

Although higher dose regimens increased the risk for transient decreases in GFR, they did not affect long-term outcomes. Based on the Cardiorenal Rescue Study in Acute Decompensated Heart Failure (CARRESS-HF) trial, in which there was worsened renal function in decompensated HF, efficacious and safe algorithms can be crafted for stepped pharmacologic care in which inotropes, nesiritide, or nitroglycerin are added to diuretics sequentially.[18]

Renin-Angiotensin-Aldosterone System Antagonists

Although decreases in GFR after RAAS blockade do not necessarily portend worse outcomes,[19] if GFR falls substantially, ACE inhibitors and ARBs may need to be temporarily decreased or withdrawn in patients undergoing diuresis or in those with advanced CKD. Alternatively, it may be necessary to reduce diuretic dosage before the ACE inhibitor dose is adjusted. Hyperkalemia also may limit the use of RAAS blockers or could be an indication for concurrent use of medications that enhance gastrointestinal potassium excretion.

Neprilysin Inhibitors

Neprilysin is a neutral endopeptidase that degrades several vasoactive peptides, including natriuretic peptides, bradykinin, and adrenomedullin. Inhibition of neprilysin increases the levels of these substances, countering the neurohormonal overactivation that contributes to vasoconstriction, sodium retention, and maladaptive remodeling. The Prospective Comparison of ARNI [Angiotensin Receptor–Neprilysin Inhibitor] with ACE-I to Determine Impact on Global Mortality and Morbidity in Heart Failure (PARADIGM-HF) trial evaluated the effects of sacubitril/valsartan versus enalapril in 8442 patients with HFrEF. Sacubitril/valsartan was superior to enalapril in reducing mortality, the risk for hospitalization for HF, and the symptoms and physical limitations of HF.[20] Importantly, the rates of renal dysfunction were less with sacubitril/valsartan versus enalapril. Thus sacubitril/valsartan could replace ACE inhibitors or angiotensin receptor antagonists as the cornerstone of therapy for HFrEF.[16] Studies on the use of neprilysin inhibitors for patients with HFpEF are under way.

Miscellaneous Therapies

A number of pharmacologic agents (e.g., nesiritide, endothelin receptor antagonists, adenosine-A1 receptor antagonists, and selective or nonselective vasopressin receptor antagonists) have been investigated, but so far large-scale trials have unfortunately proven them to be suboptimal, ineffective, or unsafe. Severe anemia should be treated based on

concurrent conditions and their severity, using iron repletion,[16] transfusions (e.g., for acute hemorrhage), and erythropoiesis stimulating agents as per CKD guidelines (see Chapter 82).

Medications Under Development

Serelaxin, a recombinant form of human relaxin-2, has shown promise in management of patients with concomitant heart and renal failure. Relaxin is a peptide hormone secreted during pregnancy and is associated with increase in cardiac output and decrease in systemic vascular resistance. The RELAXin in Acute Heart Failure (RELAX-AHF) compared the effects of serelaxin versus placebo in 1161 patients admitted for acute HF.[21] Serelaxin use was associated with significantly lower serum creatinine and plasma cystatin C levels in the first 5 days after enrollment. All-cause and cardiovascular mortality were also lower at 180 days in the serelaxin arm. However, it had no effect on readmission to hospital.

Catheter-based renal denervation is a promising therapy designed to reduce renal sympathetic activity and systemic sympathetic activation, which contribute to cardiorenal syndrome. Although animal studies showed positive results in the setting of HF, the effect of renal denervation in humans is still unclear. The Renal Artery Denervation in Chronic Heart Failure (REACH-Pilot) study on seven patients reported symptomatic improvement and significant increase in the 6-minute walk distance at 6 months.[22] Larger studies are now under way to assess the safety and efficacy of renal denervation in HF.

Nonrenal Salt and Water Removal

Nonrenal methods for salt and water removal have been proposed because they avoid TGF-mediated neurohumoral pathway activation and are effective in patients whose condition is refractory to pharmaceutical treatment. However, establishing their benefits and determining their optimal use (Box 72.2) have been controversial.

Paracentesis

In a subset of patients, intraabdominal hypertension may cause renal venous hypertension and kidney congestion. In five patients, removal of approximately 3 liters of ascites decreased intraabdominal pressure and improved GFR.[23] However, repeated paracentesis causes significant protein losses, often the need for albumin repletion, and the possibility of subsequent fluid leakage and/or infection. Nevertheless, this approach warrants further investigation, especially in low-resource settings.

Peritoneal Dialysis

Compared with more complex peritoneal dialysis (PD) exchange prescriptions for end-stage renal disease, simplified regimens can be used for fluid removal in HF (one to three exchanges per day or thrice-weekly intermittent 12-hour treatments).[24] Use of PD has restored diuretic responsiveness, reduced body weight, resulted in better echocardiographic or other objective cardiac hemodynamic parameters, improved HF biomarkers (e.g., brain natriuretic peptide and aldosterone), improved New York Heart Association (NYHA) class, increased 6-minute walk capacity, provided a bridge to cardiac transplantation, decreased hospitalization days, and improved quality of life.[25]

In a systematic review that included 21 studies and 673 patients with refractory congestive HF, after initiation of PD therapy, hospitalization days declined (6.30 vs. 1.22 days/year) and cardiac function improved significantly (both left ventricular ejection fraction and NYHA classification).[26] PD was also associated with a marked reduction in body weight (73.4 vs. 69.7 kg). The mean peritonitis rate was 14.5% per year, and the mean mortality rate was 20.3% per year. PD also might help control HF-induced ascites (thereby lowering the risk for spontaneous bacterial peritonitis and intraabdominal hypertension). However, most reports on use of peritoneal dialysis (PD)-based UF to treat HF are from small series,[27] and outcomes are confounded by baseline severity of kidney dysfunction and use of hemofiltration.

BOX 72.2 Stepwise Treatment Approach for Symptomatic Heart Failure and Cardiorenal Syndrome

Step 1

1. Compliance: Optimize adherence to medication regimen and salt restriction.
2. Electromechanical: Evaluate and treat arrhythmias and dyssynchrony
3. Anatomic, with imaging (cardiac catheterization, echocardiogram) as appropriate for:
   a. Ischemic: Angioplasty, stents, or surgery when appropriate for coronary artery stenoses
   b. Other remediable disorders, such as valvular heart disease, pericardial effusions, and constrictive pericarditis
4. Anemia control, after CKD guidelines (see Chapter 83)
5. Pharmacologic, with dose reductions for hypotension:
   a. ACE inhibitors, ARBs, or neprilysin inhibitor/ARB combination
   b. β-Blocker therapy
   c. Mineralocorticoid receptor antagonists
   d. Diuretics if volume overloaded, congestion, symptoms are present
   e. Other agents: Afterload-reducing medications (e.g., hydralazine) and digoxin

Step 2: For Worsened Renal Function, Ineffective Diuresis, Persistent Heart Failure

1. Begin stepped approach to escalate pharmacologic treatment, preferably algorithm-based. Focus on dose adjustments to avoid hypotension and further renal impairment.
2. Reevaluate for concurrent renal disease (i.e., renocardiac syndrome).
   a. Consider primary nephrologic disorders (e.g., parenchymal, obstruction)
   b. Consider evaluation for unilateral or bilateral renal artery stenosis
   c. If necessary, paracentesis or other specific therapies to reduce intraabdominal hypertension, relieve renal venous hypertension and renal congestion

Step 3: For Persistent Hypotension, Renal Dysfunction, and Acute Decompensated Heart Failure

1. Reassess to further optimize pharmacologic care with diuretics and inotropes.
2. Consider ultrafiltration but acknowledge risks for renal deterioration and catheter-related and/or anticoagulation-related complications.
3. Begin cautious extracorporeal ultrafiltration, especially if patient's condition is refractory to pressors:
   a. Intermittent slow ultrafiltration, when hypotension does not preclude adequate fluid removal over typically 4- to 6-hour sessions
   b. Continuous ultrafiltration, when equipment is available and patient becomes hypotensive or has worsening renal function with intermittent treatment sessions

ACE, Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *CKD,* chronic kidney disease.

As with any rapid use of newly placed PD catheters, patients with acute HF have increased risk for early fluid leaks and peritoneal infection. In addition, PD-induced electrolyte disturbances (e.g., hypokalemia or hypomagnesemia) may worsen rhythm control if not monitored and addressed appropriately. Because approximately half of PD ultrafiltration occurs through aquaporins, PD removes less sodium for a given ultrafiltration volume than hemofiltration. Large peritoneal fluid volumes also can potentially compromise respiration, which can be avoided by more frequent lower volume exchanges via automated cyclers.

Overall the studies suggest that chronic PD in HF has an acceptably low rate of complications and is well tolerated (i.e., the morbidity of HF has not been substituted with morbidity from PD), but no beneficial effect on mortality has been shown.[24] In practice, PD for HF is most commonly advocated as a chronic treatment, with pharmaceutical and extracorporeal methods used as initial strategies for acute decompensation.

Conventional Hemodialysis or Hemofiltration

There is extensive experience with intermittent hemodialysis techniques for fluid removal in HF, using temporary or tunneled dual-lumen catheters (see Chapter 91). Arteriovenous fistulas or grafts are often precluded because their high flow rates may further compromise cardiac function. Technical approaches include isolated UF (see Chapter 93) or traditional dialysis techniques when electrolyte disorders are already present. Many patients with unstable HF will not tolerate removal of 2 or more liters during typical 2- to 4-hour treatment times. Dialysis-related hypotension will prevent further fluid removal and can induce acute kidney injury (AKI), potentially making the patient dialysis-dependent. The key to hemodynamic stability may be to dramatically slow the UF rate (see later) using longer or continuous treatment modalities (e.g., slow extended-duration isolated UF, continuous venovenous hemofiltration). However, the literature lacks reports on larger groups of patients treated with such techniques, homogenous patient populations, appropriate control groups, well-defined outcome measures, and strict treatment protocols.

Setting the Rate of Fluid Removal

The key concept is to avoid intravascular fluid depletion by ensuring the UF rate does not exceed the rate at which the vascular plasma compartment is being refilled from interstitial spaces. The plasma refill rate can vary over the course of fluid removal because it is dependent on Starling forces (generated by the plasma oncotic pressure and the gradient between interstitial and vascular hydrostatic pressures) and the permeability of vascular basement membranes. If the UF rate exceeds the plasma refill rate, hemoconcentration, hypovolemia, hypotension, and decreased renal perfusion and function develop. Equipment that optically monitors hemoconcentration or bioimpedance vector analysis can be used to guide UF in patients with refractory HF, although the optimal way to use these technologies has yet to be elucidated.

Effect of Extracorporeal Ultrafiltration on the Pathophysiology of Heart Failure

In a report of 24 patients with refractory HF, removal of up to 4 liters of fluid in a few hours[28] did not affect plasma volume—that is, UF matched the plasma refill rate. Even at 24 hours after the procedure the patients had reduced right atrial, pulmonary artery, and wedge pressures; increased stroke volume; stable heart rates and systemic vascular resistance; and improved responsiveness to diuretics. Despite intravascular volume contraction, UF could decrease levels of norepinephrine, aldosterone, and renin in HF patients.[29] In contrast to diuretics alone, UF reduced systemic levels of inflammatory cytokines and perhaps improved exercise capacity and pulmonary function. Finally, the isotonic fluid removal with UF would be expected to remove more sodium than the hypotonic losses associated with diuretics.

Effect of Extracorporeal Ultrafiltration on Renal Function

It has been proposed that the benefits of UF for renal function occur predominantly in patients with low urine output (<1 l/day), in whom UF reverses the RAAS and SNS activation, thereby improving renal perfusion and GFR and restoring sensitivity to diuretics.[30] In contrast, in HF patients with a mean baseline GFR of 48 ml/min and preserved diuretic sensitivity, there were no significant differences in the kidney parameters before or after 2 days of either UF or intravenous diuretic therapy.[31] Although there are encouraging (but not unanimous) reports of renal function improving after UF, clinicians should target fluid removal rates that avoid a significant fall in GFR or worsen renal hemodynamics.[32,33]

Recent Advances in Extracorporeal Techniques

The barriers of extended treatment times and the need for one-to-one supervision by nurses have been overcome with commercially available modern devices dedicated to isolated UF. These devices have small extracorporeal blood volumes (<100 ml), allow blood flow rates low enough (<50 ml/min) to permit use of temporary peripheral or central venous catheters, and have preassembled tubing for one-step loading, computerized simple user interfaces with embedded help screens, remote monitoring capabilities, and miniaturization for portability. Treatment times range from 6 h/day to continuous treatment over multiple days. A feasibility study[34] demonstrated that 16- to 18-gauge catheters could deliver blood at up to 40 ml/min, resulting in up to 3.7 liters of UF over approximately 7 hours. In another study[35] of 20 patients with decompensated HF and serum creatinine levels of at least 1.5 mg/dl (132 μmol/l) and/or diuretic resistance, more than 8 liters of fluid was removed. Patients were discharged earlier without changes in GFR and had improved HF scores; some had resolution of hyponatremia and fewer readmissions. In the Relief for Acutely Fluid-Overloaded Patients with Decompensated Congestive Heart Failure (RAPID-CHF) trial on 40 patients, UF did not significantly affect weight loss but did improve fluid removal and symptoms compared with usual care.[36] However, two subsequent large prospective studies did not demonstrate these benefits.

In the UNLOAD trial (Ultrafiltration Versus Intravenous Loop Diuretics for Patients Hospitalized for Acute Decompensated Congestive Heart Failure), 200 HF patients were randomized to early UF or intravenous diuretics and followed for 90 days.[32] The UF achieved by the study was 241 ml/h for 12.3 ± 12 hours, which led to a weight reduction of 5.0 ± 3.1 kg over the 2 days, approximately 2 kg more than those in the diuretic group. Although dyspnea was improved in those undergoing UF at 8 hours, there was no difference in dyspnea or renal outcomes at 48 hours. At 90 days the UF group had fewer total rehospitalizations, rehospitalization days, and unscheduled office and emergency department visits, but the study was not powered to allow conclusions on these clinical end-points. Potential weaknesses of the study design included sponsorship by the manufacturer, submaximal medical therapy in the diuretic group, and uncertainties regarding posthospitalization care and readmission. In the CARRESS-HF[37] (Cardiorenal Rescue Study in Acute Decompensated Heart Failure) trial, 188 patients with cardiorenal syndrome were compared at 96 hours after randomization to a protocol of stepped drug therapy (sequential use of diuretics, intravenous inotropes, nesiritide, and nitroglycerin) or extracorporeal UF at a fixed rate of 200 ml/h. UF did not improve weight loss, dyspnea, well-being scale scores, or diuretic dose, and the UF group (but not the pharmacologic group) experienced a decline in GFR. At 60 days there were no differences in mortality, emergency visits, or rehospitalizations between

groups. It remains unclear whether these disappointing findings for UF can be extrapolated to all such patients and methodologies; CARRESS-HF enrolled only patients with HF-related AKI, and most UF was accomplished early in the protocol, with a mean duration of only 40 hours compared with the pharmacologic care over 96 hours. Thus it remains possible that alternative protocols with slower or more prolonged UF might have demonstrated more benefit. Furthermore, a large proportion of patients in the UF group (10%) did not receive the randomized treatment for various reasons, and 30% in this group also received intravenous diuretics after UF had ceased.

The AVOID-HF[38] (Aquapheresis Versus Intravenous Diuretics and Hospitalization for Heart Failure) trial was initially designed to include 810 hospitalized patients with acute HF but, because of slow recruitment, was terminated after just 224 patients had been enrolled. Similar to UNLOAD, the AVOID-HF trial compared early flexible UF therapy to a pharmacologic treatment that was similar to the algorithm used in CARRESS-HF. The net fluid loss was again found to be greater in the UF group than the diuretics (12.9 vs. 8.9 liters) without any adverse impact on renal function. The patients in the UF arm showed a nonsignificant trend toward better outcomes such as higher estimated number of days to first HF event.

A meta-analysis[39] that pooled results from seven randomized controlled trials (771 patients) concluded that UF therapy is associated with more efficient fluid removal and more pronounced reduction in patient weight compared with medical therapy and might also have a salutary effect on reducing the rate of rehospitalization for HF. This efficacious decongestion does not seem to be at the cost of increasing the incidence of renal dysfunction or mortality. However, given the limitations of prior trials, important questions remain about the potential benefits of UF in acute HF and further studies are needed. Based on the currently available data, use of ultrafiltration can be recommended in patients with severe fluid overload and suboptimal response to medical therapy, especially if they have a history of frequent hospital admissions for heart failure.

Safety and Risks of Extracorporeal Therapies

In CARRESS-HF,[37] UF-related complications included catheter exit-site hemorrhage and systemic infection. Similarly, a higher number of patients in the UF arm of AVOID-HF experienced "serious adverse events deemed to be related to the study therapy" (e.g., gastrointestinal bleeding and hematuria) compared with the diuretic arm. More patients in that group also experienced an "adverse event of special interest" such as symptomatic hypotension necessitating intervention, central line–associated bloodstream infection, and bleeding requiring transfusion. However, in the UNLOAD trial,[32] UF therapy proved very safe. The machines dedicated to isolated UF have an added margin of safety conferred by low rates of filtration and blood flow, as well as more robust automated monitoring software. Nevertheless, all complications that can occur in hemodialysis therapies are of course also relevant for HF patients receiving isolated UF (see Chapter 96).

SUMMARY

Despite long-standing evidence concerning the pathophysiology of fluid overload in HF and adverse neurohumoral effects from diuretics, it has been difficult to reach a consensus on the benefits or techniques of UF or diuretic therapy. PD appears to have a role in chronic HF care, especially for individuals whose management is complicated by CKD. For acutely decompensated HF, recent evidence suggests that protocolized stepped pharmacologic care can be efficacious and safer than rapid UF; however, it remains to be determined whether there can be benefits from alternative extracorporeal protocols.

SELF-ASSESSMENT QUESTIONS

1. What is the main contributing mechanism for the development of renal failure in acute heart failure (HF)?
   - **A.** Decreased renal blood flow
   - **B.** Increased central and renal venous pressure
   - **C.** A and B
   - **D.** Increased renin-angiotensin-aldosterone system (RAAS) activation
2. The established therapy in patients with acute decompensated HF and renal dysfunction is:
   - **A.** Ultrafiltration
   - **B.** High-dose intravenous and continuous diuretic therapy
   - **C.** Low-dose intravenous bolus therapy
   - **D.** No established therapy for these patients has been shown to improve outcome.
3. In the management of HF:
   - **A.** Ultrafiltration by peritoneal dialysis is most efficacious when used for acute HF.
   - **B.** Compared with pharmacologic care in acute HF, extracorporeal ultrafiltration has reduced mortality.
   - **C.** Vasopressin antagonists reduce HF mortality and morbidity.
   - **D.** Hemoconcentration is an indicator of plasma refill during ultrafiltration.
4. What is the next step in pharmacologic therapy for a 65-year-old man who has a history of HF with reduced ejection fraction who is already receiving an angiotensin-converting enzyme (ACE) inhibitor, β-blocker, and mineralocorticoid receptor antagonist, is in sinus rhythm, and has an estimated glomerular filtration rate greater than 30 ml/min/1.73 m^2?
   - **A.** Add digoxin
   - **B.** Add angiotensin II receptor blocker therapy
   - **C.** Replace ACE-inhibitor with sacubitril/valsartan
   - **D.** Replace β-blocker with ivabradine

73

Hepatorenal Syndrome

Javier Fernández, Vicente Arroyo

DEFINITION

Hepatorenal syndrome (HRS) is a potentially reversible functional renal failure that occurs in patients with acute or chronic liver disease, advanced hepatic failure, and portal hypertension. Although it may occur in patients with subacute liver failure or severe acute alcoholic hepatitis, it is mainly observed in patients with advanced cirrhosis. HRS is characterized by impaired renal function and marked abnormalities in the arterial circulation and endogenous vasoactive systems. In the kidney, there is pronounced vasoconstriction resulting in low glomerular filtration rate (GFR). In the splanchnic circulation, there is marked arteriolar vasodilation resulting in reduction of systemic vascular resistance and arterial hypotension.[1-3] Along with cardiocirculatory dysfunction secondary to portal hypertension, systemic inflammation also seems to play a major role in the pathogenesis of HRS.[4] Two forms of HRS can be identified on the basis of the progression of the disease (Box 73.1). The acute form (type 1 HRS) is characterized by an acute and rapid deterioration in renal function that occurs in the setting of multiorgan failure (acute-on-chronic liver failure [ACLF]), whereas the chronic form (type 2) has an insidious onset and is characterized by moderate renal failure that follows a steady or slowly progressive course.[1-3]

PSEUDOHEPATORENAL SYNDROME

Pseudohepatorenal syndrome describes concurrent hepatic and renal dysfunction secondary to a wide variety of infectious, systemic, circulatory, genetic, and other diseases and after exposure to a variety of drugs and toxins (Table 73.1).[5] These entities must be excluded before the diagnosis of HRS can be established. In these conditions, the liver does not play a causative role in the pathogenesis of renal failure. Pseudohepatorenal syndrome is usually easy to exclude because the causative agent is frequently known and both renal and liver functional abnormalities are often found at first clinical presentation, when there is no evidence of advanced liver failure and portal hypertension. In contrast, HRS invariably occurs after liver failure and portal hypertension are fully established and frequently develops when the patient is undergoing treatment for these conditions or their complications.

PATHOPHYSIOLOGY AND PATHOGENESIS

Circulatory Dysfunction: Renal and Systemic Hemodynamic Changes

In HRS, reduction in GFR occurs mainly because of renal cortical hypoperfusion after intense cortical renal vasoconstriction, which can be demonstrated angiographically as marked beading and tortuosity of the interlobular and proximal arcuate arteries and the absence of a distinct cortical nephrogram and vascular filling of the cortical vessels (Fig. 73.1). Intense renal vasoconstriction is the final consequence of marked systemic circulatory dysfunction, characterized by progressive splanchnic arterial vasodilation, reduction of the effective arterial blood volume, hypotension, and homeostatic activation of the vasoconstrictor systems.[3] This further compromises renal perfusion because intense renal vasoconstriction results in blunting of the autoregulation of renal blood flow, so that renal perfusion becomes more pressure dependent. In HRS, filtration fraction is also reduced, reflecting a dominant increase in afferent arteriolar tone and a decrease in the ultrafiltration coefficient. Serial systemic hemodynamic studies showed that HRS occurs in the setting of reduced mean arterial pressure (MAP), cardiac output, and wedge pulmonary pressure without change in systemic vascular resistance. These findings suggest that an inability to increase cardiac output to compensate for a decrease in preload (secondary to the accentuation of splanchnic arterial vasodilation) also contributes to the pathogenesis of HRS.[6] Vasoconstriction is not confined to the renal vascular bed. In HRS it is also observed in other extrasplanchnic territories, including the liver, brain, muscle, and skin.[2,3]

Neurohumoral Abnormalities

The renal and systemic hemodynamic changes that characterize HRS are a direct consequence of neurohumoral disturbances.[2,3] Activation of the vasoconstrictor systems (the renin-angiotensin-aldosterone system [RAAS], the sympathetic nervous system [SNS], and vasopressin) is the cause of renal vasoconstriction; meanwhile, activation of the vasodilator systems occurs mainly in the splanchnic circulation and leads to splanchnic vasodilation. Increases in the serum and urinary levels of vasoconstrictors and in the plasma level of vasodilators are observed in patients with HRS. The vasoconstrictors include renin, norepinephrine, neuropeptide Y, arginine vasopressin, endothelin and F_2 isoprostanes, and urinary cysteinyl leukotrienes; the vasodilators include plasma endotoxin, nitrite and nitrate (end-product of nitric oxide [NO] metabolism), and glucagon. The sympathetic discharges through the renal nerves are also markedly increased.

In contrast to increased plasma and urinary levels of vasoconstrictors and plasma level of vasodilators, decreased urinary levels of vasodilators have been observed in HRS. These include prostaglandin E_2, 6-keto-prostaglandin F_1 (a stable metabolite of renal prostacyclin), and kallikrein. Because the urinary level of these vasodilators is normal in compensated cirrhosis and higher than normal in decompensated cirrhosis with ascites and normal renal function, it is postulated that a reduction in the renal synthesis of renal vasodilators is the final event that leads to the development of HRS.[3]

BOX 73.1 Main Clinical Characteristics of Type 1 and Type 2 Hepatorenal Syndrome

Type 1 HRS

- Acute and rapid deterioration in renal function (serum creatinine rise ≥ 2.5 mg/dl or 220 μmol/l in <2 weeks)
- Occurs in parallel with the failure of other organs or systems (e.g., coagulopathy, hepatic encephalopathy)
- In cirrhosis, is a form of acute-on-chronic liver failure
- Frequently follows a precipitating event, mainly bacterial infection
- Rapidly fatal without treatment: Mean survival 2 to 3 weeks

Type 2 HRS

- Moderate stable renal impairment (average serum creatinine 2 mg/dl [176 μmol/l])
- Mainly causes refractory ascites
- Mean survival without treatment: 6 months

HRS, hepatorenal syndrome.

Most of these neurohumoral abnormalities found in HRS are also detected, albeit to a lesser extent, in decompensated cirrhosis (with ascites) with normal renal function and in compensated cirrhosis (without ascites). These findings support the hypothesis that HRS most likely represents one end of the spectrum of homeostatic abnormalities that occur in liver failure and portal hypertension.

Systemic Inflammation

HRS is often precipitated by bacterial infections, particularly when they trigger a severe inflammatory response.[3] This feature suggests that inflammation may represent an important pathogenic factor for HRS. There is now evidence that type 1 HRS is part of a complex syndrome (ACLF) characterized by multiorgan and/or system failure (kidneys, liver, brain, heart, peripheral circulation, gut, lungs, adrenal glands, defensive mechanisms against infections).[4,7] The mechanism of ACLF has been related to a systemic inflammatory response syndrome, activation of cytokines, NO, and other mediators, acute deterioration of systemic circulation, and organ failure. Systemic inflammation in cirrhosis mainly derives from the translocation of viable bacteria and/or pathogen-associated molecular patterns from the intestinal lumen into the intestinal mucosa and the systemic circulation with or without overt bacterial infection. The subsequent sustained activation of innate host immunity leads to the release of proinflammatory cytokines and oxidative stress that impair cardiovascular function and could also damage the kidney and other organs, impairing their function.[4]

Summary of Pathogenetic Events

Fig. 73.2 shows the pathogenesis of HRS. Liver failure and portal hypertension through pathologic bacterial translocation and endotoxemia increase systemic inflammation and vascular production of vasodilators, including NO, carbon monoxide, and glucagon in the splanchnic circulation, leading to the initiating event of splanchnic arteriolar vasodilation (the peripheral arterial vasodilation hypothesis). Splanchnic vasodilation leads to a decrease in systemic vascular resistance, but MAP is initially maintained by an increase in cardiac output, resulting in a hyperdynamic circulation. Splanchnic vasodilation also decreases arterial filling and reduces the effective arterial blood volume. The subsequent stimulation of the central volume baroreceptors leads to compensatory activation of the vasoconstrictor systems, in particular the arginine vasopressin system, RAAS, and SNS (including its hormones norepinephrine and neuropeptide Y), which help restore effective arterial blood volume. This restoration is achieved in patients with compensated cirrhosis but not in patients with decompensated cirrhosis, in whom progressive splanchnic arteriolar vasodilation leads to increased splanchnic capillary pressure, resulting in an increase in lymph formation that exceeds reabsorption capacity. In parallel, further contraction of the effective arterial blood volume leads to reduction of systemic MAP and further stimulation of the vasoconstrictor systems, resulting in sodium and water retention. The net result of these combined effects is continuous ascites formation (the forward theory of ascites formation).[2,3]

The splanchnic circulation is resistant to the effects of vasoconstrictors because of local release of vasodilators; progressive splanchnic vasodilation continues to occur as liver failure and portal hypertension progress. This leads to continued contraction of effective arterial blood volume, which, together with the progressive inability of the cirrhotic heart to respond to reduced preload, results in further reduction of MAP and more intense stimulation of the vasoconstrictor systems. Normally, the effect of vasoconstrictors on the renal circulation is counterbalanced by the reactive production of intrarenal vasodilators. It is

TABLE 73.1 Causes of Pseudohepatorenal Syndrome

Potential Causes	Predominantly Tubulointerstitial Involvement	Predominantly Glomerular Involvement
Infections	Sepsis, leptospirosis, brucellosis, tuberculosis, Epstein-Barr virus, hepatitis A virus	Hepatitis B and C viruses, HIV infection, *Schistosoma mansoni,* liver abscess
Drugs	Tetracycline, rifampin, sulfonamide, phenytoin, allopurinol, fluroxene, methotrexate (high dose), acetaminophen overdose	
Toxins	Carbon tetrachloride, trichloroethylene, chloroform, elemental phosphorus, arsenic, copper, chromium, barium, amatoxins,* raw carp bile toxins†	
Systemic diseases	Sarcoidosis, Sjögren syndrome	Systemic lupus erythematosus, vasculitis, cryoglobulinemia, amyloidosis
Circulatory failure	Hypovolemic or cardiogenic shock	
Malignancy	Lymphoma, leukemia	
Congenital and genetic disorders	Polycystic liver and kidney disease, nephronophthisis, congenital hepatic fibrosis	
Miscellaneous	Fatty liver of pregnancy, Reye syndrome	Eclampsia, HELLP syndrome,‡ cirrhotic glomerulopathy

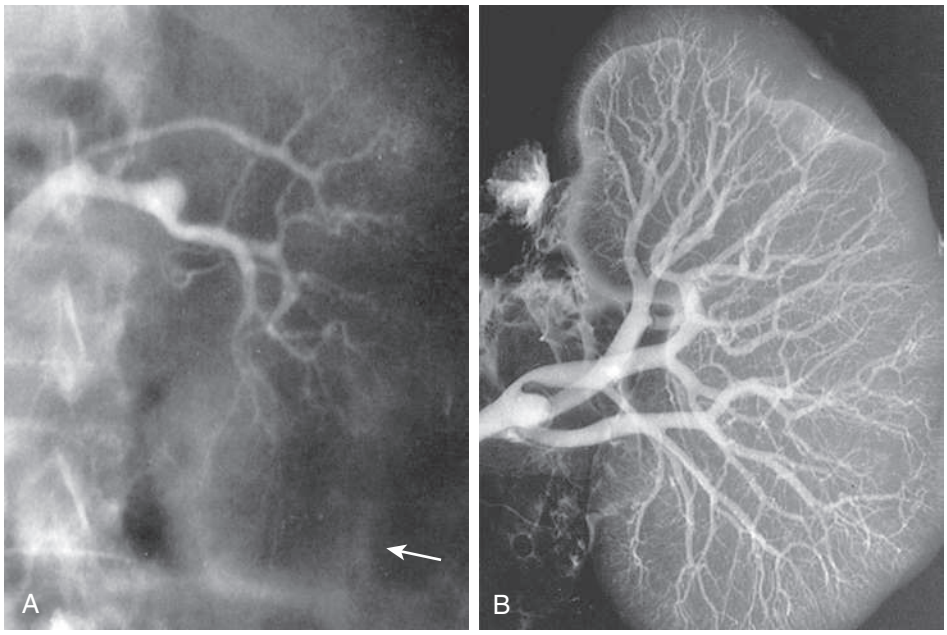

Fig. 73.1 Renal arteriography of a patient with hepatorenal syndrome (HRS). (A) Renal angiogram (the *arrow* marks the edge of the kidney). (B) The angiogram carried out in the same kidney at autopsy. Note complete filling of the renal arterial system throughout the vascular bed to the periphery of the cortex. The vascular attenuation and tortuosity seen previously (A) are no longer present. The vessels are also histologically normal. This indicates the functional nature of the vascular abnormality in HRS.[5]

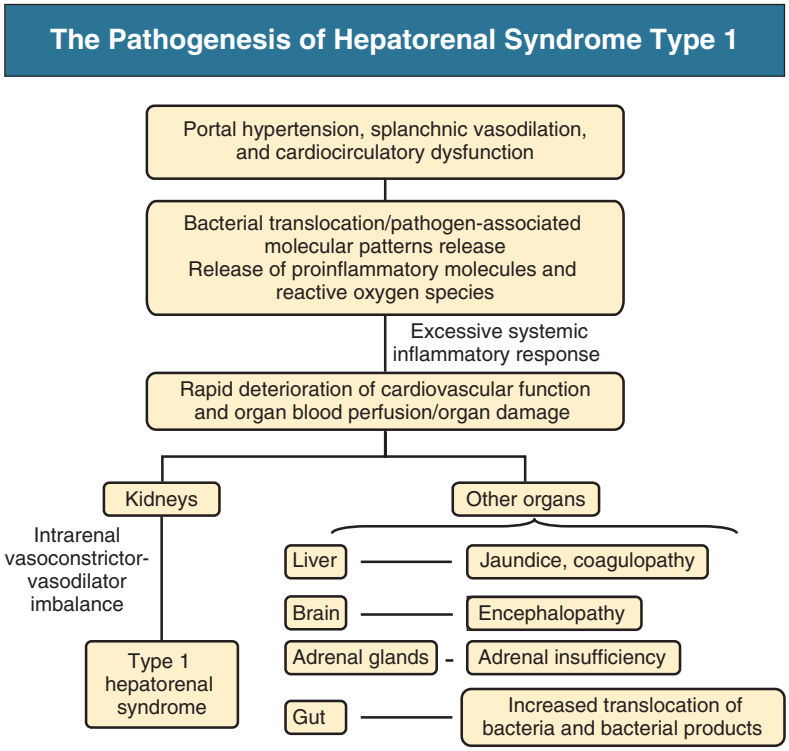

Fig. 73.2 The pathogenesis of hepatorenal syndrome *(HRS).* Mechanisms leading to type 1 HRS and multiorgan failure. Patients with cirrhosis and ascites present a severe cardiocirculatory dysfunction that may be further aggravated by infection. Although circulatory dysfunction predominantly affects the kidneys and leads to the development of type 1 HRS, it also decreases the perfusion of other organs and systems such as the liver, with marked impairment in hepatic function and aggravation of portal hypertension; the brain, with the development of hepatic encephalopathy; the adrenal glands, with the development of relative adrenal dysfunction; and the gut, decreasing intestinal motility and promoting intestinal bacterial overgrowth and bacterial translocation.[2,3]

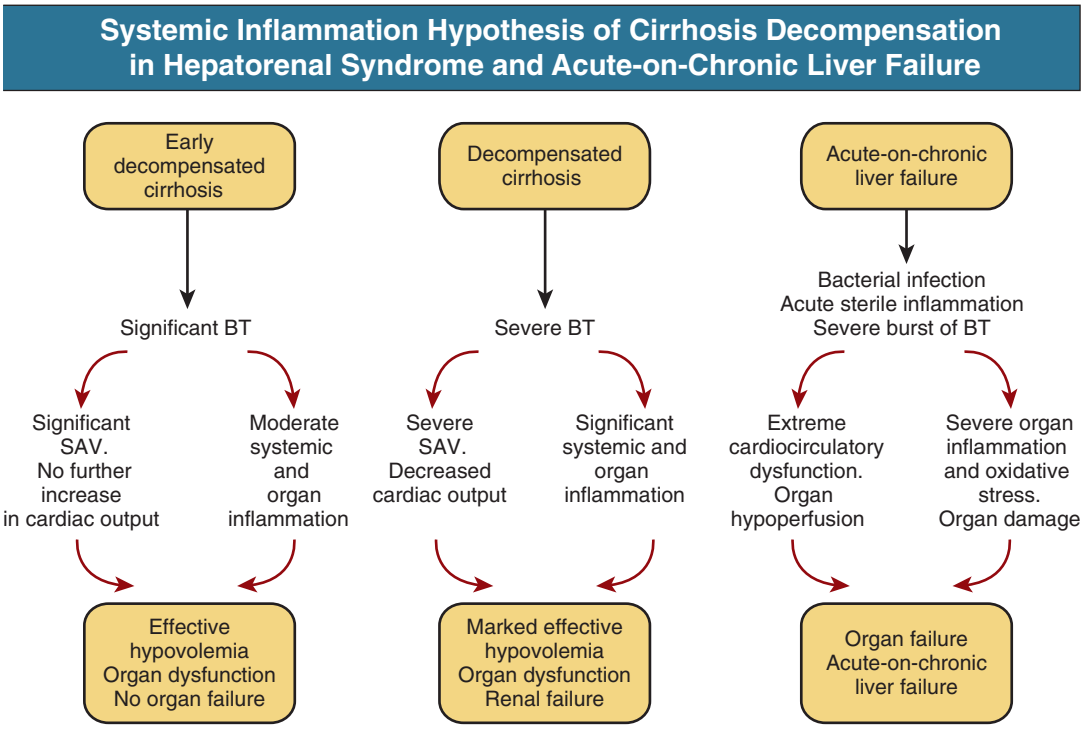

Fig. 73.3 Systemic inflammation hypothesis of cirrhosis decompensation in hepatorenal syndrome and acute-on-chronic liver failure *(ACLF).* According to the systemic inflammation hypothesis, bacterial translocation *(BT)* progressively affects the natural course of cirrhosis, from the compensated stage to hepatorenal syndrome and ACLF. An abrupt increase in systemic inflammation represents the pathophysiologic background for ACLF.[4] *SAV,* splanchnic arterial vasodilation.

postulated that HRS develops when the balance of activities between the renal vasoconstrictors and intrarenal vasodilators finally breaks down. The likelihood that this will occur increases with progressive or acute deterioration in liver function or increasing severity of portal hypertension (e.g., after acute alcoholic hepatitis) and is precipitated by events that lead to further volume contraction and reduction of the effective arterial blood volume (e.g., spontaneous bacterial peritonitis [SBP]; see later discussion).

Recently the peripheral arterial vasodilation hypothesis has been revisited. This hypothesis does not consider that patients with advanced cirrhosis frequently develop multiorgan failure (ACLF), a syndrome characterized by systemic inflammation and high short-term mortality.[4,7] The sustained activation of the innate immune system caused by an abnormal translocation of bacteria and bacterial products from the intestinal lumen (pathogen-associated molecular patterns) would lead to the persistent activation of the innate pattern recognition receptors and subsequent chronic inflammation. This inflammatory process would have two major consequences: first, splanchnic arterial vasodilation secondary to local release of endogenous vasodilators, a feature impairing systemic hemodynamics and organ perfusion, and second, the extension of splanchnic inflammation to the peripheral blood and organs, a feature that could damage these organs, contributing to multiple organ failure (Fig. 73.3).[4]

EPIDEMIOLOGY

The incidence of HRS in the cirrhotic patient is estimated to be 18% at 1 year and 39% at 5 years.[8] Neither the cause nor the Child-Pugh score or the model for end-stage liver disease (MELD) score (www.mdcalc.com/child-pugh-score-for-cirrhosis-mortality/) predicts the incidence of HRS. Rather, independent predictors of HRS include dilutional hyponatremia, impairment in systemic hemodynamics (high plasma renin activity, noradrenaline concentration, and low cardiac output),[6,8] and abnormal renal duplex Doppler ultrasound study findings (resistive index >0.7),[9] and low GFR.[3]

CLINICAL MANIFESTATIONS

Type 1 and type 2 HRS are considered to be different syndromes rather than different expressions of a common underlying disorder.[2,3] Type 1 HRS is characterized by a rapid decline in renal function (see Box 73.1) and is observed in patients with acute decompensation of advanced cirrhosis, severe acute alcoholic hepatitis, or subacute liver failure. In addition to developing rapidly progressive acute kidney injury (AKI), patients also develop multiorgan dysfunction, including severe hepatic failure (jaundice, coagulopathy), brain failure (hepatic encephalopathy), and frequently relative adrenal insufficiency. Hyponatremia is almost always present, and arterial blood pressure is usually low. Type 1 HRS may be precipitated by bacterial infections (especially spontaneous bacterial peritonitis), severe gastrointestinal bleeding, or total paracentesis without albumin administration. Left untreated, type 1 HRS tends to run a rapid and progressive downhill course, resulting in death of the patient within 2 to 3 weeks.[8]

Type 2 HRS is characterized by insidious onset and slowly progressive deterioration of renal function. This is most often observed in patients with cirrhosis and portal hypertension. These patients tend to be less severely jaundiced and mainly present with refractory ascites caused by poor response to diuretics. Low-normal arterial blood pressure, modest prolongation of prothrombin time, and moderate or marked hypoalbuminemia and hyponatremia are usually present. Type 2 HRS tends to run a slowly progressive downhill course over months, which most likely reflects the natural course of the disease because additional

precipitating factors are not usually identified.[2,3,8] Mean survival time after onset of type 2 HRS is 6 months.

PATHOLOGY

HRS is a functional renal disorder, and the presence of significant glomerular and/or tubular disease excludes the diagnosis. However, glomerular abnormalities, including mesangial expansion, capillary wall thickening, mesangial and capillary wall electron-dense deposits, and immune deposits of C3 and immunoglobulin A (IgA), IgM, and IgG, are frequently found in cirrhotic patients with normal renal function and minimal urinary abnormalities. The presence of such glomerular abnormalities in a cirrhotic patient, therefore, does not exclude the diagnosis of HRS. Protrusion of the proximal tubular epithelium into the Bowman space (glomerulotubular reflux) is not specific for HRS and is found in other conditions associated with profound renal ischemia and terminal hypotension. Although early autopsy studies demonstrated normal tubular morphology in patients who had died of HRS, detailed light and electron microscopic studies have documented proximal tubular lesions consistent with ischemic injury. However, these lesions do not explain the low GFR in HRS patients.[3]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of HRS is mainly one of exclusion and should be suspected in any patient with subacute or chronic liver disease with advanced liver failure and portal hypertension who develops progressive renal impairment. In patients with preexisting liver failure, portal hypertension, and renal failure, the use of nephrotoxic agents (e.g., nonsteroidal antiinflammatory drugs [NSAIDs] and aminoglycosides) must be stopped, and other conditions leading to renal failure must be excluded by careful history, physical examination, urine examination, and ultrasound study before the diagnosis of HRS can be considered. The absence of shock or gastrointestinal bleeding and excess gastrointestinal, peritoneal, or renal fluid loss also must be documented. Prerenal AKI must be excluded by withdrawal of diuretics and fluid challenge either with 1.5 liters of normal saline or preferably with albumin 1 g/kg body weight per day up to the maximum of 100 g/day for 2 days. Absence of microhematuria and proteinuria of less than 500 mg/day helps exclude significant coexisting glomerular or tubulointerstitial disease leading to renal failure and support the diagnosis of HRS.

The diagnostic criteria for HRS were established by the International Ascites Club in 1996[1] and were revised in 2007.[10] The main changes in the more recent criteria include the exclusion of creatinine clearance as a measure of renal function because of the difficulty in obtaining accurate urine collection data, the removal of ongoing bacterial infection as an exclusion criterion so that treatment of HRS is not delayed in these patients, the substitution of saline with albumin as the preferred fluid for plasma volume expansion, and the removal of the minor criteria. Another relevant change in the diagnostic criteria for HRS is the removal of a fixed cut-off value of serum creatinine (>1.5 mg/dl [132 µmol/l], >2.5 mg/dl [220 µmol/l] in cases of type 1 HRS). The remaining criteria are maintained (Box 73.2).[11] Consequently, patients with initial AKI stage 2 or 3 or with progression of the initial stage of AKI despite appropriate medical therapy fulfilling all other diagnostic criteria of HRS can be treated with vasoconstrictors plus albumin, irrespective of the value of serum creatinine. The potential advantage of the new diagnostic algorithm is that it may allow earlier treatments of type-1 HRS, and possibly better outcomes.

Serum creatinine concentration and blood urea nitrogen (BUN) are poor markers of GFR in cirrhosis.[3] Patients with cirrhosis may have significant renal impairment despite normal serum creatinine or BUN concentration values because they are frequently malnourished, with reduced lean body mass, and often have a low urea generation rate because of liver failure and low protein intake. Severe hyperbilirubinemia, which is often present in patients with HRS, interferes with the Jaffe reaction (picric acid) for creatinine quantification and may cause falsely low results. Enzymatic creatinine assays are less susceptible to high bilirubin levels. In cases of uncertainty, GFR may be assessed with use of iodine-125–iothalamate or chromium-51–labeled ethylenediaminetetraacetic acid (^{51}Cr-labeled EDTA). Small studies suggest that serum cystatin C could be an accurate GFR marker in the cirrhotic population.[12] However, the utility of serum cystatin C for assessing GFR in cirrhosis needs to be confirmed.

The most important differential diagnosis for renal failure in cirrhosis is between type 1 HRS and "true" AKI with tubular damage (acute tubular necrosis [ATN]) because they require rapid therapeutic decisions with different treatments. The parameters traditionally used to differentiate ATN from functional renal failure (urinary sodium excretion and urinary-plasma osmolality ratio) are of no value in patients with cirrhosis and ascites.[3] Granular casts may be found in the urinary sediment in both HRS and ATN. Recent data suggest that the determination of the neutrophil gelatinase–associated lipocalin (NGAL) level, a urinary biomarker of tubular damage, could be of help to differentiate these two entities.[13] However, further studies are needed to confirm this finding because these biomarkers also can be increased in prerenal acute injury[14] and HRS can progress to ATN.

BOX 73.2 Diagnostic Criteria Hepatorenal Syndrome According to the International Club of Ascites

- Cirrhosis with ascites
- Diagnosis of acute kidney injury (AKI) according to the ICA-AKI criteria
- No improvement in serum creatinine after at least 2 days of diuretic withdrawal and plasma volume expansion with albumin (1 g/kg of body weight)
- Absence of shock
- No current or recent treatment with nephrotoxic drugs (nonsteroidal antiinflammatory drugs, aminoglycosides, iodinated contrast media, etc.)
- Absence of structural kidney injury as indicated by proteinuria greater than 500 mg/day, microhematuria (>50 red blood cells per high-power field), and/or abnormal renal ultrasound findings.

From reference 11.
ICA, International Club of Ascites.

NATURAL HISTORY

Without treatment, the median survival rate for type 1 HRS is about 2 weeks; that of type 2 HRS is about 4 to 6 months.[3,8] Patients with type 1 HRS usually die in the setting of multiple organ failure and are now considered to have ACLF, a syndrome recently redefined and characterized by the presence not only of organ failure(s) and high mortality rate but also of systemic inflammation.[7] Severe hepatic encephalopathy, gastrointestinal bleeding, and sepsis are common final events in these patients. Patients with type 2 HRS are at higher risk for type 1 HRS after the development of a precipitating event.[3]

PREVENTION AND TREATMENT

General Principles in the Prevention of AKI

In patients with cirrhosis and ascites, excessive diuretic therapy results in volume contraction and AKI. To avoid the latter, a stepwise approach to the treatment of ascites is recommended. All patients are advised to

have bed rest and follow a low-sodium diet (60 to 90 mmol/day, equivalent to about 1.5 to 2 g of salt per day). After this, spironolactone is prescribed at increasing doses (100 mg/day as initial dose; if there is no response within 4 days, 200 mg/day). If required, furosemide is then added at increasing doses every 2 days of 40 to 80 mg/day. Maximum doses of spironolactone and furosemide are 400 and 160 mg/day, respectively. In patients with diuretic resistance, therapeutic paracentesis is indicated but must be combined with plasma volume expansion with use of albumin (8 g/l of ascites removed) to decrease the incidence of circulatory dysfunction after treatment and to prevent development of HRS. The use of renin-angiotensin system blockers as well as potentially nephrotoxic agents, including NSAIDs, aminoglycosides, and radiocontrast media, should be avoided as much as possible.[2,3] β-Blockers, used for primary or secondary prophylaxis of variceal bleeding, reduce MAP and GFR and must be used cautiously in patients with cirrhosis and ascites. Renal function should be closely monitored, especially in patients with refractory ascites. β-Blockers may increase short-term mortality in this specific cirrhotic subpopulation and should therefore be replaced by band ligation of varices.[15]

Preventive Measures

Accepting the hypothesis that HRS represents one end of the spectrum of the homeostatic abnormalities in liver failure and portal hypertension and that it is precipitated by clinical events as volume contraction or bacterial infection, it follows that a major focus of treatment must be to prevent such events and to treat them promptly when they occur. There should be a low threshold for antibiotic therapy for suspected infection in cirrhosis. Spontaneous bacterial peritonitis must be excluded by regular examination of ascites whenever a patient is admitted to the hospital or clinically deteriorates. This infection must be treated not only with broad-spectrum antibiotics but also with albumin infusion (1.5 g/kg at diagnosis and 1 g/kg at day 3) because the latter prevents the subsequent development of HRS and improves short-term survival.[16] Primary prophylaxis with norfloxacin has been shown to prevent SBP, delay the development of HRS, and improve survival in cirrhotic patients at high risk for complications (low ascitic protein level <15 g/l; advanced liver failure with Child-Pugh score ≥9 and serum bilirubin ≥3 mg/dl or impaired renal function with serum creatinine ≥1.2 mg/dl or serum sodium ≤130 mmol/l).[17] Norfloxacin is thought to exert its renoprotective effect by reducing the subclinical translocation of viable bacteria and bacterial products from the intestine, systemic inflammation, and NO generation, which in turn leads to improved hemodynamics. Prophylactic use of pentoxifylline 400 mg orally three times per day also prevents the development of HRS in patients with acute alcoholic hepatitis, probably by inhibiting the synthesis of tumor necrosis factor-α.[18]

General Approach to Treatment

In patients with preexisting liver failure, portal hypertension, and renal failure, nephrotoxic agents must be stopped. The absence of shock or gastrointestinal bleeding, as well as excess gastrointestinal, peritoneal, or renal fluid loss must be documented. Prerenal AKI must be excluded by withdrawal of diuretics and fluid challenge either with normal saline or preferably with albumin. Absence of microhematuria and proteinuria also should be confirmed.

Once HRS has been diagnosed, patients should be assessed for orthotopic liver transplantation (OLT). Suitable candidates should be placed on the waiting list for deceased donor or, if possible, living donor liver transplantation. Bridge treatments are also needed. Pharmacotherapy (see later), transjugular intrahepatic portosystemic shunt, extracorporeal liver support therapy, and (in patients with advanced uremia) renal replacement therapy should be considered, to improve renal function and potentially survival.

Pharmacotherapy

The most promising pharmacotherapy appears to be vasoconstrictors in combination with albumin, targeted at reversal of splanchnic arteriolar vasodilation and restoration of the effective arterial blood volume (Box 73.3). Vasodilators (aiming to reverse renal vasoconstriction) are contraindicated in HRS because they are ineffective and can induce marked hypotension.

Vasopressin analogues exhibit preferential vasoconstrictor action on the splanchnic versus the renal vascular bed. Terlipressin (triglycyllysine vasopressin) is a synthetic analogue of vasopressin that, in addition to having a greater effect on the vascular vasopressin receptors (V_1) than the renal vasopressin receptors (V_2), is a prodrug requiring transformation to the active form, lysine vasopressin. Because of this, terlipressin has a prolonged half-life and can be given as an intravenous bolus or as continuous intravenous infusion. Continuous administration improves the tolerability of the treatment (lower incidence of systemic ischemic side effects) and improves its effectiveness (treatment is effective at lower doses).[3,19] Long-term prospective studies[20-22] and a large retrospective study[23] in patients with type 1 and type 2 HRS have shown that terlipressin combined with daily albumin infusion improved renal function in 60% of the treated patients, with 37% surviving beyond 1 month (60% of them without OLT). Reversal of HRS was associated with improved survival.[21,23] The efficacy of terlipressin in the treatment of HRS has been confirmed in four randomized trials (Table 73.2).[24-27] Terlipressin was given at a starting dose of 2 to 6 mg/day, and in two studies the dose was titrated upward on the basis of response to a maximum dose of 12 mg/day. Both treated patients and controls were given daily albumin infusion of 20 to 40 g/day. Reversal of HRS was associated with improved survival in only one study.[26] The inclusion of patients with more severe renal failure in the treated group[25] and the unexpected high response and survival rates in controls[27] may explain the inability of some of these studies to show a survival benefit of treatment despite success in reversing HRS. The latter is likely a result of the more aggressive use of

BOX 73.3 Pharmacologic Options in the Treatment of Hepatorenal Syndrome

Terlipressin + albumin*: Terlipressin—1 mg/4-6 h to start,† increasing to a maximum of 2 mg/4-6 h if serum creatinine decreases less than 25% at day 3. Treatment is maintained until serum creatinine has decreased below 1.5 mg/dl (133 μmol/l). Maximum duration of treatment: 14 days.

Norepinephrine + albumin*: Norepinephrine—: IV infusion at 0.5 mg/h to start, increasing the dose by 0.25 to 0.5 mg/h every 4 hours up to a maximum of 3 mg/h to achieve an increase in MAP of at least 10 mm Hg. Maximum duration of treatment: 14 days.

Vasopressin + albumin*: Vasopressin—IV infusion at 0.01 U/min to start, increasing the dose upward to a maximum of 0.8 U/min to achieve an increase in MAP of at least 10 mm Hg. Maximum duration of treatment: 11 days.

Midodrine + octreotide + albumin*: Oral midodrine—2.5 to 7.5 mg/8 h + subcutaneous octreotide 100 mcg/8 h to start, increasing midodrine dose to a maximum of 12.5 mg/8 h and octreotide dose to a maximum of 200 mcg/8 h to achieve an increase in MAP of at least 15 mm Hg. Maximum duration: 14 days

*Albumin dose: 1 g/kg on day 1 (up to 100 g) followed by 20 to 40 g/day. Central venous pressure monitoring is advised (but not mandatory) to achieve a value of 10 to 15 mm Hg.
†Terlipressin also can be administered as continuous infusion (initially 3 mg/24 h; maximum dose 12 mg/24 h).
IV, Intravenous; *MAP,* mean arterial pressure.

albumin infusion in these studies because such an approach has been shown to reverse HRS in a high proportion of patients. A meta-analysis confirms that terlipressin plus albumin prolongs short-term survival in patients with type-1 HRS.[28] Response to therapy is characterized by a slow and sustained reduction in serum creatinine and improvement in systemic hemodynamics (marked suppression of the plasma levels of renin and norepinephrine, increase in MAP), urine volume, and serum sodium concentration. Median time to reversal of HRS is 7 days and depends on pretreatment serum creatinine.[3]

Recurrence of HRS after successful treatment tends to be more common in type 2 (around 50%) than in type 1 HRS (20%).[20,21,22,25,27] Retreatment with terlipressin is successful in most patients.[21,25] Younger age,[23,26] lower baseline serum creatinine level,[27] Child-Pugh score of 12 or lower,[23,26] administration of albumin,[21] serum bilirubin below 10 mg/dl, and increase in MAP over 5 mm Hg after initiation of terlipressin[29] are independent predictors of a successful response to treatment. In patients with severe alcoholic hepatitis, the absence of underlying cirrhosis increases the probability of response to treatment. Child-Pugh score (<12)[21,23,25,26] and MELD score[27] are independent predictors for survival. Transient abdominal pain and diarrhea after the first dose of terlipressin treatment are common. Significant ischemic side effects attributed to terlipressin occurred in an average of 4% to 12% of patients.[20-27]

Intravenous vasopressin has been used as an alternative to terlipressin in the treatment of HRS in countries where this drug is not available and was successful in reversing type 1 and type 2 HRS in 42% of patients in a retrospective study.[30] Responders had significantly lower mortality and a higher liver transplantation rate than nonresponders. No adverse effect related to therapy was observed.

Intravenous norepinephrine combined with intravenous albumin and furosemide reversed type 1 HRS in 10 of 12 patients; 3 survived with OLT, and 4 survived for a median of 332 days without OLT.[31] With use of a similar dosage regimen, two randomized comparative studies showed that norepinephrine is as effective as terlipressin in the treatment of type 1 and type 2 HRS (see Table 73.2).[32,33] All recurrences were successfully retreated with the original regimen. Significant treatment-related side effects were low, and the cost of treatment with norepinephrine was 3 and 15 times lower, respectively, than with terlipressin.

Administration of midodrine (an oral vasoconstrictor with α-adrenergic effect), subcutaneous octreotide, and albumin infusion has been demonstrated to be less effective in improving renal function in patients with HRS than the combination of terlipressin plus albumin. In a recent randomized controlled trial (RCT), reversal of HRS was achieved in 56% of patients receiving terlipressin plus albumin in comparison to only 5% in those receiving octreotide plus midodrine and albumin.[34] If these results are confirmed by other groups, octreotide plus midodrine and albumin should be considered a third-line treatment of patients with type 1 HRS.

In the United States and in countries where terlipressin is not available, patients with type 1 HRS should be treated with α-adrenergic drugs (intravenous norepinephrine or oral midodrine plus subcutaneous octreotide) administered with albumin.

Transjugular Intrahepatic Portosystemic Shunt

Portal hypertension is central in the pathogenesis of the homeostatic abnormalities in HRS. The high operative mortality precludes side-to-side portacaval shunts in HRS patients. The transjugular intrahepatic portosystemic shunt (TIPS) creates a parenchymal tract between branches of the hepatic and portal vein (Fig. 73.4). In experienced hands, operative mortality rates are 1% to 2%, and the morbidity rate is 10%. Procedure-related complications include intraabdominal bleeding, cardiac arrhythmia, shunt migration and thrombosis, hemolytic anemia, fever, infection, and reactions to radiocontrast media (including nephrotoxicity). The resultant diversion of portal blood flow from the liver to the systemic circulation may result in transient deterioration of liver function. Shunt stenosis and hepatic encephalopathy are the main long-term complications of TIPS. Exceptionally, TIPS induces disabling encephalopathy. In these cases, closure of the shunt should be performed.[35] In an earlier study, TIPS improved renal function in 6 of 7 HRS patients (all with Child-Pugh score <12) and achieved a mean survival of 4.7 (0.3 to 17) months.[36] A long-term study of 31 cirrhotic patients with HRS (14 type 1 and 17 type 2) who were not transplant candidates and did not have severe liver failure confirmed that TIPS improved renal function and survival compared with controls.[37] Shunt stenosis and occlusion occurred in 7 patients (treated in 6 by balloon dilation or stent prolongation), and 11 developed hepatic encephalopathy during follow-up. TIPS therefore could be an alternative treatment of type 1 HRS in patients without response to terlipressin/norepinephrine plus albumin.

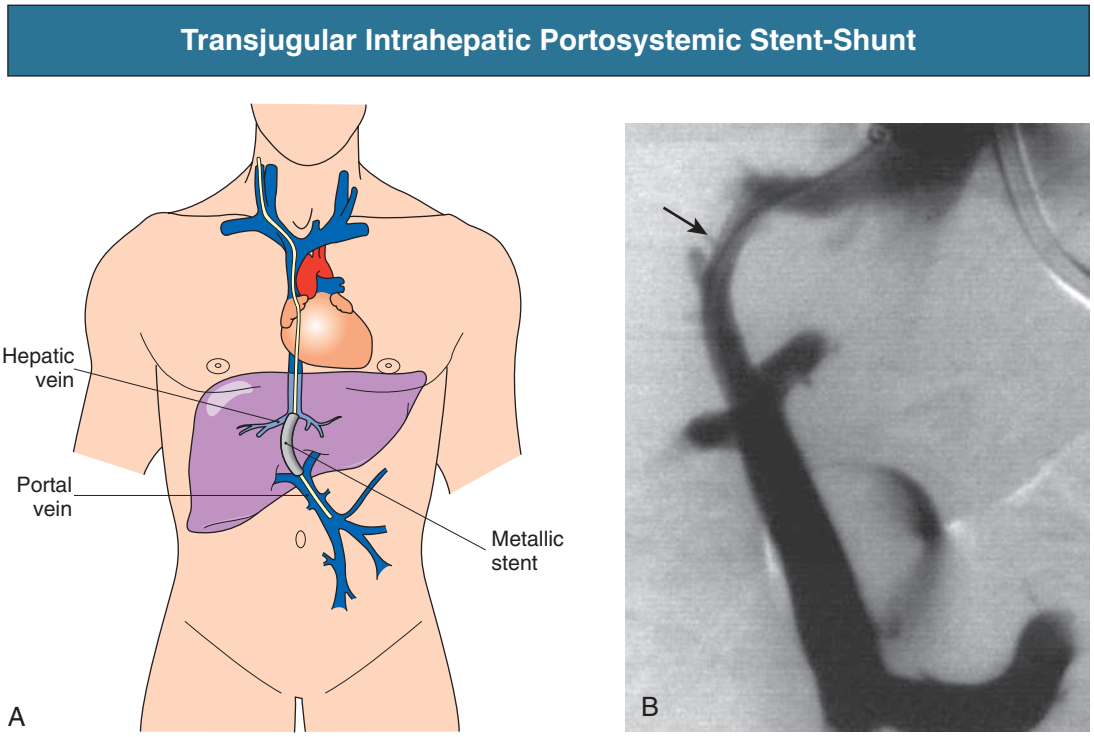

Fig. 73.4 Transjugular intrahepatic portosystemic shunt. (A) An intrahepatic tract has been created between the hepatic vein and the right portal vein. (B) The tract is dilated *(arrow)* and stented, creating a shunt as demonstrated on shuntogram. (Courtesy Dr. W. K. Tso, Queen Mary Hospital, Hong Kong.)

Combined TIPS and intravenous terlipressin therapy was performed in nine patients with type 2 HRS.[22] All seven patients who responded to terlipressin and relapsed after treatment cessation responded to TIPS. In another study, TIPS was performed in five patients with type 1 HRS after successful treatment with midodrine, octreotide, and albumin.[38] Complete normalization of renal function was observed in all patients at 12 months after TIPS. In both studies, improvement or elimination of ascites was an added benefit.

Extracorporeal Liver Support Therapy

Extracorporeal liver support therapy, as a bridge to OLT, relies on biologic (hepatocytes from human or animal source in an ex vivo perfusion system) or nonbiologic methods, including plasma exchange and albumin dialysis systems. Numerous studies have suggested that albumin dialysis (molecular adsorbent recirculating system [MARS] or fractionated plasma separation and adsorption [FPSA]) may have beneficial effects in patients with type 1 HRS. In a small RCT, a mean of five treatments with MARS effectively removed albumin-bound toxic metabolites (i.e., bilirubin and bile acids), improved renal function, and prolonged survival in eight patients (mean survival, 25 ± 5 days) with type 1 HRS and severe liver failure compared with five control patients treated only with hemodiafiltration (mean survival, 5 ± 2 days).[39] In another study of eight encephalopathic patients with acute alcoholic hepatitis (five with type 1 and two with type 2 HRS), MARS improved renal function, bilirubin, prothrombin time, grade of encephalopathy, MAP, systemic vascular resistance, and cardiac output, with four patients still alive without OLT at 3 months.[40] Three large RCTs have so far been performed evaluating albumin dialysis in patients with ACLF.[41-43] In the first study, albumin dialysis with MARS was found to be more effective than standard medical therapy in the management of patients with grade 3 or 4 hepatic encephalopathy. Most patients had HRS, and the treatment was found to be safe.[41] The two other trials compared albumin dialysis with standard medical therapy in patients with type 1 HRS (MARS) or with type 1 and 2 HRS (FPSA). A significant beneficial effect on hepatic encephalopathy was observed in the MARS study but not on survival.[42] In the FPSA trial no effect on survival was observed in the whole group or in patients with type 1 HRS, but a significant improvement was observed in patients with high MELD score (>30 points). The administered dosage of dialysis was very low in both studies (six sessions of 6 hours in 21 days). In these studies, therapy was well tolerated.[42,43] Further studies are clearly needed to ascertain the potential role of albumin dialysis in type 1 HRS. Patients with type 2 HRS are usually treated by total paracentesis or TIPS.

Renal Replacement Therapy

Hemodialysis and peritoneal dialysis in HRS patients with advancing uremia are both difficult. Conventional hemodialysis is hampered by the invariable systemic hypotension, and the efficacy and safety of peritoneal dialysis have not been well evaluated in these patients. Continuous venovenous hemofiltration (CVVH) or continuous venovenous hemodiafiltration (CVVHDF) has been advocated for the treatment of advancing uremia in HRS.[44] This is particularly true for patients with fulminant hepatic failure in whom intermittent dialysis can increase intracranial pressure. Anticoagulation should be minimized or avoided (especially in patients with severe coagulopathy) by giving the replacement fluid in the predilutional mode. When anticoagulation is needed, conventional heparin is generally recommended. Regional citrate anticoagulation is not recommended in advanced cirrhosis because the liver plays a significant role in its metabolism. If used, dose adaptation and close metabolic monitoring would be required, especially after prolonged use. Close serum calcium monitoring is mandatory because hypocalcemia is common because of impaired citrate clearance. Bicarbonate should be used instead of lactate as the buffer for the replacement solution to minimize metabolic acidosis. MARS may be combined with either CVVH

or hemodialysis for the treatment of HRS, especially in patients with severe hepatic encephalopathy.

Liver Transplantation

Liver transplantation is the treatment of choice in patients with advanced cirrhosis, including those with type 1 and type 2 HRS.[2,3,45,46] The hemodynamic and neurohormonal abnormalities associated with HRS disappear within the first month after liver transplantation. For this reason, calcineurin inhibitors should be withheld in the first few days after OLT to give the ischemic kidneys a chance to recover. Patients with HRS who undergo transplantation have more complications, spend more days in the intensive care unit, and have a higher in-hospital mortality rate than transplantation patients without HRS. The long-term survival of patients with HRS who undergo liver transplantation, however, is good (3-year survival 60%) compared with transplantation in patients without HRS (70% to 80%).[45] Although renal function improves after transplantation in HRS patients, it never reaches that observed in non-HRS patients.[47] The incidence of end-stage renal disease in patients with HRS is slightly higher than that observed in transplantation recipients without HRS (7% vs. 2%). Thus OLT is associated with comparable liver outcome but inferior renal outcome in patients with HRS. This problem cannot be overcome by performing combined kidney and liver transplantation in HRS, which overall produces outcomes no better than with OLT alone.[48] However, in the rare subgroup of patients with HRS who required prolonged pretransplant dialysis for more than 2 months, combined kidney and liver transplantation did confer an advantage in patient survival and use of hospital resources. These infrequent patients usually have normal kidney size and morphology on ultrasound but develop some additional indications of organic nephropathy during follow-up (mild proteinuria or microhematuria).[49]

The main problem with liver transplantation in type 1 HRS is that most patients die before transplantation. The introduction of the MELD score for listing has partially solved the problem because patients with HRS are prioritized for transplantation. As mentioned earlier, treatment of HRS with vasoconstrictors and albumin improves survival in the group of patients with response to treatment, increasing the number of patients reaching liver transplantation. In addition, reversal of HRS before transplantation may decrease early morbidity and mortality after transplantation and prolong survival.[46]

Therapeutic Algorithm

Fig. 73.5 shows the recommended algorithm for the management of HRS. Recent recommendations have been published by the International Club of Ascites.[11,50] OLT is undoubtedly the treatment of choice for patients with HRS, but other treatments described earlier must be used as a bridge to OLT and they may improve the renal outcome after

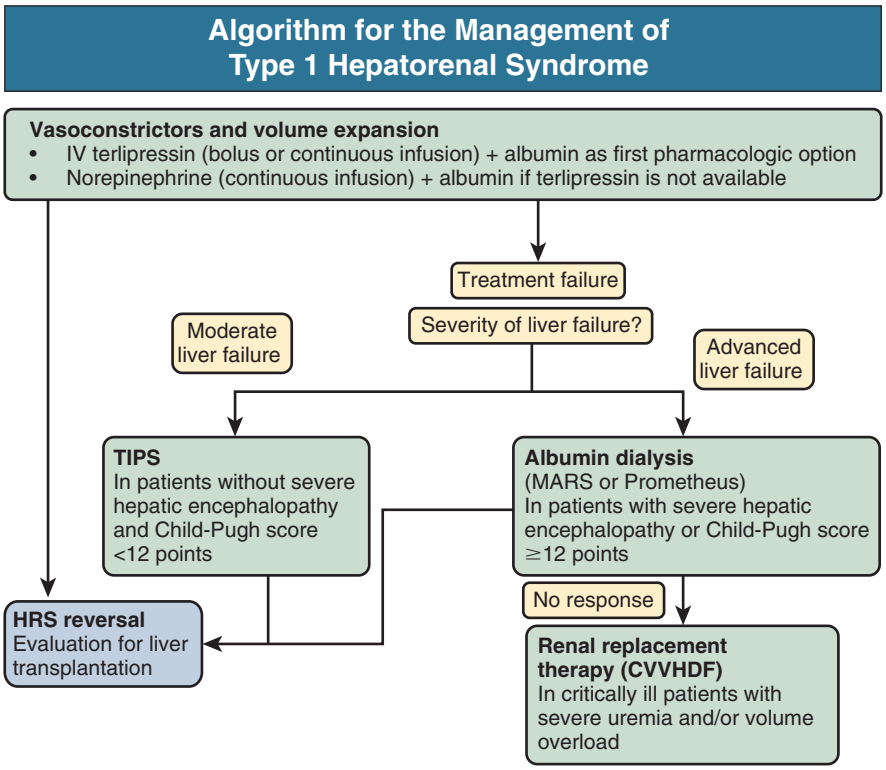

Fig. 73.5 Algorithm for the management of type 1 hepatorenal syndrome *(HRS).* Initial treatment is based on the use of vasoconstrictor therapies plus albumin. Intravenous terlipressin is the most established and is the preferred therapy.[50] If terlipressin is not available, continuous intravenous norepinephrine should be used. Patients with history of significant atherosclerotic or cardiovascular disease should be treated with norepinephrine. If pharmacologic therapy fails, the severity of liver failure should be assessed. In patients with less severe liver dysfunction (bilirubin <5 mg/dl or 85.5 μmol/l and Child-Pugh score <12) without severe hepatic encephalopathy (grade ≤2) or history of recurrent encephalopathy, transjugular intrahepatic portosystemic shunt *(TIPS)* should be considered.[3] In patients with more severe liver failure (Child-Pugh score ≥12) and/or severe hepatic encephalopathy (grade >2), albumin dialysis (molecular adsorbent recirculating system *[MARS]* or fractionated plasma separation and adsorption [FPSA]) should be considered. In critically ill cirrhotic patients with advancing renal failure, continuous venovenous hemodiafiltration *(CVVHDF)* is the treatment of choice.

successful OLT. In patients who are not transplantation candidates, these treatments are their only chance for increased survival and in some cases may improve their condition to an extent that may allow them to be reconsidered for transplantation. The choice of therapeutic modalities depends on the availability of resources and expertise on the one hand and the severity of underlying renal and liver failure and the general condition of the patient on the other. All patients should be considered for vasoconstrictor therapy combined with albumin infusion. Among the vasoconstrictor therapies, intravenous terlipressin, combined with daily albumin infusion, is most established and is the preferred therapy.[2,3,50] In countries where terlipressin is not available, continuous intravenous norepinephrine or vasopressin may be used as alternative. Patients with a history of significant atherosclerotic or cardiovascular disease should be treated with norepinephrine plus albumin. Oral midodrine combined with subcutaneous octreotide and albumin is another alternative in the treatment of HRS, especially in patients with type 2 HRS. In patients with relatively well-preserved liver function (serum bilirubin <5 mg/dl or 85.5 µmol/l and Child-Pugh score <12) without severe hepatic encephalopathy (grade ≤2) or history of recurrent encephalopathy, concurrent severe bacterial infection, or serious cardiovascular or pulmonary disease, TIPS should be considered, especially in patients with recurrence after vasoconstrictor therapy, a situation more commonly observed in HRS type 2 patients.[3] In these patients, TIPS may have the added benefit of relieving refractory ascites. TIPS also appears to achieve complete normalization of renal function in selected patients after an initial successful response to vasoconstrictor therapy. In patients with severe liver failure (Child-Pugh score ≥12) and severe hepatic encephalopathy (grade >2), MARS should be considered. In critically ill cirrhotic patients with advancing renal failure, CVVH is the treatment of choice and may be combined with other therapeutic modalities, especially MARS or FPSA.

SELF-ASSESSMENT QUESTIONS

1. Which of the following pathogenic events are observed in patients with hepatorenal syndrome (HRS)?
   - **A.** Splanchnic vasodilation
   - **B.** Cardiac dysfunction
   - **C.** Systemic inflammation
   - **D.** Tubular and glomerular lesions
2. Diagnosis of HRS is established by:
   - **A.** Liver biopsy
   - **B.** Renal biopsy
   - **C.** Measurement of plasma renin activity
   - **D.** It is a clinical diagnosis and is established by exclusion
3. Which affirmation(s) is/are incorrect in patients with hepatorenal syndrome?
   - **A.** It occurs in patients with subacute or chronic liver failure and portal hypertension.
   - **B.** Patients are normally hypertensive.
   - **C.** Plasma renin activity is usually high.
   - **D.** It can be observed in patients with and without ascites.
   - **E.** Patients can be infected.
4. Which affirmation(s) is/are incorrect regarding the treatment of patients with HRS?
   - **A.** The combination of terlipressin and albumin is the preferred treatment.
   - **B.** TIPS is an alternative treatment.
   - **C.** Patients must undergo early dialysis.
   - **D.** Albumin dialysis can be used in patients in whom pharmacologic treatment has failed.
   - **E.** The combination of midodrine, octreotide, and albumin is a good pharmacologic option.
5. Which affirmation(s) is/are correct in the prophylaxis of hepatorenal syndrome?
   - **A.** Norfloxacin prevents the development of HRS in patients with advanced cirrhosis and low-protein ascites.
   - **B.** Albumin infusion (1.5 g/kg at diagnosis and 1 g/kg at day 3) prevents the development of HRS and improves short-term survival in patients with SBP.
   - **C.** Albumin infusion prevents HRS in patients with infections other than spontaneous bacterial peritonitis.
   - **D.** Oral midodrine prevents HRS.

Principles of Drug Therapy, Dosing, and Prescribing in Chronic Kidney Disease and Renal Replacement Therapy

Matthew J. Cervelli, Graeme R. Russ

Renal impairment can alter drug pharmacokinetics and pharmacodynamics, and consequently patients with renal impairment are at risk for adverse effects. In addition, these patients take multiple drugs and are at high risk for drug interactions and drug-related problems.[1] To prescribe safely and effectively, clinicians should be familiar with the pharmacokinetics of drugs in varying stages of renal impairment and renal replacement therapy (RRT) and ideally rely on data from these populations. Unfortunately, such information is not always available, and exclusion of these patients from clinical studies can lead to restrictive licensed recommendations. This chapter describes pharmacokinetic principles and highlights common prescribing issues in patients with renal impairment, dialysis, and transplantation. Specific dose recommendations and pharmacokinetic data are not included but can be obtained elsewhere.[2-5]

PHARMACOKINETIC PRINCIPLES

Pharmacokinetics describes the behavior of a drug (or metabolite) in terms of its absorption, distribution, metabolism, and elimination (Fig. 74.1 and Table 74.1).[6,7]

Absorption: Bioavailability

Bioavailability *(F)* is the portion of a drug dose that appears in the systemic circulation after administration by a nonintravenous route. Drugs given intravenously have 100% bioavailability, whereas drugs given by alternative routes pass through a series of biologic membranes before entering the systemic circulation so that only a fraction may reach the circulation.

After oral administration, the liver can metabolize a drug during "first pass" when it is absorbed or later when it is delivered through systemic blood flow. First-pass metabolism can significantly reduce absorption. The gastrointestinal (GI) mucosa also acts as a barrier to absorption by metabolizing drugs or retarding absorption.[8] Renal impairment can influence absorption, although effects are difficult to quantify and clinical examples are limited. GI edema can limit oral drug absorption (e.g., oral furosemide in nephrotic syndrome). Nausea and vomiting from uremia can impair absorption and contact time between a drug and GI mucosa. In patients with advanced uremia, the alkalinizing effect of salivary urea may decrease absorption of drugs optimally absorbed in an acid milieu. Commonly prescribed metallic ion phosphate binders can decrease drug absorption by forming nonabsorbable complexes with drugs (Table 74.2).[9] Changes in cardiac output in renal failure can reduce the rate and extent of absorption for drugs with significant first-pass metabolism. Increased absorption in patients with renal impairment from reduced first-pass metabolism is seen with some β-blockers, dextropropoxyphene, and dihydrocodeine. Comorbidities in renal patients also can have an effect; for example, absorption can be erratic because of diabetic GI neuropathy.

Distribution

Volume of Distribution

After absorption, drugs may distribute from plasma to an extravascular compartment. Each drug has a characteristic volume of distribution (V_D), which is really an apparent V_D because it does not correspond to an anatomic space but instead relates the amount of drug in the body to its plasma concentration. V_D is used to calculate the loading dose to achieve a desired plasma concentration (V_D = dose/[plasma]). Water-soluble drugs tend to be restricted to the extracellular fluid space and have a relatively small V_D. Lipid-soluble drugs penetrate body tissues and have a large V_D. Increased V_D can occur with edema, ascites, or infection, particularly for water-soluble drugs; if usual doses are given, low concentrations result. Conversely, muscle wasting or volume depletion can decrease the V_D of water-soluble drugs and usual doses produce high concentrations.

Plasma Protein Binding

Drugs can bind extensively to plasma proteins.[10] The free (unbound) fraction of a drug is usually the portion that exerts a pharmacologic effect. If protein binding is reduced, a greater free fraction is available for any given total drug concentration, which may increase drug activity. Organic acids usually have a single binding site on albumin, whereas organic bases have multiple binding sites on glycoproteins. Protein binding can be altered in patients with renal impairment, especially when serum albumin is low (e.g., nephrotic syndrome) or when uremic toxins displace drugs from binding sites (Table 74.3). Predicting the effect of changes in protein binding is difficult. For example, a decrease in protein binding means more free drug is available at the site of action, but also that more is available for metabolism or renal excretion.

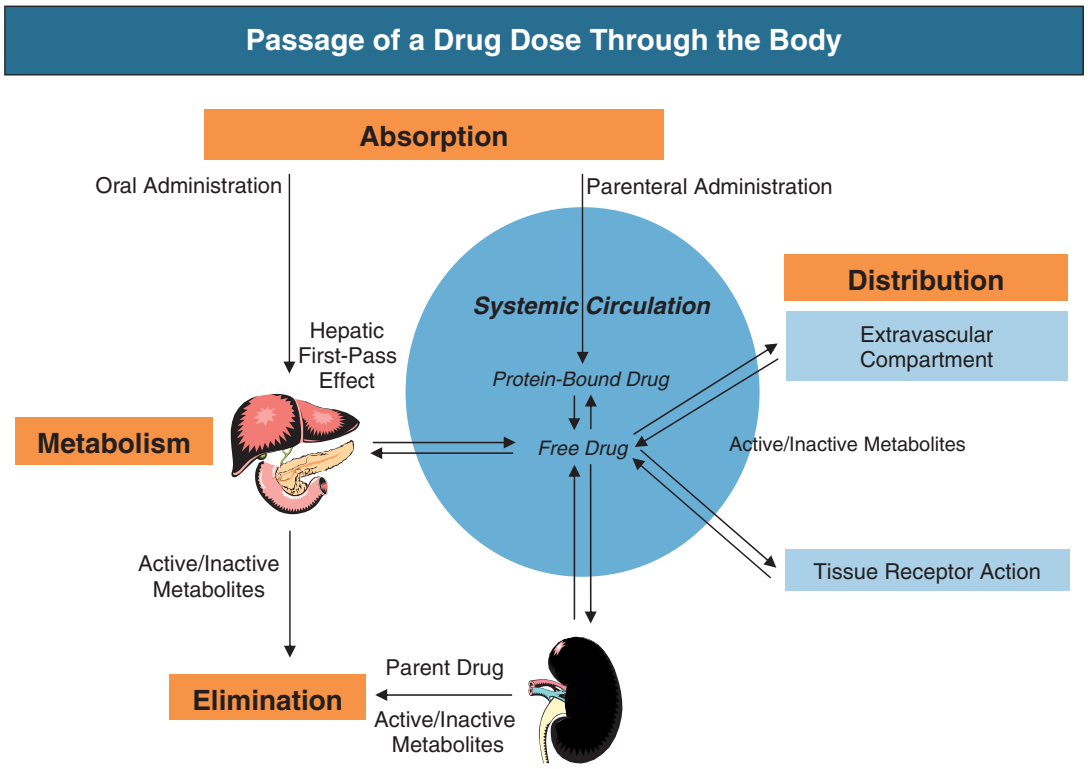

Fig. 74.1 Passage of a drug dose through the body.

TABLE 74.1 Pharmacokinetic Parameters

Parameter	Definition	Application
Bioavailability *(F)*	Percentage of a dose that appears in the systemic circulation after administration by a nonintravenous route	Determines the amount of drug reaching the systemic circulation
Volume of distribution (V_D)	Proportionality constant relating the amount of drug in the body at a given time to a simultaneously occurring drug concentration in plasma, blood, or other reference fluid at an identical time	Determines the size of loading doses
Clearance	Proportionality constant between rate of drug elimination from the body (mass/unit time) and the concentration of the drug in plasma or blood at the same point in time	Determines the maintenance dose
Half-life ($t_{1/2}$)	Time taken for the drug concentration in plasma to fall to half its current value	Determines frequency of administration and time to steady state

TABLE 74.2 Effect of Food and Phosphate Binders on Oral Drug Absorption

Drug	Effect of Food
Captopril	Decreases serum drug levels
Bisphosphonates (oral)	Significantly reduces drug absorption
Cinacalcet	Significantly increases drug absorption
Iron (oral)	Decreases absorption
Ketoconazole or itraconazole	Increases absorption with reduced pH
Sirolimus	High-fat meals increase absorption
Tacrolimus	Reduces drug absorption
Drug	**Effect of Metallic Phosphate Binders**
Bisphosphonates (oral)	Calcium-containing binders significantly reduce absorption
Fluoroquinolones	Reduction in absorption
Tetracycline	Reduction in absorption
Thyroid hormones	Reduction in absorption

Thus lower plasma concentrations can occur and drug half-life may decrease rather than increase. Phenytoin, for example, has marked decreases in protein binding in patients with renal impairment, and toxicity can occur despite normal or low total plasma concentrations because of an increase in free fraction. With albuminuria, bound drug also may be lost, which may partially explain the refractoriness of nephrotic patients to diuretics. In patients with chronic kidney disease (CKD), high plasma levels of α_1-acid glycoprotein are induced in acute and chronic inflammation, which can increase drug binding.

Metabolism

Drug metabolism is primarily a hepatic function by which drugs are converted to more water-soluble entities, which promotes elimination by the kidneys and bile. Despite the assumption that nonrenal clearance is

TABLE 74.3 Protein Binding of Drugs in Renal Disease

Major Effects	Minor Effects
Albumin: Binding Sites for Acidic Compounds	
Barbiturates (↓)	Ascorbic acid (↑)
Benzodiazepine (↑)	Valproate (↓)
Carbamazepine (↑)	Fatty acids (↑)
Fibrates (↑)	Nafcillin (↑)
Furosemide (↓)	Phenylbutazone (↓)
Mycophenolate mofetil (↑)	Probenecid (↑)
Penicillins (↑)	Thiopental (↓)
Phenytoin (↓)	Warfarin (↓)

↓, Indicates reduced protein binding in renal impairment; ↑, indicates increased protein binding in renal impairment. However, the therapeutic effect is not easily predicted (see text).

BOX 74.1 Mathematics of Drug Elimination

Total body clearance = Drug dose/AUC

Renal clearance = Total amount of drug in urine/plasma drug concentration

Total amount of drug in urine = Drug × volume of the sample collected in a fixed time

Drug half – life ($t_{1/2}$) = $V_D \times 0.693$/Clearance

AUC, Area under the concentration-time curve; V_D, volume of distribution (dose/blood concentration).

unchanged, renal impairment can alter and slow drug metabolism.[11] It is important to note that some drugs have active or toxic metabolites that are renally cleared; although insignificant with normal renal function, such metabolites can accumulate in patients with renal impairment.

Elimination

The kidney is the most important organ for drug and metabolite elimination. Terms to describe drug clearance are shown in Box 74.1. Total drug clearance equals the apparent volume of blood or plasma from which the drug is cleared per unit of time and is expressed as the dose divided by the area under the drug concentration curve (AUC). *Half-life* describes the time taken for plasma concentrations to halve and is related to V_D and clearance. Quantitation of drug elimination by the kidney is expressed as renal clearance, which depends on renal blood flow and the ability of the kidney to remove the drug. Renal drug clearance is the balance of its glomerular filtration rate (GFR), renal tubular secretion, and tubular reabsorption. Glomerular filtration depends on molecular size (<10 kDa), charge, and protein binding (increased when binding decreases). Secretion of drugs eliminated by tubular transport may change with renal disease, but measurement of tubular function is difficult. Practically, as GFR decreases, drugs dependent on tubular secretion are also excreted more slowly. Assuming no change in nonrenal clearance, as GFR falls, clearance of drugs (and metabolites) eliminated by the kidney decreases and their half-life is prolonged.

PRESCRIBING PRINCIPLES FOR CHRONIC KIDNEY DISEASE AND RENAL REPLACEMENT THERAPY

Ideally, dose modification recommendations should be made by comparing the pharmacokinetics of a drug at varying stages of renal impairment relative to normal function. However, lack of reliable data and individual patient factors limit such generalities and clinical judgment about a patient's ability to handle a drug is vital.[12] Dose nomograms, tables, and computer recommendations are helpful but not necessarily associated with better outcomes. Physicians should use clinical judgment to evaluate every situation individually, choose a dosage regimen based on factors in that patient, and continually reevaluate the response to therapy.

Initial Assessment and Laboratory Data

A targeted history is important in assessing dose in patients with renal impairment. Previous drug efficacy or toxicity should be determined and the current prescribed medications reviewed for potential interactions or nephrotoxins. Physical and laboratory parameters indicate volume status, height, weight, and extrarenal disease (e.g., liver).

Estimating Renal Function for Drug Dosage

Estimating renal function is essential in renal drug dosing. The greater the degree of renal impairment, the greater is the potential need for dose modification. With exceptions, dose modification usually is not clinically necessary until GFR is below 30 ml/min. Assessment of renal function to assist drug dosing is not a precise science. What is essential for clinical decision making is awareness that renal function is impaired, and approximately to what extent, rather than knowledge of the precise GFR.[13] For drug prescribing, renal impairment is usually graded as mild (30 to 60 ml/min), moderate (10 to 30 ml/min), or severe (<10 ml/min or on dialysis). For drug dosage calculation, estimating GFR is usually sufficient (see Chapter 3). The Cockcroft-Gault equation has been the most widely used and accepted method for drug dosage calculation. The Modification of Diet in Renal Disease (MDRD) formula and Chronic Kidney Disease–Epidemiology Collaboration (CKD-EPI) formula, if not corrected for body surface area, can lead to recommendations different from those obtained by the Cockcroft-Gault equation. An important limitation of all renal function estimates is inaccuracy of single-point estimates when renal function is rapidly changing. This may lead to overestimation or underestimation of renal function and underdosing or overdosing. In patients with severe acute kidney injury (AKI), the decline in GFR is so rapid that patients should receive dosages appropriate for GFR below 10 ml/min. The opposite is true in rapidly improving renal function after AKI or early posttransplant.

Activity and Toxicity of Metabolites

It is essential to consider the activity (or toxicity) of drug metabolites in addition to that of the parent drug itself. Renally cleared metabolites can accumulate, leading to enhanced drug action or toxicity (Table 74.4).

Fraction of Active Drug (and Active or Toxic Metabolite) Excreted Unchanged in Urine

The greater the fraction of active drug or metabolite excreted unchanged by the kidneys (fe), the greater is the need for dose modification. It is usually clinically necessary to modify doses only if the fe is greater than 25% to 50%. The reported fe is often determined from studies that do not distinguish between parent drug and metabolites. The contribution

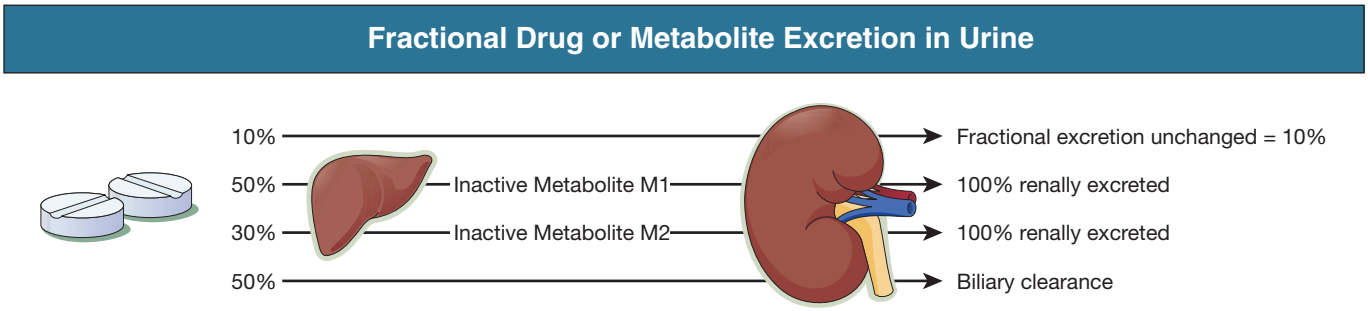

Fig. 74.2 Fraction of drug or metabolite excreted in urine. In this hypothetical example, 10% of the dose is excreted unchanged in urine (fe = 10%); 50% of the dose is metabolized to inactive metabolite M1, which is then all renally excreted; 30% of the dose is metabolized to inactive metabolite M2, which is all renally excreted; and the remaining 10% is excreted unchanged in bile. For this drug, the total excretion of drug dose in urine is 90%. However, this 90% comprises 10% as parent drug and 80% as inactive metabolites, and dose modification is probably not essential even in severe renal impairment. Total renal excretion of the dose is 90%; however, the clinically significant fraction of active drug excreted in urine is 10%.

TABLE 74.4 Drugs With Renally Cleared Active or Toxic Metabolites That Accumulate in Patients With Reduced Glomerular Filtration Rate

Drug	Active Metabolite	Consequence
Allopurinol	Oxypurinol	
Cefotaxime	Desacetyl cefotaxime	
Glyburide	4-*trans*-Hydroxyglibenclamide 3-*cis*-Hydroxyglibenclamide	Hypoglycemia
Morphine	Morphine-6-glucuronide	CNS side effects
Tramadol	*O*-Desmethyltramadol	CNS side effects
Venlafaxine	*O*-Desmethylvenlafaxine	CNS and cardiovascular side effects
Drug	**Toxic Metabolite**	**Consequence**
Dapsone	Monoacetylated metabolite	
Meperidine (pethidine)	Normeperidine (norpethidine)	CNS (seizures)
Nitroprusside	Thiocyanate	Cyanide toxicity
Procainamide	*N*-Acetylprocainamide (NAPA)	Arrhythmia
Propoxyphene	Norpropoxyphene	Cardiac toxicity

CNS, Central nervous system.

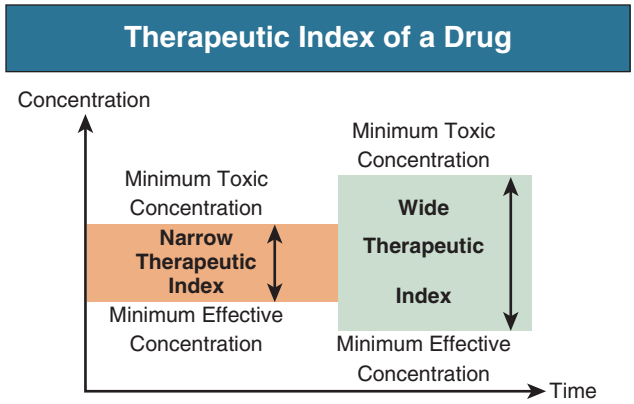

Fig. 74.3 Therapeutic index of a drug. Two examples of drugs with, on the left, a narrow therapeutic index, and on the right, a wide therapeutic index.

of inactive nontoxic metabolites to overall renal drug elimination may exaggerate the potential for harm. Active or toxic metabolites should be assessed separately for their dependence on renal elimination in the same way as the parent drug (Fig. 74.2).

Therapeutic Index of the Drug or Metabolites

The decision to modify dosage in patients with renal impairment is influenced by the therapeutic window or index of the drug. The therapeutic window is the range of plasma drug concentrations spanning the minimum concentration for clinical efficacy and toxicity. The therapeutic index is the ratio of these concentrations (Fig. 74.3). If the therapeutic window is wide (e.g., many penicillins), there may be no clinical need for dose modification despite significant renal elimination and or renal impairment. If the therapeutic window is narrow (e.g., digoxin), dose modification is more critical. Clinicians should judge the clinical relevance of increased exposure to drug or metabolites.

Avoiding Nephrotoxic Drugs

A wide range of drugs can cause nephrotoxicity (Table 74.5). Idiosyncratic nephrotoxicity (e.g., interstitial nephritis) is unpredictable and independent of dose. Predictable hemodynamic-related nephrotoxicity can occur with angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), nonsteroidal antiinflammatory drugs (NSAIDs), diuretics, antihypertensives, and laxatives. Direct tubular nephrotoxins include aminoglycosides, vancomycin, amphotericin, cisplatin, calcineurin inhibitors (CNIs), and radiographic contrast media. Obstructive uropathy can occur with tubular crystallization of acyclovir, statin-induced rhabdomyolysis, or tricyclic antidepressant use. In dialysis patients with no significant residual renal function, use of nephrotoxic drugs may be acceptable. Drug nephrotoxicity is discussed further in Chapter 66.

Drugs That Aggravate the Metabolic Effects of Renal Impairment

Some drugs have no direct adverse effect on renal function but when used in patients with renal impairment can aggravate the metabolic consequences of renal failure. Hyperkalemia is exacerbated by potassium

TABLE 74.5 Some Examples of Nephrotoxic Drugs

Examples	Mechanism	Prevention and Management
ACE inhibitors, ARBs	Impairment of angiotensin II–mediated afferent arteriole dilation during renal hypoperfusion	Withdraw in renal hypoperfusion
Aminoglycosides Amikacin Gentamicin Tobramycin	In proximal tubules, aminoglycosides bind to anionic phospholipid, are delivered to megalin, are taken up into the cell, accumulate, and cause direct toxicity	Alternative if possible Monitor drug concentrations Avoid multiple daily doses Withdraw if creatinine rises
Antifungals Amphotericin	Afferent vasoconstriction and direct action to reduce GFR Distal tubular injury via creation of pores that increase membrane permeability leading to hypokalemia, hypomagnesemia, metabolic acidosis caused by tubular acidosis, polyuria from nephrogenic diabetes insipidus	Avoid use Administer slowly with hydration Use liposomal preparation
Antivirals		
Acyclovir	Deposition of drug crystals → intratubular obstruction and foci of interstitial inflammation	Avoid bolus dose Reduce dose in renal impairment Hydrate during therapy
Cidofovir	Induces apoptosis in proximal tubule → tubular dysfunction, diabetes insipidus, renal failure	Oral probenecid and hydration
Foscarnet	Direct tubular toxicity → acute tubular necrosis, nephrogenic diabetes insipidus Crystals in glomerular capillary lumen and proximal tubular lumen	Hydration
Indinavir	Crystal neuropathy, nephrolithiasis → obstructive AKI	Hydration
Calcineurin inhibitors Cyclosporine Tacrolimus	↓ PG and ↑ 20-HETE acid production → vasoconstriction, generation of H_2O_2 resulting in depleted glutathione → decreased GFR, ischemic collapse or scarring of the glomeruli, vacuolization of the tubules, and focal areas of tubular atrophy and interstitial fibrosis	Measure plasma concentrations Avoid interacting drugs Withdraw drug (switch to mTOR inhibitor)
Chemotherapeutics		
Cisplatin	*Cis* chloride replaced by H_2O → highly reactive OH radical → DNA injury, tubular cell death Nephrogenic diabetes insipidus, hypomagnesemia (may be persistent)	Forced diuresis and hydration
Ifosfamide	Direct tubular injury and mitochondrial damage → renal tubular acidosis, Fanconi-like syndrome, nephrogenic diabetes insipidus hypokalemia	
Intravenous immunoglobulin (sucrose-containing products)	Accumulation of sucrose in proximal convoluted tubules, ↑ osmolarity → cell swelling, vacuolization, and tubular luminal occlusion	Infusion rate <3 mg sucrose/kg/min Avoid radiocontrast Avoid sucrose-containing product Hydration
Lithium	Impairment of collecting duct concentrating ability → diabetes insipidus Chronic tubulointerstitial nephropathy (tubular atrophy and interstitial fibrosis)	Measure plasma concentrations Prevent dehydration Avoid thiazides
NSAIDs	Hemodynamically induced AKI caused by vasoconstriction via reduced prostaglandin production Recruitment and activation of lymphocytes → acute and chronic tubulointerstitial nephritis, with or without nephrotic syndrome	Avoid use Withdraw during hypoperfusion Withdraw (add corticosteroids)
Proton pump inhibitors	Interstitial nephritis	Withdraw (add corticosteroids)
Radiocontrast media	High osmolarity, medullary vasoconstriction, ↑ active transport in thick ascending loop of Henle → ↑ O_2 demand	Hydration preprocedure and postprocedure Acetylcysteine
Sulfonamides	Intrarenal precipitation → kidney stone formation	Fluid intake >3 l/day; monitor urine for crystals Alkalinize urine to pH >7.15 if crystal seen

ACE, Angiotensin-converting enzyme; *AKI,* acute kidney injury; *ARBs,* angiotensin receptor blockers; *GFR,* glomerular filtration rate; *20-HETE acid,* 20-hydroxyeicosatetraenoic acid; *H_2O_2;* hydrogen peroxide*; mTOR,* mammalian target of rapamycin; *NSAIDs,* nonsteroidal antiinflammatory drugs; *PG,* prostaglandin.

supplements, potassium-sparing diuretics, aldosterone antagonists, and blockers of the renin-angiotensin system. The catabolic effects of tetracycline can exacerbate uremia. Sodium-containing drugs and those that promote sodium and water retention should be used cautiously because they may provoke fluid overload and hypertension.

Effect of Renal Impairment on Pharmacodynamic or Physiologic Mechanisms

Renal disease may alter a pharmacodynamic response or physiologic process, which in turn affects clinical response. For example, the inability of impaired kidneys to activate vitamin D precursors means that vitamins D_2 and D_3 may be less effective. Patients with renal impairment often have a coagulopathy from the effects of uremia on platelet function and may be more prone to the bleeding complications of anticoagulant and antiplatelet therapy.

Effect of Renal Impairment on the Concentration of Drug at the Site of Action

Renal impairment can alter drug concentration at the site of action. Some diuretics and antibiotics become ineffective in patients with renal impairment because they do not achieve adequate concentrations at their site of action in the renal tubules or bladder. This may preclude the use of drugs such as thiazide diuretics and nitrofurantoin or may require increased doses of others (e.g., loop diuretics).

Location of Drug Action

Drugs that have negligible bioavailability and that are used for a local or topical effect may be given safely at normal dose despite toxicity with systemic doses. These include topical NSAIDs, nebulized gentamicin, and oral vancomycin.

Method of Administration

In fluid-restricted patients, administration of intravenous drug infusions with approved fluid volumes may be undesirable. When administration exceeds daily fluid restrictions, consider alternative drugs or more concentrated solutions provided that physiochemical parameters allow. Similarly, oral drug administration with large fluid volumes (e.g., bisphosphonates) may not be advisable. In patients with severe nausea and vomiting, essential immunosuppressants should be administered intravenously.

Drug Interactions

Pharmacokinetic drug interactions are frequently problematic, and awareness of clinically significant interactions is essential, especially with regard to patients receiving transplant immunosuppressants. The most important of these are cyclosporine, tacrolimus, everolimus, and sirolimus, which are substrates of both the cytochrome P450 (3A4) drug metabolizing enzyme system and P-glycoprotein drug efflux system expressed in GI mucosa and liver (Fig. 74.4).[14] Coprescription of drugs that inhibit these systems (e.g., some azole antifungals, calcium channel blockers, macrolides, and grapefruit juice) can increase absorption and reduce metabolism of the immunosuppressant, causing toxicity. Conversely, drugs that induce these systems (e.g., barbiturates, phenytoin, carbamazepine, rifampin, and St. John's wort *[Hypericum]*) can reduce absorption and increase metabolism and therefore increase the risk for rejection (see Fig. 74.4 and Table 74.6). All drug changes in patients receiving transplant immunosuppression should be considered for their potential to interact, and appropriate dose modifications or alternatives used.

Clinical Condition of the Patient

The patient's welfare should override theoretical concerns. Higher than recommended doses may be appropriate when there is a strong clinical indication. For example, excessive reduction in initial antibiotic doses based on renal function may be inappropriate in patients with life-threatening infection when the consequences of failed therapy are greater than those of potential toxicity.

TABLE 74.6 Therapeutic Drug Monitoring in Renal Impairment

Drug	Therapeutic Range and When to Draw Sample
Aminoglycosides	Peak (30 min after a 30-min infusion)
(24-h dosing)	Trough (6-12 h after dose)
Gentamicin	Peak: >10 mg/l
	Trough: Depends on time after dose 0.5-2 mg/l
Tobramycin	Peak: >10 mg/l
	Trough: Depends on time after dose 0.5-2 mg/l
Amikacin	Peak: >30 mg/l
	Trough: depends on time after dose 1.5-6 mg/l
Immunosuppressants	
Cyclosporine	C_0 (trough): 150-250 μg/ml
	C_2 (2 h after dose): 1200-1500 μg/ml
	AUC_{0-4} >4400 μg/ml/h
Tacrolimus	C_0 (trough): 4-12 μg/ml
Sirolimus	C_0 (trough): 5-15 μg/ml
Antiarrhythmics	
Digoxin	0.8-2.0 μg/ml (trough at least 6 h after dose)
Lidocaine	1-5 μg/ml 8 h after IV infusion starts or is changed
Antipsychotics	
Lithium	Acute: 0.8-1.2 mmol/l (trough)
	Chronic: 0.6-0.8 mmol/l (trough)
Antiepileptics	
Carbamazepine	4-12 μg/ml (trough before administration)
Phenytoin	10-20 μg/ml (trough before administration)
Free phenytoin	1-2 μg/ml (trough before administration)
Phenobarbital	15-40 μg/ml (trough before administration)
Valproic acid	40-100 μg/ml (trough before administration)
Vancomycin	Trough: 10-20 mg/l

Target levels are dependent on assay methodology and clinical context.
IV, Intravenous.

METHODS OF DOSE REDUCTION

Loading Doses

For most drugs, steady-state concentrations are achieved after five drug half-lives. Hence, for some drugs, a loading dose is given to reduce time to steady state. Because renal impairment may prolong the half-life, simply reducing drug doses could be a therapeutic error because this would further delay achievement of steady state. The loading dose (milligram/kilogram) is equal to the product of the desired plasma concentration (milligram/milliliter) and V_D (milliliter/kilogram) and is independent of clearance. Provided the desired concentration and V_D are unchanged, loading doses do not require modification in patients with renal impairment. If V_D is altered, especially with hypoproteinemia or fluid overload, the loading dose of drugs with a narrow therapeutic

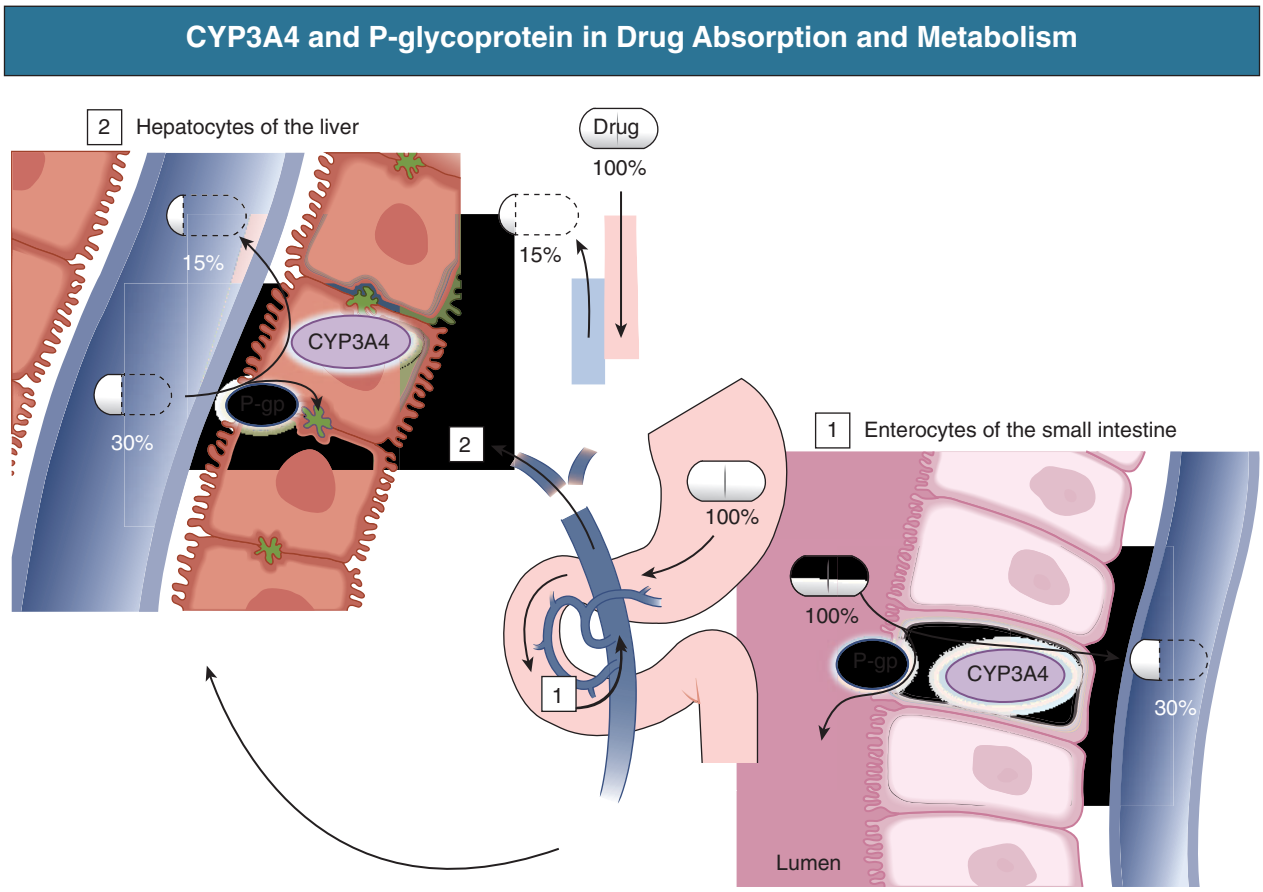

Fig. 74.4 *CYP3A4* and P-glycoprotein *(P-gp)* in drug absorption and metabolism. Schema for absorption and metabolism of drugs that are substrates for CYP3A4 and P-gp. Overall, approximately 15% of ingested drug reaches the systemic circulation. *(1)* Enterocyte: P-gp on the apical surface of enterocytes prevents drug absorption, maintaining drug in the gastrointestinal lumen; CYP3A4 in enterocytes metabolizes drug. The net effect is that approximately 30% of ingested drug reaches the portal circulation. *(2)* Hepatocyte: P-gp on the cell surface prevents drug entry into hepatocytes; CYP3A4 in hepatocytes metabolizes the drug. The net effect is that drug entry to the systemic circulation is further reduced.

index such as digoxin may be increased. Aminoglycoside doses may need to be increased in patients with fluid overload or sepsis who have an increased V_D.

Maintenance Doses

When specific pharmacokinetic information is not available, and assuming no change in nonrenal clearance, maintenance doses should be reduced in proportion to the extent of renal impairment and renal drug elimination. For example, if renal function is 50% of normal and the drug is 100% renally excreted, a maintenance dose of 50% is required. If the drug is 50% renally cleared and the patient has 20% renal function, the dose should be 60% of normal. The dose reduction factor is estimated from first principles or the following formula:

$$\text{Fraction of normal renal function dose to use in renal impairment} = 1 - fe(1 - \text{fraction of normal renal function})$$

where fe = the fraction of active drug excreted unchanged in urine.

Once a dose reduction factor has been determined, the clinician must decide on a dose reduction method. Two methods are used, either alone or in combination (Fig. 74.5).

Interval Method

Because drug clearance is reduced, a reduction in delivered dose is achieved by administering the same dose less frequently. This method is particularly useful when the size of the dose and peak blood concentrations are important for efficacy (e.g., aminoglycosides). If this method is used, practical dose intervals should be recommended rather than inconvenient or complex intervals.

Dose Method

An alternative method is to administer a smaller dose at the usual interval. This method is common, especially when the size of a dose and peak concentrations are less critical for efficacy. If this method is used, clinicians should consider the availability of smaller dose formulations and the ability of the patient to accurately and safely divide available dosage forms.

Combination Method

Sometimes, especially for drugs with a narrow therapeutic index, for which tight control of concentrations is required (e.g., digoxin), a combination of the dose and interval methods is used.

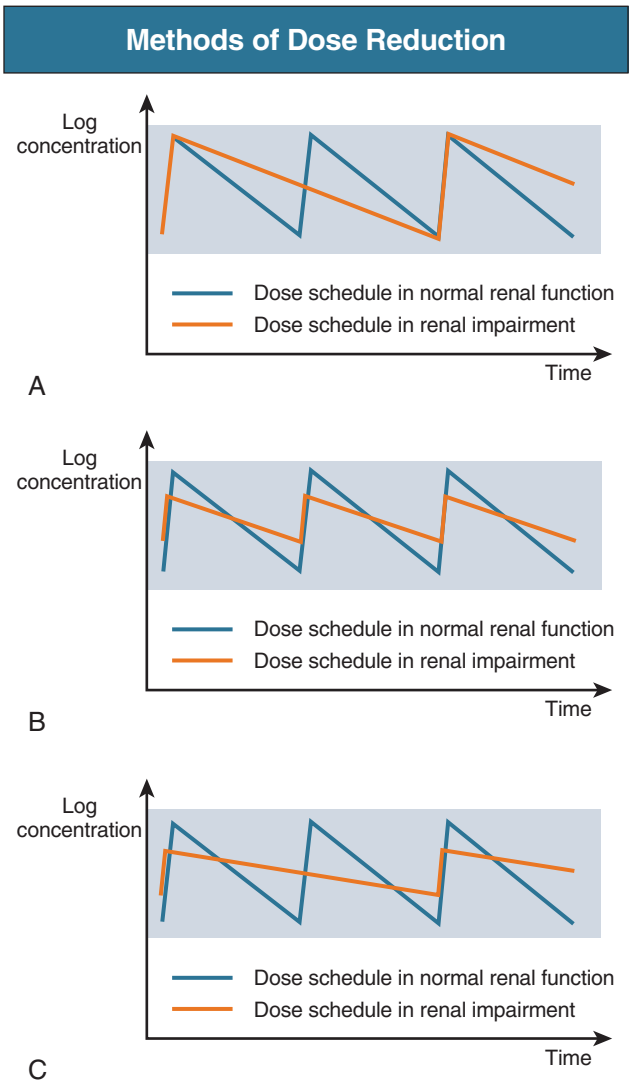

Fig. 74.5 Methods of dose reduction. (A) Interval method. (B) Dose method. (C) Combination method.

Ongoing Assessment

Even with appropriate dose modification in patients with renal impairment, clinicians should always remain vigilant and closely monitor the response to therapy to guide dose titration.

Therapeutic Drug Monitoring

Therapeutic drug monitoring can provide objective information to guide dosage calculation and is valuable for drugs such as aminoglycosides, glycopeptides, digoxin, lithium, antiepileptics, and immunosuppressants (see Table 74.1). Assays usually measure total blood concentrations and may significantly underestimate plasma levels of the active or free form of the drug.

Clinical Response

Ultimately, clinical response should influence the need to modify doses. Doses should be carefully titrated according to response and adverse effects. Exemplar measures of response include blood pressure for antihypertensives, blood glucose concentration and hemoglobin A_{1c} (HbA_{1c}) for oral hypoglycemics, and renal function for toxicity from CNIs, ACE inhibitors, and ARBs.

EXTRACORPOREAL DRUG LOSSES

Failure to consider dialysis drug clearance may significantly reduce drug efficacy.[5,7] Alternatively, dialysis may be used in overdose to assist drug removal (see Chapter 98). Studies of drug clearance with RRT modalities have often used variations in dialysis technique that make it difficult to compare results. Many studies before the 1990s report data from standard hemodialysis (HD) with low-flux membranes, which are less efficient at drug removal than the high-flux membranes now widely used. Many recommendations report the need for supplemental doses. Clinically, supplemental doses are rarely used, especially if less than 30% of the drug is cleared or the drug has a wide therapeutic index. Rather, drugs known to be significantly cleared by dialysis should be administered after dialysis (Table 74.7). When drugs are given in multiple daily doses, at least one of the daily doses should be administered soon after the completion of dialysis.

Hemodialysis

HD drug clearance occurs mainly by passive diffusion along a concentration gradient but also by convectional movement of soluble drug with ultrafiltrated plasma water.[7,15] The efficiency of drug removal depends on physiochemical drug properties. As molecular size decreases (<500 d) and water solubility increases, drug removal increases. Conversely, as protein binding and V_D increase, dialysis clearance decreases. HD factors influencing drug removal include membrane type and surface area, blood flow rates, and dialysis frequency and duration. HD can remove drug from plasma faster than it can redistribute from tissue, so drug concentrations determined from samples drawn soon after beginning or completion of HD may be low. Samples should preferably be drawn before dialysis or about 1 to 2 hours after to allow drug redistribution.

Peritoneal Dialysis

Many drug properties that affect removal by HD also apply to peritoneal dialysis (PD), but PD is usually less efficient.[16] For significant removal by peritoneal PD, the drug must have a very low V_D and low protein binding. For most drugs, there is little evidence of significant removal during chronic PD. A few studies have examined drug clearance from automated PD that uses large volumes of short dwells at night, often accompanied by one or more longer daytime dwells. Clearance of some drugs on automated PD is increased because of the increased drug concentration gradient between blood and dialysate. Increased drug dialyzability may occur with increased peritoneal dialysate flow rates or during peritonitis.

Continuous Renal Replacement Therapy

Drug clearance by continuous RRT (CRRT) with hemofiltration, HD, or hemodiafiltration differs from that by intermittent HD.[17] Relying on continuous ultrafiltration of plasma water, CRRT can remove large quantities of ultrafilterable drug. CRRT generally uses membranes with larger pore sizes and involves convective transport of solute. Hence, CRRT allows the passage of larger molecules (up to 5000 d). A large V_D and protein binding still prevents removal by CRRT. Protein binding and the device filtration rate determine the rate of removal. A series of sieving coefficients is available that allows calculation of the amount of drug actually lost if the ultrafiltration flow rate is known.[5] The sieving coefficient is the ratio of drug concentration in the ultrafiltrate to the prefilter plasma water drug concentration. The closer the sieving coefficient is to 1.0, the more it passes across the filter. There are few detailed studies of drug clearance with use of these methods, and clinicians must rely on estimates from HD, known physiochemical properties, and clinical response.

TABLE 74.7 Dialysis Clearance of Drugs

SELF-ASSESSMENT QUESTIONS

1. What percentage of the dose in normal renal function should be given for a hypothetical drug that is 80% renally cleared unchanged in urine to a person with 25% of normal renal function?
   A. 20%
   B. 30%
   C. 40%
   D. 60%
   E. 80%
2. Which of the following factors or drug characteristics does *not* increase the likelihood of drug removal by hemodialysis?
   A. High-flux membranes
   B. Low protein binding
   C. Low volume of distribution
   D. Large molecular weight
3. Which of the following drugs do not require clinically relevant dose modification in renal impairment?
   A. Amoxycillin
   B. Ribavirin
   C. Digoxin
   D. Sotalol
   E. Enoxaparin
4. Which of the following drug combinations are *least* likely to cause clinically significant drug interactions?
   A. Adding clarithromycin to the regimen of a patient on sirolimus
   B. Adding phenytoin to the regimen of a patient on prednisolone
   C. Adding fluconazole to the regimen of a patient on tacrolimus
   D. Adding roxithromycin to the regimen of a patient on cyclosporin
   E. Adding verapamil to the regimen of a patient on everolimus

Common Issues in Prescribing in Kidney Disease and Renal Replacement Therapy

Matthew J. Cervelli, Graeme R. Russ

Appropriate prescribing for people with kidney disease is underpinned by the principles discussed in Chapter 74. Even experienced physicians will frequently need to check reference sources to be sure of the correct prescribing approach to medications with which they are less familiar. Up-to-date reference databases should be used to inform prescribing in patients with renal impairment, those on dialysis, and after renal transplantation.[1-4] In this chapter, common prescribing issues in such patients are discussed.

ANALGESICS

Various analgesics undergo renal excretion, and dose modification or avoidance is required in people with impaired kidney function.[5] Fear of adverse effects often prevents use of sufficient doses. Adequate initial doses should be followed by careful assessment and dose titration.

Acetaminophen (Paracetamol)

Despite suggestions that acetaminophen is nephrotoxic and is relatively ineffective for pain relief, its lack of platelet inhibition and gastrointestinal effects make it a safer base analgesic in chronic kidney disease (CKD) and renal replacement therapy than nonsteroidal antiinflammatory drugs (NSAIDs) and opioids. Acetaminophen is hepatically metabolized and does not require dose adjustment.

Opioid Analgesics

Opioids have metabolites with variable activity and dependence on renal excretion.[6] Metabolite accumulation prolongs drug action and predisposes to central nervous system (CNS) toxicity (sedation, respiratory depression, confusion, hallucinations, and seizures). Regular opioid use in fluid-restricted renal patients can exacerbate constipation. Opioids should be used cautiously in renal impairment, with adequate doses given to establish control and titrated to the smallest effective dose. Morphine is metabolized to two renally cleared active metabolites (morphine 3-glucuronide and morphine 6-glucuronide) that can accumulate in renal impairment, causing CNS toxicity, respiratory depression, and sedation. Meperidine (pethidine) should be avoided in moderate to severe renal impairment because it is metabolized to a renally cleared metabolite (normeperidine) that can cause CNS toxicity (seizures, myoclonus, opisthotonus, mental state changes, respiratory depression, and psychosis).[7] It should be avoided in moderate to severe renal impairment. Dextropropoxyphene should be avoided because it is metabolized to the renally cleared metabolite norpropoxyphene, which can cause cardiac toxicity. Hydromorphone is metabolized to hydromorphone 3-glucuronide, which has minor activity and does not accumulate substantially. Buprenorphine is metabolized to relatively inactive metabolites, which are excreted in bile, and is relatively safe. Weaker opioids (codeine, dihydrocodeine, and hydrocodone) can still cause CNS and respiratory depression. They should be used cautiously in severe renal impairment. With appropriate titration, alfentanil, fentanyl, sufentanil, methadone, and oxycodone are relatively safer choices because they do not have significantly active metabolites. The partial opioid tramadol is metabolized to a renally cleared active metabolite, *O*-desmethyltramadol whose half-life doubles in renal impairment and predisposes to seizures, respiratory depression, and other CNS adverse effects. In opioid intoxication, naloxone may be used at normal dose for reversal.

Nonsteroidal Antiinflammatory Drugs

The most frequent nephrotoxic effect of NSAIDs is to cause acute renal impairment by preventing renal prostaglandin-mediated afferent arteriolar vasodilation (see Chapter 66). In healthy individuals, cyclooxygenase (COX) inhibition has little effect on renal function. Nephrotoxicity is more likely in those with a high renin state or renal hypoperfusion in whom renal prostaglandins are upregulated and play a supportive role in maintaining glomerular filtration. Combinations of NSAIDs with angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), diuretics, or other antihypertensives increase the potential for nephrotoxicity, and such combinations should be prescribed cautiously. If required, in stable patients with CKD, NSAIDs should be used at the lowest effective dose for the shortest period with monitoring of renal function. Increases in serum potassium and sodium, as well as fluid retention also may occur. NSAIDs (especially fenoprofen) can cause rare idiosyncratic reaction that may present with acute interstitial nephritis or nephrotic syndrome with a glomerular lesion resembling minimal change disease. Because COX-2 is expressed in the kidney, COX-2–selective agents offer no advantage in renal toxicity over nonselective inhibitors.[8] The potential for cardiovascular complications of COX-2 inhibitors is also undesirable in renal patients at high risk for cardiovascular disease.

Drugs for Neuropathic Pain

Low-dose tricyclic antidepressants are used at normal doses, although renal patients may be more sensitive to anticholinergic side effects. Low-dose valproate and carbamazepine are used at normal doses. Extreme caution and dose reductions are required with gabapentin[9] and pregabalin[10] because they are extensively renally cleared and can cause significant CNS adverse effects (somnolence, lethargy, dizziness, myoclonus, and ataxia) and falls.

ANTIMICROBIAL AGENTS

The kidneys excrete many antiinfective agents, and dose reduction is often required in patients with severe renal impairment or who are

undergoing extended therapy.[11] However, many other antiinfectives have a wide therapeutic index and dose adjustment is clinically unnecessary despite their reliance on renal excretion. An important principle of antiinfective therapy is to initiate effective drugs at sufficient doses rather than use conservative dose reductions that fail to achieve effective drug concentrations. Normal doses or doses larger than expected based on renal function may be appropriate when treating less susceptible organisms or when drug distribution to the site of infection is reduced (e.g., in meningitis). Severe infection, particularly in severely immunocompromised patients, may require extended therapy. In patients with urinary tract infection (UTI), if glomerular filtration rate GFR is below 30 ml/min and the drug does not undergo tubular secretion, inadequate renal tract concentrations may result and systemic accumulation could lead to toxicity (e.g., nitrofurantoin).

Antibacterials

Aminoglycosides

Aminoglycosides are excreted unchanged by the kidneys and can cause nephrotoxicity and irreversible vestibular and ototoxicity.[12] When use is essential, the total daily dose should be reduced, treatment courses kept to a minimum, and serum concentrations and renal function monitored. Because aminoglycosides undergo tubular secretion, high urine concentrations are achieved even in advanced renal impairment, and lower doses may be appropriate for uncomplicated UTIs.

Aminoglycoside dosage schedules. Despite short half-lives (2 to 3 hours with normal renal function), aminoglycosides are usually given once daily rather than in divided daily doses. This is based on data showing that their action depends on peak concentration and that once-daily regimens have reduced toxicity. The required dose regimen depends on volume of distribution (V_D) and renal clearance. Dosage calculation in renal impairment involves reducing the normal daily dose of 5 to 7 mg/kg for gentamicin and tobramycin or 15 mg/kg for amikacin according to renal function (e.g., with 25% remaining renal function, reduce the total daily dose to 25% of normal). Aminoglycosides should be administered at a minimum effective dose (≥2.5 mg/kg for gentamicin and tobramycin; ≥7.5 mg/kg for amikacin) to achieve target peak serum concentrations (>10 μg/ml for gentamicin and tobramycin; >30 μg/ml for amikacin). The calculated reduced normal daily dose might be lower than the minimum individual dose required to achieve target peak concentrations. If so (e.g., moderate to severe renal impairment), it may be necessary to administer the minimally effective dose at an extended interval (e.g., every 36 or 48 hours) rather than reducing the size of the individual dose.

Aminoglycoside concentration monitoring. Because of toxicity and pharmacokinetic variability in patients with infection and renal impairment, monitoring is essential to guide aminoglycoside dosing particularly when therapy is initiated or significant changes occur in renal function or clinical condition. Routine monitoring is not required for short treatment (<48 hours). Graphic methods using a single-point concentration 6 to 14 hours after administration are valid only with relatively normal renal function. They do not provide information on attainment of peak concentrations and are not recommended in patients with renal impairment. Trough concentrations can be measured but must be interpreted in the context of the time after the dose when the sample was drawn. Trough monitoring does not provide information on the attainment of peak concentrations. Some patients, especially those with severe sepsis and renal impairment, may have altered (usually higher) V_D, which results in lower peak concentrations. Measuring peak concentrations (30 minutes after dosing) is the only certain way to determine dose adequacy. Combining peak and trough monitoring provides information on both V_D and clearance and can therefore be used to determine both the size of individual doses and the administration interval. Provided the relationship between the time of administration and blood sampling is known, simple dose modifications are made on first principle estimates (see Chapter 74). Peak and trough target levels for aminoglycosides are shown in Table 74.6.

Carbapenems. Ertapenem, doripenem, imipenem, and meropenem are significantly excreted in urine but with appropriate dose modification can be used safely. Imipenem can cause significant neurotoxicity (myoclonic activity, seizures, and confusion), especially in high doses in those with underlying CNS disorders or renal impairment. Imipenem is inactivated by renal dehydropeptidase 1 and is combined with cilastatin to prevent this.

Cephalosporins. Although most cephalosporins are predominantly renally cleared, their relative safety means that normal doses are used for most short-course therapies even in dialysis patients (e.g., ceftriaxone, cefaclor, and cephalexin). High-dose parenteral therapy and prolonged courses of some agents require dose reduction in severe impairment (e.g., cefepime, cefotaxime, ceftazidime, cefoxitin, and cefazolin). Therapeutic concentrations of cefazolin are maintained after doses of 20 mg/kg after dialysis three times weekly.[13] Some cephalosporins (e.g., cefoxitin) cause a creatinine-like reaction in assays based on the picrate method, which can falsely elevate serum creatinine.[14]

Fluoroquinolones. Renal excretion is significant with ciprofloxacin, norfloxacin, and gatifloxacin, and doses are reduced if GFR is below 30 ml/min.[15] Moxifloxacin is 20% renally excreted, and dose reduction is not required. Norfloxacin is well secreted by kidneys and useful in UTIs. Quinolones are generally well tolerated but can cause CNS effects (headache, dizziness, insomnia, depression, restlessness, and tremors), interstitial nephritis, musculoskeletal effects (tendonitis and arthralgias), and crystalluria. Quinolones should be administered at least 1 hour before or 2 hours after meals and metallic phosphate binders, which reduce absorption.

Glycopeptides. Glycopeptides (vancomycin and teicoplanin) have extensive renal excretion. Because of potential nephrotoxicity and ototoxicity, dose modification is essential even in mild to moderate impairment. Nephrotoxicity is greater in those with renal impairment, prolonged therapy, high doses (typically vancomycin trough levels >40 μg/ml), and concomitant nephrotoxins. Ototoxicity may involve sensorineural deafness and tinnitus and is more likely with previous auditory compromise or impaired renal function. Rapid infusion also can cause an erythematous anaphylactoid-like reaction involving the upper body (red man syndrome) that resolves with slowing of the infusion and administration of antihistamine agents. If glycopeptide use is essential, duration of therapy should be minimized with regular monitoring of serum concentrations and renal function. Glycopeptides demonstrate time-dependent antibacterial activity, so doses should be repeated once serum concentrations have fallen below minimum inhibitory concentrations. In dialysis patients, single doses (e.g., 1 g) of vancomycin can maintain therapeutic concentrations (>15 μg/ml) for 3 to 5 days.[16] Vancomycin is removed more extensively with high-flux than with low-flux dialysis membranes.

Lincosamides. Lincosamides (e.g., clindamycin and lincomycin) are relatively safe and are not significantly excreted by the kidneys.

Macrolides. Macrolides are mostly hepatically cleared, and dose modifications are usually not required even in end-stage renal disease. Dose reduction is required with high-dose or intravenous erythromycin, which may prolong QT interval and cause ototoxicity. Various macrolides are potent inhibitors of cytochrome P450 (CYP)3A4 and P-glycoprotein, so there may be major interactions with and increased exposure to coadministered drugs that rely on CYP3A4- or P-glycoprotein–mediated absorption and metabolism (cyclosporine, tacrolimus, sirolimus, everolimus, and statins). Erythromycin and clarithromycin are the most potent inhibitors. Roxithromycin is a much weaker inhibitor causing few or

no significant interactions. Azithromycin does not significantly inhibit CYP3A4 or P-glycoprotein.

Penicillins. Most penicillins have a short half-life and are rapidly eliminated by renal filtration and secretion. Most have a relatively wide therapeutic window and are used at normal doses for short courses of oral therapy (e.g., amoxicillin). High-dose parenteral therapy or prolonged high-dose oral therapy may require dose reduction to prevent electrolyte disturbances and neurotoxicity in advanced renal failure. Because most penicillins exert little or no postantibiotic effect, the amount of time above the minimum inhibitory concentration is more important than the maximum concentration. Severe reductions in frequency of administration are not advised. Dose reduction of ticarcillin-clavulanate and piperacillin is advised.

Rifamycins. Rifamycins are mainly hepatically metabolized and used at normal doses. Orange-red coloration of body fluids (e.g., urine and peritoneal dialysis [PD] fluid) is common. Infrequently, these agents cause hepatotoxicity and blood dyscrasias. Rifampin is a potent enzyme inducer and significantly increases metabolism of drugs, including immunosuppressants such as corticosteroids. Rifabutin does not induce CYP450 enzymes to the same extent.

Tetracyclines. Tetracycline depends more on renal excretion than doxycycline or minocycline. In renal impairment, tetracycline should be avoided because it is catabolic causing uremia, hyperphosphatemia, and metabolic acidosis; it also may aggravate preexisting renal failure.[17] Doxycycline, minocycline, and tigecycline may be used as usual. Outdated (degraded) tetracycline (anhydro-4-epitetracycline) may result in renal tubular damage and a Fanconi-like syndrome.

Sulfonamides and trimethoprim. Sulfonamides are eliminated by acetylation followed by renal excretion. Acetylated metabolites may cause crystalluria and tubular damage. Sulfamethoxazole and trimethoprim display similar renal excretion except at extremes of urine pH. Alkaline urine promotes sulfamethoxazole excretion, whereas acidic urine promotes trimethoprim excretion. Both accumulate in renal impairment, and dose reduction is advisable except perhaps in the initial treatment of *Pneumocystis jiroveci* infection, in which the risk for toxicity is balanced against the seriousness of infection. Trimethoprim inhibits tubular secretion of creatinine, resulting in a reversible increase in serum creatinine[18] that can be misinterpreted as nephrotoxicity.

Other antibiotics. Linezolid is used at a normal dose. Metronidazole has a partially active, renally cleared metabolite, although only 15% of the parent drug is renally cleared. It is usually given in usual doses or reduced to twice-daily doses with dialysis.

Antimycobacterials

Antimycobacterial treatment (see also Chapter 52) requires dose modification according to renal function and avoidance of drug interactions.[19] Dose reduction with ethambutol (80% renally cleared) is essential to avoid visual toxicity. Isoniazid, pyrazinamide, and rifampin-rifabutin can be given in usual doses. Rifampin causes induction of hepatic enzymes and severe drug interactions with transplant immunosuppressants. Amikacin, kanamycin, streptomycin, capreomycin, and gatifloxacin have extensive renal clearance, are nephrotoxic, and require significant dose reduction.

Antifungals

Amphotericin. Amphotericin use is limited by nephrotoxicity (see Chapter 53). Nephrotoxicity with crystalline amphotericin may be minimized with prehydration and administration by continuous infusion. Liposomal formulations have fewer infusion-related problems and are less nephrotoxic but more expensive. Oral amphotericin is not absorbed and does not contribute to nephrotoxicity.

Azole antifungals. Most azole antifungals (ketoconazole, itraconazole, and voriconazole) are extensively metabolized and do not require dose reduction. Fluconazole is renally excreted; after an adequate loading dose, maintenance doses should be reduced in moderate to severe renal impairment, and it should be given after dialysis. Fluconazole is significantly excreted in urine and preferred for fungal UTIs. The manufacturer recommends avoiding intravenous voriconazole in severe renal impairment because of possible accumulation of the intravenous vehicle (sulfobutyl betadex sodium). Voriconazole, ketoconazole, and itraconazole are potent inhibitors of CYP3A4 and P-glycoprotein that are involved in the metabolism and absorption of a variety of drugs, including cyclosporine, tacrolimus, sirolimus, everolimus, and statins. A 2- to 10-fold reduction of the concomitant drug may be required with drug monitoring. Interactions between ketoconazole and calcineurin inhibitors (CNIs) or mammalian target of rapamycin (mTOR) inhibitors have been exploited as a cost-reducing immunosuppressant-sparing strategy. Increased exposure to statins (except pravastatin) increases the risk for rhabdomyolysis-induced renal impairment. Fluconazole is a weak enzyme inhibitor, and although caution should be exercised, the need for preemptive dose reduction of concomitant drugs is less certain. Topical azoles, including bifonazole, clotrimazole, econazole, ketoconazole, tinidazole, and miconazole, are minimally absorbed and do not cause interactions.

Other antifungals. Absorption of nystatin from topical and oral preparations is minimal and safe in renal impairment. Terbinafine is hepatotoxic, and a 50% dose reduction is suggested in moderate to severe renal impairment. Griseofulvin and caspofungin can be given in usual doses. Flucytosine has extensive renal clearance and requires significant dose reduction.

ANTIVIRALS

Many antivirals (or their active metabolites) have extensive renal excretion and can cause nephrotoxicity (see also Chapter 66).

Guanine Analogues

Acyclovir, its prodrug valacyclovir, and famciclovir have extensive renal clearance and can crystallize in tubules, causing obstructive nephropathy, especially when given intravenously. High concentrations cause severe CNS toxicity (cerebral irritation, ataxia, and myoclonus). Ganciclovir and its prodrug valganciclovir have extensive renal clearance,[20] and accumulation leads to severe bone marrow toxicity. Dose reduction based on renal function is essential, even in mild renal impairment. These agents are freely dialyzed and should be given after hemodialysis (HD).

Hepatitis B and C

Pegylated interferon alfa-2a has a larger metabolic clearance than pegylated interferon alfa-2b, which has higher renal clearance and requires dose reduction in renal impairment. Interferons can upregulate cell surface expression of class II histocompatibility antigens, which increases the potential for transplant rejection. Ribavirin and its metabolites rely on renal excretion; accumulation causes severe anemia, making it contraindicated if GFR is below 50 ml/min; significantly reduced doses are sometimes used in lower levels of GFR. Newer direct-acting antivirals for hepatitis C (boceprevir, daclatasvir, ledipasvir, sofosbuvir, ombitasvir, partitaprevir, ritonavir, dasabuvir, simeprevir, telaprevir) are less dependent on renal excretion and may be preferable in patients with renal impairment. Adefovir, entecavir, lamivudine, and telbivudine have extensive renal excretion, and significant dose reduction is essential.

Neuraminidase Inhibitors

Oseltamivir is converted by hepatic esterases to its active metabolite, oseltamivir carboxylate, which is extensively (99%) renally cleared

through filtration and secretion.[21] The area under the curve (AUC) is increased 10-fold in severe renal impairment, and, although the drug is well tolerated, dose reduction is recommended. Despite intravenous doses showing significant reliance of zanamivir on renal clearance, dose modification is not necessary because bioavailability from inhaled doses is approximately 2% and high intravenous doses are well tolerated.

Other Antivirals

Cidofovir and foscarnet have extensive renal clearance and require dose reduction in renal impairment. Both are nephrotoxic, require close monitoring of renal function, and should be administered with hydration. Cidofovir is often administered with probenecid to slow renal secretion and minimize nephrotoxicity. Agents active against HIV infection are also discussed in Chapter 56.

IMMUNOSUPPRESSANTS

Dosing of immunosuppressive agents used in renal transplantation as well as adverse effects are discussed in Chapter 102. Initial and maintenance doses in individuals are highly variable and depend on local protocol, concomitant therapy, rejection risk, drug concentrations, and response. Immunosuppression is required for the life of the transplant and should never be withheld except in exceptional circumstances (life-threatening infection or malignancy). Regimens should preferably be limited to convenient twice-daily schedules. In practice, the precise timing of doses or intake relative to time and food is not as important as consistency in relation to time and food because doses can be titrated to levels and response. Most immunosuppressants are hepatically metabolized and do not require dose modification based on altered excretion in renal impairment.

Immunosuppressants are prone to a range of significant drug interactions, which should be considered whenever a patient receiving these agents has a change in drug regimen. Significant interactions also can occur with "natural" or "herbal" medicines (e.g., St John's wort; see also Chapter 76). If these products are deemed essential, it is advisable to monitor response, renal function, blood counts, and serum drug concentrations regularly. Therapeutic monitoring is recommended for several immunosuppressants[22] (tacrolimus, cyclosporine, everolimus, sirolimus, and mycophenolate). Target levels should be interpreted in the context of patient response, immunosuppressive regimen, time after transplantation, and assay methodology.[23]

Calcineurin Inhibitors

CNIs are extensively metabolized to inactive metabolites. A major adverse effect of CNIs is nephrotoxicity (acute and chronic),[24] and regular assessment of renal function is essential. Nephrotoxicity may increase with concurrent use of mTOR inhibitors. Early detection of CNI nephrotoxicity on biopsy assists in planning maintenance therapy (see Chapters 102 and 105). Lower doses or temporary withdrawal may be used when CNIs have caused or are likely to cause nephrotoxicity (e.g., delayed graft function). Calcium channel blockers (CCBs) and blockade of the renin-angiotensin system may both reduce CNI nephrotoxicity. CNIs are substrates of P-glycoprotein and CYP3A4. Drugs that inhibit or compete as substrates for these enzymes can increase absorption and reduce metabolism of CNIs, causing increased serum concentrations and adverse effects. Drugs that induce these enzymes can reduce absorption and increase metabolism of CNIs, causing reduced serum concentrations, and increase the risk for rejection (Table 75.1). Tacrolimus trough concentrations (C_0) show good correlation with drug exposure (AUC) and are used to monitor therapy. Clinically, a combination of C_0 (trough), C_2 (concentration 2 hours after dose), and $AUC_{0\text{-}4}$ (multipoint AUC, 0 to 4 hours) is used to measure cyclosporin. Different assay methodologies (high-performance liquid chromatography [HPLC] and immunoassays) have differing abilities to detect parent compound from metabolites. Specific HPLC methods are recommended, and results from different laboratories may not be interchangeable.

Corticosteroids

Corticosteroids are predominantly cleared by hepatic metabolism to inactive metabolites. Dose modification based on renal function is not required.

Antiproliferative and Cytotoxic Agents

Various antiproliferative and cytotoxic agents are used to prevent rejection (azathioprine and mycophenolate) and in patients with autoimmune and inflammatory renal disorders (azathioprine, cyclophosphamide, chlorambucil, methotrexate, and mycophenolate). Their primary dose-limiting toxicity is bone marrow suppression, which is exacerbated by combined use with other bone marrow suppressants (e.g., ganciclovir, cotrimoxazole, and mTOR inhibitors). Regular blood monitoring is needed to guide dosage. Methotrexate relies on renal clearance and should be avoided or used cautiously at a reduced dose. Renal clearance is significant with cyclophosphamide (which also causes hemorrhagic cystitis) and chlorambucil, and dose modifications are required. Allopurinol significantly interferes with metabolism of the active metabolite of azathioprine (6-mercaptopurine), and coprescription can lead to life-threatening bone marrow suppression. The combination should be avoided by exchanging azathioprine with mycophenolate or by significant (75%) dose reduction of azathioprine or mercaptopurine.

mTOR Inhibitors

Although not nephrotoxic when used alone, mTOR inhibitors (sirolimus, everolimus) can potentiate the nephrotoxicity of CNIs. mTOR inhibitors are almost entirely hepatically metabolized to essentially inactive metabolites. Dosage is independent of renal function and based on response, serum drug levels, and specific toxicities (especially hematologic and lipids). mTOR inhibitors are substrates of CYP3A4 and P-glycoprotein and susceptible to the same drug interactions as CNIs (Table 75.2). Bone marrow toxicity (neutropenia, anemia, and thrombocytopenia) is increased when they are used in combination with other myelosuppressants (azathioprine, mycophenolate, ganciclovir, and cotrimoxazole). Trough levels show good correlation with drug exposure (AUC) and are used to monitor therapy. Different assay methodologies (HPLC vs. immunoassays) vary in their ability to detect parent drug from metabolites. Specific HPLC methods are recommended, and results from different laboratories or methods may not be interchangeable.

Immunosuppressant Antibodies

Antibodies used for immunosuppression include T cell–depleting antibodies (antithymocyte globulin, anti–interleukin-2 receptor (CD25) antibodies (basiliximab and daclizumab), and B cell–depleting antibodies (rituximab) (see Chapter 102). Dosage is independent of renal function, and these agents should be administered after plasma exchange[25] to avoid drug removal. They are not removed by HD.

ANTICOAGULANTS, ANTIPLATELET AGENTS, THROMBOLYTICS, AND HEMOSTATICS

The risk for bleeding with anticoagulants, antiplatelet agents, thrombolytics, and hemostatics is generally increased in patients with CKD.[26]

Unfractionated Heparin

Unfractionated heparin (UFH) clearance occurs by a rapid saturable mechanism of the endothelium and reticuloendothelial system and a slower nonsaturable mechanism through the kidneys. Half-life is slightly prolonged (1.5-fold) in renal impairment, especially at higher doses.

TABLE 75.1 Common Drug Dosing Recommendations in Renal Impairment and Transplant

	PREDOMINANT ELIMINATION PATHWAY			
Drugs	**Hepatic**	**Renal**	**Dosing Recommendations**	**Comments**
Analgesics				
Simple analgesics	Acetaminophen		Normal dosing	
Opioids		Morphine	Avoid/dose reduction	Renally cleared metabolites
		Pethidine	Avoid	Renally cleared metabolites
	Fentanyl		Cautious normal doses	
	Oxycodone		Cautious normal doses	
	Hydromorphone		Cautious normal doses	
	Methadone		Cautious normal doses	
	Tramadol	Tramadol	Cautious dose reduction	
NSAIDs			Avoid if possible	Potential Nephrotoxicity
Neuropathic pain		Gabapentin	Significant dose reduction	CNS adverse effects
		Pregabalin	Significant dose reduction	CNS adverse effects
	Low-dose TCAs		Normal dose	
	Carbamazepine		Normal dose	
	Valproate		Normal dose	
Anti-infectives				
Aminoglycosides		Amikacin	Avoid/dose reduction	Nephrotoxicity
		Gentamicin	Avoid/dose reduction	Nephrotoxicity
		Tobramycin	Avoid/dose reduction	Nephrotoxicity
Carbapenems		Ertapenem	Dose reduction	
		Doripenem	Dose reduction	
		Imipenem	Dose reduce	
Cephalosporins		Cephalexin	Normal dose	
		Cefotaxime	Dose reduction	
		Ceftazidime	Dose reduction	
	Ceftriaxone		Normal dose	
Fluoroquinolones		Ciprofloxacin	Dose reduction in severe impairment	PO_4 binders may impair absorption
		Norfloxacin	Dose reduction in severe impairment	PO_4 binders may impair absorption
	Moxifloxacin		Normal dose	
Glycopeptides		Vancomycin	Avoid/dose reduction	Nephrotoxicity and ototoxicity
		Teicoplanin	Avoid/dose reduction	Nephrotoxicity and ototoxicity
Macrolides	Azithromycin		Normal dose	
	Roxithromycin		Normal dose	
	Clarithromycin		Normal dose	Significant CYP3A4 interactions
		Erythromycin	Dose reduction	Significant CYP3A4 interactions
Penicillins		Amoxycillin	Normal dose	
Sulfonamides and trimethoprim			Reduce high doses	Falsely elevates creatinine
Tetracyclines		Tetracycline	Avoid	
	Doxycycline		Normal dose	
	Minocycline		Normal dose	
Antimycobacterials		Ethambutol	Dose reduction	
	Isoniazid		Normal dose	
	Pyrazinamide		Normal dose	
	Rifampicin		Normal dose	Significant CYP3A4 interactions
Azole antifungals		Fluconazole	Reduce maintenance doses	
	Ketoconazole		Normal dose	Significant CYP3A4 interactions
	Itraconazole		Normal dose	Significant CYP3A4 interactions
	Voriconazole		Normal dose	Significant CYP3A4 interactions
Other antifungals		Terbinafine	Dose reduction maintenance doses	
	Griseofulvin		Normal dose	
	Caspofungin		Normal dose

TABLE 75.1 Common Drug Dosing Recommendations in Renal Impairment and Transplant—cont'd

	PREDOMINANT ELIMINATION PATHWAY			
Drugs	**Hepatic**	**Renal**	**Dosing Recommendations**	**Comments**
Antianginals	Nitrates		Normal dose	
	Nicorandil		Normal dose	
	Perhexiline		Normal dose	
Statins	Atorvastatin		Normal dose	
	Rosuvastatin		Normal dose	
	Simvastatin		Normal dose	
		Pravastatin	Normal dose	
Fibrates		Fenofibrate	Dose reduction	
Antiarrythmics		Digoxin	Reduce dose with monitoring	Bradycardia
		Disopyramide	Dose reduction	
		Procainamide	Dose reduction	
	Amiodarone		Normal dose	
	Flecainide		Normal dose	
	Mexiletine		Normal dose	
Diuretics		Furosemide	Dose increase	
		Spironolactone	Avoid	Hyperkalemia
Diabetes				
Insulins		Insulin	Cautious dose titrations	
Biguanides		Metformin	Avoid	Lactic acidosis
Sulfonylureas	Gliclazide		Normal doses	
	Glibenclamide		Avoid/dose reduction	Active metabolites
	Glipizide		Avoid/dose reduction	Active metabolites
Thiazolidinediones	Pioglitazone		Avoid	
	Rosiglitazone		Avoid	
Gastrointestinal				
H_2-Antagonists		Ranitidine	Normal dose	
	Cimetidine		Avoid	Significant drug interactions
Proton Pump Inhibitors	Lansoprazole		Normal dose	Acute interstitial nephritis may occur (see Chapter 60)
	Esomeprazole		Normal dose	
	Pantoprazole		Normal dose	
	Omeprazole		Normal dose	
Dopamine antagonists	Domperidone		Normal dose	Extrapyramidal and CNS effects at high dose with renal impairment
	Metoclopramide		Normal dose	
	Prochlorperazine		Normal dose	
5-HT_3 antagonists	Ondansetron		Normal dose	
	Dolasetron		Normal dose	
	Tropisetron		Normal dose	
Aperients and laxatives	Low potency:			Fluid and electrolyte disturbances
	Docusate		Normal dose	
	Bisacodyl		Normal dose	
	Lactulose		Normal dose	
	Sorbitol		Normal dose	
	High potency, including phosphate containing		Avoid	
Antidiarrheal agents	Loperamide		Normal dose	
	Diphenoxylate		Normal dose	
	Atropine		Normal dose	

TABLE 75.1 Common Drug Dosing Recommendations in Renal Impairment and Transplant—cont'd

	PREDOMINANT ELIMINATION PATHWAY			
Drugs	**Hepatic**	**Renal**	**Dosing Recommendations**	**Comments**
Musculoskeletal				
Gout		Allopurinol	Reduce dose	Active metabolite
	Febuxostat		Normal dose	
Bisphosphonates		Alendronate	Normal or reduced dose	Avoid in adynamic bone disease
		Risedronate	Normal or reduced dose	
		Pamidronate	Normal or reduced dose	Rapid IV doses may be nephrotoxic
Central Nervous System–Acting Drugs				
Antiepileptics		Levetiracetam	Reduce dose	
	Valproate		Normal dose	
	Phenytoin		Normal dose with monitoring	Significant CYP3A4 interactions
	Carbamazepine		Normal dose	Significant CYP3A4 interactions
Selective serotonin uptake inhibitors	Citalopram		Normal dose	
	Paroxetine		Normal dose	
	Venlafaxine		Normal dose	
Antipsychotics	Olanzapine		Normal dose	
	Risperidone		Normal dose	
	Clozapine		Normal dose	
Benzodiazepines	Oxazepam		Normal dose	Enhanced CNS toxicity
	Clonazepam		Normal dose	Enhanced CNS toxicity
	Temazepam		Normal dose	Enhanced CNS toxicity
	Diazepam		Normal dose	Enhanced CNS toxicity

CNS, Central nervous system; *TCAs,* tricyclic antidepressants.

However, UFH is used at normal dose with titration based on activated partial thromboplastin time monitoring. In some centers, UFH is preferred in severe renal impairment because its effect is shorter and more easily measured and reversed.

Low Molecular Weight Heparins

Low molecular weight heparins (LMWHs) rely more on renal clearance than UFH and in moderate to severe renal impairment they accumulate, increasing the risk for serious bleeding. Consideration should be given to the use of UFH in this setting. If prolonged treatment doses of LMWHs are used, doses should be reduced and, if possible, anti-Xa activity measured to guide therapy.

Other Parenteral Anticoagulants

Other parenteral anticoagulants that accumulate in renal impairment and that should be avoided or used with significant dose reduction include bivalirudin, danaparoid, fondaparinux, lepirudin, ximelagatran, and melagatran. Argatroban may be used at normal dose. Prostacyclin, used to prevent platelet aggregation in HD circuits, is rapidly hydrolyzed and not affected by renal impairment.

Oral Anticoagulants

The liver extensively metabolizes warfarin, and in renal impairment it is usually commenced at normal dose and titrated according to the international normalized ratio. Warfarin is highly protein bound, and with hypoalbuminemia there may be increased sensitivity to warfarin. Similarly, hepatic metabolism may be altered with renal impairment increasing sensitivity. Warfarin promotes vascular calcification and should be avoided in patients with advanced CKD unless absolutely necessary (e.g., those with a mechanical heart valve). Newer oral anticoagulants (rivaroxaban, dabigatran, and to a lesser extent apixaban) are partially dependent on renal clearance. Dose modifications are recommended in moderate renal impairment and contraindicated by the manufacturer in dialysis patients.

Antiplatelet Drugs

Commonly prescribed doses of oral antiplatelet drugs (aspirin, clopidogrel, and dipyridamole) do not require adjustment, although patients are often more prone to bleeding. Despite their efficacy in patients with reduced renal function, eptifibatide and tirofiban are renally excreted and have been associated with bleeding in this setting. Abciximab is cleared by platelet binding and is not associated with increased bleeding risk in patients with renal impairment.

Thrombolytics

Streptokinase, anistreplase, and alteplase are used as normal, but the high risk for hemorrhage should be considered. Urokinase is also used to unclot dialysis catheters.

Hemostatics

Tranexamic acid requires dose reduction in moderate to severe renal impairment. Protamine and vitamin K are used as normal, as are fresh-frozen plasma and whole blood with critical bleeding.

DIURETICS

Diuretics must reach the renal tubule lumen unbound to exert an effect.[27] Pharmacokinetic and pharmacodynamic properties of diuretics can

TABLE 75.2 Common CYP3A4/P-gp–Mediated Interactions With Transplant Immunosuppressants (Cyclosporine, Tacrolimus, Sirolimus, and Everolimus)

Drug Class	Examples	Relative Potency
Drugs That Inhibit CYP3A4 and P-gp		
Macrolide antibiotics	Azithromycin	–
	Clarithromycin	+++
	Erythromycin	+++
	Roxithromycin	+
Azole antifungals	Fluconazole	+/–
	Itraconazole	++
	Ketoconazole	+++
	Voriconazole	+++
Calcium channel blockers	Amlodipine	+

Herbals, foods	Grapefruit juice	++
Drugs That Induce CYP3A4 and P-gp		
Antiepileptics	Carbamazepine	++
	Phenytoin	+++
	Phenobarbitone	++
Antibiotics	Rifampin	+++
Herbals, foods	St John's wort	+++

P-gp, P-glycoprotein.

change with proteinuria or renal impairment, usually causing a resistance to their effect. Diuretics in the immediate posttransplant setting may increase urine flow in native kidneys, giving a false appearance of transplant function.

Thiazide Diuretics

Thiazide diuretics (chlorthalidone, hydrochlorothiazide, and indapamide) generally become ineffective as diuretics when GFR is below 30 ml/min, although they may augment the effectiveness of a loop diuretic and retain their antihypertensive effects. Metolazone can maintain efficacy at a lower GFR.

Loop Diuretics

Loop diuretics (furosemide, bumetanide, torsemide, and ethacrynic acid) remain effective at low GFR and are generally preferred in patients with renal impairment, although higher doses are usually required.

Potassium-Sparing Diuretics

Potassium-sparing diuretics are the least effective diuretics and should be used cautiously in moderate to severe renal impairment because of the risk for hyperkalemia.

ANTIHYPERTENSIVES

Antihypertensives should be used cautiously to avoid renal hypoperfusion.[28] Hypotension during HD may require that doses be withheld or delayed on dialysis days.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

Although various ARBs and the active metabolites of ACE inhibitors are renally excreted, they can be used effectively in CKD if initiated at moderate doses and titrated to response, renal function, and serum potassium level. An increase in serum creatinine (up to 20% to 30% in the first 2 months) may be associated with blood pressure response. All ACE inhibitors and ARBs can cause acute renal impairment by inhibiting angiotensin II–mediated homeostatic vasoconstriction of the efferent renal arteriole during renal hypoperfusion (e.g., with dehydration, hypotension, blood loss, and infection) or preexisting renal impairment (see also Chapter 66). Nephrotoxicity is more likely with coadministration of drugs that reduce renal perfusion, including diuretics, antihypertensives, and NSAIDs.[29] Hyperkalemia is more likely in those with renal impairment and those taking potassium-sparing diuretics or supplements. ACE inhibitors or ARBs also can worsen anemia by reducing erythropoietin production.

β-Blockers

Most β-blockers (carvedilol, labetalol, metoprolol, pindolol, and propranolol) are hepatically metabolized and used at normal doses. Sotalol and atenolol rely on renal clearance, and dose reductions are generally required. β-Blockers may slightly elevate serum potassium.

Calcium Channel Blockers

Pharmacokinetics of CCBs are essentially unaltered in renal impairment. These drugs are generally well tolerated and used in normal doses. Dihydropyridine CCBs can cause significant edema, which can aggravate the edema of renal impairment. To varying extents, CCBs inhibit CYP3A4 and P-glycoprotein, causing increased absorption and reduced elimination of various substrate drugs, including CNIs and mTORs. Verapamil and diltiazem are moderately potent inhibitors, and dose modification of the concomitant drug is required. This interaction has been exploited so that diltiazem and often other CYP3A4 and P-glycoprotein inhibitors are used as immunosuppressant-sparing agents.[30] Other CCBs do not usually cause clinically significant interactions.

Other Antihypertensives

Methyldopa, clonidine, prazosin, terazosin, doxazosin, and minoxidil are renally cleared but can be initiated and titrated at conventional dosage. They are often associated with a higher incidence of adverse effects in patients with renal impairment. In particular, minoxidil is relatively contraindicated in CKD because it can lead to volume expansion with the development of pericardial and pleural effusions; when used, additional diuretic therapy may be required. α-Blockers cause profound orthostatic hypotension. Nitroprusside must be used cautiously because the toxic metabolite thiocyanate may accumulate with renal impairment but is hemodialyzable.

ANTIANGINAL AGENTS

Most antianginals (nitrates, CCBs, nicorandil, and perhexiline) can be used as normal.

ANTIARRHYTHMICS

Various antiarrhythmics (digoxin, flecainide, disopyramide, procainamide, and sotalol) rely on renal excretion and require dose modification. Digoxin has significant renal excretion and a narrow therapeutic window, so dose reduction is essential even in mild renal impairment. Because of reduced tissue protein binding and V_D, some physicians use

a smaller loading dose of digoxin than in patients with normal renal function. Cautious monitoring and titration can prevent accumulation and toxicity. When possible, monitoring of antiarrhythmic drug concentrations and the electrocardiogram is recommended. Other agents (amiodarone, flecainide, metoprolol, mexiletine, and verapamil) are used at normal doses.

LIPID-LOWERING AGENTS

Bile Acid–Binding Resins

Bile acid–binding resins are now rarely used, and the large fluid volumes required to administer them limit their use in patients with kidney failure. They can interfere with absorption and enterohepatic recirculation of various drugs, including mycophenolate.

Statins

Most statins (hydroxymethylglutaryl–acetyl CoA [HMG-CoA] reductase inhibitors) are extensively metabolized and can be used effectively at normal doses in renal impairment and those who have undergone transplantation.[31] Rhabdomyolysis with acute kidney injury can occur, although the risk does not appear to be greatly increased with chronic renal impairment. The risk increases with use of fibrates and drugs that inhibit the CYP3A4 metabolism of statins. Patients commencing therapy should have lipids, renal function, and creatine kinase monitored regularly.

Fibrates

Fenofibrate but not gemfibrozil has extensive renal clearance, and dose reduction is required. Combination of statins and fibrates significantly increases the risk for rhabdomyolysis and should be used only when benefits outweigh risks and with monitoring for muscle symptoms, creatine kinase, and alanine aminotransferase.

DIABETES

The kidney plays an important role in insulin metabolism, and thus renal function influences glycemic control. Diabetes is also common after transplantation because of resumed insulin metabolism by the functioning transplant and also the effect of tacrolimus and corticosteroids. Patients with renal impairment are at increased risk for hypoglycemia, and drugs should be initiated and titrated cautiously.[32] Various antidiabetic drugs depend on renal excretion, and accumulation in renal impairment can cause adverse effects.[33] Management of diabetes in CKD is discussed in Chapter 32.

Diabetes Management in Peritoneal Dialysis

Patients receiving PD may have higher antihyperglycemic requirements because of the glucose load in PD fluid. If intraperitoneal insulin is used, dosages may vary from intravenous requirements. Icodextrin solutions can significantly interfere with blood glucose monitoring because of metabolites (maltose, maltotriose, or maltotetraose) that falsely elevate blood glucose readings when monitors use the enzyme glucose dehydrogenase pyrroloquinoline quinone. This may lead to administration of insulin and the development of life-threatening hypoglycemia. A glucose-specific test strip is required to avoid interference.

Biguanides

Metformin is excreted almost entirely unchanged in urine and accumulation can contribute to severe or fatal lactic acidosis (see Chapter 32).[34] Metformin should be temporarily discontinued in situations known to increase the risk for lactic acidosis or reduce renal function (e.g., acute tissue hypoxia, dehydration, serious infection or trauma) and 24 to 48 hours before anticipated surgery or use of iodinated radiocontrast media. Metformin is not usually recommended if GFR is below 60 ml/min and certainly below 30 ml/min. Nevertheless, a patient with renal impairment established on low-dose metformin is still at risk for lactic acidosis, and any acute deterioration in renal function can reduced drug clearance at any time. Patients on this regimen should be advised to seek early medical advice in any cases of acute deterioration in health.

Insulins

As renal function decreases, insulin clearance decreases. Uremia, however, can cause peripheral resistance to insulin, requiring increased doses. Most insulin regimens can be used in patients with CKD or transplantation with cautious titration and monitoring.

Meglitinides

The nonsulfonylurea insulin secretagogues repaglinide and nateglinide can be used in patients with renal failure without dose adjustment.

Sulfonylureas

Sulfonylureas are metabolized and some (glibenclamide and glimepiride) have active, renally excreted metabolites. In moderate to severe renal impairment, hypoglycemic risk is increased.[35] These agents should be initiated at low dose and titrated to response. Gliclazide and glipizide are preferable because they do not have active metabolites. Regardless of which agent is used, the effect of sulfonylureas still may be increased because the insulin they release will itself have a prolonged action in renal impairment.

SGLT2 Inhibitors

SGLT2 inhibitors (e.g. dapagliflozin) depend on adequate renal function to lower blood glucose levels and may be less effective at achieving this in moderate or severe renal impairment although they may have additional and independent benefits in delaying diabetic kidney disease.[36]

DPP-4 Inhibitors

Many DPP-4 inhibitors (sitagliptin, vildagliptin) rely on renal excretion and require significant dose reduction in renal impairment.

Thiazolidinediones

Thiazolidinediones are extensively metabolized and excreted in bile. Their pharmacokinetics are not significantly altered by renal impairment and in fact show reduced exposure, possibly because of reduced protein binding. However, they can cause fluid retention and edema, exacerbating the difficulties of fluid management and heart failure and are generally best avoided in renal impairment. Thiazolidinediones have been associated with dilutional anemia because of an increase in plasma volume, which may complicate management of renal anemia.

DRUGS FOR THYROID DISORDERS

Thyroid hormones generally do not require dose alteration in CKD.[37] Doses should be initiated and titrated to thyroid-stimulating hormone levels and clinical effect. In circulation, thyroxine (T_4) is 99.98% protein bound (0.02% free) and triiodothyronine (T_3) is 99.8% bound (0.2% free). T_3 and T_4 bind partially, in slightly different proportions, to three different plasma proteins: thyroid-binding globulin, thyroid-binding prealbumin, and albumin. In protein-deficient states (e.g., nephrotic syndrome), there is the possibility of transient or permanent changes in thyroid hormone protein binding that may alter the free fraction of T_3 and T_4, leading to transient toxicity. Uremic toxins can inhibit enzymes associated with conversion of T_4 to T_3. Oral absorption of thyroid hormones is affected by coadministration with metallic phosphate binders and iron. Euthyroid patients with CKD may have abnormal thyroid

function test results, possibly because of decreased peripheral conversion of T_4 to T_3, decreased clearance of reverse T_3 generated from T_4, or decreased binding of thyroid hormones to proteins. Antithyroid drugs can be used at usual doses.

MINERAL AND BONE DISORDERS

Prescribing for these disorders is further discussed in Chapter 84.

Phosphate Binders

Phosphate binders should be taken with meals for maximal efficacy. Patients can be instructed to tailor phosphate binder intake to the phosphorus content and frequency of meals. Doses are not affected by renal function except that reducing function increases the need for phosphate binders. Dosage is based on phosphate levels and the need to avoid biochemical abnormalities. Acid suppression may reduce the effectiveness of phosphate binders by inhibiting hydrolysis of metallic ions in the gut. Phosphate binders also may reduce gastrointestinal absorption of drugs, including thyroid hormones, fluoroquinolones, tetracyclines, digoxin, and immunosuppressants.

Vitamin D

In patients with renal impairment, inability of the kidneys to activate 25-hydroxycholecalciferol to calcitriol may produce relative vitamin D deficiency and hypocalcemia, which requires treatment with the active vitamin D preparations calcitriol or alfacalcidol.

Calcimimetics

Cinacalcet dosage is independent of renal function except that progressive renal impairment exacerbates secondary hyperparathyroidism. When possible, cinacalcet should be administered with the evening meal to improve absorption and minimize side effects. Similarly, morning blood samples for parathyroid hormone levels should be drawn at least 12 hours after administration. Cinacalcet and etelcalcetide usage is further discussed in Chapter 84.

DYSPEPSIA, GASTROESOPHAGEAL REFLUX DISEASE, AND PEPTIC ULCERS

Proton pump inhibitors, histamine-2 (H_2) receptor blockers, and antacids are commonly used in patients with CKD (see Chapter 86).

Antacids

Alginates, magnesium trisilicate, and sodium bicarbonate are useful for symptom control but have high sodium content, which exacerbates hypertension and fluid status. Magnesium and aluminum salts can reduce the absorption of mycophenolate. Aluminum salts are often avoided in patients with advanced CKD.

Histamine-2 Antagonists

Most H_2 antagonists are renally cleared but relatively safe, so dose reduction is usually not required.[38] Protein binding and V_D are unaltered; however, the bioavailability of nizatidine is reduced in renal impairment. Cimetidine should be avoided because accumulation produces CNS effects and it causes significant interactions through the CYP450 system and falsely elevates serum creatinine levels.

Proton Pump Inhibitors

Proton pump inhibitors are generally safe and well tolerated even at normal dose, although they have rarely been associated with interstitial nephritis and there is increasing concern that their use may be associated with the development of CKD, although evidence is not definitive.

ANTIEMETICS

Dopamine Antagonists

Domperidone, metoclopramide, and prochlorperazine are not significantly renally cleared; however, extrapyramidal and CNS effects may occur in CKD, especially at high doses. Domperidone does not cross the blood-brain barrier and may be preferable for long-term management. Metoclopramide and domperidone increase gastric emptying, which may alter drug pharmacokinetics.

5-HT_3 Antagonists

Most 5-HT_3 antagonists are minimally excreted in urine and have a wide therapeutic window. Dolasetron, granisetron, ondansetron, and tropisetron are safe, and dose modification is not required.

APERIENTS AND LAXATIVES

Common low-potency agents including docusate, bisacodyl, glycerin, lactulose, liquid paraffin, senna, and sorbitol may be used for acute or chronic constipation. Normal doses should be titrated to effect while avoiding significant dehydration, fluid shifts, or electrolyte disturbances. High-potency laxatives and bowel preparations should be used cautiously. They can cause significant fluid and electrolyte disturbances, especially in susceptible renal patients. Preparations containing high amounts of phosphate should be avoided. Despite the large fluid volumes required for administration, isoosmotic laxatives may be used for bowel preparation in patients with renal impairment and dialysis.

ANTIDIARRHEALS

Opioids or their derivatives should be used with the same caution as when they are used as analgesics. Loperamide and diphenoxylate-atropine can be given in usual doses.

DRUGS FOR ERECTILE DYSFUNCTION

Phosphodiesterase-5 Inhibitors

The AUCs of sildenafil (twofold), tadalafil (fourfold), and vardenafil (20% to 30%) are increased in patients with severe renal impairment despite minimal dependence on renal excretion. However, provided that relevant cardiovascular and drug contraindications are excluded, they can be used safely. They should be initiated at low doses and titrated to response. Shorter acting agents (sildenafil and vardenafil) may be preferable. Vardenafil can prolong the QT interval.

Intracavernosal Therapy

Drugs given directly by intracavernosal injection do not achieve significant concentrations in the systemic circulation and can be used in patients with renal impairment.

MUSCULOSKELETAL DRUGS

Nonsteroidal Antiinflammatory Drugs

NSAIDs can cause significant nephrotoxicity and should be avoided or used with extreme caution in patients with CKD.

Miscellaneous Arthritis Drugs

Gold salts and penicillamine are now rarely used for rheumatoid arthritis. Both were associated with nephrotic syndrome caused by membranous nephropathy. Glucosamine and fish oil can be used safely.

Gout and Hyperuricemia

Gout is highly prevalent in patients with renal impairment. In acute therapy, short courses of oral corticosteroids are safe and preferable to NSAIDs. Colchicine accumulation in renal impairment may cause diarrhea and hypoperfusion-induced renal impairment, as well as myelosuppression. In maintenance therapy, allopurinol is effective but the dose should initially be reduced in moderate to severe renal impairment because of its renally cleared active metabolite (oxypurinol).[39] Despite this, some patients with end-stage renal disease tolerate normal doses. Allopurinol significantly interacts with azathioprine with a risk for severe myelosuppression. If the combination is unavoidable the azathioprine dose should be reduced by 75% and blood counts monitored carefully. Uricosuric agents (e.g., probenecid) inhibit secretion of acids in the proximal tubule and prevent reabsorption of uric acid from the tubular lumen. They often become ineffective with diminishing renal function and are best avoided if the GFR is below 40 ml/min. Probenecid also interferes with the tubular secretion of many drugs, causing interactions.

Bisphosphonates

Bisphosphonates are extensively excreted in urine. The fraction not excreted is incorporated into bone, from which it slowly dissociates. In renal impairment, impaired clearance of absorbed drug may increase the fraction available for incorporation into bone. The long terminal elimination half-life of these agents reflects rate-limiting dissociation from bone and may not be significantly altered in patients with renal impairment. Oral bisphosphonates appear to be safe in CKD stages 2 and 3. Their safety in CKD stages 4 and 5 is less well established, and they are contraindicated in adynamic bone disease. Rapid administration of intravenous bisphosphonates (pamidronate and zoledronic acid) without hydration has been associated with acute nephrotoxicity. Intravenous preparations should be administered slowly with hydration, and renal function assessed regularly. Oral bisphosphonate administration may be complicated by the volumes of fluid recommended. In addition, many patients with renal impairment are taking calcium-based phosphate binders or supplements that impair the absorption of oral bisphosphonates.

ANTIEPILEPTICS

Patients with CKD may be more prone to seizures (e.g., uremic encephalopathy and dialysis disequilibrium syndrome) and to the CNS effects of antiepileptics. Some antiepileptics rely on renal excretion, and dose modification is essential. Some antiepileptics (barbiturates, phenytoin, and carbamazepine) are strong inducers of drug-metabolizing enzymes. Coadministration with drugs reliant on hepatic metabolism (e.g., immunosuppressants) can reduce exposure and efficacy of the concomitant drug. Therapeutic drug monitoring is available for many antiepileptics and should be used to guide dosage.

Benzodiazepines

See the later discussion of psychotropic drugs.

Carbamazepine

Carbamazepine is administered as normal and titrated to response and blood concentrations. It is a potent enzyme inducer, and care must be taken to account for important drug interactions.

Phenytoin

Caution should be exercised with phenytoin in renal impairment because of its erratic absorption, saturable metabolism, nonlinear pharmacokinetics, reduced protein binding, and increased V_D. The concentration of free drug may be higher than in normal renal function. Because most laboratories measure total drug concentration, a low serum total phenytoin level in renal impairment should not be mistaken as subtherapeutic. Nystagmus, cerebellar ataxia, and seizures can occur in overdose, and small dose increases may result in disproportionate increases in serum concentrations. Cautious titration based on effect and monitoring of free plasma concentration is advised. Phenytoin is a potent enzyme-inducing agent, and care must be taken to account for drug interactions.

Other Antiepileptics

Levetiracetam, topiramate, and vigabatrin undergo significant renal excretion, and dose modification is required. Valproate and lamotrigine are not significantly renally excreted and do not cause enzyme induction or inhibition. Protein binding changes can increase the free fraction of valproic acid, predisposing to increased responsiveness.

ANTIPARKINSONIAN DRUGS

In addition to their use for Parkinson disease and hyperprolactinemia disorders, dopaminergic drugs are used to treat restless legs and other limb movement disorders in patients with renal impairment. Most are hepatically cleared and safe, although dopaminergic agents may exacerbate postural hypotension. Amantadine is highly dependent on renal excretion, and dose modification is essential.

ANTIMIGRAINE DRUGS

Simple analgesics (acetaminophen) are used as normal, although aspirin should be avoided at therapeutic doses and opioids used cautiously (see discussion of analgesics). NSAIDs are best avoided because of potential nephrotoxicity. 5-HT_1 agonists are effective in patients with renal impairment and transplantation. Naratriptan relies the most on renal excretion (50%), and a lower maximum dose is recommended. Sumatriptan and zolmitriptan are preferred because they are less dependent on renal excretion.

PSYCHOTROPIC DRUGS

Most psychotropics are fat soluble and nondialyzable, undergo significant hepatic metabolism, and are excreted as inactive compounds. Even so, renal patients are often more susceptible to common adverse effects (especially CNS effects).[40] Slow titration and dose modifications are required. Adverse effects are not easily distinguished from symptoms of uremia. Despite being metabolized extensively by CYP450 enzymes, very few psychotropics cause clinically significant inhibition or induction of CYP3A4.

Selective Serotonin Reuptake Inhibitors

Most selective serotonin reuptake inhibitors (SSRIs) are extensively metabolized to compounds without significant SSRI activity.[41] Normal doses of citalopram, fluvoxamine, paroxetine, and sertraline can be used with cautious dose titration. Fluoxetine is metabolized to an active metabolite (norfluoxetine), but single- and multiple-dose studies have shown little change in pharmacokinetics even in dialysis patients. Patients with renal impairment may be more prone to the CNS toxicity of SSRIs and serotonin syndrome. SSRIs can cause the syndrome of inappropriate antidiuretic hormone secretion and platelet aggregation or hemorrhagic complications, which may increase the risk for bleeding in uremic patients who are already prone to bleeding complications. Although most SSRIs have some inhibitory effect on CYP3A4, this is usually not significant.

Fluoxetine and fluvoxamine are more likely to interact than citalopram and sertraline, but all can be used in patients taking immunosuppressants. Cinacalcet can cause significant inhibition of CYP2D6-mediated metabolism of SSRIs and perhexiline. This may increase the possibility of serotonin syndrome or perhexiline toxicity.

Tricyclic Antidepressants

Tricyclic antidepressants (TCAs) are now infrequently used for depression but more for neuropathic pain, and their anticholinergic properties in urinary tract disorders. They are predominantly metabolized to metabolites with varying activity. Patients with renal impairment may be more prone to the common anticholinergic adverse effects, particularly urinary retention, orthostatic hypotension, confusion, and sedation.[42] Obstructive uropathy can occur from the anticholinergic properties. Cautious initial doses and titration of TCAs are recommended. Depending on response, many agents can be used at up to normal or maximal doses.

Monoamine Oxidase Inhibitors

Monoamine oxidase inhibitors are extensively metabolized by the liver. Although they are now rarely used, normal doses of reversible monoamine oxidase inhibitors (moclobemide) are preferred and can be titrated cautiously to full doses. Monoamine oxidase inhibitors can cause peripheral edema, which is not usually associated with fluid retention and is unresponsive to diuretics. Prostatic hypertrophy and urinary retention also may occur.

Other Antidepressants

Venlafaxine dose should be initially reduced in patients with severe renal impairment because of reduced clearance of the active metabolite *O*-desmethylvenlafaxine and the potential for hypertension. Nefazodone is used at a normal dose.

Antipsychotics

Conventional antipsychotics cause a variety of side effects to which patients with renal impairment may be susceptible (sedation, confusion, and postural hypotension). Caution is advised for atypical antipsychotics that prolong the QT interval (e.g., pimozide, thioridazine, mesoridazine, droperidol, and ziprasidone). Newer atypical agents are more commonly used and better tolerated. Clozapine, olanzapine, quetiapine, and aripiprazole are commenced at normal doses and titrated to response. Risperidone and its active metabolite 9-hydroxyrisperidone are renally excreted, and clearance is reduced by 60% in severe renal impairment. Lithium is filtered and reabsorbed mainly in the proximal tubule. It has extensive renal clearance and accumulates even in mild renal impairment, causing toxicity, and should be avoided if possible. If use is essential, the dose must be reduced with monitoring of plasma concentrations. In hyponatremic patients, tubular reabsorption of lithium is increased, leading to increased plasma concentrations and toxicity. NSAID coprescription also may increase toxicity. HD is efficient in removal of lithium and can be used in overdose; however, multiple dialysis treatments are usually required because plasma concentrations rebound soon after HD. Chronic lithium nephrotoxicity is discussed further in Chapter 62.

Benzodiazepines

Benzodiazepines are extensively metabolized by the liver to a range of active and inactive metabolites. Enhanced CNS toxicity, especially sedation, is the main concern in renal patients. Because of the potential for accumulation, chronic use should be discouraged. Short-acting benzodiazepines are preferred, and the dose should be titrated cautiously according to response. The dose of midazolam should be reduced because of changes in plasma protein binding. Hemoperfusion and dialysis are not useful in patients with benzodiazepine intoxication. Flumazenil may be used as an antidote in patients with overdose, at doses similar to those with normal renal function.

ANEMIA DRUGS

Erythropoiesis-Stimulating Proteins

The pharmacokinetics of erythropoiesis-stimulating agents (ESAs) are not affected by renal function per se. However, as renal function decreases, dose requirements may increase to account for reduced endogenous erythropoietin production. Use of ESAs is discussed in detail in Chapter 82.

Iron Therapy

Oral supplements may be sufficient in early-stage CKD or PD patients who do not have the same degree of regular blood loss as HD patients. Maximum absorption of oral iron occurs with frequent administration of small doses away from food, although gastrointestinal intolerance limits therapy. Patients with severe iron deficiency and those on HD often require intravenous supplementation (see Chapter 82).

ANTIHISTAMINES

Normal doses of sedating antihistamines generally can be used. They should be used cautiously in patients with bladder outflow obstruction because they may cause or aggravate urinary frequency or retention. Newer, less sedating antihistamines are better tolerated and have a wider therapeutic index, and accumulation rarely causes significant complications. Cetirizine relies more on renal clearance, and dose reduction is suggested. Loratadine and desloratadine have active metabolites but are safe. Fexofenadine is safe; however, terfenadine should be avoided because of the risk for arrhythmias.

VACCINES

Live vaccines (BCG [bacillus Calmette-Guerin], oral poliovirus, rubella, typhoid, yellow fever, and varicella) in immunosuppressed patients are contraindicated because of the potential for causing disease. Attenuated vaccines (diphtheria-tetanus, hepatitis B, influenza, meningococcal, and pneumococcal) may be used, but impaired response in immunocompromised individuals may lead to inadequate protection (see Chapter 83). Hepatitis B may need more doses for seroconversion to be achieved in patients on HD. Immunization should preferably occur at least 1 month before initiation of immunosuppression. After transplantation, the immune response may be inadequate for at least 6 to 8 months, meaning that vaccination should be withheld until then.[43]

VITAMIN SUPPLEMENTATION

Patients with renal impairment may become vitamin deficient as a result of poor dietary intake and the effect of dialysis on removal of water-soluble vitamins. Administration of vitamin supplements (B, C, and folic acid) is recommended after dialysis.

SELF-ASSESSMENT QUESTIONS

1. Which of the following drug require(s) clinically significant dose modification in patients with significant renal impairment. (More than one answer is possible.)
   A. Enoxaparin
   B. Gabapentin
   C. Amoxicillin
   D. Amlodipine
   E. Famciclovir
2. Which of the following drug is(are) the *most* likely to cause clinically significant drug interactions with calcineurin inhibitors (CNIs). (More than one answer is possible.)
   A. Fluconazole
   B. Clarithromycin
   C. Vancomycin
   D. Acyclovir
   E. Roxithromycin
3. Which of the following drug require(s) dose modifications in renal impairment because of a renally cleared metabolite. (More than one answer is possible.)
   A. Olanzapine
   B. Allopurinol
   C. Atenolol
   D. Amlodipine
   E. Pethidine
4. Which of the following drugs is(are) likely to be removed by hemodialysis and should therefore be dosed after dialysis? (More than one answer is possible.)
   A. Pregabalin
   B. Amiodarone
   C. Levetiracetam
   D. Pantoprazole
   E. Acyclovir

Herbal and Over-the-Counter Medicines and the Kidney

Mark S. Segal, Xueqing Yu

The use of herbal medicines and dietary supplements continues to increase globally. An estimated one third of adults in developed countries and more than 80% of the population in many low and middle income countries use herbal and folk medicines to promote health and manage a number of common maladies, such as colds, hay fever, indigestion, and constipation, as well as liver cirrhosis, cancer, heart disease, AIDS, and diabetes.[1] In Africa, up to 80% of the population depends on traditional medicine for primary health care; in China, herbal preparations account for up to 50% of the total consumption of pharmaceutical agents; and there has been a surge in the popularity of herbal medicine in the West. For instance, the U.S. herbal medicine market increased from $1.6 billion in 1994 to $6.4 billion in 2014[1,2]; complementary and alternative medicines, including Chinese herbal medicines and herbal plants, have been used by about 50% of Australians.[1]

Germany and France are the leaders in sales of over-the-counter (OTC) herbal medicines in Europe and also have large markets for prescription herbal preparations (Fig. 76.1).[3] The European Union has taken steps to regulate herbal remedies with the Traditional Herbal Medicinal Products Directive (also known as Directive 2004/24/EC), implemented in May, 2011. This mandates all herbal medicinal products obtain an authorization to market within the European Union and that herbal medicines be manufactured under Good Manufacturing Practice.

There are at least 11,000 species of plants for medicinal use, and about 500 of them are commonly used by various ethnic groups.[1,4] These herbal plants may be used either in their primary forms or in mixtures. However, the source and composition of botanical medicines vary depending on the prevalent local practices. Herbal remedies are not tested for efficacy and safety, their ingredients are largely unknown, and there is no standardization of dosage and route of administration. Organ toxicity caused by traditional medicines is directly related to a combination of poor education, poverty, lack of medical facilities, weak or absent legislation, and widespread belief in indigenous systems of medicine in rural areas. Problems related to herbal medicines arise as a result of intrinsic toxicity, adulteration, contamination, substitution, misidentification, mistaken labeling, and unfavorable herb-drug interactions.[1,4] Increasing evidence for both adverse drug reactions and poisoning events associated with the use of herbal medicines has been reported worldwide. Herbal medicines have been found to be adulterated with synthetic drugs and other potentially toxic compounds. On the other hand, coadministration of herbal medicines with conventional drugs raises the potential for herb-drug interactions, which may cause altered drug elimination, undertreatment, and/or toxicity.[1,4,5]

HERBAL MEDICATIONS AND THE KIDNEY

The kidneys are particularly vulnerable to toxic injury because of their high blood flow rate, large endothelial surface area, high metabolic activity, active uptake by tubular cells, medullary interstitial concentration, and low urine pH. Renal tubules are involved in active transport and urinary concentration, and therefore the local concentration of these toxins is potentially high, leading to direct injury to tubular cells. Herbal medicines may be nephrotoxic via one or more common pathogenic mechanisms, including alterations in intraglomerular hemodynamics, tubular cell toxicity, inflammation, crystal nephropathy, rhabdomyolysis, and thrombotic microangiopathy. Furthermore, potentially nephrotoxic exogenous substances such as paint thinners, turpentine, chloroxylenol, ginger, pepper, soap, vinegar, copper sulfate, and potassium permanganate, are often added to herbal compounds. Drug-related nephrotoxicity is becoming more common, as more people have multiple comorbidities that require multiple medications and more diagnostic and therapeutic procedures, all with the potential to harm kidney function. Patient-related risk factors for drug-induced nephrotoxicity include age older than 60 years, underlying renal impairment with glomerular filtration rate (GFR) less than 60 ml/min/1.73 m^2, volume depletion, diabetes, heart failure, and sepsis.[6] These same risk factors also may make individuals susceptible to renal toxicity from herbal medicines.

An overview of the potential renal side effects of herbal medicines is shown in Table 76.1.

ARISTOLOCHIC ACID NEPHROPATHY

Aristolochic Acids

Aristolochic acids (AAs) are a family of structurally related nitrophenanthrene carboxylic acids found in herbal medicines such as *Aristolochia* spp., including *Aristolochia fangchi, Aristolochia clematitis,* and *Aristolochia manshuriensis* (Table 76.2). The predominant AAs are AAI (8-methoxy-6-nitro-phenanthro-[3,4-*d*]-1,3-dioxolo-5-carboxylic acid) and AAII (6-nitro-phenanthro-[3,4-*d*]-1,3-dioxolo-5-carboxylic acid). AAs are activated by human NAD(P)H:quinone oxidoreductase (NQO1)[7] and react with DNA to form covalent 7-(deoxyadenosin-N^6-yl)aristolactam I (dA-AA) and 7-(deoxyguanosin-N^2-yl)aristolactam(dG-AA) adducts. These aristolactam adducts are mutagenic.[8] After even a single dose, AAI is stably detected in the kidneys. Human aristolochic acid nephropathy (AAN) is reproducible in rodents with AA intoxication, resulting in tubular atrophy and interstitial fibrosis, leading to renal failure.[9] The

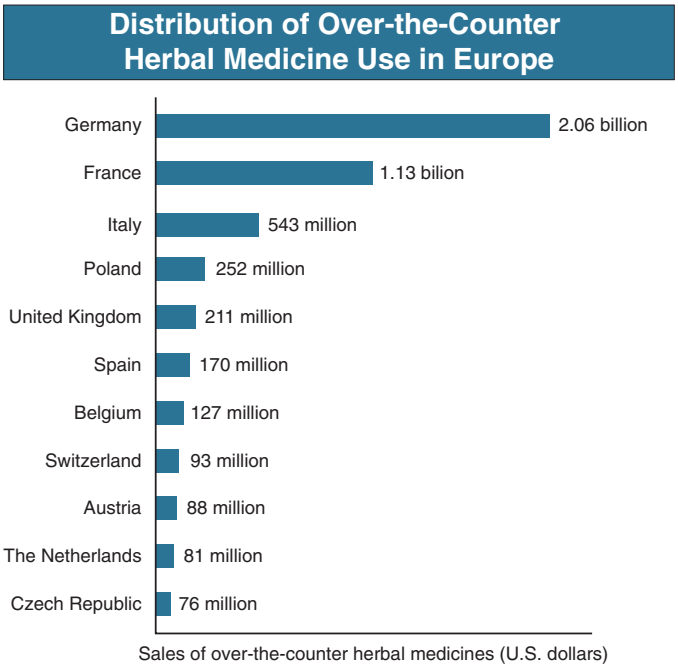

Fig. 76.1 Distribution of the $4.96 billion European market for over-the-counter herbal medicines in 2003. (Based on date from reference 3.)

TABLE 76.1 Kidney Syndromes Induced by Herbal Medicines

Syndrome	Herbal Medicine
Hypertension	*Glycyrrhiza* spp. (Chinese herbal teas, gancao, boui-ougi-tou) *Ephedra* spp. (ma huang)
Acute tubular necrosis	Traditional African medicine: Toxic plants (*Securidaca longepedunculata, Euphoria matabelensis, Callilepis laureola,* Cape aloes), or adulteration by dichromate Chinese medicine: *Taxus celebica* Morocco: *Takaout roumia* (paraphenylenediamine)
Acute interstitial nephritis	Peruvian medicine *(Uno degatta)* Tung Shueh pills (adulterated by mefenamic acid)
Fanconi syndrome	Chinese herbs containing AAs (*Akebia* spp., boui-ougi-tou, Mokutsu) Chinese herbs adulterated by cadmium
Papillary necrosis	Chinese herbs adulterated by phenylbutazone
Chronic interstitial renal fibrosis	Chinese herbs or Kampo containing AAs (*Aristolochia* spp., *Akebia* spp., Mu Tong, Boui, Mokutsu)
Urinary retention	*Datura* spp., *Rhododendron molle* (atropine, scopolamine)
Kidney stones	Ma huang (ephedrine) Cranberry juice (oxalate)
Urinary tract carcinoma	Chinese herbs containing AAs

From reference 6.
AA, Aristolochic acids.

progressive tubular atrophy is related to impaired regeneration and apoptosis of proximal tubular epithelial cells, which is considered a possible mechanism of tubular epithelial cell deletion. The resident fibroblast activation plays a critical role in the process of renal fibrosis during AA toxicity.[10] The nephrotoxic and carcinogenic effects of AAs have been reported in animals, exposure to AA causes a progressive renal interstitial fibrosis associated with urothelial malignancy. Similar toxicities are observed in humans.

Aristolochic Acid Nephropathy

The association of kidney disease with long-term consumption of *A. fangchi* was first reported in Belgium in nine young women taking slimming preparations.[11] Since then there have been case reports and series from around the world (Fig. 76.2).[12] Even though this disease may affect millions worldwide, high-quality epidemiologic data on the incidence and prevalence of AAN are lacking because of the absence of internationally agreed diagnostic criteria and global low awareness of the disease.[12] Increasing evidence supports that it is the AAs in the herbs that are responsible for their renal toxicity (Figs. 76.3 and 76.4).[9] The renal syndrome was initially referred to as *Chinese herb nephropathy* and is now known by the more specific, mechanistic name AAN.[14] The renal toxicity of AA depends on the dosage and the duration of administration.[15] It is now clear that Balkan endemic nephropathy, a condition known for several decades without a known cause, is another manifestation of AAN, in which there is contamination of wheat (flour) by *A. clematitis.*[9]

There is no evidence that AA is a causative agent more widely for chronic kidney disease (CKD) in other specific cohorts, and this is unlikely to be overlooked because no other known endemic nephropathy shares the association with urothelial malignancy, so characteristic of AA toxicity.

Definition

AAN is characterized by tubulointerstitial nephritis that progresses to fibrosis with deterioration of renal function, ultimately leading to end-stage renal disease (ESRD), sometimes within months after first exposure. There is a high associated risk for uroepithelial malignancy.

Epidemiology

Soon after its initial description, AAN was recognized as a global health problem.[9,11,12,15,16] Since the publication of the index cases, new cases of AAN have been reported, not only in Belgium but also worldwide[9-13] (see Fig. 76.2). The true incidence of AAN remains unknown and is probably underestimated because numerous ingredients known or suspected to contain AA are used in traditional medicine in China, Japan, and India (see Fig. 76.3).[9] Balkan endemic nephropathy (BEN) affects thousands of people living in discreet areas in Bulgaria, Bosnia, Croatia, Romania, and Serbia along the Danube River basin (Fig. 76.5).[16,17] BEN typically presents in the fourth or fifth decade of life and is only rarely seen in individuals younger than 20 years, presumably reflecting low-grade chronic exposure to AA.

Clinical Manifestations

The initial presentation of AAN is usually silent, and the renal disease only discovered by routine blood testing. Occasional patients present with Fanconi syndrome or with acute kidney injury (AKI) caused by acute tubular necrosis.[18] The urinary sediment is unremarkable, and the urinalysis is initially negative for albuminuria. However, urinary excretion of low molecular weight proteins (e.g., β_2-microglobulin, cystatin C) is markedly increased, and the ratio of urinary low molecular weight protein to albumin is higher than in glomerular diseases.[19] When there is prospective monitoring in endemic areas, tubular proteinuria

TABLE 76.2 Botanicals Known or Suspected to Contain Aristolochic Acid and Their Common Names

Botanical Name	Common or Other Names
Aristolochia spp.	Aristolochia, Guan Mu tong, Guang Mu tong
Aristolochia acuminata (syn. *Aristolochia tagala*)	Oval leaf Dutchman's pipe
Aristolochia bracteata	Ukulwe
Aristolochia clematitis	Birthwort
Aristolochia contorta	Ma Dou Ling (fruit), Bei Ma Dou Ling (root), Tian Xian Teng (herb)
Aristolochia cymbifera	Mil homens
Aristolochia debilis (syn. *Aristolochia longa, Aristolochia recurvilabra, Aristolochia sinarum)*	Ma Dou Ling (fruit), Tian Xian Teng (herb), Qing Mu Xiang (root), Sei-Mokkou (Japanese), Birthwort, Long birthwort, Slender Dutchman's pipe
Aristolochia fangchi	Guang Fang ji (root), Fang ji, Fang chi, Makuboi (Japanese), Kou-boui (Japanese), Kwangbanggi (Korean)
Aristolochia heterophylla	Han Fang Ji
Aristolochia indica	Indian birthwort (root), Yin Du Ma Dou Ling
Aristolochia kaempferi (syn. *Aristolochia chrysops, Aristolochia feddei, Aristolochia heterophylla, Aristolochia mollis, Aristolochia setchuenensis, Aristolochia shimadai, Aristolochia thibetica, Isotrema chrysops, Isotrema heterophylla, Isotrema lasiops*)	Yellowmouth Dutchman's pipe, Zhu Sha Lian
Aristolochia macrophylla (syn. *Aristolochia sipho*)	Dutchman's pipe
Aristolochia manshuriensis (syn. *Hocquartia manshuriensis, Isotrema manshuriensis*)	Manchurian birthwort, Manchurian Dutchman's pipe (stem), Guan Mutong (stem), Kan-Mokutsu (Japanese), Mokubai (Japanese), Kwangbanggi (Korean)
Aristolochia maxima (syn. *Howardia hoffmannii*)	Maxima Dutchman's pipe, Da Ma Dou Ling
Aristolochia mollissima	Wooly Dutchman's pipe, Mian Mao Ma Dou Ling
Aristolochia moupinensis	Moupin Dutchman's pipe, Huai Tong
Aristolochia sarpentaria (syn. *Aristolochia serpentaria*)	Virginia snakeroot, Serpentaria, Virginia serpentary
Aristolochia triangularis	Triangular Dutchman's pipe, San Jiao Ma Dou Ling
Aristolochia tuberosa	Tuberous Dutchman's pipe, Kuai Jing Ma Dou Ling
Aristolochia tubiflora	Tubeflower, Dutchman's pipe, Guan Hua Ma Dou Ling
Aristolochia versicolar	Versicoloraus Dutchman's pipe, Bian Se Ma Dou Ling
Asarum canodense (syn. *Asarum acuminatum, Asarum ambiguum, Asarum canadense, Asarum furcatum, Asarum medium, Asarum parvifolium, Asarum reflexum, Asarum rubrocinctum*)	Wild ginger, Indian ginger, Canada snakeroot, false coltsfoot, colic root, heart snakeroot, Vermont snakeroot, Southern snakeroot, Jia Na Da Xi Xin
Asarum himalai(y)cum	Tanyou-saishin (Japanese)
Asarum splendens	Do-saishin (Japanese)

From reference 16.

is usually the first manifestation of BEN. Other manifestations of tubular dysfunction include impaired acidification, decreased ammonia, increased uric acid excretion, and urine-concentrating defects with renal salt wasting, which may precede the decrease in GFR. The disease progresses to ESRD. Other hallmarks are that the severity of the anemia is disproportionate to the degree of renal impairment whereas the blood pressure is usually in the normal range until the development of ESRD.

Distinctive for AA exposure is the increased incidence of uroepithelial carcinomas. A case series with a 15-year follow-up identified upper tract urothelial carcinoma as a potent risk factor for the subsequent development of bladder urothelial carcinoma after kidney transplantation for AAN.[20]

Pathology

AAN is characterized by extensive renal interstitial fibrosis and tubular atrophy, which generally decreases in severity from the outer to the inner cortex (see Fig. 76.4). Early in the disease, the glomeruli are relatively spared, although at later stages there is some collapse of the capillaries and wrinkling of the basement membrane. There is endothelial cell swelling with consequent thickening of interlobular and afferent arterioles.[9,21] There are no immune deposits.

Pathogenesis

The striking association between AA exposure and uroepithelial abnormalities was first noted in nephroureterectomy specimens from individuals with AAN removed at the time of transplantation, demonstrating moderate atypia and atypical hyperplasia (see Fig. 76.4).[9,22] An early and massive interstitial inflammation characterized by activated monocytes and macrophages and cytotoxic $CD8^+/CD103^+$ T lymphocytes seen in experimental AAN[23,24] suggests that the pathophysiology includes an immunologic element. The persistence of AA-DNA adducts in renal tissues of the Belgian women cohort is consistent with their postulated role of DNA adducts in urothelial cancer. Of AAN patients, 40% to 45% develop multifocal high-grade transitional cell carcinomas, mainly

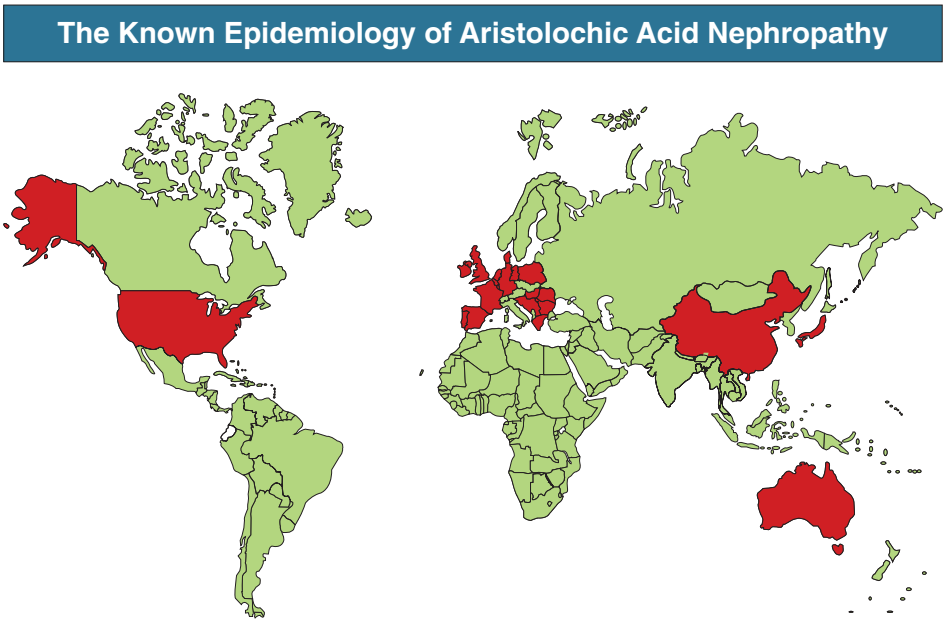

Fig. 76.2 The known epidemiology of aristolochic acid (AA) nephropathy. Countries in which cases of AA nephropathy or Balkan endemic nephropathy have been reported. It is likely that the true worldwide distribution of the diseases extends beyond the countries highlighted, especially in East and South Asia. (From reference 12.)

Fig. 76.3 Traditional Chinese pharmacy. A pharmacy selling traditional herbal remedies including Fang Chi and Mu Tong. The true incidence of aristolochic acid nephropathy (AA) is largely unknown and probably underestimated because numerous ingredients known or suspected to contain AA are used in traditional medicine in India and Eastern Asia. (From reference 9.)

in the upper urinary tract.[13] There is a strong association between DNA adduct formation, mutation pattern, and tumor development. In animal models, oral ingestion of AA is followed by extensive formation of AA-DNA adducts in the forestomach, accompanied by the development of tumors.[20] A genome-wide search in a series of cancers from Taiwan (where a significant fraction of the population is prescribed herbal medicines containing AA) demonstrated the presence of AA-DNA adducts and other DNA signatures of AA exposure in cancers of the upper urinary tract. Of additional concern was the presence of AA-DNA adducts in cancers of the liver and kidney.[25] Transitional cell cancers from patients with BEN contain AA and a characteristic pattern of tumor protein 53 (TP53) mutations, 89% occurring at A:T pairs and 78% of these being A:T to T:A transversions. These types of transversions are not seen in transitional cell carcinomas of the renal pelvis in the absence of AA exposure. Molecular epidemiologic evidence relates urothelial carcinoma in patients with BEN to dietary exposure to AA.[26]

There is now strong evidence for the role of AA in the pathogenesis of BEN. In endemic regions, bread is a dietary staple and is traditionally prepared from flour made from locally grown wheat. The seeds of *A. clematitis,* a plant native to the region, are found interspersed with the harvested wheat grain. dA-aristolactam and dG-aristolactam DNA adducts are found in the renal cortex of patients with BEN but not in those with other chronic renal diseases.[26,27] Aristolactam-DNA adducts have been found in 70% of people in endemic areas with dietary exposure to AA and in 94% of patients with specific A:T to T:A mutations in *TP53.* Neither aristolactam-DNA adducts nor specific mutations were detected in tissues of those from nonendemic regions. Because BEN occurs only in a fraction of those individuals exposed to AA, there is assumed to be a genetic susceptibility that puts individuals with a dietary exposure to AA at risk for BEN and its resultant urothelial carcinomas.[9,12]

Diagnosis

Diagnostic criteria for AAN and in endemic areas for BEN are shown in Box 76.1. An analysis of 182 patients in Serbia showed that proteinuria, urine α_1-microglobulin, and kidney size are significant predictors of BEN, whereas renal failure as well as several tubular disorders (urine specific gravity, fractional sodium excretion, and tubular phosphate reabsorption) had an insignificant predictive value.[16,30]

Treatment

There have been no randomized trials of treatment for AAN or BEN. However, a pilot study in 35 AAN patients with CKD demonstrated a significant reduction in the number of patients reaching ESRD after 1 year of corticosteroid therapy.[28] Corticosteroid therapy was later confirmed, in a larger cohort with historical controls, to slow down the progression of renal failure.[29] It is suggested that corticosteroids, 1 mg/kg of predniso(ol)ne for 4 weeks followed by a maintenance dose of 0.1 mg/kg taper ever 2 weeks, be initiated in those with biopsy-proven AAN and an estimated GFR (eGFR) greater than 20 ml/min per 1.73 m^2. It is recommended to discontinue steroid therapy after 6 months if the eGFR continues to decrease. Based on nonrandomized studies of corticosteroids in AAN, a trial of corticosteroids is reasonable in those with BEN as well, in addition to blood pressure control and management of electrolyte abnormalities. Although renin-angiotensin system

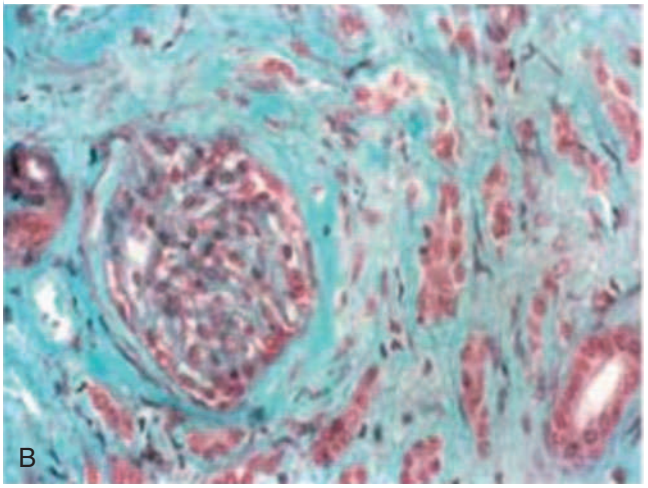

Fig. 76.4 Chinese herb or aristolochic acid nephropathy. (A) Guang Mu Tong, a Chinese herb that contains AAs. (B) Extensive paucicellular interstitial fibrosis and tubular atrophy typically found in Chinese herb or aristolochic acid nephropathy. The same pathologic appearances are seen in Balkan Endmeic Nephropathy. (From reference 9. Courtesy, Dr. Bojan Jelaković.)

Areas Where Balkan Nephropathy Is Prevalent

Fig. 76.5 Areas where Balkan nephropathy is prevalent. The endemic areas are in *red.* (From reference 16.)

BOX 76.1 Diagnostic Criteria for Aristolochic Acid Nephropathy, Including Balkan Endemic Nephropathy

- Epidemiologic pattern
- Known exposure to aristolochic acid–containing medicines or living in endemic Balkan settlements
  - Clinical features
  - GFR decrease
  - Proteinuria usually less than 1 g/24 h
  - Bland urinary sediment
  - Markers of renal tubular damage (renal glycosuria, increased urinary excretion of β_2-microglobulin or α_1-microglobulin, and *N*-acetyl-β-D-glucosaminidase)
  - Typical renal histology showing hypocellular cortical interstitial fibrosis decreasing from the outer to the inner cortex (if renal biopsy feasible)
- Exclusion of other known kidney disease (e.g., chronic pyelonephritis [obstructive and atrophic], adult dominant polycystic kidney disease, glomerulonephritis)

Modified from reference 16, 30.

blockade with angiotensin-converting enzyme inhibitors or angiotensin receptor blockers is important in managing CKD, there is no evidence that this strategy improves renal function or delays progression in AAN.[12,30]

Because patients with AAN are at increased risk for uroepithelial malignancies, all patients with AAN should undergo biannual cytologic evaluation of urine. In those patients with AAN who do not yet require renal replacement therapy (RRT), yearly surveillance is suggested with computed tomography imaging and ureteroscopy. In addition, prophylactic bilateral nephroureterectomy is strongly recommended for all patients with ESRD caused by AAN who are going to be the recipient of a kidney transplant and subsequent immunosuppression.[31]

KIDNEY INJURY CAUSED BY OTHER MEDICINALS

Aside from AAs, the use of other herbal therapy may lead to renal injury or various toxic insults, especially in renal patients. Various renal syndromes have been reported after the use of medicinal plants, including acute tubular necrosis, acute interstitial nephritis, Fanconi syndrome, hypertension, papillary necrosis, chronic interstitial nephritis, and nephrolithiasis.[6,32] Herbal plants reported as the cause for renal injury include *Securidaca longepedunculata* (or violet tree), *Euphorbia matabelensis, Crotalaria laburnifolia, Uncaria tomentosa* (cat's claw), *Lepidium meyenii* (common name: maca), *Tripterygium wilfordii* (Lei Gong Teng), licorice root *(Glycyrrhiza glabra);* irumban puli *(Averrhoa bilimbi),* cape aloe, *Callilepis laureola* (Impila), mushrooms, and djenkol beans (*Pithecellobium*). In addition, the medicinal grass carp *(Ctenopharyngodon idellus)* gallbladder has been noted to cause hepatitis and acute renal failure.[1,32-36]

ACUTE KIDNEY INJURY

T. wilfordii Hook F (TWHF) is a Chinese herbal medicine used for over 2000 years. When made into a cream it is used externally for treatment of arthritis and inflammatory swelling. Extracts of TWHF have been found to have immunosuppressive effects, which could successfully treat rheumatoid arthritis, lupus, minimal change disease, and other autoimmune disorders. The adverse effects of TWHF include gastrointestinal upset, infertility, and leukopenia. In addition, it has been reported that AKI, profound hypotension, and shock after ingestion of an extract of TWHF been reported. In rats, daily intragastric ingestion

of an effective compound extracted from TWHF for 16 days led to proximal tubular dysfunction.[32,33]

Cat's claw, or *Uno degatta,* is a Peruvian herbal preparation made from *Uncaria,* a woody vine found in the Amazon basin. It has been used for treatment of cirrhosis, gastritis, gonorrhea, cancers of the female genital tract, and rheumatism. The oxindole alkaloids from the root bark of cat's claw are thought to invoke its putative antiinflammatory effects, but other unknown substances contribute to the overall effect of cat's claw extracts. A case of reversible acute interstitial nephritis after the use of this preparation has been reported, likely an idiosyncratic allergic reaction to the remedy.[34]

Mushrooms

The majority of renal problems associated with mushrooms are a consequence of renal failure resulting from mushroom-induced hepatic failure. However, throughout Europe and North America there are a variety of nephrotoxic mushrooms that can be confused with edible mushrooms and can cause AKI. The *Cortinarius* spp. (*Cortinarius callisteus, Cortinarius cinnamomeus* group, *Cortinarius gentilis, Cortinarius orellanus, Cortinarius rainierensis, Cortinarius speciosissimus, Cortinarius splendens,* and *Cortinarius semisanguineus* group) are the most notorious. The most common nephrotoxic mushroom is probably *C. gentilis.* In 2014 there were 6474 mushroom exposures reported in the United States and its territories, with three fatalities. The type of mushroom is unknown in over 80% of the cases.[35] The history of mushroom ingestion may be remote, particularly with *Cortinarius* spp. Although gastrointestinal symptoms are usually noted at the time of ingestion, they may not be severe enough for patients to seek medical attention, and symptoms of renal failure may not manifest until 1 to 3 weeks after exposure. Presentation with a shorter latent period suggests a more severe toxicity and greater risk for severe renal failure. Improvement in renal function may occur within several weeks to months, but patients may require chronic dialysis or renal transplantation.

A more recently described mushroom syndrome involves *Amanita smithiana* or *Amanita proxima.* It is thought that the toxin is 2-amino-4,5-hexadienoic acid.[36] Although it causes acute tubular necrosis within hours of ingestion, the clinical outcome is usually good.

Diagnosis of Acute Kidney Injury Induced by Folk Remedies

An accurate assessment of the contribution of herbs to AKI is made difficult by failure to elicit a history by the physician unfamiliar with these risks or denial by the patients because of fear of stigmatization or social pressure. It is often difficult to discount the contribution to AKI of the original illness for which the herbal medicine was prescribed. AKI may be either the sole manifestation or part of a multisystem and metabolic involvement.

Treatment

Management of AKI is usually supportive and includes volume replacement and correction of metabolic abnormalities. RRT support is offered for the usual indications. About 60% all folk-remedy related AKI cases need RRT, with 25% to 75% mortality. Charcoal hemoperfusion is effective in clearing alfa-amanitin from circulation in those with poisoning from *Amanita* mushrooms.[37]

OTHER RENAL COMPLICATIONS OF HERBAL REMEDIES

Hypertension

Ma huang is an ephedra-containing herbal preparation used in the treatment of bronchial asthma, cold and flu symptoms, fever and chills, headaches and other aches, edema, and lack of perspiration. In Western countries, ephedrine and herbal ephedra preparations are used to promote weight loss and enhance athletic performance. Dietary supplements that contain ephedra alkaloids have been reported to induce hypertension, palpitations, tachycardia, and stroke. Prescribed ephedrine was not associated with a substantially increased risk for adverse cardiovascular outcomes in a registry-based case-crossover study.[38,39] However, ephedra may pose a serious health risk to some users, such as renal patients who are prone to hypertension.

The dried roots of the licorice plant *(G. glabra)* have been consumed for over 6000 years and are used as flavoring and sweating agents, as demulcents and expectorants in the Western world, and as antiallergic and antiinflammatory agents in Asian countries, including China, Japan, and Korea. Licorice contains glycyrrhizin. After oral administration of licorice preparations, glycyrrhizinic acid is hydrolyzed by intestinal bacteria into glycyrrhetic acid. Glycyrrhetic acid can inhibit distal tubule 11-β-hydroxysteroid dehydrogenase-2 (11-BOHD-2), which converts the corticosteroid hormone cortisol to cortisone. Decreased activity of 11-BOHD-2 leads to an excess of cortisol and an overstimulation of the mineralocorticoid receptor, leading to sodium and water retention and increased excretion of potassium. Large doses of glycyrrhizinic acid over a prolonged period can cause pseudoaldosteronism, with hypokalemia, hypernatremia, edema, and hypertension, as well as arrhythmia and other cardiac disorders.[1] To minimize the adverse effects, it is recommended that licorice not be ingested for longer than 4 to 6 weeks.[40]

Crystalluria and Nephrocalcinosis

Many health drinks that are well tolerated by individuals with normal renal function can cause serious problems in patients with limited renal function. One example is star fruit (carambola) juice, which can contain as much as 800 mg of oxalate in 100 ml and can provoke oxalate crystalluria. Sour carambola juice is a popular beverage in Taiwan. Although preparation of commercial carambola juice, by pickling and dilution, markedly reduces oxalate content, fresh juice or only mildly diluted postpickled juice may contain high quantities of oxalate. Cranberry concentrate tablets also can lead to an increase in oxaluria. Ingestion of ma huang have been reported to lead to kidney stones, and the use of ephedrine and guaifenesin individually or in combination has been shown to cause greater than 35% of urinary stones that are related to pharmaceutical metabolites and 0.1% of all urinary stones.[41]

Hyperkalemia

Dietary potassium restriction is a common recommendation for people with renal impairment, especially because hyperkalemia is a side effect of many medications used to slow the progression of renal disease. Common foods high in potassium include oranges, bananas, tomatoes, avocadoes, and potatoes. However, some health drinks are also very high in potassium. Noni juice, often taken to increase energy, contains more potassium than any other fruit juice. The legume alfalfa *(Medicago sativa)* and the plants dandelion *(Taraxacum officinale),* stinging nettle *(Urtica dioica),* and horsetail *(Equisetum arvense)* all contain significant amounts of potassium[42] and may induce hyperkalemia in persons with CKD.

Urinary Obstruction

Djenkol beans or Jering *(Pithecellobium jiringa)* are broad, round, reddish beans that grow during monsoon season in Myanmar, Indonesia, and Malaysia and are considered a delicacy. The Jering seeds are extolled for their supposed ability to prevent diabetes and high blood pressure. In addition, the seeds have bladder spasmodic properties and are used as a remedy to eliminate stones from the bladder. Jering poisoning or djenkolism is characterized by spasmodic suprapubic and/or flank pain, urinary obstruction, and AKI.[42] Chronic djenkol bean consumption is

associated with a fourfold higher risk for nonglomerular hematuria. The djenkol bean contains a large amount of djenkolic acid in the range of 0.3 to 1.3 g/100 g wet weight; 93% of the acid exists in a free state. Djenkolic acid crystals may lacerate renal tissue and cause bleeding or obstruction. Obstruction of the renal tubules by crystals of djenkol acid is a possible mechanism of acute tubular necrosis. Mild djenkolism requires pain control and hydration. Severe djenkolism, manifested by anuria and AKI, is usually managed with analgesia, aggressive hydration, and alkalinization of the urine with sodium bicarbonate to increase the solubility of djenkolic acid. Some cases of severe djenkolism with anuria do not respond to conservative therapy and require surgical intervention.[43]

Renal Toxicity From Contaminants Within Herbal Medicines

Herbal medicines may be contaminated with excessive or banned pesticides, microbial products, heavy metals, or chemical toxins or adulterated with orthodox drugs. These contaminants are related to the source of these herbal materials, whether grown in a contaminated environment or contaminated during collection or intentionally or intentionally during storage. The presence of orthodox drugs is often a result of the intentional adulteration of the herbal remedy by the manufacturers.[44] A report found undeclared pharmaceuticals or heavy metals in 32% of Asian medicines sold in the state of California. These included ephedrine, chlorpheniramine, methyltestosterone, phenacetin, sildenafil, corticosteroids, and fenfluramine; 10% to 15% contained lead, mercury, or arsenic. Of more than 500 Chinese drugs, approximately 10% contained undeclared drugs or heavy metals.[4]

Several case reports link these adulterations with renal injury. The first report was a 73-year-old Malaysian woman who presented with renal failure and bilateral papillary necrosis after having consumed 2 tablets daily of a traditional herbal preparation, freely available from Chinese medical halls, for 10 years for osteoarthritis. She denied the consumption of any other analgesics, but the analysis of the herbal preparation showed 120 mg of phenylbutazone in each tablet. The second report concerned a 34-year-old housewife taking a mixture of Chinese herbs who presented with Fanconi syndrome and nephrogenic diabetes insipidus. She had a urinary excretion of cadmium 50 times greater than normal. In another report, a patient presented with AKI with marked albuminuria, pyuria, and hematuria after a 4-week treatment with Tung Shueh pills for arthralgias. The cause was acute interstitial nephritis, and the Tung Shueh pills were found to contain both diazepam and mefenamic acid. In Morocco, the traditional *el badia,* a powder made of the seeds of *Tamarix orientalis,* is used as hair dye; however, in times when the *T. orientalis* seeds are scarce, they are replaced with *Takaout roumia,* which contains paraphenylenediamine. Inadvertent ingestion of paraphenylenediamine is an issue in a number of African countries; for example, in Morocco it is responsible for about 10% of all cases of AKI, 50% of all cases of rhabdomyolysis, 25% of intensive care unit admissions for poisonings, and two thirds of poisoning-related deaths.[4,6]

In Thailand and other parts of Southeast Asia and India, there are reports of contamination of herbal remedies with cadmium and/or mercury. In South Africa, about 15% of herbal remedies are contaminated with uranium. In the United States ginseng dietary supplements have been shown to contain the pesticides quintozene and hexachlorobenzene or to exceed the standard for lead content.

Herb-Drug Interactions Resulting in Adverse Renal Effects

Herbs with potential for pharmacokinetic and/or pharmacodynamic herb-drug interactions are often taken concomitantly with therapeutic drugs, without the prescribing physician's knowledge. Pharmacokinetic herb-drug interactions are caused by altered absorption, metabolism, distribution, and excretion of drugs. A frequent underlying mechanism of altered drug concentrations by concomitant herbal medicines is the induction or inhibition of hepatic and intestinal cytochrome P-450 enzymes (CYPs). There are reports of 32 drugs interacting with herbal medicines in humans. These drugs include anticoagulants (warfarin, aspirin, and phenprocoumon), sedatives and antidepressants (midazolam, alprazolam, and amitriptyline), oral contraceptives, antiretroviral agents (indinavir, ritonavir, and saquinavir), immunosuppressants (cyclosporine and tacrolimus), and anticancer drugs (imatinib and irinotecan), and digoxin. Most of them are substrates for CYPs and/or P-glycoprotein, and many have narrow therapeutic indices. Toxicity arising from drug-herb interactions may be minor, moderate, or even fatal, depending on a number of factors associated with the patients, herbs, and drugs.[1]

St. John's wort, derived from the plant *Hypericum perforatum,* has been used since ancient times for depression and anxiety. It is the most common antidepressant used in Germany. St. John's wort induces a hepatic enzyme through activation of the CYP system, leading to decreased serum levels of a wide range of prescribed drugs, with possible clinically serious consequences. For example, St. John's wort ingested for 10 days by a group of healthy volunteers reduced the bioavailability of digoxin by an average of 25%. St. John's wort ingested for 2 weeks reduced the total absorption of indinavir by 50%, which is large enough to cause treatment failure. Other reports indicated significant increases in the metabolism of warfarin, theophylline, oral contraceptives, and cyclosporine. Use of St. John's wort in transplant recipients is associated with both toxicity and underdosage of calcineurin inhibitors as a result of phytochemically triggered activity changes of isoenzyme CYP3A4 metabolism and drug transport proteins.[45,46]

Gingko biloba is one of the most popular plant extracts in Europe and is approved in Germany for the treatment of dementia. *G. biloba* is composed of several flavonoids, terpenoids (e.g., ginkgolides), and organic acids believed to act synergistically as free radical scavengers. *G. biloba* should not be administered with concomitant anticoagulation or in patients with bleeding disorders. Concomitant use of aspirin or nonsteroidal antiinflammatory drugs (NSAIDs), as well as anticoagulants such as warfarin and heparin, should be avoided. Spontaneous hyphema and spontaneous bilateral subdural hematomas has been observed in patients taking *G. biloba* and is attributed to ginkgolide B, a potent inhibitor of platelet-activating factor needed to induce arachidonate-independent platelet aggregation. Hemorrhagic complications were observed often in patients administered concomitant antiaggregate or anticoagulant therapy. However, the exact mechanism of the interaction of *G. biloba* with aspirin, warfarin, and NSAIDs remains unclear. Experimental data from rats suggest that a *G. biloba* diet markedly increased the content of CYP and activity of glutathione-*S*-transferase and markedly induced the level of CYP2B1/2, CYP3A1, and CYP3A2 messenger RNA in the liver.[47]

Most information about the toxicity of herbal medicines is found only in case reports, and precise identities of the culprit substances, toxicologic characteristics, and pathogenic mechanisms of herbal medicines remain largely unknown. Whereas many herbs have been used for centuries without evidence of acute renal damage, insidious damage caused by long-term use is a concern because many herbs have not been rigorously tested for toxicity.

OVER-THE-COUNTER MEDICINES AND THE KIDNEY

In addition to the increasing popularity of OTC health foods, nutritional supplements, and medicinal products from plants or other natural sources, there is increasing consumption in many countries of pharmaceutical products bought OTC, particularly analgesics and agents for treatment of dyspepsia.

Analgesics

OTC analgesics used for fever and minor musculoskeletal symptoms are one of the most widely used classes of drugs in the developed world. NSAIDs are also used to treat inflammatory conditions; and aspirin is used prophylactically as an anticoagulant in thrombosis-related disorders. Acetaminophen (paracetamol), aspirin, ibuprofen, and naproxen are available OTC in many countries, sometimes in combinations. Easy access to OTC analgesics runs the risk for unwarranted and unsupervised chronic intake. Although studies on the association between the long-term use of aspirin, NSAIDs, and other analgesics and ESRD have given conflicting results, many studies have suggested an association between chronic ingestion of analgesics and kidney disease.

Because analgesic use is widespread, even a small percentage of increased risk for kidney disease may have major public health implications. NSAIDs inhibit cyclooxygenase and may inhibit lipoxygenase, decreasing the production of prostaglandins and leukotrienes, which account for many NSAID-induced renal effects. In patients with volume depletion, renal perfusion depends on circulating prostaglandins to vasodilate the afferent arterioles, allowing more blood flow through the glomerulus. So the contribution of prostaglandins to renal homeostasis is most critical in elderly patients and those with circulatory disturbances, such as renal or liver dysfunction, congestive heart failure, or volume depletion.[48]

Patients who warrant chronic therapy with analgesics and NSAIDs should be monitored by regular screening with dipstick urinalysis and serum creatinine for early evidence of kidney injury. Specifically, low-risk patients should be monitored within 3 months and have studies repeated every 6 to 12 months and high-risk patients should be monitored within 1 to 3 weeks and have studies repeated every 3 to 6 months. Early detection and removal of the offending agent could halt or even reverse analgesic-induced kidney injury. There is a pressing need for multicenter prospective studies to assess the true incidence of this problem and study the effects of various analgesic agents (alone and in combination) in at-risk populations.

Analgesic Nephropathy

Analgesic nephropathy, resulting from the habitual consumption over several years of compound analgesics, is characterized by renal papillary necrosis and chronic interstitial nephritis. It is an increasingly rare condition because phenacetin (the analgesic most implicated as a causative agent) is banned in many countries. Phenacetin alone was not the cause of analgesic nephropathy (in fact phenacetin was never marketed as a single agent); it was the use of phenacetin in combination analgesics that caused the problem. A retrospective cohort study using data from the Australia and New Zealand Dialysis and Transplant Registry showed that among 31,654 patients receiving RRT over the previous 35 years, 10.2% had analgesic nephropathy, but there was a marked decrease in the incidence more recently to less than 3.5% in 2005.[49] Analgesic nephropathy is discussed further in Chapter 62.

Proton Pump Inhibitors

Proton pump inhibitors, such as omeprazole, are now available OTC in many countries and can be associated with granulomatous allergic interstitial nephritis (see Chapter 60). Use of PPIs has been linked epidemiologically to an increased risk for CKD in the general population.

SELF-ASSESSMENT QUESTIONS

1. A very slender 25-year-old international fashion model presented with renal failure, minimal hypertension, and mild proteinuria. Renal function deteriorated, and the patient received a renal transplant. Six months later, she developed bilateral urogenital tract tumors. What was the most likely cause of her kidney disease?
   A. Analgesic nephropathy
   B. Aristolochic acid nephropathy
   C. Anorexia nervosa
   D. Heavy metal intoxication
2. A 30-year-old recent emigrant from Romania presents with a 3-month history of fatigue, dyspnea on exertion, anorexia, and nausea. On physical examination, she is thin and appears chronically unwell. Blood pressure is 160/100 mm Hg, with otherwise normal physical examination findings. Laboratory workup is significant for hematocrit 22, serum potassium 5.7 mmol/l, serum bicarbonate 19 mmol/l, serum glucose 90 mg/dl, blood urea nitrogen 80 mg/dl, and serum creatinine 4 mg/dl. Urinalysis shows 1+ glucose, 2+ protein, 20 to 30 leukocytes per high-power field. Urine culture is negative for bacteria and acid-fast bacilli. Urine protein was 500 mg/24 h; renal ultrasound, right kidney, 9.8 cm; left kidney, 9.6 cm; and no hydronephrosis. What is the most likely cause of her renal impairment?
   A. Acute renal failure from tubular necrosis
   B. Chronic glomerulonephritis
   C. Chronic tubulointerstitial nephritis (Balkan endemic nephropathy)
   D. Occult diabetic nephropathy
3. A previously noncompliant patient with stage 4 chronic kidney disease secondary to hypertension comes into your office saying he has changed his ways. He has lost weight, is taking all of his medications, and is drinking homemade star fruit (carambola) juice for its antioxidant properties. His serum creatinine is 5.1 mg/dl (previously 2.4 mg/dl). In the figure, which picture are you most likely to see on urinalysis?
   A. Cystine crystal
   B. Urate crystal
   C. Triple phosphate
   D. Oxalate crystal
4. A 52-year-old woman 5 years after kidney renal transplantation is on mycophenolate mofetil and cyclosporine with stable transplant function. She reports that she just came back from a health spa and that she feels wonderful. She said she was diagnosed with depression and was started on St. John's wort by the herbalist. Which of the following transplant-related problems are you are most concerned about?
   A. Acute rejection
   B. Crystal formation in the graft
   C. Cyclosporine toxicity
   D. Hypertension

77

Epidemiology of Chronic Kidney Disease and Dialysis

Morgan E. Grams, Stephen P. McDonald

The 2015 Global Burden of Disease Study reported an enormous increase in global life expectancy between 1980 and 2015, from 61.7 years to 71.8 years.[1] Much of this improvement is attributable to declining mortality from communicable, maternal, neonatal, and nutritional disease. However, with the aging of the population, chronic kidney disease (CKD) has become one of most common noncommunicable diseases in the world as well as a leading cause of mortality. Half of the people in the United States are expected to develop CKD during their lifetime.[2] Associated with huge health system costs, particularly in the advanced stages, which includes kidney failure treated with dialysis as well as kidney transplantation, CKD has come into focus as a common, morbid, and often preventable disease.[3]

DEFINING CHRONIC KIDNEY DISEASE

Chronic Kidney Disease Staging

Over the past decade, the definition of CKD has evolved to incorporate advances in knowledge of prognosis.[4] The National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines published in 2002 classified CKD into five stages on the basis of glomerular filtration rate (GFR) and signs of kidney damage (proteinuria, abnormal urinary sediment, structural abnormalities, presence of a kidney allograft).[5] This staging system was modified in the 2012 Kidney Disease: Improving Global Outcomes (KDIGO) clinical practice guidelines to reflect the independent contributions of GFR, albuminuria, and cause of CKD.[6] Although the incorporation of cause of CKD in the classification system has been used relatively infrequently in subsequent CKD research, in part because of a paucity of data, the two-dimensional "heatmap" that classifies CKD in GFR categories (G-stages) and albuminuria categories (A-stages) has been widely accepted and robustly validated (Fig. 77.1).[7]

Classification Based on Estimated Glomerular Filtration Rate

Serum creatinine is the most commonly used filtration marker for the estimation of GFR, and GFR estimating equations incorporating serum creatinine as well as age, race, and sex generate precise and accurate assessments of kidney function in the vast majority of both CKD and non-CKD populations.[8] In North America, the best available GFR estimating equation is that developed by the Chronic Kidney Disease–Epidemiology Collaboration (CKD-EPI) collaboration, and most commercial laboratories automatically report estimated GFR (eGFR) using this equation.[9] The accuracy of GFR estimation also has benefited from universal standardization of the creatinine laboratory assay (see Chapter 3).[10]

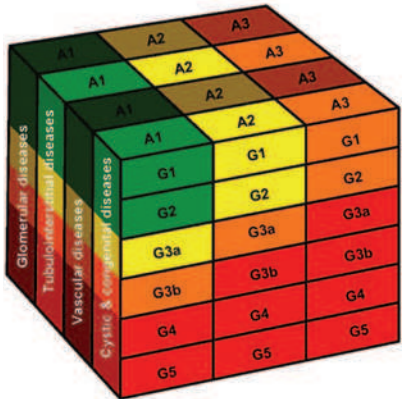
Classification Based on Albuminuria

Compared with the estimation of GFR, efforts to accurately quantify albuminuria are in their infancy. Multiple techniques exist to estimate urine albumin excretion. The semiquantitative dipstick method is most common, followed by spot and 24-hour urine protein or albumin excretion assessments. All are subject to limitations. Dipstick testing is inexpensive, but the diagnostic accuracy, particularly for moderately increased levels of albuminuria, can be low.[11] Although a full day's collection of urine albumin is generally considered the gold standard in albuminuria estimation, the process is tedious and imposes substantial burden on the patient. Thus the KDIGO guidelines recommend a spot collection of urine, with early morning timing preferred, as the initial screening test.[6] Urine albumin is recommended over urine protein assessment given the superiority of the laboratory assay and standardization as well as the relative importance in prognosis. Spot samples are standardized to urine creatinine to normalize to 24-hour excretion and account for any differences in concentration (e.g., albumin-to-creatinine ratio [ACR]). Of note, any abnormalities in GFR or albuminuria must persist over 3 months to meet the definition of CKD (see Chapter 3).

Classification Based on Chronic Kidney Disease Cause

The cause of kidney disease ("C" in the KDIGO-proposed CGA staging) is the least-studied aspect of the CKD definition. The proposed KDIGO classification categorizes disease by the presence of underlying systemic disease and the location of the abnormality (see Fig. 77.1). Thus diabetic nephropathy (DN) might be classified as a systemic disease affecting the glomerulus, and obstructive nephropathy as a primary kidney disease affecting the tubulointerstitium. Limitations of this approach include the infrequent use of kidney biopsy, the gold standard for assessment of pathologic location of kidney abnormalities. On the other hand, decisions not to perform kidney biopsies are often driven by the uncertain benefit of precise localization of pathologic abnormalities in terms of prognostic implications—a vicious circle begetting sparse evidence.

Chronic Kidney Disease Classification According to Glomerular Filtration Rate and Albuminuria



GFR categories (ml/min/1.73 m²) description and range		
G1	Normal or high	≥90
G2	Mildly decreased	60-89
G3a	Mildly to moderately decreased	45-59
G3b	Moderately to severely decreased	30-44
G4	Severely decreased	15-29
G5	Kidney failure	<15

Persistent albuminuria categories description and range		
A1	A2	A3
Normal to mildly increased	Moderately increased	Severely increased
<30 mg/g <3 mg/mmol	30-300 mg/g 3-30 mg/mmol	>300 mg/g >30 mg/mmol

Classification of CKD based on presence or absence of systemic disease and location within the kidney	
Presence of systemic disease affecting the kidney	Primary kidney diseases
Glomerular diseases	
Tubulointerstitial diseases	
Vascular diseases	
Cystic and congenital diseases	

Fig. 77.1 Depiction of chronic kidney disease classification, G-stages and A-stages. The cube denotes how the three components of the chronic kidney disease classification scheme (glomerular filtration rate [G], albuminuria [A] and underlying kidney disease) interact to influence the risk of progression to kidney failure. This risk is represented in qualitative terms (lowest to highest) by green, yellow, orange and red colors.

Odds of Laboratory Abnormalities by Estimated Glomerular Filtration Rate

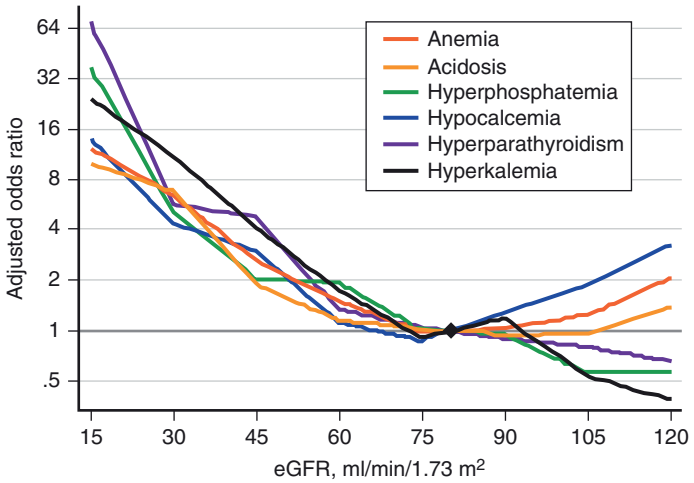


Fig. 77.2 Odds of laboratory abnormalities according to estimated glomerular filtration rate (eGFR) among people from the general United States Population. (Data are from the Continuous National Health and Nutrition Examination Survey [NHANES] during 1999–2010.)

Rationale for the Chronic Kidney Disease Definition

Associations With Adverse Outcomes

The cut-points of GFR and albuminuria used to define disease (<60 ml/min/1.73 m² and ≥30 mg/g, respectively) have been rigorously examined. Each represents a higher risk state compared with normal levels for a variety of outcomes. For example, the relationship between GFR and the prevalence of anemia, acidosis, hyperphosphatemia, hypoalbuminemia, and hyperparathyroidism demonstrates a continuous increase in risk with GFR less than 60 ml/min/1.73 m² (Fig. 77.2).[12] Furthermore, the risk for future kidney outcomes, including acute kidney injury, CKD progression, and end-stage renal disease (ESRD), all exhibit graded associations with lower GFR.[13] Although relationships with progression to ESRD are strongest, both lower eGFR and higher albuminuria are independently associated with cardiovascular mortality and all-cause mortality as well (Fig. 77.3).[7] For example, for a given value of GFR, higher albuminuria is associated with higher risk for adverse events compared with albuminuria levels below 30 mg/g.[3]

Persistent Relationships Within Subgroups

Although there remains some controversy about the use of different thresholds for different groups of people, some have argued that the pathologic threshold for GFR should be lower in older adults or that there should be sex-specific definitions of pathologic albuminuria.[14] The risk relationships between eGFR and ACR with adverse outcomes are remarkably robust in different subgroups, including older and younger adults and men and women. Although reduced GFR is more common among older individuals, it remains a strong risk factor for ESRD compared with higher levels of GFR (Fig. 77.4).[15] Similarly, the risk relationships between ACR and adverse outcomes actually appear to increase earlier in women than men, counter to the proposed sex-specific definitions that assign a higher ACR threshold in women (Fig. 77.5).[16] On the other hand, the argument that the ACR threshold of 30 mg/g may miss clinically relevant disease is supported by a continuous increase in risk beginning at levels greater than 10 mg/g.

GLOBAL BURDEN OF CHRONIC KIDNEY DISEASE

Accurate estimations of CKD prevalence are difficult because tests for creatinine and albuminuria are not uniformly performed; however, many believe the global burden of CKD to be large and increasing.[17] The best estimates are derived from nationally representative samples such as the National Health and Nutrition Examination Survey (NHANES) in the United States; estimates based on populations receiving health care may overestimate (or, in some cases, underestimate) disease prevalence.[18] In

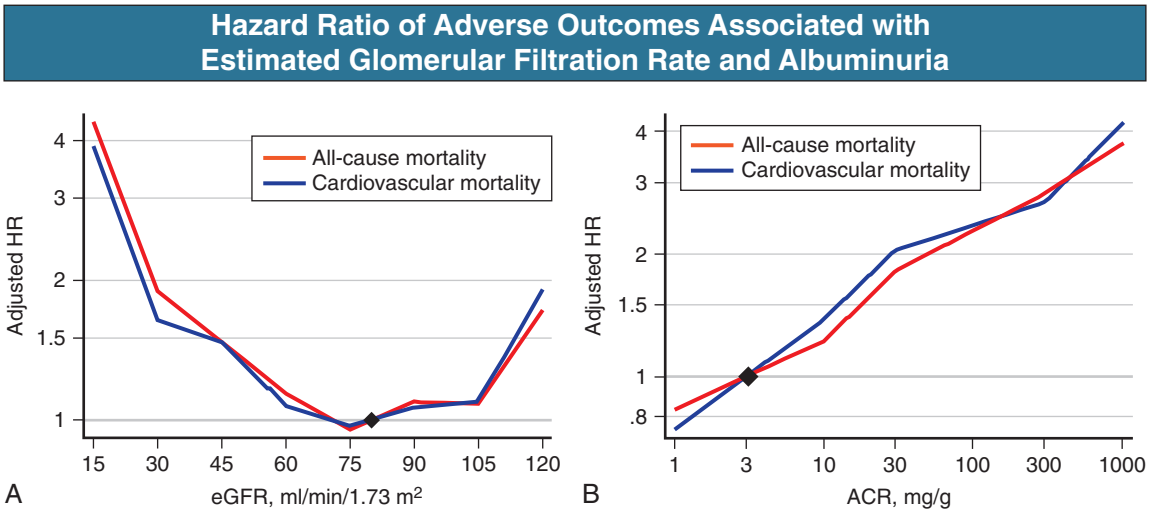

Fig. 77.3 Hazard ratios *(HR)* of adverse outcomes associated with estimated glomerular filtration rate *(eGFR)* (A) and albuminuria (B) among people from the general United States population. *ACR,* Albumin-to-creatinine ratio. (Data are from the National Health and Nutrition Examination Survey III [1988-1994] and the continuous National Health and Nutrition Examination Survey [1999-2010].)

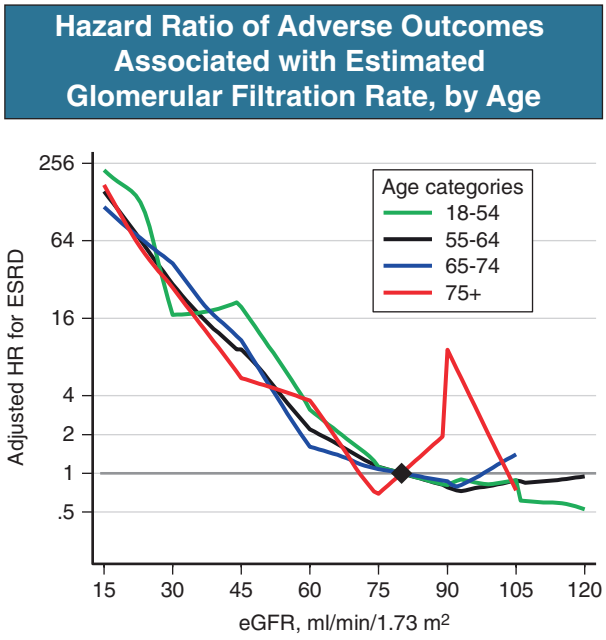

Fig. 77.4 Hazard ratios *(HR)* of adverse outcomes associated with estimated glomerular filtration rate *(eGFR),* by age. *ESRD,* End-stage renal disease. (From reference 15.)

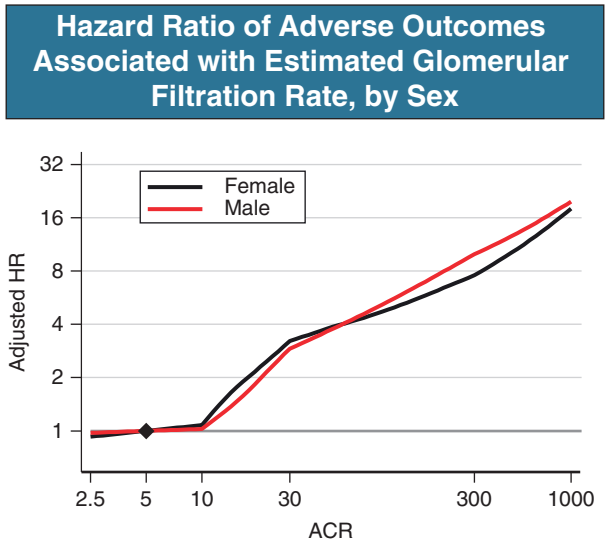

Fig. 77.5 Hazard ratios *(HR)* of adverse outcomes associated with albuminuria, by sex. *ACR,* Albumin-to-creatinine ratio. (From reference 16.)

the United States, estimates of CKD prevalence based on a one-time measurement of serum creatinine recently placed the proportion of the population with stage G3 or G4 CKD at 6.9%; using a definition of ACR greater than 30 mg/g or eGFR less than 60 ml/min/1.73 m^2, the prevalence of any CKD was 14.2%.[19] This definition likely overestimates prevalence because the persistence of albuminuria was not taken into account. Publications from countries in Europe show wide variation in CKD prevalence, from 3.3% in Norway to 17.3% in northwest Germany, but this may reflect differences in sampling strategy rather than true population-level differences.[20] Estimates in developing countries are less available, but most place the global population burden between 8% and 16%, affecting nearly 500 million adults worldwide in 2010.[21]

RISK FACTORS FOR CHRONIC KIDNEY DISEASE

Age

Many risk factors have been implicated in the development of CKD. Age is a strong risk factor for GFR below 60 ml/min/1.73 m^2, and so population aging is almost inevitably associated with an increase in CKD burden. Interestingly, although incidence rates of ESRD tend to be highest among persons over 65 years, older age is often associated with a lower risk for developing ESRD in multivariable-adjusted analyses.[3,22] In other words, for the same level of kidney function, a younger person is at higher risk for progression to ESRD than an older person, likely in part because the competing risk for pre-ESRD mortality is lower in younger persons and younger persons may be more willing to accept or likely to be prescribed a notoriously grueling therapy (dialysis or transplantation) compared with older persons.

Sex and Race

Risk for CKD differs by other demographic factors as well. Women are generally at higher risk for incident CKD but lower risk for incident ESRD than men.[2] In the United States, race demonstrates a similar, paradoxical finding: Black individuals have a lower prevalence of mild CKD and a higher prevalence of ESRD than White individuals. Two recent genetic discoveries can partially explain this disparity; two genetic risk variants common in persons of African descent confer higher risk for CKD and ESRD.[23,24] The genetic variants, sickle cell trait and the *APOL1* high-risk genotype, protect against two different parasites and are prevalent in 7% and 13% of the U.S. African American population, respectively. The presence of sickle cell trait is thought to confer risk via subclinical sickling in the oxygen-poor medulla, leading to impairments in concentrating ability and hematuria over time. The mechanism of the *APOL1* risk alleles is as yet uncertain, but it appears to be mediated through the development of albuminuria.

Social Determinants

Socioeconomic factors also play a role in CKD risk. People with lower socioeconomic status face greater burden of CKD and rapid GFR decline in the United States, and this finding has been replicated in many other developed countries.[3,6] Many postulate that racial differences would greatly attenuate with equal access to health care. Indeed, several studies have demonstrated attenuation or elimination of racial disparities in kidney outcomes with accounting for differences in income and the presence of health insurance, including risk for AKI, eGFR decline, and delay in transplantation in children.[25]

Comorbid Conditions

Diabetes mellitus and hypertension are often cited as the major attributable causes of CKD in the developed world, and recent studies suggest similarities in the developing world.[3] Nearly half of the population with CKD and ESRD has diabetes. Persons with diabetes and CKD merit concern not only for the risk for albuminuria and CKD progression but also for heightened risk for many other adverse outcomes, particularly cardiovascular disease. On the other hand, the risk for CKD among those with diabetes mellitus is eminently manageable through tight control of blood glucose, blood pressure, and the use of an angiotensin-converting enzyme inhibitor or angiotensin receptor blocker. Hypertension also has shown a graded association with the risk for ESRD in observational studies, although the relationship with kidney disease is more complex than that of diabetes and CKD because hypertension is both a cause and a consequence of CKD. Obesity may confer increased risk for CKD over the long term, possibly mediated through the development of obesity and hypertension, and smoking has been linked to higher ESRD risk.[26] Other clinical characteristics such as elevated uric acid and elevated serum osmolality have been associated with the development of CKD; however, whether there is a causal role of these risk factors has not yet been determined.

ISSUES WITH IDENTIFYING CHRONIC KIDNEY DISEASE

Lack of Awareness

Often a silent disease until the most advanced stages, CKD is largely underrecognized by providers and patients. Fewer than 10% of people with laboratory-confirmed CKD in the NHANES survey reported being aware that they had kidney disease, a finding corroborated in other regions.[3] Provider awareness may not be much higher; only 12% of patients with CKD had an associated diagnostic code in Stockholm health care.[27] Low awareness of disease may lead to low testing and referrals, because only 27% of patients with eGFR below 60 ml/min/1.73 m^2 had albuminuria screening, and 23% were appropriately referred to a nephrologist. In the Stockholm cohort, 38% of patients with diabetes were evaluated for albuminuria, very similar to the proportion among U.S. Medicare patients with diabetes.[3]

Imperfect Biomarkers

Another issue in CKD identification is the occasional fallibility of existing biomarkers. Serum creatinine, the most widely used filtration marker to estimate GFR, has non-GFR determinants, including diet and muscle mass. For example, amputees and persons with reduced muscle mass may have a falsely elevated eGFR when creatinine is used. Thus the KDIGO guidelines recommend a confirmatory measurement performed for persons in whom measuring creatinine may be less accurate.[6] To confirm diagnosis (or eGFR level for drug dosing or kidney donation), KDIGO recommends obtaining a cystatin C–based eGFR or clearance measurement. Of course, cystatin C has its own non-GFR determinants, body mass index and inflammation. For this reason, for the general population the most accurate estimating equation uses both creatinine and cystatin (see Chapter 3).[28]

Errors in Urine Albumin Assessment

Variability in albumin excretion and measurement also can confound CKD identification. In clinical practice, spot samples are usually assessed and standardized to urine creatinine to correct for error induced by differences in hydration status. However, urine albumin and creatinine excretion are thought to follow a circadian rhythm with variation induced by differences in posture, exercise, and diet.[29] Moreover, many providers quantify urine protein rather than urine albumin, a less sensitive and specific marker of glomerular permeability. Urine protein measurement is additionally hampered by interlaboratory variation in methods and calibration and the lack of a reference measurement protocol.[6] For these reasons, urine albumin assessment is generally preferred over urine protein assessment, and repeated 24-hour collections offer the most accurate estimation of true albuminuria.

OUTCOMES OF CHRONIC KIDNEY DISEASE

Associations With Adverse Outcomes

The public health implications of CKD are enormous because of the strong associations with adverse outcomes—in particular, cardiovascular disease, ESRD, and mortality. Many have argued that CKD should be considered a coronary heart disease risk equivalent, much like diabetes, and some guidelines recommend preventive statin use for all patients with CKD older than 50 years.[30] The independent associations of GFR and albuminuria with adverse outcomes has been demonstrated in general, high-risk, and CKD populations, as well as in separate geographical regions.[7,31] Albuminuria and GFR have been shown to be independent risk factors for AKI, gastrointestinal bleeding, thrombosis, and infection.

Variation in Absolute Risk for Adverse Outcomes

Increasingly, risk scores are used to inform patient counseling and treatment decisions. Guidelines encourage the incorporation of ESRD risk prediction in RRT planning, and several risk scores now exist.[6] The kidney failure risk equation developed in two Canadian cohorts is probably the most widely used, and has been validated in 31 cohorts worldwide.[22] It was noted that the absolute risk for progression to ESRD was slightly lower in non–North American countries and that this difference was not explained by differences in demographic or clinical characteristics. Variation in absolute risk for ESRD thus might suggest differences in treatment availability, patient or provider acceptance, or differences in the competing risk for death.

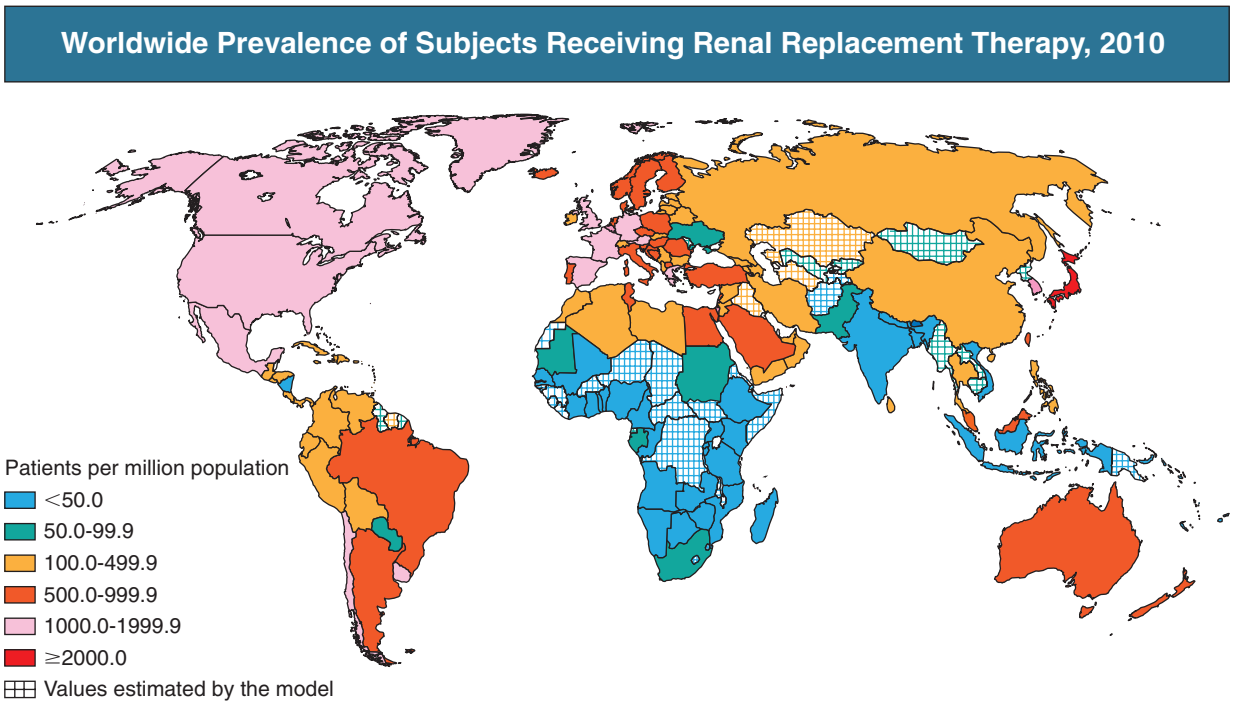

Fig. 77.6 Patients receiving renal replacement therapy in 2010. (From reference 32.)

DIALYSIS EPIDEMIOLOGY

The number of people receiving chronic RRT (dialysis or kidney transplantation) for kidney failure worldwide has progressively increased over the 50 years since these treatments became available, and this increase continues. Initially available only to selected patients in restricted centers in some countries, both long-term dialysis and kidney transplantation have become progressively more available not just in high-income countries, but also in many low-income countries. Approximately 2.5 million people were estimated to be receiving chronic RRT in 2010[32]; absolute rates are high in North America, but the highest prevalent rates (people currently receiving RRT) per million population are in Taiwan and Japan (Fig. 77.6), where the vast majority of people receive long-term dialysis. Good data are available throughout the developed world and in many parts of the developing world because of the existence of regional and national dialysis registries. These registries typically report rates, outcomes, and practice patterns of dialysis at a national level; many also have a major role in provision of hospital-specific information and other safety and quality reporting, as well as providing a substantial resource for clinical research.

Incidence and Prevalence of Chronic Dialysis

Incidence rates (the number of new RRT patients) comprise patients starting chronic or long-term dialysis and a small number of people receiving preemptive kidney transplants. Incidence rates are highest in Taiwan, Mexico, and the United States, followed by various Asian countries. There is substantial variation among countries in every region around the world (Fig. 77.7). DN has been the main factor in the increase in incidence rates in almost all countries. In most countries, DN is attributed as the cause for ESRD in 40% to 60% of cases.

The trends in incidence rates vary across different regions. In many Asian countries (e.g., Korea, Singapore, Malaysia, Thailand) rates continue to increase. However, in the United States, Canada, Western Europe, Australia, and New Zealand, incidence rates have generally stabilized over the last 5 to 10 years. Nevertheless, in these countries the *prevalent* numbers and rates of dialysis continue to increase because the number of people leaving dialysis programs (deaths and transplant recipients) is smaller than the incident number.

Not every person with kidney failure receives dialysis or transplantation. In some situations (particularly those with substantial comorbidities or limited life expectancy), dialysis may not be clinically appropriate, or a decision is made for a conservative (nondialysis) approach to treatment (see Chapters 89 and 112). Registries typically report rates of RRT, which is synonymous with ESRD, a U.S administrative term meaning treatment with dialysis or kidney transplantation for chronic kidney failure. Estimating the total burden of kidney failure requires incorporation of both the number of people commencing RRT and the number of people dying of kidney failure without treatment. This has been examined using data linkage (of registry data with death certificates) in Australia[33] and in cohort studies, most notably in Alberta, Canada.[33] These studies suggest that among the older groups (older than 75 years) dialysis therapy is used in less than 50% of people with kidney failure. Consistent with this is evidence suggesting that among older patients with comorbidities, there is little or no survival advantage of dialysis therapy.[34]

Dialysis is a resource-intensive therapy, and there is a relationship between the provision of (and access to) dialysis and the overall economic development of a country (Fig. 77.8). As with other chronic diseases, there is also a gradation seen within many societies in rates of dialysis, with higher rates seen among those at the lower end of the socioeconomic spectrum.[35,36] Gradients with income and education are also seen among predialysis patients.[37]

Incidence rates vary with sex, with rates lower among women than men.[38] Incidence rates increase with older age, up to 75 to 80 years old. There have been progressive changes differing across age-specific incidence rates over many years, with increasing incidence rates of progressively older age groups over a long period followed by stabilization in more recent years. An example of this (from Australia, but typical of that seen in developed countries) is shown in Fig. 77.9.

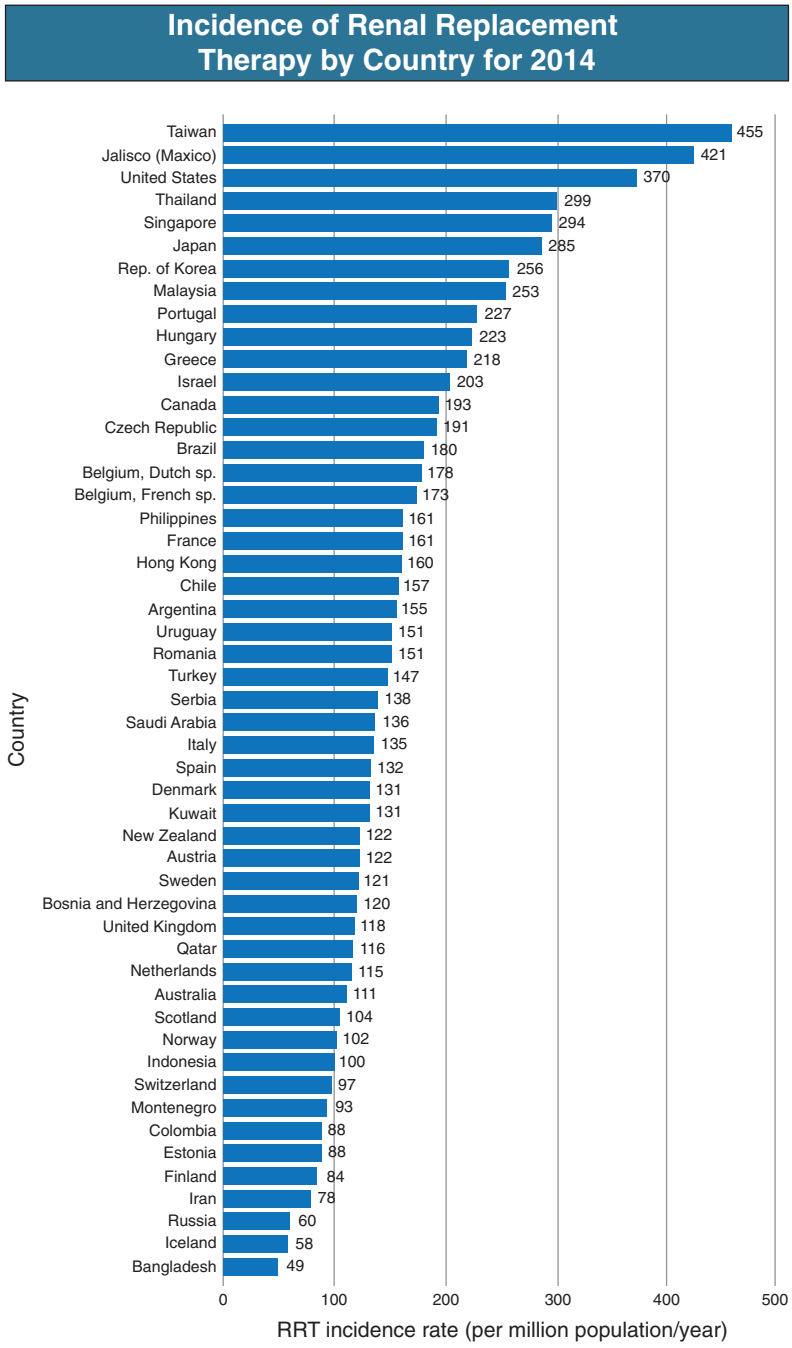

Fig. 77.7 Incidence rate of renal replacement therapy (RRT) (per million population per year), by country for 2014. (From reference 40.)

Some ethnic groups experience particularly high rates of kidney failure and dialysis. Indigenous peoples in Australia, New Zealand, Canada, and the United States have very high rates of kidney disease, poorer outcomes, and less access to transplantation.[39] The causes underlying this are complex, but common elements appear to include very high rates of diabetes, metabolic syndrome, and hypertension driving high rates of CKD.

Dialysis Practice Patterns

Dialysis practice patterns vary widely across countries, with different usage of PD, HD, and home HD. For prevalent patients the regions with the highest proportion of PD are Hong Kong (72% of prevalent patients) and the Jalisco region of Mexico (47% of prevalent patients).[40]

Home HD is most commonly used in New Zealand and Australia, where 18% and 9%, respectively, of prevalent RRT patients are treated with this modality. Practice patterns also vary in the application of various techniques of HD; for example, dialysis sessions are generally longer in Japan, with slower blood flow rates.

Outcomes

The rationale for dialysis is to prevent death from uremia, and hence the outcome for dialysis treatment is usually reported as mortality rate. Other important outcomes commonly reported include cause-specific mortality rates, hospitalizations, and technique failure. Patient-reported outcomes (including measures of quality of life and functional ability) are also extremely important but recorded much less frequently.

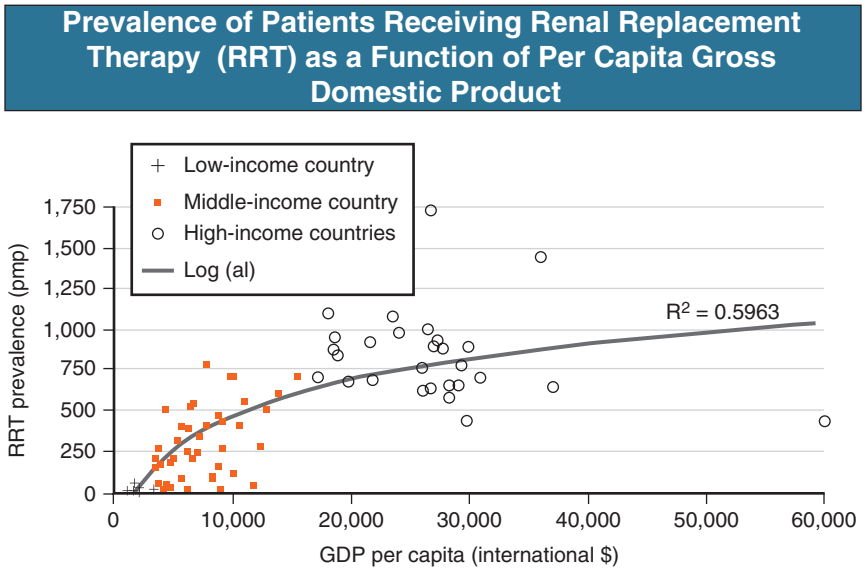

Fig. 77.8 Prevalence of patients receiving renal replacement therapy *(RRT),* as at December 31, 2002 and gross domestic product *(GDP)* per capita. *PMP,* per million population. (From reference 50.)

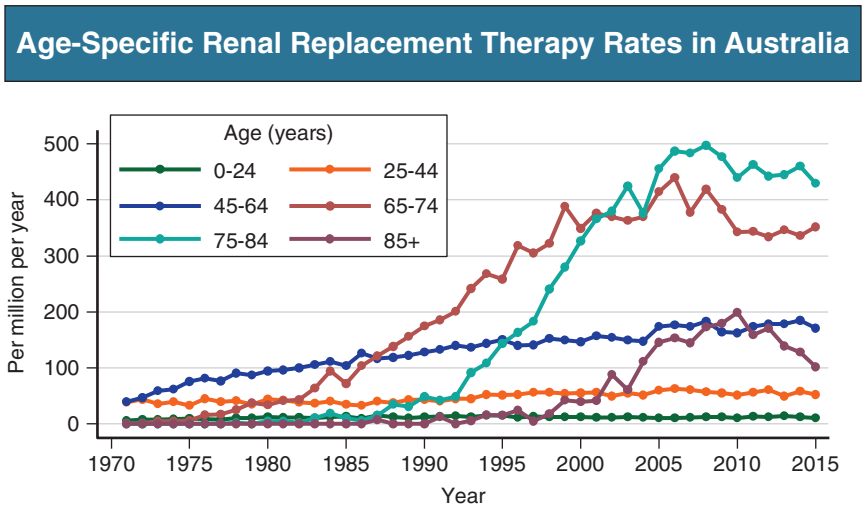

Fig. 77.9 Age-specific renal replacement therapy incidence rates in Australia. (Data from reference 51.)

Crude mortality rates vary widely; a multinational observational study (Dialysis Outcomes and Practice Patterns Study [DOPPS]) reported rates from 6.6% per year in Japan to 21.7% in the United States.[41] Mortality rates among dialysis patients are substantially higher than in the general population, a differential particularly marked among younger age groups (Fig. 77.10). The excess mortality is primarily driven by cardiovascular and infectious causes. There is also a modest (approximately threefold) excess risk for cancer among dialysis patients, even after exclusion of cancers directly related to the cause of kidney disease.[42] An issue unique to categorization of deaths among the dialysis cohort is assignment of deaths as a result of withdrawal from therapy. There is a wide range in reported frequency of withdrawal, from less than 5% to more than 20% of all deaths.[43] These differences may in part reflect different coding mechanisms but are also likely to reflect differences in practice patterns in the commencement of therapy among older patients with higher levels of comorbidity.

There is variation in mortality rates over time, with the highest rates seen in the first 3 months after commencing dialysis, particularly among older age groups (Fig. 77.11). After this period, mortality rates approximate the longer term rates. There are a number of possible contributors to this, including the risk associated with commencement of dialysis (such as the placement of central venous catheters) and increased severity of comorbidities associated (or causing) the deterioration of renal function.

Multiple observational studies have compared mortality between PD and HD, but there has been no randomized controlled trial (RCT) successfully conducted despite a number of attempts. Results from observational studies have varied across countries; common elements are the presence of multiple interactions such that the comparison depends on comorbidities and patient age, the length of follow-up, and selection biases and local/regional outcomes of each technique.

For PD (and to a lesser extent home HD), "technique survival" is a common metric. This refers to the proportion of people continuing on PD at various time points. It is a combined end-point, with patient death and transfer to HD considered failures. Typically 30 days of HD is considered to be a permanent transfer to HD. It is important to

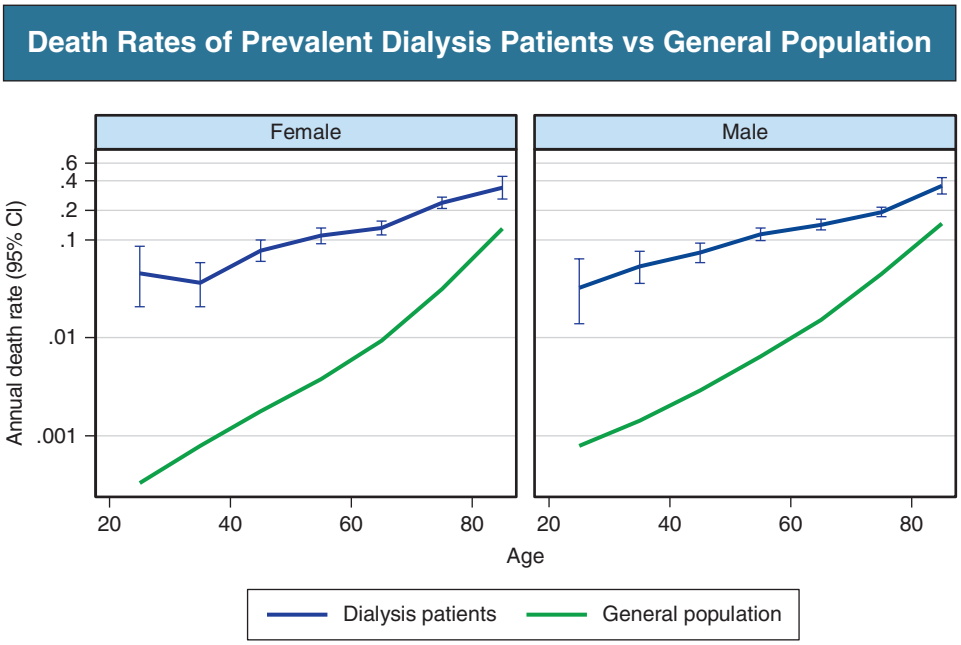

Fig. 77.10 Death rates of prevalent dialysis patients versus general population. *CI,* Confidence interval. (From reference 51.)

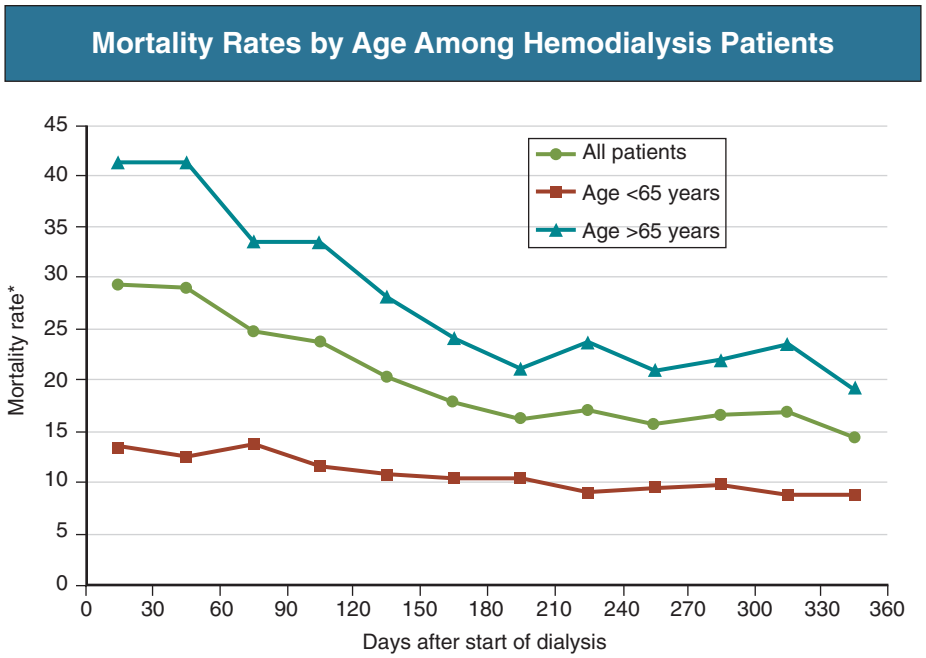

Mortality rate during the first 360 days of HD treatment												
	0-30	31-60	61-90	91-120	121-150	151-180	181-210	211-240	241-270	271-300	301-330	331-360
All patients	29.3	28.9	24.9	23.8	20.4	17.9	16.2	17.0	15.7	16.5	16.8	14.4
Age <65 years	13.3	12.6	13.5	11.6	10.7	10.4	10.2	9.1	9.3	9.7	8.9	8.7
Age >65 years	41.2	41.2	33.7	33.5	28.2	24.0	21.1	23.6	21.0	21.9	23.5	19.2

ensure consistency of definitions in comparisons of technique survival; alternative duration definitions have substantial effects on the calculated technique survival.

EPIDEMIOLOGIC CONCEPTS

Epidemiologic factors influence the reported rates of RRT; understanding the potential biases is a necessary part of interpretation of these data.

The *prevalent* number of RRT patients at any point in time receiving a form of RRT reflects both the rate of people starting treatment (for overall RRT numbers, the *incidence* rate) and the rate of people ceasing treatment (the *mortality* rate). These rates can be considered *transition probabilities* among various states. This concept can be applied to the overall number of people receiving RRT, the number receiving dialysis or transplantation, and other subgroups. For example, the determinants of the prevalent number of people receiving dialysis at any point in time can be determined from the existing population plus the number of new patients (incidence rate plus the number of people who have lost graft function) less the number of deaths (mortality rates during dialysis) and kidney transplants.

This form of multistate model is often known as a Markov model. Use of these models to estimate future trends can be used by health services and others in predicting the future number of people receiving RRT. This can be done under existing conditions and under various hypothetical scenarios to model the effects of various interventions.

The *incidence* rates reported for ESRD typically exclude dialysis for AKI. Definitions of the start point of RRT vary across registries and data collections. In many cases, an "intent" definition is used (i.e., dialysis is commenced with the intention of long-term treatment, underpinned by a diagnosis of irreversible ESRD). The other approach (used by the U.S. and European registries) is to use day 90 after dialysis start as the point at which patients are deemed to require "chronic" dialysis. Although this approach eliminates uncertainty around people with prolonged acute (or acute on chronic) kidney injury who may or may not recover, it does prevent analysis of early mortality.

Selection bias affects incidence rates. There may be constrained provision of dialysis services that affects ability to access dialysis services. There have also been changes in clinical practice over time affecting the propensity to treat in certain situations (especially among older and more frail patients). These factors will influence observed rates; differences in these selection biases will be relevant to comparisons of disease incidence among groups and also to the same group between different times. This is likely to have contributed to the increasing dialysis rates among progressively older people observed in the 1970s to late 1990s.

Lead time bias occurs when the time point of observation differs between groups. One example of this is the comparison of PD and HD cohorts. Patients commencing RRT with PD typically do so at a higher eGFR than those commencing with HD; current U.K. data suggest this mean difference is around 0.5 ml/min/1.73 m^2.[44] Although small, this may amount to 2 to 3 months of difference in starting point of analyses.

Competing risks are seen in several areas. This phenomenon arises when an illness may lead to multiple possible outcomes, but the occurrence of one precludes another. For example, changes in cardiovascular mortality may affect the incidence rate of RRT because patients who survive despite significant heart disease may avoid premature death that would preclude dialysis treatment. Another example is the influence of kidney transplantation in evaluation of survival of a dialysis cohort: increased occurrence of transplantation may lead to higher mortality in dialysis cohort.

Immortal time bias arises when an inappropriate time point is chosen for comparators. An example of this might be comparison of mortality after coronary angiography performed as a pretransplant assessment between those transplanted and not transplanted; the transplanted group will accumulate "immortal" follow-up time between angiography and transplantation, in contrast to the nontransplanted group.

EVIDENCE QUALITY

There is a relative dearth of RCTs supporting practice in the area of dialysis, compared with other disciplines. Most large-scale trials examining dialysis-specific interventions have yielded negative or inconclusive results; for example, the use of non–calcium-containing phosphate binders,[45] increased dialysis dose,[46] use of statins in dialysis patients,[47] and hemodiafiltration.[48] In response to this, clinical trials networks with a focus on nephrology have been established in several countries to catalyze the conduct of trials (particularly where there is limited commercial interest).

The outcomes examined in trials also have been critically examined. Given the time delay and multiple contributing factors to mortality, many trials have used surrogate outcomes. Given the association of many biochemical abnormalities with increased mortality, their use appears logical. However, as in other areas of medicine, use of surrogate outcomes in trials and evidence generation in nephrology has been problematic, with changes in surrogates not reflected by reduction in mortality or other hard end-points. An example of this is the use of phosphate (and parathyroid hormone) as a surrogate to assess the effectiveness of cinacalcet. Partly as a response to this, initiatives have been instituted to develop and codify the outcomes for trials.[49] An important element of this is also the inclusion of input from patients and consumers of services in setting research priorities.

SELF-ASSESSMENT QUESTIONS

1. The Kidney Disease: Improving Global Outcomes (KDIGO) 2012 chronic kidney disease (CKD) classification includes all of the following in the staging of CKD *except:*
   - **A.** The severity of hypertension
   - **B.** The severity of albuminuria
   - **C.** The level of glomerular filtration rate (GFR)
   - **D.** Cause of disease
2. Which statement is true?
   - **A.** Low GFR is unimportant in older adults.
   - **B.** Higher albuminuria is worse for men than women.
   - **C.** Higher albuminuria is associated with acute kidney injury.
   - **D.** Assays for proteinuria are more accurate than assays for albuminuria.
3. Racial disparities in ESRD incidence is in part attributable to:
   - **A.** The higher prevalence of APOL1 genetic risk variants in those of European descent
   - **B.** Lower socioeconomic status and poorer access to health care in Black individuals
   - **C.** Greater rates of smoking among Black individuals
   - **D.** Lipoxins
4. Which statement is most true about rates of new dialysis patients?
   - **A.** They are highest in Eastern European countries.
   - **B.** An increase in rates of glomerulonephritis is the major driver.
   - **C.** Rates are higher among older than younger people.
   - **D.** Rates are higher among women.
   - **E.** Rates are generally lower among groups with lower socioeconomic status.
5. Regarding competing risks in comparison of rates of new dialysis patients between groups:
   - **A.** Competing risks refers to higher rates seen among health systems in which funding is allocated on a competitive grants basis.
   - **B.** Men more than women are affected because testosterone leads to greater competitive drive.
   - **C.** Competing risks from transplantation will not be a factor if measured covariates are included and adjustment is made for them.
   - **D.** Incident dialysis rates might be higher if vascular mortality associated with CKD were lower.
   - **E.** Propensity score matching can largely address the problems raised by competing risks.

Pathophysiology of Disease Progression in Proteinuric and Nonproteinuric Kidney Disease

Ariela Benigni, Norberto Perico, Giuseppe Remuzzi

Chronic kidney disease (CKD) is a worldwide threat to public health and has a risk-multiplier effect on major noncommunicable diseases, including cardiovascular diseases.[1] More than 322 million individuals are currently affected by CKD worldwide,[2] and the number of patients with end-stage renal disease (ESRD) treated with renal replacement therapy (RRT) with dialysis or transplantation globally exceeds 2.6 million people.[3] Independent of the initial insult, progression to ESRD is relatively common in chronic nephropathies. Many forms of progressive noncystic renal disease are glomerular in origin, and yet it is the intensity of the accompanying or evolving injury of the tubulointerstitial compartment, rather than the extent of glomerular changes, that predicts the overall decline in renal function.[4] Although genetic factors contribute to susceptibility and progression of renal disease, increased glomerular capillary flow and pressure consistently leading to increased urinary protein traffic have been claimed as independent factors of progression and poor renal outcomes in nondiabetic and diabetic kidney disease.[5,6] The Ramipril Efficacy in Nephrology (REIN) study was the first trial to formally test the role of proteinuria in the progression of kidney disease.[7-9] The trial showed that in 352 patients with proteinuric nephropathies from different etiologies, higher proteinuria at inclusion was associated with faster glomerular filtration rate (GFR) decline and progression of ESRD on follow-up.[5,10] Notably, in the REIN trial, larger proteinuria reduction and less residual proteinuria at follow-up were both associated with slower GFR decline and more effective protection against progression to ESRD, independent of treatment allocation.[11] Greater proteinuria reduction predicted slower progression, as in the patients with type 2 diabetes with overt nephropathy included in the Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan (RENAAL)[6] study and Irbesartan Diabetic Nephropathy Trial (IDNT).[12] The predictive pathogenic role of proteinuria was confirmed by a pooled analysis of 2387 CKD patients included in 11 trials, which showed that, irrespective of treatment, short-term changes in proteinuria were strongly consistent with long-term outcomes, whereas no effect on proteinuria predicted no long-term benefit.[13] Thus efforts to dissect the mechanisms and mediators underlying disease progression in proteinuric nephropathies are of utmost importance to help design novel medications to further improve the efficacy of current renoprotective interventions.

FROM GLOMERULAR HYPERTENSION TO LOSS OF SIZE-SELECTIVE PROPERTIES

Studies from animal models in the early 1980s have shown that most renal diseases progress to renal failure as a consequence of functional adaptations that occur in the kidney, after the original disease process causes an initial loss of nephron units.[14] Thus a variety of insults result in a common pathway of glomerular capillary hyperperfusion and hypertension, followed by increased permeability with excess passage of proteins across the glomerular capillary wall and progressive glomerular injury.[14] Enhanced intraglomerular capillary pressure stretches the glomerular wall, which, in addition to directly injuring glomerular cells,[15] impairs the selective function of the glomerular capillary, an effect explained by the appearance of very large pores that exceed the sizes observed in normal conditions and allow increased filtration of plasma proteins[16] (Fig. 78.1). Mechanical strain also increases angiotensin II (Ang II) production and expression of Ang II type 1 (AT_1) receptors in podocytes.[17] Independent of its hemodynamic effects, Ang II may directly impair the glomerular barrier sieving function, possibly through inhibition of podocyte expression of nephrin, the essential protein component of the glomerular slit-diaphragm[18] (Fig. 78.2). This observation has been confirmed in studies in diabetic animals showing that blockade of Ang II synthesis/activity preserved the expression of nephrin in the glomeruli and prevented overt proteinuria.[19] Thus in the setting of diabetes, after the initial insult of hyperglycemia and intraglomerular hypertension, Ang II plays a relevant role in sustaining glomerular injury via persistent activation of Notch1 and Snail signaling in the podocyte, eventually resulting in persistent downregulation of nephrin expression.[20] The consistency of the findings in Zucker diabetic fatty rats with overt nephropathy and in patients with type 2 diabetes and established nephropathy provides a robust reason to infer an important role for the Ang II Notch 1/Snail axis in perpetuating loss of glomerular size–selective properties.

Podocyte Response to Protein Trafficking

After loss of size selectivity, the intercellular junction and cytoskeletal structure of the podocyte foot processes are altered and the cells show a simplified, effaced phenotype.[21] These alterations result in the disappearance of the typical slit-diaphragm structures, leading to enhanced protein trafficking. Thus podocytes are damaged by excessive protein load after size selectivity is lost.[22] Protein uptake by podocytes may occur through binding to megalin, a receptor for albumin and immunoglobulin light chains that is endocytosed after ligand binding, as shown in cultured murine podocytes.[23] Excessive protein uptake by podocytes also induces transforming growth factor-β (TGF-β) production, which contributes to cell apoptosis, an additional cause of podocyte loss in proteinuric glomerulopathies.[24]

Finally, podocytes possess a fully functional endothelin (ET) system, and evidence has highlighted the role of ET-1 in promoting structural and functional alteration of these cells in renal disease.[25] This possibility is supported by the beneficial effects of ET receptor antagonists on the development of proteinuria and glomerular injury in type 1 diabetic animals, partially attributed to attenuation of podocyte loss.[19] Although the mechanism of podocyte preservation by ET receptor antagonism

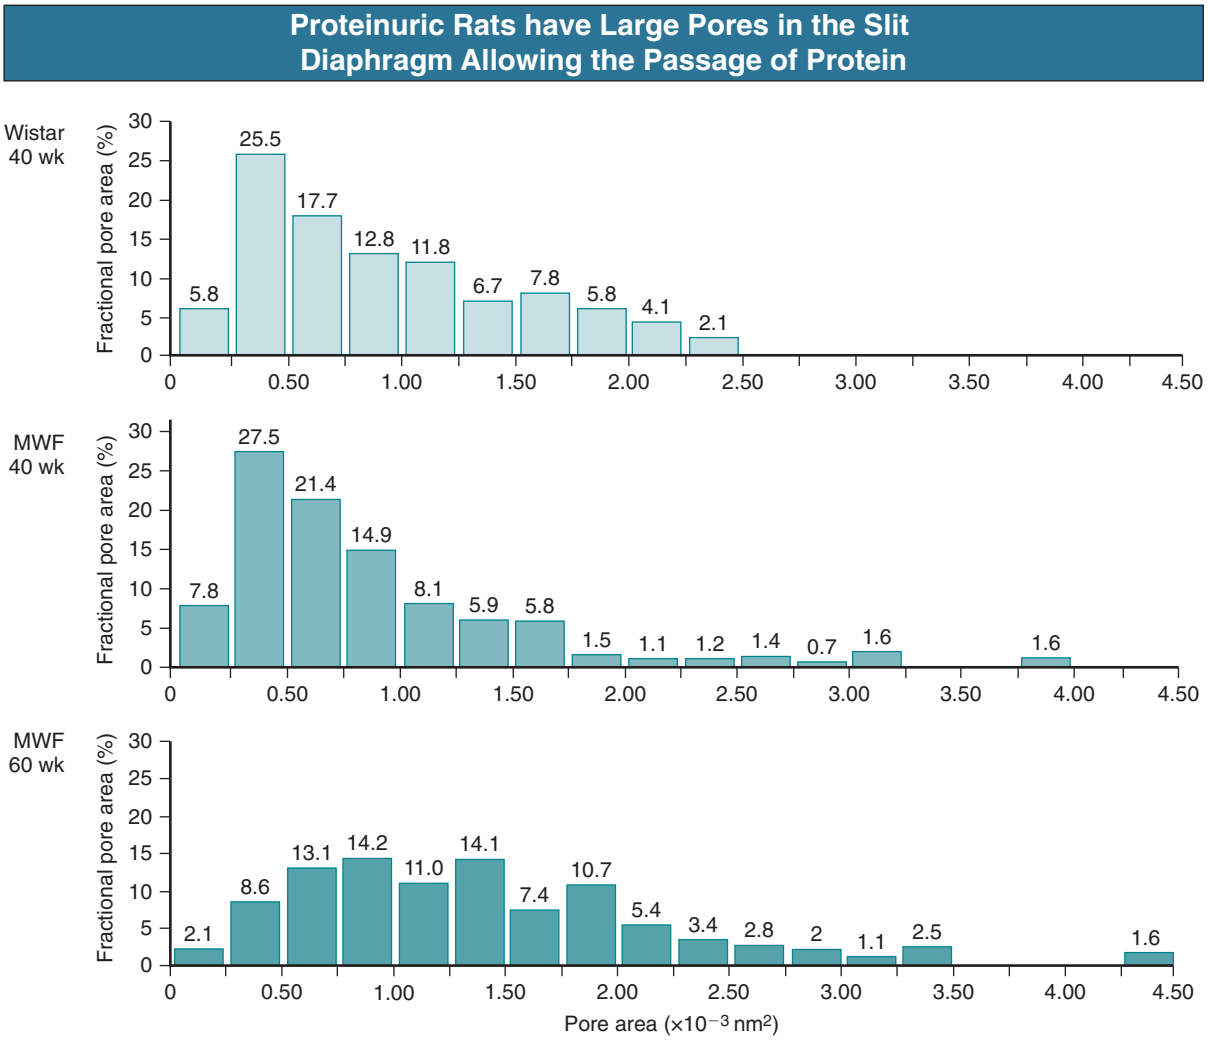

Fig. 78.1 Proteinuric Munich Wistar Fromter (MWF) rats have large pores in the glomerular capillary slit-diaphragm that exceed the size observed in normal animals. Distribution of fractional pore area (the fraction of the total pore area for given pore area interval) calculated for slit pores in 40-week-old normal Wistar rats and in 40- or 60-week-old proteinuric MWF rats. (From reference 16).

remains ill defined, recent observations indicate that ET-1 induces an epithelial-to-mesenchymal transition-like event associated with increased podocyte motility.[26] This is dependent on the activation of ET_A receptor, which recruits β-arrestin 1, leading to epithelial growth factor receptor translocation and β-catenin phosphorylation, in turn promoting the expression of migratory genes.[26]

Furthermore, the preservation of podocyte structure under ET receptor antagonism could be secondary to a reduction in the protein load reaching the cells, as suggested by recent findings in diabetic apoE knockout mice.[27] In this model, the ET_A receptor antagonist atrasentan restored the structural integrity of glomerular endothelial glycocalyx—a gel-like polyanionic carbohydrate layer that covers endothelial cells—normalizing the barrier against the excessive traffic of albumin through the capillary wall up to podocytes.[27]

Crosstalk of Podocytes With Mesangial and Endothelial Cells

The mesangial cells are a critical part of the glomerular functional unit, interacting closely with podocytes.[28] Alterations in one cell type can produce changes in the others. Whether cytokines generated by podocytes influence mesangial cells has yet to be clearly defined, but the observation that podocyte injury frequently results in mesangial cell proliferation supports the existence of such cytokine crosstalk.[28] Moreover, podocyte abnormalities are accompanied by upregulation of TGF-β messenger RNA and enhanced production of the related protein,[22] which ultimately induces differentiation of mesangial cells into myofibroblasts, abnormal extracellular matrix (ECM) deposition, and glomerulosclerosis.[29,30]

Loss of podocytes secondary to protein-induced cell injury may lead to reduced production of vascular endothelial growth factor (VEGF), a molecule constitutively expressed and secreted by podocytes,[31] influencing the formation of glomerular endothelial fenestrae and eventually promoting endothelial cell apoptosis.[32] How VEGF reaches endothelial cells against the urine flow is not yet known, however. Conversely, in vitro evidence has shown that blockade of VEGF in glomerular endothelial cells enhanced the release of ET-1, which induced nephrin shedding from podocytes,[33] leading to further dysfunction of glomerular protein permeability (Fig. 78.3).

Activation of Parietal Epithelial Cells

Changes in glomerular perm-selective function, as it occurs in proteinuric glomerulopathies, elevate the filtered load of plasma albumin and

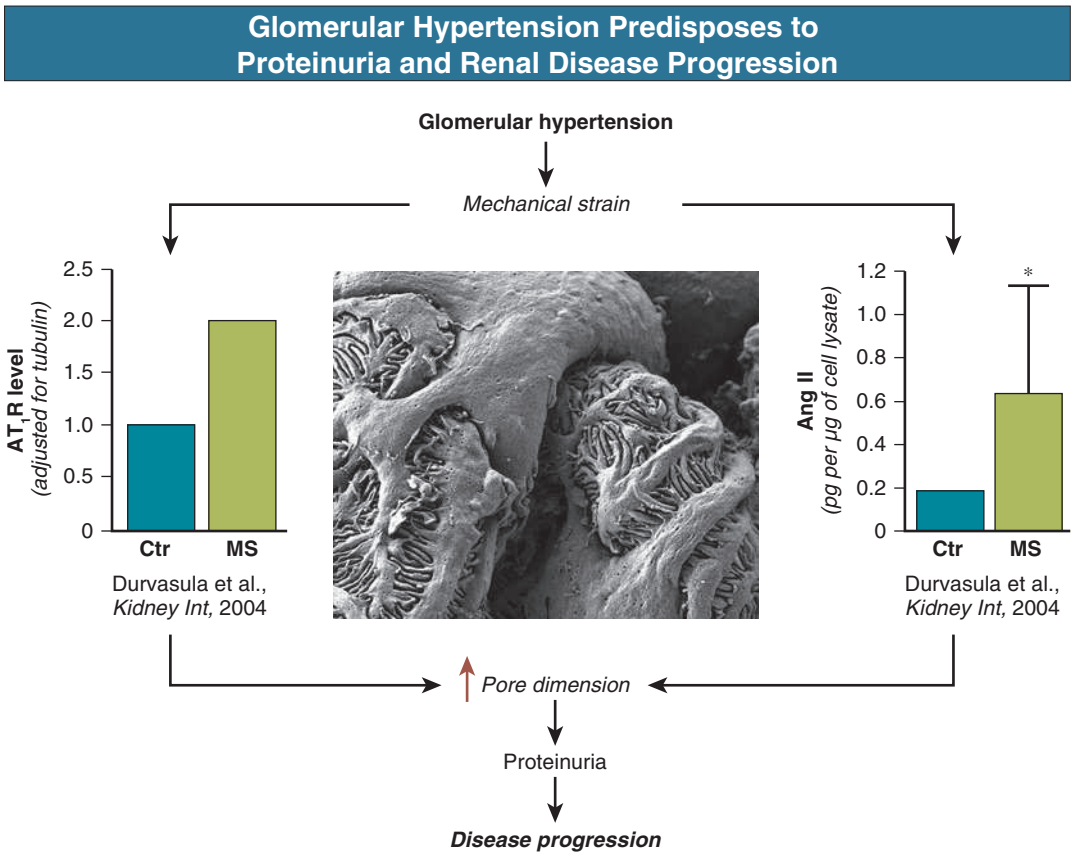

Fig. 78.2 Schematic process linking glomerular capillary hypertension to proteinuria and renal disease progression. After the original disease process causes an initial loss of nephron units, enhanced intraglomerular capillary pressure stretches the glomerular wall, impairing its size-selective function. Mechanical strain also increases angiotensin II (Ang II) production and expression of Ang II type 1 receptors (AT_1R) in podocytes, eventually directly contributing to loss of the glomerular barrier sieving function through inhibition of podocyte slit-diaphragm nephrin expression (see reference 17). Ctr, Control; MS, mechanical strain.

consequently its concentration in the Bowman space[34] (Fig. 78.4). Evidence has been provided that the abnormally filtered albumin impairs the mechanism underlying regeneration of damaged podocytes.[35] Indeed, although podocytes have limited capacity to divide, they can potentially get replaced by differentiation of a population of renal progenitor cells localized within the Bowman capsule.[36] In vitro, albumin overload blocked the differentiation of human renal progenitor cells into podocytes expressing podocin and other functional molecules. The albumin-dependent block of relevant gene transcription and of progenitor differentiation was explained by specific binding and sequestration of retinoic acid, which is endogenously synthesized by the cells from retinol (see Fig. 78.4).[35]

The abnormal concentration of proteins in the ultrafiltrate also can lead to activation and accumulation of parietal epithelial cells (PECs) within the Bowman space as a common response to glomerular injury,[37] as shown in several human proliferative glomerulonephritides. This possibility is supported by findings in Munich Wistar Fromter (MWF) rats, which are genetically programmed to undergo renal damage characterized by excessive migration and proliferation of parietal progenitor cells, leading to their accumulation into cellular lesions and glomerulosclerosis.[38] Along the Bowman capsule in the adult MWF rats, a population of PECs expressing the neural cell adhesion molecule (NCAM), a marker of metanephric mesenchyme,[39] together with CD24, a mouse and human kidney stemness marker, has been identified.[38] Double-staining of NCAM with the podocyte marker WT1 identified three cell populations lining the Bowman capsule: immature progenitor cells expressing NCAM, transitional cells expressing markers from progenitor cells and podocytes ($NCAM^+WT1^+$), and more differentiated epithelial cells, the parietal podocytes ($NCAM^-WT1^+$). $NCAM^+$ PECs in vitro differentiate into podocytes, confirming their progenitor nature.[38] We investigated the behavior and role of $NCAM^+$ PECs in the evolution of glomerular lesions in MWF rats that showed early lesions consisting of bridges between the parietal and visceral epithelium, followed by hyperplastic lesions that eventually evolve to sclerosis.[38] The majority of cells in glomerular lesions were $claudin^+$ PECs of the Bowman capsule, whereas there were few podocytes. In old MWF animals, the $claudin^+$ PECs increased in number, proliferated, and accumulated in the Bowman space, whereas parietal podocytes decreased. These findings suggested dysregulation of PECs' ability to differentiate into podocytes and to repair injury.[38]

PECs expressing the progenitor cell marker also have been reported to proliferate and accumulate into the multilayered cellular lesions in patients with glomerulonephritides characterized by extracellular capillary proliferation.[40] Upregulation of the CXCR4 chemokine receptor on these progenitor cells was found to be accompanied by high expression of its ligand, SDF-1, in podocytes.[40] Moreover, PEC proliferation was associated with increased expression of the AT_1 receptor. Renin-angiotensin system blockade normalized CXCR4 and AT_1 receptor expression on parietal progenitor cells concomitant with regression of crescentic lesions.[40] Together these findings suggest that the glomerular hyperplastic lesions derive from the proliferation and migration of renal progenitor cells in response to injured podocytes and that the

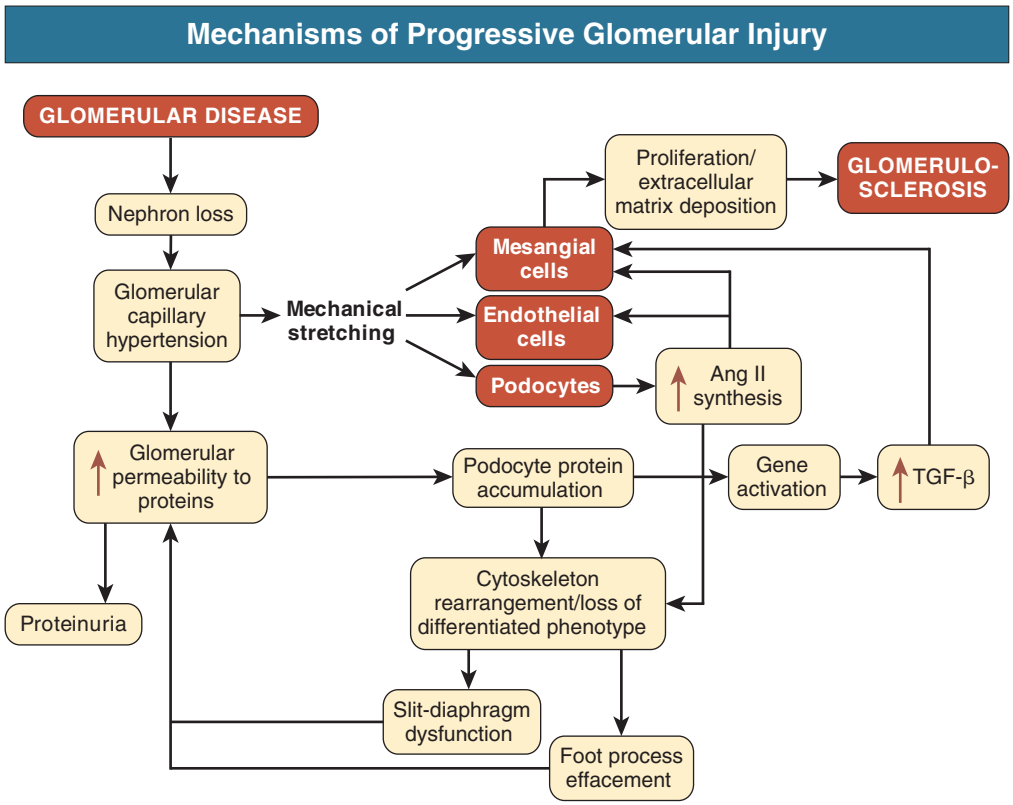

Fig. 78.3 Mechanisms of progressive glomerular injury. A reduction in the number of nephrons as a consequence of various glomerular diseases results in compensatory glomerular hemodynamic changes that are ultimately detrimental. By mechanical stretching, the increased glomerular capillary pressure directly injures glomerular cells. Glomerular hypertension also impairs the glomerular capillary size-selective function, which causes excessive protein ultrafiltration and, eventually, podocyte injury and proteinuria. Ang II, Angiotensin II; TGF-β, transforming growth factor-β.

Ang II/AT_1 receptor pathway may contribute, together with SDF-1/CXCR4 axis, to the dysregulated response of PEC precursors. A very recent study highlighted the key role of complement components C3 and C3a in determining podocyte dysfunction and loss leading to PEC activation.[41] Proliferation and migration of PECs in response to activated complement contribute to the development of glomerular sclerotic lesions.[41] Consistently, studies on renal biopsy samples from patients with proteinuric nephropathies and PEC activation showed concomitant glomerular C3 and C3a deposition, indicating the key role in the development of glomerular lesions.[41]

PROXIMAL TUBULAR CELL INJURY

Glomerular ultrafiltration of excessive amounts of plasma protein–associated factors incites tubulointerstitial damage and further promotes the effects of glomerular disease on the tubulointerstitial compartment.

The noxious substances in the proteinuric ultrafiltrate may set off tubular epithelial injury with tubular apoptosis, secondary generation of inflammatory mediators, and peritubular inflammation.[29] The mechanisms by which increased urinary protein concentration leads to toxic injury are multifactorial and involve complex interactions among numerous pathways of cellular damage.

Tubular Cell Apoptosis

Renal proximal tubular cells have a remarkable ability to reabsorb large quantities of albumin through clathrin- and megalin receptor–mediated endocytosis.[42] Kidneys in rats with albumin overload proteinuria[43] or passive Heymann nephritis (PHN)[44] showed increased numbers of terminal deoxynucleotidyl transferase nick-end labeling-positive apoptotic cells in the tubulointerstitial compartment. In tubules, most of the positive cells expressed Ang II type 2 (AT_2) receptors.[43] Findings of reduced phosphorylation of extracellular signal-regulated kinase and Bcl-2 suggested an AT_2 receptor–mediated mechanism underlying tubular cell apoptosis.[43] Similarly apoptotic cells expressing both proximal and distal tubular phenotypes were detected in biopsy specimens from patients with primary focal segmental glomerulosclerosis (FSGS), and a positive correlation was documented between proteinuria and incidence of tubular cell apoptosis.[45]

Proximal tubular cell apoptosis has been shown to contribute to tubuloglomerular disconnection and atrophy in response to proteinuria in animal models of proteinuric nephropathies.[44] When passive PHN rats were given the angiotensin-converting enzyme (ACE) inhibitor lisinopril, which limits proteinuria, tubular atrophy and disconnection were remarkably prevented.[44] PHN animals that did not respond to ACE inhibition in terms of reduction of proteinuria had a glomerular population consisting mainly of atubular glomeruli and glomeruli connected with atrophic tubules, which again is consistent with the possibility that excessive protein tubular handling favors disconnection.[44]

Tubular Cell Phenotypic Changes

Excessive protein uptake at the apical pole of the proximal tubular cells is associated with phenotypic changes characteristic of an activated state.

Insights into specific mechanisms linking protein uptake to cell activation have come from in vitro studies using polarized tubular cells

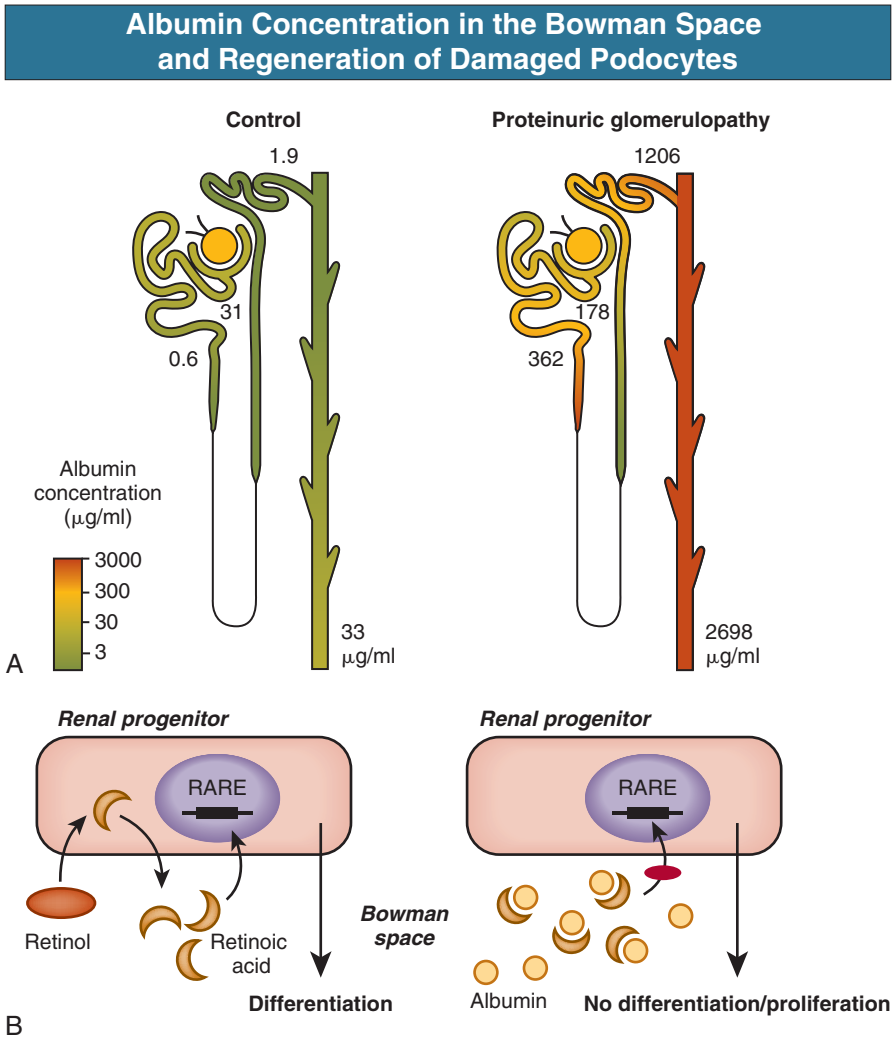

Fig. 78.4 Albumin concentration in the Bowman space and regeneration of damaged podocytes. (A) In the proteinuric glomerulopathies, changes in glomerular perm-selective function results in high concentration of albumin in the Bowman space. Color-coded graphical representation of estimated albumin concentration along the entire nephrons in two animal groups (control and renal mass ablation model). Numbers represent local group average albumin concentration in micrograms per milliliter (modified from reference 34). (B) In vitro albumin overload, prevented the differentiation to podocytes from human renal progenitor cells by sequestering retinoic acid, thus impairing retinoic acid response element *(RARE)*-mediated transcription of podocyte-specific genes. After early podocyte injury, retinol is lost through the injured glomerular filtration barrier and transformed into retinoic acid. Albumin overload also promotes proliferation and migration of renal progenitor cells into the Bowman space. (Modified from reference 35).

to assess the effect of apical exposure to proteins. Collectively, they show that protein overload induces a proinflammatory phenotype[46] (Fig. 78.5). Indeed upregulation of inflammatory and fibrogenic genes and production of related proteins have been reported after a challenge of proximal tubular cells with plasma proteins. They include cytokines, chemokines, and vasoactive substances, such as monocyte chemoattractant protein-1 (MCP-1); regulated upon activation, normal T cell expressed and secreted (RANTES); interleukin-8, fractalkine; and ET-1.[46] Moreover, levels of the profibrogenic cytokine TGF-β and its type I receptor, tissue inhibitors of metalloproteinase (TIMP-1 and TIMP-2), as well as membrane surface expression of the αvβ5 integrin were also highly increased in vitro on stimulation by plasma proteins.[46] Investigation of the molecular mechanisms underlying chemokine and growth factor upregulation in proximal tubular cells on protein challenge has focused on the activation of the transcription factor nuclear factor kappa-B (NF-kB).[46] In this context, a very recent study showed that albumin is capable of inducing chromatin modification, making the promoter region of the gene encoding miR-184, which plays a key role in tubulointerstitial nephritis of diabetic rats, more accessible to NF-kB inducing the miR-184 transcription.[47] Other studies confirmed the role of the NF-kB pathway and revealed reactive oxygen as a second messenger.[48] The link of excessive protein reabsorption to tubular cell activation has been confirmed by in vivo studies in animal models. Evidence of early activation of proximal tubule cells during nonselective proteinuria was derived from experiments in megalin knockout/NEP25 mice treated with the immunotoxin LMB2, a model of nephrotic syndrome, FSGS, and tubulointerstitial injury.[49] Megalin-deficient proximal tubule cells reabsorbed fewer proteins in vivo and expressed fewer tubular injury markers, such as MCP-1 and heme-oxygenase.[49] Moreover, a recent report using podocin knockout mice as a model of FSGS demonstrated that increased reabsorption of abnormally filtered albumin and other proteins in proximal tubule cells was associated with massive increase

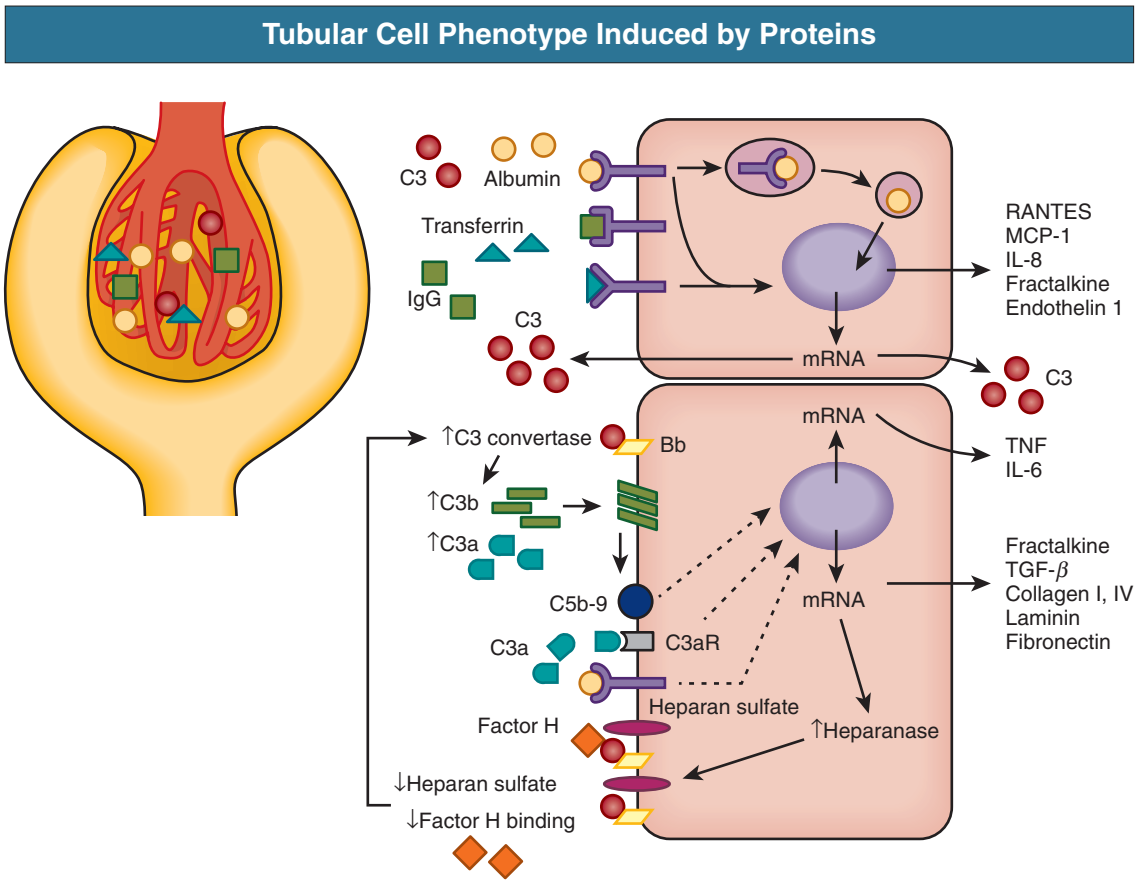

Fig. 78.5 Tubular cell phenotypic changes induced by proteins. Protein overload of proximal tubular cells as a consequence of increased glomerular permeability to proteins activates intracellular signals that promote cell apoptosis or cause increased production of inflammatory and vasoactive mediators and growth factors. IgG, Immunoglobulin G; IL-6, interleukin-6; IL-8, interleukin-8; MCP-1, monocyte chemoattractant protein-1; RANTES, regulated upon activation, normal T cell expressed and secreted; TGF-β, transforming growth factor-β; TNF, tumor necrosis factor.

of lysosomal proteolysis.[50] However, high expression of proinflammatory and profibrotic mediators (MCP-1 and TGF-β) in the kidney also occurred almost simultaneously with the increase in tubular content of megalin ligands.[50] This suggests that, despite the effective degradation of endocytosed proteins by lysosomes in this model, the excessive protein uptake by tubule cells was still capable of activating phenotypic changes by upregulation of proinflammatory and growth factor encoding genes.

With proteinuria, a putative key factor in tubular cell activation and damage is the excess glomerular filtration of plasma-derived complement C3, the central molecule in the complement system that exerts proinflammatory potential. Renal tubule epithelial cells appear more susceptible to luminal attack by the C5b-9 membrane attack complex because of the relative lack of membrane-bound complement regulatory proteins, such as membrane cofactor protein (CD46), decay-accelerating factor, or CD55 and CD59 on the apical surface.[51] In rats with reduced renal mass, C3 colocalized with proximal tubular cells engaged in high protein uptake. By limiting the transglomerular passage of proteins, treatment with ACE inhibitors was an effective manner to reduce the C3 load of tubular cells in remnant kidneys.[52] C3 and other complement proteins are also found in proximal tubules in renal biopsy material from patients with nephrosis.[53] Furthermore, proximal tubular cells are able to synthesize C3 and other complement factors and to upregulate C3 in response to serum proteins in vitro.[54] Studies in C3-deficient kidneys transplanted into wild-type mice have helped clarify that ultrafiltered C3 contributes more to tubular damage induced by protein overload than locally synthesized C3.[55]

INTERSTITIAL INFLAMMATION AND FIBROSIS

In proteinuric kidney disease, progressive inflammation and injury to the renal interstitium are secondary events after glomerular or vascular damage. Cytokines and chemokines synthesized by proximal tubular epithelial cells are released into the interstitium, where they contribute to recruit inflammatory cells and lymphocytes causing progressive fibrosis.[46]

Resident Monocyte and Lymphocyte Activation

The interstitium of normal kidneys contains numerous resident monocytic myelocytes, which express dendritic cell markers and can present antigens.[56] Dendritic cells have been described to form an immune sentinel network through the entire kidney, where they probe the environment in search of antigens.[57] An inflammatory environment converts the tolerogenic status of resident dendritic cells into an immunogenic one, favoring recruitment of T cells. The importance of kidney dendritic cell activation to renal injury has been demonstrated by the fact that in transgenic NOH mice (which selectively express the model antigens ovoalbumin and hen egg lysozyme in podocytes), dendritic cell depletion resolved established periglomerular mononuclear infiltrates.[58] In vitro experiments also have shown that exposure of rat proximal tubular cells

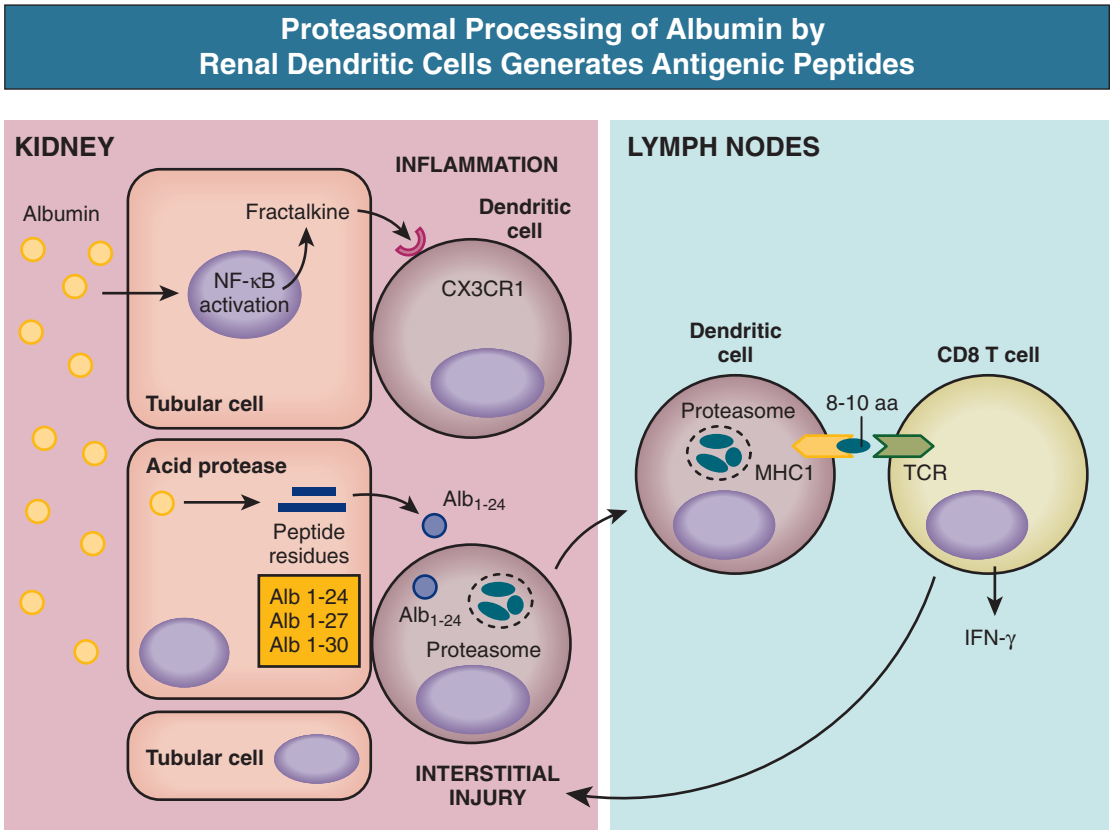

Fig. 78.6 Proteasomal processing of albumin by renal dendritic cells generates antigenic peptides. Exposure of proximal tubular cells to excess autologous albumin, as in the case of proteinuric nephropathies, results in the formation of the N-terminal 24-residue fragment of albumin. This peptide is acquired by dendritic cells, where it is further processed by proteasome into antigenic peptides. Then dendritic cells move to regional lymph nodes, where they activate effector $CD8^+$ T cells. These cells are then recruited in the renal interstitium. Alb_{1-24}, N-terminal 24-residue fragment of albumin; aa, aminoacids; IFN-γ, interferon-γ; MHC, major histocompatibility complex.

to excess autologous albumin, as in the case of proteinuric nephropathies, results in the formation of the N-terminal 24-residue fragment of albumin (ALB_{1-24}).[59] This peptide is taken up by dendritic cells, where it is further processed by proteasomes into antigen peptides. These peptides were shown to have the binding motif for major histocompatibility complex (MHC) class I and to be capable of activating $CD8^+$ T cells. Moreover, in vivo, in the rat model of renal mass ablation, accumulation of dendritic cells in the renal parenchyma peaked 1 week after surgery and decreased thereafter, concomitant with their appearance in the renal draining lymph nodes. Dendritic cells from renal lymph nodes loaded with the albumin peptide ALB_{1-24} activated syngeneic $CD8^+$ T cells in primary culture.[59] Thus inflammatory stimuli released from damaged tubules after protein overload may represent danger signals that, in the presence of albumin peptides, alert dendritic cells to promote local immune response via $CD8^+$ T cells, which are activated in regional lymph nodes and recruited in the renal interstitium (Fig. 78.6).

The interstitium infiltrate in most human chronic renal diseases consists of a number of different effector cells, including macrophages and $CD4^+$ T cells, in addition to $CD8^+$ T cells.[60] However, there is substantial functional diversity among $CD4^+$ T cells, so that certain subpopulations, such as $CD4^+CD25^+$ T cells, hinder rather than help the immune response.[61] Findings of a study using the green fluorescence protein - *Foxp3* mouse suggest that *Foxp3* expression identifies the regulatory T cell population.[62] In the murine model of adriamycin nephropathy, the adoptive transfer of *Foxp3*-transduced T cells protected against renal injury. Urinary protein excretion and serum creatinine were reduced, and there were significant decreases in glomerulosclerosis, tubular damage, and interstitial infiltrates.[63] These findings highlighted a complex interplay between effector/inflammatory cells and regulatory T cells in the setting of proteinuric chronic renal diseases.

Fibroblast Activation and Extracellular Matrix Deposition

The process of interstitial fibrosis involves the accumulation of myofibroblasts and ECM proteins[64] (Fig. 78.7). Resident interstitial fibroblasts and myofibroblasts proliferate in response to macrophage-derived profibrogenic cytokines, and their number correlates with the subsequent formation of a scar.[64] These cells may derive from trans-differentiated tubular epithelial cells or pericytes of peritubular capillaries, a process promoted by profibrogenic cytokines, including TGF-β, expressed by macrophages.[65] Activated renal fibroblasts may secrete chemokines that in turn may further attract macrophages and perpetuate interstitial injury.[66] Moreover, miRNAs are emerging as both downstream effectors of TGF-β–dependent regulation of the fibrogenic process.[67] TGF-β upregulates the expression of the profibrotic miR-21 in cultured proximal tubular epithelial cells via Smad3 signaling, both at the transcriptional and post-transcriptional level.[68] A functional link between miR-192 and TGF-β–driven renal fibrosis also has been documented, although the effect of TGF-β on miR-192 expression is not consistent across various studies.[67]

Eventually activated fibroblasts produce interstitial matrix components that contribute to interstitial collagen deposition and fibrosis.

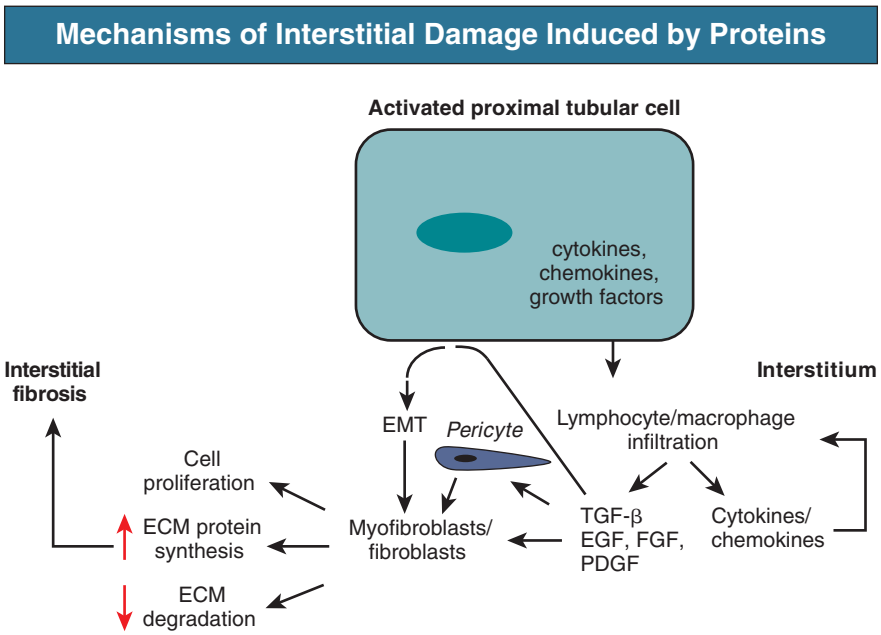

Fig. 78.7 Mechanisms of interstitial damage induced by proteins. Cytokines, chemokines, and growth factors are released from the activated tubule into the interstitium, where they contribute to recruit inflammatory cells and lymphocytes, causing progressive fibrosis. ECM, Extracellular matrix; EGF, epidermal growth factor; EMT, epithelial-to-mesenchymal transdifferentiation; FGF, fibroblast growth factor; PDGF, platelet-derived growth factor; TGF-β, transforming growth factor-β.

Increased tubulointerstitial fibrosis is a common feature of kidney injury and results from accumulation of ECM structural proteins. However, it is maintained by continuous remodeling through the proteolytic action of matrix metalloproteinases (MMPs) and the synthesis of new proteins. MMPs are inhibited by tissue inhibitors of TIMPs. Of note, TIMP-3 levels are upregulated in patients with diabetic nephropathy, which anticipates more interstitial fibrosis.[69]

Chronic Hypoxia

One of the most important contributors to the development of tubulointerstitial fibrosis is chronic ischemia.[70] The production of Ang II and the inhibition of the production of nitric oxide underlie chronic vasoconstriction, which may contribute to tissue ischemia and hypoxia.[71] In that regard, histologic studies of the human kidney have documented that there is often a loss of peritubular capillaries in areas of tubulointerstitial fibrosis.[71] Downregulation of VEGF may be functionally implicated in the progressive attrition of peritubular capillaries and tissue hypoxia. Moreover, given that the size of the interstitial compartment determines the diffusion distance between peritubular capillaries and tubular cells, interstitial fibrosis further impairs tubular oxygen supply. Focal reduction of capillary blood flow leading to the starvation of tubuli may underlie tubular atrophy and loss. Under these conditions the remaining tubules are subject to functional hypermetabolism, with increased oxygen consumption, which in turn creates an even more severely hypoxic environment in the renal interstitium. Such hypoxia stimulates fibroblast proliferation and ECM production by tubular epithelial cells.[72]

PRIMARY CHRONIC TUBULOINTERSTITIAL INJURY

Tubulointerstitial disease is common to all chronic progressive renal diseases, irrespective of the initial trigger or site of injury. Once viewed as an inconsequential corollary to pathologic events that overwhelm glomeruli, tubulointerstitial disease is now recognized as a key and prominent factor in the progression of renal disease. In addition to the setting of proteinuric nephropathies, inflammation and injury of the renal interstitium also can occur in nonproteinuric kidney disease, as exemplified by primary chronic tubulointerstitial diseases. In this case, the key event is the expression of local nephritogenic antigens. They are derived from renal cells and tubular basement membranes (TBMs) or exogenous antigens processed by tubular cells. The case of molecules, including drugs, which may become nephritogenic antigens by acting as haptens or through molecular mimicry, is particularly unusual. A humoral response underlies rare cases of interstitial nephritis in which a portion of a drug (e.g., methicillin) may act as a hapten, bind to the TBM, and elicit anti-TBM antibodies.[73] Among the numerous causes of primary chronic tubulointerstitial injury, drugs and toxins (see Table 62.1), in addition to genetic cystic diseases, are major players.

Analgesics and Nonsteroidal Antiinflammatory Drugs

Analgesic nephropathy is a specific form of renal disease characterized by renal papillary necrosis and chronic interstitial nephritis, caused by prolonged and excessive consumption of analgesic mixtures. It is invariably caused by compound analgesic mixtures containing aspirin or antipyrine in combination with phenacetin, paracetamol, or salicylamide and caffeine or codeine, in popular over-the-counter proprietary mixtures.[74] The mechanisms responsible for the renal injury are incompletely understood. Phenacetin is metabolized to acetaminophen and to reactive intermediates that can injure cells, in part by lipid peroxidation.[75] These metabolites tend to accumulate in the medulla along the medullary osmotic gradient (created by the countercurrent system). As a result, the highest concentrations are seen at the papillary tip, the site of the initial vascular lesions.[76] The potentiating effect of aspirin, with both phenacetin and acetaminophen, may be related to two factors. (1) Acetaminophen undergoes oxidative metabolism by prostaglandin H synthase to reactive quinoneimine, which is conjugated to glutathione. If acetaminophen is present alone, there is sufficient glutathione generated in the papillae to detoxify the reactive intermediate. However, if

acetaminophen is ingested with aspirin, the aspirin is converted to salicylate, which becomes highly concentrated and depletes glutathione in both the cortex and papillae of the kidney. With the cellular glutathione depleted, the reactive metabolite of acetaminophen then produces lipid peroxides and arylation of tissue proteins, ultimately resulting in necrosis of the papillae.[76,77] (2) Aspirin and other nonsteroidal antiinflammatory drugs suppress prostaglandin production by inhibiting cyclooxygenase enzymes. Renal blood flow, particularly within the renal medulla living at the edge of hypoxia, is highly dependent on systemic and local production of vasodilatory prostaglandins. The final injury is therefore due to both the hemodynamic and the cytotoxic effects of these drugs, resulting in papillary necrosis and interstitial fibrosis.

Aristolochic Acid

In 1992 nephrologists in Belgium noted an increasing number of women presenting with renal failure, often near end-stage, after their exposure to a slimming regimen containing Chinese herbs.[78,79] As of early 2000, a total of more than 120 cases had been identified. The main histologic lesion in human biopsy samples, which is located principally in the cortex, is extensive interstitial fibrosis with atrophy and loss of the tubules. Cellular infiltration of the interstitium is scarce. Important tryptase-positive mast cells were observed in the fibrotic areas in renal biopsy samples.[80] Thickening of the walls of the interlobular and afferent arterioles resulted from endothelial cell swelling. The glomeruli are spared, relatively speaking, and immune deposits are not observed. These findings suggest that the primary lesions may be centered in the vessel walls, thereby leading to ischemia and interstitial fibrosis.[81]

A plant nephrotoxin, aristolochic acid, has been proposed as the possible etiologic agent. Support for this hypothesis is provided by findings in animal models. In a first study, rabbits were given intraperitoneal injections of aristolochic acid (0.1 mg aristolochic acid/kg 5 days per week for 17 to 21 months[82]). Histologic examinations of the kidneys and genitourinary tract revealed renal tubular atrophy, interstitial infiltration/fibrosis, and atypical and malignant uroepithelial cells. Moreover, the daily subcutaneous administration of 10 mg/kg of aristolochic acid to salt-depleted rats induced, after 35 days, moderate renal failure associated with tubular atrophy and interstitial fibrosis.[83] In vitro (opossum kidney cell line) and in vivo (rats) proximal tubular injury occurs early after aristolochic acid intoxication in rats. There is a link between specific aristolochic acid–DNA adduct formation and decreased megalin expression and inhibition of receptor-mediated endocytosis of low molecular weight proteins.[84] Cytotoxicity data obtained in LLC-PK cells suggest that the nitro and methoxy groups are critical determinants of nephrotoxicology potency of aristolochic acid.[85] It remains unclear why only some patients exposed to the same herbal preparations develop renal disease. Women appear to be at greater risk than men. Other potentially important factors include toxin dose, batch-to-batch variability in toxin content, individual differences in toxin metabolism, and a genetically determined predisposition toward nephrotoxicity and/or carcinogenesis.[86]

Notably, Balkan endemic nephropathy, a chronic, familial, noninflammatory tubulointerstitial disease, most commonly seen in Southeastern Europe, also has been potentially attributed to chronic exposure to dietary aristolochic acid.[87] In the Balkan region, aristolochic acid exposure may come from the consumption of the seeds of *Aristolochia clematitis* (European birthwort), a plant native to the endemic region, which is thought to commingle with wheat used for bread.[88]

Autosomal Dominant Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease (ADPKD) is the most common monogenic renal disorder, accounting for 8% to 10% of patients receiving RRT for ESRD worldwide.[89] Its clinical phenotype is progressive and substantial enlargement of the kidneys, caused by the sustained expansion of many fluid-filled cysts that originate from the tubule wall, leading to adjacent nephrons being crowded, injury to normal parenchyma, intestinal inflammation and fibrosis, and eventually kidney failure.[90,91] The progressive enlargement of cysts derived from renal tubules is largely attributable to the proliferation of mural epithelial cells and transport of fluid into cavities generated by accelerated epithelial cell growth.[92] In vitro evidence suggests that these cells' growth and transepithelial secretion of fluid is controlled by cyclic adenosine monophosphate.[92] Moreover, the Ser/Thr kinase mammalian target of rapamycin (mTOR) activation also mediates cyst expansion.[93] Insights into the pathophysiology of ADPKD have helped develop novel disease-modifying treatments.[94,95]

CONCLUSIONS

There is now clear evidence that, rather than simply a marker of damage, abnormal ultrafiltration of proteins can be toxic to the kidney and incites complex pathways and mediators that target glomerular, tubular, and interstitial cells, eventually promoting renal disease progression to ESRD. Moreover, tubulointerstitial injury is also common in nonproteinuric kidney diseases and is critical for their progression to ESRD. More insights in the pathophysiologic mechanisms of progressive proteinuric and nonproteinuric renal diseases will be instrumental to search for novel biomarkers that allow intervention in the earlier stages of CKD and may open the way to new potential treatments.

SELF-ASSESSMENT QUESTIONS

1. What is the pathologic podocyte response to protein trafficking throughout glomerulus?
   - **A.** Podocytes start to proliferate.
   - **B.** Podocytes are damaged by excessive protein load and uptake of albumin.
   - **C.** Podocytes adhere to the Bowman capsule.
2. What is the main consequence of podocyte loss on endothelial cells during chronic renal injury?
   - **A.** Endothelial cell apoptosis
   - **B.** Endothelial cell proliferation
   - **C.** Increase of vascularization of the kidney
3. What is the role of resident dendritic cells in the kidney during proteinuric diseases?
   - **A.** Dendritic cells proliferate.
   - **B.** Dendritic cells generate albumin peptides that activate $CD8^+$ T cells.
   - **C.** Dendritic cells undergo apoptosis.
4. How does the progressive enlargement of renal cysts in autosomal dominant polycystic kidney disease develop?
   - **A.** It develops from mesangial cell proliferation.
   - **B.** It develops from endothelial cell proliferation.
   - **C.** It develops from tubular cell proliferation and fluid transport into the cyst cavity.

Retarding Progression of Kidney Disease

Samir V. Parikh, Nabil J. Haddad, Lee A. Hebert

Progression to end-stage renal disease (ESRD) usually occurs because of activity of the primary kidney disease and the mechanisms of natural progression (see Chapter 78). In those older than 40 years of age, the nephropathy of aging can contribute to progression. Its pathogenesis is unclear; however, the nephropathy of aging appears to be categorically different from that of natural progression because, unlike natural progression, the nephropathy of aging proceeds without important increases in proteinuria. Whether therapy can slow the nephropathy of aging is unclear. However, natural progression is treatable.

Natural progression creates a vicious cycle that is approached when nephron loss leads to hyperperfusion of the surviving glomeruli and to the metabolic dysfunctions of decreased glomerular filtration rate (GFR). The cycle is entered when the hyperperfusion and metabolic dysfunctions are sufficient to inflict kidney injury. This chapter discusses the evidence-based therapies to prevent entry into the cycle or slow the cycle once it has been entered.

LEVEL OF GLOMERULAR FILTRATION RATE AND THE RISK FOR NATURAL PROGRESSION

Typically, natural progression does not proceed until nephron loss exceeds 50%.[1] For example, it is very unusual for kidney donors to progress to ESRD. Nevertheless the 15-year risk for ESRD in kidney donors is 3.5 to 5.3 times higher than that of nondonors matched to donor risk factors.[2] In addition, a normal solitary kidney is vulnerable to natural progression whether congenital or acquired early in life or if it is associated with obesity, hypertension, hyperlipidemia, or hyperglycemia. Also, natural progression to ESRD can result from low birth weight, particularly in males, presumably because of paucity of nephrons or defective nephron development.[1]

PROTEINURIA MAGNITUDE AND THE RISK FOR NATURAL PROGRESSION

Proteinuria-induced glomerular and renal tubular injury is a key mechanism of natural progression (see Chapter 78). The threshold for natural progression attributable to proteinuria appears to be crossed when proteinuria exceeds 500 mg/day.[1] Proteinuria magnitude is the strongest single risk factor in chronic kidney disease (CKD) progression (Fig. 79.1).[1] An exception is highly selective proteinuria (the urine protein is almost entirely albumin), which can persist in the nephrotic range for more than 10 years without causing renal structural damage.[1] Also to be taken into account is the cause of the proteinuria. For example, at a proteinuria level of 3 to 5 g/day, primary membranous nephropathy shows relatively slow progression (<3.0 ml/min/year), whereas primary focal and segmental glomerulosclerosis (FSGS) progresses at 3 to 6 ml/min/year, and immunoglobulin A (IgA) nephropathy progresses at 6 to 9 ml/min/year.[3]

DIAGNOSIS OF NATURAL PROGRESSION

Natural progression is a diagnosis of exclusion. Therefore, in the CKD patient showing signs of progression, it must first be determined whether the primary renal disease is active. If that can be reasonably excluded, it must then be determined whether another kidney disorder has been superimposed (see Chapter 71). The nephropathy of aging also must be excluded. This is relatively easy because it starts after 40 years of age, the decline in GFR is slow (about 1 ml/year), and it generally does not involve important increases in proteinuria.[1] Findings that help confirm the diagnosis of natural progression are as follows:

- The serum creatinine generally is above the expected level for the patient's age, sex, and race (Box 79.1). Natural progression is unusual if the serum creatinine is in the normal range.
- Natural progression is usually indolent. For example, the increased serum creatinine has been stable for at least several years before signs of progression occur.[4] An exception can occur when there are extraordinarily strong forces promoting natural progression, such as a very high salt intake, poorly controlled hypertension, or both.
- Increase in proteinuria is usually the first sign of natural progression. Only after a year or more of rising proteinuria does the serum creatinine begin to increase.[4]
- The urine sediment is unremarkable, although broad hyaline and granular casts may be present.

In summary, natural progression is seen mainly in those with increased serum creatinine. Generally there is a prolonged period of increasing proteinuria before the serum creatinine begins to increase. However, keep in mind that this pattern is also commonly seen in CKD patients whose condition is progressing because of activity of the underlying glomerular disease. Also relevant are the forms of CKD that progress even though proteinuria is minimal (Box 79.2).

MONITORING KIDNEY DISEASE PROGRESSION

Progression can be monitored by structural changes, such as with renal biopsy or renal ultrasound, or by functional changes, for example, changes in GFR or proteinuria. Here we discuss the latter, which are the most practical and commonly used methods to monitor CKD progression.

Monitoring Proteinuria Trends

Proteinuria is the strongest single predictor of GFR decline.[1] In addition, the lower the eGFR, the stronger is the relationship between

BOX 79.1 Suggested Thresholds for Serum Creatinine According to Body Size, Sex, and Race

- Large (e.g., >90 kg) nonobese men: S_{Cr} ≥1.30 mg/dl (1.40 mg/dl if African ancestry)
- Small (e.g., <60 kg) men without muscle wasting/cachexia: S_{Cr} ≥1.10 mg/dl (1.20 mg/dl if African ancestry)
- Large (e.g., >70 kg) nonobese women: S_{Cr} ≥1.00 mg/dl (1.10 mg/dl if African ancestry)
- Small (e.g., <50 kg) nonobese women: S_{Cr} ≥0.80 mg/dl (0.90 mg/dl if African ancestry)

The estimates are based on experience with a clinical laboratory that reports a normal serum creatinine (S_{Cr}) range for men of 0.8 to 1.30 mg/dl, and for women of 0.60 to 1.10 mg/dl. The modification of diet in renal disease (MDRD) study estimated glomerular filtration rate (eGFR) that corresponds to each of the listed categories of S_{Cr} according to sex and race were calculated for persons aged 40 years. Each S_{Cr} value yielded an abnormal eGFR value (<90 ml/min/1.73 m^2). For men the eGFR values ranged from 65 to 86 ml/min/1.73 m^2; for women the eGFR values ranged from 65 to 79 ml/min/1.73 m^2. For persons older than 40 years, the corresponding eGFR values would be even lower.

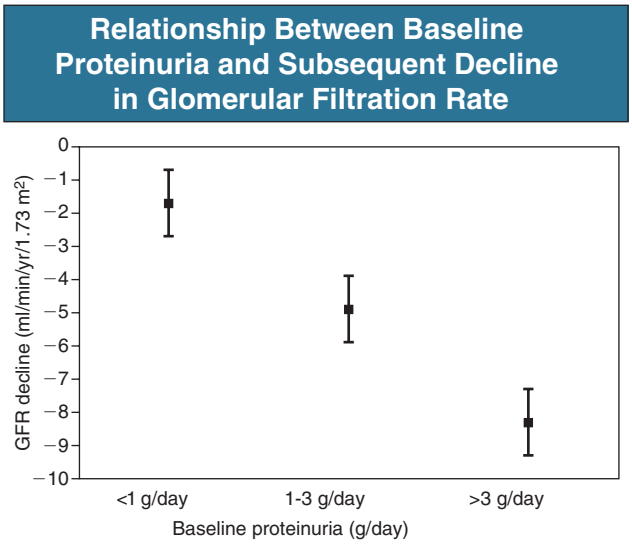

Fig. 79.1 Relationship between baseline proteinuria and subsequent decline in glomerular filtration rate (GFR). (Data from reference 52.)

proteinuria magnitude and risk for CKD progression.[5] Therapies that decrease proteinuria generally slow GFR decline (see Chapter 78).[1,6] The most widely used methods to assess proteinuria are measurement of urine albumin and urine total protein (see Chapter 4). The latter is the sum of urine albumin plus nonalbumin proteins. In the typical CKD patient the nonalbumin urine proteins consist mainly of low molecular weight proteins such as cystatin C and β_2-microglobulin. They escape reabsorption because of tubular damage (see Chapter 15). In this chapter, total proteinuria is referred to simply as *proteinuria.*

Recently, albuminuria measurement has gained favor over proteinuria measurement in CKD management. However, of the two studies that compared the urine albumin-to-creatinine ratio (uACR) and urine protein-to-creatinine ratio (uPCR) as predictors of GFR decline, one found uACR better than uPCR, and the other found uPCR not inferior to uACR.[1] The Kidney Disease: Improving Global Outcomes (KDIGO) guidelines recommend uACR. However, albumin assays cost more than

BOX 79.2 Common Forms of Chronic Kidney Disease in Which Important Progression Can Occur With Only Minimal Proteinuria

- Early phase of diabetic nephropathy, type 1 or type 2 diabetes mellitus
- Hypertensive nephrosclerosis (especially in persons of African ancestry)
- Polycystic kidney disease (autosomal dominant or recessive)
- Chronic nonsteroidal antiinflammatory drug nephropathy
- Obstructive uropathy
- Nephropathy of aging
- Bilateral renal artery stenosis caused by atherosclerosis, fibromuscular disease, or renal artery dissection
- Renal atheroembolism or thromboembolism
- Crystal induced tubulopathy:
  - A. Calcium (e.g., chronic high-dose oral Ca CO_3 ingestion, Dent disease)
  - B. Oxalate (e.g., bariatric surgery that results in fat malabsorption, primary hyperoxaluria, chronic vitamin D overdose)
  - C. Urate (e.g., leukemia causing increased uric acid production from increased cell turnover)
- Mitochondrial disease
- Radiation nephritis
- CKD of unknown etiology (such as Mesoamerican nephropathy)

Kidney diseases in which substantial progression can occur with only minimal proteinuria. For example, serum creatinine (Scr) increases to above 2.0 mg/dl, but 24-hour protein urine is low; for example, urine albumin-to-creatinine ratio (uACR) below 0.2, urine protein-to-creatinine ratio (uPCR) below 0.3. For conditions 1 through 11 see Chapters 29, 33, 44, 56, 62, and 65, respectively.

protein assays. Furthermore, when proteinuria exceeds 500 mg/day, uACR and uPCR generally change in parallel.[1] If 24-hour proteinuria is less than 500 mg/day, this relationship is lost and uACR is more sensitive.[7] On this basis, we recommend uACR for detection of early CKD progression. Thereafter, uPCR is recommended. The recommended methods for monitoring proteinuria trends in individual patients are shown in Table 79.1. The key points are as follows:

- The gold standard for monitoring proteinuria is the protein content of an accurately collected 24-hour urine specimen. Unfortunately, in practice, nominal 24-hour urine collections often are substantial undercollections or overcollections.[8]
- Creatinine should be measured in all intended 24-hour urine collections. The uPCR of the intended collection is a reliable estimate of the uPCR of the complete 24-hour collection, if the collection is at least 50% complete based on its total creatinine content.[1]
- In individual patients, the uPCR of spot (single void) urine collections is an unreliable estimate of proteinuria magnitude because of the large and inherent variability of spot uPCR[8] (Fig. 79.2).
- Urine collections of intermediate duration (e.g., overnight collections) have merit. However, such collections may not be representative of the uACR or uPCR of the entire 24-hour collection. For example, variations in diet, timing of antihypertensive medications, exercise on the day of the overnight collection, or contamination with semen may substantially alter the uACR or uPCR, rendering the overnight collection nonrepresentative.[8]
- Cost of uACR and uPCR from spot collections is essentially the same as that of uACR and uPCR from 24-hour urine collections. Given the high degree of unreliability of spot uACR and uPCR, spot collections can be regarded as having an unfavorable cost-to-benefit ratio.
- The inconvenience of 24-hour urine collections can be mitigated by the following:

TABLE 79.1 Methods for Monitoring Proteinuria or Albuminuria

Methods	Comments
Recommended	
uPCR or uACR* of intended 24-h urine collections that are at least 50% complete based on creatinine content†	Most accurate method (see text). Also can be used to assess nutrient intake relevant to CKD management (e.g., Na, K, urea nitrogen, water). Inconvenient, but this can be mitigated (see text).
uPCR or uACR ratio from overnight collections (first morning void)	More convenient than 24-h collections but provides a lower estimate of proteinuria than 24-h collections and is more vulnerable to artifacts (see text).
Not Recommended	
Intended 24-h urine collection in which protein or albumin is measured but creatinine is not measured	Large overcollections and undercollections are common in intended 24-h urine collections. If creatinine content is not measured, the degree of overcollection or undercollection cannot be reliably assessed.
Spot uPCR or uACR	Convenient but highly inaccurate estimate. Cost-to-benefit ratio is low because cost is about the same as 24-h urine testing, but often the results of spot testing are misleading.
Dipstick test for proteinuria (albuminuria)	Convenient and low-cost point-of-care measure but not reliable for monitoring CKD patients.

Methods for monitoring proteinuria or albuminuria. E = (140 – Age) × Weight (Nonobese) in kg × 0.2 × 0.85 if female.
An M/E ratio exceeding 0.5 is evidence that the collection is more than 50% complete.
*uACR is recommended if 24-hour proteinuria is <500 mg (uPCR if <0.3 for average-sized person). uPCR is recommended if 24-hour proteinuria is above 500 mg.
†Degree of completeness of an intended 24-hour urine collection = measured creatinine content *(M)*/expected creatinine content *(E)*.
CKD, Chronic kidney disease; *uACR,* urine albumin-to-creatinine ratio; *uPCR,* urine protein-to-creatinine ratio.

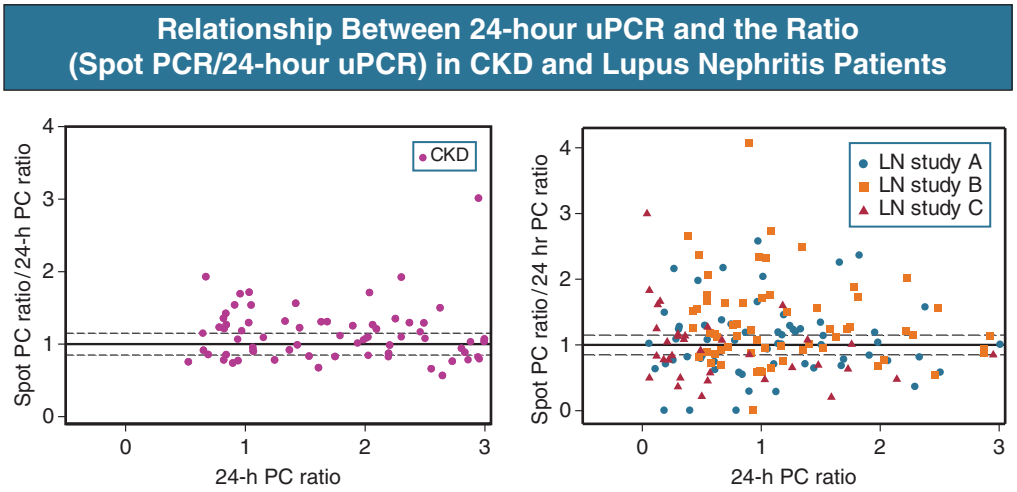

Fig. 79.2 Relationship between 24-hour urine protein-to-creatinine ratio *(uPCR)* and the ratio of spot uPCR to 24-hour uPCR in chronic kidney disease *(CKD)* and lupus nephritis *(LN)* patients. The *dashed line* indicates the expected limits of agreement if morning spot uPCR provides the same results as testing an aliquot of the intended 24-hour collection. This figure shows that spot uPCR is an unreliable estimate of 24-hour uPCR, especially in lupus nephritis. The spot collections were obtained under ideal circumstance, the morning when the 24-hour urine collection was presented. (From reference 7.)

- It is acceptable if an occasional void is missed, but the gap should not be large (e.g., the entire work day).
- A wide-mouth "sports bottle" that is carried in a duffle bag can be used to collect urine when not at home. It is not necessary to refrigerate the collected urine unless it will be several days before the urine specimen is submitted to the clinical laboratory.

Dipstick testing for proteinuria is convenient but unreliable in individual patients [9] (see Chapter 4).

Proteinuria testing in CKD is recommended every 6 to 12 months if proteinuria level is low (e.g., <500 mg/day) and every 2 to 4 months if heavier proteinuria.

If 24-hour uPCR increases from below 0.5 to 1.0 or higher, or from below 1.0 to 2.0 or higher, likely these are real changes[9] and should prompt reassessment.

Monitoring Glomerular Filtration Rate Trends

In individual patients, it is usually sufficient to monitor GFR trends by serial serum creatinine measurements. In interpreting serum creatinine change, one must keep in mind the circumstances that can change serum creatinine by mechanisms that do not involve a change in GFR, as follows: increased creatinine production (eating cooked meat, creatine ingestion, increased exercise, increasing muscle mass, fenofibrate use) or decreased creatinine production (vegetarian diet, muscle wasting, decreased exercise). Also, serum creatinine can be spuriously increased by drugs that interfere with the creatinine assay, and by increased serum ketones (from fasting or poor diabetes control) or actually increased by drugs that decrease tubular secretion of creatinine (cimetidine, trimethoprim). If a chronic progressive change in

creatinine production is occurring (e.g., muscle wasting), GFR trends can be monitored by measuring cystatin C or serial 24-hour urine creatinine clearance.[1]

GFR also can be monitored by the creatinine-based estimated glomerular filtration rate (eGFR) equations—in particular, the Modification of Diet in Renal Disease (MDRD4) and Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equations (see Chapter 3). These approaches to standardizing GFR assessment have greatly advanced the study of CKD epidemiology. However, the eGFR equations have important limitations when applied to individual patient management. First, the MDRD4 and CKD-EPI equations assume that all patients of the same age, sex, and race have the same rate of creatinine production and the same body surface area (BSA). As a result, these equations substantially underestimate actual GFR in those with high BSA and/or creatinine production and substantially overestimate actual GFR in those with low BSA and/or creatinine production.[10] Second, because of inaccuracy in quantifying normal GFR, some laboratories do not report eGFR by MDRD4 or CKD-EPI equation if the eGFR is greater than 60 ml/min/1.73 m^2. In this circumstance the clinician must determine whether the serum creatinine is likely to be normal or abnormal. The following can be helpful (see Box 79.1):

- Large persons tend to have higher serum creatinine values than small persons.
- Men tend to have higher serum creatinine values than women.
- In North America, those of African ancestry tend to have higher serum creatinine values than those of non-African ancestry.

Role of Cystatin C in Estimating Glomerular Filtration Rate for Clinical Management

Cystatin C is a small molecular weight protein produced at a constant rate by all cells. It is freely filtered in the glomerulus and not reabsorbed or secreted by the renal tubules. So, serum cystatin C blood levels reflect GFR. Compared with measurement of serum creatinine, serum cystatin C is less affected by age, sex, muscle mass, and a diet that is high in cooked meat (a major source of serum creatinine). On the other hand, serum cystatin C levels are more affected by body fat mass, inflammation, thyroid disorders, and diabetes. Cystatin C is usually not provided by the local laboratory. This incurs delays in reporting the results. There are also concerns about analytic accuracy.[11] In head-to-head clinical comparisons the variability of cystatin C is at least as great as that of serum creatinine measurement.[12] For these reasons cystatin C is not recommended for routine assessment of eGFR.

Glomerular Filtration Rate Trajectories in Chronic Kidney Disease

GFR trajectory in CKD generally is well described as a linear decline; thus GFR loss per unit of time is approximately constant.[1] However, those of African ancestry deemed to have hypertensive nephrosclerosis can experience large unexplained changes in eGFR trends, especially decreases followed by stability.[13] Noteworthy is that increased variability of GFR decline over time is associated with increased mortality.[1]

THERAPY FOR NATURAL PROGRESSION

CKD usually progresses slowly. Therefore even relatively small reductions in GFR loss can delay the onset of ESRD by years. For this reason an aggressive, multiple–risk factor intervention to slow GFR decline is warranted, except in patients with low ESRD risk. For example, those with (1) corticosteroid-responsive minimal change disease; (2) those with a solitary kidney that is normal, is acquired in adulthood, and is not accompanied by other CKD risk factors; (3) normotensive adults with hereditary nephritis or thin glomerular basement membrane in whom the only renal manifestation is microscopic hematuria; and (4) the elderly with idiopathic and moderately elevated serum creatinine (1.30 to 2.00 mg/dl), a 24-hour uPCR below 1.0, and whose renal parameters have been stable for at least 1 year. These patients are much more likely to die of cardiovascular disease (CVD) than to progress to ESRD.[1]

BOX 79.3 Recommended Kidney Protective Therapies According to Level of Recommendation

Level 1 Recommendations

Control blood pressure (BP).
Administer angiotensin-converting enzyme inhibitor, angiotensin receptor blocker, or renin inhibitor.
Avoid dihydropyridine calcium channel blockers (DH-CCBs) unless needed for BP control.
Control protein intake.

Level 2 Recommendations

Restrict NaCl intake/diuretic therapy.
Administer NDH-CCB therapy.
Control each component of the metabolic syndrome.
Administer aldosterone antagonist therapy.
Administer β-blocker therapy.
Control serum phosphorous.
Instigate smoking cessation.
Control hyperuricemia.
Administer alkali therapy.
Avoid anticoagulant-related nephropathy.
Monitor serum creatinine in patients receiving proton pump inhibitors.
Correct vitamin D deficiency.
Avoid/minimize nonsteroidal antiinflammatory drug use.

The goal for the chronic kidney disease (CKD) patient is to implement all level 1 recommendations and as many level 2 recommendations as is feasible.

Therapies recommended in this chapter are listed in Box 79.3. The goals of progression therapy are to reduce proteinuria as much as possible, ideally to less than 500 mg/day, which is a safe level of proteinuria for most forms of CKD (see earlier discussion), and slow GFR decline as much as possible, ideally to about 1 ml/min/year, which is the rate of GFR decline attributable to the nephropathy of aging (see Chapter 67).

Level 1 Recommendations to Slow Natural Progression

Control Blood Pressure

The low blood pressure (BP) goal (sitting systolic BP [SBP] in the 120s or less, if tolerated) is recommended. However, the evidence supporting the low goal is not robust.[1] It is based largely on the subset of patients in the MDRD study whose baseline proteinuria was greater than 1.0 g/day; the African American Study of Kidney Disease and Hypertension (AASK), but only in the long-term cohort study; and the Effect of Strict Blood Pressure Control and ACE Inhibition on Progression of Chronic Renal Failure in Pediatric Patients (ESCAPE) trial in children.

Another reason to favor the low BP goal is that in both the MDRD study and AASK, those assigned to the low BP goal had a significantly lower risk for ESRD during long-term (post-trial) follow-up than those assigned to the usual (higher) BP goal. This is remarkable because during the post-trial follow-up the low BP goal was recommended to all patients. In addition, in a meta-analysis of placebo-controlled randomized trials of antihypertensive drug therapy in which there was

post-trial follow-up of at least 7 years, it was found that the mortality rate during post-trial follow-up was significantly lower in the group that had been randomized to the study drug than in the group that had been randomized to placebo, even though during the post-trial follow-up both groups were advised to receive the study drug. This benefit of having received the antihypertensive study drug during the randomized trial was independent of the class of the antihypertensive study drug.[1]

The Systolic blood Pressure Intervention Trial (SPRINT) is the most recent major BP and intervention trial to study the effect of BP control on CKD progression.[14] The unique feature of SPRINT was the aggressiveness of the "intensive" BP intervention, which targeted an SBP of less than 120 mm Hg. The "standard" target was 135 to 139 mm Hg. In SPRINT the achieved mean SBP was 121 mm Hg in the Intensive cohort and 136 mm Hg in the Standard cohort. In CKD patients, the Intensive intervention did not slow CKD progression. However, SPRINT involved mainly elderly patients (mean age 68 years, 28% older than 75 years) and the CKD patients had low level proteinuria. On this basis, the results of SPRINT should not be generalized to the younger CKD population who typically have substantial proteinuria and therefore may be more susceptible to the benefits of intensive BP lowering.

When the findings cited earlier are taken together, it seems that the low BP goal is more beneficial than the usual BP goal, even though it may take several years for the benefit to be shown. These results also suggest that achieving the low goal BP sooner rather than later is important.

In CKD patients, in general, the greater the proteinuria, the greater is the benefit of the low BP goal in slowing CKD progression.[1] The low BP goal was also better than the usual BP goal at slowing the progression of proteinuria during the trials.[1] This may be evidence of kidney protection.

The BP should be taken in the sitting position after about 3 to 5 minutes of rest. Sitting BP is recommended because that was the method used in the pivotal BP intervention trials. A period of rest is recommended, to minimize the effects of white coat hypertension.

SBP is the recommended target because, in general, it correlates better with CKD progression than diastolic BP (DBP).[1] Also, specifying both SBP and DBP goals can be confusing if one goal is met but the other is not and could lead to overtreatment or undertreatment of BP.[1]

There is mounting evidence that whenever feasible, BP control should include home BP monitoring (HBPM) rather than only office or clinic BP. The latter is a poor predictor of risk compared with HBPM or ambulatory BP monitoring (ABPM).[15] Among hypertensive CKD patients, masked hypertension (BP is normal in the office or clinic but hypertensive by HBPM or ABPM) is common (e.g., 50% of CKD patients) and carries a risk for CV events comparable to that of sustained hypertension, defined as increased BP both in the office/clinic and at home.[16] The technique of HBPM is discussed in Chapter 33.

The optimum frequency of HBPM measurement has not been rigorously studied. We recommend that initially HBPM be measured twice daily—morning and evening—until the BP is at goal. The frequency of HBPM can then be decreased. The recommended minimum frequency of HBPM is every 1 or 2 weeks, including both morning and evening testing. The HBPM measures need to be recorded and averaged. The average BP should be used to determine the degree of BP control.[1]

A recent meta-analysis of the trials in which there was a head-to-head comparison of antihypertensive drugs on CV outcomes and death concluded that there was no important difference in outcome after taking into account the BP-lowering effect of the drugs. So, the most important role of antihypertensive medication is to control BP. However, in CKD management, the goals of BP control also include optimizing the use of antihypertensive drugs that protect kidney function, particularly by controlling glomerular hypertension and reducing proteinuria. These goals are reflected in algorithms in Figs. 79.3 and 79.4, which are evidence and experience based. Although the algorithms recommend beginning with a single drug, if the SBP is more than 20 mm Hg above goal, two or more antihypertensive agents will usually be needed.[1]

In the effort to achieve optimum BP control it is important to avoid overcontrol of BP. Overcontrol is usually manifested by orthostatic hypotension (decrease in SBP >10 mm Hg and symptoms of lightheadedness when changing from the sitting to standing positions). Overcontrol of BP can result in falls and acute kidney injury, as described in the ACCORD and SPRINT trials.

Renin-Angiotensin System Blockade

Renin-angiotensin system (RAS) blockade with ACE inhibitors or angiotensin receptor blockers (ARBs) is recommended first-line therapy to reduce proteinuria, CKD progression, and CV risk (see Fig. 79.3). An ACE inhibitor is the first choice because of evidence from placebo-controlled randomized trials that ACE inhibitor therapy decreased the risk for death but ARB did not.[17] However, those of African ancestry need to be cautioned that ACE inhibitors can cause angioedema of the upper airways. It is a rare but serious problem that can occur any time during ACE inhibitor therapy. RAS blockade is recommended in CKD even if hypertension is not present, because the kidney and CV protection of RAS blockade is, at least in part, independent of BP control.[1] In general, the greater the ACE inhibitor or ARB dose, the greater is the effect on control of hypertension and proteinuria.[1,18]

RAS blockers are antiproteinuric even in inflammatory glomerulonephritis and should be continued even if GFR declines to stage 4 CKD (15 to 29 ml/min/1.73 m^2).[1] For prevention of hyperkalemia, dietary potassium restriction and the concomitant use of furosemide and sodium bicarbonate may be needed.[1]

Adipose tissue expresses all RAS components. Thus angiotensin II may play a greater role in obese CKD patients. Indeed, in the Ramipril in Non-diabetic Renal Failure (REIN) trial, ACE inhibitor therapy was significantly more effective in slowing GFR decline in the obese than in the nonobese.[1]

Combination Angiotensin-Converting Enzyme Inhibitor and Angiotensin Receptor Blocker Therapy

Combination ACE inhibitor and ARB (dual) therapy is more antihypertensive and more antiproteinuric than either drug alone.[19] However, in our experience dual therapy often has not been helpful in decreasing severe proteinuria, even when combined with aldosterone antagonist, salt restriction, protein restriction, diuretic therapy, and statin therapy.

Renin Inhibitor Therapy

Aliskiren, a direct renin inhibitor, is an effective antihypertensive agent and has been shown to reduce albuminuria in diabetic nephropathy and IgA nephropathy. However, when aliskiren was added to ACE inhibitor or ARB therapy in patients with type 2 diabetes and nephropathy, there was increased risk for renal impairment, hypotension, and hyperkalemia, without evident benefit.[1] Aliskiren may be a suitable alternative RAS blocker for those intolerant to both ACE inhibitors and ARBs.

Avoid Dihydropyridine Calcium Channel Blockers

Three randomized trials in CKD have shown that those assigned to dihydropyridine calcium channel blocker (DHP-CCB) therapy experienced less kidney protection than those not assigned to DHP-CCB,[1] perhaps because of DHP-CCB–induced arteriolar vasodilation resulting in glomerular hypertension. However, in the Avoiding Cardiovascular Events Through Combination Therapy in Patients Living with Systolic

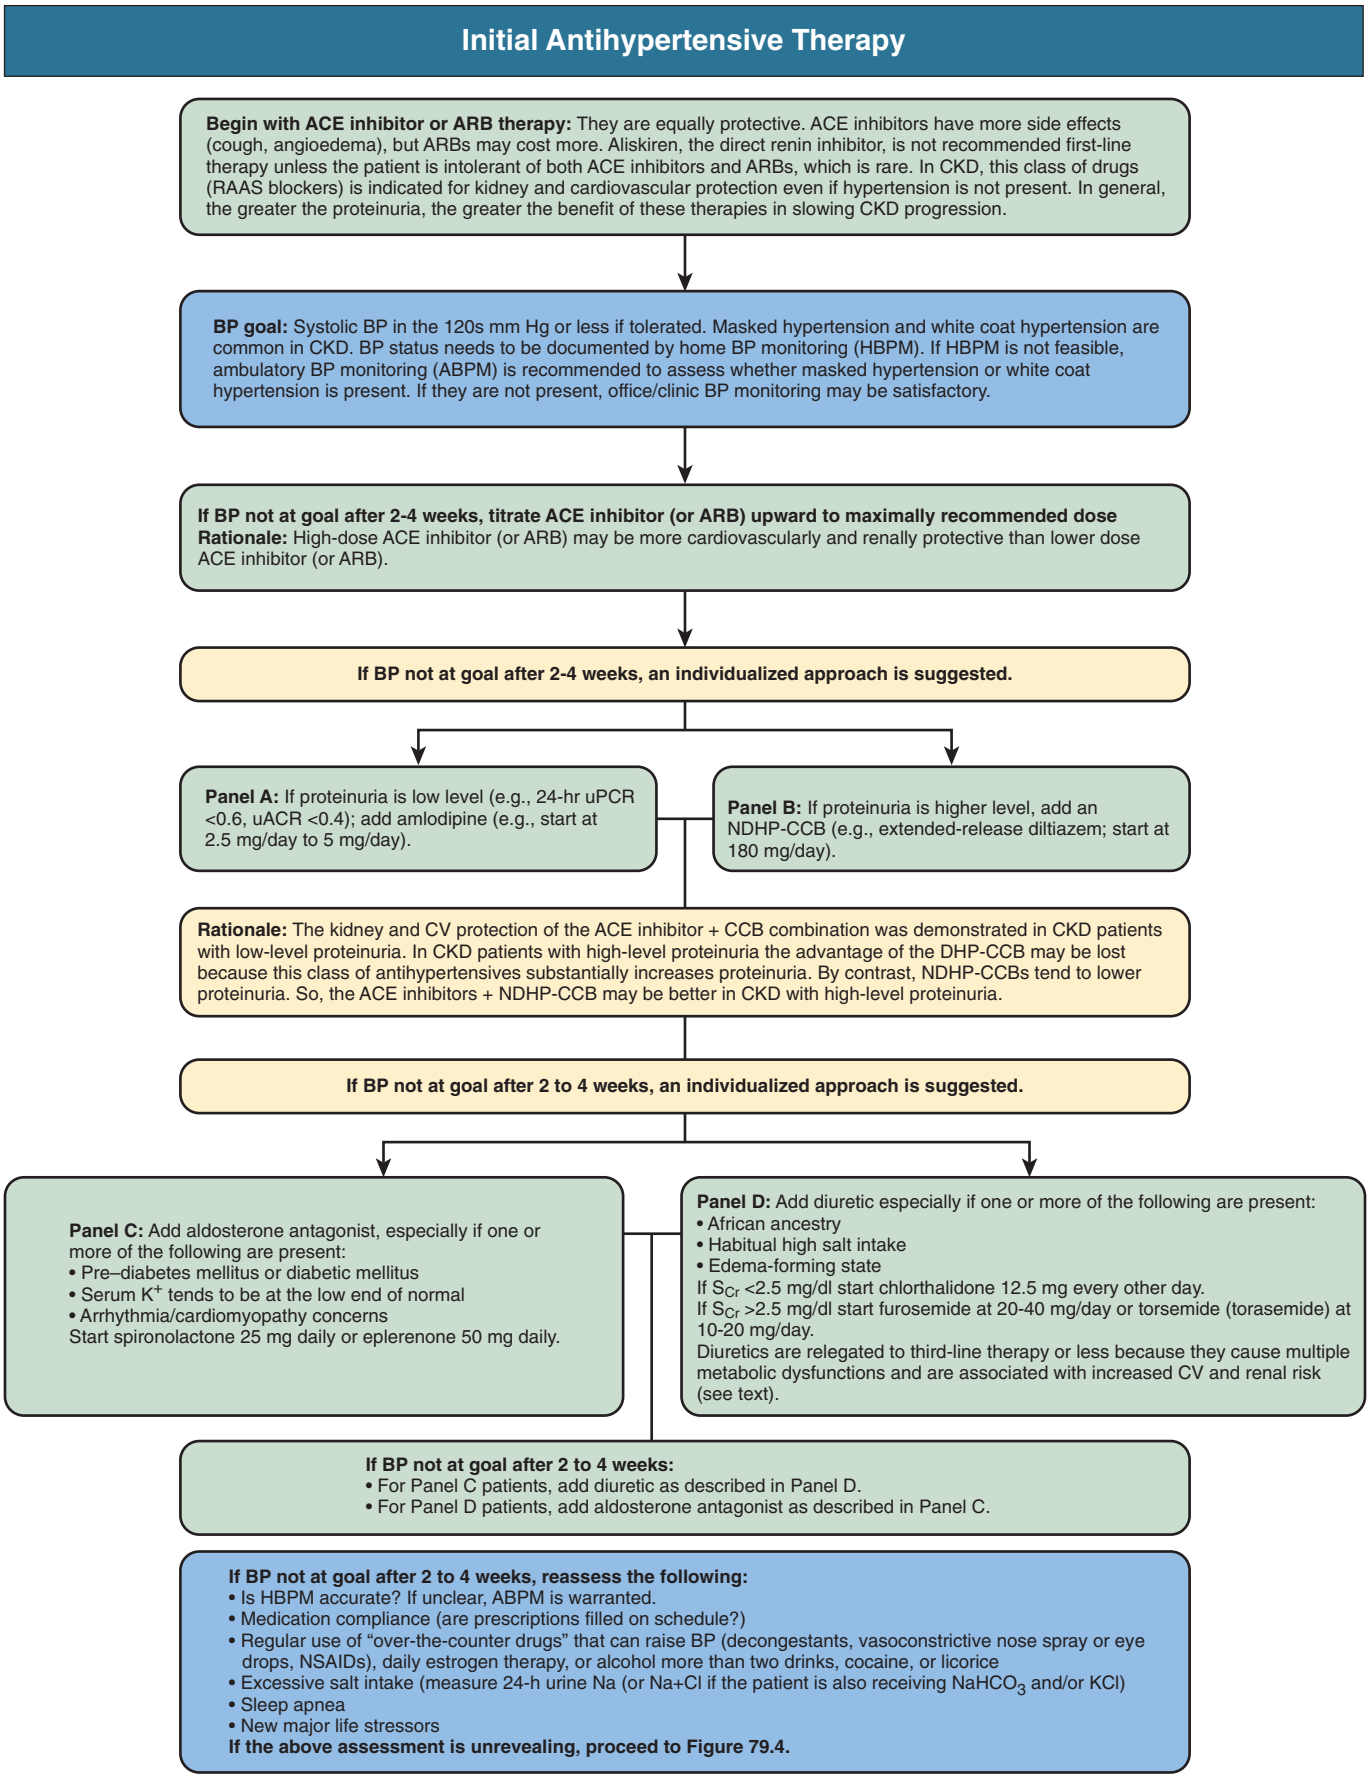

Fig. 79.3 Initial antihypertensive therapy. The algorithm shown here assumes that nonpharmacologic therapy to control blood pressure *(BP)* is in place (see text) and that the patient is not known to have renovascular hypertension, congestive heart failure, or ischemic or heart disease, and does not have hypertensive urgency. This approach focuses on BP control in proteinuric nephropathies, but is also appropriate for nephrosclerosis, polycystic kidney disease, and interstitial nephropathies. More details on each of the recommended drugs are provided in the text. *ACE,* Angiotensin-converting enzyme; *uACR,* urine albumin-to-creatinine ratio; *ARB,* angiotensin receptor blocker; *CKD,* chronic kidney disease; *CV,* cardiovascular; *NDHP-CCB,* nondihydropyridine calcium channel blocker; *NSAIDs*, nonsteroidal antiinflammatory drugs; *uPCR*, urine protein-to-creatinine ratio; *RAAS,* renin-angiotensin-aldosterone system; S_{Cr}, serum creatinine.

Recommended Approach if the Treatment Algorithm Described in Fig. 79.3 Fails to Control BP

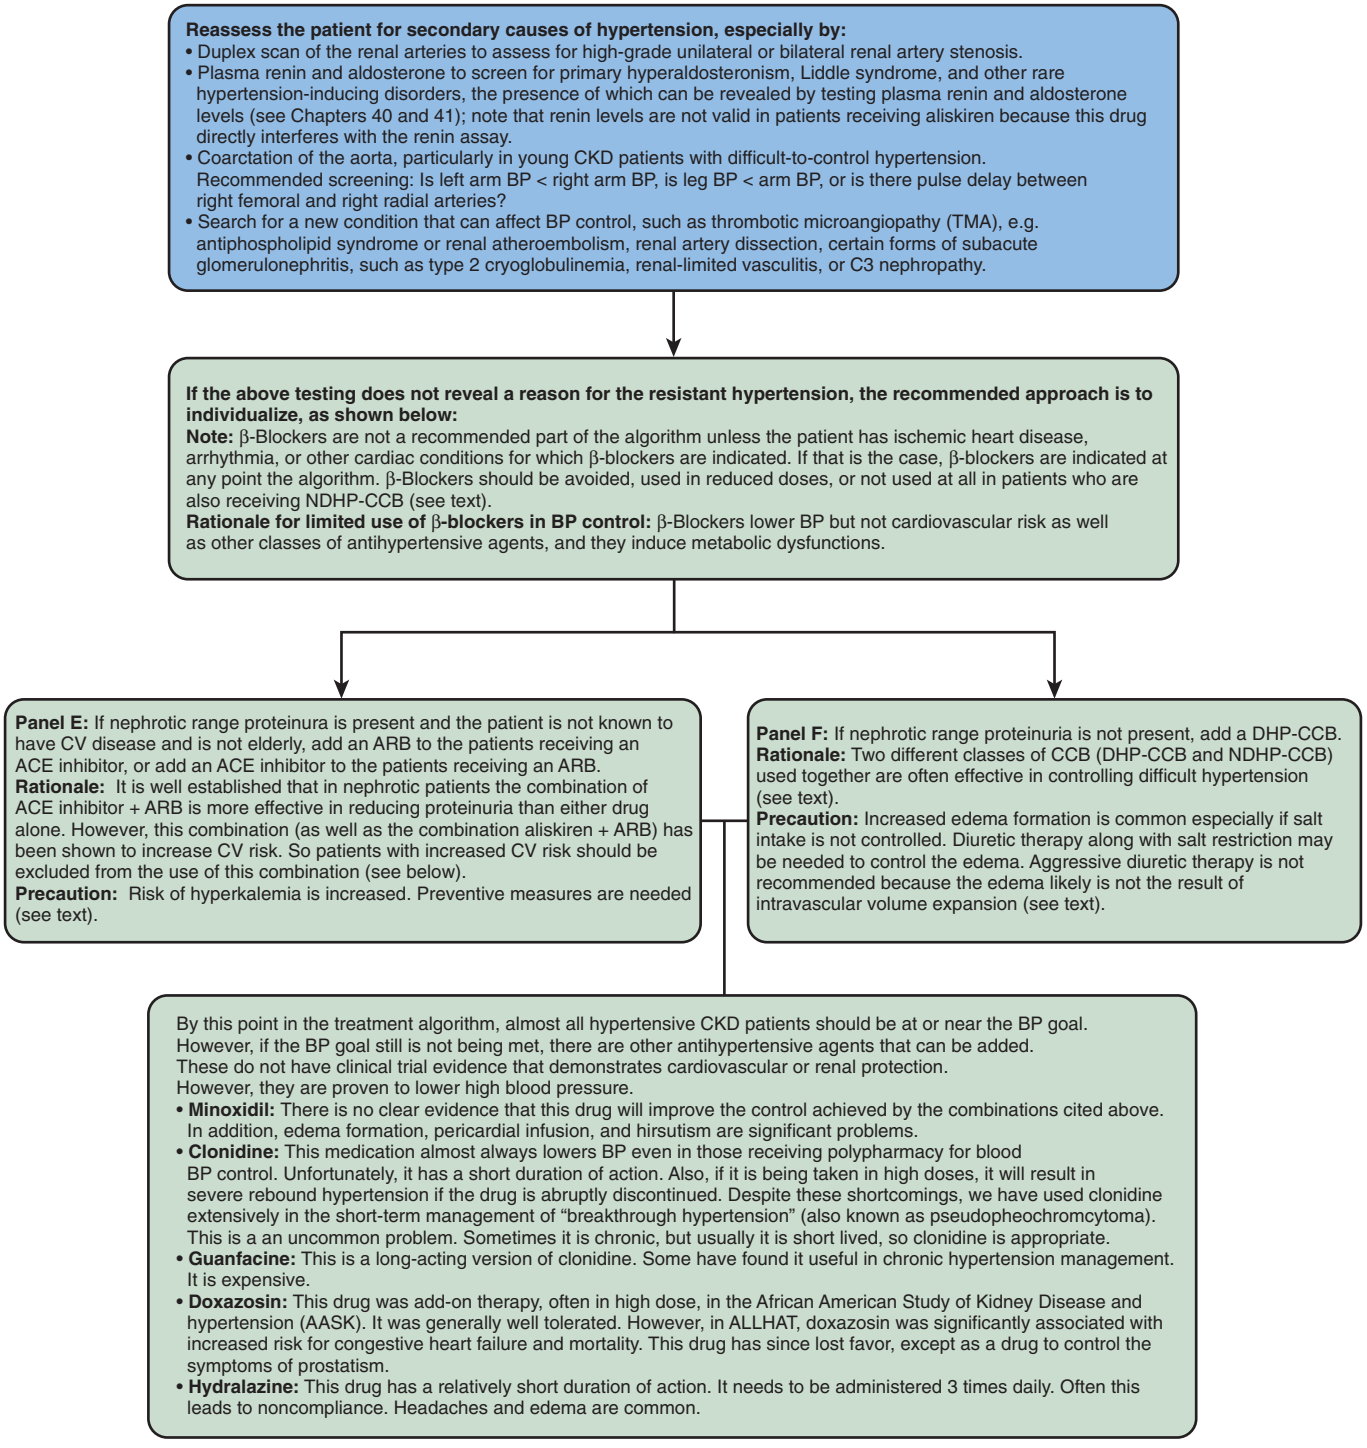

Fig. 79.4 Recommended approach if the treatment algorithm described in Fig. 79.3 fails to control blood pressure *(BP).* If patients are intolerant or allergic to the drugs recommended in the algorithms, suggested alternatives include ethacrynic acid for thiazide diuretics, aliskiren for angiotensin-converting enzyme *(ACE)* inhibitors or angiotensin receptor blockers *(ARBs),* and minoxidil for calcium channel blockers *(CCBs).* Carvedilol or doxazosin may be appropriate at any point in patients in whom stress may play an important role in their hypertension, or in whom BP is particularly labile, in the absence of correctable factors to account for the lability. *ALLHAT,* Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack trial; *CKD,* chronic kidney disease; *CV,* cardiovascular; *DHP-CCB,* dihydropyridine calcium channel blocker; *NDHP-CCB,* nondihydropyridine calcium channel blocker.

Hypertension (ACCOMPLISH) trial, ACE inhibitor plus amlodipine therapy protected kidney function better than ACE inhibitor plus diuretic therapy, especially in non-Blacks. Possibly, the benefit of amlodipine in the ACCOMPLISH study was seen because the CKD patients had low-level proteinuria. In addition, there is evidence that chronic thiazide therapy is nephrotoxic.[1] Thus, if a CCB is needed for BP control, the first choice should be a nondihydropyridine CCB (NDHP-CCB) (discussed later).

Control Protein Intake

High-protein diets predict ESRD in CKD.[20] Also, reducing dietary protein intake from the usual level (in developed countries ~1 to 1.5 g/kg ideal body weight per day) to about 0.7 g/kg ideal body weight per day (low-protein diet) slows GFR decline in those with proteinuria of more than 1 g/day.[1] Another benefit of the lower protein intake in CKD is that it slows proteinuria progression, even in those who at baseline have only low-level proteinuria.[1]

Diets incorporating plant-based (e.g., soy) proteins may be more antiproteinuric than those composed of animal proteins only.[21]

Dietary protein intake should be monitored periodically, for example, every 4 to 6 months, by measuring urine urea nitrogen excretion in 24-hour urine collections. For a 70-kg person, a 50-g protein diet would achieve the dietary goal of 0.7 g/kg ideal body weight per day. In such a patient, the 24-hour urine collection would contain about 8 g urine urea nitrogen. Monitoring protein intake is particularly important in those who are not achieving their proteinuria goal. Men and those with glomerular disease may particularly benefit from the low-protein diet.[1] Red meat intake is particularly linked to CKD risk.[22]

Excessive protein restriction (<0.6 g/kg/day) should be avoided. In the MDRD study, long-term follow-up of those on the very low protein intake showed no benefit in reducing GFR decline and appeared to have an increased risk for death.[1]

A recent randomized trial compared a low-protein diet (0.6 g/kg/day) using usual dietary proteins to a very low vegetarian protein diet (0.3 g/kg/day) supplemented with ketoanalogues of essential amino acids. The latter diet was significantly better than the traditional diet in reducing renal end-points. Unfortunately, only 14% of the randomized patients were compliant with the vegetarian/supplemented diet.[21]

Level 2 Recommendations to Slow Natural Progression

Restrict Salt Intake and Avoid Diuretic Therapy

Salt restriction as a public health measure remains controversial.[23,24] However, in CKD, high salt intake appears to cause CKD progression[25] and increase the risk for CVD. Surprisingly, evidence that high salt intake increases the risk for CKD is lacking.[26]

Nevertheless, high salt intake (e.g., 200 mmol NaCl/day = 11.6 g NaCl or 4.6 g Na) can completely override the antiproteinuric effects of ACE inhibitor, ARB, or NDHP-CCB therapy. Also, high salt intake measured at baseline is a significant predictor of more rapid GFR decline.[27] In addition, it is well established that high salt intake worsens hypertension.

The recommended NaCl intake in CKD (assuming that renal salt wasting is not present) is about 2 to 3 g Na (5 to 7.5 g NaCl, 88 to 112 mEq Na). The NaCl intake of the average North American adult is about 10 g NaCl (4 g Na, 170 mEq Na Cl). Achievement of the CKD goal for salt intake would be documented by a 24-hour urine collection containing about 80 to 120 mmol (mEq) of sodium. Urine sodium should be measured each time 24-hour urine protein is measured (see the discussion of monitoring of proteinuria). In patients receiving $NaHCO_3$ therapy, urine chloride rather than sodium should be monitored, taking into account whether the patient is also receiving KCl.[1] The rationale is that urine Cl is almost entirely derived from ingestion of NaCl, unless the patient is also receiving KCl therapy. So, if the patient is not receiving KCl, 24-hour urine chloride in milliequivalents is equal to 24-hour urine NaCl in millimoles.

High fructose intake (in the form of table sugar or high-fructose corn syrup used in sugar-sweetened beverages) should be avoided in CKD because it increases renal sodium reabsorption and can worsen BP control (see the discussion of metabolic syndrome).

In patients receiving RAS blockers, diuretic therapy improves BP control and decreases proteinuria. Nevertheless, the ideal is to avoid diuretics because of the evidence of nephrotoxicity[1] and their multiple metabolic dysfunctions, which include hypokalemia, hyperglycemia, hyperlipidemia, hypomagnesemia, hyperuricemia, and stimulation of the RAS, which are known to increase CV risk.[1] Loop diuretics are more effective than thiazides if GFR is below 30 ml/min. If the GFR is higher, the preferred diuretic is chlorthalidone or indapamide because of greater efficacy in controlling BP and protection against CV events compared with hydrochlorothiazide.[28]

Nondihydropyridine Calcium Channel Blocker Therapy

NDHP-CCB (e.g., diltiazem and verapamil) are antiproteinuric and may be renoprotective. An NDHP-CCB together with a DHP-CCB can be a potent antihypertensive combination when used along with other antihypertensive therapies (see Fig. 79.4).[1]

Control Each Component of the Metabolic Syndrome

Metabolic syndrome and each of its components are risk factors for CKD progression,[1] and the prevalence of microalbuminuria and CKD increase in parallel with the number of components of the metabolic syndrome.[29]

Obesity increases the risk for CKD and is associated with glomerulopathy, FSGS, and proteinuria. Reducing even moderate obesity can reduce proteinuria in CKD.[1] Bariatric surgery in morbidly obese CKD patients is associated with stabilization or improved eGFR.[30] In type 2 diabetes, improvement in diabetic control is also seen.

The current KDIGO guideline (www.kdigo.org) recommends a statin or a statin plus ezetimibe for all non-ESRD CKD patients 50 years of age or older, regardless of the blood lipid levels. Disregard of the lipid levels is based on the Study of Heart and Renal Protection (SHARP), which showed that the benefits of lipid therapy are not related to baseline lipid level. For non-ESRD CKD patients younger than 50 years, KDIGO does not recommend statin therapy unless there is increased CV risk. The KDIGO-recommended statin doses are low (e.g., atorvastatin 20 mg/day).

These guidelines are based on a rigorous interpretation of the available data. We suggest, however, that for certain patients shared decision making regarding a less restrictive approach to statins might be appropriate. The argument is that CKD itself is a strong CV risk factor, the risk starts early in CKD (see Chapter 81), and CVD takes many years to develop. So starting lipid therapy early in CKD patients may be prudent, as has previously been suggested.[31] In addition, statins are well tolerated in CKD, even at high doses (e.g., atorvastatin 80 mg daily).[1] With regard to statin choice in CKD, atorvastatin may be better than simvastatin[32] and rosuvastatin may have nephrotoxicity.[33,34] Also to be considered in the shared decision making is the recent meta-analysis of randomized trials of fibrate therapy compared with placebo in mild to moderate CKD. Fibrate therapy reduced CV risk and albuminuria, although ESRD risk was unchanged. Noteworthy is that serum creatinine increased during the trial in those taking fenofibrate, probably because of increased creatinine production. However, when the fibrate was stopped after the trial, serum creatinine decreased to below baseline values, suggesting that kidney function was protected during fibrate therapy.[1] Fibrates decrease triglycerides significantly. These observations

suggest a role for add-on fibrate therapy for CKD patients at high CV risk, especially those whose triglycerides are not controlled by statin therapy or a statin-ezetimibe combination.

Aldosterone Antagonist Therapy

Spironolactone and the more selective aldosterone antagonist eplerenone have substantial antihypertensive, cardioprotective, and antiproteinuric effects even at low doses (e.g., spironolactone 25 mg/day) and in the presence of combined ACE inhibitor and ARB therapy. The mechanism may involve blockade of aldosterone effects on endothelium and on fibrosis. Although there are no rigorous clinical trial data with hard end-points such as ESRD, the available evidence supports the use of aldosterone antagonists in high-risk CKD patients who have not reached their BP and proteinuria goals despite the use of an ACE inhibitor or ARB plus a CCB plus diuretic (see Fig. 79.3). However, the use of aldosterone antagonists should be restricted to those with eGFR greater than 30 ml/min. If spironolactone or eplerenone is used in patients receiving renin-angiotensin-aldosterone system (RAAS) blockers, it is especially important to prevent hyperkalemia. These measures include sodium bicarbonate therapy (see the discussion of alkali therapy), the avoidance of potassium-rich foods, and awareness of the symptoms of severe hyperkalemia. These include the relatively sudden onset of symmetric proximal muscle weakness (difficulty climbing stairs or rising from a chair) or muscle stiffness.

Aldosterone antagonists are particularly helpful in those with resistant hypertension and high salt intake[35] or those who experience aldosterone escape (failure to suppress serum aldosterone during ACE inhibitor or ARB therapy.[36]

β-Blocker Therapy

The AASK study showed that β-blocker therapy slows GFR decline better than DHP-CCB. However, β-blockers increase the likelihood of diabetes and, as monotherapy or when combined with diuretics, increase mortality compared with ACE inhibitors plus diuretics.[1] β-Blockers should be used in CKD to manage coronary heart disease or arrhythmia but may be less appropriate for the management of hypertension.[1] Carvedilol may be less likely to increase insulin resistance than metoprolol when it is used in combination with an ACE inhibitor.[1] However, carvedilol (a vasodilating β-blocker) does not lower central aortic pressure any better than the nonvasodilating β-blockers. This suggests that vasodilating β-blockers may not reduce mortality any better than nonvasodilating β-blockers, although this remains speculative.

Control Serum Phosphorous

Serum phosphorus generally does not become elevated until stage 4 CKD. In CKD, there is a significant association between increased serum phosphorous and either CKD progression or incident CKD and ESRD.[37] Phosphorus control should begin when serum phosphorus is consistently greater than 4.0 mg/dl (1.3 mmol/l). The first approach is to reduce phosphorous intake, with the precaution that severely reducing meat and dairy products could lead to protein malnutrition. Proteins in grain (e.g., a vegetarian-type diet) have a lower phosphorus content than the proteins in meat or milk. If plant-based proteins are substituted for meat and dairy products, better control of serum phosphorous can be achieved.

If dietary measures are ineffective, use of phosphate binders is generally recommended. However, which type of phosphate binder is best is controversial[38] (see Chapter 84).

Smoking Cessation

Cigarette smoking promotes progression of all forms of kidney disease in a dose-dependent manner, perhaps more in those of African American ancestry.[1]

Control Hyperuricemia

Three randomized trials[1] and one case-control study found that allopurinol therapy slows CKD progression.[39] One randomized double-blind study of febuxostat in CKD showed similar benefit.[40] In addition, abundant experimental evidence exists that uric acid is proinflammatory, vasculotoxic, and associated with increased CV and renal risk.[41]

A major concern in recommending allopurinol or, rarely, febuxostat to slow CKD is the risk, albeit very small, of severe and even fatal hypersensitivity reactions (e.g., Stevens-Johnson syndrome). A recent study also reported that febuxostat may be associated with increased cardiovascular mortality compared to allopurinol. Importantly, it is not known if febuxostat increases cardiovascular risk in subjects not receiving uric acid lowering therapy, and a few studies do suggest allopuriol may reduce cardiovascular events in subjects with CKD. A cogent argument can be made that these xanthine oxidase inhibitors have a favorable risk-to-benefit ratio in CKD, particularly in relationship to the traditional uses of these drugs, which are to treat nonlethal diseases, gout, and kidney stones.

Reducing the risk for severe hypersensitivity reaction to allopurinol in CKD patients may be accomplished by reducing the initial dose (see summary, later) and by advising patients who are about to start allopurinol or febuxostat to stop the drug immediately and call their physician should they develop rash, fever, or other signs of illness. Also, allopurinol should be avoided in patients with high-risk alleles (HLA-B58) for severe allopurinol hypersensitivity. This is particularly seen in those of Asian or African ancestry.[42] Testing for these risk alleles in these populations has been recommended.

In summary, there is evidence that xanthine oxidase inhibitors therapy, properly approached, may be helpful in hyperuricemic CKD patients to reduce cardiovascular risk and risk for CKD progression. For prevention of severe allergic reactions, the starting dose for allopurinol should be 1.5 mg × eGFR in ml/min/1.73 m^2. If after 8 weeks that dose is well tolerated, it can then be increased until the uric acid level is at goal (7 mg/dl). Also, the patient should be strongly cautioned to stop the allopurinol and seek medical advice if rash, fever, or other signs of illness develop. If febuxostat is used in CKD, the maintenance dose is unchanged.[43]

Avoid Anticoagulant-Related Nephropathy

Anticoagulant-related nephropathy (ARN) is a newly recognized clinical syndrome caused by coagulopathy because the warfarin international normalization ratio (INR) is greater than 3, typically in the mid-4s, or by coagulopathy caused by direct oral anticoagulants (DOACs) (e.g., dabigatran, rivaroxaban).[44] ARN is caused by severe glomerular hemorrhage, even though the glomeruli are normal or nearly normal. The extent to which DOACs cause ARN is unclear, but it is likely that ARN related to DOACs is not a rare occurrence.

Alkali Therapy

The evidence that alkali therapy slows CKD progression is based on three randomized trials and one nonrandomized study. In addition, metabolic acidosis may predict CVD.[1] Recommended forms of alkali are sodium bicarbonate ($NaHCO_3$), sodium citrate, and diets high in fruits and vegetables (i.e., potassium citrate). If $NaHCO_3$ therapy is used, the recommended dose is one to four 650-mg tablets twice daily. The goal is to raise plasma bicarbonate levels to greater than 22 mM/l. Alkali therapy improves protein nutrition by suppressing protein catabolism and protects against hyperkalemia. Whether metabolic acidosis needs to be present for benefit from alkali supplementation is not clear. However, benefit in slowing CKD progression is seen even in those whose pretreatment plasma bicarbonate level is within the normal range.

Monitor Serum Creatinine in Patients Receiving a Proton Pump Inhibitor

Four large retrospective studies[45] have shown an association between PPI use and incident CKD. The comparison groups were those receiving no PPI or histamine-2 (H_2) receptor blockers. However, because the treatment groups were not the results of randomization, confounding is a concern. In addition, the risk for incident CKD was low (approximately one case of CKD for each 100 persons followed for 10 years). Nevertheless, the association of PPI with incident CKD should not be ignored. It would seem sufficient to monitor serum creatinine in PPI patients twice yearly.

Correct Vitamin D Deficiency

Severe deficiency of 25-OH vitamin D is common in CKD, and vitamin D influences the activation of more than 200 genes.[46] Although some have argued against routine vitamin D supplementation in CKD based on a paucity of evidence of benefit from randomized trials, there are some encouraging signs of benefit of adequate vitamin D levels in CKD.[47,48] Vitamin D_3 supplementation is relatively inexpensive and safe. The goal is to raise serum vitamin D levels to the normal range (>30 mg/ml). Vitamin D_3 doses of 1000 or 2000 IU daily or 50,000 IU monthly will usually restore 25-OH vitamin D levels to normal. Note that serum vitamin D levels are on average about one third lower in Blacks than Whites.[49] Most of this difference is accounted for by lower vitamin D binding protein in Blacks. However, biologically active vitamin D is at normal levels. This should be considered when deciding whether vitamin D replacement is adequate. For example, if the target is a vitamin D level of 40 to 60 mg/ml, a lower level within the range might be the appropriate target for those of African ancestry.

Avoid or Minimize Nonsteroidal Antiinflammatory Drug Use

In those with normal or near-normal kidney function, fewer than 1% experience renal events during 2 years of treatment while receiving nonsteroidal antiinflammatory drugs (NSAIDS) at average daily doses of celecoxib 200 mg, naproxen 850 mg, or ibuprofen 2600 mg.[50] However, clinical experience suggests that, if these were CKD patients, many if not most would show an increase in serum creatinine after only a few weeks of NSAIDS at these doses. Also, celecoxib was dosed at relatively lower level than the naproxen or ibuprofen.[51]

SELF-ASSESSMENT QUESTIONS

1. With respect to the chronic kidney disease (CKD) cohort in the SPRINT trial, each of the following is correct *except:*
   - **A.** The SPRINT CKD cohort is regarded as elderly. The definition of elderly is older than 65 years of age.
   - **B.** The SPRINT CKD cohort manifested low-level proteinuria (maximum 24-hour urine was 1.0 g).
   - **C.** The Intensive blood pressure (BP) goal was a systolic BP less than 120 mm Hg. The Standard BP goal was a systolic BP less than 140 mm Hg with the target of a systolic BP of 135 to 139 mm Hg.
   - **D.** The Intensive BP intervention resulted in a significant reduction in proteinuria.
   - **E.** The Intensive BP intervention slowed estimated glomerular filtration rate (eGFR) decline and protected the patient from episodes of acute kidney injury (AKI).
2. In comparing the risks and benefits of angiotensin-converting enzyme (ACE) inhibitor therapy compared with angiotensin receptor blocker (ARB) therapy in the management of hypertension, each of the following is correct *except:*
   - **A.** Based on the randomized trials, ACE inhibitors cause angioedema; ARB therapy does not cause angioedema.
   - **B.** Those of African ancestry are particularly susceptible to developing angioedema on ACE inhibitor therapy.
   - **C.** ACE inhibitor–induced cough is an intractable problem.
   - **D.** Both ACE inhibitor therapy and ARB therapy are effective in slowing GFR decline in CKD.
   - **E.** Based on recent meta-analyses of randomized trials that compared ACE inhibitor to placebo or ARB to placebo, ACE inhibitor therapy was associated with a significant reduction in mortality but ARB therapy was not associated with a significant reduction in mortality.
3. With respect to the merits of monitoring proteinuria by measuring albuminuria or total proteinuria (albumin plus nonalbumin protein), each of the following is correct *except:*
   - **A.** At total 24-hour proteinuria less than 500 mg, albuminuria is more sensitive than total proteinuria in identifying change.
   - **B.** At 24-hour proteinuria greater than 500 mg, albuminuria and total proteinuria generally change in parallel.
   - **C.** The cost of measuring total proteinuria is less than the cost of measuring albuminuria.
   - **D.** In a given individual, urine protein-to-creatinine ratio (uPCR) varies widely over a given 24-hour period. Single-void (spot) uPCR reveals this variability. By contrast, the uPCR of an intended 24-hour urine collection conceals this variability. The rationale is that the uPCR of an intended 24-hour urine collection ratio is the integrated mean of the uPCR during the entire collection.
   - **E.** In individual CKD patient management, spot uPCR and the uPCR of an intended 24-hour urine collection are equally reliable in assessing proteinuria magnitude.

Clinical Evaluation and Management of Chronic Kidney Disease

Laurie A. Tomlinson, David C. Wheeler

Although many patients with chronic kidney disease (CKD) progress to end-stage renal disease (ESRD) and require renal replacement therapy (RRT), the majority die of nonrenal causes, particularly premature cardiovascular (CV) events.[1] Early diagnosis of CKD is therefore important because it provides opportunities to delay progression of CKD (see Chapter 79) and prevent CV complications (see Chapter 81).

DEFINITIONS

Chronic kidney disease is defined as abnormalities of kidney structure or function, present for at least 3 months, with implications for health (Table 80.1). The Kidney Disease: Improving Global Outcomes (KDIGO) guidelines recommend classification of CKD based on cause, category of glomerular filtration rate (GFR), and albuminuria (see Fig. 79.1).[2] Because of the impracticalities of using radioisotopes and 24-hour urine collections, the KDIGO classification system recommends that kidney function be assessed by estimating GFR (eGFR) from the serum creatinine concentration using an appropriate equation, except in circumstances in which eGFR estimations are known to be less accurate, such as when there is significant muscle wasting. Initially, the Modification of Diet in Renal Disease (MDRD) equation was used, but this has predominantly been replaced by the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation, which more accurately categorizes the risk for mortality and progression to ESRD (see Chapter 3).[3] Although staging systems for CKD based on eGFR have limitations, they have proved useful in many clinical settings and are now deeply embedded in guidelines developed for CKD management and research.

The evidence base for the management of CKD is constantly evolving. Although every effort has been made to ensure this chapter reflects current recommendations, the reader is advised to check for any relevant guideline updates.

CLINICAL PRESENTATION

CKD is usually asymptomatic until late stage G4 or stage G5 and is commonly detected by routine blood testing. Symptoms of CKD are nonspecific and need to be asked about directly (Table 80.2). There is some evidence that early diagnosis with appropriate management may slow the rate of decline of kidney function and reduce CV risk.[4] Screening of the general population for CKD is not recommended, but in the United Kingdom the National Institute for Health and Care Excellence (NICE) proposes offering testing to people with conditions associated with an increased prevalence of CKD—those with diabetes, hypertension, previous acute kidney injury (AKI), CV disease (CVD), structural renal tract disease, renal calculi, prostatic hypertrophy, multisystem diseases with potential kidney involvement (e.g., systemic lupus erythematosus), a family history of category G5 CKD, or hereditary kidney disease—and after opportunistic detection of hematuria or proteinuria.[5]

Evaluation of Chronic Kidney Disease

Establishing Chronicity

When eGFR of less than 60 ml/min/1.73 m^2 is detected, careful attention should be paid to previous blood and urine test results and the clinical history to determine if this is a result of AKI; that is, an abrupt decrease in kidney function or CKD that has been present but asymptomatic for some time.

A detailed medical history covering issues, including other medical conditions, family history of kidney disease, prescribed medication, and recreational drug use, may suggest an underlying cause. There may be hints of a history of kidney problems (e.g., hypertension, proteinuria, microhematuria) or symptoms suggestive of prostatic disease. The physical examination findings are not usually helpful, although skin pigmentation, scratch marks, left ventricular hypertrophy, and hypertensive fundal changes favor a chronic presentation (Fig. 80.1). Details of the social and personal circumstances are also crucial, particularly for patients with progressive kidney disease in whom RRT is likely to be required.

Blood tests for other conditions can be helpful because they may indicate evidence of an acute illness that could be the cause of kidney failure, such as systemic vasculitis or multiple myeloma. A normochromic normocytic anemia is usual in CKD, but also may be a feature of acute systemic illnesses and therefore is not discriminatory. Low serum calcium and raised phosphate levels also have little discriminatory value, but normal levels of parathyroid hormone (PTH) are more in keeping with AKI. Patients with grossly abnormal biochemical values—for example, blood urea nitrogen higher than 140 mg/dl, serum creatinine above 13.5 mg/dl (>1200 µmol/l), or blood urea greater than 300 mg/dl (>50 mmol/l)—who appear relatively well and are still passing normal volumes of urine are much more likely to have CKD than AKI.

Assessment of Glomerular Filtration Rate

For patients in whom the distinction between AKI and CKD is unclear, repeat testing of kidney function should be performed within 2 weeks of the initial finding of an eGFR below 60 ml/min/1.73 m^2. However, if previous results confirm that this is a chronic finding, or if repeated blood test results over a 3-month period are consistent, CKD is confirmed. Other tests (such as cystatin C or an isotope-clearance measurement of GFR) may be required for confirmation of CKD in circumstances in which eGFR based on serum creatinine is known to be less accurate.

TABLE 80.1 Criteria for Definition of Chronic Kidney Disease (CKD)

CKD is defined as abnormalities of kidney structure or function, present for more than 3 months, with implications for health. These may include the following:	
Markers of kidney damage	Albuminuria (AER ≥30 mg/24 h; uACR ≥30 mg/g [≥3 mg/mmol])
	Urine sediment abnormalities
	Electrolyte and other abnormalities caused by tubular disorders
	Abnormalities detected through histology
	Structural abnormalities detected through imaging
	History of kidney transplantation
Decreased GFR	GFR <60 ml/min/1.73 m^2

From reference 2.
AER, Albumin excretion rate; *GFR,* glomerular filtration rate; *uACR,* urinary albumin-to-creatinine ratio.

Fig. 80.1 Uremic pigmentation. Diffuse brown pigmentation as seen here suggests chronic kidney disease rather than acute kidney injury.

TABLE 80.2 Symptoms and Signs of Severe Chronic Kidney Disease

Symptoms	Signs
Difficulty sleeping	Altered respiration including Kussmaul breathing and Cheyne-Stokes respiration
Nocturia	Icteric sclera or "red eye" due to calcium deposition
Headache	Muscle weakness
Restless leg syndrome	Oral lesions including gingival bleeding or petechiae, xerostomia, periodontitis, and candidiasis
Metallic taste in the mouth	Pericardial and/or pleural rub
Shortness of breath on exertion or at rest, paroxysmal nocturnal dyspnea	Pulmonary and peripheral edema
Fatigue, often profound	Skin changes including xerosis (abnormal dryness), scratch marks, pallor, sallow coloration or hyperpigmentation
Muscle cramps and twitches	Uremic flap (asterixis)
Seizures	Uremic fetor: Ammonia or urine-like odor to the breath
Lack or loss of appetite for food, abdominal pain, nausea, vomiting, and weight loss	Uremic frost: Crystallized urea deposits that can be found on the skin
Itch, particularly on the trunk and worse at night	

Assessment of Proteinuria

Dipstick testing of the urine and urine culture is important.[6] This may reveal microhematuria, which can be a useful pointer toward an underlying diagnosis. Workup of hematuria is discussed in Chapters 4 and 59. Whether or not proteinuria is detected by dipstick, there should be a further measurement of urinary protein excretion. Proteinuria is an important diagnostic and prognostic marker, and its presence indicates a higher risk for both progression of kidney disease and CV complications.[7] KDIGO guidelines recommend that the preferred method of assessing proteinuria is by measurement of the urinary albumin-to-creatinine ratio (uACR) using an early morning urine sample.[2] The degree of albuminuria is graded by the A1 to A3 category system, replacing previous terms such as *microalbuminuria* (see Fig. 79.1). However, it is important to be aware that some patients will excrete proteins other than albumin, and a urine protein-to-creatinine ratio (uPCR) may be more useful for certain conditions.[8] Serial uPCR measurements may be particularly useful in glomerular disease because of the higher variability of uACR and the greater cost of determining albumin in urine. Where appropriate, urine tests for Bence Jones protein (immunoglobulin light chains) may be required because this is not detected by standard proteinuria or albuminuria testing.

Kidney Imaging

Imaging of the kidneys with ultrasound is useful for a number of reasons. Small kidneys with reduced cortical thickness, showing increased echogenicity, scarring, or multiple cysts, suggest a chronic process. Structural abnormalities such as autosomal dominant polycystic kidney disease (ADPKD), hydronephrosis caused by obstruction, or coarse renal scarring may be detected. NICE guidelines propose that kidney ultrasound scanning is important only in certain circumstances and suggests counseling patients if ADPKD is suspected before imaging.[5] In some situations, imaging with computed tomography, magnetic resonance, or angiography may be useful, taking into account the risks of administering contrast media (see Chapter 5).

Further Investigations

Establishing the cause of CKD is important whenever possible, and further specific testing, as indicated by the history and results of initial investigations, may be required. There may be an underlying treatable condition that requires appropriate management, or there may be a genetic cause such as ADPKD, for which counseling should be offered. Furthermore, some kidney diseases may recur after transplantation (see Chapter 108) and an accurate diagnosis may therefore influence later management. Despite thorough investigation, however, the cause of CKD is often unclear, with an unhelpful medical history, minimal

abnormalities on urinalysis, and small kidneys on ultrasound. In such patients, investigation should not be pursued relentlessly because the implications for treatment are often minimal. Attempting to obtain biopsy material from small kidneys is associated with risk, and even if a biopsy is performed, histologic assessment may simply show nonspecific chronic scarring rather than diagnostic features that explain the cause of kidney damage.

PREDICTING PROGNOSIS

With the cause of CKD established if possible, the GFR and the level of proteinuria measured, and other comorbidities categorized, it may be possible to estimate the risk for CKD progression and likely future need for RRT. KDIGO recommends consideration of the GFR and the albuminuria categories according to a "heatmap" of risk (see Fig. 79.1).[2] Other factors associated with CKD progression will help inform prognosis. These include the cause of CKD, age, sex, ethnicity, dyslipidemia, smoking, obesity, history of CVD, ongoing exposure to nephrotoxic agents, and degree of control of hypertension and hyperglycemia. However, often the best guide to future change in kidney function is the previous pattern of decline, highlighting the importance of considering results of previous blood and urine testing during the initial assessment.

Monitoring and Defining Progression

Once CKD has been identified, arrangements should be made to ensure regular monitoring of kidney function and proteinuria. In patients at low risk for rapidly declining eGFR, this can be done annually. However, assessment should be undertaken more regularly if the trajectory of the disease is not clear and in patients at higher risk for progression.

Determining a true change in kidney function may be difficult because small fluctuations in eGFR are common and not necessarily indicative of progression. They may be caused by reversible factors, such as intravascular depletion or high meat intake, so repeat testing may be required. Both NICE and KDIGO guidelines define accelerated progression as a sustained decrease in GFR of 25% or more and a change in GFR category within 12 months.[2,5] In addition, the NICE guidance refers to accelerated progression as a sustained decrease in GFR of 15 ml/min/1.73 m^2 per year.[2] In patients with CKD progression, consideration should be given to detection of reversible causes (e.g., renal tract obstruction) and specialist referral may be required.

When to Refer to the Nephrologist

Chronic management of patients with early nonprogressive CKD is becoming the responsibility of primary care physicians in many well-developed health care systems, with follow-up in secondary care for those likely to progress to ESRD and require RRT. However, early assessment by nephrologists is useful for all patients newly diagnosed with CKD in whom a treatable underlying cause is suspected, even in those with advanced disease at presentation to rule out treatable causes. Timely referral of those with progressive CKD allows preparation for dialysis, kidney transplantation, or initiation of a palliative approach if more appropriate. Substantially similar criteria for referral have been developed by NICE and KDIGO (Table 80.3). Such criteria are not absolute but should provide a guide to the primary care physician as to which patients are likely to benefit from specialist care. For example, many patients with stable category G4 CKD are successfully managed in the community, often after initial assessment by or with advice from secondary care colleagues.

Unfortunately, a substantial proportion of patients with advanced CKD are referred late, often when they need dialysis. Late referral is often avoidable, although in some cases, patients may have had a truly silent illness or an acute presentation of a disease with rapid decline in kidney function.[9] Over recent years the introduction of routine reporting of eGFR in some health care systems has facilitated better communication between primary and secondary care providers and has led to a substantial fall in late referrals.[10]

Late presentation is disadvantageous to the patient because it limits the time to select the mode of dialysis or to be listed for "preemptive" kidney transplantation. There may be increased psychological stress, making it difficult for the patient to come to terms with the illness. Furthermore, because an arteriovenous fistula takes several weeks to mature, patients presenting late start hemodialysis with central venous catheters. Catheters are prone to infectious complications and inevitably

TABLE 80.3 Suggested Criteria for Referral of Patients With Chronic Kidney Disease to a Nephrologist

	NICE 2014	KDIGO 2012
Advanced CKD	Category G4 and G5 CKD	Category G4 and G5 CKD
Proteinuria	*High proteinuria:* uACR ≥70 mg/mmol unless known to be caused by diabetes and appropriately treated	*Consistent proteinuria:* uACR ≥300 mg/g (≥30 mg/mmol)
Hematuria	Proteinuria (uACR ≥30 mg/mmol) together with hematuria	Urinary red cell casts, RBCs >20 per high-power field sustained; not readily explained
Progression of CKD	Rapidly declining eGFR: Sustained decrease in GFR of 25% or more, and a change in GFR category within 12 mo Sustained decrease in GFR of 15 ml/min/1.73 m^2 or more within 12 mo	Progression of CKD: Sustained decrease in GFR of 25% or more, and a change in GFR category within 12 mo Sustained decrease in GFR of 5 ml/min/1.73 m^2 or more within 12 mo
Uncontrolled hypertension	Hypertension that remains poorly controlled despite the use of at least four antihypertensive drugs at therapeutic doses	CKD and hypertension refractory to treatment with four or more antihypertensive agents
Hereditary kidney disease	Known or suspected rare or genetic causes of CKD	Hereditary kidney disease
Other conditions	Suspected renal artery stenosis	Recurrent or extensive nephrolithiasis Persistent abnormalities of serum potassium

Data from references 2 and 5.
CKD, Chronic kidney disease; *eGFR,* estimated glomerular filtration rate; *KDIGO,* Kidney Disease: Improving Global Outcomes; *NICE,* National Institute for Health and Care Excellence; *PTH,* parathyroid hormone; *RBC,* red blood cell; *uACR,* urinary albumin-to-creatinine ratio.

damage central veins, leading to thromboses and stenoses, which may manifest at a later stage when venous return from one or the other arm is increased by the subsequent construction of an arteriovenous fistula (see Chapter 91).[11] Late presentation of CKD also precludes effective treatment of complications such as hypertension and anemia, which may contribute to CV damage and ultimately limit life span.[12] Most important, late referral is associated with greater subsequent costs of medical care and a worse prognosis.[13]

PREVENTION OF CHRONIC KIDNEY DISEASE PROGRESSION

Management of CKD should be aimed at slowing the rate of decline of kidney function and minimizing the effects of other complications. Except for specific management of the underlying kidney disease where possible, the most effective intervention is control of blood pressure (BP), including (in patients with albuminuria) use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) (see Chapter 79). Control of glycemia for patients with diabetes and CKD is covered in Chapter 32.

Hypertension

Hypertension is very common in patients with CKD, and the level of BP is associated with the rate of loss of kidney function[14] while control slows the rate of decline (see Chapter 79). BP targets have changed to reflect the available evidence, from a focus on "the lower, the better" toward less-intensive and individualized BP control.[15] With the results of the SPRINT trial, the pendulum may be swinging back again to lower BP goals.[16] Guidelines by both NICE and KDIGO have considered management of hypertension in patients with CKD in depth.[5,17] Both sets of guidelines emphasize the importance of considering coexistent CVD, other comorbidities, and side effects when choosing medications and BP targets, particularly for elderly patients. Lifestyle modifications should be encouraged, including maintenance of a healthy weight, reductions in salt and alcohol intake, and regular exercise (see Chapter 35).

Although current recommendations are based on office BP recordings, recent studies suggest that readings obtained from home and ambulatory monitoring correlate better with CV and kidney outcomes.[18] It is alarming to note that up to 30% of CKD patients who were thought to have hypertension have normal BPs at home, and 40% of patients who were thought to be normotensive (or to have adequately treated hypertension) were hypertensive at home.[19] Although ambulatory monitoring is not yet universally recommended, there should be a very low threshold for undertaking 24-hour monitoring or asking patients to undertake self-measurements at home if they prefer.

Target BP levels and antihypertensive therapy in CKD patients are discussed in Chapter 79. ACE inhibitors or ARBs are recommended as first-line agents for patients with evidence of proteinuria, but usually multidrug regimens are required to obtain good control. Patients with CKD are vulnerable to drug side effects, particularly during intercurrent illness, when they may develop hyperkalemia and AKI.[20] The KDIGO guidelines recommend the temporary discontinuation of potentially nephrotoxic drugs and those excreted by the kidney (including ACE inhibitors, ARBs, aldosterone inhibitors, direct renin inhibitors, diuretics, nonsteroidal antiinflammatory drugs, metformin, lithium, and digoxin) in patients with a GFR below 60 ml/min/1.73 m^2 (CKD categories G3a to G5) who have serious intercurrent illness.

Dietary Advice

Detailed dietary advice and education, along with ongoing support from an appropriately trained professional, are important in the management of patients with CKD. Obesity is associated with a more rapid decline of kidney function, so in early CKD, weight loss may be appropriate. However, in advanced CKD, malnutrition is common (see Chapter 86). The causes are multifactorial but include anorexia, acidosis, insulin resistance, inflammation, oxidative stress, and urinary protein loss. Biochemical indicators may demonstrate a decrease in serum albumin, transferrin, and cholesterol. Weight should be monitored in patients who progress to CKD categories G4 and G5. Serum creatinine concentrations, which in part reflect muscle mass, may stop rising despite a progressive loss of kidney function, because of compromised nutritional status.

In light of this, recommendations to restrict protein intake have been controversial. Although there is evidence that reduced protein intake may slow progression of decline of kidney function, many patients develop protein-calorie malnutrition on a low-protein diet.[21] KDIGO has recommended that protein intake should be lowered to 0.8 g/kg/day in adults with CKD and GFR below 30 ml/min/1.73 m^2, whereas high protein intake (>1.3 g/kg/day) should be avoided in adults with CKD at risk for progression. When this recommendation is followed, detailed dietary assessment and supervision are needed to ensure that malnutrition is prevented.

One of the earliest effects of CKD is to limit the ability of the kidney to compensate for large changes in sodium and water intake (see Chapter 7). Salt and water retention are major factors contributing to hypertension in CKD patients and, in more advanced stages, to morbidity and mortality through systemic or pulmonary edema. Therefore sodium intake ideally should be restricted to less than 90 mmol/day (5 g/day of sodium chloride), except in salt-wasting conditions. Advice about optimal fluid intake at each stage of CKD is needed to prevent volume overload. Salt substitutes containing potassium should be avoided because of the risk for hyperkalemia. In categories G4 and G5 CKD, education and advice about restriction of potassium and phosphate may be required.

MANAGEMENT OF COMPLICATIONS OF CHRONIC KIDNEY DISEASE

A detailed discussion of the complications of CKD is provided in Chapters 81 to 88. With the exception of hypertension, there are usually few clinical manifestations associated with CKD categories G1 and G2 (GFR >60 ml/min/1.73 m^2). Other complications (discussed in the following sections) tend to develop progressively as GFR declines below 60 and in particular below 30 ml/min/1.73 m^2 (i.e., during CKD categories G4 and G5).

Anemia

Anemia is common in CKD categories G3a to G5 and is caused by a relative deficiency of erythropoietin, although reduced availability of iron and chronic inflammation are frequent contributory factors (see Chapter 82). Anemia may have multiple adverse effects, including worsening cardiac dysfunction by increasing cardiac output and exacerbating left ventricular hypertrophy, exacerbating the decline of kidney function, and reducing cognition and concentration. However, clear evidence that reversal of anemia using erythropoiesis-stimulating agents (ESAs) is associated with improved clinical outcomes is lacking, and randomized trials have suggested that in some circumstances these agents may cause harm. A promising new avenue for the treatment of renal anemia is the development of oral small-molecule stabilizers of hypoxia inducible factor. These offer the possibility of simple and cheaper therapy compared with ESAs, with potential benefits beyond increases in hemoglobin (Hb) level.[22]

The relevant KDIGO guideline recommends that all patients identified as having CKD categories G3a and below should have their Hb levels monitored annually, increasing to twice a year for categories G4

and G5.[2] Anemia in adults is diagnosed when the Hb concentration falls below 13.0 g/dl in men and below 12.0 g/dl in women. NICE recommends that management of anemia should be considered in patients with CKD when the Hb level is 11 g/dl or lower.[5] In anemic patients, investigations for other causes should be conducted, including measurement of iron stores, serum vitamin B_{12}, and folate levels. ESAs should not be started until treatment of iron deficiency or other underlying causes has been addressed and then only after considering the balance of benefits (from the reduced requirement for blood transfusions and abrogation of anemia-related symptoms) against the potential harms, which may include an increased risk for stroke and malignancy.

If anemia does not respond to correction of underlying causes, such as iron deficiency, KDIGO recommends that ESAs be commenced when Hb concentrations are below 10.0 g/dl, if indicated.[23] Hb target ranges are discussed in Chapter 82.

Bone and Mineral Metabolism

Hyperphosphatemia, together with a deficiency of 1,25-dihydroxyvitamin D_3, contribute to secondary hyperparathyroidism and ultimately to the development of renal bone disease. These biochemical and endocrine changes, in association with the closely related histologic abnormalities of bone and soft tissue calcification, are collectively termed the *CKD–mineral and bone disorder* (see Chapter 84).[24] Bone disease already may be manifested in CKD category G3b and is well established in ESRD, even though patients may remain asymptomatic. In addition to the need to prevent bone complications, active management of CKD–mineral and bone disorder may help prevent some of the CV complications of CKD.[25]

KDIGO recommends measuring serum levels of calcium, phosphate, PTH, and alkaline phosphatase activity in adults with GFR below 45 ml/min/1.73 m^2 (GFR categories G3b through G5). Determining the optimal level of PTH in CKD has been controversial. For patients with levels of intact PTH above the upper normal limit of the assay, efforts should be made to correct hyperphosphatemia, hypocalcemia, and vitamin D deficiency if present. KDIGO guidelines recommend that serum phosphate concentrations be maintained in the normal range according to local laboratory reference values,[26] whereas the United Kingdom Renal Association support a level between 0.9 and 1.5 mmol/l for patients with category G4 and G5 CKD.[27] Early advice on dietary phosphate management by a specialist dietician or other professional is important in helping patients achieve this. Phosphate-binding drugs may be required, and their choice is discussed in Chapter 84. Prescription of vitamin D supplements or analogues, in the absence of documented deficiency, to suppress elevated PTH concentrations in patients with CKD not on dialysis is not routinely recommended. Calcimimetics are a group of drugs that mimic the action of calcium on parathyroid glands by activation of the calcium sensing receptor and thus reduce the release of PTH. At present, because of cost restraints, cinacalcet (the sole clinically available oral calcimimetic) and etelcalcetide (which is given intravenously) are generally used for patients who are unfit for surgical parathyroidectomy. Whether these drugs have additional health benefits is not clear (see Chapter 84).

Metabolic Acidosis

The metabolic acidosis associated with CKD is caused by failure of hydrogen ion excretion and may be compounded by the accumulation of organic acids and bicarbonate loss, particularly in interstitial kidney diseases. Clinical symptoms resulting from acidosis are rare until patients reach CKD category G5, when dyspnea may occur as a result of respiratory compensation. Other causes of dyspnea in advanced CKD, such as anemia and pulmonary edema, should always be considered. Acidosis aggravates hyperkalemia, inhibits protein anabolism, and accelerates calcium loss from bone where the hydrogen ions are buffered.[28] Correction of metabolic acidosis may slow progression of kidney disease, although larger trials are required to confirm this.[29]

KDIGO recommends that in patients with CKD and serum bicarbonate concentrations below 22 mmol/l (NICE recommends a threshold of <20 mmol/l), oral bicarbonate supplementation should be given to maintain serum bicarbonate within the normal range, unless contraindicated. However, the associated sodium loading may aggravate hypertension and fluid retention, and severe metabolic acidosis associated with symptoms in a patient with CKD category G5 may be an indication to start dialysis.[2] Novel pipeline drugs include an oral polymer designed to remove acid from the body with high capacity and specificity. This raises the possibility of treatment of acidosis without the problems associated with increased sodium intake.

Cardiovascular Risk

Patients with CKD have an increased prevalence of CVD and are far more likely to die from a CVD-related cause than to progress to ESRD (see Chapter 81). Therefore appropriate management of existing CVD and minimization of future CV risk is vital for all patients with CKD.

Unfortunately, many trials of interventions for CVD have excluded patients with CKD,[30] and there is doubt about the relevance of existing standards of care of CVD to patients with CKD.[31] Nonetheless, the level of care for coronary heart disease offered to patients with CKD should not be prejudiced by their CKD. NICE suggests that antiplatelet drugs should be offered to patients with CKD for the secondary prevention of CVD, and some experts would extend this recommendation to primary prevention for those at risk for atherosclerotic events. However, there is an increased risk for minor bleeding, and a recent systematic review of antiplatelet agents for patients with CKD found that although the incidence of myocardial infarction is reduced, major bleeding is increased. Thus the risks may outweigh benefits among individuals with low risk for CV events, including those with early stages of CKD who do not have clinically evident occlusive arterial disease.[32]

For reduction of cardiovascular risk, KDIGO guidelines recommend that statin treatment be routinely offered to patients with CKD who are older than 50 years and to younger patients with additional risk factors, irrespective of baseline lipid values.[33] NICE recommends that all people with CKD should be offered atorvastatin 20 mg for the primary or secondary prevention of CVD.[34]

Risk for Infections

Infection is the second most common cause of death after CVD in patients with ESRD. This is in part because of defects in both cellular and humoral immunity, which make CKD a state of chronic immunosuppression (see Chapter 83).[35] T-cell responses to de novo antigens are deficient, partly because of impaired antigen presentation by monocytes. Neutrophil activation is defective, and although serum immunoglobulin levels are normal, antibody responses to immunization may be poor. Patients with CKD have an increased susceptibility to bacterial infection (particularly staphylococcal), increased risk for reactivation of tuberculosis (typically with a negative tuberculin skin test response), and failure to eliminate hepatitis B and C viruses after infection.

In view of these increased risks, the KDIGO guidelines recommend that all adults with CKD be offered annual vaccination with influenza vaccine unless contraindicated and that all adults with eGFR below 30 ml/min/1.73 m^2 (GFR categories G4 to G5) and those at high risk for pneumococcal infection (e.g., patients with nephrotic syndrome, with diabetes, or who are receiving immunosuppression) receive vaccination with polyvalent pneumococcal vaccine unless contraindicated.[2] Patients who have received pneumococcal vaccination are offered revaccination within 5 years. In addition, those at high risk for progression

of CKD with eGFR below 30 ml/min/1.73 m^2 (GFR categories G4 and G5) should be immunized against hepatitis B and the response confirmed by appropriate serologic testing. This should happen as early as possible to maximize the chances of seroconversion.[36]

CARE OF THE PATIENT WITH PROGRESSIVE CHRONIC KIDNEY DISEASE

To optimize the care of patients with progressive CKD, management is provided in a multidisciplinary setting where a range of professionals are able to provide education and information about diet, different RRT modalities, transplant options, vascular access surgery, and social care. Psychological comorbidity is common among patients with CKD. Health care professionals working with patients with CKD should take account of the psychological aspects of coping with the condition and offer access to support groups, counseling, or a specialist nurse. The aim is to create an environment in which patients can become informed and proactive in their care.

Chronic Kidney Disease and Risk of Acute Kidney Injury

All patients with CKD are at increased risk for AKI, and AKI is associated with the development and progression of CKD.[37,38] Imaging studies that require iodinated radiocontrast media carry a risk for AKI, and the benefit of a diagnostic scan needs to be balanced against the risks. If the investigation is needed, the lowest dose of radiocontrast should be used, the patient should be adequately hydrated, and potentially nephrotoxic agents should be withdrawn before and after the procedure; however, the fear of radiocontrast-induced AKI should not prevent or impair a necessary diagnostic workup. The potential risk for nephrogenic systemic fibrosis from gadolinium-based contrast media and measures to reduce it are discussed in Chapter 5.

Many commonly used medications increase the risk for AKI, and the level of GFR should be considered when any drug is prescribed or its dosage determined. As discussed earlier, the need for temporary cessation of all medications should be considered during periods of severe intercurrent illness. Other causes of reduction in kidney perfusion can lead to AKI, including volume depletion from excessive diuretics, insufficient fluid intake in hot weather, diarrhea or vomiting, heart failure, myocardial infarction, and tachyarrhythmias. Severe hypercalcemia, resulting from either coadministration of high doses of vitamin D and calcium-containing phosphate binders or from underlying disease, also can cause AKI.

Clinicians should always consider whether acceleration of loss of kidney function is a result of relapse of the underlying disease or of a superimposed problem such as acute interstitial nephritis (see Chapter 60), obstructive uropathy (see Chapter 58), or renal vein thrombosis.

Timing the Initiation of Renal Replacement Therapy

Despite all attempts to optimize the management of CKD, many patients will progress to needing RRT. All patients with eGFR below 20 ml/min/1.73 m^2 and/or who are likely to progress to ESRD within 12 months should receive education and counseling, with the support of a multidisciplinary team, to aid their selection of the most appropriate RRT modality (see Chapter 90). If hemodialysis is the preferred option, an arteriovenous fistula should be constructed, remembering that it may take 8 to 12 weeks for veins to become adequately arterialized before needling can be attempted (see Chapter 91). Similar plans need to be made for preemptive insertion of a peritoneal dialysis catheter to allow time for healing and training before any acute need for commencement of dialysis (see Chapter 99). Peritoneal dialysis catheters can be inserted and completely buried subcutaneously some time before patients require dialysis, then superficialized for use once clinical circumstances dictate.

Early kidney transplantation may be associated with improved long-term outcome,[39] so patients should be assessed for their suitability and, when feasible, activated on the waiting list before dialysis is commenced. This maximizes the chances of the potential recipient remaining in reasonable health. The availability of a living donor should be explored to increase the chances of preemptive transplantation before the patient begins dialysis. The KDIGO guidelines recommend that living donor preemptive kidney transplantation in adults be considered when the GFR is below 20 ml/min/1.73 m^2 and there is evidence of progressive and irreversible CKD over the preceding 6 to 12 months.[2]

Planned early initiation of dialysis is not associated with improvement in outcomes compared with commencement when indicated by signs and symptoms of uremia.[40] KDIGO suggests that dialysis be initiated when one or more of the following are present: symptoms or signs attributable to kidney failure (serositis, acid-base or electrolyte abnormalities, pruritus); inability to control volume status or BP; a progressive deterioration in nutritional status refractory to dietary intervention; or cognitive impairment.[2] These problems often but not invariably occur when the GFR is below 15 ml/min/1.73 m^2 (see Chapter 90).

Conservative Management

The potential burden of commencing RRT in terms of high short-term mortality rates, recurrent hospitalizations, time spent traveling, and limited improvement in quality of life for some elderly patients and those with multiple comorbid disease is increasingly recognized. This has led to the practice of offering patients approaching ESRD the additional option of choosing not to start dialysis, but to maintain ongoing follow-up and symptomatic support through conservative management. Although dialysis may offer longer survival, those choosing conservative management may have as many hospital free-days as those who choose hemodialysis.[41] The symptoms of advanced uremia can be distressing, and it is important to ensure that patients who choose this pathway have access to members of the multidisciplinary team with expertise in palliative care to facilitate a death free of suffering.

SELF-ASSESSMENT QUESTIONS

1. Which of the following is the most common cause of death for people with chronic kidney disease (CDK) (estimated glomerular filtration rate [eGFR] <60 ml/min/1.73 m^2)?
   - **A.** Failure of dialysis access
   - **B.** Sepsis
   - **C.** Withdrawal from dialysis
   - **D.** Cardiovascular disease
   - **E.** Cerebrovascular disease
2. The equation recommended by Kidney Disease: Improving Global Outcomes (KDIGO) for estimating GFR is:
   - **A.** The Modification of Diet in Renal Disease (MDRD) equation
   - **B.** The Cockcroft-Gault formula
   - **C.** The Chronic Kidney Disease–Epidemiology Collaboration (CKD-EPI) formula
   - **D.** The Mayo Clinic Quadratic formula
   - **E.** The Schwartz formula
3. Which of the following variables is *not* needed to calculate eGFR from the CKD-EPI formula?
   - **A.** Age
   - **B.** Weight
   - **C.** Race
   - **D.** Sex
   - **E.** Creatinine
4. Which of the following symptoms is suggestive of CKD, regardless of cause?
   - **A.** Pain in the renal angle
   - **B.** Nocturia
   - **C.** Urinary frequency
   - **D.** Tremor
   - **E.** Anuria
5. In a well patient, which of the following biochemical or hematologic abnormalities is suggestive of CKD rather than acute kidney injury?
   - **A.** Calcium 3.5 mmol/l
   - **B.** Potassium 7.5 mmol/l
   - **C.** Hemoglobin 10.7 g/dl
   - **D.** Creatinine 13.5 mg/dl
   - **E.** Sodium 132 mmol/l

Cardiovascular Disease in Chronic Kidney Disease

Peter Stenvinkel, Charles A. Herzog

Diminished estimated glomerular filtration rate (eGFR) and albuminuria are powerful graded, independent predictors of cardiovascular (CV) morbidity and mortality[1] and all-cause mortality (Fig. 81.1). Even subtle kidney dysfunction, as suggested by albuminuria, increases CV risk because it may reflect microvasculature health, including endothelial function. Patients with end-stage renal disease (ESRD) face an extraordinary risk for premature death, largely because of CV complications. However, patients with eGFR below 60 ml/min/1.73 m^2 are much more likely to die than to develop ESRD, reflecting the burden of cardiovascular disease (CVD) in this population. The most effective strategy for reducing CV morbidity and mortality would be to target patients with mildly reduced eGFR for prevention and treatment.

Patients with chronic kidney disease (CKD) were often excluded from randomized controlled trials (RCTs) targeting CVD, possibly reducing acceptance of evidence-based therapies (validated in nonrenal patients) and fostering "therapeutic nihilism" in clinicians who treat CKD patients. Thus novel treatment strategies are urgently needed to reduce the unacceptable high CV event rate.

Like conventional atheromatous occlusive vascular disease, CKD is characterized by generalized vasculopathy, with other characteristics, including left ventricular hypertrophy (LVH), vascular calcification, and vascular noncompliance. Numerous CVD risk factors are specific to CKD and operate in addition to conventional risk factors found in the general population.

EPIDEMIOLOGY

Prevalence of Cardiovascular Complications in Chronic Kidney Disease

Interpretation of epidemiologic studies of CVD is problematic because of the difficulty in defining cause of death. Unexpected sudden death most likely results from arrhythmia, but a subarachnoid hemorrhage, massive embolic stroke, or aortic dissection might be indistinguishable from a primary arrhythmic event without an autopsy. Defining "coronary heart disease" (CHD) is also problematic: in the general population, sudden cardiac death is a primary complication of CHD, but this is unlikely to be true for dialysis patients. A history of angina cannot reliably classify a patient as having CHD because angina (resulting from supply-demand mismatch) can occur in patients with LVH and angiographically pristine coronary arteries. This probably relates to the increased myocardial fibrosis, diminished relative capillary density, and increased thickening of the intramyocardial vessel walls in uremia. At lower levels of eGFR (especially in dialysis patients), the burden of nonatherosclerotic (vs. atherosclerotic) CVD is relatively increased (Fig. 81.2).[2] Although occlusive CHD is common in CKD, acute myocardial infarction (AMI) accounts for only 14% of cardiac deaths; 66% of cardiac deaths in the U.S. Renal Data System (USRDS) database are attributable to arrhythmias.

Of incident dialysis patients, 75% have LVH and 75% to 85% have hypertension. Hypertension, anemia, vascular noncompliance, and volume overload contribute to LVH. Based on echocardiography, 85% to 90% of patients have a left ventricular (LV) ejection fraction (EF) of 50% or higher, despite frequent congestive heart failure (CHF), that is, heart failure with preserved EF (HFpEF), not heart failure with reduced EF (HFrEF), characterizes most CHF episodes. Therefore, many volume overload episodes in dialysis patients may be attributable to diastolic dysfunction or circulatory congestion. Fig. 81.3 provides a snapshot of CVD event rates in prevalent dialysis patients.

Cardiovascular Disease Is Present Before the Start of Renal Replacement Therapy

In elderly CKD patients at stage 2 or 3, traditional risk factors seem to be the major contributors to CV mortality. Atherosclerosis Risk in Communities (ARIC) data suggest that both traditional and novel risk factors are relevant at CKD stage 4, and novel risk factors are far more prevalent in dialysis patients than in the general population (Fig. 81.4).[3] The Framingham predictive instrument does not accurately predict coronary events in CKD. Mild to moderate CKD is associated with increased risk for venous thromboembolism, supporting the concept of hypercoagulability in CKD. Fig. 81.5 shows the burden of CVD in elderly patients with CKD. Because the incidence of CV events is much higher in the first weeks after hemodialysis (HD) initiation, concerns have been raised that the dialysis procedure per se may trigger CV events.[4]

Racial and International Differences in Cardiovascular Disease Prevalence

In the United States, survival is better for African American than for White dialysis patients. However, overall CV mortality among dialysis patients from the United States is significantly greater than is observed in Japan and Europe, even after adjustment for standard risk factors and dialysis dose. Higher mortality rates in U.S. dialysis patients may be related to higher prevalence of sicker or diabetic patients, differences in dialysis practice patterns, cultural habits, differences in diet, or genetic variations.

Reverse Epidemiology

Reverse epidemiology (preferably called *confounded epidemiology*) refers to the paradoxical observation that the association among hypercholesterolemia, hypertension, obesity, and poor outcomes, including CV death, in the general population does not exist and may be reversed in CKD. Patients with wasting and inflammation appear to mostly account for poor survival and confounded epidemiology.

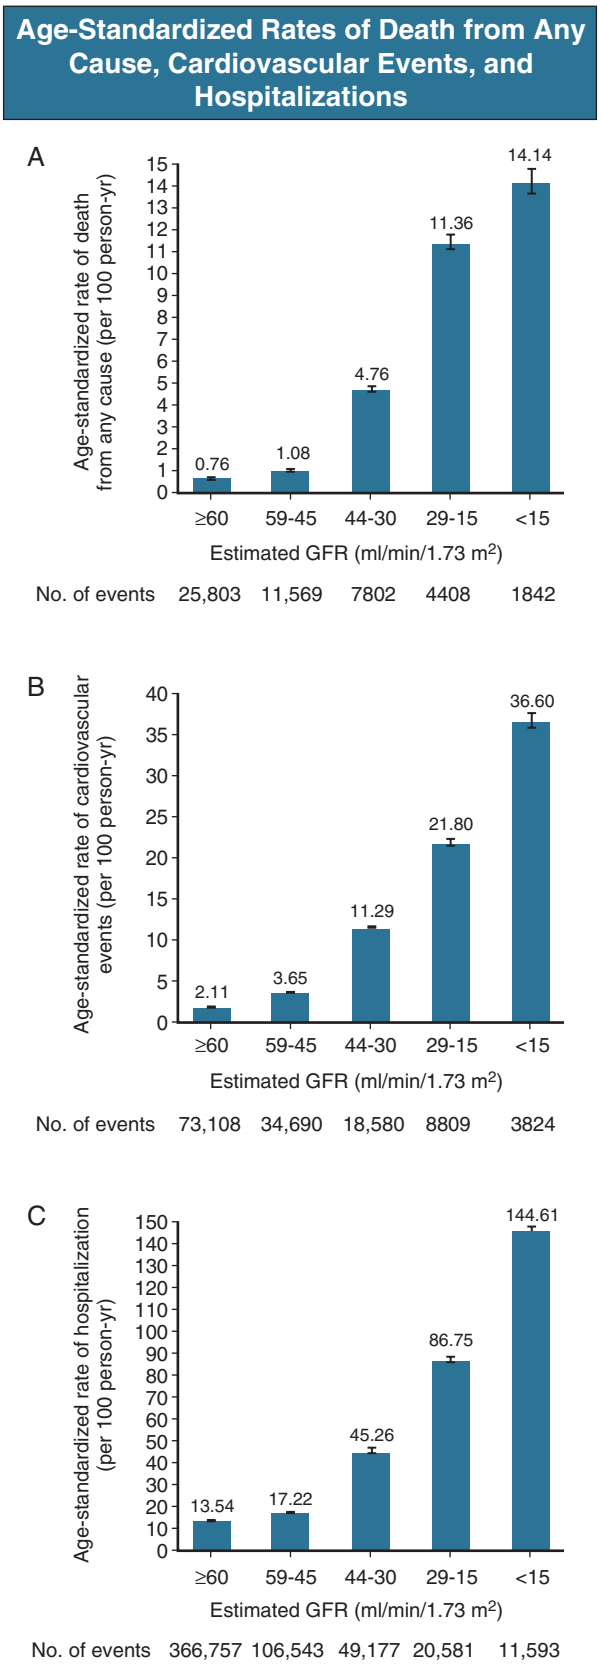

Fig. 81.1 Age-standardized rates of death from any cause (A), cardiovascular events (B), and hospitalization (C) according to estimated glomerular filtration rate *(GFR)* among 1,120,295 ambulatory adults. A cardiovascular event was defined as hospitalization for coronary heart disease, heart failure, ischemic stroke, or peripheral arterial disease. Error bars represent 95% confidence intervals. The rate of events is listed above each bar. (From reference 1.)

ETIOLOGY AND RISK FACTORS

Traditional Risk Factors

Age, Gender, and Smoking

The U.S. National Health and Nutrition Examination Surveys (NHANES) show the prevalence of CV factors and CVD prevalence in relation to age and CKD stage. In the United States, the average age at renal replacement therapy (RRT) initiation is 63 years, when CVD is common. An individual-level meta-analysis including more than 2 million participants showed that low eGFR and high albuminuria were independently associated with mortality and ESRD regardless of age. Female gender is associated with a 4% independent increased risk for mortality in incident dialysis patients and smoking with a 52% increased risk for death in dialysis patients.

Diabetes Mellitus

Diabetes accounted for 44% of incident U.S. ESRD patients in 2010[5] and is the most common cause of ESRD in many countries. Diabetic patients starting RRT have numerous CV risk factors, including dyslipidemia, hypertension, persistent inflammation, increased oxidative stress, and protein-energy wasting. Diabetes at dialysis initiation is a

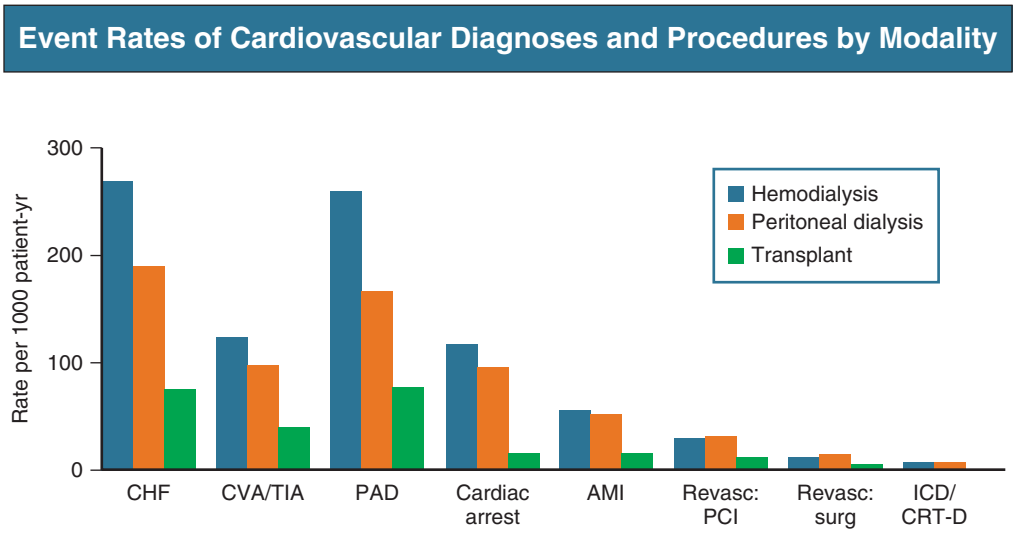

Fig. 81.3 Event rates of cardiovascular diagnoses and procedures by modality. Chronic kidney disease	No change	↓	No change*	↑↑
Hemodialysis	No change	↓	No change*	↑↑
Peritoneal dialysis	↑	↓	↑	↑
Transplantation	↑↑	No change	↑	↑

*Composition altered.

potent independent risk factor for all-cause and CVD-related deaths, including after coronary revascularization or AMI. Nevertheless the rate of incident AMI is even higher for patients with CKD stages 3b to 4 without diabetes than for patients with diabetes and CKD stages 1 or 2.

Hypertension

Hypertension is common but variably treated in CKD patients. Of NHANES subjects with CKD stages 3 to 4, 80% had a blood pressure (BP) of 130 or greater/80 or greater mm Hg, and only 20% were aware of it and had BP adequately controlled. In CKD stages 1 and 2, 63% were hypertensive and only 11% were adequately controlled. Recent NHANES data suggest modest improvement in hypertensive people with CKD stages 3 or 4.[6] Hypertension predicts mortality in CKD patients before or at dialysis initiation. Isolated systolic hypertension with increased pulse pressure is by far the most prevalent BP anomaly in dialysis patients, resulting from arterial medial sclerosis with secondary stiffening. Stiff vessels cause increased pulse wave velocity, resulting in increased systolic BP (SBP) peak pressure by a prematurely reflected pulse wave, progressive LV dysfunction, and finally CHF. At this stage, mean arterial and diastolic pressure may decrease. The relationship between BP and mortality is U shaped; isolated systolic hypertension and increased pulse pressure probably indicate high long-term risk in dialysis patients, whereas low mean and diastolic BPs (DBPs) predict early mortality. CKD patients are frequently "nondippers" and experience sleep apnea and sympathetic nervous system activation.

Dyslipidemia

The relationship between hypercholesterolemia, CVD, and mortality in CKD is weak because some CV abnormalities, such as cardiomyopathy and arteriosclerosis, may be less dependent on dyslipidemia than on other factors. Low rather than high serum cholesterol level is associated with poor survival in HD patients, likely related to confounding by protein-energy wasting and inflammation. After adjustment for C-reactive protein (CRP) levels, high cholesterol level predicts risk in noninflamed ESRD patients.

Progressive CKD leads to changes in blood lipids typically associated with vascular disease, including decreased apolipoprotein A (apoA)-containing lipoproteins and increased apoB-containing lipoproteins (Table 81.1). Serum triglycerides are elevated in most ESRD patients, whereas

Risk Factors for Cardiovascular Disease in Chronic Kidney Disease

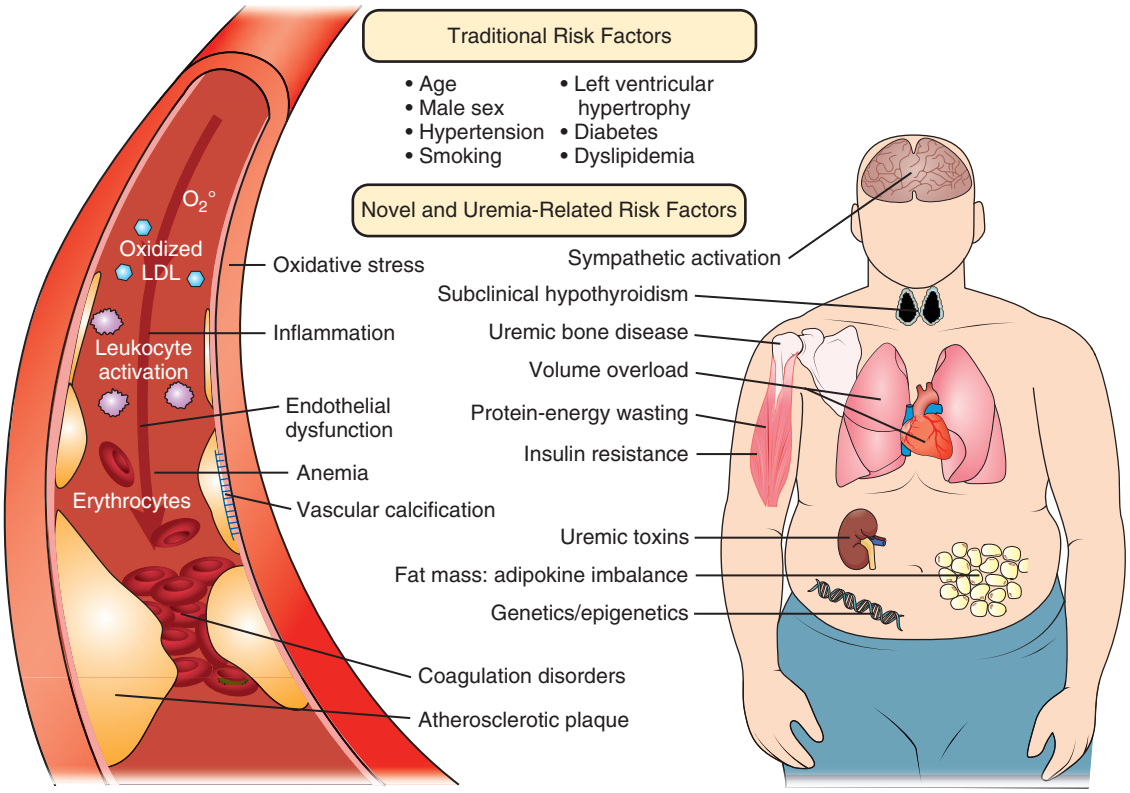

Fig. 81.4 Risk factors for cardiovascular disease in chronic kidney disease. Overview of traditional (i.e., Framingham) risk factors and novel and uremia-related risk factors. *LDL,* Low-density lipoprotein. (From reference 3.)

Cardiovascular Disease in Patients with or Without CKD

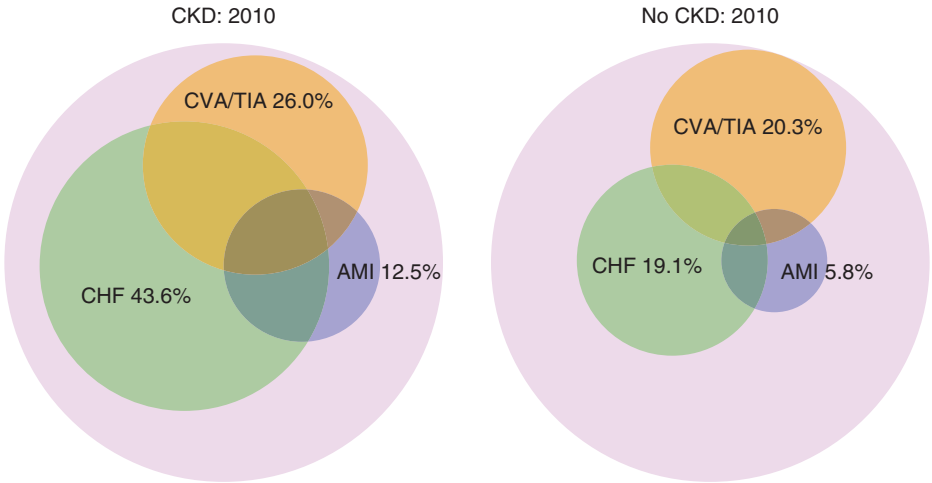

Fig. 81.5 Cardiovascular disease in patients with or without chronic kidney disease *(CKD),* 2010. Relative frequency of cardiovascular disease in Medicare enrollees, age 66 and older, with or without CKD. *AMI,* Acute myocardial infarction; *CHF,* congestive heart failure; *CVA,* cerebrovascular accident; *TIA,* transient ischemic attack. (From reference 5.)

total serum cholesterol is variable, depending on nutritional status and presence of inflammation. High-density lipoprotein (HDL) cholesterol is typically reduced, and low-density lipoprotein (LDL), intermediate-density lipoprotein, and very low-density lipoprotein cholesterol, as well as lipoprotein(a) levels, tend to be increased. Because of altered molecular composition, the antiinflammatory activity of HDL is reduced in the uremic milieu. Compared with long-term HD patients, peritoneal dialysis (PD) patients more often have both hypercholesterolemia and hypertriglyceridemia. Both groups are characterized by low HDL and elevated oxidized LDL cholesterol levels; elevated lipoprotein(a) levels are associated with increased CVD mortality.

Insulin Resistance and Atherosclerosis

In the general population, impaired insulin-stimulated glucose disposal in muscle is often part of a metabolic syndrome that includes dyslipidemia, hypertension, endothelial dysfunction, and sympathetic overactivity. Many of these abnormalities are present in CKD. Although insulin resistance was found to be an independent predictor of CV mortality in dialysis patients, its magnitude of contribution in CKD mortality is uncertain.

Nontraditional and Uremia-Specific Risk Factors

Even mild CKD is an independent risk factor for CVD, and similar in magnitude to diabetes and hypertension. The uremic milieu may affect both quality and quantity of the atherosclerotic plaques. Coronary lesions in uremic patients, compared with nonrenal controls, are characterized by increased media thickness, infiltration and activation of macrophages and marked media calcification. The mechanism(s) by which a uremic milieu may promote vascular senescence and accelerate premature vascular aging[7] are not well established, but prevalence and magnitude of several nontraditional risk factors, such as oxidative stress, inflammation, and advanced glycation end-products (AGEs), increase as renal function deteriorates. Other uremic retention solutes, such as asymmetric dimethylarginine (ADMA), guanidine, indoxyl sulfate, and *p*-cresol, which accumulate in CKD, may have proatherogenic properties.[8] Finally, failing kidneys produce fewer substances that may inhibit CVD and atherogenesis—for example, renalase, a soluble monoamine oxidase that regulates cardiac function and BP.

Oxidative Stress

Oxidative stress may be implicated in the pathogenesis of atherosclerosis, the increased risk for atherosclerotic CV events, protein-energy wasting, and anemia. Increased production of reactive oxygen species in the vascular wall characterizes atherosclerosis. Moderate CKD, and in particular uremia, is a prooxidant state resulting from reduced antioxidant systems (vitamin C and selenium deficiency, reduced intracellular vitamin E levels, reduced glutathione system activity), and increased prooxidant activity associated with advanced age, diabetes, chronic inflammation, retained uremic solutes, and dialysis membranes and solutions. Four oxidative stress pathways can be hypothesized in CKD: carbonyl stress, nitrosative stress, chlorinated stress, and classic oxidative stress (Fig. 81.6).

Inflammation

Most dialysis patients are in a state of chronic inflammation. Inflammatory biomarkers, such as CRP, interleukin 6 (IL-6), pentraxin 3 (PTX3), fibrinogen, and white blood cell count, are independent predictors of mortality in CKD patients. Hypoalbuminemia, strongly associated with systemic inflammation, is another strong outcome predictor in CKD. Whereas both dialysis-related factors and non–dialysis-related factors (infection, comorbidity, genetic factors, hypogonadism, diet, renal function loss) may contribute to chronic inflammation, its

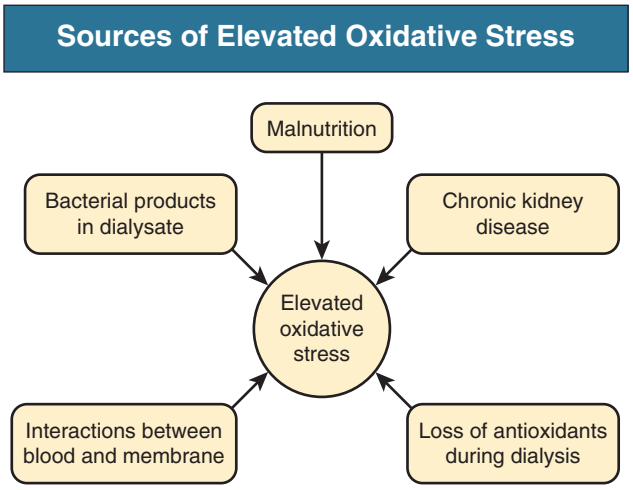

Fig. 81.6 Sources of elevated oxidative stress.

primary causes are not always evident. The senescence-associated secretory phenotype caused by increased numbers of senescent vascular cells also may be a significant contributor to uremic inflammation. Whether the acute-phase response reflects only established atherosclerotic disease or is involved in the initiation and progression of atherosclerosis is unclear. Some inflammatory biomarkers, such as IL-6, PTX3, and tumor necrosis factor, may have proatherogenic properties, such as promoting vascular calcification, oxidative stress, and endothelial dysfunction (Fig. 81.7). Evidence suggests associations between inflammation and development of albuminuria. Persistent inflammation may change the risk factor profile for traditional risk factors, such as cholesterol and obesity.[9] The link between septicemia and subsequent increased risk for death and CV events, including AMI, further supports inflammation as a trigger for CV events.

Gut Dysbiosis

The uremic milieu affects the intestinal microbiota and the integrity of the intestinal wall, possibly contributing to inflammation and increased production of uremic toxins such as proatherogenic indoxyl sulfate, phenylacetic acid, and *p*-cresol sulfate. The uremic milieu and volume retention may damage the intestinal wall, promoting increased leakiness of endotoxins and translocation of intestinal bacteria. The microbial metabolite trimethylamine N-oxide contributes to the development of atherosclerotic heart disease and is related to adverse CV outcomes in the general population[10] and in CKD patients.

Endothelial Dysfunction

Endothelial dysfunction (as evaluated by impaired endothelium-dependent vasodilation) is common in CKD. Reasons include inflammation, ADMA retention, oxidative stress, elevated fibroblastic growth factor-23 (FGF-23), dyslipidemia, hyperglycemia, and hypertension. Serum ADMA concentrations are associated with endothelial function in uremic resistance vasculature. Surrogate markers of endothelial dysfunction, such as ADMA, PTX3, and adhesion molecules, independently predict death.[3] Detached circulating endothelial cells are potential markers of endothelial damage and have prognostic value in HD patients.[3] Normally, in response to an ischemic insult and cytokine stimulation, endothelial progenitor cells are mobilized from the bone marrow to repair endothelial injury, and this seems to be impaired in CKD.

Anemia

Anemia is a major cause of LVH and LV dilation in CKD. Although partial correction of anemia with erythropoiesis-stimulating agents

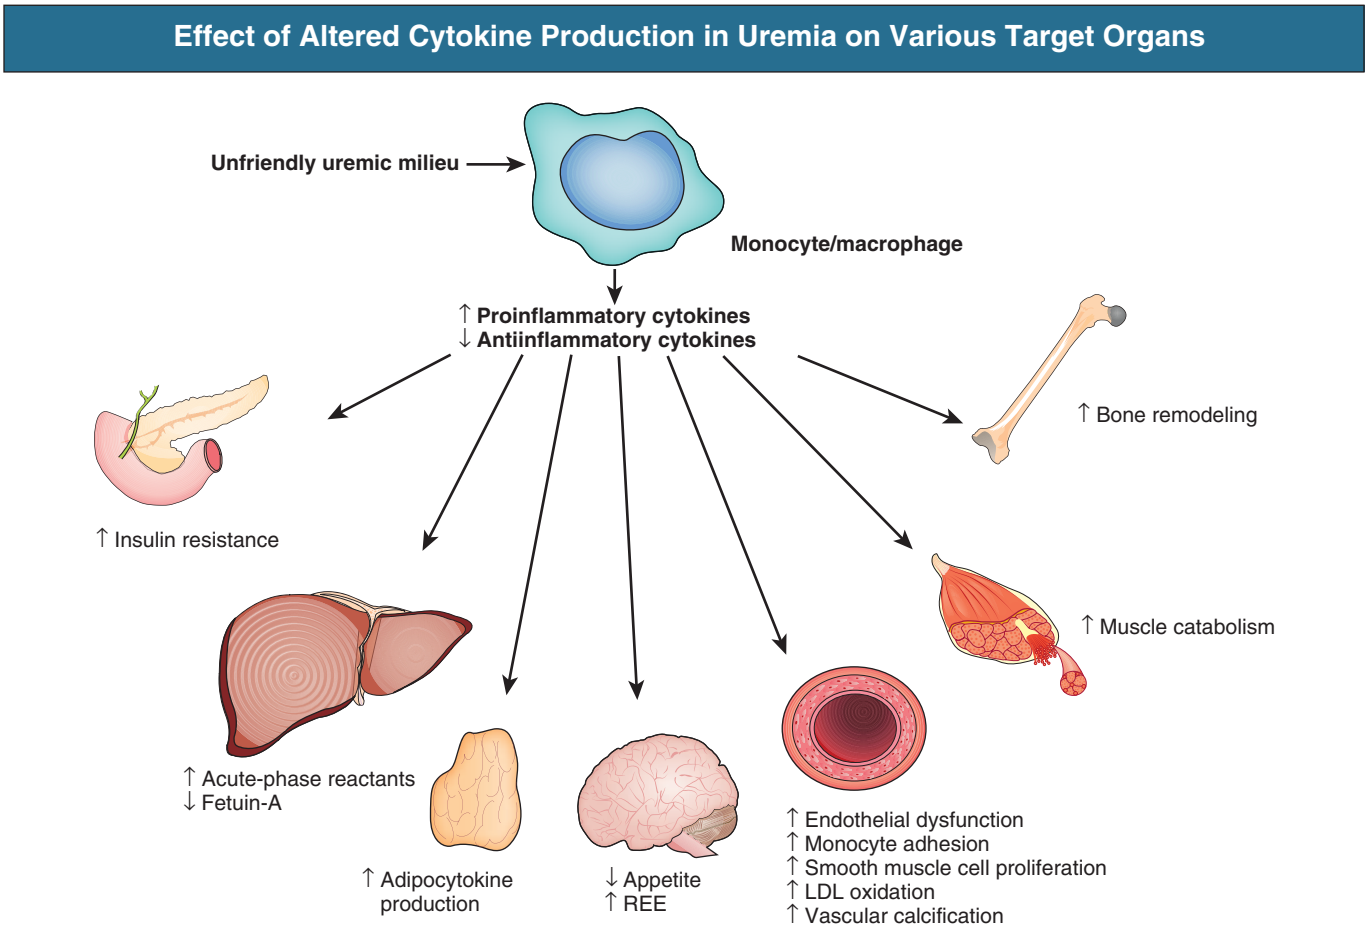

Fig. 81.7 Potential mechanisms by which elevated circulating levels of proinflammatory and antiinflammatory cytokines may promote accelerated atherosclerosis, other uremic complications, and wasting. *LDL,* Low-density lipoprotein; *REE,* resting energy expenditure. (From reference 8.)

(ESAs) results in LVH regression, current information suggests no CV outcome benefit of normalized hemoglobin (see Chapter 82).

Secondary Hyperparathyroidism and Mineral Metabolism

Disturbances of calcium and phosphate metabolism might accelerate calcifying atherosclerosis and arteriosclerosis (see also Chapter 85). Recent evidence suggests that chronically elevated FGF-23 levels contribute directly to high rates of LVH, atrial fibrillation (AF), and mortality. In registry data, a strong independent mortality risk is predicted by hyperphosphatemia, an intermediate risk by elevated serum calcium levels, and a weak risk by high or low serum intact parathyroid hormone (PTH) levels. The overall mortality risk prediction attributable to mineral metabolism disorders is estimated to be about 17% in HD patients.

Cardiovascular Calcification

CV calcification may affect the arterial media, atherosclerotic plaques, myocardium, and heart valves. Medial calcification causes arterial stiffness and, consequently, increased pulse pressure. The pathophysiologic role of plaque calcification is less clear because soft plaques are assumed to rupture and cause AMI; atherosclerotic calcification is a potent risk marker for CV events, but its utility as a risk marker for clinical management of CKD patients remains controversial. Valvular calcification mostly affects the aortic and mitral (annulus) valves in dialysis patients and contributes to progressive stenosis and associated morbidity and mortality. In dialysis patients, extensive vascular, especially coronary artery, calcification can occur at young ages. Calciphylaxis (calcific uremic arteriolopathy) is discussed in Chapter 88.

Vascular calcification is not derived only from passive calcium and phosphate precipitation. Rather, it involves differentiation of vascular smooth muscle cells toward osteoblasts induced by phosphate, calcium, and other factors, such as calcitriol and proinflammatory cytokines. Uremic bone disease and protein-energy wasting may be additional risk factors for vascular calcification.[11] One way by which chronic inflammation promotes vascular calcification may involve downregulation of fetuin-A, the most potent circulating inhibitor of extraosseous calcification and a component of calciprotein particles. Apart from fetuin-A, other inhibitors, such as magnesium, probably counteract unwanted calcification. Leptin, matrix GLA protein, FGF-23, pyrophosphates, bone morphogenic proteins (e.g., BMP-2 and BMP-7), and osteoprotegerin may be related to accelerated vascular calcification in ESRD. Deficiency of vitamin K and/or treatment with vitamin K antagonists (warfarin) may accelerate the vascular calcification process in the uremic milieu.

Advanced Glycation End-Products

AGEs accumulate in CKD patients as a result of nonenzymatic glycation, oxidative stress, intestinal food components, and diminished clearance of AGE precursors. Stable AGE residues of long-lived proteins are biomarkers of cumulative metabolic, inflammatory, and oxidative stress; carbonyl stress is speculated to contribute to tissue aging and

long-term CKD complications. Whether AGE inhibition may affect CV disease in CKD is unknown.

Dialysis Modality

Reports from dialysis registries are inconsistent regarding whether HD or PD is associated with better outcomes. Valid mortality comparisons between HD and PD modalities are not available because this would require stratification of patients according to underlying ESRD cause, age, and level of baseline comorbidity. Cardiac arrhythmias, such as AF, seem to occur more often on the day of HD compared with PD.

CLINICAL MANIFESTATIONS AND NATURAL HISTORY

Fig. 81.8 shows survival of patients with CV diagnoses and procedures, by RRT modality.

Chest Pain, Coronary Heart Disease, and Acute Myocardial Infarction

AMI in dialysis patients is associated with poor long-term survival. The unadjusted 2-year mortality rate is not changing: 71% in 1977 to 1984 and 72% in 2008,[12] despite dramatic improvements in AMI outcomes in the general population (Fig. 81.9). Significant improvement has occurred only in patients with ST-segment elevation myocardial infarction (STEMI), specifically related to in-hospital mortality. Rates of non-STEMI (NSTEMI) mortality or postdischarge mortality have not improved.[12] In-hospital deaths increase with decreasing GFR.[13] This poor outcome has been attributed to underrecognition resulting from atypical presentations, underuse of appropriate diagnostic investigations, and undertreatment (therapeutic nihilism).[14] A U.S. registry of dialysis patients hospitalized for AMI found the following[14]:

- 45% of dialysis, versus 21% of nondialysis patients, were diagnosed incorrectly with respect to acute coronary syndrome (ACS).
- 44% of dialysis, versus 68% of nondialysis patients, experienced chest pain.
- 19% of dialysis, versus 36% of nondialysis patients, had ST-segment elevation.
- After other clinical exclusions, only 10% of dialysis, versus 25% of nondialysis patients, were eligible for acute coronary reperfusion.
- Of those who were eligible, 47% of dialysis and 75% of nondialysis patients actually received reperfusion.
- In-hospital death was 21% for dialysis and 12% for nondialysis patients. In-hospital cardiac arrest occurred twice as frequently in dialysis as in nondialysis patients (11% vs. 5%).

Similar findings occur across the CKD spectrum; the likelihood of increased mortality and lower prevalence of both STEMI and chest pain are correlated with severity of non–dialysis-dependent CKD in

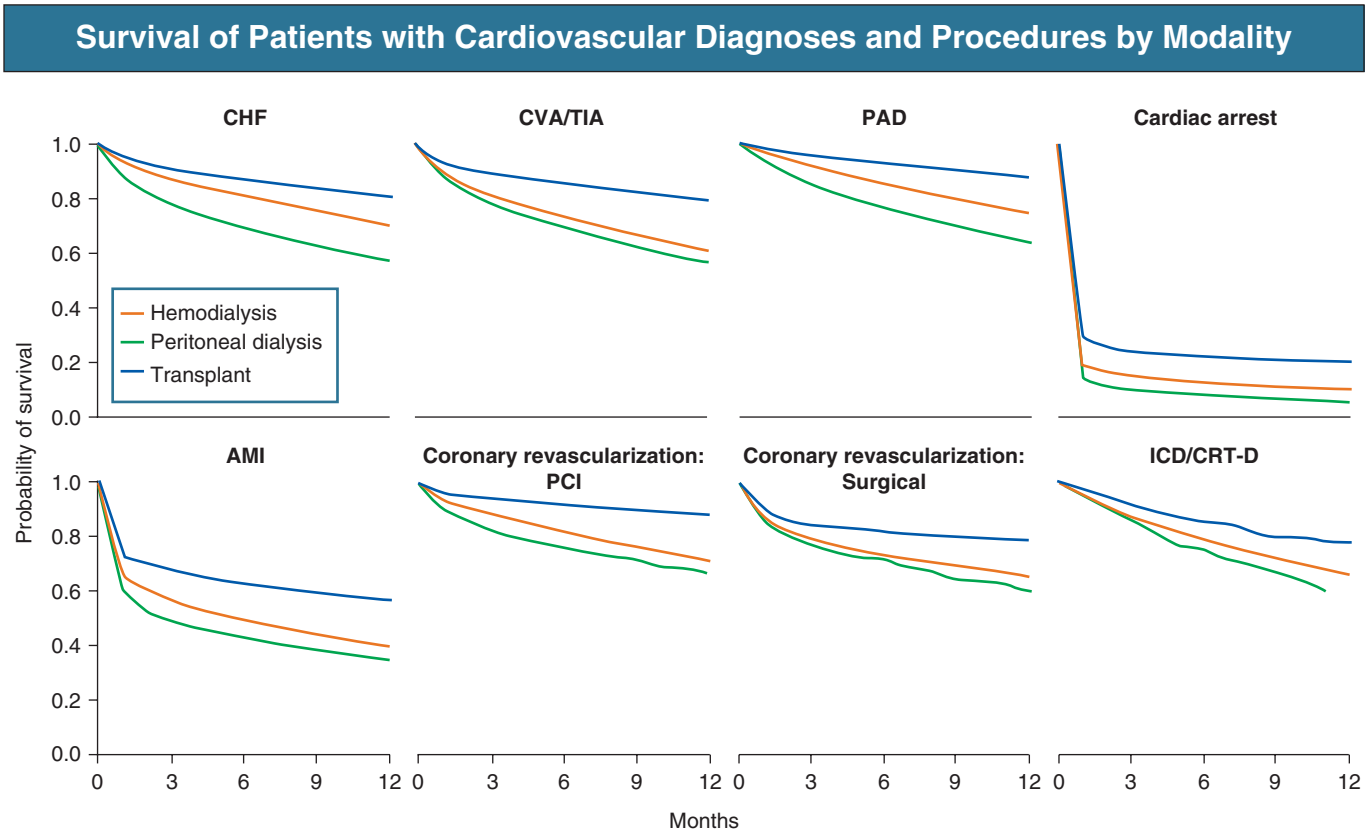

Fig. 81.8 Survival of patients with cardiovascular diagnoses and procedures, by modality. patients with AMI.[13,15] Patients with eGFR below 45 ml/min/1.73 m^2 are three times as likely to present with AMI as the initial manifestation of CHD, rather than stable angina.

Peripheral Arterial Disease

Risk for peripheral arterial disease (PAD) is highest for dialysis patients with diabetes or preexisting atherosclerosis. In HD patients, PAD is also associated with time on dialysis, hypoalbuminemia, low PTH levels, and low predialysis DBP. Vascular medial calcification of large peripheral arteries may not indicate occlusive disease, and peripheral gangrene is often caused by diabetic or other small-vessel disease or rarely by calcific uremic arteriolopathy (see Chapter 88). PAD is associated with increased mortality; outcomes after revascularization are worse than for the general population, in part reflecting advanced vasculopathy. Although one fourth of CKD patients and half of HD patients have PAD,[5,16] knowledge gaps regarding their treatment are large.[17]

Cerebrovascular Disease and Atrial Fibrillation

Cognitive impairment is severe in more than a third of dialysis patients, and only 15% have normal cognition. Cognitive impairment prevalence increases approximately 10% per 10 ml/min/1.73 m^2 of eGFR less than 60 ml/min/1.73 m^2. Microalbuminuria and stage 3 CKD increased stroke risk 1.5-fold to 2-fold in a multivariate model and stroke risk increases to 6-fold in incident dialysis patients; 11% of stroke hospitalizations in dialysis patients were attributed to hemorrhagic stroke. Silent cerebral microbleeds occur in 20% of CKD patients, predict CVD,[18] and may explain the fourfold to sevenfold increase in stroke incidence that immediately follows dialysis initiation.[19] Stroke accounts for 3% of ESRD deaths in the USRDS registry[5] (see Chapter 86 for more details).

AF is the most common dysrhythmia in CKD patients, and its incidence is increasing in older patients initiating dialysis in the United States.[20] Incident AF is an independent risk factor for development of ESRD in CKD.[21] Prevalence among dialysis patients is 15% to 20%, and this increased to 27% (58% of these episodes were paroxysmal AF[22]) and 40% in small series employing implantable loop recorders. Among AF patients with stage 3 CKD, adjusted-dose warfarin was associated with a 76% reduction in the relative risk for ischemic stroke or systemic embolism.[23] In AMI patients with AF, warfarin treatment was associated with a lower 1-year risk for the composite outcome of death, AMI, and ischemic stroke without a higher risk for bleeding, irrespective of CKD severity. In contrast, the usefulness of warfarin for primary prevention of stroke in dialysis patients with AF is controversial; some observational studies suggest harm, and current Kidney Disease: Improving Global Outcomes (KDIGO) recommendations do not include routine warfarin therapy for primary prevention of stroke in AF patients with CKD stage 5D (however, warfarin for secondary prevention of stroke is recommended).[17,24]

The therapeutic approach to primary prevention of stroke in ESRD remains controversial. There are few data on the safety and efficacy of novel oral anticoagulants (NOACs), and warfarin use is made challenging by the difficulty of maintaining dialysis patients in optimal anticoagulation range and the potential for accelerated vascular calcification with vitamin K antagonists. The case favoring NOACs rather than warfarin in moderate CKD is less controversial, based on post hoc analysis of RCTs (Fig. 81.10). No data support the sole use of aspirin for prevention of stroke in CKD patients with AF.

Left Ventricular Remodeling and Hypertrophy

LVH occurs early in progressive CKD, probably because of high hypertension prevalence, including frequent nocturnal hypertension. Pressure overload, caused by hypertension and arterial stiffness, results in concentric hypertrophy. Volume overload manifests as eccentric hypertrophy. LV dilation strongly predicts poor outcome. It may be an end result of severe LVH, diffuse ischemic damage, or recurrent volume overload; a high-output arteriovenous fistula may contribute. Diastolic dysfunction is strongly associated with LVH and with increased risk for intradialytic hypotension because relatively small reductions in left atrial filling significantly affect cardiac output in these stiff, hypertrophied preload-sensitive hearts, together with the Bezold-Jarisch reflex activation through stimulation of LV posterior wall stretch receptors in underfilled, hypercontractile, hypertrophied ventricles.

The term *uremic cardiomyopathy* is misleading; *cardiomyopathy of advanced CKD* more accurately describes the structural heart disease that occurs before ESRD onset. There is no change in LV mass index in patients with eGFR below 20 ml/min/1.73 m^2 (not on dialysis) serially imaged with echocardiograms and subsequently imaged after dialysis initiation (i.e., after incident ESRD).[25] Dialysis initiation was associated with a small drop in LVEF in some but not all studies. In patients with stage 4 CKD (and no clinical heart failure), 75% had LVH and only about 10% had normal LV geometry.[26]

Conventional HD delivery can produce repetitive myocardial injury, leading to global and segmental reduction in LV systolic function; the occurrence of HD-induced myocardial stunning is associated with increased 1-year mortality. Even pediatric HD patients can experience HD-induced myocardial stunning, indicating that large-vessel obstructive CHD is not a prerequisite for this pathologic finding. Biofeedback dialysis or reduced dialysate temperature both help reduce intradialytic hypotension and severity of HD-induced myocardial stunning.

Extracellular Volume Overload

Extracellular volume overload resulting from loss of sodium excretory capacity is the major cause of hypertension in dialysis patients. Whether prevention of recurrent hypervolemia reduces CV morbidity and mortality remains unproved. If adjustments are made for comorbidity and advanced age, a strong, incremental risk for all-cause and CV mortality is associated with interdialytic weight gains. Recurrent hypervolemia may result in LVH and LV dilation, peripheral or pulmonary edema,

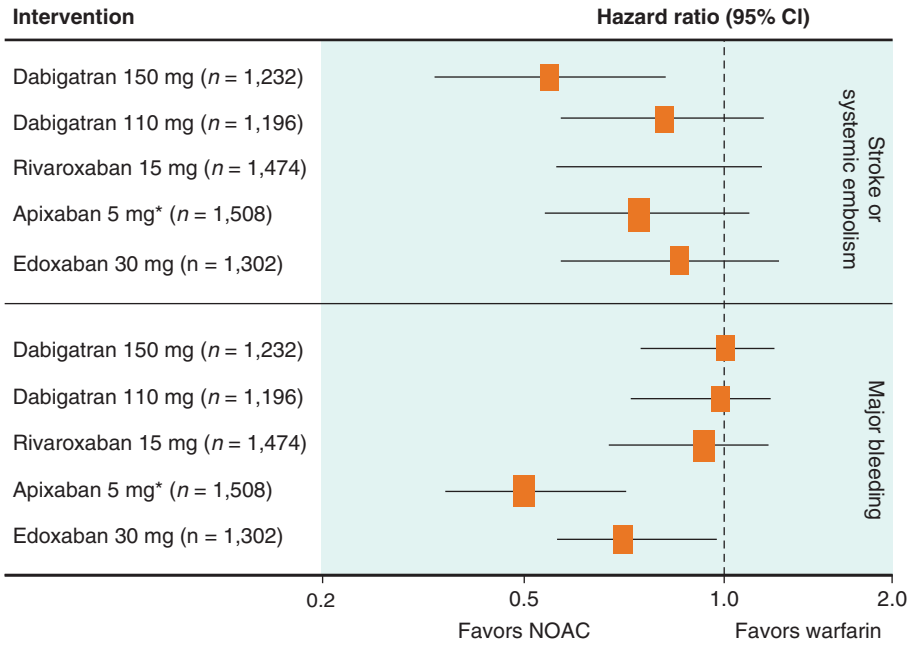

Fig. 81.10 Efficacy and safety of novel oral anticoagulants *(NOACs)* versus warfarin in the subgroup of patients with moderate chronic kidney disease from randomized, clinical trials in atrial fibrillation. (From Qamar A, Bhatt DL. Stroke prevention in atrial fibrillation in patients with chronic kidney disease. *Circulation* 2016;133(15):1512-1515.)

raised jugular vein pulse, or a third heart sound, or it may be largely asymptomatic. Tolerance of large ultrafiltration volumes may indicate that the dry weight target (see Chapter 96) has not been reached. Reaching an optimal dry weight, however, does not necessarily lead to immediate BP correction; a lag phase of some weeks can precede improvement.

Pericarditis

Dialysis-associated pericarditis may be related to intercurrent illnesses (including viral infections), fistula recirculation leading to underdialysis, or underlying diseases such as systemic lupus. Fever with pericardial pain or a rub on heart auscultation, unexplained cardiomegaly on chest films, or hemodynamic instability should prompt echocardiography. An effusion causing overt hemodynamic compromise (i.e., pericardial tamponade) or large pericardial effusions judged unlikely to resolve with conservative measures require echocardiographically guided or computed tomography (CT)-guided pericardiocentesis or surgical drainage. Intensive dialysis is indicated for true uremic pericarditis; the optimal treatment of dialysis-associated pericarditis is much less clear in patients without hemodynamic compromise. Citrate-based anticoagulation is preferred given the risk for hemorrhage-induced pericardial tamponade.

Autonomic Dysfunction

There is decreased baroreflex sensitivity in CKD, which has been linked to increased risk for sudden death. Increased sympathetic nerve activity, including secondary to sleep apnea, is a common alteration in CKD patients and associated with adverse outcome.

Valvular Disease

The rate of progression of calcific aortic stenosis is approximately three times faster in dialysis patients than in the general population. Annual echocardiography is recommended for asymptomatic dialysis patients with an aortic valve area of 1.0 cm^2 or less[27] who are suitable candidates for valve replacement. A meta-analysis of dialysis patients undergoing valve replacement surgery found no difference in survival for patients receiving tissue versus mechanical valves and fewer valve-related complications with tissue valves. The overall mortality is high, with in-hospital mortality about 20% (four times higher than in non-CKD patients) and 2-year survival of 40%. Transcatheter aortic valve replacement may be appropriate in dialysis patients with symptomatic aortic stenosis who are not good candidates for surgery. In kidney transplant recipients, in-hospital mortality was 11% for tissue and 15% for mechanical valve patients, and 2-year mortality rates were 62% and 60%, respectively. In the entire cohort of kidney transplant patients, the rate of endocarditis after valve surgery was 5% per year.[28]

Infective Endocarditis

Estimated incidence of infective endocarditis in U.S. dialysis patients is 267 cases per 100,000 patient-years. Vascular access, including temporary and semipermanent catheters, is an important source of infection; heightened risk for bacteremia related to HD therapy is likely an important aspect of endocarditis risk. Dialysis patients with bacterial endocarditis have poor in-hospital and long-term survival. One-year survival for U.S. dialysis patients with endocarditis who subsequently received valve replacement surgery was about 50%.[29] A risk model for operative mortality may be helpful in managing these high-risk patients.

Sudden Cardiac Arrest

In the USRDS database, two thirds of all cardiac deaths and one quarter of all-cause mortality in dialysis patients are attributable to arrhythmias.[5] The reported rate of cardiac arrest in HD centers is 3.8 to 7.1 events per 100,000 dialysis sessions. Strong predictors of sudden cardiac death are history of CHD, PAD, diabetes, elevated inflammatory biomarkers, and reduced LVEF. Even a modest reduction in LVEF to 40% to 50% is prognostically important in both HD[30] and PD patients. Myocardial fatty acid imaging might identify patients at risk for sudden death. Factors probably contributing to the special vulnerability of ESRD patients to sudden cardiac arrest include LVH; rapid electrolyte shifts and hyperkalemia in HD; autonomic dysfunction and sympathetic overactivity, including sleep apnea; and abnormalities in myocardial

ultrastructure and function, including endothelial dysfunction, interstitial fibrosis, decreased perfusion reserve, and diminished ischemia tolerance.[31] Low-potassium dialysate (<2 mmol/l) doubles the risk for cardiac arrest.[32] The rate of cardiac arrest is 50% higher for HD than for PD patients 3 months after dialysis initiation but is higher for PD patients at 3 years. The highest rate of sudden cardiac death occurs in the first 2 months after HD initiation.[33] In cardiac arrests occurring in HD centers, the predominant rhythm is ventricular fibrillation (66%), followed by pulseless electrical activity (23%), and asystole (10%).

In women with CHD, eGFR below 40 ml/min/1.73 m^2 was associated with a 2.3-fold increased risk for sudden cardiac death. Despite a graded, incremental risk for arrhythmic death and impaired renal function, the overall magnitude of risk in stage 3 CKD patients is small compared with that in dialysis patients.

Onsite defibrillation capability in HD centers (preferably with automatic external defibrillators) was recommended in a U.S. practice guideline in 2005.[27] The role that implantable cardioverter-defibrillators (ICDs) may play in reducing mortality in CKD patients is controversial, particularly regarding primary prevention. CKD may attenuate the survival advantage of ICDs, but older age and medical comorbidity should not routinely exclude patients from receiving ICDs. In dialysis patients who survived cardiac arrest, ICD implantation was associated with a 14% to 42% reduction in long-term mortality.[34] The role of ICDs in dialysis patients is uncertain: the Wearable Cardioverter Defibrillator in Hemodialysis Patients (WED-HED) trial (clinicaltrials.gov, NCT02481206) was a prospective RCT, testing wearable defibrillators for prevention of sudden cardiac death in incident HD patients who do not qualify for ICDs under current guidelines. Unfortunately, the trial was terminated in 2017 due to low enrollment.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Key issues in the diagnosis of CVD are underrecognition of symptoms, underuse of appropriate diagnostic investigations, and interpretation of those investigations.

Blood Pressure Measurements

Outcome prediction by ambulatory BP monitoring is not necessarily better than by office BP measurements. However, ambulatory monitoring is useful to identify high-risk nondippers and inverted dippers, allowing consequent treatment adjustments.

Electrocardiography and Echocardiography

The National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (KDOQI) clinical practice guidelines for CVD in dialysis patients recommend an electrocardiogram at dialysis initiation and then annually.[27] Diabetic HD patients presenting without sinus rhythm (11% of the cohort) were 89% more likely to die and 164% more likely to sustain a stroke. CKD patients (eGFR <60 ml/min/1.73 m^2) with increased QRS duration had 15% greater risk for incident CHF, 13% greater risk of incident CHD, and 17% greater risk for mortality per 10-ms increase; prolongation of the QT interval was independently associated with adverse outcome.

KDOQI guidelines recommend echocardiography in all dialysis patients after they achieve "dry weight" targets, preferably 1 to 3 months after dialysis initiation on an interdialytic day for HD patients and at 3-year intervals thereafter.[27] The rationale for this guideline is that diminished LV systolic function, an important independent risk factor for CVD and mortality,[27] is not accurately diagnosed by history, physical examination, or chest radiography. Detection of unsuspected cardiomyopathy is also important, given that carvedilol therapy in such patients improved LV systolic function, decreased hospitalization, and reduced mortality. As in the general population, CKD patients with LVEF below 40% should be evaluated for CHD (exceptions are pediatric or young adult patients with nondiabetic CKD and other patients known to be at low risk for CHD).

A new classification scheme for CHF staging specifically targeted for dialysis patients has been proposed by the Acute Dialysis Quality Initiative (ADQI) XI Workgroup.[35] The three key elements are as follows:

1. Standardized echocardiographic evidence of structural and/or functional cardiac abnormalities.
2. Dyspnea occurring in the absence of primary lung disease, including isolated pulmonary hypertension (i.e., not secondary to elevated pulmonary capillary wedge pressure).
3. Improvement of congestive symptoms after RRT/ultrafiltration.

The justification for the KDOQI 2005 Guidelines (recommending echocardiograms in incident dialysis patients) *and* the validity of the first element of the proposed ADQI XI heart failure staging scheme (standardized echocardiographic evidence of structural and/or functional heart disease) are both supported by the finding that right ventricular dysfunction was associated with a 66% increased risk for death.[36]

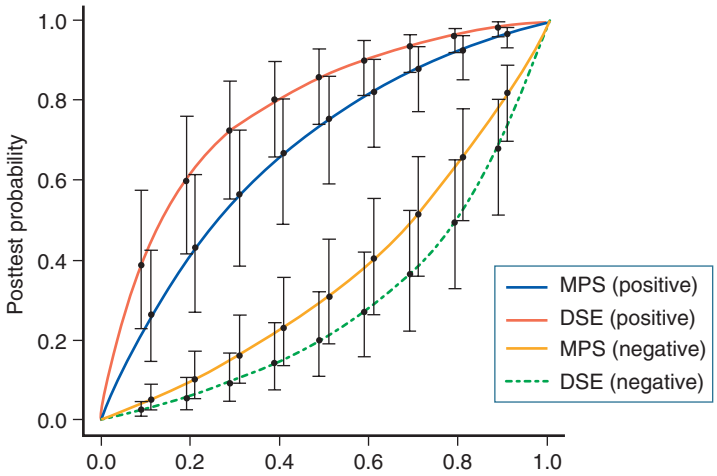
Stress Tests and Screening Renal Transplant Candidates

ESRD patients are poorly suited for conventional exercise stress electrocardiography because of limited exercise tolerance and frequent resting electrocardiographic abnormalities. Accuracies of pharmacologic stress echocardiographic and nuclear scintigraphic techniques are remarkably variable across the world; they are operator dependent, and the approach of individual sites to cardiac screening should rely on institutional expertise. Moreover, prediction of the likelihood of future events may differ considerably from prediction of coronary anatomy. In severe CKD, dobutamine stress echocardiography is an independent predictor of long-term mortality. Sensitivities and specificities for detection of CHD in renal transplant candidates have been reported to range from 44% to 90%. A meta-analysis concluded that presence of inducible myocardial ischemia by any stress-imaging test is independently predictive of increased AMI risk and cardiac death, whereas a fixed or resting defect or abnormality is predictive of cardiac death but not AMI. A subsequent meta-analysis by the Cochrane Collaboration (Fig. 81.11) concluded that dobutamine stress echocardiography is probably more accurate than myocardial stress nuclear scintigraphy for noninvasive detection of CHD in renal transplant candidates.[37]

The major problem with "screening" is use of test results for clinical management. The evidence for prophylactic revascularization of asymptomatic renal transplant candidates (or any other patient group) is weak.[38] The International Study of Comparative Health Effectiveness with Medical and Invasive Approaches–Chronic Kidney Disease Trial (ISCHEMIA-CKD; clinicaltrials.gov, NCT01985360) is a prospective RCT testing the comparative efficacy of a conservative versus invasive strategy for treatment of stable CHD in patients with eGFR less than 30 ml/min/1.73 m^2, including dialysis patients. The best observational data supporting the usefulness of preemptive coronary revascularization showed 3-year cardiac event–free survival of 90% for wait-listed revascularized patients.[39] Optimal medical therapy (which should constitute the treatment strategy for all patients) may potentially attenuate the putative benefit of prophylactic coronary revascularization. One algorithm for screening and management of CHD in renal transplant candidates is presented in Fig. 81.12.

Coronary Angiography

Coronary angiography should be considered in stable ESRD patients with evidence for inducible myocardial ischemia, unstable patients with ACS (performed urgently for STEMI), and patients with LVEF below 40%. In



Test	Pretest probability of (%) coronary artery disease	Posttest probability (%) after positive result	Posttest probability (%) after negative result*
Dobutamine Stress Echocardiography (DSE)	Low risk (10-29)	42-72	3-10
	Intermediate risk (30-59)	73-90	10-27
	High risk (60-90)	91-98	28-70
Myocardial Perfusion Scintigraphy (MPS)	Low risk (10-29)	24-54	5-15
	Intermediate risk (30-59)	55-81	16-38
	High risk (60-90)	81-96	39-79

Fig. 81.11 Accuracy of dobutamine stress echocardiography versus myocardial perfusion scintigraphy for diagnosing coronary artery disease coronary artery disease in renal transplant candidates. (From reference 67.)

CKD and dialysis patients with residual renal function, fear of contrast nephropathy may restrain use of coronary angiography (see Chapter 70 for preventive measures); one retrospective study of 76 nondialysis patients with mean eGFR of 12.5 ml/min/1.73 m^2 found no significant postangiographic deterioration in renal function. However, patients sustaining acute kidney injury (AKI) after coronary angiography are at heightened risk for long-term mortality, ESRD, and hospitalization.[40] However, fear of AKI should not deter clinically mandated coronary angiography. Echocardiography should be performed before any nonemergent coronary angiography in CKD patients to diagnose clinically unsuspected valvular disease or cardiomyopathy, to gauge preprocedure volume status, and to assess LV function (to avoid excessive exposure to radiocontrast media through unwarranted ventriculography).

Noninvasive coronary CT angiography (CCTA) may be problematic in dialysis patients because of medial calcification interfering with angiographic interpretation. Nevertheless, noninvasive CCTA has diagnostic sensitivity to detect obstructive CHD nearly comparable to invasive coronary angiography and markedly superior to noninvasive nuclear single-photon emission computed tomography imaging.[41] Generalizability of these findings must be interpreted in the context of individual institutional expertise. Noninvasive gadolinium-based magnetic resonance angiographic imaging in patients with severe CKD remains problematic because of lingering concerns about nephrogenic fibrosing dermopathy; the usefulness of imaging without contrast media is uncertain.

Imaging of Vascular Calcification

Vascular calcification can be visualized by conventional x-ray techniques and by multislice spiral CT or electron-beam CT. Valvular and large-artery calcification can be visualized by ultrasound techniques, and (if present) predicts worse outcome in dialysis patients, although the value of coronary artery calcification in dialysis patients as a surrogate for CHD severity has been questioned.

Biomarkers

Plasma brain natriuretic peptides (BNP and NT-proBNP), cardiac troponins (cTnT, cTnI), and high-sensitivity (hs) CRP are prognostic risk markers in the evaluation of heart disease in ESRD.[42] BNP reflects cardiac filling pressures (not limited to the left heart), troponins reflect myocardial cell death (but not necessarily ischemia), and hsCRP reflects inflammation. Elevation of cTnT occurs even in pediatric CKD patients and is associated with cardiac dysfunction. Elevated levels of serum troponin in ESRD patients should not be uncritically attributed to myocardial ischemia caused by obstructive coronary artery disease. Elevated levels of cTnT are associated with the presence and severity of HD-induced myocardial stunning.[43] The cardiac biomarker–based diagnosis of ACS requires a time-appropriate rise and fall of the biomarker. The most cost-effective combination of biomarkers for risk stratification in dialysis patients might be high-sensitivity cardiac troponin and a natriuretic peptide, but this is speculative. A recent study underscored the robustness of IL-6 as a classifier of clinically overt CVD and predictor of

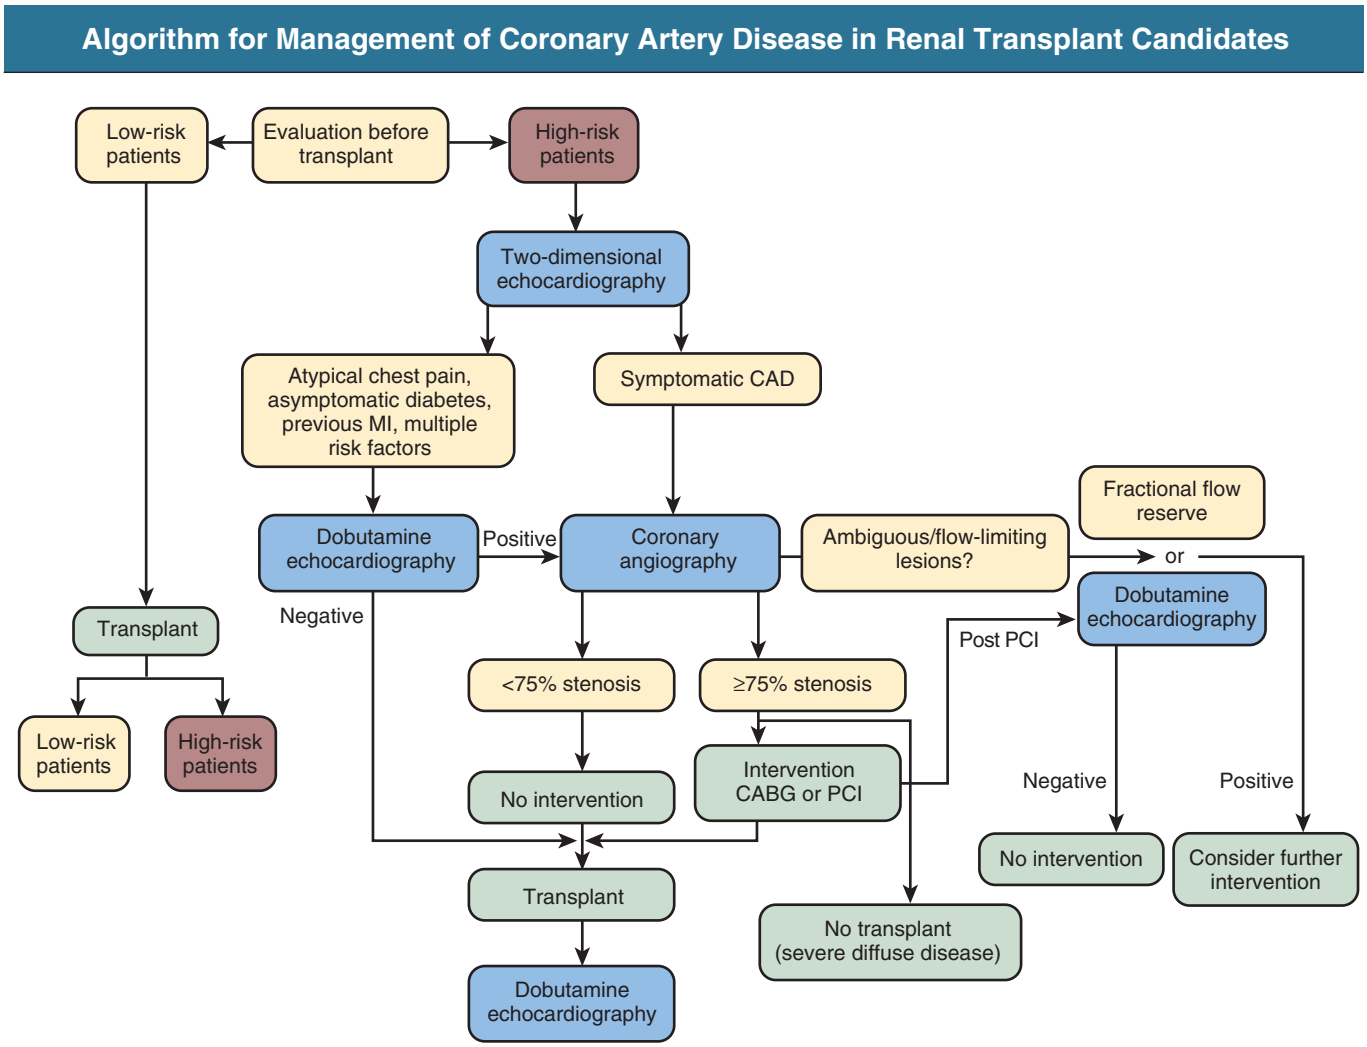


Fig. 81.12 Algorithm for management of coronary heart disease in renal transplant candidates. *CABG,* Coronary artery bypass graft surgery; *CAD,* coronary artery disease; *MI,* myocardial infarction; *PCI,* percutaneous coronary intervention. (Modified from Herzog CA. Acute MI in dialysis patients: How can we improve the outlook? *J o Critical Illness* 1999;14(11):613-621.)

all-cause mortality in CKD stage 5.[44] In CKD, NT-proBNP and BNP are equivalent predictors of decompensated heart failure, but NT-proBNP is a better predictor of survival. Fig. 81.13 graphically displays the relationship of cTnT and cTnI levels in asymptomatic dialysis patients and long-term survival. On the basis of these data, the U.S. Food and Drug Administration approved the measurement of cTnT in dialysis patients for risk stratification (mortality prediction).[27]

High-sensitivity cardiac troponin (hs-cTn) assays, which offer the advantage of high precision, serve dual, complementary (but distinct) roles: the diagnosis of AMI, which now includes cardiac biomarkers and risk stratification based on detection of hs-cTn in an asymptomatic, nonischemic setting (e.g., perhaps a marker for apoptosis). Hs-cTn–based risk stratification should employ reference change values over time, rather than simple thresholds, particularly when data are inconclusive regarding acceptable normal values in special populations, such as dialysis patients, known to have chronically elevated cardiac troponin levels.[45]

FGF-23 has also proven to be a strong outcome predictor in CKD patients, but further studies are needed to demonstrate its role as an additional clinical biomarker.

An improved CV prediction risk score was recently developed for use in HD patients (http://aro-score.askimed.com/).[46]

TREATMENT AND PREVENTION OF CARDIOVASCULAR DISEASE

Risk Factor Reduction

Lifestyle Factors and Smoking

Because physical inactivity is associated with albuminuria and CV mortality, CKD patients should be advised to stay as physically active as possible and to avoid smoking.

Weight and Diet

Lifestyle changes, including balanced diets with regard to saturated fat and carbohydrates (in diabetic patients), probably reduce CV morbidity and should be encouraged. However, in all CKD stages, protein-energy wasting must be avoided; especially in dialysis patients, increased body mass index has been associated with improved outcomes, possibly reflecting confounded epidemiology; thus the obesity paradox only exists in HD patients with inflammation.[9]

Hypertension and Coronary Heart Disease

BP targets for CKD patients, in particular those with diabetes or proteinuria greater than 1 g/day, are discussed in Chapter 79. A goal of

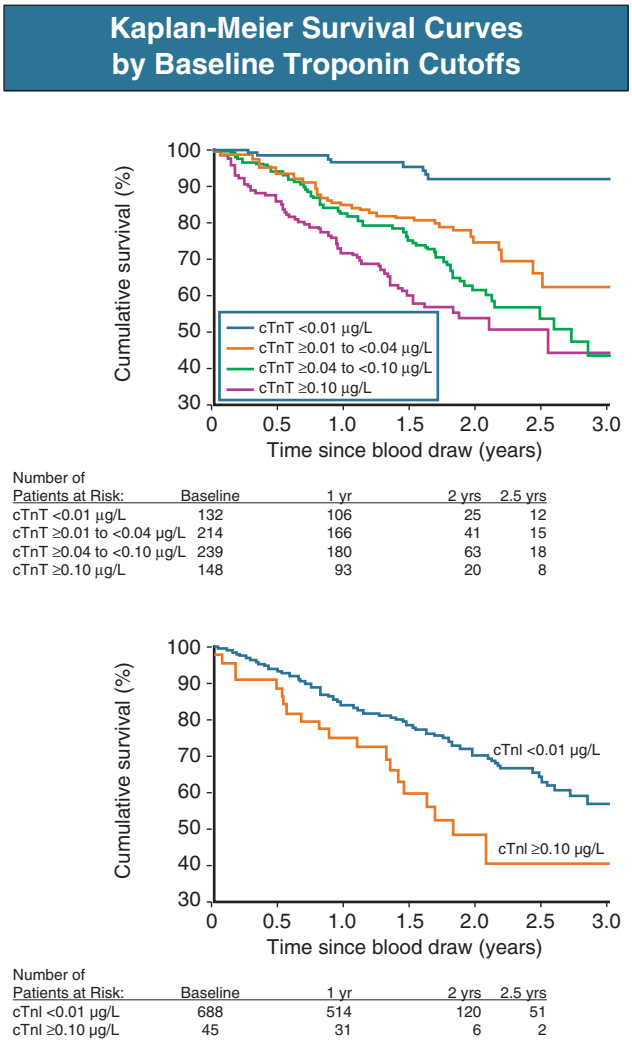

Fig. 81.13 Kaplan-Meier survival curves by baseline troponin cutoffs. *cTnI,* Cardiac troponin I; *cTnT,* cardiac troponin T. (From reference 42.)

therapy is volume control (see Chapter 79) and prevention of sodium overload, particularly through dietary sodium restriction. Longer or more frequent HD sessions may be beneficial in controlling hypertension. Because of their parallel cardioprotective effects, angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), and vasodilating β-blockers (e.g., carvedilol) are the first-line drugs to treat CKD- and ESRD-related hypertension. Calcium channel blockers and most other antihypertensive drugs, including centrally acting sympathetic inhibitors, are useful in combination with first-line agents. Pure vasodilators (e.g., minoxidil) should be avoided because they may increase volume overload or occasionally cause pericardial effusion. Novel approaches to drug-resistant hypertension, such as renal sympathetic denervation, have become controversial in view of recent trials. Because sleep-disordered breathing occurs in about 50% of CKD stage 4 and 5 patients and is associated with hypertension, sleep apnea should be considered in therapy-resistant hypertension.

CHD and CHD-related events should be treated with the same medications and active interventions indicated in the general population in the absence of convincing CKD-specific data to the contrary. Medical treatment includes use of antiplatelet agents, ACE inhibitors, ARBs, β-blockers, nitroglycerin, and statins. There is no rationale for a less aggressive therapeutic approach in CKD than in the nonrenal population.

Diabetes Mellitus

Optimal glycemic control (see Chapter 32), reaching BP target levels, and lipid monitoring (with subsequent dyslipidemia treatment) are crucial in managing diabetic CKD patients. CHD and other CVD should be treated aggressively in this high-risk group. Because the harm associated with severe hypoglycemia might counterbalance the potential benefit of intensive glucose-lowering treatment, treating to a hemoglobin A_{1c} (HbA_{1c}) level below 7.0% (53 mmol/mol) is not recommended in CKD stages 3 to 5.[47]

Dyslipidemia

Because CKD, like diabetes and hypertension, is considered a CV risk equivalent, CKD patients should be treated to achieve the guideline goal for secondary prevention for LDL cholesterol (<100 mg/dl [2.6 mmol/l]). This goal is not supported by clinical trials targeting dialysis patients. Post hoc subgroup analyses in the Heart Protection Study, Cholesterol and Recurring Events (CARE) study, and Treating to New Targets (TNT) study, together with a meta-analysis, provide inferential support for the role of statins in improving outcomes in CKD stages 1 and 2. The Study of Heart and Renal Protection (SHARP) showed that reducing LDL cholesterol with simvastatin 20 mg/day plus ezetimibe 10 mg/day safely reduced the incidence of major atherosclerotic events in patients with advanced CKD.[48] Thus statin treatment is recommended in CKD patients older than 20 years, with LDL cholesterol level goals below 130 mg/dl (3.4 mmol/l) or below 100 mg/dl (2.6 mmol/l) for secondary prevention; however, the negative results from the 4D study and A Study to Evaluate the Use of Rosuvastatin in Subjects on Regular Hemodialysis: An Assessment of Survival and Cardiovascular Events (AURORA) do not support this guideline in dialysis patients. The possibility that statins have a procalcifying effect in the uremic milieu deserves further attention.[49]

Volume

In predialysis CKD, sodium restriction and diuretics are important to counteract fluid retention. In ESRD, longer and more frequent HD sessions may permit more effective volume control. In the HD center in Tassin, France, more than 90% of patients were normotensive with 8 hours of dialysis three times per week, with dietary salt restriction and no antihypertensive drugs. In the Frequent Hemodialysis Network (FHN) trial, frequent (six times per week) HD (vs. conventional three times per week) led to better hypertension control, a drop in LV mass index over 12 months,[50,51] and less myocardial stunning.[50,51] Episodes of dialysis-related hypotension should prompt reevaluation of dry weight, antihypertensive treatment, and exclusion of pericardial effusions, valvular disease, cardiomyopathy, and silent myocardial ischemia (see Chapter 98).

Anemia

Partial correction of severe anemia with ESAs results in regression of LVH. Treatment of severe anemia is also associated with fewer ischemic symptoms in CHD patients. However, evidence for reduction of CV mortality by ESAs is based on observational data only. To date, RCTs in HD and CKD patients have shown no benefit of normalized anemia on mortality as a primary end-point (see Chapter 82). Thus anemia correction in patients with advanced CKD to a hemoglobin level of 10 to 12 g/dl appears logical.

Inflammation

Data from statin trials in dialysis patients (4D, AURORA) showed lower CRP levels in the statin arms but no association with fewer CV events. A careful search for infectious processes, such as periodontal disease, is recommended in dialysis patients with inflammation. Restriction of

catheter use is also important; short daily dialysis with better fluid status was associated with decreasing CRP levels compared with conventional HD. Volume status should be carefully monitored to avoid inflammation. Altered intestinal microbial flora as a potential risk factor for systemic uremic inflammation merits further study. It was recently demonstrated that medium cut-off dialysis membranes reduce uremic inflammation[52]; thus larger trials with longer treatment periods are encouraged.

Oxidative Stress

Two placebo-controlled interventional studies showed that vitamin E and *N*-acetylcysteine decreased the number of CV events in HD patients. Unfortunately, both studies were small and of limited duration, so adequately powered randomized trials are warranted. A recent meta-analysis showed that use of ultrapure dialysate results in decreased markers of inflammation and oxidative stress in HD patients.[53] However, administration of mixed tocopherols and α-lipoic acid did not influence biomarkers of inflammation and oxidative stress or the erythropoietic response in a recent randomized trial in HD patients.[54] Because CKD 4 patients allocated to the antioxidant synthetic triterpenoid bardoxolone experienced excessive CVD and especially CHF,[55] the beneficial effects of antioxidant treatment strategies in this patient group remains to be proven.

Chronic Kidney Disease–Mineral Bone Disorder

Recent meta-analyses and the updated KDIGO CKD-MBD guidelines (www.kdigo.org) conclude that calcium-free phosphate binders such as sevelamer reduce CV events, calcifications, and mortality compared with calcium-containing binders (see Chapter 85). Thus, these agents should be preferred for CKD patients with significant life expectancy, particularly patients on the transplant waiting list, independent of the presence or absence of calcifications.

Because vitamin D treatment is associated with improved survival in dialysis patients, vitamin D insufficiency should be considered. However, results from the Dialysis Outcomes and Practice Patterns Study (DOPPS) call into question the survival advantage for HD patients taking vitamin D. In the Paricalcitol Capsules Benefits Renal Failure Induced Cardiac Morbidity in Subjects With Chronic Kidney Disease Stage 3/4 (PRIMO) study, 48 weeks of paricalcitol therapy did not alter LV mass index or improve measures of diastolic dysfunction.[56]

The Evaluation of Cinacalcet HCl Therapy to Lower Cardiovascular Events (EVOLVE) study[57] showed that cinacalcet only reduced the risk for death or major CV events in dialysis patients with moderate-severe secondary hyperparathyroidism after adjustment for age. In a second trial in similar dialysis patients, cinacalcet plus low-dose vitamin D sterols tended to attenuate vascular and cardiac valve calcification compared with an exclusively vitamin D sterol–based approach.[58]

FGF-23, a bone hormone, is cardiotoxic and induces LVH but does not induce vascular calcification.[59] In a post-hoc analysis of EVOLVE data, treatment of secondary hyperparathyroidism with cinacalcet was associated with reduced FGF-23 levels and patients with a 30% or 50% drop in FGF-23 levels experienced significantly fewer CV events.[60]

Revascularization

CKD is a strong risk factor for death after coronary revascularization with percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG).[61,62] Coronary revascularization complicated by AKI is associated with excess mortality; operative mortality for non-ESRD patients who require acute dialysis after cardiac surgery is 44%.

Observational studies suggest lower mortality in CKD (including dialysis) patients undergoing coronary revascularization compared with no revascularization. A post hoc analysis of CKD patients in the Fast Revascularization During Instability in Coronary Artery Disease (FRISC II) trial indicated a superior outcome with an early invasive strategy in ACS compared with conservative management. However, the optimal coronary revascularization method in CKD remains controversial. A post hoc analysis of CKD patients enrolled in the Arterial Revascularization Therapies Study (ARTS) found similar outcomes for coronary artery bypass grafting (CABG) or multivessel percutaneous coronary intervention (PCI) with non–drug-eluting stents (DESs) for death, myocardial infarction, or stroke. In elderly non–dialysis-dependent CKD patients, the incidence of ESRD is lower after PCI (5.4% at 3 years vs. 6.8% for CABG), but long-term risk for death (28% 3-year mortality with CABG, 33% with PCI) or the combined event of death or ESRD is lower after CABG. The relative survival advantage of CABG (vs. PCI) occurs only more than 6 months after revascularization.[63] Dialysis patient survival after CABG is better than after PCI with non-DESs[64] and DESs,[65] but 2-year mortality remains high at 44% (vs. 52% for PCI).[64] Based on three large observational studies,[64-67] we recommend the following strategy for dialysis patients who do not require acute reperfusion therapy for STEMI, which would typically be treated with emergent PCI first:

1. Patients with multivessel CHD (including the left anterior descending coronary artery [LAD]) who are anatomically suitable candidates for internal mammary artery grafts should undergo CABG surgery; concomitant ACS additionally favors CABG surgery.
2. The CABG survival advantage occurs more than 6 months after revascularization. Patients with limited life expectancy or who are concerned about perioperative morbidity (higher with CABG) might choose PCI (better outcomes at less than 6 months).
3. If the left internal mammary graft (to the LAD) is not part of the surgical strategy, CABG likely provides no advantage.

In the general population, advantages of DESs (compared with non-DESs) include lower incidence of in-stent restenosis and improved survival.[67] In dialysis patients, reliance on clinical surrogates (e.g., chest pain) leads to underestimation of the true restenosis incidence. The most complete angiographic follow-up of DESs noted a 22% to 31% incidence of restenosis with DESs and 24% to 43% with non-DESs. Clinically silent restenosis is a rationale for surveillance stress imaging (see Fig. 81.12).

SELF-ASSESSMENT QUESTIONS

1. Which of the following is *not* an established risk factor for cardiovascular disease in patients with advanced chronic kidney disease?
   - **A.** Inflammation
   - **B.** Smoking
   - **C.** Dyslipidemia
   - **D.** Hyperhomocysteinemia
   - **E.** Diabetes
2. What is *not* true about cardiovascular complications in end-stage renal disease patients?
   - **A.** Left ventricular hypertrophy is present in about 75% of the patients.
   - **B.** In dialysis patients the incidence of atrial fibrillation is about 15% per year.
   - **C.** Low levels of cholesterol predict death.
   - **D.** In dialysis patients, extensive vascular, especially coronary artery, calcification can occur even at young ages.
   - **E.** The calcific aortic stenosis progression rate is only slightly higher in dialysis patients compared to the general population.
3. What is the *most* common cause of death in dialysis patients?
   - **A.** Congestive heart failure
   - **B.** Infection
   - **C.** Arrhythmic death
   - **D.** Stroke
   - **E.** Valvular heart disease
4. Which drug has been shown to reduce mortality in dialysis patients with dilated cardiomyopathy and systolic heart failure?
   - **A.** Atorvastatin
   - **B.** Digoxin
   - **C.** Carvedilol
   - **D.** Metoprolol
   - **E.** Atenolol

Anemia in Chronic Kidney Disease

Iain C. Macdougall, Kai-Uwe Eckardt

Anemia is an almost universal complication of chronic kidney disease (CKD). It contributes considerably to reduced quality of life of patients with CKD and has been associated with a number of adverse clinical outcomes. Before the availability of recombinant human erythropoietin (rHuEPO, or epoetin), patients on dialysis frequently required blood transfusions, exposing them to the risks of iron overload, transmission of viral hepatitis, and human leukocyte antigen (HLA) sensitization, which reduced the chances of successful transplantation. The advent of rHuEPO in the late 1980s changed this situation completely. The ability to correct anemia has had consequences beyond simply an improvement in general fatigue and reduced physical capacity, to impact on a broad spectrum of physiologic functions. Thus there is a strong rationale for managing anemia in CKD patients, and yet the optimal treatment strategies are still incompletely defined. Apart from therapy with erythropoiesis-stimulating agents (ESAs), iron replacement is essential for anemia management. It is important to note that CKD patients on dialysis require target thresholds of iron parameters different from those for normal individuals to ensure optimal rates of red blood cell (RBC) production. The costs of anemia management are considerable, and it has become apparent that full anemia correction may cause harm; therefore a rational and careful consideration of the risks and benefits is mandatory.

PATHOGENESIS

Renal anemia is typically an isolated normochromic, normocytic anemia with no leukopenia or thrombocytopenia. Both RBC life span and the rate of RBC production are reduced, but the latter is more important. The normal bone marrow has considerable capacity to increase the rate of erythropoiesis, and compensation normally could be easily made for the reduction in erythrocyte life observed in association with CKD. However, this EPO-induced compensatory increase in erythrocyte production is impaired in CKD. Serum EPO levels remain within the normal range and fail to show the inverse exponential relationship with blood oxygen content characteristic of other types of anemia. EPO is normally produced by interstitial fibroblasts in the renal cortex, in close proximity to tubular epithelial cells and peritubular capillaries.[1,2] In addition, hepatocytes and perisinusoidal, or Ito, cells in the liver can produce EPO (Fig. 82.1). Hepatic EPO production dominates during fetal and early postnatal life but does not compensate for the loss of renal production in adult organisms. Subtle changes in blood oxygen content induced by anemia, reduced environmental oxygen concentrations, and high altitude stimulate the secretion of EPO through a widespread system of oxygen-dependent gene expression.[2-4] Central to this process is a family of hypoxia-inducible transcription factors (HIFs). The two most important members of this family, HIF-1 and HIF-2, are composed of an oxygen-regulated α subunit (HIF-1α or HIF-2α) and a constitutive β subunit. The production of HIF-1α and HIF-2α is largely independent of oxygen, but their degradation is related to cellular oxygen concentrations. Hydroxylation of specific prolyl and asparagyl residues of HIF-α, for which molecular oxygen is required as a substrate, determines proteasomal destruction of HIF and inhibits its transcriptional activity. Apart from EPO, several hundred HIF target genes have been identified. HIF-2, rather than HIF-1, is the transcription factor primarily responsible for the regulation of EPO production.[5,6]

The role of renal EPO production in the pathogenesis of renal anemia is supported by the particularly severe anemia in anephric individuals. However, the mechanisms impairing renal EPO production in diseased kidneys remain poorly understood. The production capacity for EPO remains significant, even in end-stage renal disease. Thus patients with anemia and CKD can respond with a significant increase in EPO production to an additional hypoxic stimulus.[1] The main problem therefore appears to be a failure of EPO production to increase in response to chronically reduced hemoglobin (Hb) concentrations. In line with this view, endogenous EPO production can be induced in CKD patients by pharmacologic inhibition of HIF degradation (see later discussion).

EPO is a glycoprotein hormone consisting of a 165–amino acid protein backbone and four complex, heavily sialylated carbohydrate chains.[1] The latter are essential for the biologic activity of EPO in vivo because partially or completely deglycosylated EPO is rapidly cleared from the circulation. This is why rHuEPO has to be manufactured in mammalian cells; bacteria lack the capacity to glycosylate recombinant proteins.

EPO stimulates RBC production by binding to homodimeric EPO receptors, which are primarily located on early erythroid progenitor cells, the burst-forming units erythroid (BFU-e) and the colony-forming units erythroid (CFU-e). Binding of EPO to its receptors salvages these progenitor cells and the subsequent earliest erythroblast generation from apoptosis, thereby permitting cell division and maturation into RBCs.[7] Inhibition of RBC production by yet unknown uremic inhibitors of erythropoiesis may contribute to the pathogenesis of renal anemia, and dialysis per se can improve renal anemia and the efficacy of ESAs. Moreover, the interindividual dose requirements for ESAs vary significantly among CKD patients, and the average weekly dose is much higher than estimated production rates of endogenous EPO in healthy individuals. An alternative view to the accumulation of inhibitors of erythropoiesis in CKD is that in many patients there is overlap between renal anemia and the anemia of chronic disease, which is characterized by inhibition of EPO production and EPO efficacy, as well as by reduced iron availability, mediated through inflammatory cytokines.[8] The hepatic release of hepcidin, the key regulator of iron metabolism, is upregulated in states of inflammation; it simultaneously blocks iron absorption from the gut and promotes iron sequestration in macrophages.[9]

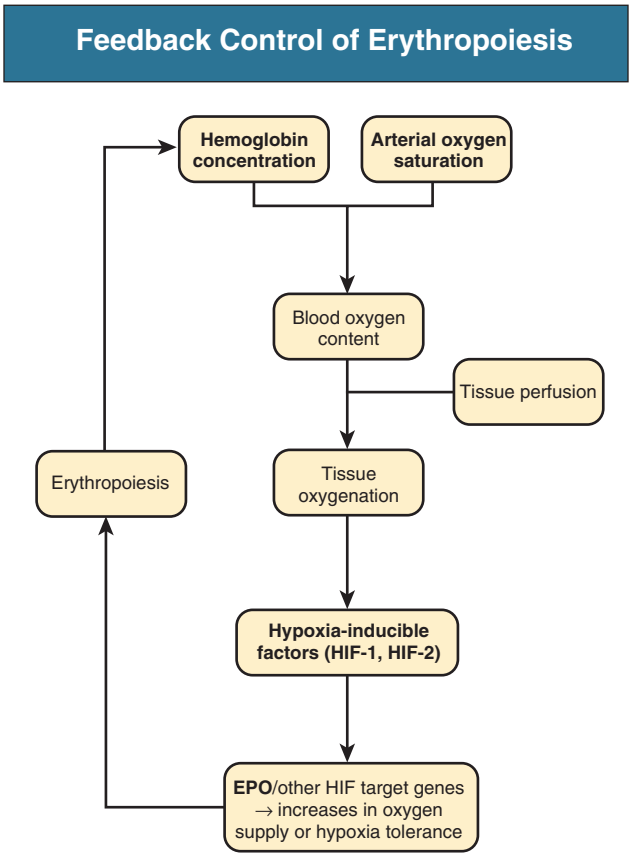

Fig. 82.1 Feedback control of erythropoiesis. *EPO,* Erythropoietin.

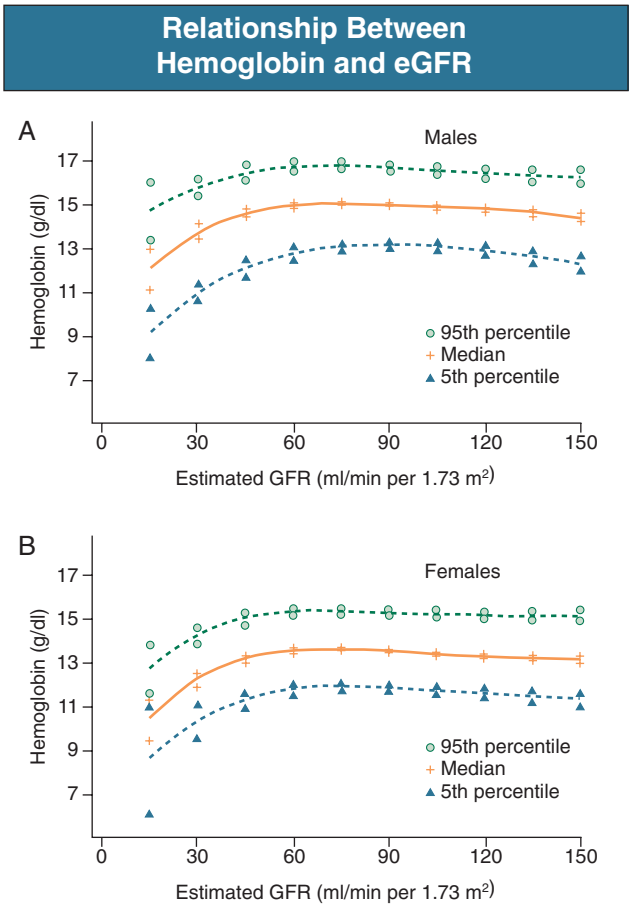

Fig. 82.2 Relationship between hemoglobin (Hb) concentration and estimated glomerular filtration rate *(GFR).* Data are from a cross-sectional survey of individuals randomly selected from the general U.S. population (Third National Health and Nutrition Examination Survey [NHANES III]). Results and 95% confidence interval are shown for males (A) and females (B) at each estimated GFR interval. (From reference 11.)

EPIDEMIOLOGY AND NATURAL HISTORY

In general, there is a progressive increase in the incidence and severity of anemia with declining renal function. The reported prevalence of anemia by CKD stage varies significantly and depends to a large extent on the definition of anemia and whether study participants are selected from the general population, are at high risk for CKD, are diabetic, or are already under the care of a nephrologist. Data from the National Health and Nutrition Examination Survey (NHANES) showed that the distribution of Hb levels starts to fall at an estimated glomerular filtration rate (eGFR) of less than 75 ml/min/1.73 m^2 in men and 45 ml/min/1.73 m^2 in women (Fig. 82.2).[10] The prevalence of Hb values below 13 g/dl increases below an eGFR of 60 ml/min/1.73 m^2 in men and 45 ml/min/1.73 m^2 in women in the general population. Among patients under regular care for CKD, the prevalence of anemia was found to be much greater, with mean Hb values of 12.8 (CKD stages 1 and 2), 12.4 (CKD stage 3), 12.0 (CKD stage 4), and 10.9 (CKD stage 5).[11] Although anemia develops largely independently of the cause of kidney disease, there are two important exceptions. Diabetic patients develop anemia more frequently, at earlier stages of CKD, and more severely at a given level of renal impairment.[12,13] Conversely, in patients with polycystic kidney disease, Hb is on average higher than in other patients with similar degrees of renal failure, and polycythemia may occasionally develop.

With the advent of rHuEPO and its derivatives, Hb values in patients with CKD have changed. In particular, in patients on dialysis, average Hb values have steadily increased for many years and then declined again in view of new evidence suggesting lower target levels.[12] The average Hb value still varies considerably among countries, reflecting variability in practice patterns (Table 82.1).[13] Moreover, Hb values vary considerably among patients in the same treatment setting as well as within patients over time, mainly reflecting persistent and time-dependent changes in responsiveness (see later discussion).

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of anemia and the assessment of its severity are best made by measuring the Hb concentration rather than the hematocrit (Hct). Hb is a stable analyte that is measured directly in a standardized fashion, whereas the Hct is relatively unstable, indirectly derived by automatic analyzers, and lacking standardization. Within-run and between-run coefficients of variation in automated analyzer measurements of Hb are half and one third those for Hct, respectively.[12]

There is considerable variability in the Hb threshold used to define anemia. According to the most recent definition in the Kidney Disease: Improving Global Outcomes (KDIGO) guidelines, anemia should be diagnosed at Hb concentrations of less than 13.0 g/dl in men and less than 12.0 g/dl in women.[14] These values represent the World Health Organization definition of anemia. In children, age-dependent differences in the normal values have to be taken into account. Normal Hb values are increased in high-altitude residents. It is important to note

TABLE 82.1 Hemoglobin Levels in Patients on Dialysis

	AMONG PATIENTS ON DIALYSIS FOR LONGER THAN 180 DAYS			AMONG PATIENTS NEW TO ESRD, AT START OF DIALYSIS		
Country	n	Mean Hb (g/dl)	Hb <11 g/dl (% of patients)	n	Mean Hb (g/dl)	Hb <11 g/dl (% of patients)
Sweden	456	12.0	23	168	10.7	55
United States	1690	11.7	27	458	10.4	65
Spain	513	11.7	31	170	10.6	61
Belgium	442	11.6	29	213	10.3	66
Canada	479	11.6	29	150	10.1	70
Australia and New Zealand	423	11.5	36	108	10.1	70
Germany	459	11.4	35	142	10.5	61
Italy	447	11.3	38	167	10.2	68
United Kingdom	436	11.2	40	93	10.2	67
France	341	11.1	45	86	10.1	65
Japan	1210	10.1	77	131	8.3	95

Mean hemoglobin (Hb) levels and percentage of patients with Hb levels below 11 g/dl who have been on dialysis therapy for more than 180 days and at the time of starting dialysis, by country.
Data are from the Dialysis Outcomes and Practice Patterns Study, Phase II (DOPPS 2), and are derived from 308 randomly selected, representative dialysis facilities. Note that there are marked differences among countries, but at least one fourth and up to three fourths of dialysis patients, and, in most countries, more than two thirds of patients starting chronic dialysis have Hb values below the recommended lower target of 11 g/dl.
ESRD, End-stage renal disease.
Modified from reference 13.

that thresholds for the diagnosis of anemia and evaluation of the causes should not be interpreted as being thresholds for treatment of anemia.[14]

In addition to the Hb value, the evaluation of anemia in CKD patients should include a complete blood count with RBC indices (mean corpuscular Hb concentration [MCHC], mean corpuscular volume [MCV]), white blood cell count (including differential), and platelet count. Although renal anemia is typically normochromic and normocytic, deficiency of vitamin B_{12} or folate may lead to macrocytosis, whereas iron deficiency or inherited disorders of Hb formation (such as thalassemia) may produce microcytosis. Macrocytosis with leukopenia or thrombocytopenia suggests a generalized disorder of hematopoiesis caused by toxins, nutritional deficit, or myelodysplasia. Hypochromia probably reflects iron-deficient erythropoiesis. An absolute reticulocyte count, which normally ranges between 40,000 and 50,000 cells/μl of blood, is a useful marker of erythropoietic activity.

Iron status tests should be performed to assess the level of iron in tissue stores or the adequacy of iron supply for erythropoiesis. Although serum ferritin is the only available marker of storage iron, several tests reflect the adequacy of iron for erythropoiesis, including transferrin saturation (TSAT), the percentage of hypochromic red blood cells (PHRC), the reticulocyte hemoglobin content (CHr), the MCV, and the MCHC. Storage time of the blood sample may elevate PHRC, and MCV and MCHC are below the normal range only after long-standing iron deficiency; in clinical practice, TSAT remains the most frequently used parameter.

It is important to identify anemia in CKD patients because it may signify nutritional deficits, systemic illness, or other conditions that warrant attention. Moreover, even at modest degrees, anemia reflects an independent risk factor for hospitalizations, cardiovascular disease (CVD), and mortality.[12] The diagnosis of renal anemia, that is, anemia caused by CKD, requires careful judgment of the degree of anemia in relation to the degree of renal impairment and exclusion of other or additional causes. Because there is significant variability in the degree of anemia in relation to the impairment in renal function, no simple diagnostic criteria can be applied. Causes of anemia other than EPO deficiency should be considered when (1) the severity of anemia is disproportionate to the impairment of renal function, (2) there is evidence of iron deficiency, or (3) there is evidence of leukopenia or thrombocytopenia. Concomitant conditions such as sickle cell disease may exacerbate the anemia, as can drug therapy. For example, inhibitors of the renin-angiotensin system may reduce Hb levels by (1) direct effects of angiotensin II (Ang II) on erythroid progenitor cells,[15] (2) accumulation of *N*-acetyl-seryl-lysyl-proline (Ac-SDKP), an endogenous inhibitor of erythropoiesis in patients treated with angiotensin-converting enzyme (ACE) inhibitors,[16] and (3) reduction of endogenous EPO production, possibly because of the hemodynamic effects of Ang II inhibition. Myelosuppressive effects of immunosuppressants may further contribute to anemia.[17] The measurement of serum EPO concentrations is usually not helpful in the diagnosis of renal anemia because there is relative rather than absolute deficiency, with a wide range of EPO concentrations for a given Hb concentration that extends far beyond the normal range of EPO levels in healthy, nonanemic individuals. Abnormalities of other laboratory parameters should be looked for, such as a very low MCV or MCHC, a high MCV, or an abnormal leukocyte or platelet count, and further tests should be performed as indicated to explore these potential contributory causes (see earlier). However, when there are no such pointers to other confounding causes of anemia, and iron deficiency has been excluded, a trial with rHuEPO or its derivatives is warranted, even when the eGFR is only moderately reduced.

CLINICAL MANIFESTATIONS

In the early clinical trials of rHuEPO performed in the late 1980s, the mean baseline Hb concentration was about 6 to 7 g/dl, and this

progressively increased to about 11 or 12 g/dl after treatment. Patients subjectively felt much better, with reduced fatigue, increased energy levels, and enhanced physical capacity, and there were also objective improvements in cardiorespiratory function.[18] Thus it is now clear that many of the symptoms previously attributed to the "uremic syndrome" may have been caused by severe anemia associated with CKD (Boxes 82.1 and 82.2). Although the avoidance of blood transfusions and improvement in quality of life are obvious early changes, there are also possible effects on the cardiovascular system (see Box 82.1). The physiologic consequences of long-standing anemia are an increase in cardiac output and a reduction in peripheral vascular resistance. Anemia is associated with the development of left ventricular hypertrophy in CKD patients and is thought to exacerbate left ventricular dilation. Sustained correction of severe anemia in CKD patients tends to reverse most of these CV abnormalities, with the notable exception of left ventricular dilation (although anemia correction may prevent further dilation in some patients[19]). Other effects of anemia correction reported in clinical trials include improvements in quality of life, cognitive function, sleep patterns, nutrition, sexual function, menstrual regularity, immune responsiveness, and platelet function. The majority of these trials, however, were not placebo-controlled, so the spectrum and extent of possible benefits remain uncertain.

Over the years, there has been considerable debate about the optimal target range of Hb in CKD patients. A presumed improvement in quality of life and expectations of positive effects on CV function and renal disease progression with increasing Hb concentrations led to suggestions of a level above 10 to 11 g/dl in all CKD patients,[12,13] but several studies have indicated increased risks associated with attempts to completely correct anemia. In particular, no survival benefit is evident at a higher level of anemia correction,[20-23] and attempts to normalize Hb concentrations have shown various risks, including increased rates of thromboembolic events, strokes, and possibly death. Thus there is a possible tradeoff among improved quality of life, reduced transfusion requirements, and risk for harm (see discussion later), and a target Hb level of above 13 g/dl should be avoided.[12,14]

BOX 82.1 Cardiovascular Effects Resulting from Anemia Correction

- Reduction in high cardiac output
- Reduced stroke volume
- Reduced heart rate
- Increase in peripheral vascular resistance
- Reduction in anginal episodes
- Reduction in myocardial ischemia
- Regression of left ventricular hypertrophy
- Stabilization of left ventricular dilation
- Increase in whole blood viscosity

BOX 82.2 Other Effects of Anemia Correction

Beneficial

- Reduced blood transfusions
- Increased quality of life
- Increased exercise capacity
- Improved cognitive function
- Improved sleep patterns
- Improved immune function
- Improved muscle function
- Improved depression
- Improved nutrition
- Improved platelet function

Adverse

- Hypertension
- Vascular access thrombosis
- Increased risk for stroke

TREATMENT

Erythropoiesis-Stimulating Agents

Epoetin Therapy

Manufacture of rHuEPO is achieved by gene transfer into a suitable mammalian cell line such as Chinese hamster ovary (CHO) cells. The early clinical trials of rHuEPO were conducted with both EPO alfa and EPO beta, both produced in CHO cells. Like the endogenous hormone, rHuEPO consists of a 165–amino acid backbone with one *O*-linked and three *N*-linked glycosylation chains. Invariably, however, there are some differences in the glycosylation pattern among different preparations of rHuEPO and the endogenous hormone. "Biosimilar" EPO preparations have been licensed in Europe after demonstration of their efficacy and safety in an abbreviated trial program.[24] Many other "copy" EPOs are available in several parts of the world, which are not necessarily produced to the same regulatory standards.

Before 1998, EPO alfa in Europe was formulated with human serum albumin, but this was replaced with polysorbate 80. EPO beta is formulated with polysorbate 20, along with urea, calcium chloride, and five amino acids as excipients. The importance of the formulation of the EPO products was highlighted in 2002 with an upsurge in cases of antibody-mediated pure red cell aplasia (PRCA) in association with the subcutaneous use of EPO alfa after its change of formulation. Patients affected by this complication develop neutralizing antibodies against both rHuEPO and the endogenous hormone, which result in severe anemia and transfusion dependence.[25] The cause of this serious complication in which there is a break in B cell tolerance remains obscure, although it seems likely that factors such as a breach of the cold storage chain are relevant, and the subcutaneous application route is a prerequisite; circumstantial evidence also suggests that rubber stoppers of prefilled syringes used in one of the albumin-free EPO alfa formulations may have released organic compounds that acted as immunologic adjuvants.[26] Although this unfortunate combination of adverse factors was specific for one compound, the development of neutralizing anti-EPO antibodies was subsequently also observed during a clinical trial with an epoetin alfa biosimilar[27] and a low rate of PRCA also occurs with EPO beta and darbepoetin alfa.

The EPOs are administered either intravenously or subcutaneously. The bioavailability after intraperitoneal administration (in peritoneal dialysis [PD] patients) is too low. The earliest clinical trials of EPO used intravenous injections two or three times per week. This was partly because of the short half-life of EPO (6 to 8 hours after intravenous administration)[28] and partly because of the convenience for the patient on dialysis. With use of this regimen, 90% of patients show a significant increase in Hb concentration. Good iron management is pivotal for the success of EPO therapy (see later discussion). Although the bioavailability of subcutaneous EPO is 20% to 30%, the prolonged half-life after subcutaneous administration compared with intravenous administration allows less frequent injections. Furthermore, the dose required to achieve the same Hb response is about 30% lower with subcutaneous than with intravenous administration.[28] There appears to be little difference in efficacy among the thigh, arm, or abdomen as injection sites.

Darbepoetin Alfa

Darbepoetin alfa is a second-generation ESA that is a supersialylated analogue of EPO, possessing two extra *N*-linked glycosylation chains. This property confers a lower clearance rate in vivo, and the elimination half-life of this compound in humans after a single intravenous administration is 25.3 hours versus 8.5 hours for epoetin alfa. Thus this agent can generally be given less frequently than the standard epoetins, with administration intervals of once weekly and once every 2 weeks with similar dose requirements.[29] In contrast to the epoetins, dosage requirements for darbepoetin alfa in CKD patients are the same for intravenous and subcutaneous administration. The conversion factor for switching patients from epoetin alfa or beta to darbepoetin alfa is usually quoted as 200:1, but there may be considerable variability in this, depending on the patient population, the dose, and the route of administration.

Methoxy Polyethylene Glycol–Epoetin Beta (C.E.R.A.)

Alternative bioengineering techniques to prolong the half-life of EPO further resulted in the development of C.E.R.A., a pegylated derivative of epoetin beta with an elimination half-life of around 130 hours when administered either intravenously or subcutaneously. Phase III studies suggested that many patients are able to be maintained with once-monthly administration of C.E.R.A., and a superiority study suggested greater efficacy with this frequency of administration compared with once-monthly dosing of darbepoetin alfa when administered intravenously to hemodialysis (HD) patients.[30]

Adverse Effects of the Erythropoiesis-Stimulating Agents

Adverse effects of ESA therapy include a moderate increase in blood pressure and an increased rate of thromboembolic events, including vascular access thrombosis. Whereas these effects probably depend to a large degree on the increase in Hb concentration, there are some concerns that ESA therapy may enhance thrombogenicity and tumor growth in patients with malignant disease, as well as exacerbate vascular events in CKD independently of Hb concentrations. Thus attempts should be made to use the lowest doses of ESA possible to avoid the presumed pleiotropic effects of this class of drugs. Similarly, because no "safe" upper dose level has been determined, it is advisable to avoid repeated dose escalations.[14] In the Trial to Reduce Cardiovascular Events with Aranesp Therapy (TREAT), patients with a history of malignancy were found to have an increased rate of cancer-related deaths when treated with darbepoetin.[23] Although no study has investigated anemia management in patients with CKD and active cancer, ESAs should be used only with great caution in such patients, in particular when cure from cancer is the anticipated outcome.[14] Similarly, in patients with a history of stroke or recent venous thromboembolic event, careful consideration should be given to the benefit-to-risk ratio of using ESA therapy (see later discussion).

Peginesatide

Peginesatide (previously called *Hematide*) is an EPO-mimetic peptide, the amino acid sequence of which is completely unrelated to native or recombinant EPO,[24] although it shares the same functional and biologic properties as EPO. It has been shown to be an effective treatment for anti-EPO antibody–mediated pure RBC aplasia because of a lack of cross-reactivity with anti-EPO antibodies.[31] Peginesatide was also shown to be equivalent to epoetin and darbepoetin in raising Hb concentrations in dialysis and nondialysis patients, respectively, but in nondialysis patients, a higher rate of CV events was observed.[32,33] Approximately a year after its introduction, peginesatide had to be withdrawn from the market because of severe hypersensitivity reactions, including fatal anaphylactic events. Currently no EPO-mimetic peptide is available as rescue therapy for anti-EPO antibody–induced PRCA.

Hypoxia-Inducible Transcription Factor Stabilizers

The HIF stabilizers are competitive inhibitors of HIF prolyl hydroxylases [2,24,34] and asparagyl hydroxylase enzymes involved in the metabolism of HIF and its transcriptional activity. The HIF stabilizers, also referred to as *prolyl-hydroxylase domain protein inhibitors* (PHD-inhibitors) cause an increase in endogenous EPO production from both liver and the diseased, nonfunctioning kidneys.[34,35] Such compounds are orally active, and several of these drugs (e.g., roxadustat, daprodustat, vadadustat, and molidustat) are currently being tested in phase II and III clinical trials.[34] The results of phase II trials published so far have shown efficacy in terms of increasing or maintaining the Hb level in both dialysis-dependent and non–dialysis dependent CKD patients and revealed no evidence of acute adverse effects.[36-38] Levels of endogenous EPO induced by prolyl-hydroxylase inhibitors are lower than those observed under intravenous treatment with ESAs, potentially avoiding dose-dependent toxicity of ESAs. On the other hand, prolyl-hydroxylase inhibitors are likely to have a range of consequences additional to increasing levels of EPO through activation of other HIF-target genes or interference with other cellular pathways.[2,34] Such pleiotropic effects could be beneficial, for example, by improving iron availability or reducing lipid levels.[35] However, given the widespread biological role of HIF, including its effects on neoangiogenesis and vascular function, the long-term benefit-to-risk relationship is difficult to predict and can be assessed only through rigorous long-term observation.

Initiation of and Maintenance Therapy With Erythropoiesis-Stimulating Agents

Before ESA therapy is considered in CKD patients, it is essential to exclude and to correct causes of anemia other than EPO deficiency, such as iron and vitamin deficiencies (Fig. 82.3). If the serum ferritin concentration is below 100 ng/ml, the first therapeutic approach in anemic patients should be iron supplementation. Iron is best given by intravenous administration, although oral iron can be considered in patients not yet on dialysis.[39] Some patients may respond to intravenous iron alone (see later discussion). If the ferritin level is above 100 µg/l (in the absence of systemic inflammation) or there is a suboptimal response to iron, ESA therapy is an option. However, the Hb level at which ESAs should be initiated remains controversial, mainly because the topic has not been rigorously studied. In TREAT, the largest ESA trial performed so far, darbepoetin therapy (with a target Hb level of 13 g/dl) was compared with placebo, with a rescue protocol when a patient's Hb dropped below 9 g/dl.[23] In the darbepoetin arm, the number of patients transfused was lower and there was a small increase in quality of life, but the stroke rate was twice as high, so that the benefit-to-risk relationship was clearly negative. Whereas these data argue strongly against the initiation of ESA therapy in patients with mild anemia, there is only one, much smaller randomized controlled trial (RCT) (in HD patients) that tested two different target ranges of 9.5 to 11.0 g/dl and 11.5 to 13.0 g/dl against placebo in patients with severe anemia.[40] Patients in both EPO treatment arms experienced improved quality of life and exercise capacity, but there was no difference between the arms. Based on these findings, the KDIGO guidelines recommend use of ESAs to prevent the Hb level from falling below 9 g/dl.[14] However, individualization is possible, acknowledging the fact that some patients have improved symptoms at higher Hb levels and are prepared to take increased risks. A commonly used target Hb range is between 10 and 12 g/dl.

The usual intravenous or subcutaneous starting dose of epoetin is about 25 to 50 IU/kg (e.g., 2000 IU two or three times weekly), of darbepoetin alfa is 20 to 30 mcg once weekly, and of C.E.R.A. is 30 to 60 mcg once every 2 weeks. Within 3 to 4 days after treatment initiation, an increase in the reticulocyte count is seen, and within 1 to 2

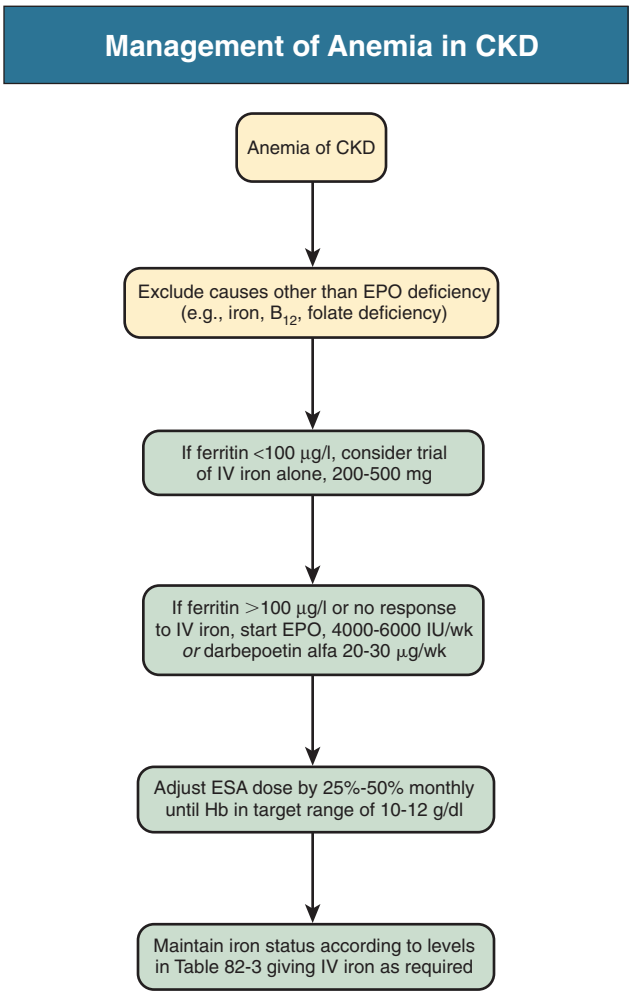

Fig. 82.3 Management of anemia in patients with chronic kidney disease *(CKD). EPO,* Erythropoietin; *ESA,* erythropoiesis-stimulating agent; *Hb,* hemoglobin; *IV,* intravenous.

weeks, there is a significant rise in the Hb concentration, usually of the order of 0.25 to 0.5 g/dl/wk. Thus, over the course of 1 month, a significant increase of 1 to 2 g/dl in Hb concentration is usually achieved. If a patient fails to respond satisfactorily to ESAs, the dose is increased in stepwise upward titrations of 25% to 50%, and if there is still an inadequate response, causes of resistance to ESA therapy should be investigated (see later discussion).

Given the risks observed in trials aiming at Hb normalization, it is recommended that the Hb level should not be intentionally increased to 13 g/dl or higher and should generally not be maintained above 11.5 g/dl.

Hyporesponsiveness to Erythropoiesis-Stimulating Agents

According to the most recent guidelines, hyporesponsiveness to ESA therapy is identified when the Hb concentration does not increase from baseline after the first month of ESA treatment on appropriate weight-based dosages or if after treatment with stable doses, patients require two increases in ESA doses up to 50% beyond the dose at which their condition had previously been stable.[14] Patients who are hyporesponsive have a worse prognosis than those who do respond.[41] The causes of resistance to ESA therapy are listed in Table 82.2, and it is important to correct them when possible. The major causes include iron deficiency

TABLE 82.2 Causes of a Poor Response to Erythropoiesis-Stimulating Agent Therapy

MAJOR (FREQUENT)	MINOR (LESS COMMON)
Iron deficiency	Poor compliance, poor adherence to ESA therapy
Infection, inflammation	Blood loss
Underdialysis	Hyperparathyroidism
	Aluminum toxicity (now rare)
	Vitamin B_{12} or folate deficiency
	Hemolysis
	Primary bone marrow disorders (e.g., myelodysplastic syndrome)
	Hemoglobinopathies (e.g., sickle cell disease)
	ACE inhibitors, angiotensin receptor blockers
	Carnitine deficiency
	Anti-EPO antibodies causing PRCA

ACE, Angiotensin-converting enzyme; *EPO,* erythropoietin; *PRCA,* pure red cell aplasia.

(see later discussion), infection or inflammation, and underdialysis.[12,14] If the patient is self-administering (e.g., for PD patients), poor adherence to or compliance with therapy must be excluded. If there is any doubt about the possibility of iron deficiency, a trial of intravenous iron may be useful. Vitamin B_{12}, folate, and thyroxine deficiency may be excluded easily by the appropriate laboratory tests, as may be severe hyperparathyroidism. Aluminum toxicity is no longer a significant cause of ESA resistance. Depending on the ethnic origin of the patient, a hemoglobinopathy should be excluded by performing Hb electrophoresis. Some patients taking ACE inhibitors or angiotensin receptor blockers may require higher doses of ESA therapy, although it is rarely necessary to stop these drugs. The possibility of a primary bone marrow disorder, such as myelodysplastic syndrome, should be investigated by a bone marrow examination (aspirate and trephine) if all other causes have been excluded. A bone marrow test also may be necessary in the diagnosis of antibody-mediated PRCA, although measurement of the reticulocyte count and anti-EPO antibodies may provide an earlier clue.[25] If a patient receiving ESA therapy has a high reticulocyte count, the bone marrow is generating more than adequate quantities of new RBCs and bleeding or hemolysis should be investigated by means of endoscopy or hemolysis screen (Coombs test, serum bilirubin, lactate dehydrogenase, and haptoglobin levels).

There is no defined upper dose limit of ESA, and doses of 60,000 IU of EPO per week have not uncommonly been used in the United States, but there is recent concern that high doses of ESA may increase side effects independently of Hb concentrations, as described earlier. In patients with acute illness requiring hospitalization, Hb frequently falls despite continued ESA therapy, indicating increased blood loss and temporary hyporesponsiveness. The optimal management of anemia under these conditions remains unclear. Whereas cost considerations may speak for withholding of ESA therapy until responsiveness is reestablished, it has been proposed that doses should be increased in an attempt to overcome hyporesponsiveness. Anecdotally, very high doses can be effective even in critically ill patients in intensive care units, but an RCT[42] failed to demonstrate a reduction in transfusion requirements and observed an increase in deep vein thrombosis. From a practical point of view, and pending evidence to the contrary, it seems sensible to continue the same dose of ESA.

Iron Management

Iron is an essential ingredient for heme synthesis, and adequate amounts of this mineral are required for the manufacture of new RBCs. Thus, under enhanced erythropoietic stimulation, greater amounts of iron are used, and many CKD patients (particularly those on HD) have inadequate amounts of available iron to satisfy the increased demands of the bone marrow.[43] Even before the introduction of ESA therapy, many CKD patients were in negative iron balance as a result of poor dietary intake, poor appetite, and increased iron losses from occult and overt blood losses (see Chapter 86). Losses in HD patients are up to 5 or 6 mg/day, compared with 1 mg in healthy individuals, and this may easily exceed the absorption capacity of the gastrointestinal tract, particularly when there is any underlying inflammation. Iron absorption capacity in patients with CKD is considerably lower than in nonuremic individuals, particularly in the presence of systemic inflammation, and this is mediated by hepcidin upregulation.[9] For this reason also, traditional oral iron therapy (e.g., with ferrous sulfate) is ineffective in many CKD patients, and parenteral iron administration is required, particularly in those receiving HD.[43] However, recently, a newer preparation of oral iron (ferric citrate) that shows greater absorption of iron from the gut has become available in the United States and Japan, and the role that ferric citrate may play in iron management in CKD awaits further elucidation.

An inadequate supply of iron to the bone marrow may be caused by an absolute or a functional iron deficiency.[43] Absolute iron deficiency occurs when there are low whole-body iron stores, as indicated by a serum ferritin level less than 30 ng/ml. Functional iron deficiency occurs when there is ample or even increased storage iron but the iron stores fail to release iron rapidly enough to satisfy the demands of the bone marrow. Several markers of iron status are available, but none of them is ideal (Table 82.3). Serum ferritin is a marker of storage iron but is spuriously raised in inflammatory conditions and liver disease. TSAT is a function of the circulating serum iron in relation to the total iron-binding capacity and is often regarded as a better measure of available iron; however, levels can be highly fluctuant because of significant diurnal variation in the measurement of serum iron.[43] The percentage of hypochromic RBCs and the CHr are RBC and reticulocyte parameters, respectively, that are indirect measures of how much iron is being incorporated into the newly developing or mature RBC. No one measure of iron status is usually adequate to exclude iron deficiency, and the recommended levels for these measures are based on limited scientific evidence. Functional iron deficiency is usually diagnosed when there is a normal or increased ferritin level and a reduced TSAT (<20%) or increased hypochromic RBCs (>10%). The KDIGO guidelines on renal anemia management suggest a trial of iron in CKD patients with anemia who are not on iron and ESA therapy and in whom an increase in Hb concentration is desired and in patients on ESA therapy in whom an increase in Hb concentration or a decrease in ESA dose is required when TSAT is 30% or lower and ferritin level is 500 ng/ml or lower[14] (see Table 82.3). Levels of ferritin above this threshold usually do not confer any clinical advantage and may exacerbate iron toxicity. The optimal TSAT is above 20% to 30% to ensure a readily available supply of iron to the bone marrow. No upper limits of ferritin or TSAT were specified in the KDIGO anemia guidelines, largely because there is no robust evidence to determine a threshold beyond which harm or loss of efficacy supervenes. However, until more informative data become available, the treating nephrologist would be well advised to exercise caution in administering intravenous iron to patients with ferritin levels above 800 ng/ml or TSAT above 30%. Several studies support maintaining the percentage of hypochromic RBCs at less than 6% and the CHr at greater than 29 pg/cell. Other measures of iron status, such as serum transferrin receptor levels and erythrocyte zinc protoporphyrin levels, are mainly research tools.

Oral iron is generally poorly absorbed in uremic individuals, and there is a high incidence of gastrointestinal side effects. Intramuscular administration of iron is not recommended in CKD, given the enhanced bleeding tendency, the pain of the injection, and the potential for brownish discoloration of the skin. Thus intravenous administration of iron has become the standard of care for many CKD patients, particularly those receiving HD.[43] Several intravenous iron preparations are available worldwide, including iron dextran, iron sucrose, iron gluconate, and the newer iron preparations ferric carboxymaltose, ferumoxytol, and iron isomaltoside 1000. The last three iron preparations allow higher doses of intravenous iron to be administered more rapidly, without the need for a test dose. All of the iron preparations contain elemental iron surrounded by a carbohydrate shell, which allows them to be injected intravenously. The lability of iron release from these preparations varies, with iron dextran being the most stable and iron gluconate being the least stable. Iron is released from these compounds to plasma transferrin and other iron-binding proteins and is then taken up by the reticuloendothelial system.

In HD patients, it is easy and practical to give low doses of intravenous iron (e.g., 10 to 20 mg) at every dialysis session or, alternatively, 100 mg weekly. In PD and nondialysis CKD patients, however, such low-dose regimens are impractical and larger doses may be administered. The more stable the iron preparation, the larger the dose administration rate that can be used. For example, 1 g of iron dextran may be given by intravenous infusion, whereas the maximum recommended dose of iron gluconate is 125 mg. The usual dose of ferumoxytol is 510 mg, whereas up to 1 g of ferric carboxymaltose or iron isomaltoside 1000 may be given as a single administration. All intravenous iron preparations carry a risk for immediate hypersensitivity reactions, which may be characterized by hypotension, dizziness, and nausea. These reactions are usually short-lived and caused by too large a dose given in too short a time. Iron dextran also carries the risk for acute anaphylactic reactions because of preformed dextran antibodies, although this was largely a problem with the high molecular weight intravenous iron dextran preparations, which have now been withdrawn from the market. Other, longer term concerns about intravenous administration of iron include the potential for increased susceptibility to infections and oxidative stress. Much of the scientific evidence for this has been generated from in vitro experiments, the clinical significance of which is unclear.[43]

Despite these concerns, the lack of efficacy of traditional oral iron preparations in HD patients has resulted in the widespread use of intravenous iron to correct the negative iron balance in this patient population. In general, the greater the use of intravenous iron, the lower is the dose requirement of ESA therapy; however, the optimum balance

TABLE 82.3 Recommended Iron Status Levels in CKD

Test	Recommended Range
Serum ferritin	100-500 µg/l (CKD) 200-500 µg/l (HD)
Transferrin saturation	20%-40%
Hypochromic red cells	<10%
Reticulocyte hemoglobin content (CHr)	>29 pg/cell
Serum transferrin receptor	Not established
Erythrocyte zinc protoporphyrin	Not established

CKD, Chronic kidney disease; *HD,* hemodialysis.

between intravenous iron and ESA therapy remains unknown. This gap in knowledge may be partly addressed by the ongoing PIVOTAL RCT, which is comparing a more liberal use of intravenous iron versus a restrictive policy in 2141 HD patients recruited across 50 sites in the United Kingdom.[44]

In nondialysis patients, both oral and intravenous iron may be used and there are advantages and disadvantages for each route of administration, which have been compared in two recent RCTs. The FIND-CKD study showed that both routes of administration were effective in this patient population, although higher dose intravenous iron resulted in a faster and greater rise in Hb, with no safety concerns.[39] The REVOKE study, however, suggested that the rate of cardiovascular- and infection-related serious adverse events was greater in the intravenous iron treatment group compared with the oral iron group.[45] The reasons for these discrepant findings remain unknown. Thus the physician has to balance the low costs and convenience of oral iron treatment with known poor adherence to treatment, gastrointestinal side effects, and reduced efficacy; intravenous iron on the other hand requires special facilities and set-up for administration and carries a very small risk for hypersensitivity reactions and potential additional risks.

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements is *false* regarding the characteristics of renal anemia?
   - **A.** The red blood cells (RBCs) produced are usually normochromic and normocytic.
   - **B.** There is usually no associated leukopenia or thrombocytopenia.
   - **C.** The reticulocyte count is usually around 40,000 to 50,000/μl of blood.
   - **D.** Serum erythropoietin levels are usually within the normal range.
   - **E.** The RBC life span is usually normal.
2. Which of the following statements is *false*?
   - **A.** Dose requirements of epoetin are generally 20% to 30% less when the agent is administered subcutaneously compared with intravenously.
   - **B.** Erythropoiesis-stimulating agent (ESA) therapy should be used with caution in patients with previous or current malignancy.
   - **C.** Patients who are hyporesponsive to ESA therapy have a worse prognosis than those who do respond.
   - **D.** The defined upper dose limit of epoetin is 60,000 IU/wk because it is known that cardiovascular toxicity occurs above this dose level.
   - **E.** Angiotensin-converting enzyme (ACE) inhibitors may confer resistance to ESA therapy in some patients.
3. Which of the following statements is *false* regarding the TREAT study?
   - **A.** Patients receiving darbepoetin alfa were randomized to either a target hemoglobin (Hb) of 13 or a target Hb of 9 g/dl.
   - **B.** Patients randomized to a target Hb of 13 g/dl had a small increase in quality of life compared with the control arm.
   - **C.** There was a significant reduction in the use of RBC transfusions in patients randomized to a target Hb of 13 g/dl.
   - **D.** There was a doubling of the rate of stroke in patients randomized to a target Hb of 13 g/dl.
   - **E.** There was a significant increase in cancer-related mortality in the subset of patients with a history of malignancy who were randomized to a target Hb of 13 g/dl.
4. Which of the following statements is *true* regarding intravenous iron supplementation?
   - **A.** All intravenous iron preparations require a test dose before their first administration, as per their product label.
   - **B.** All the newer intravenous iron preparations (ferumoxytol, ferric carboxymaltose, and iron isomaltoside 1000) have the advantage that up to 1 g may be administered as a single dose.
   - **C.** Intravenous iron preparations vary in their lability and speed of iron release from the carbohydrate shell, with iron gluconate being the most stable and iron dextran the least stable compound.
   - **D.** Intravenous iron may improve the anemia of chronic kidney disease in up to 30% of patients not receiving ESA therapy who have a low ferritin level.
   - **E.** Hypersensitivity reactions are more common with low molecular weight iron dextrans than with high molecular weight iron dextran compounds.

Other Blood and Immune Disorders in Chronic Kidney Disease

Matthias Girndt, Gunnar H. Heine

IMMUNE DYSFUNCTION

Patients with chronic kidney disease (CKD) have a high morbidity and mortality as a result of infection. This is in part directly caused by alterations in the immune system, although multiple other factors are involved.

Bacterial Infections

Infections are a major cause of hospitalization in patients with CKD; infection-related hospitalization rates are at least three to four times (nondialysis CKD) or eight times (dialysis) higher than in individuals with normal renal function.[1] The number of days spent in hospital for infections has slightly decreased over the last decade. Nevertheless, they are still higher than those for cardiovascular disease (4 vs. 2.2 days per patient year[1]). Infection is also an important cause of mortality, accounting for 8% of deaths in dialysis patients. Pulmonary infections and infections of the genitourinary system in particular increase with decreasing renal function. For example, patients with CKD stage 4 have a 15-fold higher risk for severe pulmonary infections compared with those with an estimated glomerular filtration rate (eGFR >60 ml/min/1.73 m^2). Furthermore, mortality from pneumonia is markedly enhanced by concurrent CKD.[2]

In hemodialysis (HD) patients, bloodstream infections are another major cause of infection-related hospitalization, particularly in patients with central venous catheters as dialysis access.[3] Catheter-based HD is among the major risk factors for the development of bacterial endocarditis. More than 50% of cases of bacteremia are caused by *Staphylococcus aureus*. Nevertheless, there is also a relevant rate of gram-negative bacteremias in dialysis patients, indicating that contamination or infection of the dialysis access is not the only cause for bloodstream infection.

The high incidence of bacterial infection in CKD patients may be one clinical consequence of immune dysfunction; another is atypical clinical presentations of infections such as the lack of fever in 20% to 40% of bacteremic patients. When bacteremia is suspected, blood cultures should be obtained frequently. Another aspect of immune dysfunction is the high rate of false-negative tuberculin (Mantoux) skin tests with anergic skin reactions in the presence of positive interferon-γ release assays (IGRA tests), indicating impaired T-lymphocyte function.[4]

However, other factors besides immune dysfunction also predispose to infection in persons with CKD. Thirty-nine percent of patients with end-stage renal disease reported by the U.S. Renal Data System are above 65 years of age,[1] and in other countries this fraction exceeds 50%. Besides their age, many CKD patients have underlying renal or extrarenal autoimmune disease that requires therapeutic immunosuppression and other comorbidities that facilitate infection such as diabetes or heart failure. Dialysis patients and patients with the cardiorenal syndrome often have excess pulmonary fluid, which may impair alveolar bacterial clearance and contribute to the risk for pneumonia. Repeated breaks in the skin barrier by cannulation provide opportunity for bacterial invasion. Finally, dialysis patients frequently receive intravenous iron preparations, and iron overload is a risk factor for bacterial infection as a result of inhibition of monocyte and macrophage function.

Viral Infections

Viral hepatitis has been a scourge of dialysis ever since renal replacement therapy (RRT) became a routine treatment. Only rigorous standard hygienic precautions and active vaccination against hepatitis B virus (HBV) made large-scale HD safe. However, impaired immune defense was only one among other causes for the high prevalence of viral hepatitis in this patient group. The viruses can be easily transmitted nosocomially in HD patients without proper precautions. Nevertheless, the early outbreaks of HBV infection showed an abnormal clinical course related to the immune defect in CKD.[5] The acute infection could sometimes only be detected by measurement of transaminases. The clinical syndrome of icterus, subfebrile temperatures, and malaise, which is typical for patients with normal renal function, was missing. The majority of affected dialysis patients developed chronic persistent infection, which occurs in only 10% of patients with intact renal function.

The clinical manifestations of HCV infection are not significantly influenced by the immune deficiency of renal failure. The infection usually runs a rather subclinical course and becomes chronic even in the absence of CKD.

Vaccinations in Chronic Kidney Disease

Immune deficiency leads to a high rate of nonresponse to hepatitis B vaccination. Dialysis patients should always receive double-dose vaccination and extended vaccination protocols (Fig. 83.1), but even with the most recent vaccines some 20% of patients do not develop protective antibody levels.[6] This impaired response led to the development of specifically adjuvanted vaccines or intracutaneous application protocols[7] with improved efficiency in former nonresponders.

Other vaccinations are also affected by the immune defect in CKD. The Kidney Disease: Improving Global Outcomes (KDIGO) guidelines[8] recommend annual influenza vaccinations. Studies comparing vaccination efficiency in patients with CKD and healthy individuals have methodologic limitations; therefore the extent to which immune dysfunction compromises these vaccination results is not clear. Most likely, the efficacy is lower in dialysis patients. A recent systematic review on the protective effects with regard to hard end-points such as mortality or hospitalization pointed out that the universal recommendation to vaccinate—albeit very plausible—has a weak evidence base.[9]

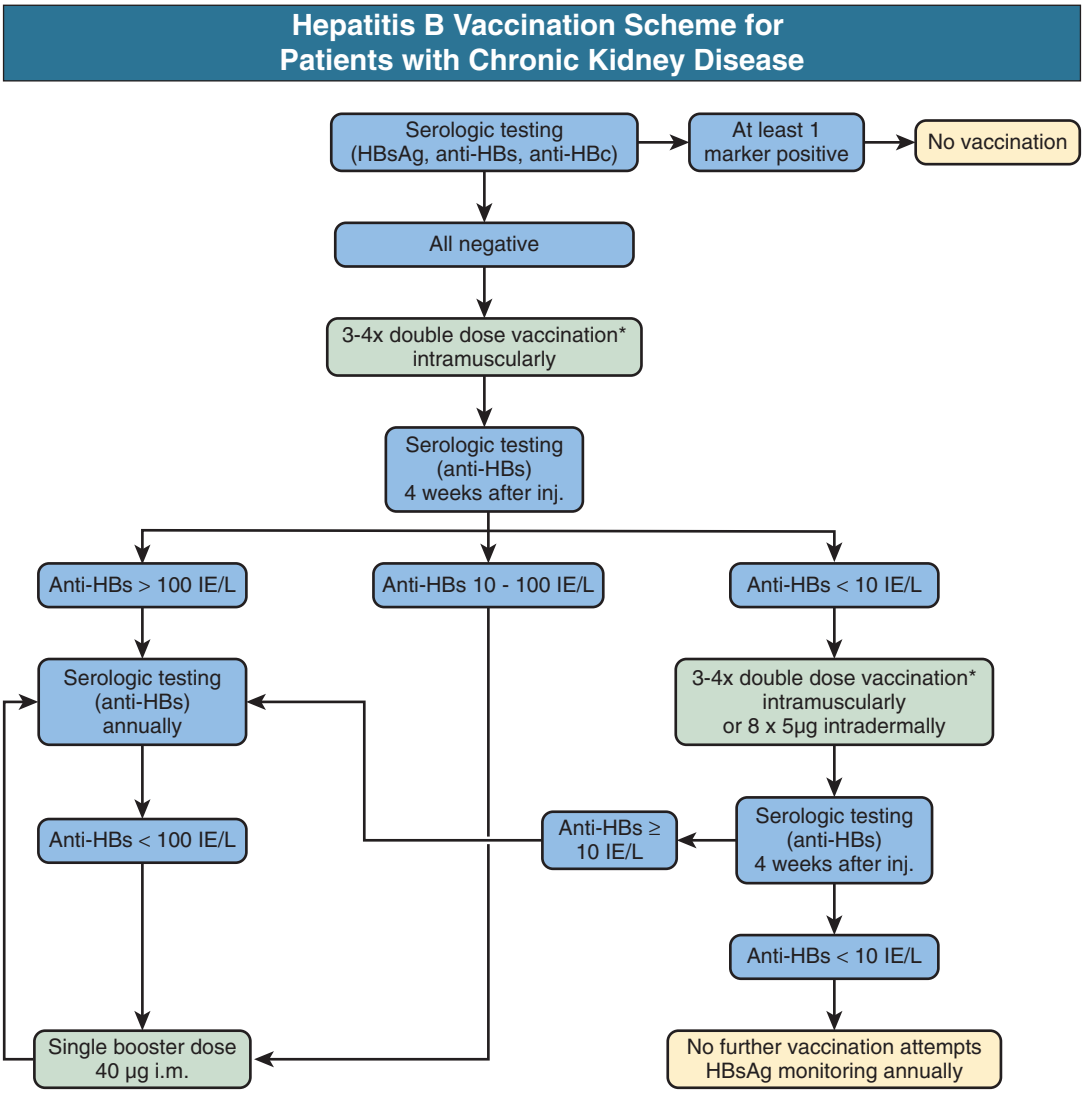

Fig. 83.1 Hepatitis B vaccination scheme for patients with chronic kidney disease (CKD). *The schedule varies with different vaccine preparations.

In contrast to antiviral vaccinations, those against bacteria appear to be less influenced by CKD. Vaccination against pneumococcal infections is universally recommended[8] for adults with eGFR less than 30 ml/min/1.73 m^2. Evidence of efficacy in terms of antibody titers comes from very old studies or series with small patient numbers. Likely, maximum antibody titers are lower and protection lasts shorter in CKD patients,[10] but data on hospitalization or mortality can be derived only from observational studies.[11] Because multiple vaccine preparations are available, the congruence of local epidemiology and the vaccine coverage should be considered (Fig. 83.2). Newer conjugate vaccines have a rather narrow spectrum of serotype coverage while being highly effective in inducing seroprotection; thus there is an argument to vaccinate CKD patients sequentially with conjugate vaccine first, followed in 6 to 12 months by the broad polysaccharide vaccine. Revaccination with the polysaccharide vaccine is recommended after 6 years.

Further recommendations for vaccination in CKD are given in Table 83.1.

INFLAMMATION

Chronic inflammation is typical for patients with CKD 4 or 5 or on RRT, and C-reactive protein (CRP) and plasma cytokines increase steadily

TABLE 83.1 Vaccination Recommendations for Adult Patients With Chronic Kidney Disease

Vaccination Against	Recommendation
Hepatitis B virus (HBV)	All patients susceptible to HBV infection, double dose (see Fig. 83.1)
Influenza	Annually according to WHO recommendation, standard dose
Streptococcus pneumoniae	All patients, conjugate vaccine, can be boostered by polysaccharide vaccine at 6 mo, revaccination after 6 y
Tetanus	All patients according to recommendations for general population, standard dose
Diphtheria	All patients according to recommendations for general population, standard dose
Hepatitis A	Not routinely indicated, can be given for travel

Modified from reference 49.
WHO, World Health Organization.

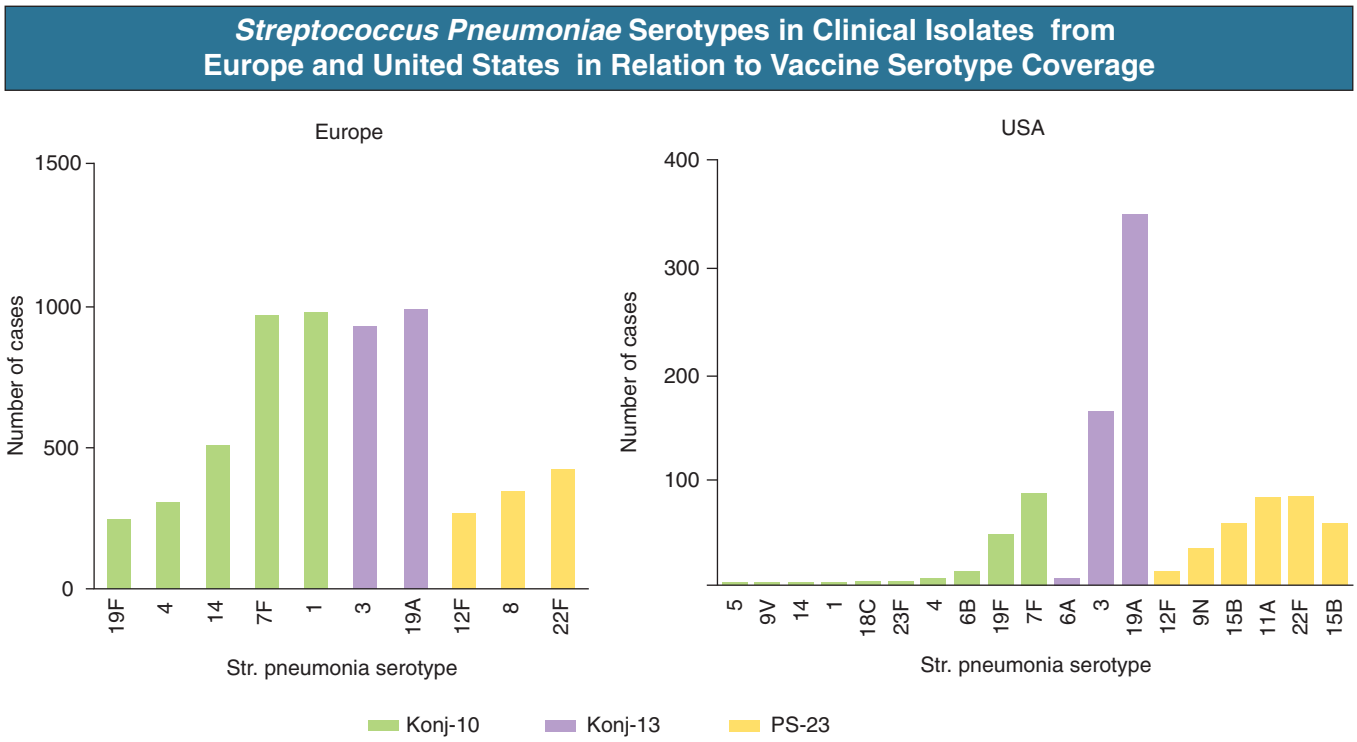

Fig. 83.2 ***Streptococcus pneumoniae*** **serotypes in clinical isolates (as of 2010) from Europe (European Center of Disease Control) and United States (Centers for Disease Control and Prevention) in relation to vaccine serotype coverage.** Conj-10: 10-valent conjugate vaccine; Conj-13: 13-valent conjugate vaccine; PS-23: 23-valent polysaccharide vaccine. Low isolate numbers for the serotypes covered by Conj-10 in the United States are result of successful vaccination programs.

with every stage of CKD. The majority of HD and peritoneal dialysis patients periodically or permanently have CRP values above the normal limit in the absence of clinical infection.[12]

Causes of Inflammation

Although early research in this field focused on dialysis membrane bioincompatibility, contamination of dialysis fluids, or vascular access as causes of inflammation, chronic inflammation also occurs in patients with CKD stages 3 and 4. One important reason may be the renal clearance of circulating proinflammatory cytokines.[13] Impaired kidney function leads to prolonged cytokine serum half-life, thus enhancing and prolonging inflammatory episodes that usually would have abated quickly.

At least 30% of patients with advanced CKD have diabetes mellitus, a comorbidity that promotes inflammation both by itself and through diabetic complications such as ulcers. In addition, many patients with CKD have poor dental health and periodontitis is associated with systemic inflammation.[14]

Whether inflammation is also related to classic uremic toxicity remains a matter of debate. Typical toxins with increased plasma levels are indoxyl sulfate, paracresyl sulfate, and trimethylamine N-oxide (TMAO). Across stages of CKD, plasma levels of TMAO show a positive correlation with inflammatory markers, and both decrease after renal transplantation.[15] Several studies show that serum levels of indoxyl sulfate or paracresyl sulfate increase with renal dysfunction in parallel with inflammatory markers; however, a causal relationship remains to be proven.

The extent of inflammation is at least in part controlled by the genetic predisposition of the individual. This may be clinically relevant in patients with CKD because inherited single-nucleotide polymorphisms in the gene of the antiinflammatory cytokine interleukin-10 (IL-10) influence the quantity of its production in response to inflammatory stimuli and thus the way a patient can contain and limit inflammation.[16]

Consequences of Inflammation

Inflammation is closely associated with the occurrence of CV complications (reviewed in Chapter 81) and immune dysfunction. When using the response to HBV vaccination as a surrogate for clinical immune function, there is a close correlation between inflammation and decreased immunity. This is confirmed by the finding that the IL-10 gene polymorphism, which influences the extent of inflammation, also predicts vaccination responses in dialysis patients.[16]

IMMUNE CELL ABNORMALITIES

Monocytes

Monocytes are bone marrow–derived cells with specific functions in immune surveillance and antigen presentation. During their differentiation, they briefly circulate in the blood, produce cytokines, and then migrate into tissues to become macrophages.[17] Injury and infection lead to rapid enhancement of circulating monocyte numbers, which then migrate to the site of tissue injury and initiate the local immune response. Monocyte-derived macrophages are constituents of atherosclerotic plaques, and imaging studies have revealed that monocytes patrol along the vascular endothelium, where they detect endothelial defects.[18]

Monocyte subpopulations are defined by the expression of the lipopolysaccharide (LPS) receptor CD14 and the immunoglobulin Fcγ receptor CD16.[19] The classic monocytes only express CD14 and account for some 80% of all circulating monocytes in healthy individuals;

intermediate monocytes express both CD14 and CD16 (~5% to 7%), and nonclassic monocytes express high levels of CD16 while showing limited staining for CD14 (~10% to 12%). Genetic analysis revealed that $CD14^{++}CD16^{+}$ intermediate monocytes particularly express markers related to antigen presentation, inflammation, and angiogenesis.[20]

In CKD, the intermediate and nonclassic monocyte subtypes are significantly expanded. This finding is related to the CV risk[21]; patients with the highest rate of $CD14^{++}CD16^{+}$ monocytes in blood had the lowest CV event-free survival.

Mouse models confirm differences between monocyte subpopulations in their ability to invade atherosclerotic plaques.[22] In CKD the expansion of proinflammatory monocyte subsets and their epidemiologic association with CV events make a causal role of these cells for atherosclerotic disease likely. Furthermore, monocytes also express components of the angiotensin system. The angiotensin-converting enzyme (ACE) that turns angiotensin I (Ang I) into vasoactive angiotensin II (Ang II) is expressed in atherosclerotic plaques and colocalizes with monocyte-derived macrophages.[23] ACE is also expressed on circulating monocytes, particularly on those with the $CD14^{++}CD16^{+}$ phenotype.[24] Dialysis patients with high expression of ACE on intermediate monocytes have a dramatically enhanced CV mortality risk.[24]

Expression of ACE on monocytes is strongly upregulated by the uremic milieu.[25] A consequence of this might be that monocytes transmigrate into the subendothelial space of arteries and provide high levels of ACE in the atherosclerotic plaque. The local production of Ang II through ACE is thought to contribute to further leukocyte attraction, inflammatory activation, and plaque growth. In addition, expression of ACE on monocytes alters their functional capacities. In vitro assays show that a higher expression of ACE leads to stronger endothelial adhesion and transmigration of the monocytes. This effect appears to be mediated via locally produced Ang II, because adhesion and transmigration could be inhibited by losartan.[25]

Monocytes also express ACE-2, a peptidase that degrades Ang II to Ang1-7, a vasodilatory peptide. Whereas CKD leads to the overexpression of ACE, the ACE-2 enzyme is downregulated compared with healthy individuals.[26] Experimental overexpression of ACE-2 in a rodent model of atherosclerosis limited the progression of disease. These findings suggest that the uremic milieu alters monocyte function in a strongly proatherogenic way.

Monocytes are closely related to circulating blood dendritic cells. Dendritic cells are mainly found in organs and tissues, where they have strong capabilities in antigen presentation and activation of immune reactions. Their immature precursors circulate in blood in low numbers. There are different subtypes of circulating dendritic cells, but investigators have used different marker sets for their detection. This limits comparison among different studies, so that understanding of dendritic cell quantification and pathophysiology remains limited. There is a relation between elevated numbers of $CD14^{++}CD16^{+}$ monocytes in the blood and the propensity of these cells to differentiate into dendritic cells in cell culture.[27] Other studies[28] found significantly lower numbers of dendritic cells in advanced CKD compared with healthy controls. The finding may be related to CV disease, because studies in patients with coronary heart disease and normal renal function also reported reduced circulating numbers of dendritic cells.

T Lymphocytes

Impaired vaccination responses against viral antigens such as HBV or influenza, as well as reduced skin reaction in the Mantoux test, result from impaired T cell activation. T cells are an important component of the antigen-specific adaptive immune defense. Their activation depends on antigen-presenting cells (APCs) that present foreign antigens with major histocompatibility complex and provide important costimulatory signals. Only T cells with specificity of their T cell receptor toward the particular antigen are activated and proliferate.

Major APCs are dendritic cells and their precursors are monocytes. Early studies showed that proliferative T cell responses are impaired in dialysis patients and this impairment is directly correlated with nonresponses to HBV vaccination. Both replacement of the patient's APCs in in vitro assays with cells from healthy donors and overexpression of costimulatory molecules on the APCs normalize proliferation of T cells, indicating that the major defect leading to reduced T cell activation is in the APC.[29] However, these rather crude assays did not consider T cell subpopulations. Helper T cells express the surface marker CD4 and interact with various other cell types. The $CD4^{+}$ helper T cell is particularly needed for activation of B cells for antigen-specific seroresponses to viral antigens as in HBV vaccination. The $CD8^{+}$ cytotoxic T cells are important for antiviral defense because they are able to lyse infected host cells. In CKD the relation of $CD4^{+}/CD8^{+}$ T cells is reduced.

$CD4^{+}$ helper cells can be further distinguished into cells that mainly support cellular immune reactions (T helper cells Type 1, Th1) and others that are more important for immunoglobulin production by members of the B cell lineage (Th2). These cell types differ in the pattern of cytokines they produce, with interferon-γ being the major cytokine of Th1 and IL-4 the main cytokine of Th2 cells. CKD leads to a marked deviation of T cell differentiation toward the Th1 phenotype.[30] Most likely the major cause is elevated production of IL-12 by monocytes and APCs in the context of their inflammatory activation.[30]

Another T-lymphocyte subpopulation is regulatory T cells (Tregs) that are important for the downregulation of immune responses once the aim of an antiinfectious response is reached. They prevent ongoing inflammation and the development of autoimmunity. The typical Treg cells originate in the thymus and have a distinct pattern of surface molecule expression. In patients with CKD the number of circulating Treg cells is unaltered, but their capacity to downregulate $CD4^{+}$ helper T cell activity is impaired.[31]

B Lymphocytes

Impaired vaccination efficacy in CKD suggests impaired function of immunoglobulin producing B-lymphocytes and plasma cells; thus a major dysfunction of this cell type might be expected. However, CKD patients have normal circulating immunoglobulin levels. Their B cell lymphopenia is modest and probably not very clinically relevant. It is caused by a higher rate of apoptosis of these cells compared with healthy individuals.[32] Lymphopenia appears to result from reduced numbers of the majority of B cell subpopulations (naïve B cells, memory B cells, etc.).[33] Taken together, the alterations of B-lymphocytes in CKD appear to be less pronounced than alterations of other immune cell types. Impaired vaccination responses are caused by altered interaction of APCs, helper T lymphocytes, and the cytokine network in CKD rather than by abnormalities of B lymphocytes.

Granulocytes

Polymorphonuclear granulocytes (neutrophils) are components of the antigen-independent innate immune system. Their main activity is to kill and phagocytose invading pathogens via numerous enzymes that produce bactericidal substances. Among them are defensins, proteolytic enzymes, and enzymes that produce highly active oxygen species such as hypochlorous acid. In CKD patients these nonspecific defense systems are highly activated and the cells spontaneously release more reactive oxygen species.[34] Inflammation, activation of different cell types, antiinfectious defense, and vascular disease are closely interwoven. Thus the elevation of oxygen species H_2O_2 and malondialdehyde has predictive value for CV events and mortality in CKD.[35]

Another important function of granulocytes is phagocytosis, which is also mildly compromised in CKD.[36]

It is difficult to establish whether these alterations can be improved by dialysis. HD inevitably involves marked contact between blood and foreign surfaces. When cellulose-based membranes were still in use, the activation of the complement system by these membranes led to marked depletion of circulating granulocytes within the first 20 minutes of a dialysis session.[37] Newer synthetic membranes lead to minimal complement activation, and the leukocyte drop is much less pronounced. These findings on immune cells relate to CKD. It is important to consider that some primary diseases, in particular diabetes mellitus, further influence immune cell function.

PLATELET DYSFUNCTION AND PLATELET INHIBITORS IN CHRONIC KIDNEY DISEASE

Normal hemostasis begins with platelet adhesion to vascular endothelium and requires a relatively vasoconstricted vessel wall, integrity of platelet glycoproteins (GPs), and a normal quantity of large molecular weight, multimeric von Willebrand factor (vWF) (Figs. 83.3 and 83.4). Main platelet GPs are GPIb, the platelet receptor for vWF, involved in platelet adhesion, and GPIIb/IIIa, the platelet receptor for fibrinogen, involved in platelet aggregation.

Under static conditions, GPIb and vWF have no affinity for each other. However, these molecules develop a specific affinity for each other at high shear stress, resulting in arterial platelet adhesion. Aggregated fibrinogen-platelet mesh acts as a trap for binding and activation of other plasma clotting factors. The exposure of the preceding clotting factors to tissue factors, present on damaged endothelial cells, catalyzes the conversion of prothrombin to thrombin, which converts fibrinogen to fibrin. Subsequent cross-linking of insoluble fibrin results in a stable hemostatic plug.

Hemorrhagic Diathesis and Uremic Platelet Dysfunction

Patients with CKD have a high risk for bleeding. This hemorrhagic diathesis frequently has cutaneous (easy bruising, ecchymoses, or prolonged hemorrhage from needle puncture or postoperative sites) and mucosal (epistaxis; gastrointestinal or gingival bleeding) manifestations. More dramatic—albeit infrequent—manifestations are hemorrhagic pericarditis/hemopericardium, hemorrhagic pleural effusion/hemothorax, and intracranial and retroperitoneal bleeding.[38]

This hemorrhagic diathesis is not reflected in a prolongation of the prothrombin time or the partial thromboplastin time. Similarly, even though platelet counts may be moderately decreased because of platelet consumption outperforming platelet production, severe thrombocytopenia is rarely seen in uremia; the occurrence of very low platelet counts therefore requires a thorough search for alternative causes.[39] Instead, platelet dysfunction is generally considered as the central contributor to the high bleeding risk, and a high number of pathophysiologic alterations have been suggested to contribute, comprising alterations in platelet function and structure, and extrinsic factors (see Table 83.1). Unfortunately, many studies on platelet functions in CKD date back to early days of clinical nephrology, when clinical care and dialysis treatment were less sophisticated, and when less advanced laboratory methods were available for evaluation of hemostasis. For the various pathophysiologic alterations listed in Box 83.1, controversial data have been published.

In the search for uremic toxins inducing platelet dysfunction, a direct pathologic role of urea can be ruled out because no correlation exists between blood urea levels and bleeding time[40] and individuals

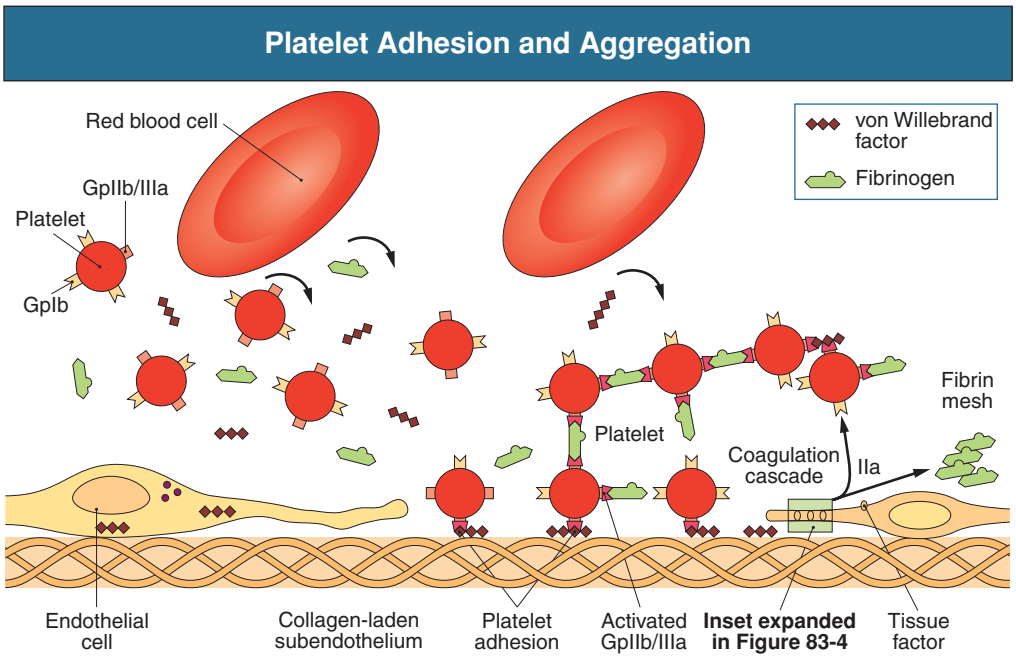

Fig. 83.3 Platelet adhesion and aggregation. Platelets are pushed peripherally toward the vascular wall by red blood cells traversing centrally through the bloodstream. Damage to the vessel wall results in a disruption of the nonthrombogenic endothelial cell lining and exposure of subendothelial structures. Whereas collagen supports initial platelet adhesion (and subsequent aggregation), von Willebrand factor (vWF) deposition on the subendothelium serves as the main anchor for platelet adhesion through platelet GPIb receptor. Postadhesion conformational change in platelet GPIIb/IIIa receptor (fibrinogen or vWF receptor) results in interlinking platelet aggregation.

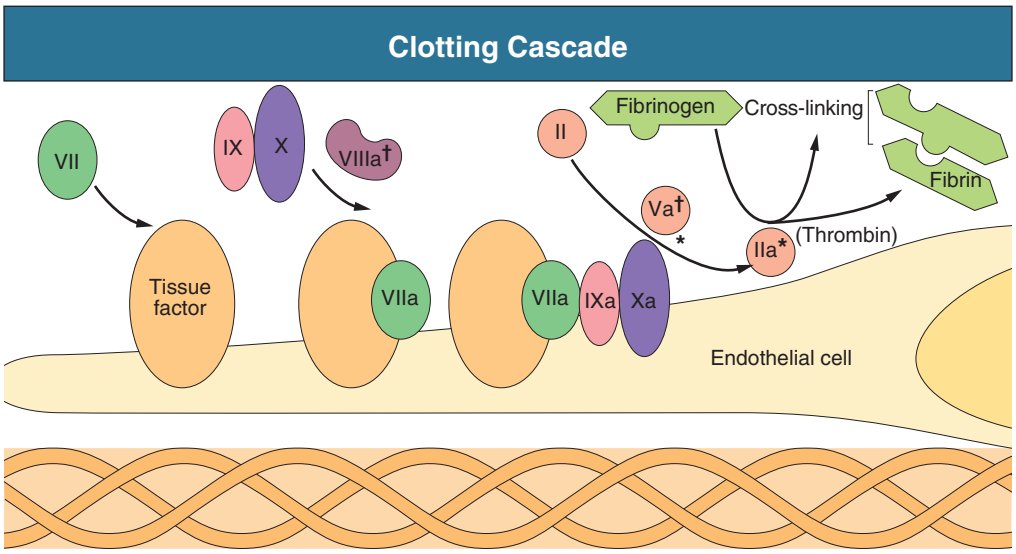

Fig. 83.4 Clotting cascade. Expansion of the inset in Fig. 83.3 shows the clotting cascade that takes place at the damaged vessel wall. Exposure of subendothelial tissue factor, present on pericytes and fibroblasts, allows eventual activation of prothrombin (factor II) to thrombin. Thrombin converts fibrinogen to fibrin, activates fibrin cross-linking, stimulates further platelet aggregation, and activates anticoagulant protein C. Naturally occurring anticoagulants antithrombin III, protein C, and protein S help maintain control and counterbalance on coagulation. *Site of anticoagulant effect for antithrombin III. †Site of anticoagulant effect for protein C–protein S complex. BOX 83.1 Proposed Contributors to Platelet Dysfunction in Uremia

Intrinsic Factors That Contribute to Platelet Dysfunction

- Dysfunction of glycoprotein IIb/IIIa
- Abnormal expression of platelet glycoprotein
- Altered release of adenosine diphosphate (ADP) and serotonin from platelet α-granules
- Faulty arachidonic acid and depressed prostaglandin metabolism, decreased platelet thromboxane A2 generation
- Abnormal platelet cytoskeletal assembly with reduced incorporation of actin and diminished association of actin binding proteins (α-actin and tropomyosin) with the cytoskeleton

Extrinsic Factors That Contribute to Platelet Dysfunction

- The action of uremic toxins
- Anemia
- Increased nitric oxide (NO) and cyclic guanosine monophosphate (cGMP) production
- Functional von Willebrand factor abnormalities
- Decreased platelet production
- Abnormal interactions between the platelet and the endothelium of the vessel wall

Modified from Berns JS, Coutre S. Platelet dysfunction in uremia. UpToDate, http://www.annemergmed.com/article/S0196-0644(15)00034-7/pdf; reference 38.

with high serum urea levels but otherwise normal renal function have no bleeding tendency.[41]

Among the different extrinsic factors that contribute to platelet dysfunction, the contribution of anemia has gained particular interest. Physiologically, erythrocytes occupy the center of a vessel, displacing platelets from the axial flow toward the vessel walls. This allows platelets to adhere to injured endothelial cells and initiate the formation of a platelet plug. In anemia, platelets are more dispersed, which impairs their adherence to the endothelium. Moreover, in CKD, red blood cells may affect coagulation by releasing adenosine diphosphate (ADP), by inactivating PGI_2, and by scavenging nitric oxide (NO), which are all central regulators of platelet function.[39]

Treatment of Uremic Platelet Dysfunction

Despite the previously discussed pathophysiologic considerations, few data establish the extent to which initiation of RRT reduces the risk for bleeding in CKD.

In the early decades of HD, the interaction of blood with cellulose-based dialyzer membranes resulted in complement activation and transient thrombocytopenia during the dialysis procedure. When using more biocompatible dialyzer membranes, such complement-induced platelet reduction no longer has clinical relevance. Nonetheless, HD treatment may still affect bleeding disorders; while potentially removing uremic toxins, which affect platelet function, it requires systemic anticoagulation and exposes patients to the potential risk for heparin-induced thrombocytopenia (HIT). Moreover, HD may disrupt the platelet cytoskeleton, induce repeated platelet stress, decrease the percentage of RNA-rich platelets, and reduce the percentage of available reticulated platelets.[42] As RNA-rich and reticulated platelets are more able to be activated, the accumulation of less RNA-rich and less reticulated platelets indicates the presence of less reactive platelets. Although treatment of anemia may improve some parameters of platelet dysfunction,[42] it has not been demonstrated to ameliorate bleeding or risk for bleeding.

In summary, dialysis and anemia treatment will not completely normalize platelet function. Therefore drug treatment should be considered for those patients who have active bleeding or are scheduled to undergo an invasive diagnostic or therapeutic procedure with bleeding risk.

Desmopressin

Desmopressin (1-deamino-8-D-arginine-vasopressin, DDAVP) is a synthetic derivative of the antidiuretic hormone with little vasopressor activity. It acts by stimulating the release of large factor VIII:von Willebrand factor multimers from endothelial cells into the plasma and potentially by increasing the membrane glycoprotein expression of platelets.

At a dose of 0.3 mcg/kg (if given intravenously [in 50 ml of saline over 15 to 30 minutes] or subcutaneously]) or 3 mcg/kg (if given intranasally), desmopressin improves the bleeding time over the subsequent 4 to 8 hours. Typical side effects include water retention, hyponatremia, moderate thrombocytopenia, facial flushing, mild transient headache, nausea, abdominal cramps, and mild tachycardia; thrombotic events are rarely observed.[38]

Although its efficacy on laboratory measures of platelet function is undisputed, its clinical efficacy for preventing or treating bleeding remains unproven. Additionally, depletion of endothelial stores of the factor VIII:von Willebrand factor multimers after a second DDAVP injection may result in tachyphylaxis, which precludes its chronic use.

Cryoprecipitate

In many uremic patients, cryoprecipitate may improve the bleeding time within 1 hour after infusion. This effect is supposed to be mediated by the provision of factor VIII:von Willebrand factor multimers, fibrinogen, and by other factors that enhance platelet aggregation. However, this effect is short-lasting (4 to 24 hours). Moreover, cryoprecipitate may have infectious, hemorrhagic and anaphylactic complications, and not all patients respond to cryoprecipitate.[38,39,42] Thus use of cryoprecipitate should be limited to patients with life-threatening bleeding who are resistant to treatment with desmopressin and blood transfusions.

Tranexamic Acid

As an antifibrinolytic agent, tranexamic acid (TXA) is licensed for treatment of heavy bleeding, as well as before dental interventions in patients with coagulopathies. Its use in CKD has been reported in several (mostly small) cohort studies, which often focused on surrogate markers of hemorrhagic diathesis. Therefore TXA may be considered for life-threatening bleeding events in CKD patients. However, it should be reserved for those in whom other treatments have failed to control bleeding, because renal excretion is the main route of TXA clearance. TXA has an unpredictable pharmacokinetic profile in advanced CKD patients, who are at particular risk for neurologic side effects of TXA (i.e., seizures).[43]

RECOMBINANT ACTIVATED FACTOR VII

Recombinant activated factor VII (rFVIIa) was developed for treatment of hemorrhage in individuals with hemophilia with antibodies inactivating factor VIII or IV. Because of the central role of activated factor VII in coagulation, rFVIIa has been used off label in a variety of other severe bleeding disorders, including some case reports that claimed successful use of rFVIIa for treatment of bleeding in CKD patients.[39] This very limited evidence, together with a substantial risk for thromboembolic events, mandates very prudent use of rFVIIa, which should be considered only in very severe bleeding when other interventions have failed.

ESTROGENS

Estrogens may improve bleeding time in CKD patients in a dose-dependent manner. Their mode of action involves a reduced production of L-arginine, which is a precursor of NO. Thus estrogens may lower elevated NO production in CKD patients and subsequently reduce NO-induced guanylyl cyclase stimulation and cyclic guanosine monophosphate (cGMP) synthesis, which will finally increase thromboxane A and ADP availability. Estrogens may additionally lower hemorrhagic diathesis by affecting production of coagulation factors and their inhibitors.

Estrogens may be given intravenously, orally, or cutaneously. Compared with other approaches, estrogen treatment may affect bleeding tendency for a prolonged time. However, its long-term safety has again not been assessed in prospective studies.

IMPLICATIONS FOR ANTIPLATELET AGENT THERAPY

Uremic platelet dysfunction and the increased bleeding risk also implies that treatment with antiplatelet agents—particularly aspirin, clopidogrel, prasugrel, and ticagrelor—may induce more bleeding events among CKD patients than in the general population. At the same time, CKD patients are at high CV risk and use of aspirin or other antiplatelet agents may reduce their risk for myocardial infarctions and stroke.

A recent KDIGO guideline[8] recommends that "adults with CKD at risk for atherosclerotic events be offered treatment with antiplatelet agents unless there is an increased bleeding risk that needs to be balanced against the possible CV benefits." However, it remains unclear how to identify the patients who may benefit from antiplatelet agents, and risk scores from the general population work poorly among CKD patients.

Antiplatelet agents should not routinely be prescribed to all CKD patients because the increased risk for major bleeding appears to outweigh the CV benefits, at least in CKD patients with low risk for atherosclerotic events.[44] Their use among CKD patients with overt atherosclerotic vascular disease is strongly recommended (see Chapter 81). However, dual-antiplatelet therapy should be limited to the very early period after acute myocardial infarction or after coronary stenting among CKD patients, whose bleeding risk with dual-antiplatelet therapy is much higher than in patients with intact renal function.

CIRCULATING COAGULATION FACTORS

Despite their elevated bleeding risk, patients with advanced CKD also may show features of a hypercoagulable state. Although general measures of the coagulation system—prothrombin time and partial thromboplastin time—are within normal ranges, venous thromboembolism (VTE) occurs more frequently in patients with low GFR and/or high albuminuria than among individuals with intact kidney function. A variety of factors may contribute, which include elevated levels of factor VIII and vWF, and a variety of comorbidities, including immobilization, congestive heart failure, and obesity. Iatrogenic factors may additionally play a part in CKD-associated hypercoagulation, such as drug treatment (erythropoietin, corticosteroids), intravascular interventions, and devices.

THERAPEUTIC INTERVENTION

Components of the coagulation system are targets of many drugs for prevention or treatment of thrombotic disease, including unfractionated and low molecular weight heparin (LMWH), vitamin K antagonists (VKA) and of non–vitamin K antagonist oral anticoagulants (NOAC).

First, unfractionated and LMWH are routinely used during HD for preventing clotting in the extracorporeal circulation. Thus nearly all

HD patients are exposed to potential side effects of heparin, which comprise an increased bleeding risk and some less frequent adverse events, of which the development of HIT is the most serious complication. HIT is a clinical syndrome induced by antibodies that bind to heparin and platelet factor IV complexes on the platelet surface and thereby cause platelet activation. Clinically, HIT often manifests with arterial or venous thrombosis; less frequent complications are venous limb gangrene, adrenal hemorrhagic necrosis, necrotizing skin lesions at heparin injections sites, and acute systemic reactions within a few minutes after exposure to unfractionated heparin or LMWH injections. Of note, many patients have heparin-dependent antibodies without clinically apparent HIT. Therefore, to avoid over-diagnosing HIT, immunologic tests should not be ordered in patients with a low clinical likelihood but focused on patients in whom HIT is suspected clinically (as suggested by the 4T score; Table 83.2). This is of particular importance for HD patients, in whom an incorrect diagnosis may result in the withdrawal of heparin treatment during HD and in the initiation of less established (and more expensive) anticoagulation strategies. In the absence of CKD-specific pathways, the diagnosis of HIT should follow recommendations from the general population. Here, the likelihood of HIT should first be estimated with clinical prediction tools and use of antigen assays for confirmation of HIT antibodies should focus on patients with high and intermediate clinical likelihood (Fig. 83.5). Importantly, these antigen assays for detection of HIT antibodies have a high sensitivity but poor specificity. Wherever available, functional assays (serotonin release assays or heparin-induced platelet activation)

TABLE 83.2 4 Ts Score to Determine the Likelihood of Heparin-Induced Thrombocytopenia (HIT)

	Score = 2	Score = 1	Score = 0
***T*hrombocytopenia:** Compare the highest platelet count within the sequence of declining platelet counts with the lowest count to determine the percent of platelet fall (select only one option)	>50% platelet fall *and* nadir of ≥20 k per uL *and* no surgery within preceding 3 days	>50% platelet fall *but* surgery within preceding 3 days *or* Any combination of platelet fall and nadir that does not fit criteria for score 2 or score 0 (e.g., 30%-50% platelet fall or nadir 10-19)	<30% platelet fall Any platelet fall with nadir <10
***T*iming** (of platelet count fall or thrombosis*) Day 0 = First day of most recent heparin exposure (select only one option)	Platelet fall day 5-10 after start of heparin Platelet fall within 1 day of start of heparin *and* exposure to heparin within past 5-30 days	Consistent with platelet fall days 5-10 but not clear (e.g., missing counts) Platelet fall within 1 day of start of heparin AND exposure to heparin in past 31-100 days Platelet fall after day 10	Platelet fall day 4 or earlier without exposure to heparin in past 100 days
***T*hrombosis** (or other clinical sequelae) (select only one option)	Confirmed new thrombosis (venous or arterial) Skin necrosis at injection site Anaphylactoid reaction to intravenous heparin bolus Adrenal hemorrhage	Recurrent venous thrombosis in a patient receiving therapeutic anticoagulants Suspected thrombosis (awaiting confirmation with imaging) Erythematous skin lesions at heparin injection sites	Thrombosis suspected
o*T*her cause for Thromboycytopenia† (select only one option)	No alternative explanation for platelet fall is evident	Possible other cause is evident: Sepsis without proven microbial source Thrombocytopenia associated with initiation of ventilator Other	Probable other cause present: Within 72 h of surgery Confirmed bacteremia/fungemia Chemotherapy or radiation within past 20 days DIC as a result of non-HIT cause Post-transfusion purpura (PTP) Platelet count <20 *and* given a drug implicated in causing D-ITP‡ (see list) Non-necrotizing skin lesions at LMWH injection site (presumes DTH) Other

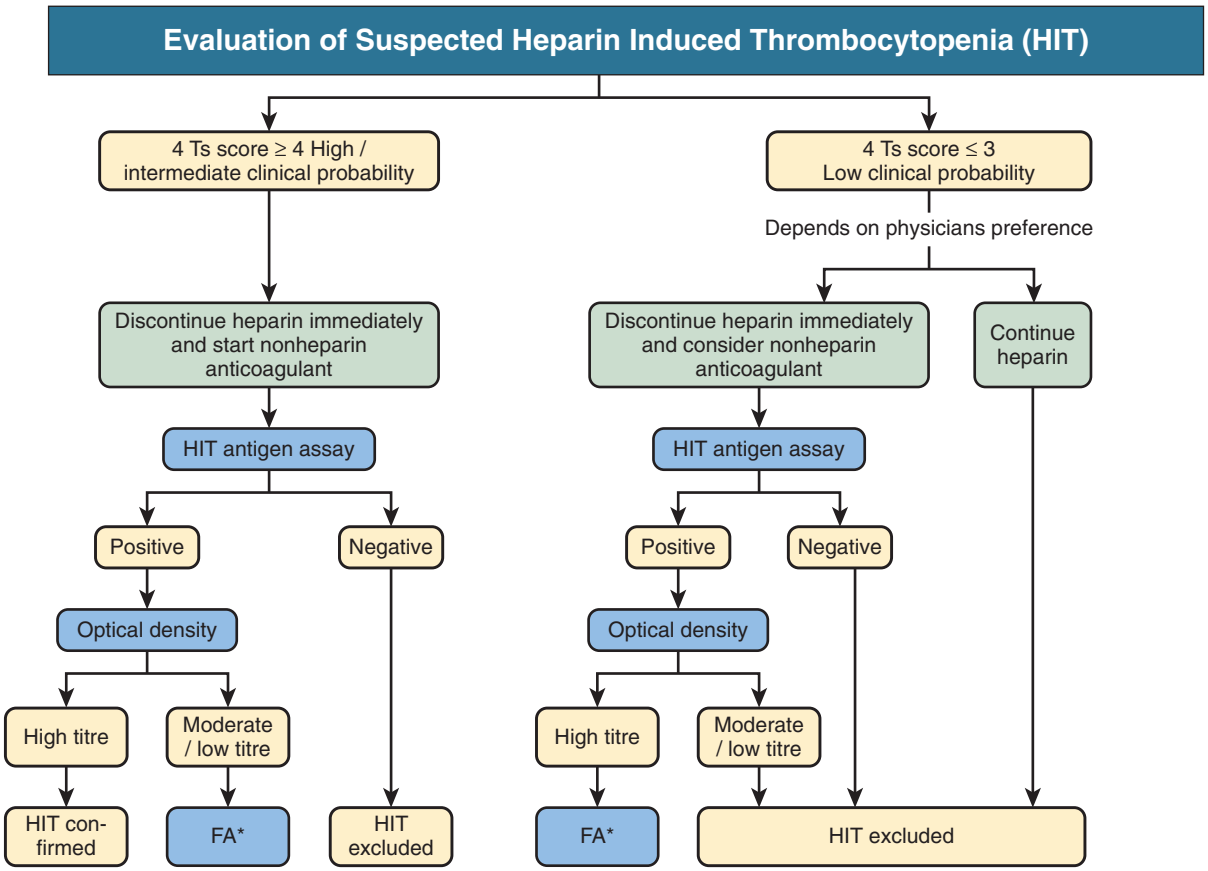

Fig. 83.5 Diagnostic work-up of suspected heparin-induced thrombocytopenia (HIT). Because of the high number of patients with antibodies against heparin without clinical HIT, a diagnostic algorithm is needed to have a high a priori likelihood of HIT before ordering antibody tests. There is no algorithm specific to patients with CKD, and the diagnosis should be made as in patients with normal renal function. *Confirm with functional assay (FA), if available. "4T" refers to a risk score based on four clinical parameters (*t*hrombocytopenia, *t*iming of platelet count fall or thrombosis, *t*hrombosis [or other clinical sequelae], and o*t*her cause for thrombocytopenia; see Table 83.2 for a detailed description).

should be used to confirm positive findings from antigen assays in the majority of patients with suspected HIT.

Once a patient has a high or intermediate clinical probability of HIT, all heparin treatment must be stopped and alternative anticoagulation initiated. The most relevant treatment options are listed in Table 83.3. Of note, no VKA should be initiated at this stage because these agents may reduce activation of anticoagulatory protein C and thus further perpetuate the prothrombotic state.

Additionally, anticoagulants are approved for prevention of thromboembolic stroke in patients with atrial fibrillation, for prevention and treatment of VTE (particularly deep-vein thrombosis and pulmonary embolism), and for prevention of clotting in patients with mechanical heart valves. In the latter case, the need for life-long anticoagulation with VKA is indisputable. Similarly, in patients with proximal deep-vein thrombosis and symptomatic pulmonary embolism, anticoagulation is indicated for a minimum of 3 months. Recommendations on extended anticoagulation are mainly derived from the general population, in whom indefinite anticoagulation with either VKA or NOAC (Table 83.4) may be considered in patients with unprovoked proximal deep-vein thrombosis and symptomatic pulmonary embolism, whereas anticoagulation should be stopped after 3 months in patients with provoked VTE with one or more transient risk factors. In patients with active cancer and VTE, data from the general population suggest indefinite anticoagulation with LMWH. When considering indefinite anticoagulation in patients with advanced CKD, their elevated bleeding risk must be considered.

For patients with advanced CKD, the use of anticoagulants in atrial fibrillation is controversial (see also Chapter 81). In the general population, patients who have one or more risk factors for cerebral stroke or systemic embolization (defined as a CHA_2DS_2-VASc score of ≥1 in men and ≥2 in women) should receive oral anticoagulation. Similarly, use of warfarin (if adjusted to target INR 2.0-3.0) has been shown to reduce stroke risk substantially in patients with CKD 3a/3b.[45] In these patients, NOACs are at least as efficient as VKA for prevention of thromboembolic events, but may cause fewer intracerebral bleeding events. For patients with GFR <30 ml/min/1.73 m^2, few data demonstrate the efficacy (i.e., prevention of thromboembolic events) and safety (i.e., major bleeding events) of either VKA or NOAC because most prospective clinical trials excluded patients with advanced CKD. Moreover, VKA accelerates vascular calcification[46] and possibly also CKD progression, in particular if overdosed.[47] In dialysis patients with atrial fibrillation, retrospective cohort studies yielded conflicting findings on whether oral anticoagulation lowers stroke incidence.[48]

For the time being, patients with atrial fibrillation and at least moderate risk for thromboembolism (defined by CHA_2DS_2-VASc score ≥2 for women, and ≥1 for men) should be offered NOACs if they have

TABLE 83.3 Characteristics of Anticoagulants Used to Treat Patients With Heparin-Induced Thrombocytopenia

Characteristic	Argatroban	Danaparoid	Bivalirudin	Fondaparinux
Target	Thrombin	Factor Xa (predominantly)	Thrombin	Factor Xa
Elimination	Hepatobiliary	Renal	Enzymatic (80%)/renal (20%)	Renal
Approved for patients with HIT*	Treatment/PCI	Treatment	PCI/cardiac surgery	No

mild to moderate CKD (CKD 1 to 3b), unless they have prohibitive high risk for bleeding. For CKD 4 and 5 patients with atrial fibrillation, lack of evidence precludes strong recommendations whether to use NOACs, VKA, or no anticoagulation.

Both LMWH and NOACs require dose adjustment in patients with CKD because they undergo renal excretion. As of 2017, only one NOAC (apixaban) has been licensed for use among dialysis patients in the United States, but not yet in Europe. Compared with other NOACs, apixaban is characterized by the least accumulation in CKD, but still requires (like all NOACs) dose adjustment for renal function. Notably, pharmacokinetic studies (and subsequent recommendations on NOAC dosages) used GFR estimated with the Cockcroft-Gault equation. In

clinical practice, eGFR is now mostly calculated using the Modification of Diet in Renal Disease (MDRD) or Chronic Kidney Disease–Epidemiology (CKD-EPI) formula. Substituting the latter for the former may cause large dosage errors, particularly when physicians fail to consider that the more recent equations yield estimates standardized for a body surface area of 1.73 m^2, and nonstandardized measures of renal function (as provided by Cockcroft-Gault equation) are suggested for dose adjustment.

SELF-ASSESSMENT QUESTIONS

1. The following diagnostic finding is reliable (sensitive and specific enough to be useful) in patients with chronic kidney disease (CKD) even in the presence of their typical immune dysfunction:
   - **A.** Fever as a sign of bacteremia
   - **B.** Radiologic infiltration on chest x-ray film for pneumonia
   - **C.** Mendel-Mantoux skin reaction for tuberculosis
   - **D.** Blood culture for bacteremia
   - **E.** C-reactive protein for infection
2. Viral hepatitis is a typical complication of hemodialysis treatment. Which statement describes viral hepatitis in advanced CKD correctly?
   - **A.** Hepatitis B virus (HBV) infection leads to chronic infection in the majority of affected CKD patients.
   - **B.** Acute HBV infection in CKD patients is typically severe, characterized by jaundice and fever.
   - **C.** HBV infection can be easily prevented in CKD patients by vaccination as recommended to the general population.
   - **D.** The clinical course of hepatitis C infection is largely different in CKD patients and those with normal renal function.
   - **E.** Standard hygienic precautions have largely failed to reduce HBV transmission in dialysis centers. Only vaccination succeeded in preventing nosocomial transmission.
3. The hemorrhagic diathesis in CKD patients is typically mirrored by which of the following?
   - **A.** A prolongation of the prothrombin time
   - **B.** A prolongation of the partial thromboplastin time
   - **C.** Severely thrombocytopenia
   - **D.** Hyperchromic anemia
   - **E.** None of these
4. The spectrum of interventions that may allow reducing hemorrhages in advanced CKD does not include which of the following?
   - **A.** Desmopressin
   - **B.** Conjugated estrogens
   - **C.** Tranexamic acid (TXA)
   - **D.** Cryoprecipitates
   - **E.** Clopidogrel

Bone and Mineral Disorders in Chronic Kidney Disease

Kevin J. Martin, Jürgen Floege, Markus Ketteler

DEFINITION

Disturbances of mineral metabolism are common if not ubiquitous in chronic kidney disease (CKD) and lead to serious and debilitating complications unless these abnormalities are addressed and treated. The spectrum of disorders includes abnormal concentrations of serum calcium, phosphate, and magnesium and disorders of parathyroid hormone (PTH), fibroblast growth factor-23 (FGF-23), and vitamin D metabolism. These abnormalities as well as other factors related to the uremic state affect the skeleton and result in the complex disorders of bone known as *renal osteodystrophy;* it is now recommended that this term be used exclusively to define the bone disease associated with CKD. The clinical, biochemical, and imaging abnormalities heretofore identified as correlates of renal osteodystrophy should be defined more broadly as a clinical entity or syndrome called *chronic kidney disease–mineral and bone disorder* (CKD-MBD).[1] The spectrum of skeletal abnormalities seen in renal osteodystrophy includes the following (Fig. 84.1):

- Osteitis fibrosa, a manifestation of hyperparathyroidism characterized by increased osteoclast and osteoblast activity, peritrabecular fibrosis, and increased bone turnover.
- Osteomalacia, a manifestation of defective mineralization of newly formed osteoid most often caused by aluminum deposition; bone turnover is decreased.
- Adynamic bone disease (ABD), a condition characterized by abnormally low bone turnover.
- Osteopenia or osteoporosis.
- Combinations of these abnormalities termed *mixed renal osteodystrophy.*
- Other abnormalities with skeletal manifestations (e.g., chronic acidosis, β_2-microglobulin amyloidosis [Aβ_2M amyloidosis]).

EPIDEMIOLOGY

The prevalence of the various types of renal osteodystrophy in patients with end-stage renal disease (ESRD) is illustrated in Fig. 84.2.[2] In patients on hemodialysis (HD), osteitis fibrosa, and ABD now occur with almost equal frequency. In contrast, in patients on peritoneal dialysis (PD), the adynamic bone lesion predominates. Osteomalacia represents only a small fraction of cases in either group but is more common in certain ethnic groups, particularly Indo-Asians. Skeletal abnormalities associated with CKD start while the estimated glomerular filtration rate (eGFR) is still relatively preserved (~50 ml/min/1.73 m^2).

PATHOGENESIS

Several biochemical and hormonal abnormalities associated with CKD contribute to renal osteodystrophy and can be affected by efforts at prevention and therapy. The major factors may vary as CKD progresses (Fig. 84.3). Similarly, the predominance of one particular pathogenetic mechanism over another may contribute to the heterogeneity of bone disorders. We therefore discuss separately the two major entities—high- and low-turnover osteodystrophy.

OSTEITIS FIBROSA: HYPERPARATHYROIDISM—HIGH-TURNOVER RENAL BONE DISEASE

Elevated levels of PTH in blood, hyperplasia of the parathyroid glands, and elevations in FGF-23 are seen once eGFR declines below approximately about 50 ml/min/1.73 m^2. Whereas the level of free (i.e., non–protein bound) calcium in blood is normally the principal determinant of PTH secretion, several metabolic disturbances associated with CKD also alter the regulation of the secretion of PTH.

Abnormalities of Calcium Metabolism

There are three main body pools of calcium: the bony skeleton (mineral component), the intracellular pool (mostly protein bound), and the extracellular pool (see Chapter 10). The calcium in the extracellular pool is in continuous exchange with that of bone and cells and is altered by diet and excretion. Calcium metabolism depends on the close interaction of two hormonal systems: PTH and vitamin D. Perturbations of both systems occur during the course of CKD, with adverse consequences on the skeleton. Total serum calcium tends to decrease during the course of CKD as a result of phosphate retention and decreased production of 1,25-dihydroxyvitamin D (calcitriol) from the kidney, decreased intestinal calcium absorption, and skeletal resistance to the calcemic action of PTH, but the levels of free calcium remain within the normal range in most patients[3] as a result of compensatory hyperparathyroidism. Because calcium is a major regulator of PTH secretion, persistent hypocalcemia is a powerful stimulus for development of hyperparathyroidism and also contributes to parathyroid growth.

Abnormalities of Phosphate Metabolism

With progressive CKD, phosphate is retained, at least, transiently, by the failing kidney. However, hyperphosphatemia usually does not become evident before CKD stage 4. Until then, compensatory

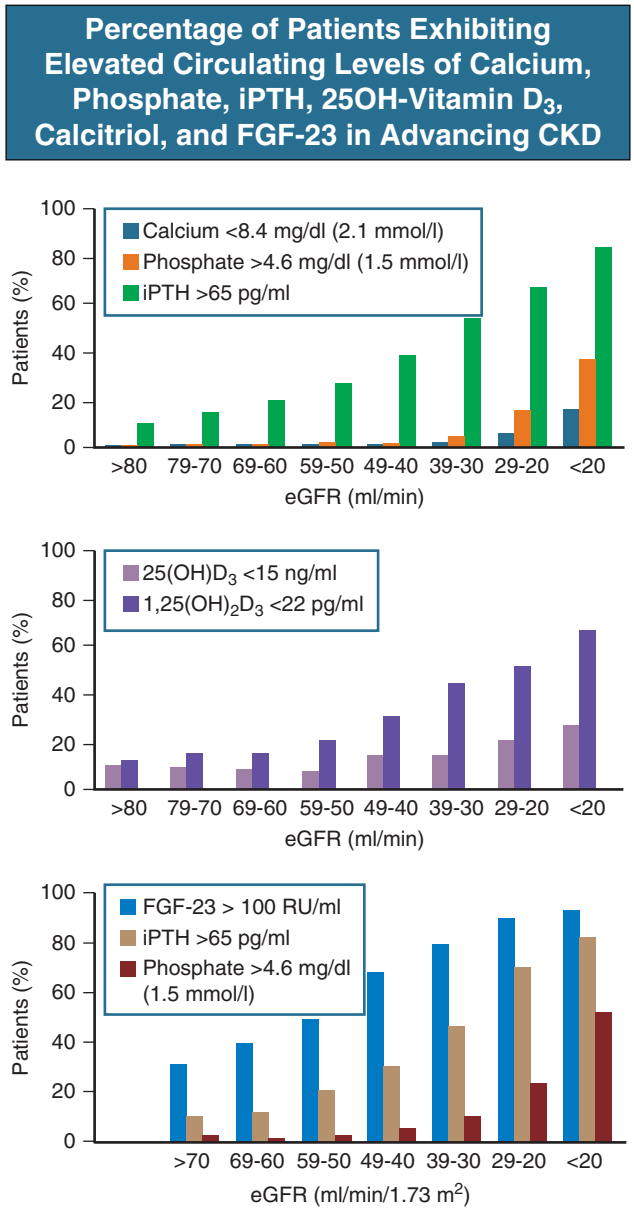

Fig. 84.3 Percentage of patients exhibiting elevated circulating levels of calcium, phosphate, intact parathyroid hormone (iPTH), 25OH-vitamin D_3, calcitriol, and fibroblastic growth factor-23 (FGF-23) in advancing chronic kidney disease (CKD). Particularly in early CKD stages there is wide variability at the individual level, and some patients, for example, may exhibit increased FGF-23 and normal iPTH, whereas others may have elevated iPTH levels with normal FGF-23 or elevations of both. (Data from references 54 and 55.)

hyperparathyroidism and increases in circulating FGF-23 result in increased phosphaturia, maintaining serum phosphate levels in the normal range.[4]

One mechanism by which phosphate retention may lead to hyperparathyroidism is by a decrease in serum free calcium, which in turn stimulates the secretion of PTH (Fig. 84.4). Thus a new steady state is achieved in which serum phosphate is restored to normal at the expense of a sustained high level of PTH. This cycle is repeated as renal function declines until sustained and severe hyperparathyroidism is present. Second, phosphate retention leads to decreased production of calcitriol by the kidney, either directly or by increasing the levels of FGF-23 (which decreases the activity of 1α-hydroxylase). The decrease in calcitriol allows increases in PTH gene transcription by direct action and also decreases intestinal calcium absorption, leading to hypocalcemia, which in turn stimulates PTH secretion. Third, hyperphosphatemia is associated with resistance to the actions of calcitriol in the parathyroid glands, which also favors development of hyperparathyroidism and induces resistance to the actions of PTH in bone. Finally, phosphate per se appears to affect PTH secretion independently of changes in serum calcium or serum calcitriol.[5,6] Phosphate may have an effect on parathyroid growth independent of serum calcium.[7,8] Regardless of the mechanism by which phosphate retention causes hyperparathyroidism, experimental studies suggest that restriction of dietary phosphate in proportion to the decrease in GFR can prevent development of hyperparathyroidism. Current evidence suggests that FGF-23 also acts directly on the parathyroid gland and has inhibitory effects on PTH secretion and parathyroid growth.[9,10] This suggests that the main effects of FGF-23 on the pathogenesis of hyperparathyroidism are indirect as a result of the potent effect of FGF-23 to decrease calcitriol production. These various actions may explain, at least in part, the association between higher levels of FGF-23 and adverse clinical outcomes.[11]

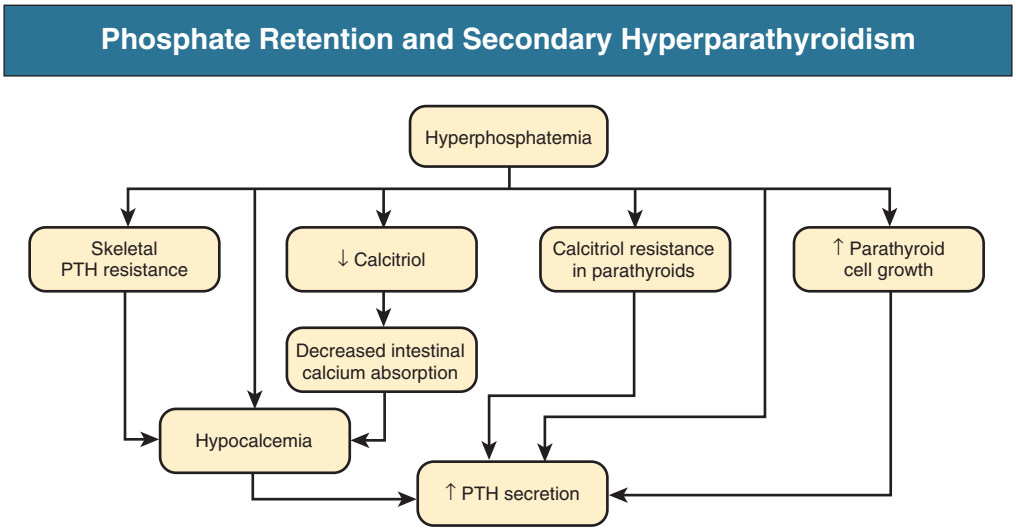

Fig. 84.4 Role of phosphate retention in the pathogenesis of secondary hyperparathyroidism. Hyperphosphatemia stimulates parathyroid hormone *(PTH)* secretion indirectly by inducing hypocalcemia, skeletal resistance to PTH, low levels of calcitriol, and calcitriol resistance. Hyperphosphatemia also has direct effects on the parathyroid gland to increase PTH secretion and parathyroid cell growth. *eGFR,* Estimated glomerular filtration rate.

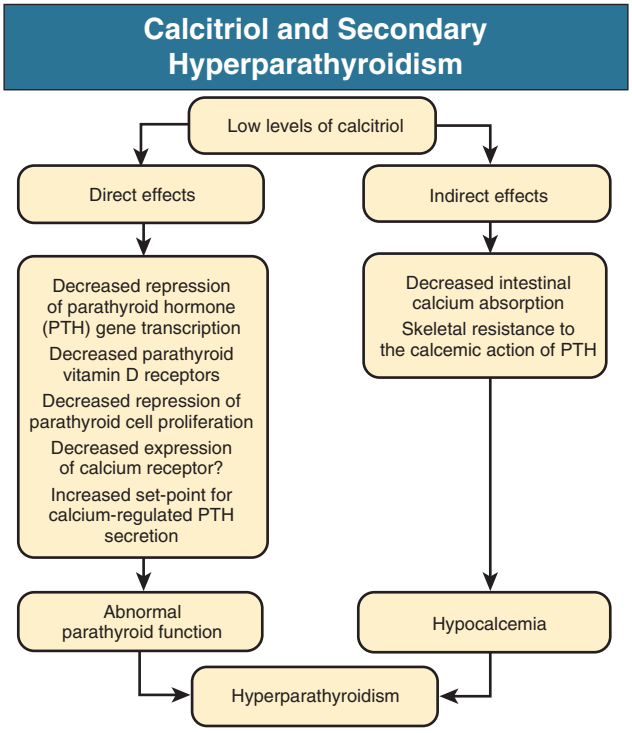

Fig. 84.6 Role of low levels of calcitriol in the pathogenesis of secondary hyperparathyroidism.

Abnormalities of Vitamin D Metabolism

The conversion of 25-hydroxyvitamin D to its active metabolite 1,25-dihydroxyvitamin D occurs mainly in the kidney by the enzyme 1α-hydroxylase. Extrarenal production of calcitriol also occurs and contributes to the circulating levels of calcitriol. Renal calcitriol production progressively declines in parallel with eGFR as a result of several mechanisms (Fig. 84.5).

Calcitriol production is compromised in CKD by a reduction in 25-hydroxyvitamin D levels[12] and the decrease in GFR, which further limits the delivery of 25-hydroxyvitamin D to the site of the 1α-hydroxylase in the proximal tubule. Phosphate retention either directly or by inducing an increase in FGF-23 also decreases the activity of 1α-hydroxylase. Finally, circulating PTH fragments may directly decrease calcitriol production. The resultant decreased levels of calcitriol contribute to the pathogenesis of hyperparathyroidism by several direct and indirect mechanisms as described earlier (Fig. 84.6). Low levels of calcitriol directly release the gene for PTH from suppression by the vitamin D receptor and allow increased PTH secretion. In many tissues, vitamin D regulates its own receptor by positive feedback; in CKD the vitamin D receptor content is decreased in parathyroid tissue. Administration of calcitriol has been shown to increase the vitamin D receptor content in the parathyroid glands coincident with the suppression of PTH secretion. Studies in vitro have shown that calcitriol is a negative growth

BOX 84.1 Parathyroid Abnormalities in Chronic Kidney Disease

- Parathyroid gland hyperplasia: diffuse, nodular
- Decreased expression of vitamin D receptors
- Decreased expression of calcium receptors
- Increased set-point of calcium-regulated parathyroid hormone secretion

regulator of parathyroid cells, and therefore calcitriol deficiency in patients with CKD may facilitate parathyroid cell proliferation. Other direct consequences of low levels of calcitriol contributing to the pathogenesis of secondary hyperparathyroidism include an increase in the parathyroid set-point for calcium-regulated PTH secretion and possibly a decrease in the expression of calcium receptors.

Low levels of calcitriol also may promote the development of hyperparathyroidism indirectly. First, decreased calcitriol production as renal function decreases can lead to progressive reductions in intestinal absorption of calcium, leading to hypocalcemia and stimulation of PTH release. Second, low levels of calcitriol have been implicated in skeletal resistance to the calcemic actions of PTH, which may contribute to the development of hyperparathyroidism.

Abnormalities of Parathyroid Gland Function

CKD is associated with intrinsic abnormalities in parathyroid gland function, in addition to those caused by hypocalcemia, low levels of calcitriol, and skeletal resistance to the actions of PTH (Box 84.1).

Parathyroid hyperplasia is an early finding in CKD. In experimental models, hyperplasia begins within a few days after the induction of CKD and can be prevented by dietary phosphate restriction or by the use of calcimimetic agents.[8,13] Resected parathyroid glands from patients with severe hyperparathyroidism have nodular areas throughout the gland, which represent monoclonal expansions of parathyroid cells. Within these nodules, there is decreased expression of vitamin D receptors as well as of calcium receptors. The decreased expression of calcium receptors renders efforts to therapeutically affect these enlarged hyperplastic glands difficult.

The parathyroid calcium receptor is centrally involved in the regulation of PTH secretion by calcium.[14] Its expression and synthesis are decreased in the parathyroid glands from hyperparathyroid patients, leading to altered calcium-regulated PTH secretion. Increased concentrations of calcium are required in vitro to suppress PTH release from the parathyroid cells of uremic patients compared with those of normal controls. Thus the set-point for the concentration of calcium required to decrease PTH release by 50% appears to be increased.

Abnormal Skeletal Response to Parathyroid Hormone

In patients with CKD, there is an impaired response of serum calcium to the administration of PTH and a delay in the recovery from induced hypocalcemia in the presence of larger increments in PTH levels. Thus in CKD the skeleton is relatively resistant to the calcemic actions of PTH. The resultant decrease in serum calcium levels stimulates PTH secretion and contributes to the pathogenesis of secondary hyperparathyroidism. Factors involved in the skeletal resistance to PTH in CKD include decreased levels of calcitriol, downregulation of the PTH receptor, and phosphate retention. In addition, circulating fragments of PTH, truncated at the *N*-terminus, which still react in the older, second-generation two-site PTH assays, have been suggested to oppose the calcemic actions of PTH, possibly acting at a presumed receptor for the C-terminal region of PTH.[15,16]

Clinical Manifestations of High-Turnover Renal Osteodystrophy

Clinical manifestations of hyperparathyroidism are usually nonspecific and often preceded by biochemical or imaging abnormalities. Nonspecific aches and pains are common, occur in the lower back, hips, and legs, and are aggravated by weight bearing. Acute, localized bone pain can occur and may be suggestive of acute arthritis. Pain around joints may be caused by acute periarthritis, which is associated with periarticular deposition of calcium phosphate crystals, especially in patients with marked hyperphosphatemia. The symptoms may be confused clinically with gout or pseudogout and often respond to nonsteroidal antiinflammatory drugs (NSAIDs). The gradual onset of muscle weakness is also common in patients with ESRD. Many factors are probably involved in its pathogenesis, including hyperparathyroidism and abnormalities of vitamin D. β_2-Microglobulin amyloidosis ($A\beta_2M$) (see later discussion) should be considered in the differential diagnosis in very-long-term dialysis patients.

Bone abnormalities may occur in patients with severe hyperparathyroidism, particularly in children, and are manifested on x-ray films by subperiosteal erosions, resorption of terminal digits. In adults, deformities arise as a result of fractures, sometimes induced by brown tumors (see later discussion); the axial skeleton is most commonly affected. This can lead to kyphoscoliosis or chest wall deformities. Slipped epiphysis may occur in children, and frank rachitic features are occasionally evident. Growth retardation is also common in children, and although some improvement has been shown with calcitriol, this has not been the universal finding.

Extraskeletal calcifications are frequently encountered in patients with advanced CKD and are aggravated by persistent elevation of the calcium-phosphate product. Most commonly, vascular calcifications are seen, but calcifications may occur in other sites, such as the lung, myocardium, and periarticular areas (Fig. 84.7).

In the skin, hyperparathyroidism can manifest as pruritus (see Chapter 87). Rarely, it can also underlie the development of calciphylaxis, or calcific uremic arteriolopathy (see Chapter 87, Figs. 87.6 and 87.7).

Diagnosis and Differential Diagnosis

In addition to the clinical manifestations of renal osteodystrophy, a variety of biochemical and radiographic techniques are helpful to establish the specific diagnosis and serve as a guide for the initiation and adjustment of therapy. Although bone biopsy is not widely used in clinical practice, it remains the gold standard for the diagnosis of renal osteodystrophy.

Serum Biochemistry

The levels of free calcium and phosphate in serum are usually normal in patients with mild to moderate CKD. Normally in stage 4 CKD the levels of serum calcium tend to fall and hyperphosphatemia manifests. Hypercalcemia may result from the administration of large doses of calcium-containing antacids or vitamin D metabolites or from severe hyperparathyroid bone disease. It is important to identify the cause of hypercalcemia in patients with CKD (see Chapter 10) because the management will vary greatly according to the cause. Also, the levels of serum calcium and phosphate, when used alone, are not useful in predicting the specific type of bone disease.

Parathyroid Hormone

Measurements of PTH are important for diagnostic purposes and therapeutic guidance in the management of renal osteodystrophy. With renal impairment, there is accumulation of circulating PTH fragments, which complicates the interpretation of PTH assays, including the two-site

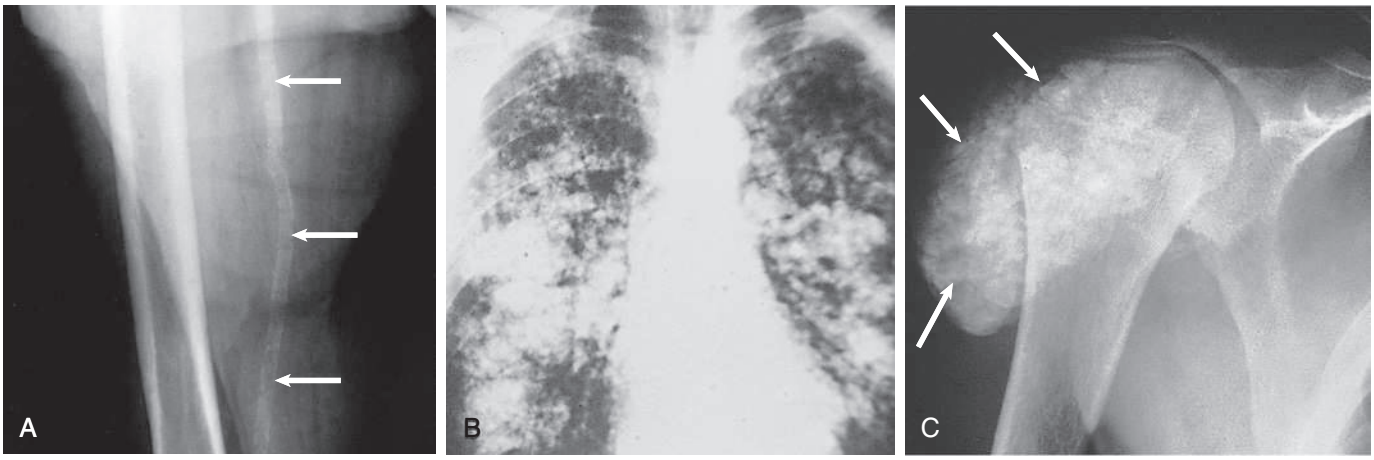

Fig. 84.7 Extraskeletal calcification in chronic renal failure. (A) Arterial calcification *(arrows).* (B) Pulmonary calcification. (C) Periarticular calcification *(arrows).*

immunometric assays, which were thought to measure "intact" PTH (iPTH). Refinements in PTH assays have demonstrated that these iPTH assays also measure some large fragments of PTH, which are truncated at the *N*-terminus. More specific assays for so-called "biointact" PTH (PTH 1-84) have been developed that exclude these fragments from measurement, but their clinical usefulness continues to be defined.[17-19] The presence of oxidized PTH, which is biologically inactive, in patients with ESRD may further complicate PTH measurements.[20] Standardization needs to be improved among different PTH assays from various laboratories and various manufacturers of assay reagents. With existing iPTH assays (upper limit of the reference range, ~60 pg/ml), only values at the extremes are useful in the noninvasive diagnosis of renal osteodystrophy. In dialysis patients, iPTH levels above approximately 600 pg/ml are characteristic of patients with osteitis fibrosa. The threshold values for earlier stages of CKD are not well defined. It is well accepted, however, that there is an element of skeletal resistance to PTH in patients with CKD; therefore supranormal levels of PTH appear to be required to maintain normal bone turnover. Serial measurements of PTH are useful in the initial evaluation of patients with renal osteodystrophy and are essential during the management of these disorders to assess response to therapy and to avoid overtreatment and undertreatment because either can have detrimental effects on bone histology. There are marked differences among commercial PTH assay results so that precise recommendations of desired ranges cannot reliably be provided and results obtained in different laboratories cannot be easily compared.[21]

Vitamin D Metabolites

The levels of calcitriol in patients with CKD are not helpful in differentiating the histologic lesions of renal osteodystrophy. Measurements of calcitriol are not used routinely for diagnostic purposes unless extrarenal production of this metabolite is suspected, as in granulomatous disorders (see Chapter 10).

Vitamin D deficiency in CKD rarely results in osteomalacia in the United States and Europe but may contribute to hyperparathyroidism. In patients with CKD and marked proteinuria, there is loss of vitamin D–binding protein in the urine, which may result in decreased levels of 25-hydroxyvitamin D. Vitamin D deficiency may be encountered in patients with limited sun exposure, in those with intestinal malabsorption or malnutrition, and in susceptible racial groups, particularly South Asians. Assessment of vitamin D nutrition is by measurement of serum 25-hydroxyvitamin D_3.

Markers of Bone Formation and Bone Resorption

Levels of circulating alkaline phosphatase offer an approximate index of osteoblast activity in patients with CKD. High levels are commonly present in hyperparathyroid bone disease. The discriminatory power of alkaline phosphatase measurements is enhanced by measurement of bone-specific alkaline phosphatase (BAP) isoenzyme, especially in conjunction with PTH values. Serial measurements of alkaline phosphatase may be useful in assessing the progression of bone disease. Osteocalcin is another marker of osteoblastic activity, but it is not superior to alkaline phosphatase. Tartrate-resistant acid phosphatase and collagen degradation products are both markers of osteoclastic activity but are considered investigational at present.

Radiology of the Skeleton

Routine x-ray examination of the skeleton is relatively insensitive for the diagnosis of renal osteodystrophy, and x-ray films can appear virtually normal in patients with severe histologic evidence of renal osteodystrophy. However, subperiosteal erosions are often present in severe secondary hyperparathyroidism, detected in the hands (Fig. 84.8), clavicles, and pelvis. Skull x-ray films may show focal radiolucencies and a ground-glass appearance, known as *pepper pot* skull. Osteosclerosis of the vertebrae is responsible for the "rugger-jersey" appearance of the spine (Fig. 84.9). Very rarely, brown tumors, focal collections of giant cells and typical of severe hyperparathyroidism, are seen as well-demarcated radiolucent zones in long bones, clavicles, and digits (Fig. 84.10). They may be confused with osteolytic metastases. Looser zones or pseudofractures are characteristic of osteomalacia. Routine skeletal x-ray films are not indicated unless there are symptoms.

Measurements of Bone Density

Dual-energy x-ray absorptiometry (DEXA) is widely used to assess bone density. Although DEXA does not identify the nature of the underlying osteodystrophy or distinguish this from osteoporosis, it does allow prediction of fracture risk in patients with CKD. Vascular and soft tissue calcifications may contribute to errors in bone density measurements.

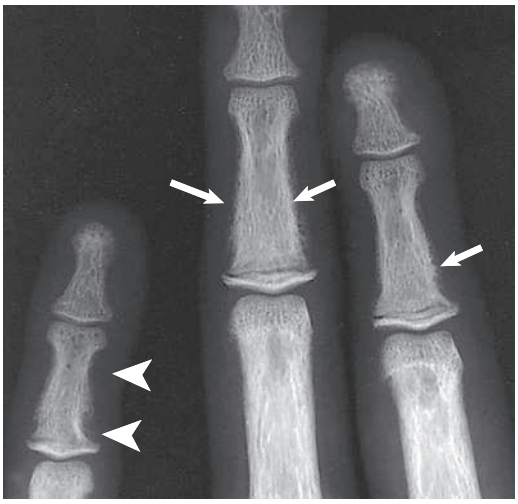

Fig. 84.8 Subperiosteal erosions in hyperparathyroidism. Severe subperiosteal erosions as a manifestation of hyperparathyroidism *(arrows)*. The extensive scalloped appearance of the middle phalanx on the left *(arrowheads)* represents a small brown tumor.

Fig. 84.9 "Rugger-jersey spine" in hyperparathyroidism. Vertebral bodies show the increased density of the ground plates and central radiolucency, which gives the striped appearance of a rugger jersey.

Bone Biopsy

Biopsy of bone and the microscopic analysis of undecalcified sections after double tetracycline labeling provide a definitive and quantitative diagnosis of renal osteodystrophy.[22] To standardize reports on bone histology, the Kidney Disease: Improving Global Outcomes (KDIGO) Chronic Kidney Disease–Epidemiology Collaboration (CKD-MBD) work group proposed the TMV classification, an assessment of turnover (T), mineralization (M), and bone volume (V).[1] Bone mineralization is assessed by the administration of two different tetracyclines spaced apart (e.g., tetracycline 500 mg three times daily for 2 days, followed by a 10-day interval, then demeclocycline 300 mg three times daily for 3 days) and biopsy 4 days later; the quantitation of bone mineralization rate is achieved by measuring the distance between the two fluorescent tetracycline bands.

Fig. 84.10 Brown tumor *(arrow)* in a hemodialysis patient with severe hyperparathyroidism. The tumor can easily be confused with a lytic bone metastasis.

Although noninvasive testing is useful to distinguish low or normal from high bone turnover, there is considerable overlap, and therefore biopsy might be required for definitive diagnosis when biochemistry is not conclusive (e.g., PTH in recommended range but bone alkaline phosphatase elevated, hypercalcemia with PTH only modestly elevated, or bone pain).

Osteitis fibrosa (hyperparathyroid bone disease) is characterized by increased bone turnover, increased number and activity of osteoblasts and osteoclasts, and variable amounts of peritrabecular fibrosis (Fig. 84.11A). Osteoid may be increased but usually has a woven pattern distinct from the normal lamellar appearance. Osteomalacia is characterized by increased osteoid seam width, increase in the trabecular surface covered with osteoid, and decreased bone mineralization as assessed by tetracycline labeling (see Fig. 84.11B). The presence of aluminum can be detected on the mineralization front by specific staining (see Fig. 84.11C). Aluminum-related bone disease is defined by aluminum staining exceeding 15% of the trabecular surface and a bone formation rate of less than 220 mm^2/day. Features of osteitis fibrosa may occur together with features of osteomalacia; the combination is termed *mixed renal osteodystrophy.*

Treatment of High-Turnover Bone Disease

Prevention is the primary goal in management of renal osteodystrophy. Therapy for hyperparathyroidism ideally should be initiated in CKD stage 3 so parathyroid gland hyperplasia can be prevented. Because renal osteodystrophy is usually asymptomatic early in the course of CKD, attention often is not paid to secondary hyperparathyroidism. By the time CKD is advanced, patients may have already developed significant skeletal abnormalities or nodular parathyroid hyperplasia, and more aggressive therapy is required to prevent the long-term consequences of renal osteodystrophy. The successful approach to the prevention and management of this disorder involves the integration of a variety of measures directed toward the suppression of PTH secretion and prevention of parathyroid hyperplasia.

Prevention of Hypocalcemia

Hypocalcemia, if present, should be corrected because it is a potent stimulus for PTH secretion. In patients with hypoalbuminemia, ionized

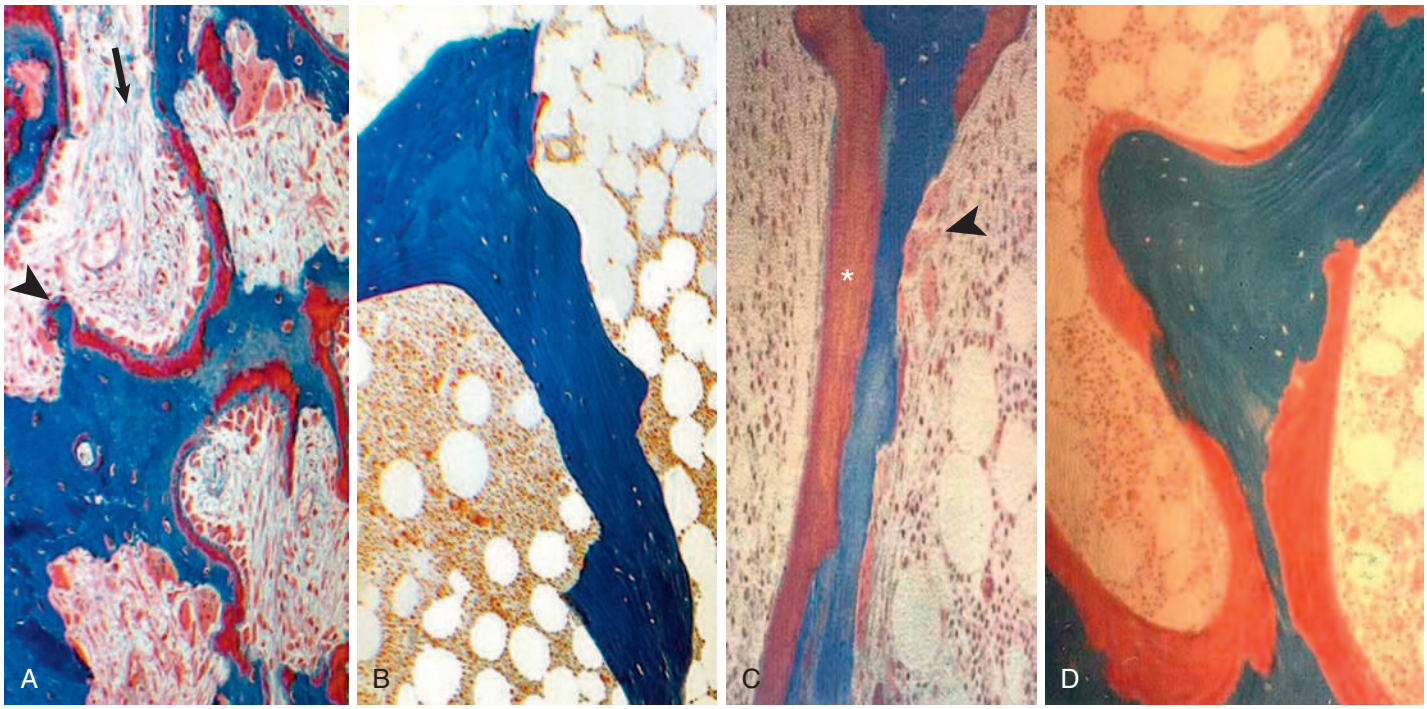

Fig. 84.11 Bone histology in renal osteodystrophy. (A) Osteitis fibrosa: Characteristic manifestations of severe hyperparathyroidism with increased osteoclast and osteoblast activity and peritrabecular fibrosis (stained blue; *arrow*). (B) Adynamic bone disease: There is no cellular activity along the bone surface and no osteoid visible. (C) *(arrowhead)* Mixed renal osteodystrophy: There is evidence of active osteoclasts on one bone surface *(arrowhead)* and evidence of thickened osteoid (stained red; *asterisk*) indicating a mineralization defect on the other. (D) Osteomalacia: Marked excess of unmineralized osteoid *(stained red)* surrounding the mineralized bone *(stained blue)*.

calcium should be measured. The initial approach to therapy for hypocalcemia in patients with mild to moderate CKD is the administration of calcium supplements such as calcium carbonate, taken between meals with increasing doses as required. Assessment of vitamin D status should be undertaken by measurement of 25-hydroxyvitamin D, and this should be corrected if it is below 30 ng/ml. The determination of 1,25-dihydroxyvitamin D levels is not helpful in this respect, given its 8-hour half-life. Assessment of efficacy of therapy is by follow-up determinations of serum calcium and PTH. Adjunctive therapy with active vitamin D sterols should be considered if hyperparathyroidism or hypocalcemia persists. In patients with ESRD, active vitamin D sterols are often required. In dialysis patients, the goal is to achieve levels of iPTH that are approximately two to nine times above the upper limit of the assay used.[23] Also, iPTH trends over time should be closely monitored. In CKD stages 3 to 5, progressive rises in iPTH above the normal range should be abrogated by correction of hypocalcemia, vitamin D deficiency, and hyperphosphatemia. The latter should be corrected before the correction of hypocalcemia.

Control of Phosphate

Control of phosphate is the cornerstone of effective management of secondary hyperparathyroidism. In mild to moderate CKD, a normal serum phosphate concentration does not necessarily indicate normal parathyroid status, and except for the late stages of CKD, normophosphatemia may be maintained at the expense of elevated serum PTH and FGF-23. Therefore efforts to control phosphate, including dietary phosphate restriction and the use of phosphate binders, should not be delayed until frank hyperphosphatemia develops.

Dietary Phosphate Restriction

In experimental animals with mild CKD, dietary phosphate restriction can prevent excessive PTH synthesis and secretion, as well as parathyroid cell proliferation, independently of changes in serum calcium and calcitriol concentrations. Accordingly, restriction of dietary phosphate intake might be considered in patients with CKD stage 2 or 3. The input of a dietician is essential. Protein restriction and avoidance of dairy products (especially processed foods containing high amounts of added phosphate) are the mainstays of the regimen. Phosphate-protein restriction increases the serum levels of calcitriol in patients with mild to moderate CKD. However, restriction of phosphate by severe dietary protein restriction below 0.8 g/kg/day may lead to protein-calorie malnutrition.

Phosphate Binders

Whereas dietary phosphate restriction is usually sufficient in early CKD, the control of phosphate becomes more difficult as renal function deteriorates. It then becomes necessary to also use agents that bind ingested phosphate in the intestinal lumen to limit its absorption. Compounds used for this purpose include calcium-containing antacids, magnesium salts, aluminum hydroxide, and non–calcium-containing, non–aluminum-containing phosphate binders (Fig. 84.12). Most phosphate binders, especially in advanced CKD, have to be given in large numbers (often accounting for 50% of the daily pill burden) and consequently patient adherence with the medication is a major problem.

Aluminum-containing antacids are effective phosphate binders, but in patients with CKD, their long-term use can no longer be recommended because of the risk for aluminum toxicity. Ingestion of

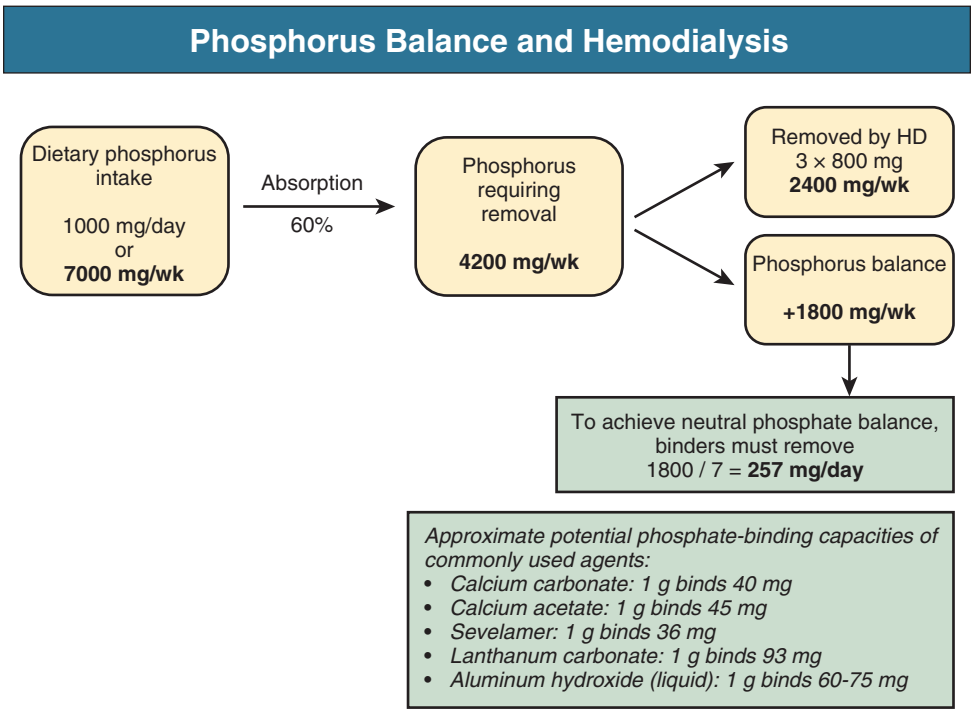

Fig. 84.12 Phosphate balance and phosphate binders used in hemodialysis patients.

aluminum-containing antacids together with foods containing citric acid (e.g., fruit juices and foods with sodium, calcium, or potassium citrate) may significantly increase aluminum absorption and therefore should be avoided.

Calcium carbonate or calcium acetate taken with meals effectively binds phosphates and limits their absorption. They are effective phosphate binders in 60% to 70% of patients on HD. The doses required to prevent hyperphosphatemia may vary according to patient compliance with dietary phosphate restriction as well as the CKD stage. Hypercalcemia and calcium loading are the major potentially serious side effects. Current recommendations are to limit the ingestion of elementary calcium to 1500 mg/day. Consideration of overall calcium balance may be important with the use of calcium-containing phosphate binders.

Magnesium salts are effective phosphate binders for patients who become hypercalcemic with calcium-containing phosphate binders, but they should be administered with caution in CKD patients not on dialysis because hypermagnesemia may have serious adverse effects. In patients on dialysis, magnesium carbonate (elemental magnesium 200 to 500 mg/day) has been used successfully, with prevention of hypermagnesemia through a reduction in dialysate magnesium concentration. The use of magnesium carbonate also allows reduction of the dose of calcium carbonate required by about half, but its use is frequently complicated by diarrhea.

Nonabsorbable, calcium-free polymers, such as sevelamer hydrochloride in a dose range of 2.4 to 4.8 g/day, provide effective phosphate control. Agents such as sevelamer may offer great advantage over calcium-containing phosphate binders in terms of limiting the calcium load, although they are significantly more expensive. Studies have suggested that the use of sevelamer is associated with decreased progression of vascular calcification.[24] Sevelamer hydrochloride has largely been replaced by sevelamer carbonate, which has similar properties. Sevelamer may be combined with both calcium- and magnesium-containing phosphate binders if necessary. Lanthanum carbonate also is an effective phosphate binder. No significant toxicity has been observed, although some lanthanum appears to accumulate in bone, liver, and gastric mucosa. Newly approved iron-containing phosphate binders include ferric citrate and sucroferric oxyhydroxide. Ferric citrate allows significant oral iron uptake and therapy necessitates monitoring of iron stores, whereas iron uptake from sucroferric oxyhydroxide is low.[24]

Use of Vitamin D Metabolites

Calcitriol and other 1α-hydroxylated vitamin D sterols, such as 1α-hydroxyvitamin D_3 (alfacalcidol), 1α-hydroxyvitamin D_2 (doxercalciferol), and 19-nor-1α,25-dihydroxyvitamin D_2 (paricalcitol), are effective in the control of secondary hyperparathyroidism. Calcitriol lowers PTH levels and improves bone histologic status. In patients with very high levels of PTH and markedly enlarged glands with severe nodular hyperplasia, the effectiveness of vitamin D metabolites may be limited because the levels of vitamin D receptor are low in such tissue. Accordingly, it would appear rational to initiate treatment of secondary hyperparathyroidism with vitamin D metabolites early in CKD when the parathyroid glands are more sensitive to such therapy and thereby prevent the progression to a refractory stage. A beneficial effect of vitamin D metabolite therapy in treatment of secondary hyperparathyroidism in patients with mild to moderate CKD has been shown, but the concern with initiation of vitamin D therapy at this stage of CKD is acceleration of the progression of renal disease should hypercalcemia occur. Because of the effect of calcitriol to increase intestinal phosphate absorption, hyperphosphatemia and elevations in calcium-phosphate product may predispose patients to the development of metastatic calcification; however, it appears that doses of 1α-hydroxyvitamin D_3 or calcitriol up to 0.5 mcg/day are not commonly associated with hypercalcemia, hyperphosphatemia, or worsening renal impairment. Another concern with the use of vitamin D metabolites before dialysis is that oversuppression of hyperparathyroidism may increase the risk for adynamic bone. Accordingly, vitamin D therapy should be monitored carefully and should not be instituted without documentation of hyperparathyroidism, correction of 25-hydroxyvitamin D deficiency, and prior control of serum phosphate.

In patients with ESRD, indications for therapy with vitamin D metabolites are better defined; however, hypercalcemia and aggravation of hyperphosphatemia are frequent complications of therapy. Vitamin D metabolites are increasingly used as oral or intravenous pulses given intermittently (e.g., three times weekly) rather than as continuous oral therapy. Analogues of calcitriol that have less calcemic activity than the parent compound and yet retain the ability to suppress PTH release in vivo have been developed. Such analogues of vitamin D studied in patients with ESRD are 22-oxacalcitriol, 1α-hydroxyvitamin D_2, and 19-nor-1α,25-dihydroxyvitamin D_2 (paricalcitol). Direct comparisons between these compounds are not available. It is likely that a wider therapeutic window may be offered by these analogues. Several but not all studies have suggested there may be a survival advantage associated with active vitamin D administration in patients with CKD as well as with ESRD.[25,26]

Role of Calcimimetics

An additional approach to the treatment of hyperparathyroidism in ESRD is the use of a calcimimetic agent, such as cinacalcet, which targets the calcium-sensing receptor and increases its sensitivity to calcium. In dialysis patients, cinacalcet results in a significant fall in PTH levels and can facilitate the control of hyperparathyroidism. The addition of cinacalcet to standard therapy in patients with iPTH serum levels exceeding 300 pg/ml while receiving standard therapy allowed significantly more dialysis patients to achieve guideline targets for calcium, phosphate, and iPTH.[27] Cinacalcet is especially useful in patients with marginal or frank hypercalcemia or with hyperphosphatemia and can be used in conjunction with other therapies. Central side effects include hypocalcemia and nausea and vomiting; the latter can be somewhat improved by administering cinacalcet at night. Cinacalcet may attenuate progression of cardiovascular (CV) calcification.[28] A large randomized controlled trial (RCT)—Evaluation of Cinacalcet HCl Therapy to Lower Cardiovascular Events (EVOLVE)—to examine the effect of cinacalcet therapy on CV events and survival in HD patients with secondary hyperparathyroidism was nondefinitive because of, at least in part, significant migration from the control arm to commercial cinacalcet and an age difference between the two arms, whereby the cinacalcet patients were older on average and thus at higher CV risk.[29] In that trial, however, cinacalcet significantly reduced rates of parathyroidectomies and of calciphylaxis.[29] In CKD patients not on dialysis, the use of calcimimetics is accompanied by significant phosphate retention and is currently not recommended. The potent, parental peptide-based calcimimetic etelcalcetide was recently licensed in dialysis patients. Although the parenteral administration offers improved patient adherence, gastrointestinal adverse events were similar to those with cinacalcet.[30]

Role of Parathyroidectomy

Although the strategies discussed previously are effective for the control of hyperparathyroidism in many patients, there are occasions when these steps fail or are contraindicated and surgery should be considered (Box 84.2). Parathyroidectomy is indicated for patients with severe hyperparathyroidism that cannot be controlled medically. Severe hyperphosphatemia in these patients precludes the use of vitamin D metabolites because of the risk for metastatic calcification. Some control of iPTH levels may be obtained with calcimimetics, but even these compounds may fail in severe hyperparathyroidism because of downregulated calcium-sensing receptors in the parathyroid glands. Some patients with severe hyperparathyroidism may become hypercalcemic. It is important to be certain that hypercalcemia represents severe hyperparathyroidism and is not caused by adynamic bone or other disease. In some cases, a bone biopsy may be required for a definite diagnosis.

BOX 84.2 Indications for Parathyroidectomy

- Severe hyperparathyroidism
  - With persistent hyperphosphatemia
  - Unresponsive to calcitriol and calcium
  - With hypercalcemia
  - With intolerance or unresponsiveness to calcimimetics
  - In renal transplantation candidate
  - With evidence of metastatic calcification
- Calciphylaxis with evidence of hyperparathyroidism
- Severe pruritus, only if additional evidence of hyperparathyroidism

For hypercalcemia to occur because of hyperparathyroidism in CKD, the levels of iPTH generally exceed 1000 pg/ml and BAP is usually elevated. Surgical parathyroidectomy might be considered in patients with very severe hyperparathyroidism who may receive a renal transplant in the near future, particularly if they are female and have significant osteopenia. Parathyroidectomy in these patients can help avoid post-transplantation hypercalcemia and hypophosphatemia (caused by PTH-induced phosphaturia), as well as osteopenia. By avoiding hypercalcemia, this may lead to improved graft function and possibly to less intragraft calcification. Parathyroidectomy might be considered in patients with severe hyperparathyroidism who have evidence of metastatic calcification. The development of calciphylaxis is an urgent indication for parathyroidectomy if PTH levels are elevated (see Chapter 87). Before parathyroidectomy, consideration should be given to the possibility of coexisting aluminum accumulation, with deferoxamine testing and bone biopsy performed if necessary, because this might predispose to osteomalacia after parathyroidectomy.

The most commonly used surgical procedures are subtotal removal of the parathyroid glands and total removal of the parathyroid glands with reimplantation of parathyroid tissue in the forearm. Recurrence of hyperparathyroidism occurs in about 10% of patients. Total parathyroidectomy alone is less commonly performed; although this is an appropriate procedure for patients remaining on dialysis, hypoparathyroidism after renal transplantation may lead to marked hypercalciuria with nephrocalcinosis and progressive renal failure. This may become less of an issue now that recombinant PTH has become available. Total parathyroidectomy with forearm implantation (our preference) or subtotal parathyroidectomy in the neck, marking remaining tissue with clips, may be performed. Unregulated tumor-like growth of parathyroid tissue implants has been described and may be related to the monoclonal nature of the nodular hyperplasia of severe hyperparathyroidism.

Recurrence of hyperparathyroidism may respond to further medical therapy, but more surgery to remove the forearm implant or further neck exploration to search for additional glands is often necessary and may be guided by parathyroid imaging.

Synthesis of Therapeutic Strategies

The general recommendations for the prevention and therapy of renal osteodystrophy are summarized in Fig. 84.13, in which therapeutic maneuvers are stratified according to the degree of CKD.

Therapy should be initiated if possible in stage 2 or 3 CKD (GFR, 30 to 90 ml/min), and dietary phosphate intake may be restricted once patients enter CKD stage 3. Levels of iPTH should be measured; if elevated above the normal range, the levels of 25-hydroxyvitamin D should be measured and corrected if less than 30 ng/ml. If hyperparathyroidism persists, phosphate binders may be considered. As CKD progresses within stage 3, dietary phosphate restriction should be continued or intensified, and the doses of phosphate binders should be

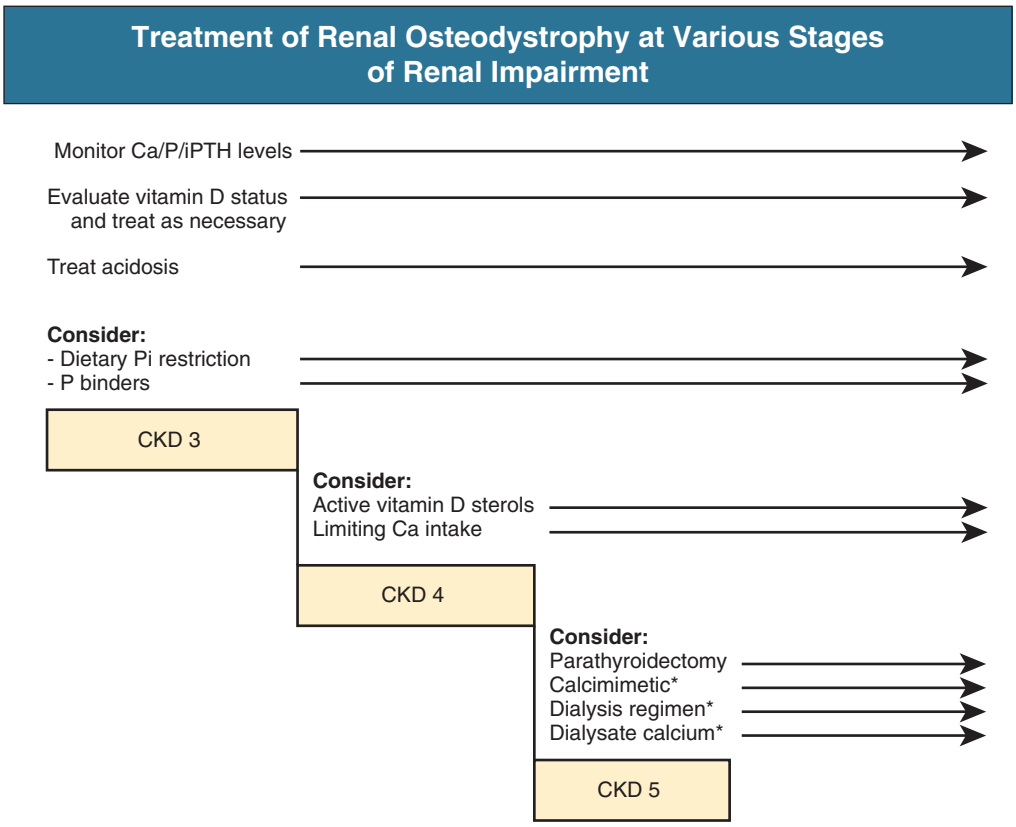

Fig. 84.13 Treatment of renal osteodystrophy at various stages of renal impairment. *Consider in CDK5D (i.e., dialysis dependent) only. *Ca,* Calcium; *CKD,* chronic kidney disease; *iPTH,* intact parathyroid hormone; *P,* phosphate; *Pi,* inorganic phosphate. (Modified from reference 56.)

adjusted based on serial measurements of iPTH, with careful attention to avoid hypercalcemia or excessive calcium load. Acidosis, if present, should be treated with oral sodium bicarbonate because persistent acidosis has deleterious effects on the skeleton. The additional sodium load may require further salt restriction or increases in diuretics. Aluminum-based phosphate binders should be avoided. If hyperparathyroidism (iPTH more than two to three times above the upper normal range of the assay) persists despite these measures, consideration should be given to the addition of calcitriol (0.25 to 0.5 mcg/day), vitamin D analogues, or vitamin D prohormones to the regimen. This therapy should be monitored carefully to avoid hypercalcemia and acceleration of progression of CKD.

In CKD stages 4 and 5, the preceding therapies may need to be intensified and larger amounts of phosphate binders may be required to avoid hyperphosphatemia. The use of aluminum-containing phosphate binders is particularly undesirable at this stage in view of the increased risk for aluminum accumulation with worsening renal function. In patients on dialysis, calcitriol therapy can be intensified, with attention to the serum levels of calcium and phosphate and monitoring of iPTH levels. In CKD stage 5, iPTH levels should be maintained approximately two to nine times above the upper limit of the assay used to maintain normal bone turnover.[23] Calcitriol may be administered orally either daily or intermittently (pulse therapy) or administered intravenously to patients on HD. During therapy with calcitriol, it is imperative to ensure serum phosphate remains controlled and elevations of serum calcium do not occur to prevent metastatic calcification. Vitamin D analogues, which are less calcemic and phosphatemic than calcitriol and yet retain the ability to suppress the levels of PTH, may be useful. Cinacalcet provides additional effective control of hyperparathyroidism in patients with ESRD and may be used alone or in combination with the other strategies if iPTH levels do not fall into the target range. Parathyroidectomy should be considered in selected circumstances. Bone biopsy may be indicated in selected patients, particularly if aluminum overload is suspected. Aluminum overload may require chelation therapy with deferoxamine in selected circumstances, especially if it is symptomatic, but in most patients the prevention of further aluminum exposure is sufficient to allow a gradual reduction in the serum levels of aluminum. During therapy with potent vitamin D metabolites, attention should be given to the dialysate calcium concentrations because high concentrations may aggravate hypercalcemia. However, the increasingly frequent use of lower dialysate calcium levels, such as 1.25 mmol/l, requires careful monitoring of the patient to ensure compliance with calcium-containing phosphate binders and vitamin D metabolites to avoid progressive negative calcium balance. Dialysate calcium should remain within the range of 1.25 to 1.75 mmol/l and, when possible, should be individually prescribed.

LOW-TURNOVER RENAL BONE DISEASE

ABD describes the morphologic consequences of low-turnover osteopathy in CKD. As CKD progresses, hyperparathyroidism initially develops as an adaptive response to counteract the increasing skeletal PTH resistance and phosphate overload. ABD mainly results from too rigorous suppression of this adaptive response. ABD is increasingly important in CKD-MBD because of the high percentage of affected individuals (>40% in CKD stage 5) and because of its association with CV calcification and mortality.[31,32] Furthermore, fracture incidence is estimated to be twice as high in individuals with low than in those with high bone turnover. ABD prevalence is markedly increasing in bone biopsy registries of dialysis patients, which may relate to the increasing

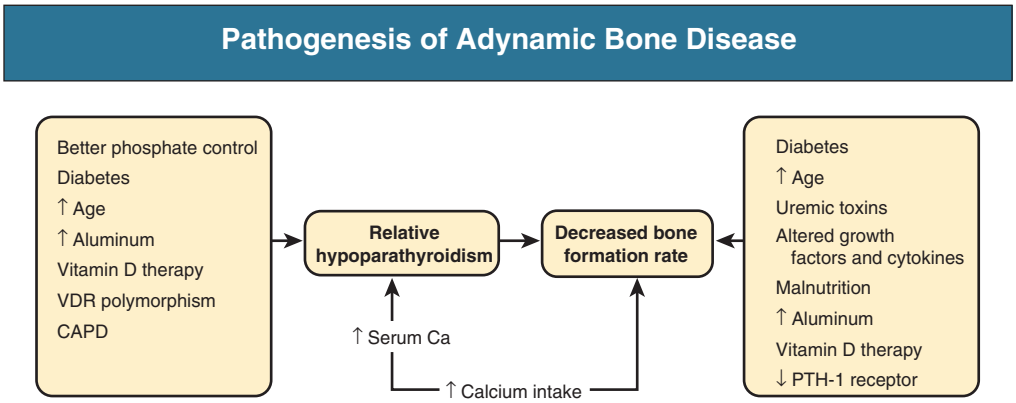

Fig. 84.14 Pathogenesis of adynamic bone disease. *Ca,* Calcium; *CAPD,* continuous ambulatory peritoneal dialysis; *PTH,* parathyroid hormone; *VDR,* vitamin D receptor. (Modified reference 57.)

prevalence of its key risk factors—advanced age and diabetes mellitus. PD also represents a risk factor, possibly because of an often continuous exposure to high dialysate calcium as opposed to the cyclic exposure associated with HD.

Pathogenesis of Adynamic Bone Disease

Given that the bone develops a relative resistance of the PTH-1 receptor to its ligand PTH as CKD progresses, PTH levels above the normal range are required to maintain adequate bone turnover. Unfortunately, there are no definite ranges of elevated PTH levels that can reliably differentiate an adaptive response (normal bone turnover) from a maladaptive response (increased bone turnover) because PTH resistance individually varies and because it depends on the stage of CKD. Accordingly, ABD is a consequence of inadequately low PTH levels, which cause suppression or cessation of both osteoblast and osteoclast activities, resulting in a reduced bone formation rate and low bone mass. Iatrogenic oversuppression of PTH in CKD mainly results from high-dose active vitamin D metabolite treatment, from calcium loading (high doses of calcium-containing phosphate binders, high dialysate calcium concentration), or after parathyroidectomy. The effects of calcimimetic treatment on bone turnover have been prospectively evaluated in HD patients, and patients in this cohort had significant high-turnover osteopathy at baseline (average iPTH >1200 pg/ml). Therapy with cinacalcet decreased elevated bone formation rate and improved bone histologic status.[33] ABD occurred only if iPTH was suppressed below the KDIGO target range of two to nine times the upper reference range of the assay. Finally, diabetes, uremic toxins, malnutrition, and potentially, C-terminal PTH fragments may be additional factors favoring a state of low bone turnover (Fig. 84.14).

Diagnosis and Differential Diagnosis

Serum Biochemistry

Low iPTH levels (<100 to 150 pg/ml) are almost always indicative of low bone turnover in CKD stage 5D. However, histologically proven ABD may occur in many dialysis patients with iPTH levels of up to 300 pg/ml and, in exceptions, of up to 600 pg/ml.[34,35] Therefore PTH levels alone are not a sensitive biomarker of ABD. Serum levels or activities of alkaline phosphatase or bone alkaline phosphatase are usually normal or low; downward trends may indicate the development of ABD. Serum calcium and phosphate can be normal or elevated, dependent on the choices of cotreatment (phosphate binders, vitamin D metabolites) and nutritional status. Particularly in instances of calcium and phosphate loading, hypercalcemia and hyperphosphatemia may be pronounced because adynamic bone is unable to buffer calcium and phosphate loads by osseous deposition (Fig. 84.15).

In CKD stages 3 and 4, there are uncertainties about the diagnosis of ABD and its clinical consequences. It is unclear which PTH levels are required to maintain adequate bone turnover in these stages. It seems reasonable to correct vitamin D deficiency, hyperphosphatemia, and hypocalcemia when PTH levels start to rise, but beyond that, no firm recommendations can be given.

Bone Biopsy

The gold standard for diagnosis of ABD is bone biopsy. According to the TMV classification (see earlier discussion),[1] ABD is characterized by low turnover, normal (or high secondary) mineralization, and low bone (osteoid) volume. The individual indication to perform bone biopsy should be considered in symptomatic patients based on inconsistencies of biochemical parameters associated with unexplained fractures, bone pain, progressive extraosseous calcifications, or hypercalcemia. The KDIGO initiative recently investigated more than 492 bone biopsy samples and concomitant serum samples to identify biomarker patterns that may allow noninvasive assessment of bone turnover status. ABD was quite strongly associated with low-normal to low BAP levels. In general, PTH and BAP could distinguish low from non-low and high from non-high bone formation rate.[36] However, there is considerable heterogeneity between the extremes. Aluminum toxicity is a relevant differential diagnosis versus ABD. Thus, if the patient's history suggests significant aluminum exposure, aluminum bone deposition should be excluded by measurement of serum aluminum and specific staining of a bone biopsy specimen.

Radiology and Measurements of Bone Density

There are no typical features of ABD in conventional bone radiographs or DEXA. In the latter, bone density may be low, normal, or high, depending on the primary or secondary mineralization state, but it never reflects the actual turnover and is therefore not a helpful diagnostic test (Fig. 84.16). A very high CV calcification burden on conventional radiographs may raise the suspicion of a low bone turnover state if accompanying biochemical parameters are compatible with this diagnosis. Biopsy-proven ABD is associated with the highest magnitude of vascular calcification in dialysis patients.[31]

Treatment of Adynamic Bone Disease

The key therapeutic approaches in the treatment of ABD are to avoid PTH overexpression and restore adequate PTH levels, without triggering the progressive development of secondary hyperparathyroidism. Such a stepwise treatment approach may include avoidance of calcimimetics, reduction or withdrawal of active vitamin D metabolites, reduction or withdrawal of calcium-containing phosphate binders, and reduction

of the dialysate calcium concentration (usually to 1.25 mmol/l). Indeed, a recent RCT found a histologic improvement of low bone turnover when the dialysate calcium concentrations were decreased from 1.5 or 1.75 mmol/l to 1.25 mmol/l.[37] Any aluminum should be withdrawn. After these interventions, biochemical parameters (PTH, calcium, phosphate, perhaps alkaline phosphatase, and especially BAP) should be monitored more frequently than usual.

Studies comparing calcium-containing with non–calcium-containing phosphate binders in dialysis patients[35,38] found that the administration of calcium-containing phosphate binders was associated with a higher proportion of individuals who developed ABD. This development was associated with a fall in serum PTH because of the higher calcium load. In an observational study, high-dose calcium-containing phosphate binder intake was associated with both low bone turnover and increased aortic calcification.[39]

Other therapeutic approaches to ABD have not been systematically studied. They include optimized diabetes control, a change from PD to HD to facilitate a more flexible dialysate calcium prescription, the administration of recombinant PTH (e.g., for patients after total parathyroidectomy), and calcilytics (agents that antagonize the calcium receptor and thus increase endogenous PTH).[40] At present, many patients with ABD remain refractory to treatment.

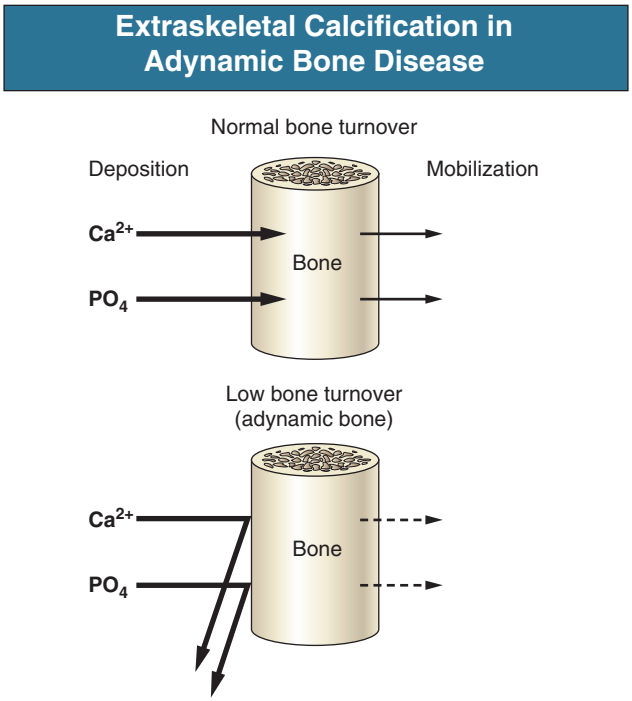

Fig. 84.15 Bone turnover in adynamic bone disease. Reduced bone turnover leads to increased extraskeletal calcification. Ca^{2+}, Calcium ion; PO_4, phosphate.

OSTEOPOROSIS IN CHRONIC KIDNEY DISEASE

Whereas abnormal bone is common and fracture risk is increased in CKD patients, the relative contribution of classic osteoporosis (as defined by World Health Organization [WHO] criteria) to the CKD-MBD complex is not well defined. Data from studies of antiosteoporosis agents are mostly available for patients in CKD stages 1 to 3, and subjects with features of CKD-MBD were largely excluded. Nevertheless, postmenopausal women and elderly men are highly prevalent in late-stage CKD populations, and it is thus likely that classic osteoporosis also contributes to their bone disease.

Pathogenesis of Osteoporosis in Chronic Kidney Disease

Osteoporosis may be associated with low, normal, or high bone turnover and is characterized by thin and disconnected trabeculae and loss of the plate-like bone structure. Many patients with CKD have abnormal

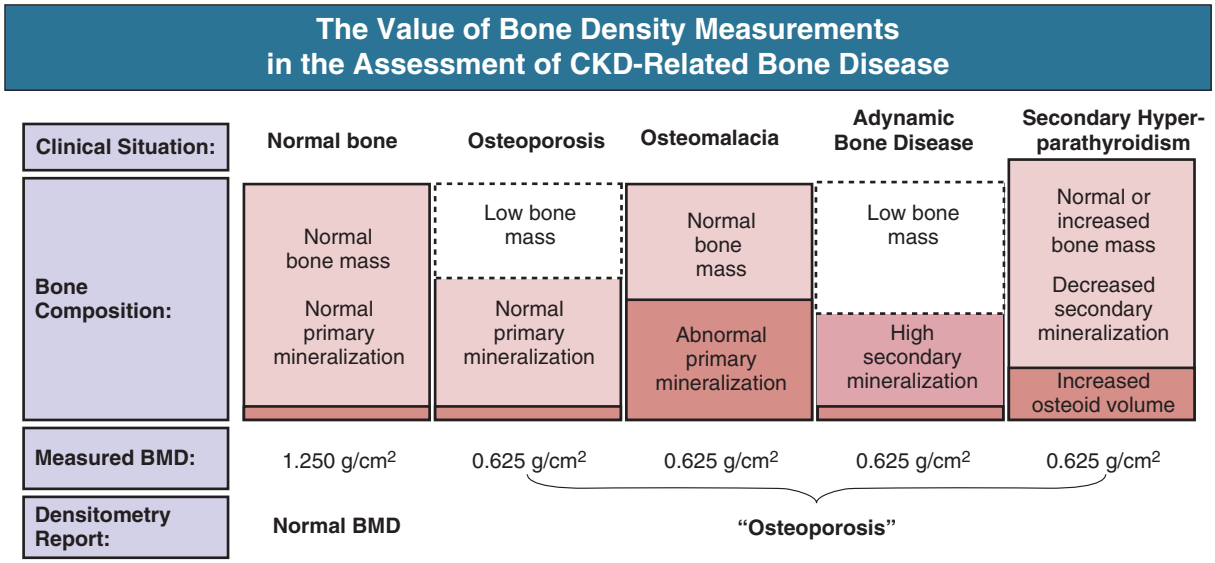

Fig. 84.16 The value of bone density measurements in the assessment of chronic kidney disease (CKD)–related bone disease. *Pink boxes* indicate mineralized bone; *red boxes* indicate osteoid. *BMD,* Bone mineral density. (Courtesy Prof. M. H. Lafage-Proust, St. Etienne, France.)

mineralization and increased osteoid, which is quite atypical for osteoporosis. Typical pathogenetic factors of osteoporosis, including hypoestrogenemia, immobilization, and corticosteroid use, are frequent in CKD patients, although some postmenopausal women with late-stage CKD may have relatively normal estrogen levels. However, the sum of CKD-MBD–related biochemical disturbances probably represents the decisive factors as to which bone phenotype predominates. Secondary hyperparathyroidism, relative hypoparathyroidism (as in ABD), and 25-hydroxyvitamin D, as well as 1,25-dihydroxyvitamin D deficiencies, may dominate and "overrule" the bone phenotype of osteoporosis even if classic risk factors are present.

Diagnosis and Differential Diagnosis

In patients with advanced CKD, bone turnover biomarkers and measurements of bone mineral density by DEXA are of no value (see Fig. 84.16) in the differential diagnosis of classic osteoporosis versus other CKD-MBD–related bone disease. Assays for biomarkers, such as β-CrossLaps (C-terminal cross-linked, CTX; marker of bone collagen degradation), procollagen type I *N*-terminal propeptide (PINP; marker of bone collagen synthesis), and tartrate-resistant alkaline phosphatase 5b (TRAP5b; marker of osteoclast activity) are insufficiently validated in CKD patients, and low bone mineral density can be found in CKD-MBD–induced high-turnover bone disease, ABD, and osteomalacia (see Fig. 84.16). However, there is recent evidence that bone mineral density (as measured by DEXA) does predict fracture risk in CKD patients to an extent similar to that in the general population, so this method may become useful in monitoring therapeutic drug effects or risk assessments. Still, DEXA remains unable to distinguish osteoporosis from CKD-MBD–associated bone phenotypes. Peripheral quantitative tomography (pQCT) of the radius may be a superior methodology for assessment of CKD patients in the future but awaits validation in sufficiently large patient cohorts.[41] The only reliable methodology to diagnose osteoporosis and discriminate it from other bone manifestations in CKD patients is bone biopsy. In a large bone biopsy study, including 1429 samples from dialysis patients, osteoporosis was diagnosed in 52% of individuals and 49% of them also had ABD.[42] These proportions may be quite different in patients in earlier CKD stages, but there are no systematic data available on such cohorts.

Treatment of Osteoporosis in Chronic Kidney Disease

Post hoc analyses of large prospective treatment studies using antiosteoporotic medications indicate that it is safe and efficacious to treat postmenopausal women in stages CKD 1 to 3 if they have a high risk for fractures (according to WHO criteria) and no features of CKD-MBD.[43-46] In such populations, bisphosphonates, denosumab, raloxifene, and teriparatide appear to be feasible therapeutic options. The former three drugs antagonize high bone turnover with an antiresorptive mode of action; teriparatide exerts bone anabolic effects (PTH analogue). With bisphosphonates, there may be concerns of an extended oversuppression of osteoclasts, but only in patients with advanced CKD. A recent subanalysis of patients in CKD stages 2 to 4 from the Following Rehabilitation, Economics and Everyday-Dialysis Outcomes Measurements (FREEDOM) trial demonstrated a significantly reduced fracture risk with denosumab treatment versus placebo, independent of the stage of CKD.[47] In contrast, for patients in CKD stages 3 to 5 with features of CKD-MBD, no data are available on the safety and efficacy of any of these antiosteoporotic medications. In CKD patients with ABD, bisphosphonates and denosumab may aggravate osteoclast paralysis. In CKD patients with secondary hyperparathyroidism, these antiresorptive agents may upregulate PTH secretion. Patients with advanced CKD (stages 4 and 5) may develop particularly severe hypocalcemia when treated with denosumab; coadministration of vitamin D analogues may be required to blunt this effect. However, given the growing evidence that antiresorptive therapies may be effective at least in patients with CKD stages 3 and 4, and the lack of definite evidence that these drugs induce ABD in this population, it may not be necessary to perform a bone biopsy before treatment initiation, if a clinical response is otherwise suspected.

β_2-MICROGLOBULIN–DERIVED AMYLOID

β_2-Microglobulin–derived ($A\beta_2M$) amyloidosis, also termed *dialysis-associated amyloidosis,* exclusively affects patients with stage 5 CKD. It is a systemic amyloidosis. Clinical manifestations are largely confined to the musculoskeletal system. In recent years the disease has become notably infrequent. $A\beta_2M$ amyloidosis in CKD stage 5 should not be confused with a rare hereditary systemic amyloidosis derived from the Asp76Asn variant of β_2-microglobulin, which manifests in the absence of CKD.

Pathogenesis

Fibrils of $A\beta_2M$ amyloid are derived from the circulating precursor protein β_2-microglobulin, the nonvariable light chain of the human leukocyte antigen (HLA) class I complex. The pathogenesis appears to involve three events:

1. Pronounced renal retention of β_2-microglobulin (11.8 kDa), leading to plasma levels that can be elevated up to 60-fold in dialysis patients[48]; however, even massive overproduction of β_2-microglobulin in mice was not sufficient to induce amyloid deposits and thus further steps must be important.[49]
2. Modifications of the β_2-microglobulin molecule that render it more amyloidogenic, such as limited proteolysis or the formation of different sugar-protein cross-links.[50]
3. Local factors that contribute to and determine the spatial localization of the amyloidosis.

Epidemiology

Histologic studies from the 1990s observed amyloid deposits in 100% of dialysis patients treated for more than 13 years.[51] Most amyloid deposits never cause clinical problems. The main risk factors for $A\beta_2M$ amyloid deposition are age at onset of renal replacement therapy (RRT) and the duration of (nontransplant) RRT.[48-50] $A\beta_2M$ amyloid–related symptoms presently are largely confined to patients who have been dialyzed for more than 15 years.

Clinical Manifestations and Diagnosis

$A\beta_2M$ amyloidosis mainly manifests at osteoarticular sites, particularly synovial membranes; visceral manifestations are rare.[48-50] Carpal tunnel syndrome occurs and symptoms typically worsen at night and during HD. It is often bilateral and usually requires surgery. Osteoarthropathy of peripheral joints, resulting from amyloid deposition in periarticular bone and the synovial capsule (Fig. 84.17), is characterized by recurrent or persistent arthralgias, stiffness of large and medium-sized joints, and swelling of capsules and adjacent tendons. Recurrent joint effusions and synovitis, often in the shoulders and knees, may occur. The clinical presentation may vary from frank, acute arthritis to slow, progressive destruction of the affected joints. Destructive spondyloarthropathy (Fig. 84.18) resulting from $A\beta_2M$ amyloidosis can manifest as asymptomatic deposits, radiculopathy, stiffness, "mechanical ache," and, finally, medullary compression with resulting paraplegia or cauda equina syndrome. Other manifestations include camptodactyly (a flexion deformity resulting in bent fingers that cannot completely extend or straighten) resulting from amyloid deposits along the flexor tendons of the hands (Fig. 84.19).

Patients undergoing dialysis also can have subcutaneous tumorous deposits of $A\beta_2M$ amyloid; however, diffuse infiltration of the subcutaneous fat or skin has not been observed.

Case reports of clinically relevant organ manifestations are usually in patients treated with HD for more than 15 years and have described heart failure, odynophagia (painful swallowing), intestinal perforation of both small and large bowel, gastrointestinal bleeding and pseudoobstruction, gastric dilation, paralytic ileus, persistent diarrhea, macroglossia or functional tongue disturbances (abnormal taste, mobility, articulation), ureteral stenosis, and renal calculi.

Diagnosis

Serum levels of β_2M do not distinguish between patients with amyloidosis and those without. Ultrasound can detect synovial $A\beta_2M$ amyloidosis as thickening of the joint capsules of the hip and knee, biceps tendons, and rotator cuffs, as well as the presence of echogenic structures between muscle groups and joint effusions.[48-50] On radiologic examination, affected joints may present with single or multiple juxtaarticular, "cystic" (i.e., amyloid-filled) bone radiolucencies (Fig. 84.20; see also Fig. 84.17). Such bone defects are prone to pathologic fractures. Diagnostic criteria for $A\beta_2M$ amyloid–induced cystic bone radiolucencies have been published.[52] They include (1) diameter of lesions more than 5 mm in wrists and more than 10 mm in shoulders and hips, (2) normal joint space adjacent to the bone defect, (3) exclusion of small subchondral cysts in the immediate weight-bearing area of the joint and of defects of the "synovial inclusion" type, (4) increase of defect diameter of more than 30% per year, and (5) presence of defects in at least two joints. Scintigraphy, using either radiolabeled serum amyloid P component or β_2-microglobulin,[53] offers more specific detection of amyloid deposits but is not widely available. The definitive diagnosis of $A\beta_2M$ amyloidosis relies on histologic findings. Fat aspiration and rectal biopsy are not helpful in $A\beta_2M$ amyloidosis, but diagnostic material can be obtained from synovial membranes, synovial fluid, or bone lesions.[48]

Treatment and Prevention

Therapy for established $A\beta_2M$ amyloidosis is symptomatic. NSAIDs and physical and surgical measures, such as carpal tunnel

(C and D) Anterior and lateral views of the head of the tibia with two very large, cystic lesions *(arrows)* resulting in posterior bulging of the tibial plateau.

decompression, endoscopic coracoacromial ligament release, and bone stabilization in areas of cystic destruction, are all used.[48] Although some dialysis modalities allow significant removal of β_2M, there is at present no convincing evidence that this is of therapeutic value in established $A\beta_2M$ amyloidosis. Renal transplantation is the preferred treatment because it leads to rapid symptomatic improvement and halts further progress of the disease, but whether this can actually lead to regression of established $A\beta_2M$ amyloid deposits is a subject of controversy.

A number of strategies exist for prevention of the clinical manifestations of $A\beta_2M$ amyloidosis.[48] The risk for carpal tunnel syndrome is reduced by 40% to 50% in patients treated with high-flux hemo(dia) filtration and minimal in patients receiving online hemodiafiltration. A dramatic reduction in the prevalence of carpal tunnel syndrome occurred in patients dialyzed with ultrapure dialysate. In another study, an 80% reduction of amyloid signs in a chronic HD population appeared to relate to dialysate factors such as microbiologic purity and the use of bicarbonate buffer. Finally, in uncontrolled studies a β_2M adsorption column was reported to decrease $A\beta_2M$ amyloid–associated symptoms, but the effect on bone lesions was not significant.

SELF-ASSESSMENT QUESTIONS

1. A 56-year-old White woman with end-stage renal disease (ESRD) secondary to presumed hypertensive nephrosclerosis has been on maintenance hemodialysis (HD) for 3.5 years. She reports to dialysis treatments regularly and is being adequately dialyzed. Laboratory data over the past few months reveal that intact parathyroid hormone (PTH) levels have ranged from 360 to 545 pg/ml, serum calcium 9.5 to 10.5 mg/dl (2.4 to 2.6 mmol/l), and phosphorus 5.5 to 7.0 mg/dl (1.83 to 2.33 mmol/l). She has been treated with increasing doses of paricalcitol, dietary phosphate restriction, and calcium carbonate as a phosphate binder. A few days ago, she was seen by her internist regarding vague symptoms that included abdominal pain. At that time, blood tests showed serum phosphorus 7.6 mg/dl (2.5 mmol/l) and calcium 10.1 mg/dl (2.5 mmol/l). The rest of the metabolic profile was within normal limits. A kidney, ureter, and bladder (KUB) film of the abdomen showed calcification of the abdominal aorta. What is the most appropriate next step in the management of this patient's chronic kidney disease–mineral and bone disorder (CKD-MBD)?
   A. Increase the dose of paricalcitol
   B. Increase the dose of calcium carbonate to improve phosphate control
   C. Stop calcium carbonate and add a non–calcium-containing phosphate binder
   D. Refer for parathyroidectomy
   E. Decrease dialysate calcium
2. A 75-year-old White man on HD because of diabetic nephropathy exhibits rapid progression of vascular calcification. His total serum calcium fluctuates around the upper limit of normal, with occasional episodes of mild hypercalcemia. Serum phosphorus is around 7 mg/dl (2.3 mmol/l) despite various changes of his phosphate binder medication. The latest intact PTH level is 105 pg/ml (previous levels ranged from 90 to 180 pg/ml). Current medication includes fluvastatin, calcium acetate, low-dose aspirin, a β-blocker, and insulin. What is the most appropriate next step in the management of this patient's CKD-MBD?
   A. Continue the described therapy.
   B. Increase the dose of calcium acetate to improve phosphate control.
   C. Repeat dietary counseling.
   D. Add low-dose calcitriol (e.g., 0.25 mcg/day).
   E. Replace calcium acetate with a calcium-free phosphate binder.
3. A 68-year-old White woman with an estimated glomerular filtration rate (eGFR) of 25 ml/min as a result of presumed hypertensive nephrosclerosis presents for a regular checkup. She has no specific complaints. Medication consists of an angiotensin-converting enzyme (ACE) inhibitor, a loop diuretic, a β-blocker, and low-dose aspirin. Current laboratory values include intact PTH level 90 pg/ml (reference range: <60), serum calcium 8.1 mg/dl (2.0 mmol/l) and phosphorus 5.7 mg/dl (1.8 mmol/l), 25(OH)-vitamin D_3 17 µg/l (target range 30 to 100). What step in the management of this patient's CKD-MBD is *not* appropriate?
   A. Educate the patient about phosphate content in food.
   B. Initiate therapy with a phosphate binder.
   C. Initiate substitution of 20,000 IU vitamin D_3 every second week.
   D. Educate the patient about food additives.
   E. Initiate therapy with a low dose of a calcimimetic.

Neurologic Complications of Chronic Kidney Disease

Julian L. Seifter, Martin A. Samuels

Disorders of the nervous system may coexist with renal disease in patients with systemic disorders (e.g., hypertensive encephalopathy, thrombotic microangiopathies, atheroembolic and atherosclerotic disease, vasculitides) and fluid and electrolyte abnormalities. Neurologic complications accompany acute kidney injury (AKI) in the intensive care setting and in outpatients with chronic kidney disease (CKD). Furthermore, patients with CKD are at increased risk for toxin- and pharmacologic agent–induced neurotoxicity. This chapter focuses on the direct neurologic consequences of CKD.

UREMIC ENCEPHALOPATHY

The syndrome of uremic encephalopathy (UE) involves a spectrum of brain abnormalities that may clinically range from nearly imperceptible changes to coma.

Pathogenesis

The brain in CKD has decreased metabolic activity and oxygen consumption.[1,2] As long as the underlying renal disease has not affected cerebral hemodynamics and responsiveness to carbon dioxide, these functions appear intact, but subtle disturbances have been detected after dialysis.

Many theories support the role of uremic toxins that accumulate in CKD. The balance of excitatory and inhibitory neurotransmitters may be disrupted by organic substances,[3] in particular guanidino compounds, which are increased in cerebrospinal fluid.[4,5] These compounds antagonize γ-aminobutyric acid ($GABA_A$) receptors and at the same time have agonistic effects on *N*-methyl-D-aspartate glutamate receptors, leading to enhanced cortical excitability. Asymmetric dimethylarginine,[6] which is increased in CKD, inhibits endothelial nitric oxide synthase, and levels correlate with cerebrovascular complications in uremia. Disturbances in monoamine metabolism include a depletion of norepinephrine and suppression of central opamine, which has been linked to the impairment of motor activity in uremic rats. Myo-inositol, carnitine, indoxyl sulfate, and polyamine content, as well as disrupted solute transport and permeability, have been implicated in the neuronal dysfunction of uremia. Metabolites of drugs such as cimetidine and acyclovir are increased in uremia because of inhibition of organic anion transporter 3 (OAT3) and may result in neurotoxic syndromes.[7] Levels of opiates and in particular metabolites of meperidine increase in plasma because of decreased excretion through renal cation secretory transport, with subsequent neurotoxicity.[8]

Secondary hyperparathyroidism also may play a role in UE[9,10] because brain calcium is increased in CKD and calcium transporters within neurons are sensitive to parathyroid hormone. Increased cellular calcium may play a role in neuroexcitation.

Appetite regulation is abnormal in uremia (see Chapter 86). A high rate of tryptophan entry across the blood-brain barrier may increase the synthesis of serotonin, a major appetite inhibitor.[11] High levels of cholecystokinin, a powerful anorectic, and low levels of neuropeptide Y, an appetite stimulant, have been observed. Cachexia may result from anorexia, acidosis, and inflammation. Inflammatory cytokines such as leptin, tumor necrosis factor-α, and interleukin-1 may signal anorexigenic neuropeptides such as proopiomelanocortin and α-melanocyte–stimulating hormone in the arcuate nucleus of the hypothalamus.

Clinical Manifestations

Whereas 20% of patients with AKI in an intensive care unit setting developed neurologic impairment,[12] the syndrome in CKD is more subtle, not correlating closely to the level of renal function.[13] Cross-sectional studies in hemodialysis (HD) patients found cognitive impairment in 30%, with about 10% exhibiting severe impairment. Neurocognitive deficits may have special implications for CKD in early childhood, adversely affecting development of the brain.[14]

UE can manifest as complex mental changes or motor disturbances (Box 85.1). The full-blown syndrome is a risk factor for morbidity and mortality.[1,2] Mental findings include emotional changes, depression, disturbing and disabling cognitive and memory deficits, and, in the most severe form, a generalized disorder characterized by delirium, psychosis, seizures, coma, and ultimately death. Severe motor symptoms or signs are rare. Depression, anxiety, and even suicide are important underdiagnosed and undertreated aspects of uremia and may be related to metabolic or poor nutritional state and fear of dialysis or death. Other known causes of depression should always be sought.

Stable UE manifests with fine action tremor, asterixis, and hyperreflexia. Asterixis is characterized by intermittent loss of muscle tone in antigravity muscles. It is distinguished from tremor by the fact that it is not an oscillation but rather an intermittent loss of tone. Myoclonus is also seen in patients with UE. It is similar in timing to asterixis (10 to 100 ms) but is caused by activation of antigravity muscles. For this reason, some consider asterixis to be a form of negative myoclonus. The distinction between asterixis and myoclonus is less important than once thought because both or either may be present in many metabolic encephalopathies and some structural brain diseases as well. Asterixis and myoclonus may be elicited with the hands outstretched but may be more sensitively assessed by looking at the protruded tongue or the index finger raised with the hand resting on a firm surface. Asterixis and myoclonus may be seen in patients with renal impairment who have received various drugs (e.g., metoclopramide, phenothiazines, antiepileptic drugs including gabapentin, and opioids, especially meperidine). With increased use of opiates it is imperative for the treating physician to understand the life-threatening complications of drugs in

BOX 85.1 Clinical Manifestations of Uremic Encephalopathy

Early Encephalopathy

Mental Changes

- Mood swings
- Impaired concentration, loss of recent memory
- Insomnia, fatigue, apathy

Motor Changes

- Hyperreflexia
- Tremor, asterixis
- Dysarthria, altered gait, clumsiness, unsteadiness

Late Encephalopathy

Mental Changes

- Altered cognition and perception
- Illusions, visual hallucinations, agitation, delirium
- Stupor, coma

Motor Changes

- Myoclonus, tetany
- Hemiparesis
- Seizures

TABLE 85.1 Opioid Use in End-Stage Renal Disease

Drug	Active Metabolites	Comments
Codeine Hydrocodone Meperidine	Morphine Hydromorphone Normeperidine	Active metabolites accumulate in patients with renal failure; should avoid in dialysis.
Morphine	Morphine-3-glucuronide Morphine-6-glucuronide	Active metabolites accumulate in patients with renal failure; can cause myoclonus and respiratory depression; mostly replaced by hydromorphone.
Hydromorphone Oxycodone	Hydromorphone-3-glucuronide Oxymorphone Noroxycodone	Mostly metabolized in liver. Active metabolites removed by dialysis, but small amounts accumulate in patients with renal failure.
Fentanyl	No active metabolites	Metabolized in liver; not removed by dialysis
Methadone		Fecal excretion; not removed by dialysis

this class for the patient with CKD before and after initiation of dialysis[8] (Table 85.1). Metabolic acidosis may produce an indistinguishable encephalopathy, as can aluminum toxicity. Therefore a careful search for other causes is required before features potentially consistent with UE are attributed to advanced uremia requiring renal replacement therapy (RRT).

Advanced UE is usually characterized by a reduced level of consciousness, anorexia, asterixis, myoclonus, and upper motor neuron signs that result in disturbances of gait and speech.

Diagnosis and Differential Diagnosis

Severe UE is unlikely to occur in patients with CKD who are followed closely before initiation of RRT (see Chapter 90). UE is more likely

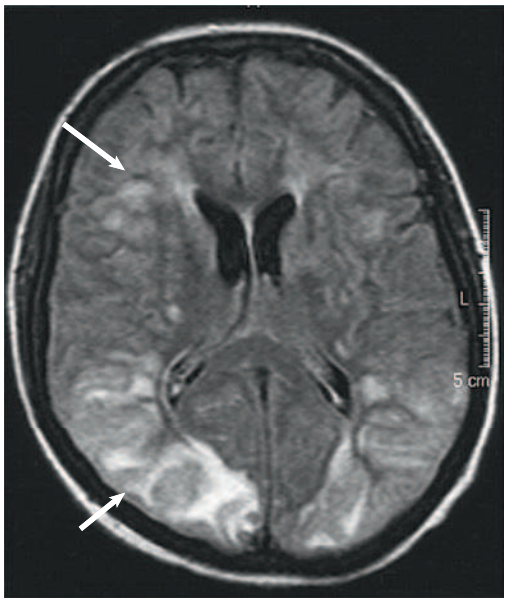

Fig. 85.1 Magnetic resonance imaging (MRI) findings in uremic encephalopathy. Axial T2-weighted MRI (fluid-attenuated inversion recovery) scan from a 40-year-old woman. The extensive hyperintense lesion involves the cortical and subcortical areas of both occipital lobes and, in a more focal distribution, the basal ganglia and the frontal white matter *(arrows)*. The volume of the affected brain parenchyma is increased. Reversibility of the MRI changes was noted 2 weeks after the initiation of regular dialysis. (Courtesy A. Thron, Aachen, Germany.)

to occur in the patient who initially presents with kidney failure or a dialysis patient after missing many treatments. The blood urea nitrogen concentration most commonly exceeds 200 mg/dl. Hypertension is often present, and the manifestation may be mistaken for hypertensive encephalopathy. The diagnosis of UE is based on clinical findings and their improvement after adequate therapy (see next section). If the patient develops more insidious signs of cognitive impairment while undergoing dialysis, inadequate dialysis treatment must be distinguished from dialysis-associated dementia, Alzheimer disease, or other cause of chronic impairment. Lumbar puncture, electroencephalography, and imaging procedures largely serve to exclude other causes in patients in whom the clinical diagnosis is doubtful. In UE the cerebrospinal fluid is often abnormal, sometimes demonstrating a modest pleocytosis (usually <25 cells/mm^3) and increased protein (usually <100 mg/dl). The electroencephalogram is usually abnormal but nonspecific. Generalized slowing in the theta and delta wave ranges is found.[15] Brain imaging usually shows cerebral atrophy and enlargement of the ventricles (Fig. 85.1).

The differential diagnosis of UE is shown in Table 85.2. Seizure activity may be secondary to UE, hypertensive encephalopathy, cerebral embolism, cerebral venous thrombosis, or electrolyte and acid-base abnormalities. Tetany can develop when treatment involves alkalinization of an acidemic patient with renal disease and hypocalcemia. Severe electrolyte abnormalities, including hypocalcemia, hypomagnesemia, hyponatremia and hypophosphatemia, may manifest with delirium.

Treatment

Most nephrologists consider advanced cognitive or memory impairment an indication for initiation of RRT. Most of the manifestations of central nervous system (CNS) involvement are reversible with dialysis within days or weeks, but mild signs of UE may persist. Patients who do not manifest severe signs of encephalopathy often notice improvement in

TABLE 85.2 Differential Diagnosis of Uremic Encephalopathy

Differential Diagnosis	Comment
Hemodynamic or Vascular Encephalopathy	
Systemic inflammatory response syndrome (SIRS)	Observed in septic patients.
Systemic vasculitis	Vasculitis or lupus with cerebral involvement.
Cerebral atheroembolic disease	Follows recent aortic or cardiac angiography; associated with peripheral manifestations, including lower extremity cyanosis, livedo reticularis, and eosinophilia.
Drug-Induced Neurotoxicity	
Analgesics	Meperidine, codeine, morphine, gabapentin.
Antibiotics	High-dose penicillins (may cause seizures), acyclovir, ethambutol (optic nerve damage), erythromycin and aminoglycosides (may cause ototoxicity), nitrofurantoin and isoniazid (peripheral neuropathy).
Psychotropics	Lithium, haloperidol, clonazepam, diazepam, chlorpromazine.
Immunosuppressants	Cyclosporine, tacrolimus.
Chemotherapeutics	Cisplatinum, ifosfamide.
Others	High doses of loop diuretics (ototoxic), ephedrine, methyldopa, aluminum metoclopramide (myoclonus, dystonia).
Subdural Hematoma	
Posterior reversible encephalopathy syndrome (PRES)	Observed particularly after renal transplantation as a result of reversible, abnormal permeability of the blood-brain barrier. Often manifests with headache followed by mental depression, visual loss, and seizures in the context of volume expansion, acute hypertension, and often treatment with corticosteroids or calcineurin inhibitors. Lesions in the parietal, temporal, and occipital lobes may be seen on imaging studies.

cognitive function once they start RRT. Some may describe this as a "fog lifting." In dialyzed patients with persistent or recurrent symptoms, increasing the delivered dialysis dose may improve clinical findings. Successful renal transplantation usually results in resolution of the UE syndrome within days.

Correction of anemia with recombinant erythropoietin in the dialysis patient to a target hemoglobin level (see Chapter 82) may be associated with improved cognitive function and decreased slowing on the electroencephalogram.[16] Too rapid overcorrection of anemia may be associated with seizures. Treatment of psychosis in kidney disease must consider the pharmacokinetics of the specific agent. For example, risperidone may be useful, but dose reduction is necessary because of prolonged half-life in CKD.

PERIPHERAL NEUROPATHY

Patients with CKD are susceptible to both polyneuropathies and mononeuropathies. The pathophysiologic process of polyneuropathy involves axonal degeneration in a length-dependent fashion. Primary demyelinating neuropathies are rare in the context of CKD except when the renal disease is the result of an illness that also causes demyelination (e.g., multiple myeloma). Mononeuropathies in CKD may be caused by nerve entrapment with compression of metabolically weakened nerves, particularly in wheelchair-bound or bed-bound patients. Mononeuritis multiplex should raise the possibility of vasculitic neuropathy, especially when systemic vasculitis (e.g., antineutrophil cytoplasmic antibody–positive small-vessel vasculitis or polyarteritis nodosa) is causing the CKD. Functional sparing of small-diameter axons in uremia is suggested by relatively intact thermal thresholds (hot and cold thermal threshold testing is a surrogate for pain threshold). The modestly slowed nerve conduction velocities in the polyneuropathies of uremia may be related to the reversible inhibition of the sodium-potassium adenosine triphosphatase by a uremic toxin. According to the middle molecule hypothesis, accumulated toxins in the range of 300 to 12,000 d, including peptide hormones and polyamines, may lead to progression of neuropathy in HD patients.[4,9,10] Lower limb motor axons in uremic patients are depolarized before but not after dialysis, consistent with a role of hyperkalemia in the development of altered nerve excitability.[17] Elevated magnesium levels will also slow nerve conduction velocity. In vitro, extracellular acidosis contributes to decreased sodium conductance in large sensory neurons. Very slow nerve conduction velocities (i.e., less than half normal) suggest a demyelinating neuropathy, a finding that should lead the physician to seek a specific cause (e.g., a paraprotein).

Uremic neuropathy may progress rapidly in advanced CKD.[1,17,18] Characteristic symptoms and signs are sensory loss, pain, paresthesias, and insensitivity to temperature, particularly cold. These findings can advance to include motor findings, such as foot drop. Phrenic neuropathy may cause dyspnea because of poor diaphragmatic movement, whereas hiccups are more likely a result of the CNS effects of uremia. The distal lower extremities are usually affected first because axonal polyneuropathies are length dependent. Decrease in vibratory sensation and position sense and Romberg sign (i.e., greater instability of stance with eyes closed than with eyes open) are common signs. Muscle stretch reflexes are reduced or absent. In the patient with diabetes who is on dialysis and has progressive neuropathy, it is important to establish adequacy of dialysis as well as glucose control. Uremic polyneuropathy is aggravated by malnutrition, inadequately controlled hypertension, certain comorbid conditions (e.g., diabetes mellitus, alcohol abuse, atherosclerotic vascular disease), and medications (e.g., nitrofurantoin, isoniazid, hydralazine).

The diagnosis of uremic polyneuropathy can usually be made from clinical findings. Nerve conduction velocity is modestly reduced, and needle electromyography shows evidence of chronic denervation and sometimes reinnervation. If electromyography and nerve conduction tests are performed, they should not be done in an extremity bearing an arteriovenous fistula because vascular access surgery may cause local nerve injury, which can complicate the interpretation of these studies.[17]

Lead polyneuropathy should be considered, particularly when there is a known exposure history. Lead accumulates in the dialysis patient but could also be the cause of CKD. A lower motor neuron syndrome caused by lead toxicity may be mistaken for amyotrophic lateral sclerosis. A bone lead scan using K-line x-ray fluorescence spectroscopy of the tibia is a promising new noninvasive test that may become useful. Serum lead values and red cell protoporphyrin levels may be normal if exposure is remote. There may be associated depression, the so-called "saturnine

temperament," so named because the ancients believed that Saturn was made of lead and was associated with a melancholy disposition. Gout, hypertension, renal glycosuria, and microcytic anemia also may be caused by lead toxicity.

Other conditions in the differential diagnosis of mixed polyneuropathy include other heavy metals (e.g., arsenic, mercury), nutritional deficiencies (e.g., pyridoxine, thiamine, niacin), HIV-related neuropathy, amyloid, vasculitis, sarcoid, lupus, and a paraneoplastic syndrome.

Progressive polyneuropathy may be an indication for initiation of dialysis or renal transplantation. Symptoms usually will not deteriorate further or may even show a slow improvement thereafter. If polyneuropathic symptoms worsen in a dialysis patient, the dialysis dose should be increased. Physical therapy is an important component of the management. Patients experiencing neuropathic pain may be treated with tricyclic antidepressants (e.g., amitriptyline 10 to 25 mg, increasing to 75 to 150 mg at bedtime) or antiepileptic drugs (e.g., carbamazepine 200 to 400 mg initially, increasing to 1200 mg maximally; phenytoin 100 to 200 mg initially, maximally 600 mg).[1,2] Gabapentin is an antiepileptic drug that is sometimes used to treat neuropathy but may result in oversedation and myoclonus in CKD because of marked prolongation of the drug's half-life. When gabapentin is used, it should be monitored closely at reduced doses. Deficiencies of cobalamin (vitamin B_{12}), folate, and pyridoxine may be reflected in an elevated serum homocysteine level. Methylmalonic acid may be elevated in vitamin B_{12} deficiency, and it is critical to promptly diagnose this deficiency because irreversible changes to the nervous system may develop within months. Loss of balance and position sense may be mistaken for neuropathy in pernicious anemia. Vitamin B_{12} deficiency and folate deficiency manifest with a megaloblastic or macrocytic anemia. If folate is given to a patient deficient in vitamin B_{12}, the acute posterior column findings of subacute combined degeneration of the spinal cord may develop as the low store of vitamin B_{12} is used to correct the anemia. Thiamine deficiency, often associated with malnutrition, can aggravate neuropathy, but whether replacement of any of these vitamins is effective in preventing or curing polyneuropathy in uremic patients is not well established. Thiamine deficiency is the cause of Wernicke encephalopathy in dialysis or malnourished patients. This syndrome is suspected when the triad of mental change (often amnesia), ataxia, and oculomotor disturbances (most often abducens palsies with gaze-evoked nystagmus) is seen in any patient whose diet is deficient in B vitamins. When amnesia is combined with a polyneuropathy, the term *Korsakoff psychosis* applies. In malnourished patients, the cause of Korsakoff psychosis is usually multiple subclinical attacks of Wernicke encephalopathy, hence the term *Wernicke-Korsakoff disease.*

Specific mononeuropathic syndromes include ulnar nerve entrapment, associated with uremic tumoral calcinosis and subsequent ischemia, and carpal tunnel syndrome, for example, caused by β_2-microglobulin–derived amyloidosis (see Chapter 84) or by an arteriovenous fistula.[1,18] These syndromes may be treated with antiinflammatory agents, anticonvulsants, and surgical decompression. It is important to ensure adequacy of dialytic treatment.

Pruritus in the uremic patient may be severe and is not primarily a skin disorder (see also Chapter 87). Rather, it may represent a form of sensory neuropathy. This symptom usually improves with RRT. Antihistamines, with their sedating effect, are not always effective. Gabapentin and carbamazepine block the afferent pathway in uremic neuropathic itch. Gabapentin and pregabalin inhibit calcitonin gene–related peptide from primary afferent neurons by inhibiting GABA and opioid receptor antagonists (naloxone and naltrexone) and may antagonize transmission of itch. Antidepressants also have been successful, possibly by interfering with reuptake of serotonin and norepinephrine to reduce pruritus perception.[19]

AUTONOMIC NEUROPATHY

Autonomic neuropathy is also very common in patients with advanced CKD, probably because diabetes is a common cause of CKD. Hyperglycemia may be more difficult to control in CKD because glucose filtration is decreased. Amyloidosis, a less common cause of CKD, is associated with autonomic neuropathy. A typical manifestation is orthostatic hypotension, which is most severe in patients with diabetes mellitus or amyloidosis as a cause of CKD. Some dopaminergic drugs used in Parkinson disease or parkinsonism itself may cause orthostasis. Some patients have evidence of peripheral neuropathy and may manifest hyporeninemic hypoaldosteronism with hyperkalemia and renal tubular acidosis. The low blood pressure (BP) may preclude antiproteinuric treatment with angiotensin antagonists in the predialysis patient and may complicate fluid removal during dialysis. Patients on peritoneal dialysis (PD) may be particularly affected. CKD patients were thought to have decreased baroreceptor function, but normal baroreceptor responses to graded decrements in mean arterial BP have been described.[20] Instead, CKD patients have sympathetic hyperactivity, which contributes to hypertension, more rapid progression to renal failure in the predialysis patient, and greater cardiovascular (CV) risk. Accordingly, α- and β-adrenergic blockade has been advocated in CKD.[20] Autonomic neuropathy is caused by axonal disease and thus is length dependent. For that reason, the longest autonomic nerve, the vagus, is usually the first affected, resulting in the loss of the normal sinus arrhythmia, significant reductions of day-night BP variation, and possibly sudden cardiac death related to the loss of the balance between the sympathetic and parasympathetic limbs of the autonomic nervous system. Reports of gastrointestinal problems include gastroparesis, particularly problematic for the diabetic patient. In the predialysis patient, nausea and early satiety associated with gastroparesis may be confused with uremia. Several medical regimens have been used for the uremic patient with gastroparesis; they include erythromycin, which can activate the gastric motilin receptor. Levodopa-carbidopa, as a dopamine agonist, may be effective, as may metoclopramide 10 mg before sleep or domperidone 10 to 20 mg. Nocturnal diarrhea is another consequence of vagal neuropathy. Erectile dysfunction and incontinence (urinary more commonly than fecal) also may be related to autonomic neuropathy.

CRANIAL NEUROPATHIES

Cranial nerve involvement is most often vestibulocochlear. Hearing loss needs to be distinguished from drug-induced ototoxicity or the neurosensory deafness of hereditary nephropathy.[1,2] Bilateral vestibular failure leads to inability to stand or to walk normally without vertigo or nystagmus. It is often related to the use of aminoglycoside antibiotics in the patient with CKD, unless the dose is properly adjusted. *N*-Acetylcysteine given with aminoglycosides may reduce the risk for cochlear toxicity. Sulfa-based loop diuretics, often used at high doses in patients with CKD, may cause vestibular or cochlear damage. Decreased olfactory function, especially a reduced ability to discriminate among and identify odors, and dysgeusia are commonly seen in patients with CKD.

SLEEP DISORDERS

Many HD and PD patients exhibit obstructive sleep apnea that is independent of obesity.[21] The associated sleep deprivation contributes to fatigue and cognitive impairment and increases the risk for CV complications.[21] Both obstructive and central sleep apnea are seen in patients with CKD. Obstructive sleep apnea is a condition in which blockage of the upper airway can interfere with nocturnal breathing. Nighttime

oxygen and continuous positive airway pressure (CPAP) may help. Treatment of obstructive sleep apnea is effective, including use of CPAP (as in nonuremic individuals) and conversion to nocturnal HD.[21] Central sleep apnea, often accompanied by heart failure, causes prolonged apneic episodes and may respond to oxygen. Initiation of dialysis may be helpful.

Daytime sleepiness is common and underdiagnosed in patients with CKD and contributes not only to worsened hypertension and increased CV risk but also to social dysfunction. Whether obstructive sleep apnea and its associated excessive daytime sleepiness is an independent risk factor for the progression of renal failure is not yet settled. It is assessed by a multiple sleep latency test, that is, the duration of time from "lights out" to the onset of sleep. If it is less than 5 minutes, it is consistent with sleep deprivation. There was also a reduced proportion of rapid eye movement sleep. An increased arousal frequency is related to periodic limb movements during sleep and the presence of sleep apnea.

Sleep-wake complaints are common in patients on dialysis, with an incidence of up to 80%. Contributors include peripheral neuropathy, pain, and pruritus.

RESTLESS LEGS SYNDROME (EKBOM SYNDROME)

Restless legs syndrome (RLS), described by K. A. Ekbom in 1944,[22] is frequent in CKD, particularly in women. It may result from a decrease in dopaminergic modulation of intracortical excitability, with reduced supraspinal inhibition and increased spinal cord excitability. RLS is characterized by unpleasant "creeping" sensations in the extremities and a compulsive need to move the limbs, usually the legs.[23-25] The movement is worsened by periods of rest or inactivity and is relieved by walking or stretching. Symptoms are worse at night and may lead to insomnia and consequent daytime sleepiness and reduced quality of life. Nocturnal muscle cramps are common in CKD and should be distinguished from RLS. The Ekbom syndrome consists of restless legs plus other obsessive-compulsive–like disorders including various pica behaviors, such as pagophagia (ice eating), geophagia (clay eating), and amylophagia (starch eating).

Periodic limb movement disorder is characterized by episodes of involuntary repetitive extension of the big toe and dorsiflexion of the ankle, as well as flexion of the knee and hip.[24,25] This disorder is more likely to occur in those with RLS.

Iron deficiency or iron transport into the CNS plays a central role in RLS. Iron is a cofactor for the enzyme tyrosine hydroxylase, the rate-limiting step in the biosynthesis of dopamine, possibly explaining the link between iron deficiency and dopamine deficiency in RLS. Overt iron deficiency is easily diagnosed and should be treated.[24,25] In patients with normal red blood cell indices and serum iron and total iron-binding capacity, serum ferritin should be tested. Transferrin saturation ratio may be an even more sensitive indicator of iron deficiency. Although not clinically indicated for RLS, analysis of spinal fluid ferritin may reveal a subtle CNS iron-deficiency syndrome. RLS often persists after initiation of dialysis but may improve after transplantation and has been linked to abnormalities in calcium and phosphorus metabolism as well as to anemia. Iron replacement should be initiated if there is any indication of iron deficiency Intravenous iron may be required (see Chapter 82). Dopaminergic treatment is often helpful, usually starting with the dopamine receptor agonists pramipexole and ropinirole. Levodopa combined with decarboxylase inhibitors (e.g., carbidopa-levodopa) may be used as well as gabapentin, opioids, and benzodiazepines.[23-25] As mentioned, gabapentin should be used cautiously because of toxicity with accumulation, the symptoms of which are sedation, cognitive slowing, and various movement disorders, including tremor, ataxia, and asterixis (see previous discussion). Older dopamine receptor agonists, such as bromocriptine and pergolide, are rarely used now for RLS.

NEUROLOGIC SYNDROMES ASSOCIATED WITH RENAL REPLACEMENT THERAPY

RRT is associated with an increased incidence of subdural hematoma and intracranial hemorrhage, presumably connected to hypertension and anticoagulation with HD as well as Wernicke encephalopathy (see earlier discussion).[1,2] A syndrome of muscle weakness has been attributed to L-carnitine depletion from dialysis, leading to decreased mitochondrial fatty acid usage.

Dialysis disequilibrium syndrome is a rare complication of rapid metabolic changes occurring with HD, usually affecting patients in whom HD is being initiated (see Chapter 95).[26] It is most common in patients with severe uremia of long duration and with severe hypertension. Characterized by acute onset of headache, nausea, vomiting, disorientation, a state of confusion, and seizures, it is a diagnosis of exclusion. It usually results from acute changes in osmolality during HD, in which the rapid decrease in urea in the extracellular fluid favors water movement into brain cells, resulting in cerebral edema. Alternatively, other intracellular osmolytes within brain cells may draw water from the extracellular fluid. The syndrome normally reverses spontaneously after a period of regular HD. If no improvement is seen after a month of HD, one should investigate for other possible causes of the clinical syndrome by imaging the brain, obtaining an electroencephalogram, and examining the spinal fluid. Dialysis disequilibrium syndrome may be prevented by decreasing HD length to 2 to 3 hours, dialyzing daily, and reducing HD efficacy during the first sessions.

Dialysis encephalopathy (formerly called *dialysis dementia*) is probably a multifactorial syndrome occurring in sporadic-endemic and epidemic types. In particular, in the epidemic type, aluminum-based phosphate binders and exposure to a dialysate containing more than 20 mcg of aluminum per liter are considered to be major causes.[27,28] Aluminum transferred to the nervous system by transferrin results in a characteristic clinical condition with prominent stuttering that usually worsens toward the end of a dialysis session and encephalopathy, initially responding well to intravenous benzodiazepines but then becoming unresponsive, leading to severe encephalopathy and death. With the almost universal preparation of dialysate water by reverse osmosis and the marked reduction in aluminum-containing phosphate binder use, aluminum-induced encephalopathy has virtually disappeared. If it is present, aluminum toxicity is treated with deferoxamine (see Chapter 84). Renal transplantation is an effective treatment for dialysis dementia.

SELF-ASSESSMENT QUESTIONS

1. A 50-year-old man with chronic hypertension, chronic kidney disease (CKD), and estimated glomerular filtration rate (eGFR) of 8 ml/min/1.73 m^2 who is not yet on dialysis presents with confusion, lethargy, and myoclonus. Which of the following factors may contribute to the neurologic changes?
   - **A.** Use of gabapentin for neuropathic pain
   - **B.** Poorly controlled secondary hyperparathyroidism
   - **C.** Poorly controlled anemia with iron deficiency
   - **D.** Poor dietary protein intake resulting in decreased blood urea level
   - **E.** A and D
   - **F.** All of the above
2. A 25-year-old woman has hypertension, seizures, and encephalopathy, believed to be caused by uremia. Her blood pressure is 200/120 mm Hg. Her blood chemistries reveal Na 120 mEq/l, K 4 mEq/l, Cl 80 mEq/l, and HCO_3^- 15 mEq/l. The anion gap is 25 mEq/l, glucose 70 mg/dl, and blood urea nitrogen (BUN) 200 mg/dl. Which of the following is the *best* answer?
   - **A.** Hypotonic hyponatremia may contribute to the altered neurologic picture.
   - **B.** The seizures may be from severe hypertension.
   - **C.** This presentation is characteristic of uremic encephalopathy.
   - **D.** The BUN should be decreased to normal promptly with dialysis.
   - **E.** Both A and D are incorrect.
   - **F.** A, B, and C are correct.
3. Findings associated with restless legs syndrome include all of the following *except:*
   - **A.** Obsessive-compulsive behavior
   - **B.** Amylophagia (starch craving)
   - **C.** Iron overload and deposition in the basal ganglia
   - **D.** Response to dopaminergic medication
   - **E.** Commonly, improvement during daytime hours and with exercise

Gastroenterology and Nutrition in Chronic Kidney Disease

Gemma Bircher, Graham Woodrow

GASTROINTESTINAL PROBLEMS IN CHRONIC KIDNEY DISEASE

Gastrointestinal (GI) symptoms and disease are common in patients with chronic kidney disease (CKD), including those receiving renal replacement therapy (RRT) (Table 86.1). Anorexia, nausea, and vomiting arising from uremic toxicity may indicate the need to start dialysis or be a manifestation of inadequate dialysis clearances. GI disturbances contribute to development of malnutrition and wasting, which are common complications of advanced CKD and carry an adverse prognosis for survival. Some GI conditions are a result of uremia or the effects of RRT or medications. Other GI symptoms are manifestations of conditions also responsible for the renal disease.

GASTROINTESTINAL DISEASE IN CHRONIC KIDNEY DISEASE

Oral Disease in Chronic Kidney Disease

Glossitis can result from deficiency of iron, vitamin B_{12}, other B vitamins, or folic acid. Halitosis is a feature of uremia, and reduced taste sensation or abnormal taste can impair dietary intake. Gingival hyperplasia is a frequent complication of treatment with calcium channel blockers or cyclosporine. Oral candidiasis occurs in patients receiving immunosuppressive drugs, including corticosteroids, those receiving antibiotics, and those with diabetes or who are malnourished. If extensive, particularly with esophageal involvement, candidiasis may lead to dysphagia and should particularly be suspected where there is associated retrosternal pain in patients with risk factors, who also may have oropharyngeal thrush. Treatment requires systemic antifungal therapy such as azoles, echinocandins, or amphotericin B (Fig. 86.1).

Gastroesophageal Reflux Disease and Esophagitis

Gastroesophageal reflux leading to heartburn or mucosal changes arising from reflux of caustic gastric contents into the esophagus occurs more frequently in patients with CKD because of GI tract dysmotility or delayed gastric emptying and may be more prevalent with peritoneal dialysis (PD) because of increased intraabdominal pressure. It is more common in patients with scleroderma with reduced esophageal peristalsis. Esophagitis also results from the irritant effects of drugs, including slow-release potassium preparations, tetracyclines, iron, aspirin, nonsteroidal antiinflammatory drugs, and bisphosphonates. Typical features appear on endoscopy but may be absent in symptomatic patients. Other investigations include 24-hour ambulatory esophageal pH monitoring and demonstration of reflux on barium swallow examination. It is important to consider cardiac ischemia as an alternative cause of atypical symptoms in CKD. Management includes weight loss in obese patients; avoiding bedtime snacks, fatty foods, cigarettes, and alcohol; and raising the head of the patient's bed. Proton pump inhibitors (PPIs) are the most effective medical treatment, and maintenance therapy may be required. Other drugs include histamine H_2-receptor antagonists and antacid preparations. Sucralfate should be avoided in advanced CKD because of the risk for aluminum accumulation.

Peptic Ulcer Disease, Gastritis, and Duodenitis

Despite effective acid-reducing drug therapies and improvement in dialysis therapy, peptic ulcer disease remains more common in CKD than in the general population, with highest incidence in dialysis patients.[1] It is an important cause of GI hemorrhage in CKD.[2] Peptic ulcers in patients with CKD are more likely to occur in multiple locations than are ulcers in the general population and are more often postbulbar, but pain is less frequent.[3]

Gastritis and duodenitis are common in patients with CKD. Hypergastrinemia occurs with CKD but is not important in causation of gastritis, duodenitis, or peptic ulcers. Despite high urea concentrations in patients with CKD, incidence of *Helicobacter pylori* infection is not increased.[4] Where *H. pylori* infection is present, eradication of this (with combined antibiotic and PPI treatment) reduces risk for bleeding in CKD, with greater benefit in earlier initiation of treatment.[5] The presence of *H. pylori* infection in PD has been suggested as a possible cause of anorexia, inflammation, and malnutrition.[6]

Dyspepsia without other warning features (weight loss, vomiting, hemorrhage) may be managed by testing for *H. pylori* with a breath test or stool antigen test and an empiric course of acid-suppressing therapy. Persistent symptoms of new onset in patients older than 55 years warrant upper GI endoscopy to exclude malignant disease. The frequent coexistence of other symptoms in CKD, such as nausea, vomiting, and weight loss, may lead to more frequent need for endoscopy. Management includes use of PPIs or histamine H_2-receptor antagonists. There is a risk for excess calcium and magnesium absorption with some antacids in CKD, and aluminum- or bismuth-containing preparations should be avoided because these metals can accumulate in patients with markedly reduced estimated glomerular filtration rate (GFR).

Delayed Gastric Emptying and Gastroparesis

Gastric emptying is impaired in uremia (especially in PD patients)[7,8] and also in some conditions leading to renal disease, particularly diabetes and amyloidosis. This results in reduced appetite, early satiety, nausea, vomiting, and malnutrition.[7] Mechanisms in uremia may include autonomic neuropathy and retained GI peptides. The diagnosis is confirmed by scintigraphic measurement of gastric emptying and may be suspected

TABLE 86.1 Important Causes of Common Gastrointestinal Symptoms in Patients With Chronic Kidney Disease

Clinical Feature	Important Causes in CKD
Anorexia	Uremic toxicity Inadequate dialysis clearances Delayed gastric emptying
Nausea and vomiting	Uremic toxicity Delayed gastric emptying/gastroparesis Gastritis, duodenitis Peptic ulcer disease Drugs
Constipation	Drugs, including opioid analgesia GI pseudoobstruction Diverticular disease
Diarrhea	Diabetic enteropathy Dialysis-related amyloidosis Diverticular disease *Clostridium difficile* infection
GI hemorrhage	Gastritis, duodenitis Esophagitis Peptic ulcer disease Angiodysplasia Intestinal ischemia Dialysis-related amyloidosis Vasculitis
Acute abdominal pain	Gastritis, duodenitis Complications of peptic ulcer disease Acute pancreatitis Intestinal ischemia Diverticulitis GI pseudoobstruction Colonic perforation from fecal impaction Complications of peritoneal dialysis (peritonitis, dialysis catheter malposition, dialysate infusion or drain pain) Complications of autosomal dominant polycystic kidney disease Retroperitoneal hemorrhage

CKD, Chronic kidney disease; *GI,* gastrointestinal.

when endoscopy demonstrates residual gastric contents despite fasting. Endoscopy is important to exclude gastric outlet obstruction. Reversible causes should be addressed, including optimization of diabetic control (gastroparesis may be an indication for continuous subcutaneous insulin infusion treatment in type 1 diabetes), correction of electrolyte abnormalities, and discontinuation of drugs that impair gastric emptying (e.g., those with anticholinergic and opioid effects). Treatment involves prokinetic drug therapy, including metoclopramide, domperidone, and erythromycin. Prokinetic drugs improve nutritional state in patients with delayed gastric emptying.[9] However, concerns about neurologic side effects with metoclopramide and cardiac arrhythmias with domperidone (in countries where it is available) restrict their longer term use. Dietary measures, with frequent smaller low-fat meals and avoiding nondigestible solids, and antiemetic agents are often ineffective. Nutritional support through nasoenteric or jejunostomy feeding tubes may be required.

Large Bowel Disorders

The incidence of diverticular disease is similar in CKD patients to that in the general population, except in patients with autosomal dominant polycystic kidney disease (ADPKD), in whom its incidence is increased.[10] It manifests as acute diverticulitis or colonic perforation and is associated with PD peritonitis caused by enteric organisms. There is a greater risk in CKD for diverticular bleeding (because of uremic bleeding tendency) and perforation in patients receiving high-dose corticosteroids.

Constipation is common in CKD because of dietary restrictions, restricted fluid intake, and electrolyte abnormalities, including hypercalcemia. In PD, constipation results in impaired dialysate drainage and catheter malposition. Severe constipation is a risk factor for large bowel perforation. Management includes stool-softening agents, stimulant laxatives, and fiber preparations. Drugs predisposing to constipation include calcium-based phosphate binders, sevelamer, oral iron, opioid analgesics, and calcium resonium. Some other phosphate binders such as iron-containing agents may conversely cause looser stools and thus may be useful in this situation.

Gastrointestinal Pseudoobstruction

Pseudoobstruction manifests with acute or more chronic features of abdominal pain, vomiting, constipation, or diarrhea. It arises from disordered gut motility and is more common in dysmotility states, including diabetes, amyloidosis, and scleroderma. Drugs that reduce bowel motility (especially narcotics) and electrolyte disturbances (e.g., hypokalemia) predispose to pseudoobstruction, which may be acutely precipitated by surgery, constipation, and retroperitoneal hemorrhage. Investigations include plain abdominal radiography, computed tomographic scanning, and bowel contrast studies. Management includes nutritional support (which may require parenteral feeding) and prokinetic agents. Nasogastric tube insertion and aspiration may be needed for symptomatic control. Complications include intestinal perforation[11] and bacterial overgrowth.

Vascular Disease of the Gastrointestinal Tract

Intestinal ischemia is an important cause of an acute abdomen in older CKD patients. Some cases result from nonocclusive mesenteric ischemia (where there is no critical vascular occlusion)[12] and may be precipitated by excessive intradialytic fluid removal. Predisposing factors include hypotension, cardiac failure, hypoxia, increased plasma viscosity, and constipation (which increases intraluminal pressure, impairing vascular perfusion). Presentation is with abdominal pain, diarrhea, or lower GI

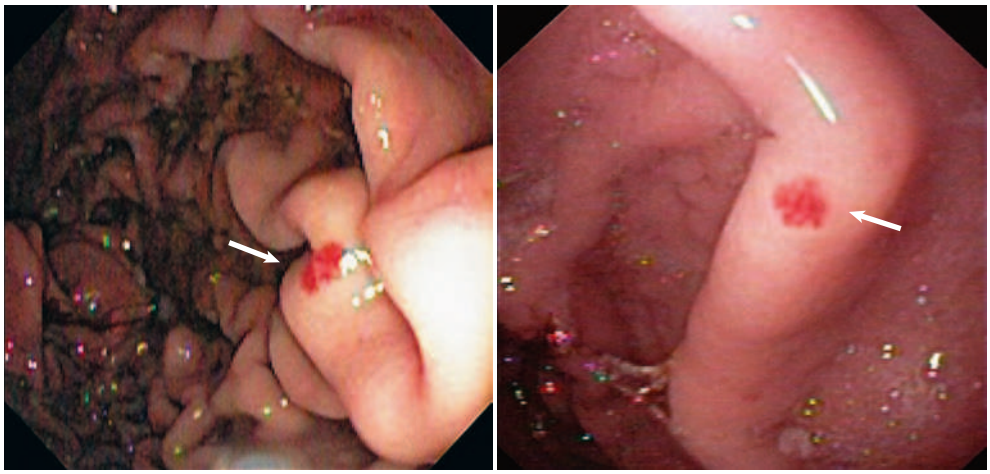

Fig. 86.2 Two examples of gastric angiodysplasia *(arrows)* in a dialysis patient. (Courtesy Drs. R. Winograd and C. Trautwein, Aachen, Germany.)

bleeding. Abdominal examination can be misleadingly benign at presentation, but often peripheral neutrophil leukocytosis and progressive lactic acidosis are present. Milder cases may settle with hemodynamic resuscitation. Patients with more severe features of peritonitis and intestinal infarction require laparotomy and have a high mortality rate.

GASTROINTESTINAL HEMORRHAGE

GI hemorrhage is more common in CKD compared with the general population, and the risk for mortality when bleeding occurs is also higher in CKD patients than those with normal kidney function. Causes of hemorrhage include a greater incidence of lesions such as peptic ulcers, gastritis and duodenitis,[13] angiodysplasia, and, more rarely, systemic vasculitis (Fig. 86.2). Nonulcer, nonvariceal bleeding is more common in CKD and particularly in hemodialysis (HD) patients.[14] Uremic hemostatic defects and anticoagulation during HD also are important. GI endoscopy is the major diagnostic investigation and allows therapeutic procedures. Investigations for when the cause remains unclear include angiography, small bowel enteroscopy or capsule study, and radiolabeled red cell scanning.

Resuscitation requires careful monitoring in CKD. Adequate fluid replacement to maintain renal perfusion in patients with residual renal function is crucial, and monitoring for hyperkalemia (if blood transfusions are given) and fluid overload is also important. Correction of coagulation defects in CKD includes optimization of dialysis clearance, correction of anemia, and use of desmopressin or cryoprecipitate. Drugs that increase bleeding risk should be discontinued when possible. HD (if required) should be performed without heparin. Specific treatment is directed at the cause of hemorrhage.

Clostridium difficile Infection

Clostridium difficile is a major cause of nosocomial diarrheal illness. Clinical manifestations vary from mild diarrhea to severe pseudomembranous colitis (Fig. 86.3). Patients with CKD are at risk for more frequent or severe infection, slower treatment response, more frequent relapse and have a higher risk for death,[15,16] especially with end-stage renal disease (ESRD). Reasons include the older age of CKD patients, frequent use of acid-suppressing drugs, and antibiotics. Diagnosis is made by identifying *C. difficile* toxin in diarrheal stools. In severe cases, there are radiologic appearances of acute colitis with mucosal edema, but these are not specific for *C. difficile.* A pseudomembrane may be visualized on sigmoidoscopy, but diarrhea can occur in its absence. The

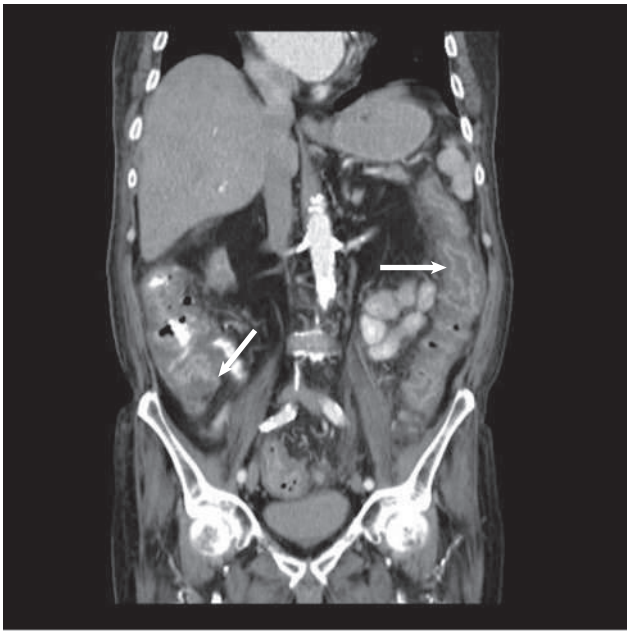

Fig. 86.3 Computed tomographic appearance of *Clostridium difficile* colitis in a hemodialysis patient, demonstrating pancolitis with markedly edematous haustra *(arrows)* after treatment with broad-spectrum antibiotics. (Courtesy Dr. M. Weston, Leeds, United Kingdom.)

precipitating antibiotic should be stopped or switched to one less likely to promote *C. difficile* infection. Treatment depends on disease severity with oral metronidazole or oral vancomycin usually being first-line antibiotic therapy. Fidaxomicin is a newer agent that may be used for severe or recurrent infection and results in less frequent relapse.[15] Intravenous immunoglobulin (Ig) has been used for refractory cases,[17] and fecal transfer has been successfully used in severe or recurrent infections. Fluid and electrolyte replacement are important, and drugs that reduce diarrhea or impair gut motility must be avoided because they may precipitate toxic megacolon. Colectomy may be required in life-threatening disease. *C. difficile* infection is a major problem in the hospital setting, including renal units. Preventive measures are essential, including hand washing, cleanliness of physical environment, and isolation of

affected inpatients with barrier nursing. Antibiotic policies should minimize use of broad-spectrum antibiotics, which induce *C. difficile* infection.

Acute Pancreatitis

Acute pancreatitis may be more common in CKD, especially in PD patients.[18] Most cases are secondary to biliary tract disease or alcohol use or are idiopathic. Rarer causes in CKD patients are hypercalcemia, vasculitis, and drugs, including corticosteroids, azathioprine, angiotensin-converting enzyme (ACE) inhibitors, and diuretics. Serum amylase is the usual diagnostic measure, although levels are elevated up to threefold in renal failure and lowered in PD patients receiving icodextrin dialysate (because of competitive inhibition of icodextrin metabolites with the amylase assay). Serum lipase is an alternative diagnostic marker (although it is also elevated in uremia). Thus pancreatic enzyme levels may be less reliable in CKD, but values more than three times the normal range are strongly suggestive of acute pancreatitis in end-stage renal failure patients. Amylase and lipase concentrations may be measured in dialysate in PD patients with suspected pancreatitis. Radiology, including ultrasound, computed tomography, and magnetic resonance imaging, is useful to confirm the diagnosis and detect underlying biliary disease and complications, including pancreatic necrosis and pseudocyst formation. In PD patients with acute pancreatitis, dialysate may be bloody, cloudy from increased leukocytes, or cola-colored.

Acute Abdomen

Some causes of acute abdominal pain occur more commonly in or are specific to CKD patients. A high index of suspicion for ischemic bowel is important because of the frequency of vascular disease in CKD. Pain may result from complications of polycystic kidney disease. Retroperitoneal hemorrhage can arise from anticoagulation, including during HD. In PD, abdominal pain arises from peritonitis, infusion pain (as a result of dialysate acidity), drain pain with automated PD, catheter malposition, constipation, or encapsulating peritoneal sclerosis. Other surgical conditions need to be distinguished from dialysis-specific causes. Although air uncommonly enters the peritoneal cavity during PD, in the setting of acute abdominal symptoms, free gas present on radiologic imaging of the abdomen suggests visceral perforation.

COMBINED GASTROINTESTINAL AND RENAL DISEASES

A number of conditions have both renal and GI manifestations (Table 86.2).

Diabetes

Diabetes is commonly complicated by disordered gut motility. Gastroparesis should be distinguished from uremic upper GI symptoms. Diarrhea caused by diabetic enteropathy is also common, typically is nocturnal, and usually is neurogenic in origin. Treatment usually consists of antimotility agents. Bacterial overgrowth is uncommon and is diagnosed by the hydrogen breath test. GI symptoms may be exacerbated by drug treatments for diabetes, including metformin, glucagon-like peptide-1 agonists, dipeptidyl peptidase-4 inhibitors, and α-glucosidase inhibitors. Gastroparesis results in difficulties with glycemic control, fluid and electrolyte imbalance, drug malabsorption, and malnutrition. The speed of colonic transport is decreased in diabetes, which may result in constipation.

Systemic Vasculitis

GI manifestations of vasculitis include intestinal ischemia or infarction, hemorrhage, and perforation with peritonitis. Abnormal liver function test results arise from hepatitis, and cholecystitis and pancreatitis have been described. Serositis with abdominal pain is a feature of systemic lupus erythematosus. Abdominal pain, vomiting, and GI hemorrhage are typical of Henoch-Schönlein purpura.

Systemic Amyloidosis

Primary AL amyloidosis may result in both renal and GI involvement. Conversely, inflammatory bowel disease is an important cause of secondary AA amyloidosis, which may result in renal involvement. Thus, in a patient with renal amyloidosis who has GI symptoms, it is important to characterize the type of amyloid and the underlying cause of GI disturbance.

Autosomal Dominant Polycystic Kidney Disease

Abdominal hernias are more common in ADPKD[19] and are a particular problem in PD patients. Colonic diverticular disease occurs more

TABLE 86.2 Gastrointestinal-Renal Syndromes Conditions Typically Resulting in Both Renal and Gastrointestinal Disease

Disorder	Renal Involvement	GI Involvement
Diabetes	Proteinuria, CKD	Gastroparesis, diabetic enteropathy, constipation
Systemic vasculitis	Proliferative glomerulonephritis, CKD	Intestinal ischemia, GI hemorrhage, bowel perforation, hepatobiliary involvement, acute pancreatitis
Systemic amyloidosis	Nephrotic syndrome, CKD	Diarrhea, malabsorption, splenic rupture
Autosomal dominant polycystic kidney disease	CKD, cyst hemorrhage, and infection	Abdominal pain (from renal or hepatic cysts), diverticular disease, hernia
Inflammatory bowel disease	AA amyloidosis, drug-induced interstitial nephritis, IgA nephropathy, oxalate renal calculi (with terminal ileal Crohn disease)	Abdominal pain, diarrhea, GI hemorrhage, malabsorption
Scleroderma	CKD, acute scleroderma, renal crisis	Dysphagia, constipation, malabsorption, and bacterial overgrowth
Fabry disease	Hematuria, proteinuria CKD	Abdominal pain, episodes of diarrhea, or constipation
Celiac disease	IgA nephropathy	Malabsorption, iron-deficiency anemia
IgG4-related tubulointerstitial nephritis	Tubulointerstitial nephritis	Autoimmune pancreatitis

CKD, Chronic kidney disease; *GI,* gastrointestinal; *IgA,* immunoglobulin A.

frequently. The enlarged kidneys can result in abdominal pain, hemorrhage, abdominal fullness, and anorexia. Hepatic cysts and occasionally massive hepatomegaly may cause chronic abdominal pain and fullness. Common bile duct dilation, of uncertain significance, occurs more frequently in ADPKD.

Inflammatory Bowel Disease

Inflammatory bowel disease may be complicated by AA amyloidosis and IgA nephropathy. Drug therapy, such as aminosalicylates, can lead to renal disease, including chronic interstitial nephritis. Terminal ileal disease in Crohn disease can cause hyperoxaluria and oxalate renal calculi.

Celiac Disease

Celiac disease occurs with increased frequency in association with other autoimmune conditions, such as diabetes mellitus. There is also a reported association with IgA nephropathy.[20]

DRUGS AND GASTROINTESTINAL DISEASE IN CHRONIC KIDNEY DISEASE

Drugs commonly used in CKD can lead to GI complications (Table 86.3). Phosphate-binding drugs commonly result in abdominal symptoms. Nausea and vomiting are important complications of calcimimetics. Other drugs important in CKD that may cause GI problems include statins, ACE inhibitors, iron supplements, sodium bicarbonate, bisphosphonates, and metformin. Acid-suppressing drugs including PPIs and H_2-receptor blockers are commonly prescribed in CKD. They are often inappropriately continued for long periods[21] and increase the risk for *C. difficile* infection, interstitial nephritis, and CKD (see Chapter 60). PPIs can result in nausea, vomiting, abdominal pain, diarrhea, and constipation. By reducing gastric acidity, they also may reduce the effectiveness of calcium carbonate prescribed as a phosphate binder (which is only soluble in an acid environment).

TABLE 86.3 Gastrointestinal Side Effects of Drugs Commonly Used in Patients With Chronic Kidney Disease

Drug	GI Side Effects
Calcium-based phosphate binders	Constipation, abdominal discomfort
Sevelamer	Constipation, dyspepsia, bowel obstruction (very rare)
Lanthanum carbonate	Dyspepsia, nausea, diarrhea
Cinacalcet	Anorexia, nausea, vomiting
Statins	Abdominal discomfort, diarrhea, constipation
ACE inhibitors	Nausea, constipation, diarrhea, acute pancreatitis
Iron supplements	Nausea, epigastric pain, constipation, diarrhea
Bisphosphonates	Esophagitis, esophageal ulcers and strictures
Polystyrene sulfonate (calcium resonium, Kayexalate)	Severe constipation, colonic necrosis
Calcium channel blockers	Constipation, intestinal pseudoobstruction
Metformin	Anorexia, nausea, vomiting, diarrhea
Proton pump inhibitors	Nausea, vomiting, abdominal pain, constipation, diarrhea
Glucagon-like peptide-1 agonists	Anorexia, nausea, vomiting, diarrhea, risk for acute pancreatitis
Dipeptidyl peptidase-4 inhibitors	Nausea, diarrhea, risk for acute pancreatitis
Mycophenolate mofetil	Diarrhea, abdominal pain, vomiting
Azathioprine	Dyspepsia, acute pancreatitis, hepatitis

ACE, Angiotensin-converting enzyme; *GI,* gastrointestinal.

SPECIFIC GASTROINTESTINAL COMPLICATIONS OF RENAL REPLACEMENT THERAPY

Idiopathic Dialysis-Related Ascites

Idiopathic ascites occurs in HD patients and may be caused by suboptimal dialysis clearances. Diagnosis is by exclusion of other causes of ascites. Aspirated fluid usually has an elevated protein content. Management includes fluid and sodium intake restriction and ultrafiltration by dialysis. Small-solute clearance must be optimized, and paracentesis may be required for symptom control. The condition may resolve after renal transplantation, and switching to PD can be tried.

Peritoneal Dialysis–Related Gastrointestinal Conditions

Complications relating to PD may affect the abdomen, including infectious peritonitis, pain on dialysate infusion and drainage, and encapsulating peritoneal sclerosis (see Chapter 97). Hemoperitoneum in PD is typically related to the menstrual cycle, occurring during menstruation or ovulation, or may be self-limited, probably resulting from minor peritoneal membrane trauma from the PD catheter (Fig. 86.4). Rarely, underlying pathologic causes are present, including encapsulating peritoneal sclerosis, malignant disease, pancreatitis, hepatobiliary disease, and hemorrhage from polycystic kidneys.

Dialysis-Related Amyloidosis

Amyloidosis caused by deposition of β_2-microglobulin in very rare patients on very-long-term dialysis can result in GI hemorrhage, diarrhea, pseudoobstruction, ischemia, and perforation (see Chapter 84).

Transplantation and Gastrointestinal Disturbance

A variety of GI problems occur after renal transplantation (see Chapters 105 and 106). Gastritis or duodenitis results from corticosteroid therapy,

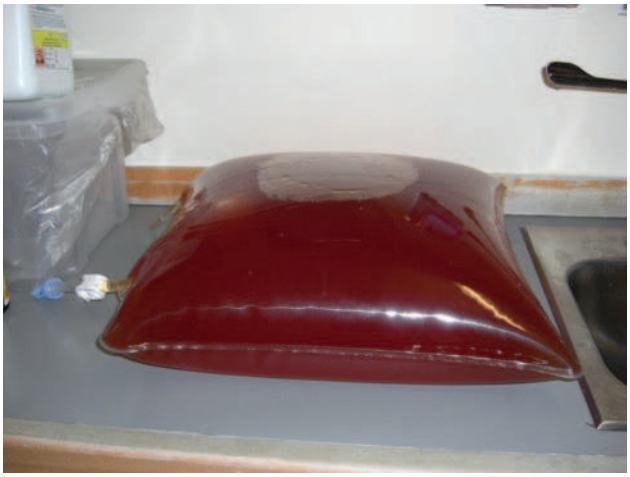

Fig. 86.4 Hemoperitoneum. Blood-stained peritoneal dialysate from a peritoneal dialysis patient who has developed acute pancreatitis.

and peptic ulcers occur most commonly in the initial year after transplantation.[22] Mycophenolate mofetil commonly leads to diarrhea, abdominal pain, or vomiting. Infectious complications of the GI tract include oral and esophageal candidiasis, cytomegalovirus disease, and diarrhea from *C. difficile* infection. Post-transplantation lymphoproliferative disease may involve the GI tract.

Nutrition in Chronic Kidney Disease

Nutrition plays an important role in the management of hypertension, obesity, hyperlipidemia, and diabetes, all of which affect CKD progression. As the GFR deteriorates, retention of nitrogenous metabolites, decreased ability to regulate levels of electrolytes and water, and certain vitamin deficiencies can be affected by dietary changes. In addition, protein-energy depletion is commonly observed and predicts a poor outcome.

Malnutrition: Protein-Energy Wasting

Patients with CKD, particularly more advanced stages, frequently exhibit a progressive loss of muscle and fat mass that may not be related to a reduced intake alone.

Because *malnutrition* refers to an intake that is inadequate for the needs of the individual, it can be misleading to use this blanket term when reduced intake is not necessarily the sole cause of wasting. Protein-energy wasting (PEW) is defined as a state of nutritional and metabolic derangements in patients with CKD that may negatively affect nutritional status and lean body mass, leading to frailty.[23] Inflammation often coexists, and nutrition intervention in isolation may not successfully reverse the loss of skeletal muscle and fat mass.

The prevalence of PEW in dialysis patients ranges from 10% to 70%, depending on the choice of nutritional marker and the population studied.[24,25] There is also diminished nutritional status before initiation of dialysis, which strongly predicts mortality on dialysis. Several factors contribute to the high incidence of PEW:

- Inadequate protein and calorie intake. There is a spontaneous reduction in nutrient intake that parallels the decrease in GFR and is largely driven by CKD-associated anorexia.[26] This anorexia is caused by impaired taste acuity and diminished olfactory function, medications, autonomic gastroparesis, psychological and socioeconomic factors, and inadequate dialysis.
- Frailty, poverty, advanced age, and multiple acute or chronic comorbidities also may contribute to suboptimal intake.
- Inappropriate dietary restrictions may be recommended, which is particularly relevant for patients with ESRD.[27,28]
- Protein and amino acid losses occur during dialysis treatment. These may increase significantly during episodes of PD peritonitis.
- Metabolic acidosis and periods of acute or chronic illnesses may induce protein catabolism. This is mediated in large part through the ubiquitin-proteasome pathway of protein degradation.[29]
- Protein catabolic effects that can further compromise patients early after transplantation include large doses of corticosteroids, the stress response to surgery, and delayed graft function.
- Chronic inflammation may contribute to both an increase in nutritional needs and anorexia. Alterations in intestinal microbiota and increased permeability of the intestinal barrier may play a pivotal role in the pathogenesis of inflammation (see Chapter 81).[30]
- Endocrine disorders, such as insulin resistance (associated with increased muscle breakdown), vitamin D deficiency and increased parathyroid hormone concentrations have long been considered contributors to PEW, although the data remain inconclusive regarding the exact mechanisms involved. There is some evidence of an association between fibroblast growth factor-23 (a phosphate regulating hormone) and inflammation in CKD.[31]

Obesity Paradox in Chronic Kidney Disease

Although there is a high prevalence of PEW in patients with CKD associated with poorer outcomes, paradoxically a higher body mass index (BMI) is associated with better survival. This is termed *reverse epidemiology* (see Chapter 81).

Assessment of Nutritional Status

The measurement of nutritional status does not lend itself to one simple test, and a panel of measures is required. Table 86.4 summarizes some of the methods used for assessment of nutritional status.

Estimation of Intake

Diet history, recall, and food diaries are the mainstays for estimation of dietary intake. In addition, a gradual decrease in blood urea nitrogen and reduced phosphate and potassium levels may indicate a decrease in protein intake in dialysis-dependent patients, and low serum cholesterol level may indicate a poor calorie intake.

The excretion or removal of urea is easily measured and is often used to estimate adequacy of dialysis. The protein equivalent of total nitrogen appearance (PNA) can be estimated on HD from interdialytic changes in urea nitrogen concentration in serum and the urea nitrogen content of urine and dialysate. nPNA is the term for PNA related to body weight. On the basis of the assumption that nitrogen excretion equals nitrogen intake in steady state, nPNA has been used to approximate

TABLE 86.4 Assessment of Nutritional Status

Area	Assessments
Physical Examination	
Assessment of dietary intake	Diet history, food diaries, appetite assessment questionnaires
Anthropometric measurements	Body weight, height, body mass index Percentage weight change Skinfold thickness Midarm muscle circumference
Body composition	Bioelectrical impedance Dual-energy x-ray absorptiometry (DEXA) Near-infrared reactance Neutron activation Total body potassium
Biochemical determinations	Serum electrolytes Serum proteins PNA, PCR Serum cholesterol Creatinine index*
Nutritional scoring systems	Subjective global assessment, malnutrition inflammation score (MIS) Geriatric nutritional risk index (GNRI)
Immunologic assays	Blood lymphocytes Delayed cutaneous hypersensitivity tests
Functional tests	Grip strength

*The creatinine index is measured as the sum of creatinine removed from the body (measured from the creatinine removed in dialysate, ultrafiltrate, and/or urine), any increase in the body creatinine pool, and the creatinine degradation rate. See also www.kidney.org/professionals/kdoqi/pdf/KDOQI2000NutritionGL.pdf.
PCR, Protein catabolic rate (mathematically identical to PNA); *PNA,* protein equivalent of total nitrogen appearance.

Fig. 86.5 Routine measurement of skinfold thickness. The dominant arm, which does not have an arteriovenous fistula or graft, is used in patients with renal failure.

dietary protein intake in the short term. However, results need to be interpreted with caution (urea kinetic modeling and adequacy of dialysis are further discussed in Chapters 94 and 96). Equations for estimation of nPNA have been recommended by the Kidney Disease Outcomes Quality Initiative (KDOQI).[32]

Body Mass Index

The BMI (BMI = weight [kg]/height [m^2]) is the most commonly used parameter for nutritional assessment. BMI cannot distinguish muscle from fat mass and is affected by hydration status.

Body Composition

A range of techniques can distinguish body compartments on the basis of physical characteristics, which can provide information about nutritional state (body lean tissue and fat content) and hydration. Some are costly, less accessible, and used more for research purposes. A couple of the more widely available techniques are mentioned in the following discussion.

Skinfold thickness can be used to assess body fat, and muscle mass can be assessed by measurement of mid–upper arm muscle circumference (MAMC; Fig. 86.5). The midpoint of the upper dominant arm is used because this is the arm less likely to have an arteriovenous fistula.

$$\text{MAMC (cm)} = \text{Midarm circumference (cm)} - [3.14 \times \text{Triceps skinfold}]\ \text{(cm)}$$

The measurement is taken after dialysis for patients on HD. Although these anthropometric parameters are inexpensive and relatively easy to measure, they are limited by intervariability and intravariability. Nevertheless, serial measures over time can be useful to track changes in the same patient when they are used in conjunction with other nutritional indices.

Observation of trends using serial measures of bioelectrical impedance are increasingly being used as an adjunct to the day-to-day clinical assessment of hydration status and body composition management of dialysis patients. However, bioelectrical impedance is not without its limitations and further prospective controlled trials are required to determine the best role for this technology in clinical practice.[33,34,52]

Visceral Protein

Fluid status, impaired liver function, age, and acute inflammatory conditions can affect albumin levels. However, despite its relatively long half-life (20 days), albumin remains an important measure of nutritional status and health of the patient. Clinically, it may be possible to observe the growth of white nails when there has been a transient period of hypoalbuminemia (Fig. 86.6). Other serum protein markers of nutritional status are difficult to interpret because of the influence of factors other than nutrition. Serum transferrin is linked to body iron stores and may be altered with changes in iron status. Prealbumin levels can be increased by CKD because of impaired metabolism in the kidney. Levels of prealbumin also decline rapidly during episodes of acute inflammation.

Fig. 86.6 White nails in hypoalbuminemia. The white band grew during a transient period of hypoalbuminemia caused by nephrotic syndrome.

Tools to Diagnose Protein-Energy Wasting and Assess Nutritional Status

Given the low specificity and sensitivity of many of the anthropometric and biochemical markers, a range of measurements along with evaluation of the subjective well-being of the patient is needed to assess nutritional status (Table 86.5).

Four main established categories are recommended for the diagnosis of PEW: serum biochemistry, body mass, muscle mass, and dietary intake.[23] Subjective global assessment (SGA) is a reliable nutritional assessment tool for patients on dialysis.[35] Questions about recent changes in nutrient intake are used with simple observations of the patient's body weight and muscle mass to assess the nutritional status of the individual; patients are classified as well nourished, mildly malnourished or with suspected malnutrition, or severely malnourished. Figs. 86.7 and 86.8 show muscle wasting in a patient on HD who was classified by SGA as severely malnourished. SGA is by definition subjective and has been criticized for being insufficiently sensitive to define the degree of malnutrition. The malnutrition inflammation score (MIS), the PEW definition criteria, and the geriatric nutritional risk index are alternative tools used by some centers and continue to be evaluated.

Nutritional Guidelines

Guidelines are useful, but it is important that dietary restrictions are not unnecessarily imposed and that advice be tailored to the individual and altered as circumstances dictate. Table 86.6 summarizes the nutritional recommendations for CKD.

Hyperlipidemia

Although disturbances in lipid metabolism are commonly seen in CKD, there is a paucity of data on the effect of diet therapy in this group. A diet low in fat (particularly saturated fat) with an increased intake of soluble fiber may be helpful in reducing cholesterol levels, although the role of cholesterol lowering in CKD patients is controversial (see Chapter 81). Losing weight if overweight and consuming a diet lower in sugar may improve hypertriglyceridemia, but a balance needs to be

Fig. 86.7 A severely malnourished hemodialysis patient. There is marked wasting of the quadriceps and calf muscles. In addition, note skin lesions from scratching due to uremic pruritus.

TABLE 86.5 Some Indices of Malnutrition

Assessment	Indices
Biochemical parameters	Serum albumin below the normal range Serum prealbumin <300 mg/l (30 mg/dl) (for maintenance dialysis patients only, because levels may vary according to GFR level for CKD 2-5) Low predialysis serum creatinine, phosphate, potassium, urea levels Serum cholesterol <150 mg/dl (3.8 mmol/l) Low creatinine index Low PNA, PCR
Anthropometric parameters	Continuous decline in weight, skinfold thickness, midarm muscle circumference BMI <20 kg/m^2 (note ISRNM suggest a lower threshold of 23 kg/m^2 is used)[23] Body weight <90% of ideal Abnormal muscle strength

BMI, Body mass index; *GFR,* glomerular filtration rate; *ISRNM,* International Society of Renal Nutrition and Metabolism; *PCR,* protein catabolic rate; *PNA,* protein equivalent of total nitrogen appearance.

struck between healthy eating concepts and nutritional adequacy. Additional fiber has the benefit of helping regulate bowel function, which is particularly important in PD patients.

Hypertension

The role of diet in the prevention and treatment of hypertension is discussed fully in Chapter 35.

Vitamins, Minerals, and Trace Elements

Vitamin, mineral, and trace element abnormalities in CKD relate to dietary restriction, dialysate losses, and the necessity of intact kidney function for normal metabolism of certain vitamins. However, the dietary requirements for patients with CKD are not clear-cut.

Protein and potassium restrictions can lead to inadequate intakes of pyridoxine, vitamin B_{12}, folic acid, vitamin C, iron, and zinc. The use of recombinant human erythropoietin may increase the requirement for iron and folic acid (see Chapter 82).

Increased serum homocysteine is a known risk factor for cardiovascular morbidity in CKD (see Chapter 81). However a cochrane review

Fig. 86.8 A severely malnourished hemodialysis patient.

showed that lowering of serum homocysteine concentration with folic acid, vitamin B_{12}, and pyridoxine supplements has no effect on mortality or risk of cardiovascular events in dialysis patients.[36]

A variety of vitamin preparations are available that contain a recommended water-soluble vitamin profile for dialysis patients. The preparations vary slightly, but the following is one example: vitamin C, 120 mg; vitamin B_1, 3.0 mg; vitamin B_2, 1.7 mg; vitamin B_6, 10 mg; vitamin B_{12}, 6 µg; biotin, 300 µg; folic acid, 1 mg; nicotinamide, 20 mg; and pantothenic acid, 10 mg.

In the absence of firm guidance, it is prudent to have a low threshold for commencing such a water-soluble vitamin preparation. The European Best Practice (www.european-renal-best-practice.org) on nutrition gives opinion-based recommendations for patients on HD.[37]

High-dose vitamin C supplements (although popular in the general population) should not be taken in CKD because of the increased risk for secondary tissue oxalate deposition.

A review on fat-soluble vitamins in advanced CKD concluded there is universal agreement that supplementation with vitamin A is generally not recommended (unless a patient is receiving total parenteral nutrition) because deficiencies are rare, dialysis losses are minimal, and accumulation leading to toxicity can occur.[38] Vitamin E has been suggested to have antioxidant properties and beneficial effects for patients with CKD.[39] However, appropriately powered studies with longer follow-up are needed for confirmation.

Vitamin K functions as a cofactor for the enzyme γ-glutamyl carboxylase and may have a role in inhibiting vascular calcification (see Chapter 84). Evidence suggests most dialysis-dependent patients have subclinical vitamin K deficiency, and there is no known toxicity. Research is ongoing to determine if supplementation of vitamin K may have a beneficial role in preventing vascular calcification and reducing mortality in patients with advanced CKD.

Guidelines for vitamin D, phosphorus, and calcium are summarized in the Kidney Disease: Improving Global Outcomes (KDIGO) guidelines (see Chapter 84).

TABLE 86.6 Nutritional Recommendations in Chronic Kidney Disease

Recommendations Are for Typical Patients but Always Should Be Individualized on the Basis of Clinical, Biochemical, and Anthropometric Indices.

Daily Intake	Predialysis CKD	Hemodialysis	Peritoneal Dialysis
Protein (g/kg ideal BW) (see KDOQI[32] for estimation of adjusted edema-free BW)	0.6-1.0 Level depends on the view of the nephrologist. 1.0 for nephrotic syndrome.	min ≥1.1[51] Recommendations are in conjunction with an adequate energy intake. Requirements may be higher during illness because of multiple comorbidities or during acute periods of infection, including peritonitis.	min 1.0-1.2[51]
Energy (kcal/kg BW)	35[32] (younger than 60 y) 30-35[32] (older than 60 y)	35[32] (younger than 60 y) 30-35[32] (older than 60 y) 30-40 kcal/kg ideal BW[37]	35[32] including dialysate calories (younger than 60 yr) 30-35[32] including dialysate calories (older than 60 yr)
Sodium (mmol)	<100 (more if salt wasting)	<100	<100
Potassium	Reduce if hyperkalemic	Reduce if hyperkalemic	Reduce if hyperkalemic; potassium restriction is generally not required. May need to increase potassium intake if hypokalemic.
	If hyperkalemic, advice will take the form of decreasing certain foods (e.g., some fruits and vegetables) and giving information about cooking methods.		
Phosphorous	Reduce because of phosphate retention. Monitor levels. Advice will take the form of reducing certain foods (e.g., dairy, offal, some shellfish) and processed foods with high content of added phosphates, and giving information about the timing of binders with high-phosphorus meals and snacks.		

BW, Body weight; *CKD,* chronic kidney disease; *KDOQI,* Kidney Disease Outcomes Quality Initiative.

Recommendations for sodium, potassium, and phosphorus are shown in Table 86.6.

Monitoring and Treatment

Monitoring of patients with CKD involves a combination of nutritional assessment, noting relevant biochemistry (potassium, phosphate, lipids), checking dialysis adequacy, and observation of fluid status. The challenge comes in balancing the restrictions of the kidney diet against the risk for compromising nutritional status. When anorexia is present despite optimal management, nutrient intake may be maximized by one or more of the methods discussed in the following sections.

Enteral Supplementation

If food fortification advice is insufficient, supplements, in the form of high-protein, high-calorie drinks, powders, and puddings, should be considered. Enteral tube feeding is also an option if nutrient intake cannot be increased sufficiently by use of oral supplements. Renal-specific tube feeds and supplements are available that have lower fluid and electrolyte contents. A systematic review suggested that enteral multinutrient support increases serum albumin concentration and improves total dietary intake in patients receiving maintenance dialysis.[40] In addition, maintenance HD patients with albumin levels of 3.5 g/dl or lower received intradialytic oral nutritional supplements in a recent large retrospective matched-cohort study. Despite limitations, the results indicated significantly better survival in the supplemented group versus similarly matched patient controls.[41,42]

Supplementation of Dialysate Fluids

The GI route is the preferred choice for nutritional supplementation. However intradialytic parenteral nutrition (IDPN) has been used to provide intensive parenteral nutrient therapy with use of concentrated hypertonic solutions infused into the venous blood line three times weekly during HD treatments for patients who cannot tolerate oral or enteral administration of nutrients. IDPN typically provides 800 to 1200 kcal three times weekly, in the form of glucose and fat emulsion and 30 to 60 g of protein and so will only supplement rather than provide full nutritional needs.

A systematic review concluded that the evidence from clinical studies is insufficient to demonstrate either a net benefit or a net harm associated with providing IDPN to malnourished HD patients and that further clinical research is needed in this area.[43] The high cost of the therapy is a barrier to performing adequately powered clinical trials.

Intraperitoneal amino acids (IPAAs) can be used in PD. A 1.1% amino acid solution is substituted for glucose in PD fluid, and about 80% of the amino acids are absorbed in a 4-hour period.[44] The long-term effects of IPAAs on nutritional status and clinical outcomes are not known, and the solution is often used primarily to reduce glucose exposure.

Expert opinion on the use of these approaches is inconsistent. The KDOQI has suggested that IPAAs (for PD) or IDPN (for HD) should be considered for patients who have evidence of protein or energy malnutrition and inadequate protein or energy intake and who are unable to tolerate adequate oral supplements or tube feeding.[32] The European Society of Enteral and Parenteral Nutrition has provided criteria for use of IDPN.[45] However, the American Society for Parenteral and Enteral Nutrition recommends that IDPN not be used as a nutritional supplement in malnourished HD patients because studies so far do not offer strong support for IDPN.[46]

Appetite Stimulants

Megestrol acetate, a progesterone derivative, moderately improves appetite in HD patients in small studies. However, megestrol acetate has adverse effects, and larger trials are required before recommendations can be made for CKD patients.[47] More studies are also required for ghrelin, an orexigenic hormone, and melanocortin-receptor antagonists.

Gut-Targeted Therapeutics

There is accumulating evidence that the GI tract maybe a major source of chronic inflammation in CKD. It is hypothesized that altered diets (low potassium, phosphorus, and fiber) may affect the gut microbiome, resulting in overgrowth of bacteria that produce uremic toxins and a leaky epithelial barrier that allows toxins to get into the circulation.

It has been suggested that prebiotic and probiotic formulations may lower serum levels of uremic toxins. However more trials investigating

gut-targeted therapeutics are needed before they could be recommended for use in clinical practice.

Metabolic Acidosis

Although some trials have shown no detrimental effect of mild metabolic acidosis, many others have reported that normalization of serum bicarbonate concentration (see Chapter 12) is beneficial for protein nutritional status and bone metabolism. Current guidelines recommend the correction of acidosis in dialysis-dependent patients.[37,48,49]

Exercise

There is a large body of research on exercise training for adults with CKD that shows significant benefits on physical fitness, CV parameters, well-being, and nutritional markers.[50] Trials are ongoing, and the future is likely to hold more guidance in this area for clinical practice.

Potassium Binders

Novel, orally administered potassium-exchanging compounds are being investigated as possible treatment options for the management of hyperkalemia. Sodium zirconium cyclosilicate and patiromer act by enhancing potassium removal, predominantly through the GI tract.

SELF-ASSESSMENT QUESTIONS

1. A 60-year-old woman commenced hemodialysis 6 years ago. At a recent outpatient appointment she reported breathlessness. Predialysis blood pressure (BP) is 150/80 mm Hg.
   - Dialysis: 4 hours three times per week
   - Target weight: Stable for last 2 years at 55 kg
   - Height: 1.47 m
   - Body mass index (BMI): 25 kg/m^2
   - Intradialytic weight gain average 0.9 kg
   - Passes small amounts of urine

   Monthly laboratory testing reveals blood results as follows:

	Creatinine (mg/dl)	Urea (mg/dl)	Phosphate (mg/dl)	Potassium (mmol/l)	Albumin (g/dl)	Cholesterol (mg/dl)	Hemoglobin (g/dl)
Predialysis	5.3	27	3.16	4.5	3.5	100	13.85
Postdialysis	1.54	7.86	1.30	2.9			

   What would your next course of action be?
   A. Reduce the dialysis time because she is receiving more dialysis than required.
   B. Investigate dietary intake, in particular protein and calorie intake, and assess target weight.
   C. Increase target weight.
   D. Start diuretics and fluid restriction.

2. A 38-year-old White man with progressive chronic kidney disease is feeling tired, reporting weight loss, nausea, and a metallic taste in the mouth. His BP is 156/90 mm Hg, and urinalysis reveals +++ protein and traces of blood. There are no signs of peripheral edema. He trains at the gym three times per week.
   - Weight: 78 kg
   - Height: 1.7 m
   - BMI: 27 kg/m^2
   - Amlodipine 5 mg/day commenced
   - Sodium bicarbonate commenced
   - Diet history reveals an average daily protein intake of 120 g, an approximate calorie intake of 2600 kcal, and sodium intake of 190 mmol/day.

   Laboratory findings are as follows:

GFR (ml/min)	Creatinine (mg/dl)	Urea (mg/dl)	Phosphate (mg/dl)	Calcium (mg/dl)	Potassium (mmol/l)	Bicarbonate (mEq/L)
13	5.1	74	4.96	10.02	5.1	16

   What would your next course of action be?
   A. Put the patient on a reduced-calorie diet.
   B. Start dialysis.
   C. Moderate protein and salt intake.
   D. Start a low-potassium diet.

3. A 59-year-old man with end-stage renal disease resulting from type 1 diabetes has been treated with continuous ambulatory peritoneal dialysis for 12 months. He reports reduced appetite, occasional nausea, and feeling full only midway through modest-sized meals; he has lost 3.3 kg over the previous 2 months. He weighs 79.2 kg and he has a BMI of 34 kg/m^2. He dialyzes with four exchanges of volume, 2 liters each. Measurement of dialysis clearances shows a weekly Kt/V for urea of 1.8 (target minimum 1.7). What would your next course of action be?
   A. Reduce dialysis fluid volumes in case they are contributing to his gastrointestinal symptoms.
   B. Advise weight reduction because BMI may be contributing to feelings of fullness.
   C. Start amino acid-containing peritoneal dialysate.
   D. Start a prokinetic agent.

Dermatologic Manifestations of Chronic Kidney Disease

Pieter Evenepoel, Dirk R. Kuypers

Cutaneous disorders are common in patients with chronic kidney disease (CKD). Many of these cutaneous disorders are caused by the underlying renal disease, whereas others relate to the severity and duration of uremia. Skin lesions associated with cutaneous aging have a high incidence in CKD patients, including wrinkling, senile purpura, actinic keratoses, and hair loss.

Improved treatments in dialysis patients have resulted in changes in the frequency and types of skin disorders observed in conjunction with end-stage renal disease (ESRD). Dermatologic conditions such as uremic frost, erythema papulatum uremicum, uremic roseola, and uremic erysipeloid now rarely occur. Pigmentary alterations, xerosis, ichthyosis, half-and-half nails, acquired perforating dermatosis, bullous dermatoses, pruritus, and calcific uremic arteriolopathy (CUA) remain prevalent, whereas nephrogenic systemic fibrosis (NSF) is a rare and waning entity now that the causative agent has been identified (Fig. 87.1). The last four prevalent skin disorders are the focus of this chapter because they are associated with significant morbidity or mortality and/or represent an ongoing diagnostic or therapeutic challenge.

UREMIC PRURITUS

Clinical Manifestations

Uremic pruritus (UP) is a frequent symptom of ESRD, with a reported prevalence ranging from 22% to 48%. Although its incidence in adult dialysis patients has declined as a result of improved dialysis efficacy and the introduction of so-called "biocompatible" dialysis membranes, pruritus remains a frustrating problem for patients, causing serious discomfort and skin damage, often in association with disturbance of day and night rhythm, sleeping disorders, depression, anxiety, and diminished quality of life.[1,2] The intensity and spatial distribution of UP vary significantly among patients and over time throughout the course of renal disease. Excoriations, induced by uncontrollable scratching with or without superimposed infection, are frequently encountered in severely affected patients and, rarely, lead to prurigo nodularis—a treatment-resistant lichenified or excoriated papulonodular chronic skin eruption (Fig. 87.2). The most frequently involved body areas are the back, limbs, chest, and face; 20% to 50% of patients report generalized pruritus.[3]

Pathogenesis

Many uremic factors are thought to contribute to UP. Parathyroid hormone (PTH) and divalent ions (calcium, phosphate, magnesium) have been implicated because itching is a frequent symptom accompanying severe secondary hyperparathyroidism and elevated calcium-phosphate product. However, the lack of consistent correlations between serum and skin levels of PTH, calcium, phosphorus, and magnesium with the severity of UP indicates that other factors contribute to its development. Histamine released by mast cells has been implicated in UP. The number of dermal mast cells is increased in uremic patients, and higher tryptase and histamine plasma concentrations are reported in severe cases. Histamine release is triggered by substance P, a neurotransmitter involved in itch sensation. The role of elevated serotonin (5-hydroxytryptamine [5-HT_3]) levels in dialysis patients with UP is debated; clinical trials using a selective inhibitor of 5-HT_3 have yielded conflicting results (see later discussion). Xerosis is a common skin problem in dialysis patients (60% to 90%) that predisposes to UP. Skin dryness is caused by primary dermal changes associated with uremia, such as atrophy of sweat glands with impaired sweat secretion, disturbed stratum corneum hydration, sebaceous gland atrophy, and abnormal arborization of free cutaneous nerve fiber endings.

There are two major hypotheses of the pathogenesis of UP. The opioid hypothesis proposes that UP is caused by overexpression of opioid μ receptors in dermal cells and lymphocytes. Consistent with this hypothesis, activation of the κ opioid system using a κ-receptor agonist was efficient in reducing pruritus in a mouse model. In contrast, the immune hypothesis considers UP an inflammatory systemic disease rather than a local skin disorder. Studies examining the beneficial effects of ultraviolet B (UVB) exposure on pruritus showed that UVB attenuates the development of Th1 T-helper cells in favor of Th2 T-helper cells. Indeed, the number of CXCR3-expressing and interferon-γ–secreting $CD4^+$ cells (indicating Th1 differentiation) is significantly increased in the circulation of dialysis patients with pruritus compared with those without. Levels of serum markers of inflammation, such as C-reactive protein, interleukin-2 (IL-2), IL-31, and IL-6, are also higher in patients with UP.

Treatment

Common causes of UP in CKD and dialysis patients, such as primary skin disorders (e.g., urticaria, psoriasis, atopic and contact dermatitis), liver disease (e.g., hepatitis), and endocrine diseases (e.g., hypothyroidism, diabetes mellitus) should be ruled out and adequately treated. The treatment approach to UP is shown in Fig. 87.3.

Optimizing Dialysis and Mineral Metabolism Therapy

Optimizing dialysis biocompatibility and efficacy and improving nutritional status may result in a reduced prevalence and severity of UP. Adequate control of calcium and phosphorus serum concentrations by short-term use of dialysate with low calcium and magnesium concentrations ameliorated pruritus symptoms in only a few small studies

Fig. 87.1 Cutaneous disorders in patients with end-stage renal disease. (A) A spectrum of pigmentary alterations occurs in dialysis patients, with brownish hyperpigmentation in sun-exposed areas being the most prevalent. (B) Xerosis, a dry or roughened skin texture, is seen in up to 75% of dialysis patients. (C) Half-and-half nails (also termed *red and white nails*) occur in as many as 40% of patients on dialysis. The nails exhibit a whitish or normal proximal portion and an abnormal brown distal portion. (D) Acquired perforating dermatosis affects approximately 10% of the dialysis population. The lesion is usually asymptomatic and consists of grouped dome-shaped papules and nodules, 1 to 10 mm in diameter. The trunk and the extremities are most commonly involved.

and may lead to worsening of renal osteodystrophy in cases of prolonged use. Parathyroidectomy is not advocated for relief of UP because no consistent beneficial effects have been demonstrated.

Skin Emollients

Emollients continue to be the primary treatment given by nephrologists, although the literature is mixed on the overall efficacy of this approach. The use of simple emollients without perfumes or other additives is preferred. Continuous bath oil therapy containing polidocanol, a mixture of monoether compounds of lauryl alcohol and macrogol, seems to be of value for some patients. Sericin, a biopolymer protein from the silkworm *(Bombyx mori)* contains 32% serine, is the main amino acid of the natural moisture factor in human skin, and suppresses the release of proinflammatory cytokines. Sericin was shown to effectively reduce UP in a randomized, double-blind, placebo-controlled 6-week study in 50 dialysis patients.[4]

Antihistaminic Drugs

Classic antihistamines have similar efficacy compared with emollients; newer, second-generation antihistamines (e.g., desloratadine) might

have some effect in UP. Ketotifen (2 to 4 mg/day), a putative mast cell stabilizer, was beneficial in one small study.

Phototherapy

Ultraviolet light, especially UVB (wavelength, 280 to 315 nm), is effective for treatment of UP and is well tolerated except for occasional sunburn. The duration of the antipruritic effect of thrice-weekly total body UVB therapy (total, 8 to 10 sessions) is variable but may last for several months. Potential carcinogenic effects of UV radiation require serious consideration, and its prolonged use is contraindicated in patients with a fair complexion (skin phototypes I and II).

Fig. 87.2 Prurigo nodularis. (Courtesy I. Macdougall, London, United Kingdom.)

5-Hydroxytryptamine Antagonist

Ondansetron, a selective 5-HT_3 antagonist, was used successfully in a small study in peritoneal dialysis patients. However, a subsequent larger randomized, placebo-controlled study failed to show superiority over placebo in patients on hemodialysis (HD).

Opioid Receptor Agonists

A κ-opiate receptor agonist, nalfurafine, given intravenously after HD, was tested in two randomized, double-blind, placebo-controlled trials comprising 144 patients. Itching intensity, excoriations, and sleep disturbances were significantly reduced in patients receiving the active compound without an excess of drug-related side effects compared with placebo.[5] Oral daily doses of 2.5 to 5 mg nalfurafine were equally effective in reducing UP scores compared with placebo during a 2-week treatment period in 337 dialysis patients.[6] A subsequent 1-year study (n = 211) confirmed the sustained beneficial effect of 5 mg nalfurafine on UP, with the most frequently reported adverse events being insomnia (19%), constipation (7%), and increased blood prolactin concentrations.[7]

Gabapentin

Gabapentin, an anticonvulsant drug, administered after dialysis (300 mg) was effective in reducing pruritus. A reduced dose is required if it is given chronically to patients with ESRD, because it has a narrow therapeutic window and can accumulate and cause neurotoxic side effects.[8] The UP score was significantly reduced in two controlled studies after 4 weeks of gabapentin therapy at a dose of 100 to 300 mg administered thrice weekly after dialysis. Gabapentin was well tolerated; no patients stopped therapy because of side effects, which were limited to dizziness, somnolence, fatigue, and nausea. Similar effects were demonstrated in a smaller study using pregabalin and recent randomized trials comparing gabapentin with doxepin and ondansetron.[9,10]

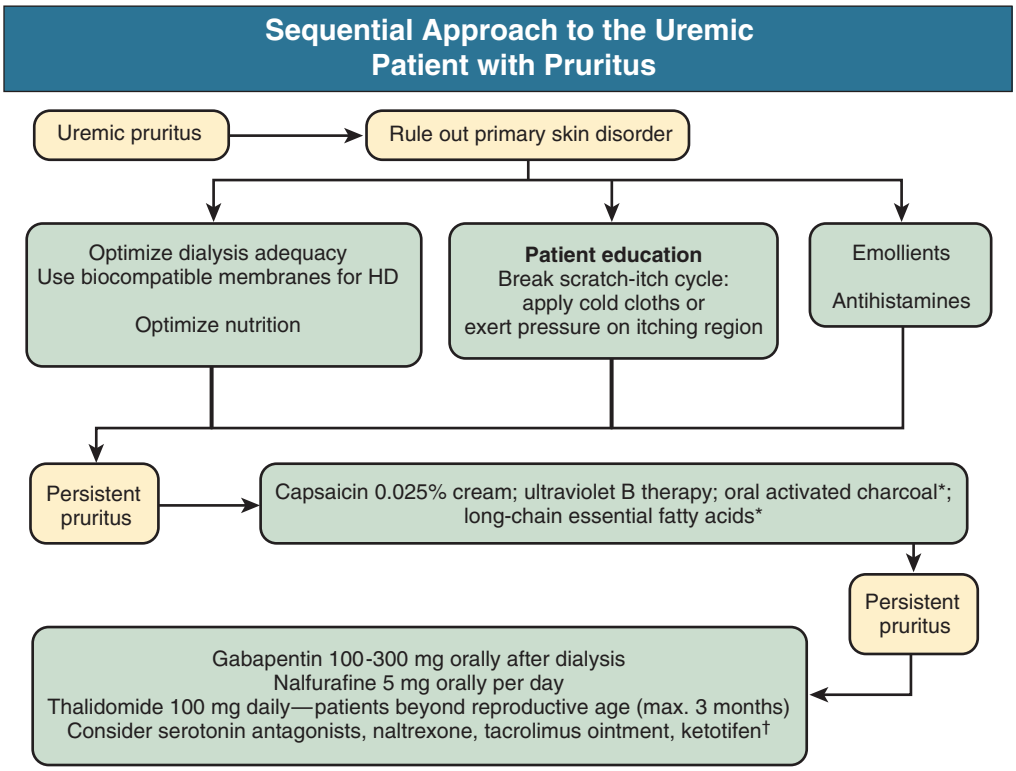

Fig. 87.3 Sequential approach to the uremic patient with pruritus. *See text for details. †Therapeutic benefit in studies has been described variably; see text for details. *HD,* Hemodialysis.

Immunomodulators and Immunosuppressive Agents

A 7-day course of thalidomide reduced the intensity of UP by up to 80% in a placebo-controlled crossover study of 29 HD patients. Because of its strong teratogenic properties, thalidomide should probably be reserved for therapy-resistant severe UP in individuals outside the reproductive-age category. Adverse effects of thalidomide, such as peripheral neuropathy and cardiovascular side effects, limit its continuous longer use. A prospective, single-center study of 25 chronic dialysis patients with UP demonstrated that 6 weeks of treatment with tacrolimus ointment (0.1%) significantly reduced the severity of UP. Tacrolimus was well tolerated in this trial and caused no detectable systemic exposure or side effects.[11] However, a subsequent, smaller vehicle-controlled trial showed equal relief of UP with vehicle and tacrolimus. The risks of long-term topical use of these agents are currently unknown, and their prolonged use is not recommended until more data are available.

Long-Chain Essential Fatty Acids

Oral administration of γ-linoleic acid (GLA)-rich primrose oil resulted in significant improvement of UP in chronic dialysis patients. Supplementation of GLA-rich primrose oil is thought to augment synthesis of antiinflammatory eicosanoids. Similar effects could be obtained through use of fish oil, olive oil, and safflower oil.

Capsaicin

Capsaicin (*trans*-8-methyl-*N*-vanillyl-6-nonenamide) is a natural alkaloid found in the pepper plant that depletes the cutaneous type C sensory nerve endings of substance P. Two clinical studies showed that application of a 0.025% capsaicin cream significantly alleviated UP in dialysis patients, who exhibited no side effects.

Oral Activated Charcoal

Pruritus symptoms completely disappeared or were significantly reduced in chronic dialysis patients treated with activated charcoal (6 g/day) for 8 weeks. In two different clinical studies, comparable results were obtained with this inexpensive and well tolerated compound, rendering it a valuable alternative for patients with UP.

Miscellaneous

Various other types of therapies have been examined in the treatment of pruritus but are, despite the effectiveness of some, not considered first choice in chronic HD patients because of undesirable side effects, cumbersome use, or incompatibility with renal replacement therapy (sauna, cholestyramine, nicergoline). Other therapies that have not reduced UP convincingly in a controlled setting and are therefore not advocated include acupuncture, low-protein diet, intravenous lidocaine, sertraline, zinc sulfate, topical vitamin D, and mexiletine.

BULLOUS DERMATOSES

Bullous dermatoses are reported in up to 16% of patients on maintenance dialysis. This skin disease entity mainly comprises pseudoporphyrias (e.g., secondary to nonporphyrinogenic drugs and chemicals) and other photodermatoses, whereas true porphyrias (e.g., porphyria cutanea tarda [PCT], variegate porphyria) remain a rare entity.[12] Pseudoporphyrias, true porphyrias, and photodermatoses are clinically and histologically similar and are characterized by a blistering photosensitive skin rash. The dorsal hands and the face are the most affected areas (Fig. 87.4).

PCT is caused by abnormalities in the porphyrin-heme biosynthetic pathway, leading to an accumulation of highly carboxylated uroporphyrins in the plasma and skin. Phenotypic expression of the disease also requires one or more of a number of external contributory factors,

Fig. 87.4 Porphyria cutanea tarda. Tense bullae, erosions, and crusts of the dorsal hands. (With permission from reference 12.)

including alcohol, estrogens, iron overload, and infection with hepatitis B and C viruses. It is important to distinguish PCT from other porphyrias in which patients are at risk for development of potentially fatal neurologic attacks if they are exposed to porphyrinogenic drugs and other precipitants. Therapeutic options include avoidance of environmental triggers, HD with high-flux membranes, repeated small-volume phlebotomies, and iron chelators.

The term *pseudoporphyria* was originally used for patients with normal plasma porphyrins who exhibited PCT-like skin lesions secondary to drugs and chemicals. However, some dialysis patients also develop similar skin lesions that spontaneously heal and leave a hypopigmented area; this entity is known as *dialysis porphyria;* a proportion of these patients have raised plasma porphyrins but without the disturbances in porphyrin metabolism classically found in the porphyrias. In rare patients, an offending medication can be identified. However, in most dialysis patients, protection from sun exposure appears to be the only preventive measure.

CALCIFIC UREMIC ARTERIOLOPATHY (CALCIPHYLAXIS)

Definition

CUA, or calciphylaxis, is a devastating and life-threatening ischemic vasculopathy confined primarily to patients with CKD.[13,14] There are also reports of this disease in nonuremic patients. The ischemia may be so severe that frank infarction of downstream tissue develops. The most common and most noticeable damage is in the skin and subcutaneous tissues.[12,13] CUA should be distinguished from benign nodular calcification (calcinosis cutis), which can develop in patients with very high serum calcium-phosphate product (Fig. 87.5).

Epidemiology, Pathogenesis, and Risk Factors

Although hard epidemiologic data are lacking, it is generally believed that the incidence of CUA is increasing. This might in part result from increased physician awareness and the high-risk profile of contemporary dialysis patients. The estimated incidence ranges from 1 to 4 per 100 patient-years. The pathogenesis of CUA is complex and incompletely understood.[13,15] Recent data suggest that CUA involves a cell-mediated, bone morphogenetic protein-2–driven osteogenic process with extensive subcutaneous extracellular matrix remodeling and deposition of hydroxyapatite.[16] A cascade consisting of matrix remodeling, calcification, endothelial damage and thrombus formation, luminal obstruction, and finally full-blown CUA has been postulated.[16] Female gender, White race, obesity, diabetes, dialysis vintage, and last but not least vitamin

Fig. 87.5 Benign nodular calcification (calcinosis cutis). Firm subcutaneous nodule adjacent to the elbow.

K antagonism are established risk factors. In a case control study, the incidence of CUA was 10-fold higher in dialysis patients treated with vitamin K antagonists (warfarin or coumarins). Endogenous inhibitors of vascular calcification, such as matric Gla protein are dependent on vitamin K for their activation. Patients treated with warfarin or coumarins may thus not be able to appropriately inhibit vascular calcification. CUA prevalence is higher in patients with hyperphosphatemia and those receiving calcium-containing phosphate binders. In acute CUA, serum calcium and phosphate levels can be low. Although data from the Evaluation of Cinacalcet HCl Therapy to Lower Cardiovascular Events (EVOLVE) trial indicate cinacalcet may reduce the incidence of CUA in HD patients who have moderate to severe secondary hyperparathyroidism,[17] registry data fail to confirm a key role for uncontrolled hyperparathyroidism in the pathogenesis of CUA.[18] Finally, both low- and high-turnover bone disease have been associated with CUA.

Clinical Manifestations

CUA is typically characterized by areas of zoster-like tenderness and ischemic necrosis of the dermis, subcutaneous fat, and, less often, muscle.[13] These ischemic changes lead to livedo reticularis or violaceous, painful, plaque-like subcutaneous nodules on the trunk, buttocks, or proximal extremity—that is, in areas of greatest adiposity (proximal CUA; Fig. 87.6A). The early purpuric plaques and nodules progress to ischemic or necrotic ulcers with eschars that often become infected. Proximal CUA is frequently precipitated by a specific event, such as local skin trauma or a hypotensive episode. CUA also can affect the hands, fingers, and lower extremities, thereby mimicking atherosclerotic peripheral vascular disease (distal CUA; see Fig. 87.6B). Peripheral pulses are preserved distal to the area of necrosis. Myopathy, hypotension, fever, dementia, and infarction of the central nervous system, bowel, or myocardium have been described in association with cutaneous necrosis. This condition is termed *systemic CUA*.

Pathology

The histologic features of CUA are suggestive but not pathognomonic.[13] Specimens from incisional biopsies of early lesions show subtle histologic changes. Late lesions characteristically show epidermal ulceration, dermal necrosis, and mural calcification with intimal hyperplasia of small and medium-sized blood vessels in the dermis and subcutaneous tissue (Fig. 87.7).

Diagnosis and Differential Diagnosis

Many clinicians base the diagnosis of CUA on physical examination findings only. Although ulceration is an obvious presentation of CUA, increasing awareness of the condition should allow diagnosis at an earlier, nonulcerative stage when a distinct subcutaneous tenderness can be felt below the early skin lesions. Biopsies are discouraged by most but not all experts because of potential ulceration in the region of the incision and the risk for sampling error. Other potentially useful diagnostic procedures include measurements of transcutaneous oxygen saturation, bone scintigraphy (Fig. 87.8), and xeroradiography.[19]

The following conditions should be considered in the differential diagnosis: herpes zoster, systemic vasculitis, peripheral vascular disease, pyoderma gangrenosum, atheroemboli, cryoglobulinemia, warfarin-induced skin necrosis, and systemic oxalosis. A skin biopsy should be performed when clinical circumstances do not suggest CUA or when clinical and laboratory examinations, including the assessment of coagulation and immunologic parameters, point to an alternative diagnosis.

BOX 87.1 Treatment Options in Patients With Calcific Uremic Arteriolopathy*

1. **Reduction of procalcifying factors**
   - Intensified dialysis (e.g., daily hemodialysis, switch from peritoneal dialysis to hemodialysis, low-calcium dialysate)
   - Avoidance of vitamin D and calcium supplements; administration of calcium-free phosphate binders; bisphosphonate administration (caution if adynamic bone disease is suspected)
   - Parathyroidectomy (in the case of hyperparathyroidism) or administration of cinacalcet
2. **Improving the status of calcification inhibitors**
   - Halt vitamin K antagonists (warfarin)
   - Aggressive treatment of infections or other proinflammatory stimuli to increase fetuin-A levels
   - Experimental:
     - Administration of high-dose vitamin K_2, and if unavailable, vitamin K_1?
     - Administration of fetuin-A (e.g., by fresh frozen plasma or plasma exchange?)
3. **Prevention or reversal of calcium-phosphate precipitation**
   - Administration of sodium thiosulfate
4. **Supportive measures**
   - Avoidance of additional local tissue trauma by atraumatic wound care with gentle debridement of necrotic tissue and avoidance of subcutaneous injections
   - Anticoagulation (heparin and low molecular weight heparin)
   - Adequate pain management
   - Adequate infection control

Modified from reference 20.
*Theoretical options based on pathophysiologic considerations that have not been tested in clinical practice are printed in italics.

Natural History

Despite intensive combined treatments, the prognosis of patients with CUA remains poor; the overall 1-year survival is 45% and the 5-year survival is 35%, with a relative risk for death of 8.5 compared with that for other dialysis patients. Patients with ulcerative or proximal CUA have the worst prognosis. Infection accounts for up to 60% of the mortality.[13]

Prevention and Treatment

Preventive approaches include controlling bone and mineral metabolism and optimizing nutritional state.[13] Specific therapeutic regimens have been limited to uncontrolled case series (Box 87.1). Intervention should include an aggressive program of wound care and prevention of superinfection, adequate pain control, and correction of underlying abnormalities in serum calcium and phosphorus concentrations. This includes

Fig. 87.6 Proximal (A) and distal (B and C) calcific uremic arteriolopathy.

cessation of vitamin D supplementation, intensification of the dialysis regimen, and use of a low-calcium dialysate and non–calcium-containing phosphate binders (e.g., sevelamer, lanthanum carbonate). Furthermore, local tissue trauma, including subcutaneous injections, should be avoided. Parathyroidectomy is effective in the control of CUA in some series but not in others and should be reserved for patients with severe hyperparathyroidism. In such patients, calcimimetic agents may be a suitable noninvasive alternative. Vitamin K (preferentially vitamin K_1) supplementation is advised, especially in patients with warfarin- or coumarin-associated CUA. Novel and promising therapies include sodium thiosulfate and bisphosphonates. Sodium thiosulfate has recently been licensed as an orphan drug for CUA by the European Medicines Agency. It enhances the solubility of calcium deposits[20] because exchange of calcium for sodium results in extremely soluble calcium thiosulfate. Besides being a chelator of calcium, sodium thiosulfate is also a potent antioxidant. Sodium thiosulfate is given intravenously at the end of every HD session (12.5 to 25 g over 30 to 60 minutes). Apart from nausea and vomiting, the therapy is well tolerated. The major side effect of sodium thiosulfate infusion is the development of metabolic acidosis. The optimal duration of treatment and potential effects of long-term treatment on bone are unknown. Efficacy has been suggested by several case-series, but definite proof by a randomized controlled trial is lacking.

NEPHROGENIC SYSTEMIC FIBROSIS

Definition

NSF, formerly known as *nephrogenic fibrosing dermopathy*, is a scleroderma-like fibrosing disorder that develops in the setting of renal failure. The fibrotic process affects the dermis, subcutaneous tissues, fascia, and other organs, including striated muscles, heart, and lungs.[21]

Pathogenesis

Gadolinium-based contrast (GBC) agents have been identified as the cause of NSF; exposure to gadolinium before the onset of disease was

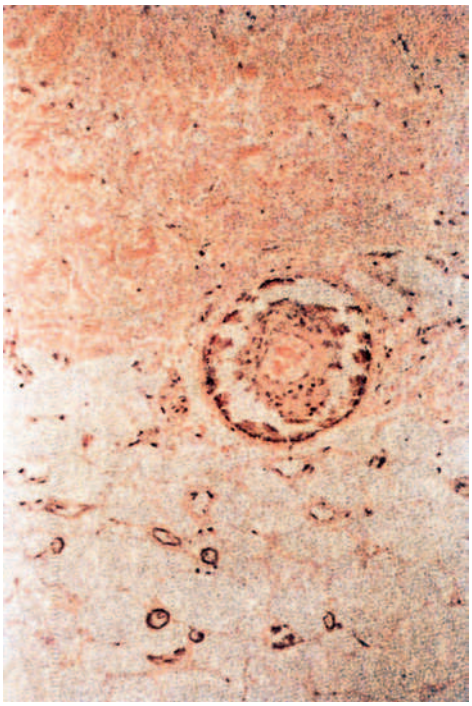

Fig. 87.7 Histopathologic features of calcific uremic arteriolopathy. Medial calcification and intimal hyperplasia of an arteriole at the dermal-subcutaneous junction. Note calcification of interlobular capillaries in the subcutaneous tissue. (Van Kossa stain.) (With permission from reference 12.)

confirmed in more than 95% of reported cases. Free gadolinium ions are highly toxic to tissues. The toxic effects of gadolinium are circumvented by sequestration of the metal by chelates, large organic molecules that form a stable complex with gadolinium and make the ion biochemically inert and nontoxic. Under normal circumstances, GBC agents are eliminated by the kidney through glomerular filtration. Evidence points toward aberrant activation of circulating fibrocytes as a central event in the genesis of NSF. Other investigators have suspected that the strongly profibrotic mediator transforming growth factor-β may be involved in the pathogenesis of NSF.

Epidemiology

NSF is a rare disorder. Since the identification of the first patients with NSF in 1997, the NSF registry (www.icnfdr.org) has confirmed more than 380 patients from medical centers worldwide. NSF equally affects men and women. The risk for development of NSF after GBC agent exposure is related to the degree of renal failure and stability of the chelate. The incidence of NSF in patients with severe renal dysfunction (glomerular filtration rate [GFR] <30) varies from 0.2% to 4%. Gadodiamide (marketed as OmniScan in the United States), the linear nonionic chelate–based formulation, appears to be associated with the highest risk for NSF on the basis of epidemiologic data and animal studies. Gadopentetate, the linear ionic chelate–based product, probably has a medium risk, less than linear nonionic chelates but more than macrocyclic chelates. Other factors reported to be associated with NSF (without definitive proof) include coagulation abnormalities and deep venous thrombosis, recent surgery (particularly vascular surgery), hyperphosphatemia, and the use of high doses of recombinant erythropoietin. Angiotensin-converting enzyme inhibitors might protect against NSF. After warnings issued by the U.S. Food and Drug Administration and European Medicines Agency regarding the association of linear GBC agents with NSF in individuals with renal dysfunction, the incidence of NSF declined and in recent years, no new cases of NSF have been reported.

Clinical Manifestations and Natural History

The lesions of NSF are typically symmetric and develop on limbs and trunk. A common location is between the ankles and midthighs and between the wrists and mid-upper arms bilaterally. On occasion, swelling of the hands and feet, sometimes associated with bullae, is noted. The primary lesions are skin-colored to erythematous papules that coalesce into erythematous to brawny plaques with a peau d'orange appearance (Fig. 87.9A). These plaques have been described as having an ameboid advancing edge. Nodules are sometimes also described. Involved skin becomes markedly thickened and woody in texture. Joint contractures may develop rapidly, with patients becoming wheelchair-dependent within days to weeks of onset (see Fig. 87.9B). Patients often report pruritus, causalgia, and sharp pains in the affected areas.[21] Although NSF has not been reported as a cause of death, this disorder has led to reduced mobility and/or superinfection that ultimately resulted in a protracted hospital course and death.

Pathology

The histopathologic changes in affected skin include marked proliferation of spindle cells, the presence of numerous dendritic cells, and accumulation of mucinous material and thick collagen bundles (Fig. 87.10). Most dermal spindle cells in NSF have the immunophenotype of a circulating fibrocyte, a recently characterized circulating cell that expresses markers of both connective tissue cells and circulating leukocytes. Metastatic calcification and NSF may be found in the same lesion.

Diagnosis and Differential Diagnosis

The gold standard of diagnosis is histopathologic examination of skin biopsy specimens from an involved site. Skin lesions also can be visualized by [^{18}F]-fluorodeoxyglucose whole-body positron emission tomography. NSF resembles other fibrosing skin disorders, including

Fig. 87.9 Nephrogenic systemic fibrosis. (A) Peau d'orange appearance. (B) Swelling of the hands, accompanied by palmar erythema, blisters, and contracture of the fingers.

scleromyxedema, scleroderma, eosinophilic fasciitis, eosinophilia-myalgia syndrome, and Spanish toxic oil syndrome. The specific distribution of cutaneous involvement, the occurrence in the setting of renal failure, the history of recent exposure to linear GBC agents, and the unique histopathologic features distinguish NSF from the other fibrotic disorders.

Treatment and Prevention

There is no consistently effective therapy for NSF. There is variable evidence for the efficacy of plasma exchange. Other therapeutic modalities that have been used (or are under investigation) include imatinib, oral and topical corticosteroids, selective histamine blockade, calcipotriene ointment, cyclophosphamide, cyclosporine, thalidomide, interferon-α, photopheresis, and psoralen ultraviolet A therapy. Intensive physiotherapy is advised in every patient to prevent or to reverse limb disability related

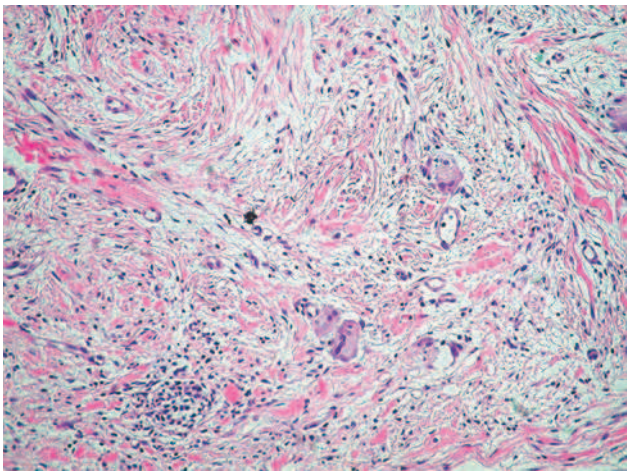

Fig. 87.10 Histopathologic features of nephrogenic systemic fibrosis. Haphazardly arranged dermal collagen bundles with surrounding clefts and a strikingly increased number of similarly arranged spindled and plump fibroblast-like cells.

to contractures of the joints. At present, prevention of NSF seems more important than any of the currently available interventions, and widespread clinical awareness of this condition is required. Avoidance of linear GBC agents in high-risk patients (acute kidney injury and patients with CKD with estimated GFR [eGFR] rate <30 ml/min/1.73 m^2) is the best measure to prevent this catastrophic complication. If GBC agent exposure is required, use of the smallest dosage of a macrolytic chelate is strongly advised (www.esur.org/guidelines/). HD (three sessions within 72 hours) should be considered after GBC agent exposure in patients who are already on this modality.

SELF-ASSESSMENT QUESTIONS

1. Uremic pruritus in dialysis patients is:
   - **A.** A local skin disorder
   - **B.** A systemic disorder caused by uremia
   - **C.** A neurologic disorder caused by overexpression of opioid skin receptors
   - **D.** An inflammatory systemic disorder caused by dysregulation of the immune system
   - **E.** All of the above
2. Skin emollients in dialysis patients should be used:
   - **A.** Only in patients without underlying primary skin diseases
   - **B.** Only in patients with proven xerosis
   - **C.** Only in patients without skin defects
   - **D.** Only in patients with therapy failure
   - **E.** In all patients
3. Treatment of uremic pruritus with oral nalfurafine:
   - **A.** Is limited to patients with proven overexpression of μ receptors in their skin
   - **B.** Is limited to patients free from sleeping disturbances
   - **C.** Is limited to patients with therapy failure
   - **D.** Is limited to patients with baseline normal blood prolactin concentrations
   - **E.** Is not limited to any subgroup of patients with uremic pruritus
4. Which of the following drugs predisposes to calcific uremic arteriolopathy?
   - **A.** Acetylsalicylic acid
   - **B.** Heparin
   - **C.** β-Blocker
   - **D.** Warfarin and coumarins
   - **E.** Calcium-free phosphate binders
5. Nephrogenic systemic fibrosis:
   - **A.** Is a self-limiting disease with benign prognosis
   - **B.** Is related to exposure to linear gadolinium chelates
   - **C.** Is painless
   - **D.** Is especially prevalent in renal transplant recipients
   - **E.** Is related to exposure to iodine radiocontrast agents

Acquired Cystic Kidney Disease and Malignant Neoplasms

Anja S. Mühlfeld, Peter Boor

DEFINITION

Acquired cystic kidney disease (ACKD) was first recognized in 1847 by John Simon in patients with chronic Bright disease. He described the development of cystic renal changes with cysts ranging from "mustard seed to as large as cocoa nuts" and also noted that they "run a slow and insidious progress during life, and often leave in the dead body no such obvious traces as would strike the superficial observer." ACKD was "rediscovered" by Dunnill and colleagues[1] in 1977 in kidneys from dialysis patients.

ACKD is a specific entity of chronic kidney disease (CKD) of any etiology and has to be differentiated from other types of cystic kidney disease (see Chapters 44 and 45). It is usually defined as more than three macroscopic cysts in each kidney of a patient who does not have a hereditary cause of cystic disease. Some authors consider ACKD preneoplastic.[2,3]

PATHOGENESIS

The exact mechanisms of tubule transformation into cysts in ACKD are unknown. Responses to CKD with slow, progressive parenchymal (nephron) loss are believed to be involved. Progressive nephron loss results in initial tubular hypertrophy followed by hyperplasia and is likely aggravated by tubular distortion and distal tubular outflow obstruction, such as by advanced tubular atrophy, interstitial fibrosis, or calcium oxalate crystals, which are all common in ACKD (Fig. 88.1).[4] ACKD can appear before dialysis is started and does not correlate with dialysis modality or underlying renal disease. The cysts seem to develop from various tubular segments. Most cysts are lined by a single layer of flat to cuboidal epithelial cells, but also cuboidal cells with eosinophilic, foamy, and occasionally also clear cytoplasm, with particularly the latter being considered precursor lesions of renal neoplasias.[2,3,5,6] Other factors implicated in the development of tubular hyperplasia include plasticizers, ischemia, or uremic or other humoral metabolites. In some instances the cysts size decreased after renal transplantation.

With the continuing presence of mitogenic stimuli, intracystic epithelium becomes multilayered or forms micropapillary proliferates. Further accumulation of mutations, activated protooncogenes, or chromosomal abnormalities, in conjunction with additional factors such as genetic background, environmental chemicals, and sex hormones, most likely accounts for the transition to renal cell carcinoma (RCC) (see Fig. 88.1).[7]

EPIDEMIOLOGY

Among adult and pediatric patients starting maintenance dialysis treatment, prevalence of ACKD ranges from 5% to 20%. In both chronic hemodialysis (HD) and peritoneal dialysis patients, prevalence then increases at a similar rate and reaches 80% to 100% after 10 years of treatment (Fig. 88.2).[8-11] Several but not all studies have reported an increased frequency or faster progression in men than in women. The rate of progression appears to slow after 10 to 15 years of dialysis.

The frequency of ACKD as well as of renal tumors in dialysis patients may be underestimated on the basis of imaging alone. Renal cysts are detectable by ultrasound, with a minimum size of 0.5 cm. Data obtained in native nephrectomy specimens at the time of transplantation identified ACKD in 33%, renal adenomas in 14%, and RCCs in 4% of the cases.[12] In unselected series of chronic dialysis or transplant patients, the cumulative incidence of RCC complicating ACKD as demonstrated by imaging is below 1%, although rates up to 7% have been reported in some small studies. These data indicate an up to 40- to 100-fold increased risk for RCC in ACKD patients compared with RCC in the general population. Risk factors include male gender (male-to-female ratio, 7:1), African American ethnicity, long duration of dialysis, and severe ACKD with marked organ enlargement.

CLINICAL MANIFESTATIONS

ACKD can manifest as unilateral or bilateral cysts, which are mostly cortical and variable in size and number. Rarely, severe ACKD can become macroscopically indistinguishable from adult polycystic kidney disease (PKD). In contrast to hereditary cystic diseases, the cysts of ACKD are strictly confined to the kidneys. The disease is usually asymptomatic and discovered accidentally during abdominal imaging procedures. Alternatively, it may be manifested by the following potential complications or consequences of ACKD[13]:

- Cystic hemorrhage with or without hematuria; bleeding may occur with cyst rupture with subsequent perinephric hemorrhage or retroperitoneal hemorrhage, which can rarely lead to hypovolemic shock.
- Calcifications in or around cysts and in rare cases stone formation (calcium-containing stones or β_2-microglobulin stones).
- Cyst infection, abscess formation, or sepsis.
- Erythrocytosis in advanced cases, similar to the erythrocytosis observed in PKD.
- Malignant transformation.

Acquired Cystic Kidney Disease–Associated Renal Cell Carcinoma

About 85% of RCCs in ACKD are asymptomatic at the time of diagnosis. The remaining cases mostly manifest with bleeding, usually gross hematuria. In cases in which nephrectomy had to be performed in dialysis patients for intractable hematuria, previously undetected RCCs were diagnosed in about one third of the patients. Compared with sporadic

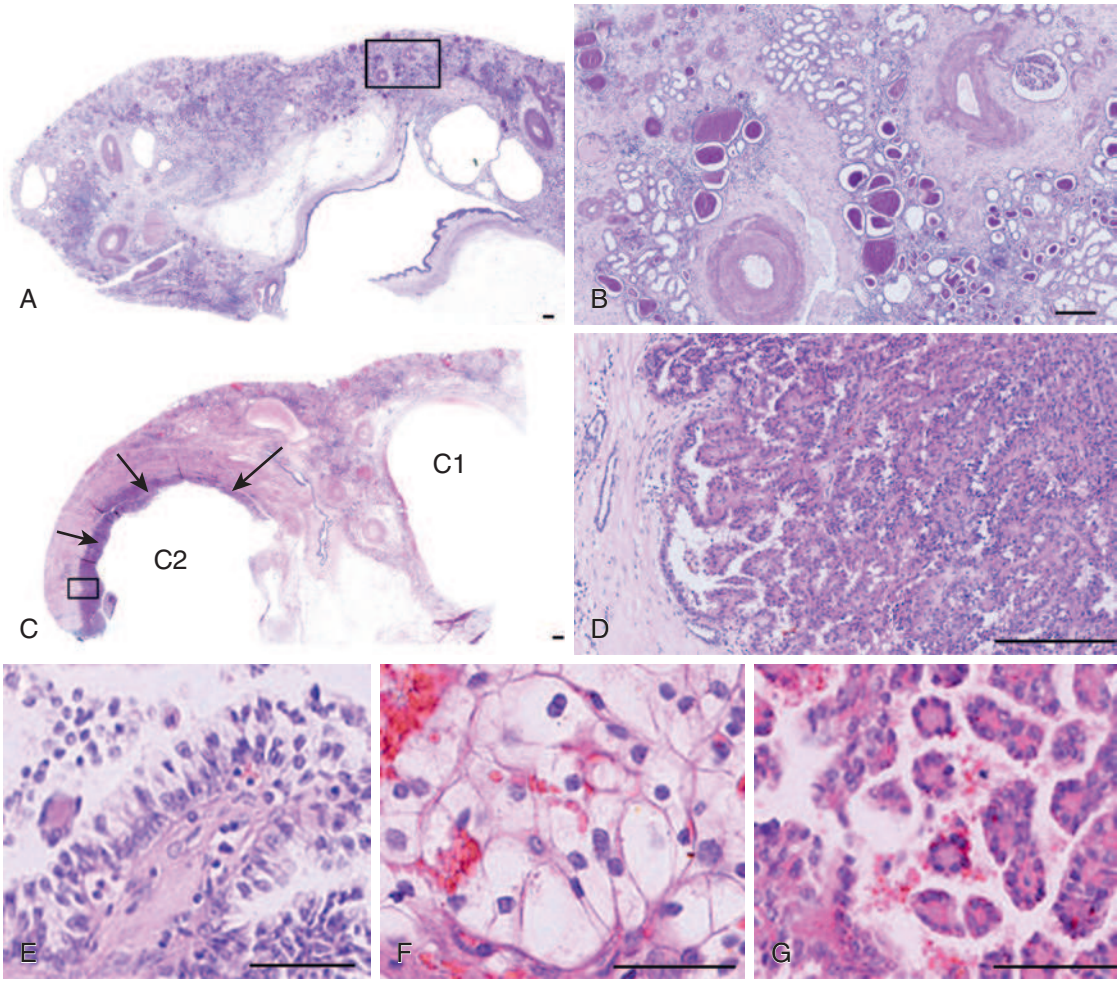

Fig. 88.1 Typical histomorphologic appearance of acquired cystic kidney disease (ACKD) and commonly found renal cell carcinomas (RCC) in ACKD. (A) The kidney shows numerous cysts of different sizes and a prominent atrophy of renal parenchyma. At higher magnification in (B) global glomerulosclerosis, tubular atrophy with typical focal areas of thyroidization (i.e., intratubular periodic acid–Schiff [PAS]-positive casts), interstitial fibrosis, and arteriosclerosis (PAS-stained section) are noted. (C) Another area of the same kidney specimen as shown in A, with two cysts. The right cyst is lined by inconspicuous and at this magnification invisible single-layered epithelium (C1). The left cyst (C2) is lined by a thick cell-dense layer *(arrows),* which at higher magnification (D) is characterized by tubular and papillary proliferates of atypical epithelial cells, characteristic for intracystic ACKD-associated RCC (hematoxylin-eosin–stained section). (E) Another tumor often found in ACKD is composed of well-differentiated clear cells in a papillary arrangement, characteristic for clear cell papillary RCC. (F) A clear cell RCC, a tumor commonly found in ACKD and the most common renal tumor in the general population. It is composed of nests and sheets of atypical cells with clear cytoplasm. (G) Papillary RCC, another tumor commonly found in ACKD and the second most common RCC in the general population. It is composed of eosinophilic epithelial cells in a papillary arrangement. In this case the tumor size was 3 cm; therefore the diagnosis of papillary RCC (type 1) was made; if the size were less than 1.5 cm, the same histologic tumor pattern would be classified as papillary adenoma. In the presented cases and typical for ACKD, most clear cell and papillary RCCs in ACKD are well-differentiated, that is, the nuclei show little or no nucleoli and little nuclear pleomorphy. The scale bars in A through D represent 250 µm and in E through G 50 µm. The insets in A and C represent areas shown in higher magnification in B and D, respectively.

RCCs, ACKD-associated RCCs are characterized by younger age of the patient, male predominance, more frequent multicentric and bilateral manifestation, and less frequent metastases.[2]

PATHOLOGY

Cystic changes in ACKD are typically bilateral but may vary between kidneys. Most ACKD kidneys are smaller than normal, and all show advanced parenchymal atrophy and chronic injury. An increase in size of the ACKD kidneys above normal may result from cyst hemorrhage or malignant transformation. The cysts are usually restricted to the renal cortex. The size of the cysts ranges from microscopic to about 2 cm; about 60% of the cysts are smaller than 0.2 cm.[2] Preneoplastic changes include atypical cyst-lining cells with clear cell morphology, forming multiple cell layers and intracystic papillary or nodular proliferates.

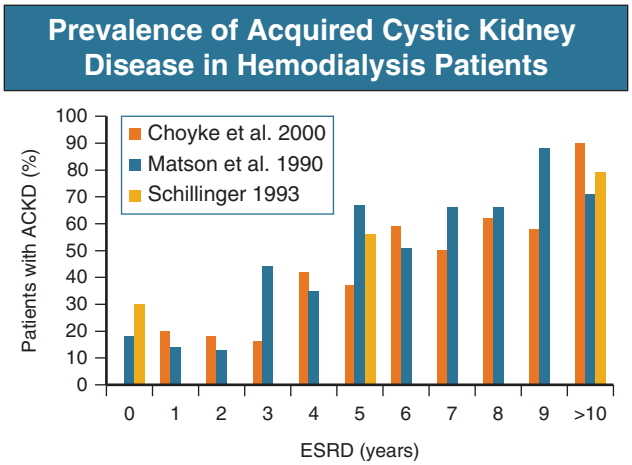

Fig. 88.2 Prevalence of acquired cystic kidney disease (ACKD) in hemodialysis patients. Summary of reported ACKD prevalences in chronic hemodialysis (HD) patients in relation to the length of HD treatment. (Modified from references 9 to 11.)

Up to 25% of kidneys with ACKD harbor tumors when examined histologically. About one quarter to one third of these are carcinomas. Adenomas are only defined for well-differentiated papillary tumors and are arbitrarily considered adenomas when less than 1.5 cm, whereas those greater than 1.5 cm are considered carcinomas, given the higher metastatic probability of larger tumors. All other tumors showing typical histology of RCCs regardless of size (e.g., invasive groups of clear cells) are diagnosed as RCCs.

The most common type of RCC that is specific for ACKD is ACKD-associated RCC, which accounts for about 36% of RCCs found in ACKD. The histologic appearance of ACKD-associated RCCs varies from tubular, papillary, acinar, microcystic, to solid. They are mostly composed of eosinophilic tumor cells with prominent nucleoli and frequent intratumoral calcium oxalate crystals (see Fig. 88.1).[6] The second most common ACKD-specific RCCs (24%) are clear cell papillary RCCs, which show papillary, tubular, or cystic arrangement of relatively well-differentiated clear cells.

Other commonly observed RCCs in ACKD are those commonly observed in the general population, such as papillary (18%), clear cell (10%), and chromophobe RCCs (6%). RCCs arising from ACKD are multicentric in about 50% of cases and bilateral in about 10%. Multiple histologic subtypes may occur in the same kidney. Clear cell RCCs contain cells in solid, tubulocystic or alveolar arrangement, whereas papillary RCCs show eosinophilic, papillary arranged tumor cells (see Fig. 88.1). In difficult cases with overlapping histologic appearance, immunohistochemistry helps differentiate between these entities. The precise diagnosis is important because ACKD-associated RCCs and clear cell papillary RCCs seem to be more indolent than classic RCCs, but in rare cases can metastasize. In addition, all RCCs in ACKD tend to have a better clinical course most likely as a result of early detection given close follow-up of these patients.

RCCs in renal transplant patients tend to be smaller, exhibit a lower T stage and a lower grade at diagnosis compared with RCCs in patients with end-stage renal disease. Tumors are more often multifocal, bilateral, and papillary.[14,15] Likely because of the earlier stage at detection the prognosis of RCCs after renal transplantation generally is more favorable.

No imaging modality is able to distinguish between the different benign and malignant subtypes of renal neoplasms found in ACKD; therefore histopathologic analysis remains the only means for their diagnosis.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnostic approach to ACKD usually involves ultrasound (Fig. 88.3).[4,9] However, the differentiation between simple cysts and RCCs can be difficult given the echogenicity of end-stage kidney parenchyma and the complexity of cysts in ACKD. Computed tomography (CT) scanning, in particular with early contrast enhancement, is superior to ultrasound in detecting small malignant lesions (see Fig. 88.3).[4,9,16] A classification of renal cysts (Fig. 88.4) based on their appearance in CT scans, introduced by Bosniak,[17,18] is now widely accepted and is also applied to ultrasound and magnetic resonance imaging (MRI) (see Table 59.5). Criteria that favor the diagnosis of RCC as opposed to a simple cyst include thickened and irregular walls, the presence of septa or renal tissue within the lesions, contrast enhancement, multilocularity, and large size (≥4 cm). Given the risk for nephrogenic fibrosis after exposure to gadolinium-containing contrast agents (see Chapter 5), MRI without contrast enhancement has was shown in a pilot study in renal transplant recipients to be superior to renal ultrasound alone.[19] Another small study found that contrast enhanced ultrasound for the assessment of complex cysts in renal transplant recipients was better than standard ultrasound in correctly characterizing Bosniak I and II cysts.[20]

Because of the risk for malignant transformation, screening for ACKD and follow-up imaging when ACKD is detected have both been advocated. A proposal for ACKD and tumor screening is outlined in Fig. 88.5. However, the cost of screening has to be weighed against the risk-to-benefit ratio of nephrectomy in dialysis patients. A decision analysis[21] concluded that screening for ACKD (by either ultrasound or CT scanning) in young patients with a life expectancy of 25 years offers as much as a 1.6-year gain in life expectancy. This is similar to the gain obtained in young healthy people who stop smoking. In contrast, in ACKD patients older than 60 years, no significant gain in life expectancy is achieved by regular screening.[22] In a different analysis of 797 dialysis patients who had developed RCCs (90% identified by screening), screening provided a mean survival benefit of 3.3 years after adjustment for age and dialysis vintage.[22] Screening during transplant evaluation by ultrasound followed by CT in the case of suspicious lesions is recommended on the basis of recent data showing a prevalence of renal cancer in up to 4% of the patients and concerns about the role of immunosuppression in accelerating tumor growth.[23]

NATURAL HISTORY

Cystic dilations of renal tubules may develop at a glomerular filtration rate lower than 70 ml/min.[24] ACKD thereafter progresses and reaches a prevalence of nearly 100% after more than 10 years of dialysis (see Fig. 88.2). The constant increase in kidney volume seems to reach a plateau after about 20 years of HD, and at least partial regression may occur after very-long-term HD.[25] In malignant transformation, tumor growth rates are highly variable. Death is usually associated with widespread metastases and accounts for about 2% of the deaths in renal transplant patients.

It is not established whether renal transplantation affects the natural history of RCC complicating ACKD, although immunosuppression has been suggested as a risk factor for RCC in transplant patients with ACKD.[13] A prospective, single-center ultrasound screening of the native kidneys in 561 renal transplant recipients identified ACKD in 23%.[26] The mean duration of dialysis was 4 to 5 years, and the mean time after transplantation was 9 years. In this cohort, ACKD was slightly less frequent than had been reported in dialysis patients, possibly indicating that renal transplantation might inhibit the development of ACKD.[26] The prevalence of RCCs among all 561 patients was 4.8%. However,

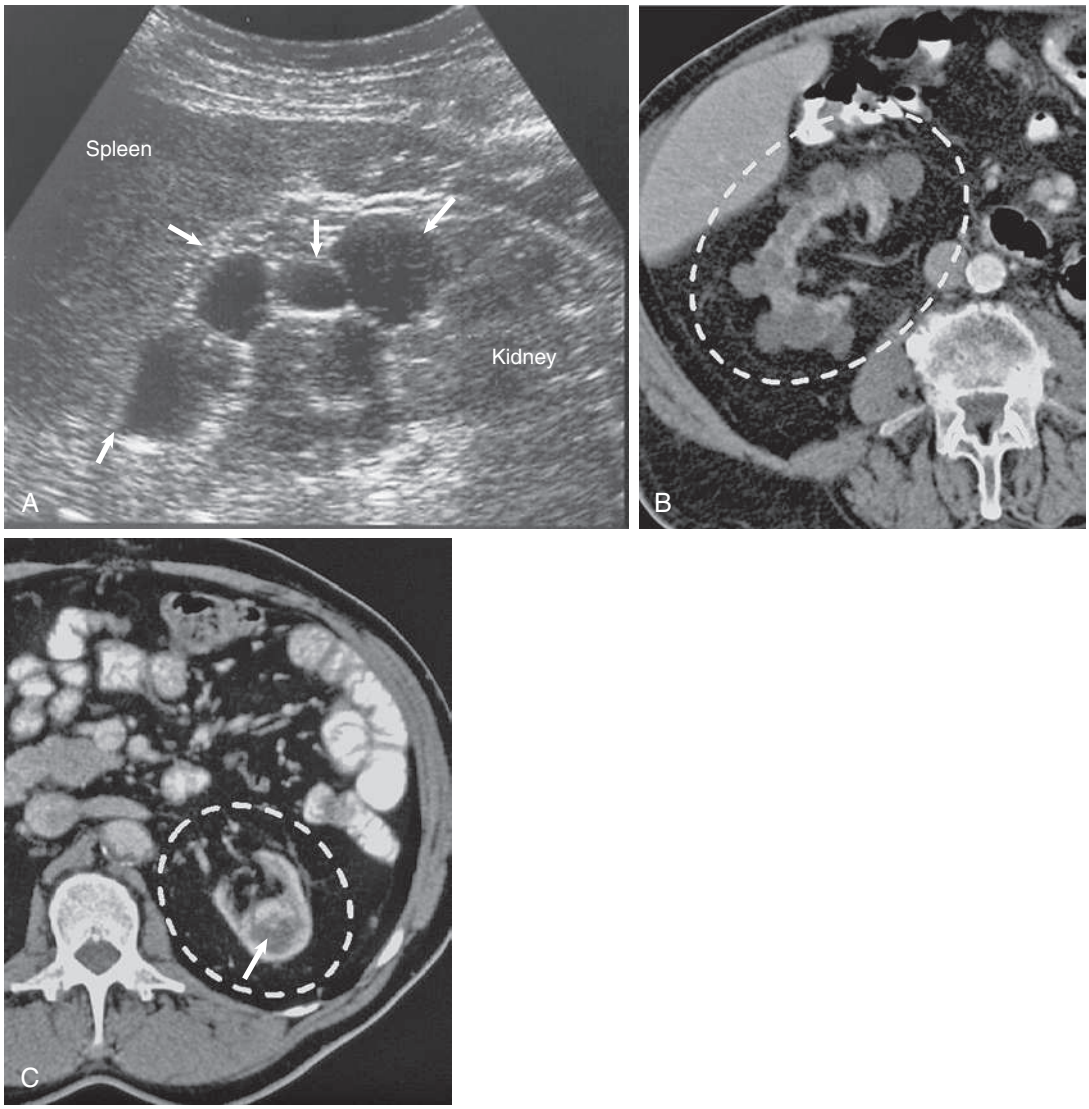

Fig. 88.3 Imaging studies in acquired cystic kidney disease (ACKD). (A) Ultrasound image of the left native kidney of a patient after 16 years of chronic hemodialysis (HD). Multiple cysts are present in the renal cortex *(arrows).* (B) CT image of a patient after 5 years of chronic HD demonstrating multiple cysts within the right kidney *(dashed circle).* (C) Contrast-enhanced CT image of a renal transplant patient who developed a renal cell carcinoma *(arrow)* originating from the left native kidney with ACKD *(dashed circle).*

among patients with ACKD, RCCs were detected in almost 20%, but in only 0.5% of patients without ACKD.[26]

TREATMENT

Treatment of ACKD is warranted only when complications such as hemorrhage, cyst infection, or malignant transformation develop. Whereas the first two complications may be handled conservatively and only rarely require surgery, malignant transformation should raise the question of nephrectomy. Given the perioperative morbidity and mortality of nephrectomy, in particular in multimorbid dialysis or transplant patients, it is not surprising that the threshold for surgical intervention in cases of RCC is still controversial.

Most agree that tumors larger than 3 cm in diameter justify nephrectomy because above this size, RCCs in the general population frequently metastasize (see Fig. 88.4).[11] However, this strategy is based on an extrapolation from otherwise healthy persons and a more aggressive approach may be required under certain circumstances. This is particularly true because tumor size in ACKD is often difficult to establish given its frequent multilocular development and because metastases have been described in ACKD even when renal tumors were not detected by imaging studies.

In the case of tumors of less than 3 cm in diameter with no complications, the slow tumor growth may justify observation with repeated imaging studies (see Fig. 88.4). Patients with high life expectancy or listed for transplantation might be considered for nephrectomy also in case of tumors with diameters less than 3 cm. In general, tumor enlargement should be used as an indication for nephrectomy if it is permitted by the patient's status.

A prophylactic contralateral nephrectomy, in the case of unilateral tumors, is not routinely recommended because of the morbidity associated with the procedure, the worsening of anemia, and the loss of residual renal function in those who are not considered transplant candidates. A delay of transplantation is generally not suggested in patients who have had an asymptomatic RCC associated with ACKD in their nephrectomy. In such a setting, a contralateral nephrectomy

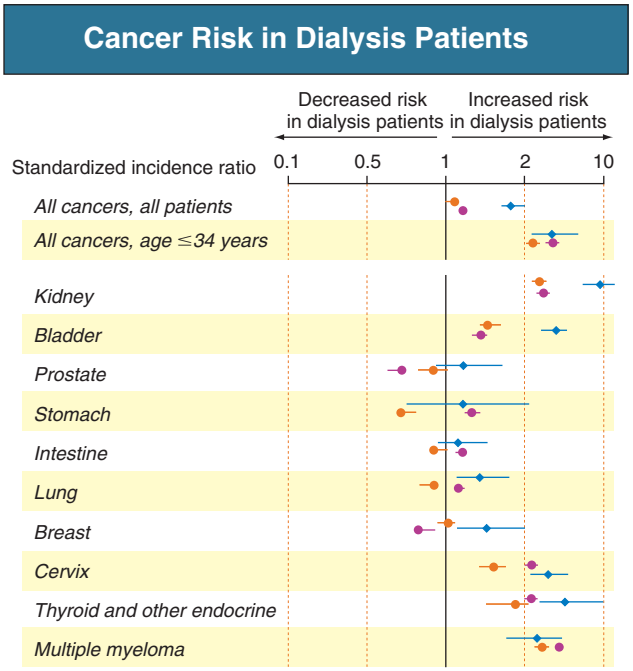

Fig. 88.5 Cancer risk in dialysis patients. Relative risk for cancer (plus 95% confidence interval) compared with the general populations in 831,804 dialysis patients from Australia/New Zealand *(blue diamonds),* Europe *(orange circles),* and the United States *(purple circles).* (Modified from reference 29.)

can be recommended to decrease the potential risk for neoplastic growth and avoid a delay of transplantation.

We recommend performing screening for renal masses in transplant recipients on a yearly basis using ultrasound. In suspicious cases, contrast-enhanced CT scanning or MRI might help differentiating blood-filled cysts from solid tumors. In the case of a suspicious mass or RCC in the native kidneys, nephrectomy should be performed. However, although immunosuppression is possibly associated with the development of RCC, it does not seem to diminish the likelihood of cure, especially because RCCs in transplant patients, possibly as a result of regular screening for malignancy, tend to be detected at an earlier stage.[27] In addition, nephrectomy in renal transplant recipients can be safely performed without a high risk for surgical complications.[28]

CANCER IN DIALYSIS PATIENTS

Even if the risk for malignant transformation of ACKD is disregarded, dialysis patients have a slightly higher cancer risk compared with the general population. Analysis of more than 800,000 dialysis patients in three registries from the United States, Europe, and Australia/New Zealand revealed that most of the increased risk was due to cancers of the kidney, bladder, and endocrine organs (see Fig. 88.5).[29] Besides the specific risk associated with malignant transformation of ACKD, some of the increased risk is directly related to the underlying renal disease or to the immunosuppression that may have been administered to patients with immune-mediated renal disease. Cyclophosphamide therapy, for example, may predispose to bladder and ureteral cancer that

manifests after patients have been initiated on dialysis. Renal disease or immunosuppressive therapy may underlie the apparent risk in dialysis patients for development of multiple myeloma (see Fig. 88.5). In addition, patients with analgesic nephropathy or aristolochic acid nephropathy are at high risk for development of transitional cell carcinoma (TCC) of the upper urinary tract.[30] Particularly after renal transplantation, these tumors tend to be less differentiated and in an advanced stage and therefore the patients have a relatively poor outcome. For this reason, patients with analgesic nephropathy or aristolochic acid nephropathy should be evaluated for the presence of TCC before transplantation and annually after transplantation. It has been advocated that testing should include cystoscopy, retrograde ureteral catheterization with washings and brushings, and sonography imaging.[31] Other malignancies that have been observed at increased frequencies in dialysis patients include carcinoma of the cervix, thyroid and other endocrine neoplasias (see Fig. 88.5), and, at least in the U.S. Renal Data System database, a 1.5- to 2-fold increase in the risk for non-Hodgkin's lymphoma, Hodgkin's disease, and leukemias.[29]

SELF-ASSESSMENT QUESTIONS

1. A 52-year-old White man comes to your clinic with new onset of hematuria. He is on chronic hemodialysis (HD) treatment for end-stage renal disease (ESRD) because of diabetic nephropathy. Ultrasound of his kidneys reveals four cysts on the left side and five cysts on the right. On the right side, two of the cysts are not echo free and have a thickened wall with multiple calcifications. Which of the following statements is correct?
   - **A.** His previous diagnosis of diabetic nephropathy causing ESRD is false. Renal ultrasound clearly depicts the typical picture of autosomal dominant polycystic kidney disease (ADPKD).
   - **B.** Acquired cystic kidney disease (ACKD) is a common finding in patients on maintenance HD treatment and is a possible cause of hematuria.
   - **C.** This patient needs to be carefully evaluated for the presence of renal cell carcinoma (RCC) because renal cysts in patients on renal replacement therapy (RRT) almost always undergo malignant transformation.
   - **D.** Most patients with ACKD have cystic disease outside of the kidneys (liver, pancreas) and need to be screened for cerebral aneurysms.
   - **E.** ACKD is associated with exposure to toxic compounds such as benzidine and 2-naphthylamine.
2. A 45-year-old African American woman on maintenance HD because of lupus nephritis is asking for your advice. She has heard about an increased risk for malignant tumors in HD patients. Which of the following statements is *false*?
   - **A.** The increase in risk for tumor development in patients on RRT is in part related to the underlying renal disease or to the immunosuppression that may have been administered to patients with immune-mediated renal disease.
   - **B.** Most of the increased risk is due to cancers of the kidney, bladder, and endocrine organs.
   - **C.** Cyclophosphamide therapy may predispose to cancer of the bladder.
   - **D.** Patients with analgesic nephropathy or Chinese herbs/aristolochic acid nephropathy are at increased risk for development of transitional cell carcinoma (TCC) of the upper urinary tract.
   - **E.** Data from large registries reveals a nearly 10-fold increase in the risk for colorectal cancer in patients on HD treatment.
3. A renal transplant recipient with ESRD secondary to focal segmental glomerulosclerosis presents for a regular checkup. He reports that his primary care physician had ordered an abdominal ultrasound because of recurrent right upper quadrant pain. As an incidental finding, multiple cysts in his native kidneys were noted. Which of the following statements about his condition is *false*?
   - **A.** ACKD is a common finding in patients with ESRD.
   - **B.** Up to 25% of kidneys with ACKD harbor tumors, about one third of which are carcinomas.
   - **C.** ACKD is mostly asymptomatic; however, clinical manifestations include cyst hemorrhage, cyst infection, and malignant transformation.
   - **D.** Bilateral nephrectomy is the treatment of choice for asymptomatic ACKD in renal transplant recipients because malignant transformation occurs in almost 90% of cases.
   - **E.** Contrast-enhanced CT and MRI are the methods of choice to detect small malignant lesions in patients on RRT.

Geriatric Nephrology

Mitchell H. Rosner, Emaad Abdel-Rahman, Antonelli Pani

Aging is associated with a decline in kidney function that which can manifest as early as the fourth decade of life and accelerates between the fifth and sixth decades. These changes affect glomerular and tubular function, systemic hemodynamics, and body homeostasis. This chapter focuses on the management of the population older than 65 to 70 years.

AGING-ASSOCIATED STRUCTURAL CHANGES

Anatomic Changes

The human kidney reaches a maximum size of approximately 400 g (12 cm in length) in the fourth decade of life. A natural decline of approximately 10% in renal mass per decade then follows. This natural decline is associated with cortical thinning and decrease in the number of functional nephrons. An analysis of living kidney donors examined the changes in nephron number and structure over time.[1] Between the youngest and oldest age groups (18 to 29 years vs. 70 to 75 years), the number of nonsclerotic glomeruli decreased by 48%, whereas cortical volume decreased by only 16% and the proportion of globally sclerotic glomeruli on biopsy increased by only 15%. The authors concluded that the incomplete representation of nephron loss with aging by either increased glomerulosclerosis or cortical volume decline is consistent with atrophy and reabsorption of globally sclerotic glomeruli and hypertrophy of remaining nephrons.

Glomerular Changes

Structural glomerular changes with age include basement membrane thickening and development of focal and segmental or global glomerulosclerosis, which increases to 10% to 30% and in some studies even exceeding 70% of glomeruli by the eighth decade (Figs. 89.1 and 89.2).[2] Preserved glomeruli often show an increase in overall tuft cross-sectional area, consistent with glomerular hypertrophy. Neither kidney function nor chronic kidney disease (CKD) risk factors can explain the strong association between age and glomerulosclerosis in healthy adults.

Tubular and Interstitial Changes

Tubulointerstitial injury associated with aging is most pronounced in the outer medulla, with tubular dilation and atrophy, mononuclear cell infiltration, and interstitial fibrosis. Some tubules (especially in the distal tubule and collecting duct) may develop small diverticuli; it has been suggested that these diverticuli may play a role in the development of upper urinary tract infections (pyelonephritis) by harboring bacteria.[3]

Vascular Changes

Arterioles often develop hyalinosis with aging. Thickening of the arterioles with an increase in the ratio of medial thickness to lumen diameter is common with aging but is observed almost exclusively in hypertensive individuals.[3] The arcuate arteries become more angulated and irregular with aging, and there is increased tortuosity and spiraling of the interlobar vessels. These changes occur independently of hypertension but are augmented in its presence. With aging, some afferent arterioles, particularly of juxtamedullary glomeruli, develop vascular shunts to the efferent arterioles, thereby bypassing glomeruli, leading to "aglomerular arterioles."[4]

AGING-ASSOCIATED CHANGES IN RENAL FUNCTION

Glomerular Filtration Rate

Inulin clearance studies document a progressive fall in glomerular filtration rate (GFR) after the age of 40 years, with a relatively greater decline in men (Fig. 89.3).[5] However, the fall in GFR is not inevitable; in as many as one third of patients who remain normotensive, there is no decrease in creatinine clearance with age.[3]

In addition to the decrease in GFR with aging, there may be a reduction in renal "reserve." Whereas some studies suggest that aging humans show a normal increase in GFR after amino acid infusion, others have shown a marked reduction in increases in renal plasma flow (RPF) and GFR in response to concurrent infusion of amino acids and dopamine in healthy older individuals.[6,7]

Renal Plasma Flow

RPF also decreases from a mean of 650 ml/min in the fourth decade to 290 ml/min by the ninth decade, with increasing renal vascular resistance (Fig. 89.4).[3] Because RPF decreases relatively more than GFR, filtration fraction (defined as GFR/RPF) increases with age. Studies have demonstrated that there is a true reduction in renal blood flow when it is factored for renal mass.[8] The decrease in renal blood flow especially involves the cortex, and blood flow to the medulla is relatively preserved.

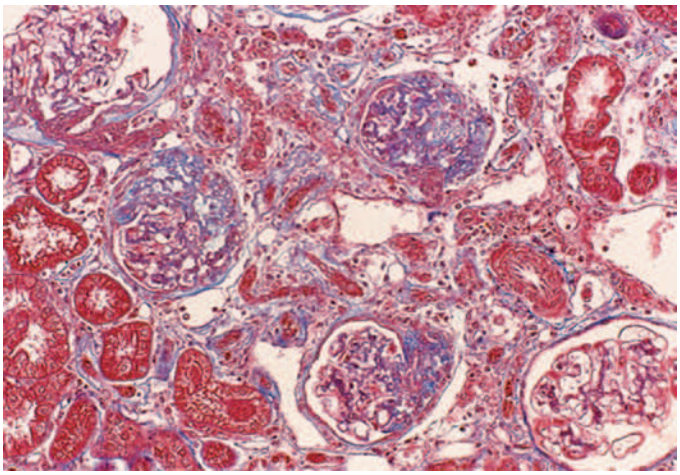

Fig. 89.1 Glomerulosclerosis and tubulointerstitial fibrosis in an aging rat. Similar changes, consisting of focal segmental glomerulosclerosis, tubular atrophy, and interstitial fibrosis, occur in humans. (Trichrome stain; original magnification ×400.)

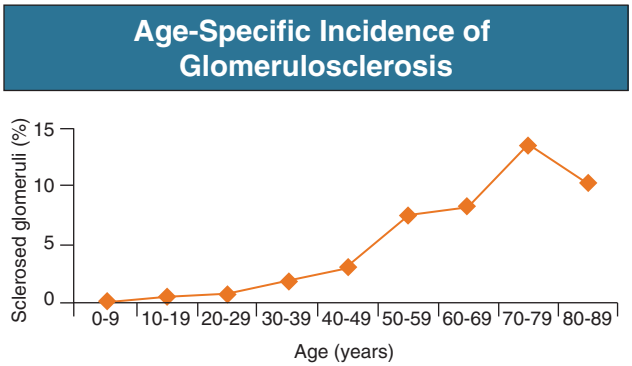

Fig. 89.2 Glomerulosclerosis increases with aging. (Modified from reference 2.)

ASSESSMENT OF RENAL FUNCTION IN THE ELDERLY

Serum creatinine is a less reliable indicator of renal function in the aging population. After the age of 60 years, there is a progressive decrease in urinary creatinine excretion, which largely reflects muscle mass decreases with aging (Fig. 89.5).[9]

There is no consensus on the optimal approach to estimation of GFR in elderly people. Whereas the Modification of Diet in Renal Disease (MDRD) study equation and the Cockcroft-Gault formula for estimating GFR use age in their calculations (see Chapter 3), neither has been validated in people older than 70 years and both underestimate true GFR in those older than 65 years compared with gold-standard techniques. Although the MDRD equation may be more accurate than the Cockcroft-Gault formula,[10] serum cystatin C, which is independent of muscle mass, may be superior to both.[11] A new GFR-estimating equation was derived from patients who were older than 70 years using iohexol clearance as the gold standard. This Berlin Initiative Study equation worked particularly well in classifying patients with CKD stage 2 to 4 kidney function.[12] Most recently, a full age spectrum estimated GFR (eGFR) equation was developed that has improved validity across the full age-spectrum, allowing less bias at the extremes of age and perhaps allowing for improved clinical decision making.[13]

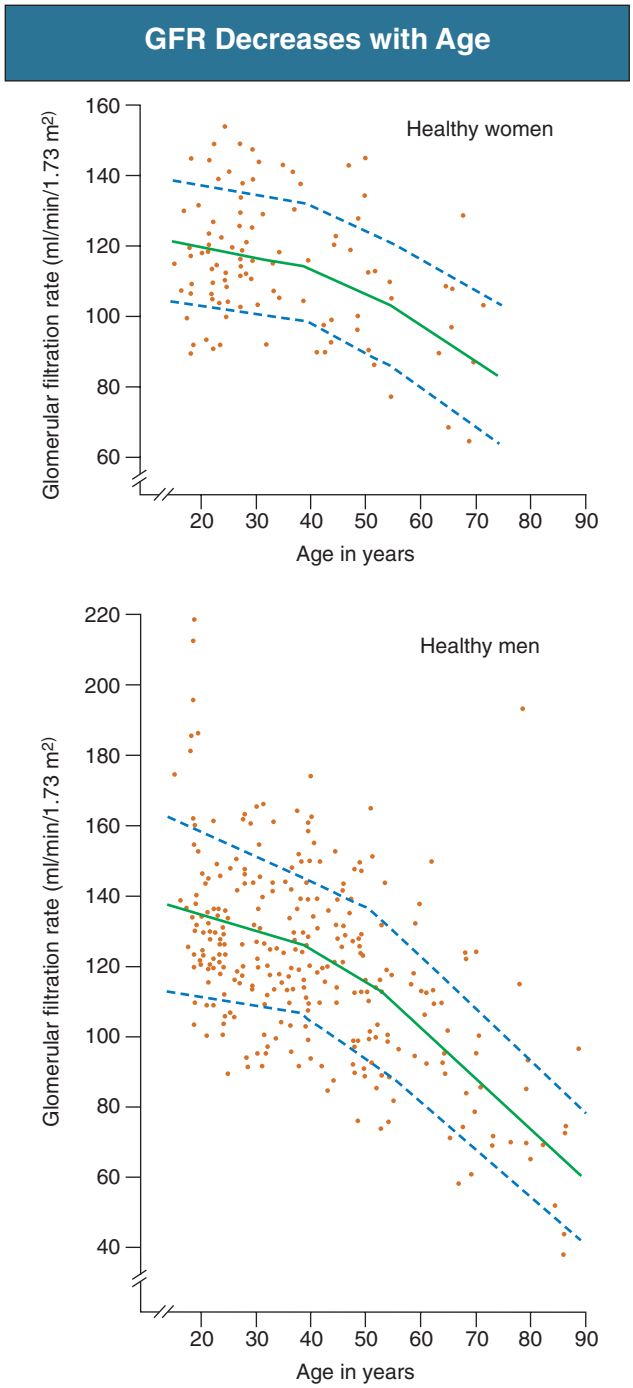

Fig. 89.3 Glomerular filtration rate (GFR) decreases with age. GFR (inulin clearance) begins to fall at age 40 years, and the rate of decline is more rapid in men than in women. (Modified from reference 5.)

Albuminuria

The prevalence of albuminuria increases progressively after the age of 40 years. The increased prevalence is most marked in diabetic and hypertensive patients but is also observed in patients lacking these risk factors; whether age per se is associated with proteinuria is debatable.[14]

Hematuria

Malignant neoplasms of the urinary tract are more common in older patients, and so the diagnostic workup for hematuria in patients aged

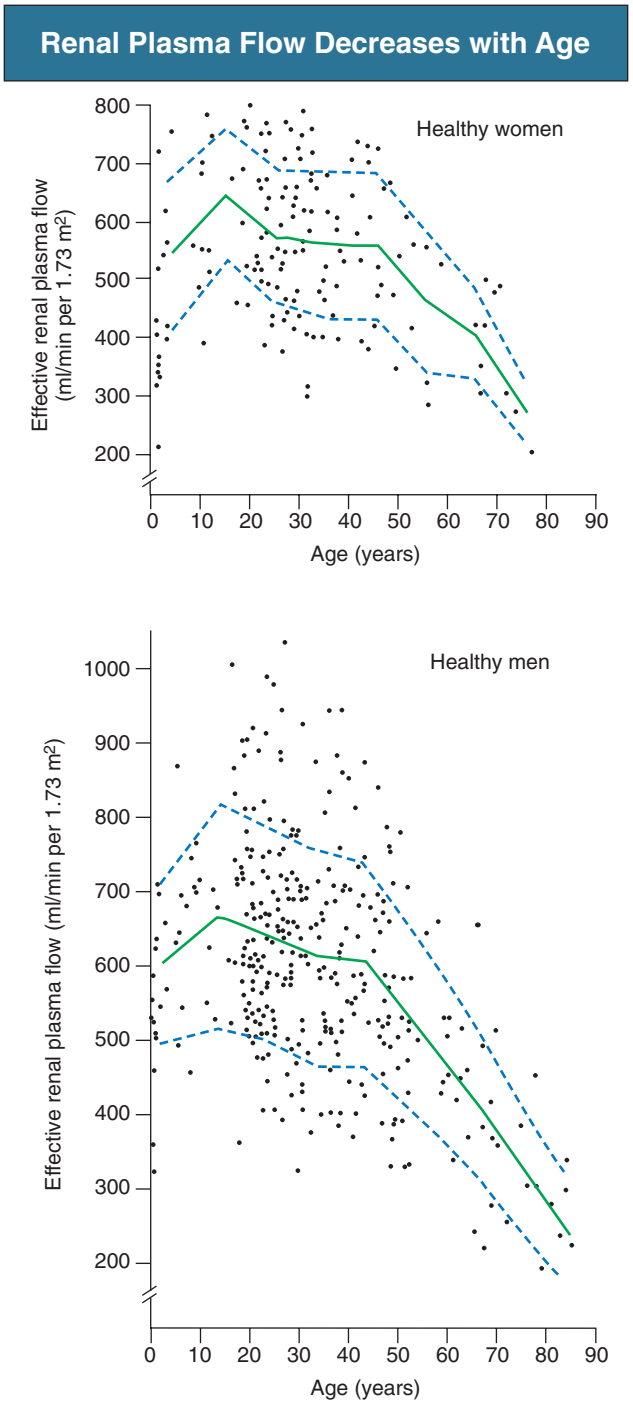

Fig. 89.4 Renal plasma flow (RPF) decreases with age. RPF (*p*-aminohippurate clearance) begins to fall rapidly after the age of 50 years, and the rate of decline is more rapid in men than in women. (Modified from reference 5.)

50 years should include cystoscopy and urinary tract imaging. Renal cell carcinomas (RCCs) are most commonly diagnosed in the seventh decade. RCC is more aggressive in the elderly, and treatment decisions can be difficult, especially in the setting of significant CKD in which nephrectomy may lead to dialysis dependence.[15] However, increased use of biopsy to determine whether a mass lesion is cancer and localized resection of the mass alone or surveillance over time have become more common and the preferred approach to RCC in patients with CKD.

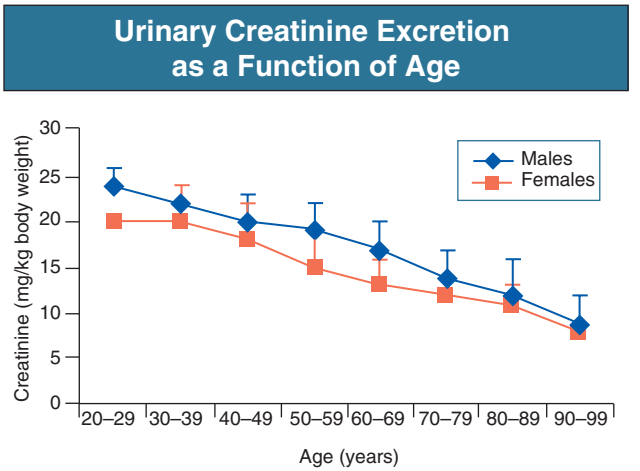

Fig. 89.5 Urinary creatinine excretion (factored for body weight) decreases with age. (Modified from reference 9.)

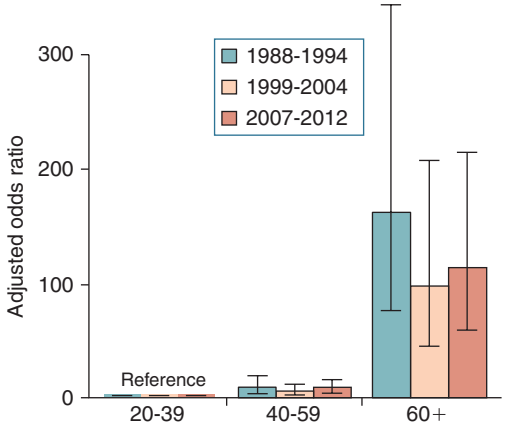

Fig. 89.6 Adjusted odds ratios of estimated glomerular filtration rate less than 60 ml/min/1.73 m² in NHANES participants, by age, 1998-2012. (Data from reference 47.)

Other causes of hematuria may need to be considered, as discussed in Chapter 4.

PREVALENCE OF CHRONIC KIDNEY DISEASE IN THE ELDERLY

According to the U.S, Renal Data System's Annual Data Report and the National Health and Nutrition Examination Survey (NHANES) study, the incidence of CKD is increasing most rapidly in people aged 65 years and older (Fig. 89.6).[16] Importantly, an eGFR of 50 to 59 ml/min/1.73 m² does not increase mortality among patients age 65 years or older compared with patients with eGFR of more than 60 ml/min/1.73 m² and the significance of this mild reduction in eGFR is uncertain among older people.[17] These observations have led to debate about the clinical significance of mild decreases in eGFR among older people and whether the term *chronic kidney disease* in such cases should be replaced with *age-related reduced kidney function.*[18]

RISK FACTORS FOR CHRONIC KIDNEY DISEASE IN THE ELDERLY

The variability in the severity of aging-related renal disease in humans has suggested that there may be specific risk factors for its development

and for declines in GFR greater than would be expected from aging alone. According to a community-based survey, age, annual income, use of oral analgesics, metabolic syndrome, hyperuricemia, and hemoglobin were risk factors for CKD in both elderly and nonelderly patients.[19] In elderly patients, medical history of diabetes mellitus (DM), CKD, stroke, and analgesic use positively correlated with CKD.[24] In another prospective study, increased levels of physical activity correlated with a lower risk for rapid GFR decline (defined as loss greater than 3 ml/min/1.73 m^2 per year, as estimated by longitudinal measurements of cystatin C levels) in a general population of older adults.[20]

PATHOGENESIS OF AGE-RELATED CHRONIC KIDNEY DISEASE

A variety of mechanisms have been proposed for aging-related renal changes (Box 89.1). The kidney is the only known source of the antiaging hormone Klotho. Mice with Klotho deficiency recapitulate features of systemic and renal aging. Klotho is synthesized by the distal nephron and is secreted as a circulating hormone.[21] The mechanisms whereby Klotho (and its deficiency) regulates the aging process are being elucidated in animal models, but this protein may be a future target for antiaging strategies.

Additional mechanisms of renal aging may involve telomere shortening of chromosomal DNA, loss of mitochondria, and accelerated apoptosis. Aging-associated renal disease also may be mediated by activation of the renin-angiotensin system, which may lower renal Klotho expression. Other mechanisms may include hyperfiltration injury and glomerular hypertension as well as vascular changes associated with arteriolar stiffening and higher pulse wave velocity, progressive reduction in nitric oxide production by endothelial cells, progressive capillary loss with ischemia, and accumulation of advanced glycation end-products.[22-26] A more recent finding is that endogenous metabolism of fructose can lead to aging-associated kidney disease because mice deficient in fructokinase did not develop kidney damage with age.[27]

BOX 89.1 Proposed Mechanisms for Aging-Associated Kidney Disease

Hemodynamic
- Glomerular hypertension and hyperfiltration
- Intrarenal activation of renin-angiotensin system
- Endothelial dysfunction (loss of nitric oxide)
- Renal ischemia
- Decreased renalase

Metabolic
- Accumulation of advanced glycation end-products
- Chronic effects of uric acid
- Chronic metabolism of endogenous and exogenous fructose

Cellular dysfunction
- Oxidative stress
- Decreased Klotho
- Senescence (with telomere shortening and loss of mitochondria)

Renal transformation growth factor β (TGF-β) expression

FLUID AND ELECTROLYTES IN AGING

Sodium Balance and Hypertension

Aging is associated with impaired excretion of a salt load and defective conservation in the setting of sodium restriction.[28] Proximal sodium reabsorption is increased in aging, whereas distal sodium reabsorption may be reduced.[29] Because the diet of most individuals in developed countries contains excess sodium (8 to 10 g of salt daily), there is a tendency in the elderly population for total body sodium excess. This relative defect in sodium excretion and increased total body sodium may be predisposing factors for the development of hypertension, the prevalence of which increases with age. After the age of 60 years, most people are hypertensive (Fig. 89.7).[30] Salt sensitivity occurs in more than 85% of aging people, and sodium restriction will result in a significant fall (>10 mm Hg) in mean arterial pressure.[31] Populations that ingest low-sodium diets, such as the Yanomamö Indians of southern Venezuela, do not show an increase in blood pressure with age.[32] Loss of vascular compliance also may contribute to aging-associated hypertension, as may endothelial dysfunction, perhaps mediated by oxidative stress. Aging-associated renal and vascular changes may explain why correction of secondary forms of hypertension (e.g., primary aldosteronism, Cushing syndrome, and renovascular hypertension) is less effective at curing hypertension in older patients. In one study, diastolic blood pressure fell to below 90 mm Hg in 24 of 25 patients younger than 40 years after treatment of the mechanism responsible for the secondary hypertension

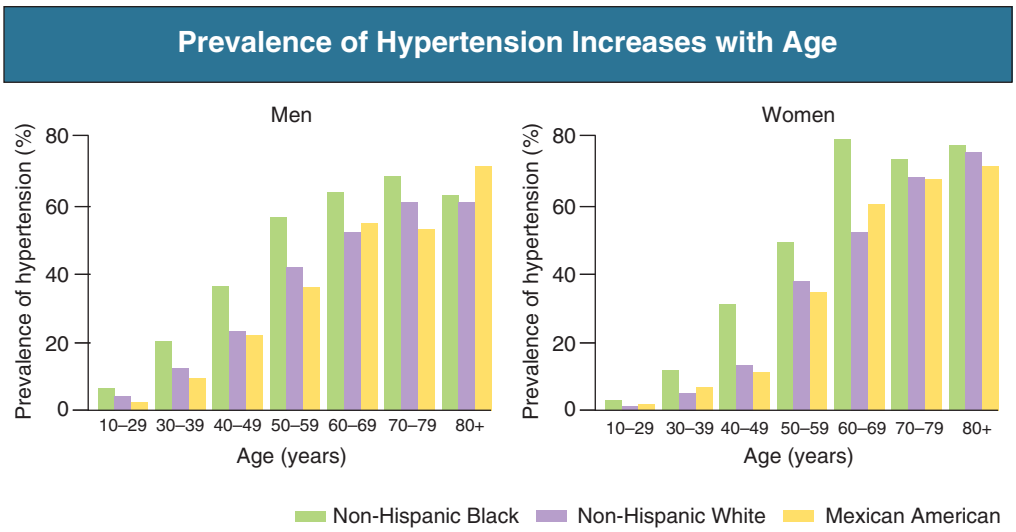

Fig. 89.7 Prevalence of hypertension based on age, gender, and race. (Modified from reference 30.)

but in only 38 of 61 patients older than 40 years.[33] Recent data suggest that treatment of hypertension in the elderly (older than 75 years) should be similar to that in the younger population because treating to a systolic blood pressure (SBP) target of less than 120 mm Hg (compared with an SBP target of less than 140 mm Hg) resulted in significantly lower rates of fatal and nonfatal major cardiovascular events.[34] Reaching these lower BP goals in the elderly may be more difficult, require more medications, and have risk for orthostatic and diastolic hypotension.

Osmoregulation and Water Handling

The most common electrolyte abnormalities in the elderly are the consequence of impaired water handling with aging. Hyponatremia has been found in up to 11% of the ambulatory geriatric population and 5.3% of hospitalized elderly patients.[35] Hypernatremia is found in about 1% of patients older than 60 years admitted to the hospital.[35] Both concentration and dilution of the urine are affected by aging and account for part of the susceptibility to dysnatremias.

In the elderly, the maximal urinary osmolality and thirst response to hyperosmolality are reduced, which may predispose to dehydration and hypernatremia. The impairment in urine concentrating ability results from a defect in the concentrating gradient in the medullary region and can lead to nocturia.[36] Compounding the risk for hypernatremia is that the ill elderly patient may not have ready access to water.

The elderly also have an impaired ability to dilute the urine and thus have a decreased ability to excrete a water load, leading to an increased predisposition to hyponatremia that is often compounded by the use of medications such as thiazide diuretics and selective serotonin reuptake inhibitors.[37] Whether age per se is an independent risk factor for the development of hyponatremia has been questioned, because after adjustment for frailty, the relationship between age and sodium disorders is no longer significant.

Other Tubular Defects and Electrolyte Problems

Potassium excretion is impaired in the elderly, and the transtubular potassium gradient is decreased.[38] Hyperkalemia occurs more frequently in elderly patients treated with drugs that interfere with potassium excretion (such as potassium-sparing diuretics). Other factors contributing to hyperkalemia in the elderly include decreased GFR, lower basal levels of aldosterone, and tubulointerstitial scarring. Hypokalemia is also common because of renal or extrarenal losses.

Most elderly individuals can maintain acid-base balance under normal conditions. However, during conditions of stress when acid production is increased (sepsis or acute kidney injury [AKI]), an inability to excrete an additional acid load may be uncovered. This is supported by a study demonstrating that elderly patients could not increase net acid excretion to the same level as younger adults in response to a protein meal.[39]

Hypercalcemia occurs in 1% to 3% of elderly patients. Causes include malignant tumors, hyperparathyroidism, immobilization, and use of thiazide diuretics. Hypocalcemia is less common and is observed mainly in patients with advanced CKD (in association with vitamin D deficiency and hyperphosphatemia), chronic malabsorption, and severe malnutrition. Hypomagnesemia is reported in 7% to 10% of elderly patients admitted to the hospital; most commonly, this is the result of malnutrition or laxative or diuretic use. Hypermagnesemia is less common and is found primarily in patients with CKD or who are taking large doses of magnesium-containing antacids. Gout (as well as an elevation in serum uric acid levels) is also more common in older people.

ENDOCRINE FUNCTION AND RENAL HORMONES

Elderly women with eGFR below 60 ml/min have lower calcium absorption and lower 1,25-hydroxyvitamin D levels, probably because of diminished conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D by the aging kidney.[40]

The kidney removes about 50% of insulin in the peripheral circulation by filtration and proximal tubular uptake and degradation. The decline of renal function in the elderly leads to a decrease in insulin clearance. This is in part offset by diminished glucose tolerance, which may relate to the increasing frequency of obesity observed in aging individuals. However, the risk for hypoglycemia related to insulin use is increased in the elderly.

CLINICAL MANIFESTATIONS

General Considerations

Aging is associated with declines in renal function that ultimately limit the ability to defend against destabilizing events. Moderate fluid loss (e.g., an episode of diarrhea) and moderate fluid loading (e.g., inappropriate perioperative intravenous fluids) may be poorly tolerated and lead to hypovolemia and fluid overload, respectively. Hypovolemia in those taking multiple medications, including ACE inhibitors, may lead to AKI. Overzealous administration of water as 5% dextrose or 0.45% saline may result in hyponatremia especially in patients taking selective serotonin reuptake inhibitors, which may increase levels of antidiuretic hormone. The use of nonsteroidal antiinflammatory drugs (NSAIDs) in the elderly is associated with increased risk for hyponatremia, hyperkalemia, hypertension, and impaired renal function.

Glomerular Diseases

Elderly patients may have treatable kidney diseases identifiable on renal biopsy.[41] In a study of 235 biopsy specimens in patients older than 80 years, 67% of the patients had treatable lesions.[42] The pathologic spectrum of glomerular disease seen in elderly people is similar to that seen in the general population, although the prevalence of various pathologies differs. For example, diabetic kidney disease is seen with increasing frequency in the aging population. Among patients with nephrotic syndrome who are older than 60 years, membranous nephropathy is the most common diagnosis (32.1% of patients), followed by amyloidosis (typically light chain derived) and minimal change disease (Fig. 89.8).[42] Other important causes of AKI as a result of glomerular disease in the elderly include rapidly progressive glomerulonephritis (GN) resulting from pauci-immune (antineutrophil cytoplasmic antibody-associated) GN (accounting for about 30% of elderly patients with AKI who undergo kidney biopsy).[41] A recently described entity, immunoglobulin G4 (IgG4)-related renal disease is seen with a higher frequency in men older than 65 years.[43] In contrast, certain glomerular disorders, such as lupus nephritis and IgA nephropathy, are uncommon in elderly people. Only 2% of patients with lupus nephritis present after the age of 60 years.[41,42]

Renovascular and Atheroembolic Disease

There is an increased frequency of renovascular and atheroembolic disease with aging. In several case series, AKI resulting from atheroembolic disease accounted for 4% to 7% of cases.[44] Atherosclerotic renal artery stenosis is estimated to be present in about 7% of patients older than 65 years and is a major cause of secondary hypertension, ischemic nephropathy, and CKD in the elderly.[44] In elderly people with hypertension, elevated serum creatinine, and a history of vascular disease, testing for renovascular disease with magnetic resonance angiography or renal artery duplex scanning may be considered (see Chapter 41). Percutaneous transluminal renal angioplasty and renal artery stenting are of variable value in the elderly because many patients have significant arteriosclerosis, which may limit the benefits of intervention.[44] Thus an individualized approach to therapy is warranted.

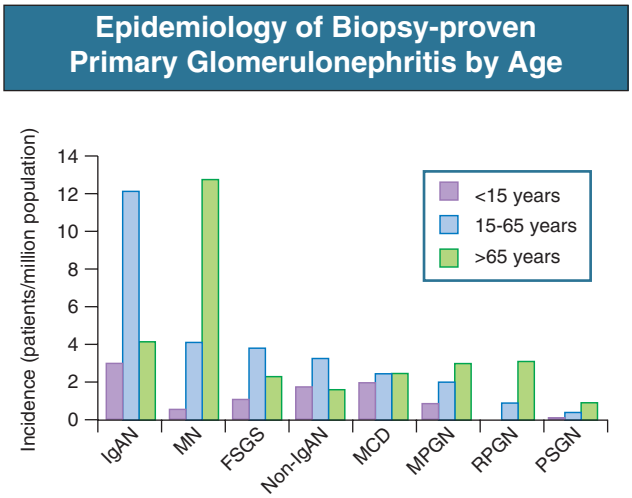

Fig. 89.8 Epidemiology of biopsy-proven primary glomerulonephritis by age. Children presenting with nephrotic syndrome are often treated empirically for minimal change disease (MCD); thus diagnosed MCD is likely underrepresented in data derived from biopsy registries. *FSGS,* Focal segmental glomerulosclerosis; *IgAN,* IgA nephropathy; *MGN,* membranous nephropathy; *MPGN,* membranoproliferative glomerulonephritis; *non-IgAN,* other mesangial proliferative glomerulonephritis; *PSGN,* poststreptococcal glomerulonephritis; *RPGN,* rapidly progressive glomerulonephritis. (Modified from Vendemia F, Gesualdo L, Schena FP, D'Amico G. Epidemiology of primary glomerulonephritis in the elderly. Report of the Italian Registry of Renal Biopsy. *J Nephrol.* 2001;14:340-352.)

Diabetic Nephropathy

DM is a common disease in the elderly; more than half of all diabetic individuals in the United States are over 60 years of age. The prevalence of DM peaks in persons 65 to 74 years of age.[45] Relatively healthy older adults with no major comorbidities may benefit from more intense glucose control (target HbA_{1c} <7%), whereas more lenient targets may be more appropriate for elderly with major comorbidities, established diabetic end-organ damage, or limited life expectancy. The doses of oral hypoglycemic agents and insulin may need to be decreased as the renal function declines, and more so in the elderly, to avoid hypoglycemia and other side effects.[46]

Acute Kidney Injury

Polypharmacy associated with aging greatly increases susceptibility to the development of AKI as a result of drug toxicity.[47] Whereas the causes of AKI in the elderly patient encompass the same spectrum of prerenal, renal, and postrenal causes that are seen in other age groups, the elderly patient has a higher relative risk for developing AKI from obstructive uropathy or sepsis and associated with cancer. Decision making regarding whether to provide active intervention such as with continuous renal replacement therapy (RRT) in elderly patients with AKI and multisystem organ failure will be influenced by comorbidity and the expected likelihood of a good clinical outcome.

Nephrotoxicity and Drug Dosage

Elderly patients are prone to increased nephrotoxicity because they are often administered medicines on the assumption that normal or nearly normal serum creatinine concentration is consistent with normal renal function. Thus the dosage may be inappropriate; it is critical not to rely solely on serum creatinine values for determination of dosages, and eGFR should be used in this regard. Elderly patients with CKD usually are prescribed multiple medications, and this creates a great risk for drug-drug interactions that can be exacerbated when renal clearance is impaired.

End-Stage Renal Disease and Renal Replacement Therapy

The mean age for a patient to initiate RRT is currently over 60 years in the United States and Europe. The mean age of ESRD patients requiring dialysis in most low- and middle-income countries is much lower (32 to 42 years) than that in wealthy countries. In the United States there has been a decline in the incidence of ESRD in patients older than 65 years, with a continued high incidence in those older than 75 years.[48] Despite the frequency of CKD among elderly patients, ESRD is far less common than cardiovascular morbidity or mortality. For example, older patients with CKD stage 3 are more likely to die and less likely to reach ESRD than are their younger counterparts.[49]

The decision to offer RRT should not be based solely on the age of the individual. It is important to recognize that such a decision involving an elderly patient is more complex and fraught with more challenges than in younger patients and requires a multidisciplinary approach that involves family members. Nonmedical barriers may be particularly important in the elderly—for example, limited transportation, family support, and cost. Nursing home patients who began dialysis experienced sharp and sustained declines in their ability to perform basic daily activities.[50] A year after beginning dialysis, 58% of the patients had died and only 13% still functioned at the same level as they had before beginning dialysis. Thus, although dialysis may extend life, it does not necessarily lead to improvements in functional status in older patients. In fact, the increased longevity associated with institution of dialysis may be entirely accounted for by increased days in the hospital without improvements in quality of life.[51]

As with other populations, the survival of arteriovenous fistulas (AVFs) in elderly patients is significantly greater than that of arteriovenous grafts.[52] In fact, successful use of an AVF in the elderly has results similar to those in younger people, with prolonged patencies and low incidence of infections and thromboses, and thus age alone should not preclude AVF creation. Similarly, use of tunneled hemodialysis (HD) catheters is also associated with increased mortality in older HD patients.[52] However, the high prevalence of comorbidities, particularly DM, peripheral vascular disease, and congestive heart failure, usually make vascular access creation more difficult in the elderly. Furthermore, many of these patients may have an insufficient vasculature for fistula maturation. Finally, many fistulas may never be used because of the competing risk for death before dialysis initiation. In these cases, an arteriovenous graft or a central venous catheter becomes a valid alternative form of vascular access. Limitations of HD in the elderly may include their sensitivity to fluid shifts and the presence of significant cardiac dysfunction; hence peritoneal dialysis (PD) may theoretically offer some advantage by offering a slow, sustained degree of ultrafiltration that leads to greater hemodynamic stability. Unfortunately, inherent functional limitations and lack of social support may provide impediments to broader use of PD in the elderly.[53] Studies have demonstrated similar outcomes in elderly patients undergoing HD versus PD.[53] Comprehensive care programs have been designed to support elderly patients to perform PD in their community or at nursing facilities and may offer options to increase the choices patients have regarding treatment options.[54]

Transplantation should be considered in the management of elderly patients with ESRD because selected elderly recipients benefit from renal transplantation by a significant reduction in mortality compared with wait-listed ESRD patients.[55] This survival benefit is most striking for patients with ESRD caused by diabetes or hypertension, but it declines with longer projected waiting times for transplantation. Even when

expanded-criteria donor kidneys are used, a 25% mortality reduction has been shown in those who undergo transplantation compared with those who are wait-listed.[55] Overall graft survival for the elderly transplant patient is similar to that in younger patients.[55] It has been argued that lower doses of immunosuppression are sufficient in elderly renal transplant recipients. However, the Eurotransplant Senior Program, allocating kidneys from donors 65 years or older to recipients 65 years or older regardless of human leukocyte antigen (HLA) matching, found 5% to 10% increased rejection rates in this "old to old" group compared with two better HLA-matched groups, the "old to any" and the "any to old," within the Eurotransplant Kidney Allocation System.[56] In a subanalysis of the Efficacy Limiting Toxicity Elimination (ELiTE)-Symphony study, a large prospective, randomized trial comparing immunosuppressive regimens in renal transplant patients, equal rates of rejection in elderly (60 years or older) versus younger (younger than 60 years) recipients were demonstrated.[57] Furthermore, this subanalysis suggested that older recipients who receive a marginal kidney from an older or expanded-criteria donor may fare worse than younger recipients, with an increased likelihood of death, delayed graft function, graft loss, treatment failure, and reduced graft function.

For those who decide not to pursue RRT, symptomatic therapy (supportive management and palliative care) is an option. This concept underscores the importance of individualizing patient goals with a focus on quality of life. For those with severe functional or cognitive impairment or for whom complications of dialysis have negatively affected their quality of life, dialysis discontinuation is an important consideration. Hospice services remain underused for ESRD patients but may provide an important support mechanism for patients and their families who wish to discontinue dialysis.

Depression in Elderly Patients With Kidney Diseases

Depression is common in older adults with CKD, particularly those with ESRD, and almost 24% of older adults reported depressed mood at the start of dialysis. Progressive decline in cognitive function and sleep disorders were also noted in these adults.[58] Undertreatment of depression in the elderly and in patients with CKD is likely related to the difficulty in diagnosing depression in these patients, given the presence of confounding somatic symptoms that mimic those found in depression. Management of depression in the elderly patient with CKD is similar to that in other patient populations in that both pharmacologic and nonpharmacologic interventions are used.

SELF-ASSESSMENT QUESTIONS

1. An 82-year-old man has a sudden onset of severe lower extremity edema and weight gain (6 kg in 10 days). He has been taking allopurinol for gout prophylaxis, celecoxib for pain associated with osteoarthritis, losartan for hypertension, and metformin for type 2 diabetes. He has smoked half a pack of cigarettes daily for the past 60 years. His blood pressure (BP) is 160/90 mm Hg. Other than the pitting lower extremity edema, the physical examination findings, including findings from a retinal examination, are within normal limits. A chest x-ray examination shows mild emphysematous changes and small bilateral pleural effusions. A urinalysis reveals 4+ protein and 1+ blood. Serum creatinine is 3.6 mg/dl, and serum albumin is 2.1 g/dl. The erythrocyte sedimentation rate is 90 mm/h (Westergren). Blood glucose is 140 mg/dl (nonfasting). Electrolytes show sodium of 132 mEq/l, potassium of 5.5 mEq/l, bicarbonate of 20 mEq/l, and chloride of 98 mEq/l. A renal biopsy is performed. Complete blood count is within normal limits. Which one of the following lesions is *most* likely to be present in the renal biopsy?
   A. Minimal change disease (MCD) with interstitial nephritis
   B. Amyloidosis
   C. Crescentic glomerulonephritis
   D. Membranous nephropathy
   E. Immunoglobulin A nephropathy
2. An 87-year-old woman with hypertensive nephrosclerosis was started on hemodialysis (HD) 3 months ago. Before dialysis initiation, she had significant weight loss and anorexia, with a serum albumin of 2.8 g/dl. Most recently, her appetite has improved and with this her albumin has improved to 3.2 g/dl, with a serum phosphorus of 5.4 mg/dl and a serum calcium of 9.6 mg/dl. She is currently living in a nursing facility and unable to ambulate without assistance. She appears depressed and apathetic and reports that she has little energy and motivation to participate in any exercise. The family has asked you to meet with them to tell them what they can expect for their mother's health in the future. Which *one* of the following statements is correct?
   A. Dialysis will likely continue to improve her energy level and appetite; the family should expect continued improvement over the next few months.
   B. Her inability to ambulate, frailty, and depression will likely not improve with dialysis, and her condition is likely to continue to deteriorate over time.
   C. Home HD should be considered because this modality is associated with improved outcomes in this age group.
   D. Assisted peritoneal dialysis (PD) should be considered as a way to keep the patient at home; this modality is associated with increased survival over in-center HD.
3. A 79-year-old patient who recently started HD for ESRD secondary to drug-induced interstitial nephritis approaches you to discuss his potential for kidney transplantation. His clinical history includes hypertension, mild angina-like symptoms, and hyperlipidemia. He does not smoke and is very active. In your region, the average time for patients with his blood type to be on the wait list is 5 years before transplantation. Which of the following statements would *most* accurately inform the patient with regard to his candidacy for renal transplantation?
   A. He is unlikely to gain any benefit from transplantation because there is a high risk for death in the first year postoperatively in patients older than 75 years.
   B. He would likely benefit from transplantation, and he should consider living donation as the best option.
   C. He should seek transplant listing but not seek a living donor.
   D. He should be advised to avoid going on the extended-criteria donor waiting list.

Approach to Renal Replacement Therapy

Hugh C. Rayner, Enyu Imai, Vijay Kher

The number of patients starting renal replacement therapy (RRT) each year varies enormously across countries (Fig. 90.1). The incidence per million population in most countries has risen steadily over the last decade (Fig. 90.2), although some have seen a decline in recent years (Fig. 90.3). The incidence of RRT is influenced by multiple factors: the incidence and prevalence of diseases that may lead to end-stage renal disease (ESRD), especially diabetes; the ability of health care systems to identify chronic kidney disease (CKD) and to slow progression to ESRD[1]; the level of kidney function at which RRT is commenced; and the availability of resources to provide RRT.

RRT is costly and time consuming; once started, it may continue for many years. All patients likely to reach ESRD, their families, and their caregivers require physical and psychological preparation, including education about future treatment options, given in a form that they find accessible.

PREDICTION OF END-STAGE RENAL DISEASE

Preparation for ESRD treatment requires two things: identification of those patients who are at high risk for reaching ESRD and prediction of the likely time when RRT may be needed.[2]

Diabetes, heavy proteinuria, declining estimated glomerular filtration rate (eGFR) and previous episodes of acute kidney injury make it more likely that a patient will progress to ESRD. Prediction of when someone may need RRT is made easier by a graphical display of eGFR. The trajectory of the eGFR accurately reflects changes in the true GFR over time[3] and is easier to understand than columns of figures (Fig. 90.4). The graph should be shared with patients to help them understand how their disease is progressing. If patients with a declining trend in eGFR are systematically identified, the number of patients initiating RRT without adequate preparation may be reduced and the rising trend in RRT incidence slowed.[1]

MULTIDISCIPLINARY CARE IN ADVANCED CHRONIC KIDNEY DISEASE

Advanced CKD care aims to address several issues: preservation of remaining kidney function; prevention or treatment of complications of CKD; involvement of the patient, the family, and caregivers in making an informed choice in regard to peritoneal dialysis (PD), hemodialysis (HD) and conservative kidney management; creation of dialysis access in good time; and, in appropriate patients, preparation for kidney transplantation ideally before dialysis is started. Patients who receive consistent predialysis care have better outcomes[4] and incur lower health care costs.

Patients need time (often months) to understand and make decisions about dialysis and its implications. The best approach is to transfer patients with a declining GFR to a multidisciplinary team at least 12 months before dialysis is started. The start date can be predicted by extrapolating a trendline of the eGFR forward until it reaches 10 ml/min/1.73 m^2.[5] Using the 12-month prediction rather than an arbitrary value of eGFR to prompt referral avoids elderly patients with slowly declining GFR being referred unnecessarily for dialysis preparation.

The trajectory of the eGFR graph may not be linear; intercurrent illness can cause a sudden drop in GFR and precipitate urgent dialysis in patients at stage 5 CKD. It is therefore prudent to refer all patients for multidisciplinary care once the eGFR reaches 15 ml/min/1.73 m^2.

Predialysis Education Programs

Conventional office consultations with a nephrologist may not enable patients with advanced CKD to gain sufficient knowledge and understanding to make good decisions about RRT.[6] Patients receiving additional care from a predialysis multidisciplinary team have better biochemical results, are more likely to start dialysis in a planned way with less hospitalization, and may even have improved survival rates once they have started dialysis. As well as being good clinical practice, these programs may make good financial sense because the savings in inpatient costs can exceed those required to run the clinics.[7]

Although clinicians are expert in the technical aspects of dialysis and transplantation, patients know best about their own needs and preferences and should be encouraged to share in decision making.

Patient education should follow the principles of adult learning: first, assess the patient's existing level of knowledge and understanding; second, build on this knowledge by delivering appropriate information in an appropriate form; and third, establish that the patient has understood and accepted the information given. Education can be delivered both individually and in groups. In a group education session, patients may learn more from fellow patients than from the group's facilitator. Furthermore, support groups help patients and their relatives appreciate that they are not alone in facing the demands of ESRD.

The team ideally includes a dietician, nurse educator, pharmacist, physical therapist, occupational therapist, social worker, and sometimes a trained peer-support volunteer. A controlled trial in California studied the value of social worker input to the predialysis program in reducing

Geographical Variation in the Incidence of End-Stage Renal Disease

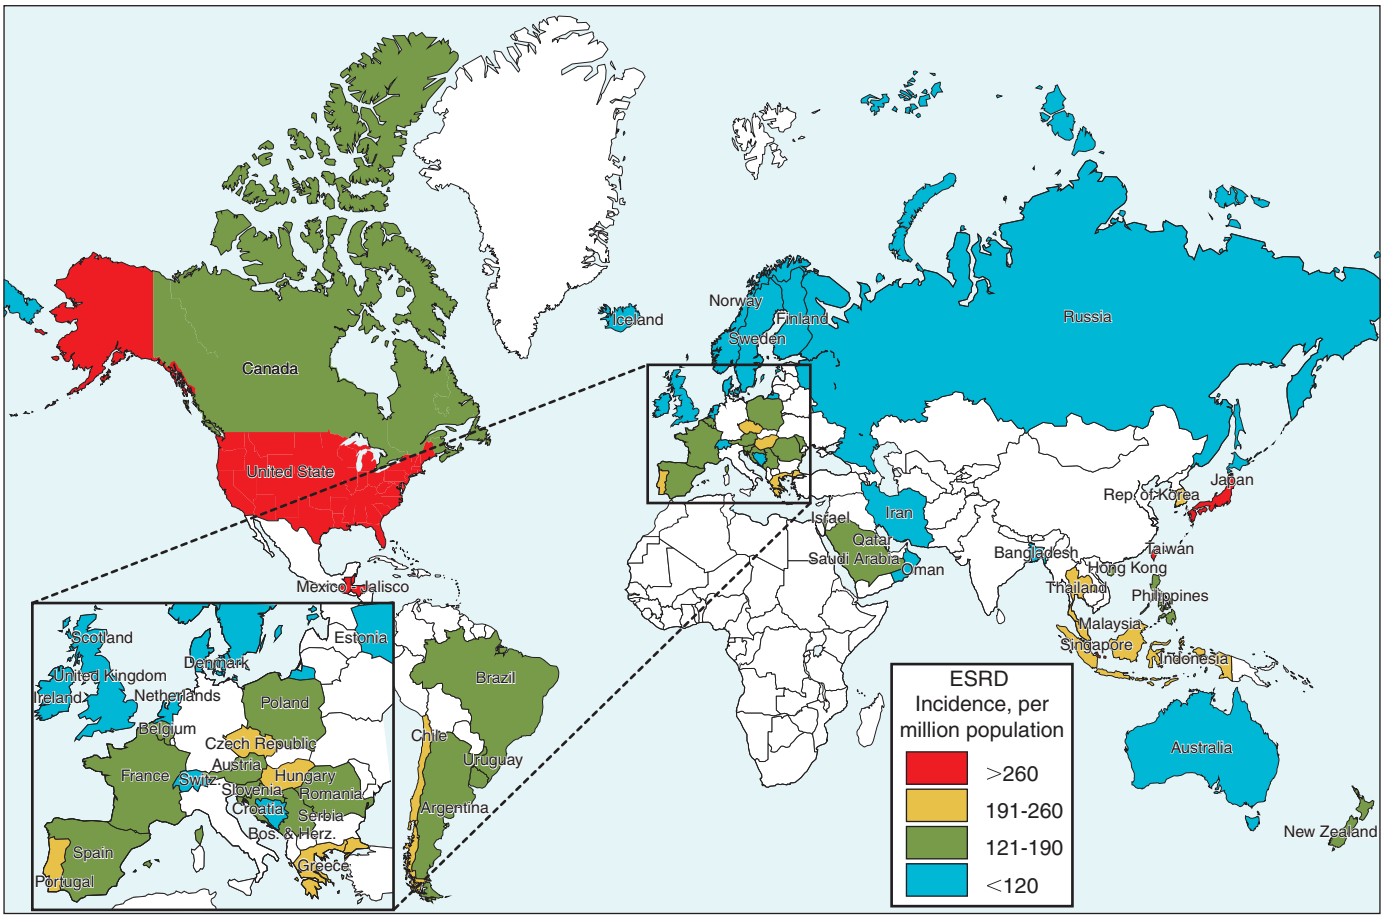

Fig. 90.1 Geographical variation in the incidence of end-stage renal disease (ESRD) per million population, by country, 2013. Data presented only for countries from which relevant information was available. All rates are unadjusted. Data for Indonesia represent the West Java region. Data for France include 22 regions. Data for Spain include 18 of 19 regions. (Data from Special Analyses, U.S. Renal Data System, ESRD Database.)

unemployment.[8] In the intervention group, patients and their relatives met regularly with a licensed social worker both before and after starting dialysis, to explore strategies for continuing the patient's current employment. Blue-collar workers in the intervention group were 2.8 times more likely to continue working. Patients in work had a better quality of life, greater self-esteem, and a more positive attitude to work. Because it is difficult for dialysis patients to regain jobs once they are lost, this result is particularly valuable for the long-term rehabilitation of patients.

Patients should be directed to the wide range of educational materials available. Many national organizations, such as the National Kidney Foundation in the United States (www.kidney.org), provide web-based patient information and produce printed and audiovisual material. Decision aids can help patients think through their options and choose the treatment that suits them best. A good online example is choosing-dialysis.org. Each consultation should be followed by a letter or report, ideally written directly to the patient[9] and copied to the patient's family doctor.

Education About Transplantation

For many, transplantation offers the best prospect for improved survival and quality of life, especially in younger patients. Even in older patients with greater comorbidity, transplantation can improve survival and be cost effective.[10]

The options of transplanting kidneys from a deceased or living donor should be discussed, as well as combined kidney and pancreas transplants for some people with diabetes. Although outcome data from the local transplant center should be made available, published data can be used, such as from the U.S. Scientific Registry of Transplant Recipients (www.srtr.org) or NHS Blood and Transplant in the United Kingdom (www.odt.nhs.uk).

The ideal time for the transplant to be performed is before dialysis has begun—preemptive transplantation. This avoids the need for access surgery and, in most studies, patient survival, graft survival and acute rejection rates are better.[11]

WHEN SHOULD DIALYSIS BE STARTED?

There is no single measure that can be used to determine the right time to start dialysis. A low eGFR, rising serum phosphate, and falling serum bicarbonate may indicate end-stage kidney failure, but these levels are also affected by muscle mass and protein intake. Falling serum albumin may indicate inflammation rather than malnutrition secondary to uremia.

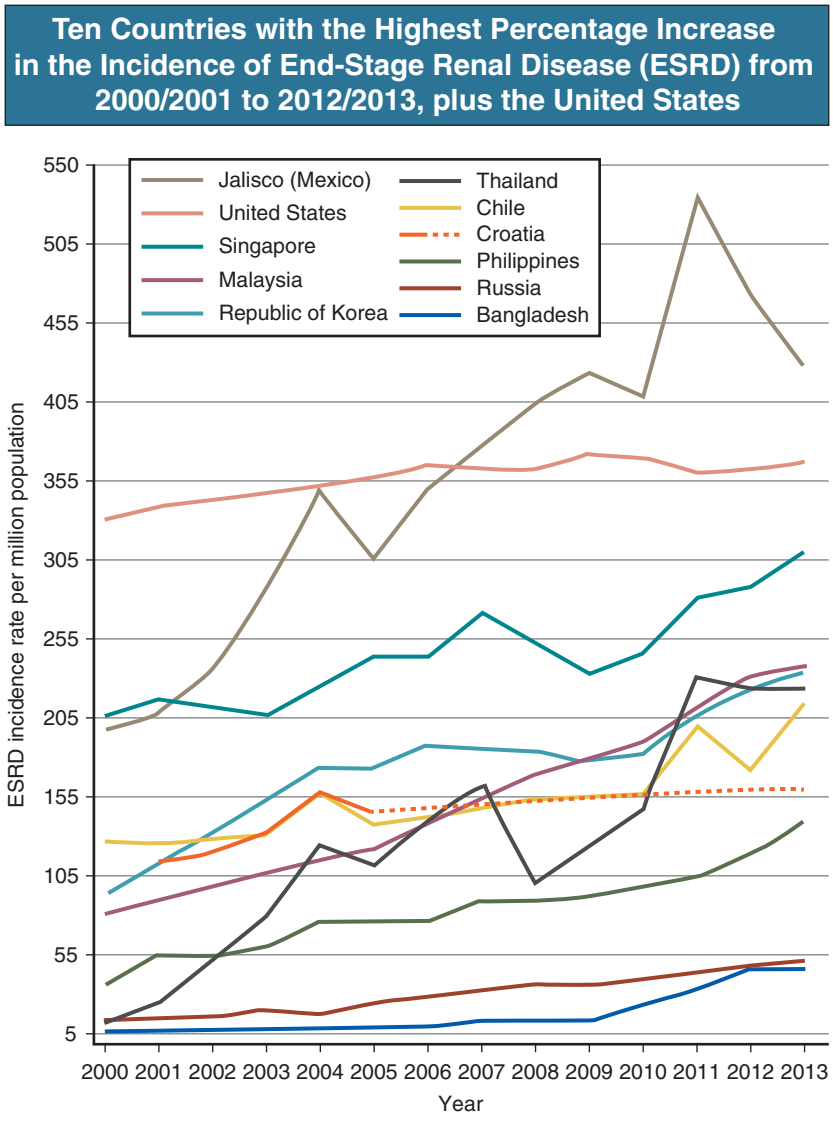

Fig. 90.2 Ten countries having the highest percentage increase in the incidence of end-stage renal disease (ESRD) from 2000/2001 to 2012/2013, plus the United States. All data are unadjusted. Data for Croatia are missing from 2006-2011, indicated by the *dashed line*. Data for United States are shown for comparison purposes. (Data from Special analyses, U.S. Renal Data System, ESRD Database.)

The eGFR at the start of dialysis has steadily increased over recent years and varies across countries. Mean eGFR (in ml/min/1.73 m^2) of Japanese patients at the start of dialysis increased from 5.0 in 1989 to 6.5 in 2007.[12] In the United Kingdom, the mean eGFR at the start of dialysis increased from 6 in 1997 to 8.6 in 2014.[13] In the United States in 1996, 13% of incident ESRD cases started RRT with an eGFR of 10 ml/min/1.73 m^2 or greater. This rose to 43% in 2010 but decreased to 39% in 2015.[14] In the United States, dialysis was started at a consistently lower eGFR within the Department of Veterans Affairs, a non–fee-for-service health system, than with other providers.[15] Aging of the CKD population may have contributed to the earlier initiation of dialysis; in Japan the median age at initiation of dialysis increased from 59 to 68 years between 1989 and 2007.[12]

Limitations of a Purely Clinical Approach to the Initiation of Dialysis

Waiting for uremic symptoms to develop before starting RRT carries the risk that the patient will be malnourished when they start dialysis, with an increased risk for mortality. The chronic nature of progressive kidney disease means that patients may remain unaware of the severity of their illness. Protein intake may fall spontaneously so that symptoms of uremia do not develop, at the expense of a loss of lean body mass. Similarly, patients may gradually reduce their activities as their exercise tolerance declines. Many patients appreciate how ill they had become only once they have rehabilitated on a dialysis program. Lack of awareness can be avoided by questioning the patient for insidious symptoms of uremia. For example, patients should be asked to compare their current eating habits and level of activity with those 6 to 12 months previously. Close friends and relatives may provide a useful third-party view of the patient's well-being.

Limitations of a Purely Laboratory Results–Based Approach to the Initiation of Dialysis

Early initiation of dialysis would need to have proven benefits to justify the additional inconvenience to the patient, risk for dialysis-related complications, and cost. Dialysis treatment has a finite life, either from

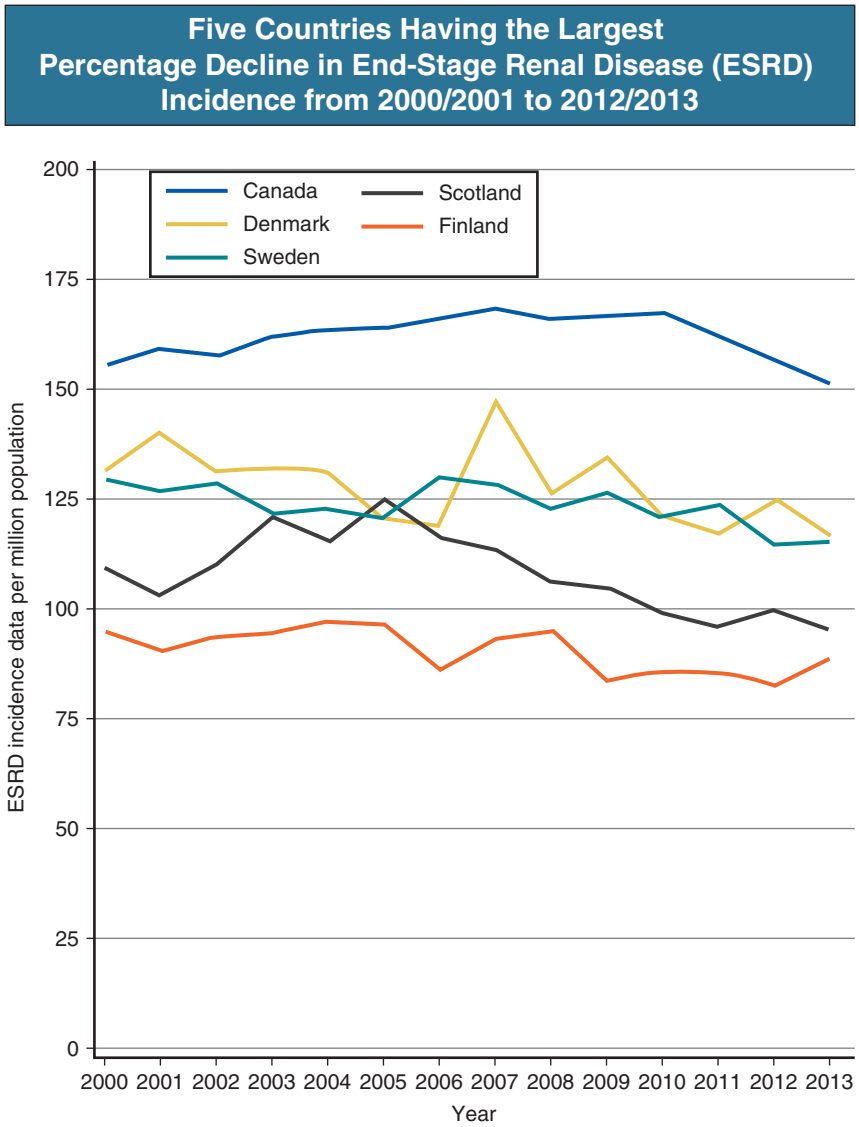

Fig. 90.3 Five countries having the largest percentage decline in end-stage renal disease (ESRD) incidence data from 2000/2001 to 2012/2013. All data are unadjusted. The interpretation and reporting of U.S. Renal Data System (USRDS) data are the responsibility of the author(s) and in no way should be seen as an official policy or interpretation of the U.S. government. (Data from Special Analyses, U.S. Renal Data System, ESRD Database.)

loss of peritoneal function or failure of HD access; thus starting treatment earlier will bring forward the time when further procedures or a change of modality are needed.

Moreover, there is likely to be resistance from many patients to the suggestion that they should start dialysis if they have no symptoms of uremia. Starting dialysis is the first step in a lifelong commitment to RRT, and patients will be asked to comply with a wide variety of inconvenient and sometimes unpleasant treatments. A high level of compliance is required for a successful outcome, and there is concern, particularly in the United States, about the level of noncompliance associated with increased mortality. Commitment to dialysis is likely to be greater if the patient feels better after it has started.

A randomized trial comparing patients who started dialysis at an eGFR of 9.0 ml/min/1.73 m^2 with those who started 6 months later at an eGFR of 7.2 ml/min/1.73 m^2 showed no difference in survival or quality of life (Fig. 90.5).[16] Starting dialysis earlier was not associated with better quality of life and incurred higher health care costs.[17] The one advantage in the earlier-start group was that a higher proportion of those patients who had previously chosen PD actually started dialysis with PD (80% vs. 70%, $P = 0.01$).

Some clinicians advocate an incremental start to HD, using twice rather than three times weekly treatments in patients with sufficient residual kidney function.[18] Less frequent dialysis is popular with patients and may help preserve residual kidney function and prolong vascular access survival. In the developing world, twice-weekly dialysis is often the norm, mostly due to financial constraints. Studies need to be done in these countries to optimize less costly ways of delivering dialysis.[19]

THE CHOICE BETWEEN PERITONEAL DIALYSIS AND HEMODIALYSIS

The mix of PD and HD in the dialysis population varies considerably across countries (Fig. 90.6). Higher expenditure on health care, a larger

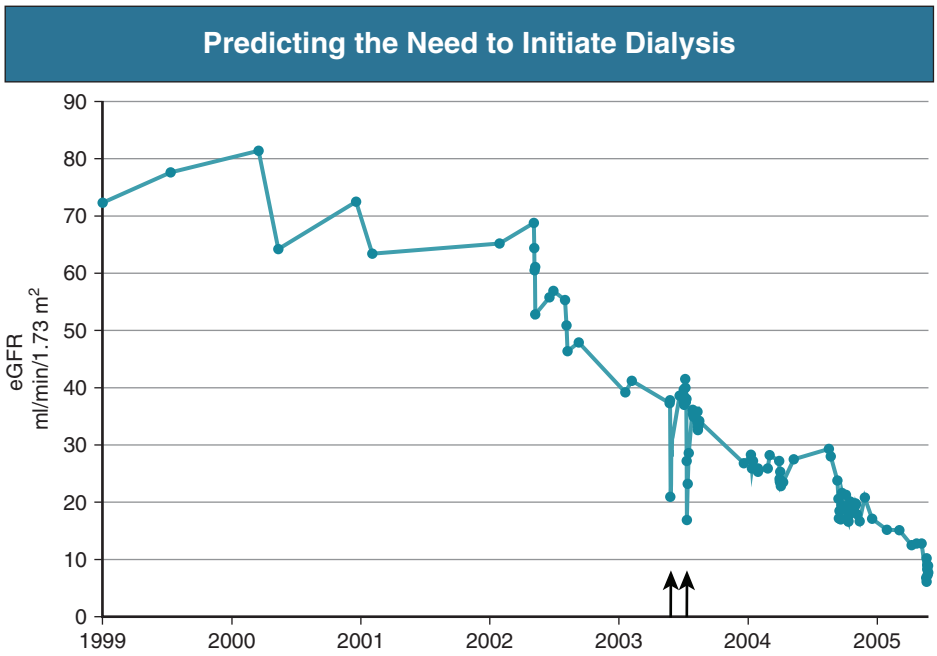

Fig. 90.4 Predicting the need to initiate dialysis. Graph of estimated glomerular filtration rate *(eGFR)* over time for a patient with diabetes and progressive chronic kidney disease. The graph displays sequential eGFR values, telling the story of how the patient's kidney disease progressed. Acute episodes can be distinguished from the underlying chronic progression. 1996: Diabetes mellitus diagnosed. 2000: Blood pressure 196/108 mm Hg and proteinuria detected. 2002: Acute myocardial infarction followed by acute decline in GFR. 2003: Two episodes of radiocontrast-induced acute kidney injury *(arrows)* following a CT scan and a coronary angiogram. 2005: Dialysis started.

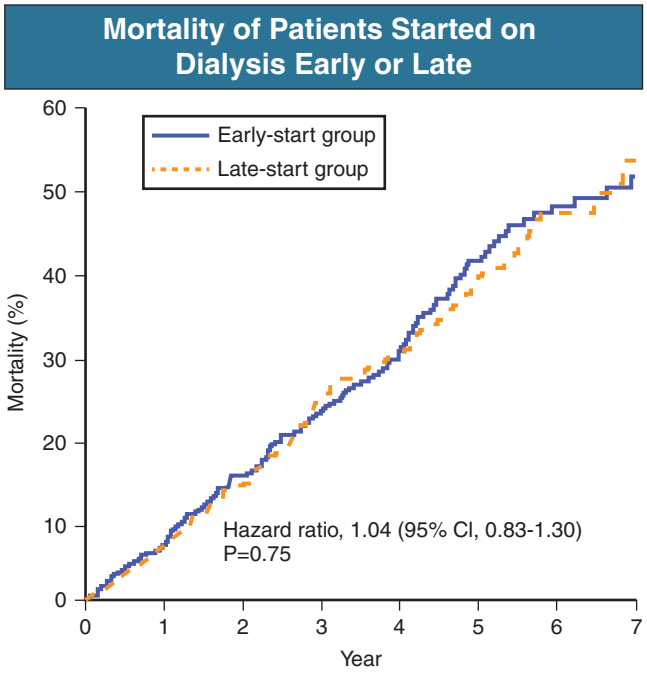

Fig. 90.5 Mortality of patients started on dialysis early or late. Kaplan-Meier Curves for the time to death.[16]

proportion of dialysis units being private-for-profit, and higher costs of PD consumables relative to staffing, as well as the prevalence of diabetes, are associated with a higher proportion of patients having HD.[20]

Most patients with ESRD are suitable for treatment with either PD or HD. How should one choose between the two? Ideally we would apply evidence from a randomized clinical trial (RCT) of PD versus HD. Variations in the way PD and HD are delivered make designing a balanced comparative trial difficult. One attempted RCT, the Netherlands Cooperative Study on the Adequacy of Dialysis (NECOSAD) study had to be stopped because of low recruitment. Retrospective and prospective nonrandomized comparative studies have failed to indicate a consistent survival advantage for either modality. There is some evidence that PD may be inferior to HD over the longer term in patients with coronary heart disease and congestive heart failure.[21] This contradicts a commonly expressed opinion that PD is more "gentle" for such patients by avoiding rapid fluid shifts and causing less ischemic "stress" on the heart. Change in treatment from PD to HD is associated with an increased risk for hospitalization and mortality, especially when this is unplanned. Patients having PD for longer than 7 years are at an increased risk for encapsulating peritoneal sclerosis, which may prompt a planned change to HD.

Contraindications to Peritoneal Dialysis

There are a few situations in which PD is contraindicated (Box 90.1). Relative contraindications to PD include those discussed in the following section.

Fresh Intraabdominal Foreign Body

Patients with prosthetic aortic grafts have been successfully treated with PD. HD is usually used for up to 16 weeks to allow the graft to be covered with epithelium and so avoid the risk for graft infection via peritoneal dialysate. However, this risk must be balanced against that of bacterial seeding from the patient's HD access.

Body Size Limitations and Intolerance of Intraabdominal Fluid Volume

Body size can be a problem at both ends of the spectrum. Small patients may be intolerant of the volume of dialysate needed to achieve adequate

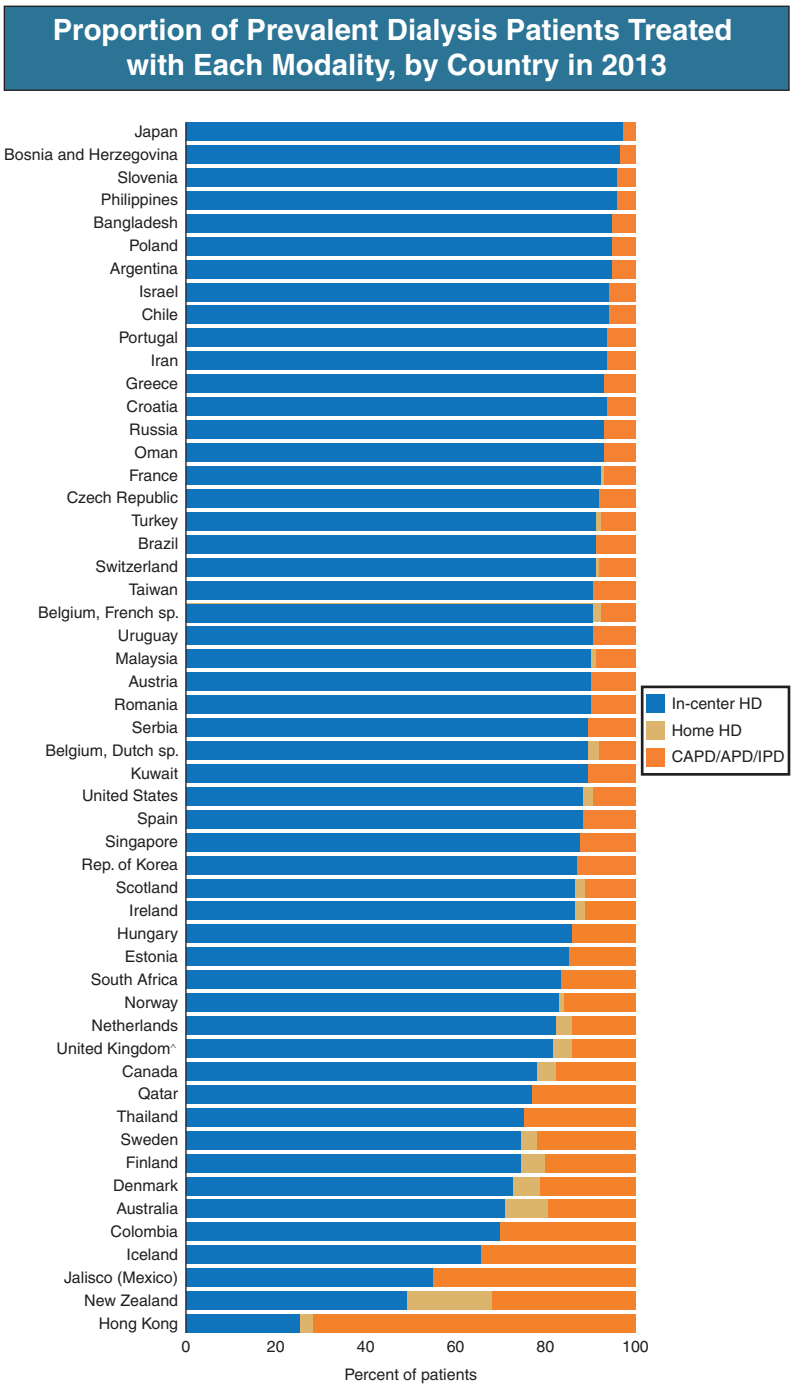

Fig. 90.6 Distribution of the percentage of prevalent dialysis patients using in-center hemodialysis *(HD),* home HD, or peritoneal dialysis (PD) 2013. Denominator is calculated as the sum of patients receiving HD, PD, or home HD; does not include patients with other/unknown modality. ^United Kingdom: England, Wales, and Northern Ireland (Scotland data reported separately). Data for Spain include 18 of 19 regions. Data for France include 22 regions. Data for Belgium do not include patients younger than 20. *APD,* Automated peritoneal dialysis; *CAPD,* continuous ambulatory peritoneal dialysis; *ESRD,* end-stage renal disease; *IPD,* intermittent peritoneal dialysis; sp., speaking. (Data were supplied by the U.S. Renal Data System.)

dialysis, particularly if they have negligible residual kidney function. Alternative methods of fluid exchange such as automated PD (APD) can be used to overcome this limitation. Larger dwell volumes or APD are required to achieve adequate solute clearance and ultrafiltration in patients with a body mass index greater than 35 kg/m^2. Discomfort as a result of increased intraabdominal volume can be significant in patients with chronic respiratory disease, low-back pain, or large polycystic kidneys. In general, it is hard to predict a patient's tolerance of intraabdominal fluid and so these limitations usually appear after a patient has started PD.

Bowel Disease and Other Sources of Infection

The presence of ischemic bowel disease, inflammatory bowel disease, or diverticulitis is likely to increase the incidence of peritonitis caused

BOX 90.1 Contraindications to Dialysis Modalities

Peritoneal Dialysis

Absolute

- Loss of peritoneal function producing inadequate clearance
- Adhesions blocking dialysate flow
- Surgically uncorrectable abdominal hernia
- Abdominal wall stoma
- Diaphragmatic fluid leak
- Inability to perform exchanges in absence of suitable assistant

Relative

- Recent abdominal aortic graft
- Ventriculoperitoneal shunt
- Intolerance of intraabdominal fluid
- Large muscle mass
- Morbid obesity
- Severe malnutrition
- Skin infection
- Bowel disease

Hemodialysis

Absolute

- No vascular access possible

Relative

- Difficult vascular access
- Needle phobia
- Cardiac failure
- Coagulopathy

(Modified with permission from *American Journal of Kidney Disease* 2006;48[Suppl 1]:S91-S97. Clinical practice guidelines for peritoneal adequacy, update 2006. PD Adequacy 2006 Work Group.)

by organisms passing through the bowel wall into the peritoneum. Abdominal wall infection may lead to peritonitis via the exit site and catheter tunnel.

Screening for methicillin-resistant *Staphylococcus aureus* (MRSA) before all elective surgical procedures is good practice. Clearance of nasal *S. aureus* with topical mupirocin cream reduces the risk for staphylococcal infection at the exit site.

Severe Malnutrition or Morbid Obesity

Severe malnutrition may lead to poor wound healing and leakage from the catheter tunnel. In addition, peritoneal protein losses during dialysis may exacerbate hypoalbuminemia. At the other end of the spectrum, it may prove difficult to satisfactorily place a peritoneal catheter through the abdominal wall in patients with morbid obesity and the risk for infection is greater. Thereafter, absorption of glucose from the dialysate, which may average as much as 800 calories per day, may contribute to further weight gain.

Contraindications to Hemodialysis

Contraindications to HD are few (see Box 90.1). As discussed in Chapter 91, access to the circulation usually can be obtained, even in patients with extensive vascular disease or previous surgery. An aversion to needle puncture of the atrioventricular fistula (AVF) is common in the early stages but usually can be overcome by careful use of local anesthetic and nursing encouragement. Severe coagulopathy may make management of anticoagulation for the extracorporeal circuit difficult.

HOME HEMODIALYSIS

In the 1960s, maintenance dialysis was mostly done by the patient and the family at home. Because in-center HD programs were established and then PD became available, patients could choose not to have HD at home. This removed the burden of dialysis from the patient and family and avoided the cost of installing a dialysis machine with its associated water treatment. In the United Kingdom the percentage of the dialysis population having home HD fell from 35% in 1984 to 2% in 2005.

However, home HD can provide significant benefits; it removes the inconvenience of traveling to and from the dialysis facility, gives patients the freedom to dialyze at a time that suits them, and reduces the cost of nursing and support staff. Although there is no RCT comparing hospital and home HD, comparative studies in which correction has been made for differences in comorbidity suggest that patients on home HD have lower morbidity and mortality than in-centre HD and PD.[22]

Patients at home often perform more than three treatments per week, and some dialyze overnight. More frequent dialysis significantly reduces the time taken to recover after each treatment, reduces dietary restrictions and antihypertensive medications, and leads to improved quality of life and reduced mortality.[23]

Over recent years there has been increasing recognition of the benefits of home HD, and, along with better technology, this has increased nephrologists' enthusiasm for it,[24] leading to a growth in the proportion receiving home HD in the United Kingdom to 4.2% in 2015.[13] Canada, Denmark, and Finland also have had significant increases, and in 2013 the proportion of patients on home HD in New Zealand was 18.4% (see Fig. 90.6).

Hemodialysis or Hemodiafiltration

Hemodiafiltration (HDF) is increasingly used throughout Europe and elsewhere but is not available in the United States because of regulatory restrictions. HDF adds the removal of fluid containing larger molecules by convection to the clearance of smaller molecules by diffusion. For example, β_2-microglobulin levels are lower in patients treated by HDF than by HD. In this way, HDF theoretically mimics glomerular filtration more closely and potentially may benefit ESRD patients with little or no residual kidney function.

A number of trials comparing outcomes with HD and HDF have been conducted, yielding conflicting results (see Chapter 94). Evidence suggests that high convection volumes (>30 l/week/m^2) need to be removed and replaced to deliver better patient outcomes.[25]

PATIENT CHOICE OF HEMODIALYSIS OR PERITONEAL DIALYSIS

Ideally all patients entering the ESRD program would be given "modality-neutral" counseling and allowed to select their preferred mode of treatment. When this was done in a U.K. center, about 45% of patients without a medical contraindication to PD selected PD.[26] Independent predictors for choosing PD include being married, being counseled before the start of dialysis and increasing distance from the base unit, and predictors for choosing HD are increasing age, comorbidity, and male sex. However, although 45% of patients may choose PD, not all of them start dialysis on this modality. Patients who require urgent dialysis often receive HD rather than PD, although PD can be started urgently if the necessary resources are available.[27] Once started on HD, only a small proportion of patients transfer to PD, even if this was their original preference. Patients presenting late for dialysis should still have access to an education program about their options for long-term treatment.

Frail patients can be assisted to have PD at home by a spouse, family member, or trained assistant. This can avoid the burden of in-center HD and improve quality of life,[28] and patients may progress to independent PD after a month or two of assistance.

The major differences in dialysis modality across countries (see Fig. 90.6) suggest that the type of dialysis patients receive is more often determined by physicians and organizational factors rather than by patients, as discussed in the following section.

Economic Factors

The arrangements by which doctors and dialysis facilities are reimbursed for the cost of providing treatment vary widely around the world, and

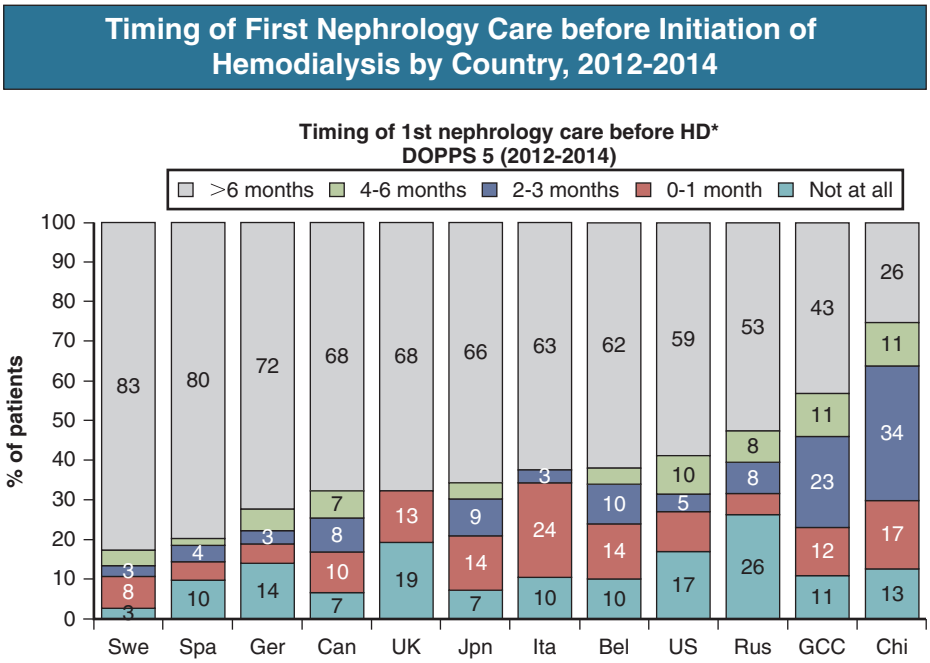

Fig. 90.7 Country differences in timing of first nephrologist care before starting dialysis among patients enrolled in the Dialysis Outcomes and Practice Patterns Study (DOPPS) within 60 days of starting dialysis (2012-2014). Data were calculated among patients on dialysis for <60 days at the time of enrolment in the DOPPS study. *Swe,* Sweden; *Spa,* Spain; *Ger,* Germany; *Can,* Canada; *Jpn,* Japan; *Ita,* Italy; *Bel,* Belgium; *Rus,* Russia; *GCC,* Gulf Cooperation Council countries; *Chi,* China. there is wide variation in the relative levels of payment for HD and PD. These factors have a profound effect on the mix of dialysis modality within a country.[29] PD is generally less expensive than HD,[30] and some countries, such as Hong Kong, have a deliberate "PD first" policy.[31] In the United States, assisted PD is not reimbursed and so is available only if the patient or the family organizes the assistance. In HD facilities, if payment depends on the number of patients being treated, there will be an incentive to increase patient numbers and fill any unused capacity, especially if the nephrologist has a financial interest in the facility.

Physician Preference

In the past, there has been a clear preference among physicians for HD. When surveyed in 1996, a much greater proportion of U.S. patients on HD than on PD thought that the choice had been made by the medical team rather than either by themselves or by joint decision. Ten years later, only 61% of U.S. dialysis patients remembered having PD discussed with them before they started dialysis. Best practice guidelines emphasize the ethical, and in many countries legal, imperative to advise patients of all their treatment options.[32]

THE IMPORTANCE OF DIALYSIS ACCESS

Before starting dialysis, every patient would ideally have made an informed choice between PD and HD after weeks or months of counseling and preparation, and those choosing HD would have a functioning AVF. Sadly, dialysis is frequently started in less than ideal circumstances. The percentage of patients presenting shortly before starting dialysis varies between dialysis units and countries (Fig. 90.7). This is a particular issue in the United States, where in 2015 36% of new ESRD patients had received little or no nephrology care before beginning therapy.[14]

Patients presenting to a nephrologist shortly before starting dialysis have a longer initial hospital stay and a higher incidence of major complications and death.[4] Late presentation is one reason why HD is started using a catheter rather than an AVF (Fig. 90.8) and a significant part of the increased mortality is related to this.

The timing of AVF placement is complex.[33] If an AVF is created many months before the patient is predicted to reach ESRD the chances that a catheter is used will be reduced. However, elderly patients may die without the AVF ever being used. International data from the Dialysis Outcomes and Practice Patterns Study show that the risk for death is higher for patients dialyzing in units that use central venous catheters in a high proportion of their patients.[34] The risk is also increased if arteriovenous grafts are commonly used. Catheters can cause complications such as infection, pulmonary embolism, and central venous stenosis.

There is wide variation across countries in the time required for permanent access to be created and used. If a fistula can be created swiftly and used as soon as it is mature, perhaps after only 2 weeks, the need for a catheter may be avoided. Details of HD access surgery are discussed in Chapter 91 and PD catheter placement in Chapter 96.

THE DECISION WHETHER TO OFFER RENAL REPLACEMENT THERAPY

The Availability of Dialysis Facilities

Because of its high cost, RRT is not available to most people with ESRD worldwide. The practice of rationing dialysis has been candidly documented in a report from a South African center[35] in which more than half the patients with ESRD assessed between 1988 and 2003 were not offered dialysis. Socioeconomic factors such as age, race, employment, and marital status outweighed medical factors in the decision to begin treatment.

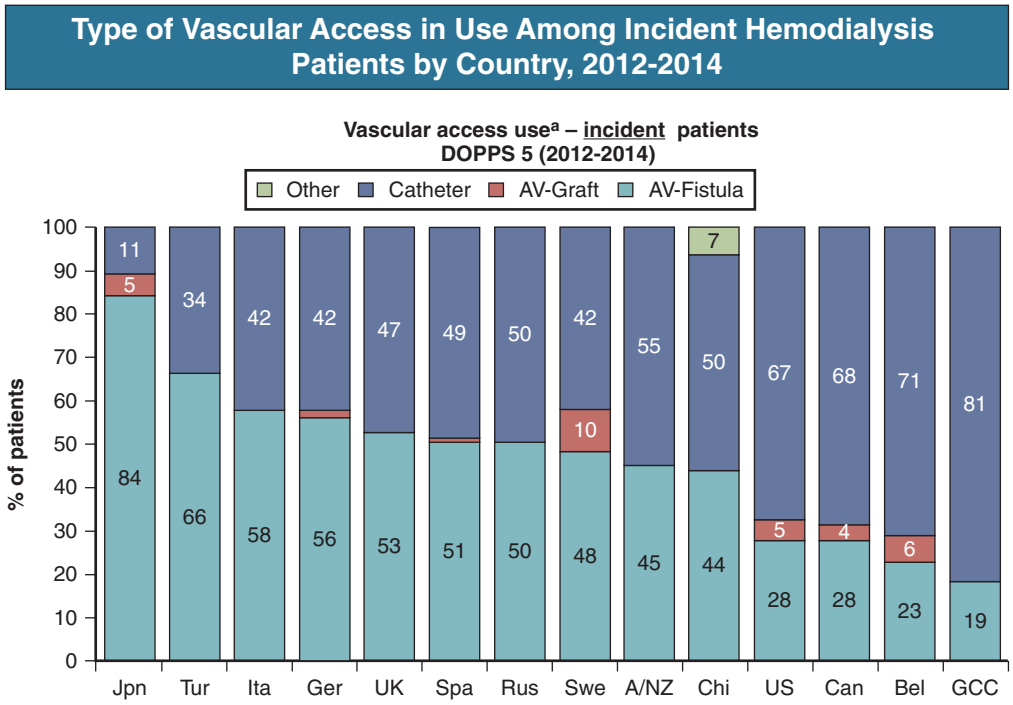

Fig. 90.8 Country differences in type of vascular access in use among incident hemodialysis patients participating in the Dialysis Outcomes and Practice Patterns Study (DOPPS) within 60 days of starting dialysis (2012-2014). Data were calculated among patients on dialysis for <60 days at the time of enrolment in the DOPPS study. *Jpn,* Japan; *Tur,* Turkey; *Ita,* Italy; *Ger,* Germany; *Spa,* Spain; *Rus,* Russia; *Swe,* Sweden; *A/NZ,* Australia/New Zealand; *Chi,* China; *Can,* Canada; *Bel,* Belgium; *GCC,* Gulf Cooperation Council countries. (Reproduced from Pisoni et al. *Am J Kidney Dis.* 2015;65(6):905-915, with permission.)

The phenomenon of "supply-sensitive care" applies to dialysis as it does to health care in general.[36] RRT incidence is independently associated with a country's gross domestic product (GDP), the percentage of GDP spent on health care, and the reimbursement rate relative to GDP for HD dialysis facilities. In more developed countries, those with a greater proportion of private for-profit facilities have a higher incidence of dialysis.[37]

Selection of Patients by Physicians and Nephrologists

Although incidence rates of RRT in most countries have increased over recent decades (see Fig. 90.2), not all of this is due to more patients developing ESRD.[38] In other words, physicians have become more willing to offer dialysis to patients with ESRD. The practice of starting dialysis in patients who are very elderly or dependent on others for their care or who have multiple comorbid conditions varies significantly across countries and among nephrologists within those countries. For example, in 2005 the percentage of patients who were living in a nursing home or who were unable to eat independently within 90 days of starting dialysis was much higher in the United States (11.6%) and Japan (19.2%) than in France (1.3%), Germany (6.4%), Italy (4.7%), Spain (2.0%), and the United Kingdom (1.5%).[39] Severe cognitive impairment in a patient would much more strongly influence a nephrologist in the United Kingdom not to start dialysis than in the United States. Furthermore, nephrologists in the United States were much more likely than those in the United Kingdom and Canada to start dialysis in patients with dementia or in a persistent vegetative state, if pressured to do so by family members. In Japan in 2010, dementia severe enough to require care was present in 9.9% of chronic dialysis patients. Fear of litigation was particularly influential in persuading nephrologists to offer treatment.

Rationing Versus Rational Dialysis Treatment

How dialysis should be used has raised a range of bioethical issues over the years.[40] In the 1960s, committees would meet to decide who should be offered dialysis, on the grounds that the greatest good should be derived from the limited resources available. Patients who were expected to survive for only a few months would not be offered dialysis. As resources became more widespread, a rationing approach became unacceptable and was replaced by decisions based on the balance of benefit and harm gained from dialysis for each individual.

Predictive Factors

Are there objective criteria that can be applied to identify patients for whom the harms of dialysis will outweigh the benefits? One criterion to be dismissed is age. Although advanced age was used as a simple exclusion criterion in the early days of dialysis, the elderly are now the most rapidly growing section of the dialysis population.

A Canadian study of patients starting dialysis[41] used a comorbidity scoring system to quantify factors likely to predict early death. The predictive value of this scoring system was compared with the value of an estimate made by the patient's nephrologist of the probability that the patient would die within 6 months. It was not possible to predict early death accurately using either the comorbidity scoring system or the clinician's opinion. Indeed, it was impossible even to identify the small proportion of patients with a very poor prognosis. Clinicians were more accurate than the scoring system in identifying patients with less than a 50% risk for death by 6 months, but they tended to overestimate the risk for death in the worst prognostic groups. For example, 30% of patients whose predicted probability of death was considered to be 80% or greater survived for more than 6 months.

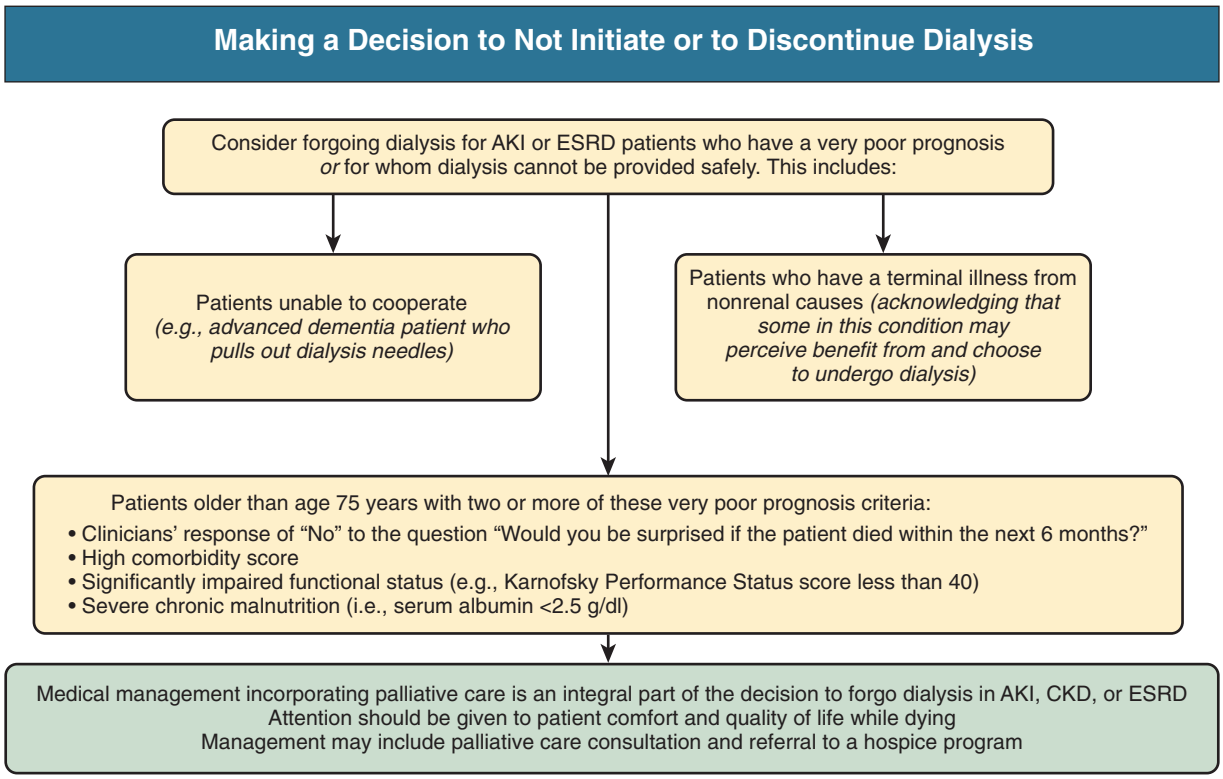

Fig. 90.9 Making a decision to not initiate or to discontinue dialysis. *AKI,* Acute kidney injury; *CKD,* chronic kidney disease; *ESRD,* end-stage renal disease.

ADVISING PATIENTS ABOUT PROGNOSIS ON DIALYSIS

Despite these uncertainties, an individual patient should be given an estimate of his or her likely future on dialysis. The Renal Physicians Association (RPA) has suggested the following criteria to help identify patients over 75 years of age who have a poor prognosis on dialysis[42]: (1) clinicians' response of "No, I would not be surprised if my patient died in the next 6 months"; (2) high comorbidity score; (3) significantly impaired functional status (e.g., Karnofsky Performance Status score less than 40); and (4) severe chronic malnutrition (i.e., serum albumin less than 2.5 g/dl using the bromocresol green method). Quality of life is also strongly predictive of mortality, even after statistical correction for these comorbid factors.

For patients whose prognosis is particularly uncertain, or where there is disagreement between the views of the patient and the dialysis team, a time-limited trial of dialysis may be offered. This may give the patient and family a better understanding of what life on dialysis entails and allow time for further discussion between all parties. The duration of the trial should be judged for each individual, and clinical and biochemical parameters such as serum albumin reviewed regularly.

The RPA in the United States has issued guidelines for decisions to not initiate or to discontinue dialysis (Fig. 90.9) and provide a comprehensive toolkit to support shared decision making.[42]

CONSERVATIVE KIDNEY CARE

Conservative kidney care describes the care of patients with ESRD using all necessary and acceptable treatment apart from dialysis. It is increasingly adopted for a subset of patients with ESRD and multiple comorbidities.[43] There is a lack of high-quality evidence to inform discussions about conservative care as an alternative to dialysis. This matters because information provided by clinicians has a strong influence on the beliefs held by patients about their likely outcomes on dialysis or with conservative care.[44]

Most people would agree that patients who are certain to have an unacceptable quality of life should not be subjected to the discomfort of HD. Patients choosing conservative kidney management are spared surgical procedures and the inconvenience and discomfort of traveling to the dialysis unit. Depending on age and the number of comorbidities, survival with dialysis may be no longer, and much of any additional time is made up of days having or recovering from dialysis treatments.[45] Quality of life will be better without dialysis, and more are likely to die at home.

Many of the symptoms and complications of ESRD, such as anemia, acidosis, pruritus, insomnia, depression, fluid overload, and hypertension, can be treated with medication and diet. Patients may not report symptoms such as pain that they do not associate with kidney failure and so should be asked specifically about them. Itching and insomnia are common and, when severe, usually can be relieved by low doses of gabapentin or pregabalin.[46]

Conservative therapy is best delivered by the specialist predialysis multidisciplinary team and should include a dietitian, a social worker, psychological support, and a link to palliative care specialists.

THE PATIENT WHO DOES NOT WANT DIALYSIS

Nephrologists may be presented with the dilemma of a patient who has decision-making capacity and whom they would normally treat but who does not wish to have dialysis. From an ethical viewpoint, a

patient's decision not to start dialysis or to discontinue it is justified on the principle of individual autonomy. Legally, in the United Kingdom this is based on the individual's common-law right to self-determination and in the United States on the constitutional right of liberty. Where the patient is able to express a clear wish, the physician is obliged to respect this because to treat a patient against the patient's will constitutes an assault.

The physician must nonetheless ensure that all reversible factors have been addressed, such as unfounded fears about what dialysis will entail or a depressive illness affecting the patient's judgment and ideally request a psychiatric evaluation. It is not uncommon for patients to express a strong desire not to have dialysis, particularly if they are relatively asymptomatic, only to change their mind when they become more symptomatic. At this late stage, the basic "will to survive" comes to the fore. An advance directive not to have dialysis written by the patient should never be held as a reason against a change of mind.

DISAGREEMENT ABOUT A DECISION TO DIALYSE

There will inevitably be differences of opinion about the harms and benefits of dialysis to individual patients. Dialysis nurses may disagree with the nephrologist's decision to treat a patient. If the dialysis nurses and doctors are functioning well as a team, they should feel able to express these reservations and have the issue adequately discussed. It is demoralizing for staff to feel pressured into giving treatment they believe to be inappropriate.

The nephrologist may remain reluctant to offer dialysis despite the insistence of either the patient or, more often, the patient's family or caregivers, the legal agent, or another doctor (see Fig. 90.9). Dialysis must never be given if it is against the patient's clearly expressed wishes, despite the insistence of others. However, if the patient insists on treatment against the nephrologist's advice, dialysis usually should be given while a resolution is reached.

Extensive discussions and explanations of the treatment options and prognosis may be needed to gain a better understanding of the reasons behind the differing views. Helpful advice may be obtained from another physician, particularly the patient's family doctor, who will have a broader understanding of the patient's circumstances. It may be appropriate to involve a psychologist, social worker, or religious counselor.

It may be necessary to refer the case to a formal ethics committee, if one exists locally, to clarify the issues of disagreement and enable a resolution. A physician cannot be compelled to offer treatment against his or her professional judgment, but the physician is ethically and legally obliged to attempt to transfer the care of the patient to another physician. Only as a last resort, if no alternative dialysis unit can be found and after adequate notice has been given, should dialysis be withdrawn. The RPA Clinical Practice Guideline Toolkit provides a systematic approach to conflict resolution if there is disagreement regarding the benefits of dialysis (https://c.ymcdn.com/sites/www.renalmd.org/resource/resmgr/Store/Shared_Decision_Making_Recom.pdf)[42] (Fig. 90.10).

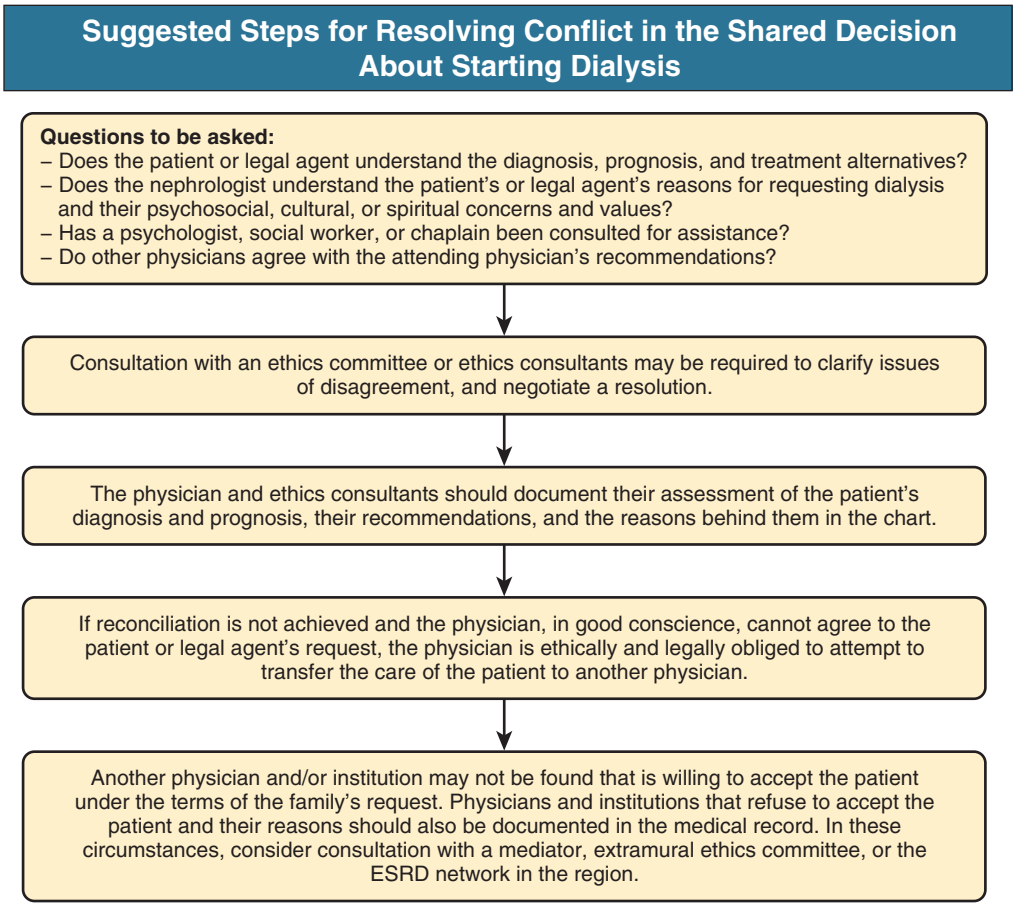

Fig. 90.10 Suggested steps for resolving conflict in the shared decision about starting dialysis. *ESRD,* End-stage renal disease. (Modified from reference 42.)

BOX 90.2 Suggested Steps for Dealing With Disruptive Patients

Identify and document problem behaviors and discuss them with the patient.

- Seek to understand the patient's perspective.
- Identify the patient's goals for treatment.
- Share control and responsibility for treatment with the patient.
  - Educate the patient so he or she can make informed decisions.
  - Involve the patient in the treatment as much as possible.
  - Negotiate a behavioral contract with the patient.
- Consult a psychiatrist, psychologist, or social worker for assistance in patient management or determination of decision-making capacity.
- Be patient and persistent, try not to be adversarial.
- Allow the patient to vent concerns but do not tolerate verbal abuse or threats to staff or patients.
- Contact law enforcement officials if physical abuse is threatened or occurs.
- If satisfactory resolution has not occurred with these strategies, contact the local ESRD Network to discuss the situation and ensure due process.
- As a last resort, consider transferring the patient to another facility or discharging the patient.
- Consult with legal counsel before proceeding with plans for discharge and do not discharge without advance notice and a full explanation of future treatment options.

Modified from reference 42.

MANAGEMENT OF DISRUPTIVE PATIENTS ON DIALYSIS

Most nephrologists have had experience of treating a small number of patients who, for one reason or another, will not comply with the discipline required for maintenance dialysis and who become disruptive to the staff and other patients. This behavior can range from noncompliance with treatment, which harms the patient but is merely inconvenient to the staff, to verbal or even physical aggression toward the staff and other patients in the unit. The impact of this small number of patients can be very great.

The strategy for dealing with such patients must be tailored to the individual, particularly the person's decision making capacity. Useful suggestions for resolving conflict have been provided by the RPA (Box 90.2). They emphasize the importance of understanding, information, patience, and persistence. However, the bottom line for patients who have capacity and are aggressive toward staff while on dialysis must be that they are taken off treatment and sent home.

RESUSCITATION AND WITHDRAWAL OF DIALYSIS

Cardiopulmonary Resuscitation

If patients are to be fully involved in decision making about their treatment, two sensitive issues need to be discussed: cardiopulmonary resuscitation (CPR) and the possibility of withdrawal of dialysis. The two are not necessarily linked; patients may wish to continue with dialysis but express a desire that resuscitation not be attempted should they have cardiac arrest. Outcome of CPR in dialysis patients is worse than in the general population, the odds ratio for mortality being 1.24 (95% confidence interval, 1.11-1.3; P <.001). In 2011 survival after CPR in the United States was 31% but a greater proportion of patients with ESRD who survived were discharged to skilled nursing facilities.[47]

A decision not to attempt CPR must be documented in the patient's medical and nursing records, and all nursing staff must be made aware of it. It is important to be clear what is meant by "cardiac arrest" and for there to be agreement on how the nursing staff should respond if the patient experiences a hypotensive "crash" while on dialysis. These notes may form part of an advance directive, as discussed later.

Withdrawal of Dialysis

It is not possible to predict accurately which patients will gain prolonged benefit from dialysis; thus many nephrologists offer dialysis to all patients with ESRD who wish to have it. This policy ensures that no patients are denied dialysis but has the inevitable consequence that some patients started on dialysis subsequently have an unacceptable quality of life. The possibility of withdrawing dialysis needs to be addressed if these patients are not to suffer unreasonably.

Rates of withdrawal vary widely between countries and cultures. Withdrawal rates in Eastern and Southern Europe are much lower than those in Northern European countries.[48] In the United States, African Americans have about one third the withdrawal rate of Whites. Rates of withdrawal vary across dialysis units and are significantly associated with the medical director's opinion about whether withdrawal is allowed or facilitated in that unit. This suggests that patients' wishes are not always fully included in these decisions.

Patients may be very reticent to express a wish to withdraw from dialysis. Many see it as their duty as a patient to go along with the treatment recommended by their physician and do not wish to appear ungrateful for the efforts that are being made to keep them alive. Their physician may be the last member of the team to learn about the patient's views, and it is very important that good communication exists within the multidisciplinary team so that any clues that the patient gives are acted upon. Staff should adopt a proactive approach and raise the issue of withdrawal of dialysis with patients who are not thriving.

The willingness of patients to engage in a discussion about planning for the end of their life will be affected by factors such as age, ethnicity, cultural background, and religious beliefs, as well as the circumstances of their daily lives. Qualitative research suggests that, when done sensitively, raising the subject of death with patients does not destroy their hope for the future. Early discussion of these issues can lead to a more satisfactory outcome for patients, relatives and staff when the patient eventually dies. In the United States, formal advance directives play an important part in these discussions and helpful guidance on how to conduct sensitive interviews has been published.[49]

In the United Kingdom, dialysis teams may enter patients on an "at risk" register so they can receive appropriate assessment and care. The dialysis unit should have close links with palliative care specialists so there is a smooth transition from maintenance to palliative dialysis, where priority is given to symptoms and person-centered outcomes. Palliative care for people with kidney disease is discussed further in Chapter 112. Patients who take a long time to recover after a dialysis treatment may benefit from reducing the number of treatments per week.[50]

When a patient is no longer competent to make a decision, an advance directive can provide a clear legal basis for the decision to stop dialysis. Indeed, some American states (e.g., Missouri and New York) insist that dialysis must be continued in the absence of such clear and convincing written evidence. In other U.S. states and the United Kingdom, the physician is given the task of deciding on the patient's behalf. Helpful advice for dialysis staff and patients wishing to complete an advance directive is available in the RPA Clinical Practice Guideline Toolkit (see Fig. 90.9).[42]

Once a patient has expressed a wish for dialysis to be withdrawn, or his or her relatives have raised the issue, the first priority must be to identify any reversible factors that may improve the patient's health sufficiently for the decision to be reversed. In particular, any depression must be identified and treated. Once all these factors have been ruled

BOX 90.3 Key Principles Underlying the Process of Withdrawal of Dialysis

- The ultimate responsibility for the decision rests with the physician, not the relatives or caregivers.
- The patient's interests and dignity should be protected at all times.
- The process should not be rushed. If there is any doubt about the correctness of the decision, treatment should continue.
- There should be an open discussion among the multidisciplinary team to avoid any damaging disagreements.
- The psychological needs of the health care team should not be overlooked.
- Palliative care must be given in the most appropriate environment (e.g., a hospice or, ideally, the patient's own home).

out, the process of withdrawing dialysis should be managed according to some key principles (Box 90.3).

Withdrawing dialysis should not be seen as an admission of failure but as a final stage in the process of RRT. The opportunity for patients to complete unfinished emotional and financial business can make the subsequent bereavement period much less traumatic. Managing this terminal phase can be uniquely rewarding, particularly if it allows a patient and his or her family and caregivers to prepare themselves for the patient's death.

SELF-ASSESSMENT QUESTIONS

1. Which of the following provides the *best* outcomes in a patient with advanced chronic kidney disease (CKD)?
   - **A.** Deceased donor transplant
   - **B.** Preemptive living donor transplant
   - **C.** Home hemodialysis
   - **D.** Peritoneal dialysis
2. Early initiation of dialysis is associated with:
   - **A.** Improved patient survival
   - **B.** Improved quality of life
   - **C.** Decreased morbidity
   - **D.** Higher health care costs
3. Dialysis should be started in a patient with advanced CKD when:
   - **A.** Estimated glomerular filtration rate (eGFR) is less than 15 ml/min/1.73 m^2 (CKD stage 5)
   - **B.** Urine output is decreased
   - **C.** The patient develops clinical and biochemical features of azotemia
   - **D.** Serum bicarbonate is less than 20 mEq/L
4. A decision to transfer a patient to multidisciplinary renal care should be made when:
   - **A.** The patient develops symptoms of renal failure
   - **B.** The eGFR reaches 10 ml/min/1.73 m^2
   - **C.** The patient is in CKD stage 4 with stable eGFR
   - **D.** The trajectory of eGFR indicates a likely need to start RRT within the next 12 months
5. The nephrologist may withhold dialysis from a patient with end-stage renal disease:
   - **A.** If the patient has verbally expressed his or her wish not to have dialysis
   - **B.** If it is against the judgement of the nephrologist
   - **C.** If the patient is disruptive on dialysis
   - **D.** If the dialysis nurses do not wish to continue dialysis
6. Which of the following is *not* predictive of a poor prognosis on dialysis?
   - **A.** Karnofsky performance status score less than 40
   - **B.** Severe chronic malnutrition
   - **C.** Age older than 75 years
   - **D.** Physician would not be surprised if the patient died within the next 6 months

Vascular Access for Dialytic Therapies

Jan H. M. Tordoir

Functional vascular access is needed for all extracorporeal dialytic therapies and remains the lifeline for patients treated with chronic hemodialysis (HD). The ideal HD access should have a suitable superficial vein that allows for cannulation in two places more than 5 cm apart and delivers blood flow for effective dialysis, usually of the range 400 to 1500 ml/min. A vascular access should have good primary patency, have a low risk for complications and side effects, and leave opportunities for further procedures in the event that patency or flow rates are compromised. Ideally, a first access should be an arteriovenous fistula (AVF) placed peripherally at the wrist. However, upper arm and lower limb access sites are increasingly used because the contemporary dialysis patients (typically older and with multiple comorbidities) often have poor and diseased arm vessels that may be unsuitable for the creation of a simple wrist fistula.

Vascular access should be created with minimal delay by a surgeon experienced in vascular access creation and ideally in time to avoid the use of a central venous catheter (CVC) for initiation of dialysis. CVC use should be minimized because of the increased risk for sepsis and the development of central venous stenosis or thrombosis, which compromises further access in the upper limbs. Dialysis catheters are also associated with excess mortality compared with arteriovenous access, although it is uncertain whether this association is causal. Unfortunately, many patients require a CVC either to start dialysis or as a bridge between the failure of a permanent access and the creation of a new AVF.[1]

Many accesses eventually require surgical revision to manage access-related complications, including thrombosis, central venous obstruction, and ischemia. A multidisciplinary approach to access creation and maintenance (involving nephrologists, interventional radiologists, access surgeons, and dialysis nurses) appears helpful for optimizing HD access–related outcomes and minimizing costs.

EVALUATION OF THE PATIENT FOR VASCULAR ACCESS

The earlier a patient with chronic kidney disease (CKD) is seen by a vascular access surgeon, the better the chance for the patient to have a well-functioning access at the initiation of HD. An early decision on the type, side, and site of the first vascular access will be based on the following:

- *Clinical examination* with careful palpation of arterial pulses and venous vasculature. Particular attention is paid to the venous filling capacity, with use of a blood pressure cuff and variable pressures, and to the presence of venous collaterals and swelling. The nondominant arm is not necessarily the preferred side, and the decision should be based on the quality of the vessels.
- *Vascular mapping by Doppler ultrasound.* This provides information about the venous vasculature (particularly in obese patients and in the upper arm) and the diameter of the brachial, radial, and ulnar arteries; detects vascular calcifications; and reveals the blood flow volume in the brachial artery. The resistance index (a measure of arterial compliance) can be calculated from the differences between the high-resistance triphasic Doppler signal with clenched fist and the low-resistance biphasic waveform after the fist is released. A preoperative resistance index of 0.7 or higher in the feeding artery indicates insufficient arterial compliance (often associated with arterial calcification), so the chance of successful creation of an AVF is reduced. Current guidelines recommend ultrasound mapping in all patients. Additional angiography and/or phlebography is needed only in very difficult cases or in patients with previous ipsilateral CVCs to rule out central vein obstruction; the use of radiocontrast media should be minimized.

Preservation of veins during the earlier stages of CKD is crucial for the success of vascular access. Patients should be instructed to protect their veins, restricting blood sampling and intravenous cannulas to the dorsum of the hand whenever possible.

PRIMARY AUTOGENOUS VASCULAR ACCESS

Radiocephalic Arteriovenous Fistula

A well-functioning distal radiocephalic AVF in the nondominant arm is the ideal permanent access for HD. This usually gives adequate blood flow and a long length of superficial vein for needling. It also leaves proximal sites for further procedures in the event of failure. A distal radiocephalic AVF should be possible in a majority of incident patients but may be compromised if the cephalic and antecubital fossa veins are unusable because of thrombophlebitis and/or thrombosis from previous intravenous cannulas or venipunctures.

A radiocephalic AVF is usually created at the wrist but can be created more proximally in the forearm if distal vessels are inadequate (Fig. 91.1). On occasion, three or four radiocephalic AVFs can be created at progressively more proximal sites in the forearm before a brachiocephalic AVF is created. The radiocephalic AVF at the wrist was initially described as a side-to-side anastomosis, but an end-to-side configuration is preferred by most to reduce the risk for venous hypertension in the radial aspect of the hand.

The patency of radiocephalic fistulas varies from center to center, and reported primary failure rates vary from 5% to 41% and 1-year patency rates from 52% to 71% (Table 91.1).[2-7] Early thrombosis and nonmaturation of an AVF in the older comorbid population, who have poor upper limb vessels, are the major causes of these high primary failure and low patency rates. The patency of radiocephalic AVFs is

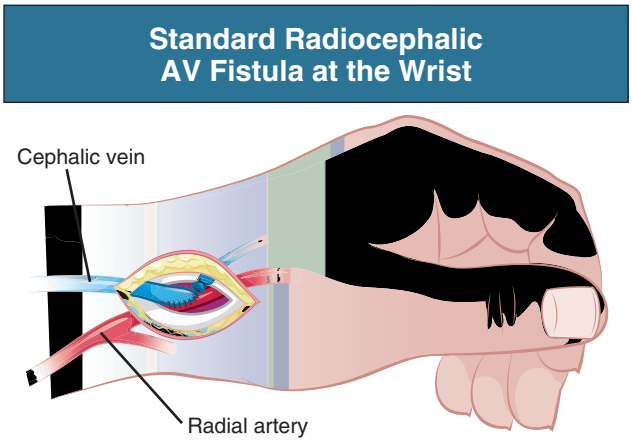

Fig. 91.1 Standard radiocephalic arteriovenous fistula at the wrist. Anastomosis of end of vein to side of artery.

TABLE 91.1 Early Failure and 1-Year Patency Rates of Radiocephalic Arteriovenous Fistulas

Author	Year	Number of Fistulas	Early Failure (%)	1-Year Patency (%)
Ravani et al[2]	2002	197	5	71
Rooijens et al[3]	2005	86	41	52
Korten et al[5]	2007	148	11	57
Biuckians et al[6]	2008	80	37	63
Goh et al[4]	2016	204	12	66
Wilmink et al[7]	2016	689	26	70

poorer in women, so a proximal elbow or upper arm AVF might be preferable if the forearm cephalic vein or radial artery is small.

Nonmaturation of Radiocephalic Arteriovenous Fistula

The autogenous radiocephalic AVF needs time to mature and for the vein to enlarge to a size at which it can be needled for dialysis. Usually 6 to 10 weeks for maturation is advised. Earlier cannulation can damage the thin veins. Nonmaturation rates vary from 25% to 33%. The essential components of a successful AVF are a sufficient vein diameter of 4 to 5 mm for needling and a high blood flow so that blood can be drawn from the fistula at 300 to 400 ml/min. This requires a fistula flow of at least 400 ml/min to prevent excessive recirculation and to permit adequate dialysis within the usual 4-hour time frame of HD treatment. Fistulas that fail immediately are the consequence of poor selection of vessels or poor technique. Regular duplex ultrasound investigation early after AVF formation, especially in fistulas that are not maturing, can detect poor flow, stenosis, and accessory branches, guiding the interventional radiologist and surgeon to the appropriate treatment. A randomized controlled trial (RCT) compared brachial plexus block (BPB) with local anaesthesia for AVF creation and showed superiority of BPB, with significant improvement in the primary outcome of patency at 3 months. Consideration should therefore be given to using BPB for all AVF creation.[8]

SECONDARY AUTOGENOUS VASCULAR ACCESS

Although a primary radiocephalic AVF is preferable, the first-choice procedure is increasingly an upper arm AVF with use of an autogenous superficially located arm vein, especially in the dialysis population with comorbidities such as diabetes mellitus, coronary heart disease, and peripheral arterial occlusive disease.[1]

The upper limb is preferred to the lower limb for vascular access because of the ease of cannulation, comfort for the patient, and considerably lower incidence of complications. Similarly, autogenous conduits are preferable to the use of prosthetic grafts because of better patency and lower risk for infection.

Forearm Cephalic and Basilic Vein Transposition and Elevation

Vein transposition or elevation increases the possibilities for creating a forearm fistula. The cephalic vein is preferred, but if it is unsuitable, the more deeply located basilic vein can be transposed from the ulnar to the radial side along a straight subcutaneous course from the elbow to the radial artery. Alternatively, an anastomosis from the basilic vein to the ulnar artery can be performed with additional volar transposition to facilitate needling for dialysis.

Different surgical techniques (with or without vein transposition) have been advocated according to the forearm artery and vein location. In one study,[9] 91% fistula maturation was achieved with a range of techniques; 15% were suitable for a straightforward AVF, 33% required vein transposition from dorsal to volar for anastomosis to the appropriate artery, and the remaining 52% required superficial transposition of a vein on the volar aspect of the forearm before arterial anastomosis. Primary patency rates were 84% at 1 year and 69% at 2 years.

Cannulation of fistulas may be difficult, particularly in obese patients. Vein elevation or transposition techniques can be applied in these patients with radio and/or brachiocephalic AVFs and cannulation difficulties; the primary failure rate is 15%, with a 1-year patency rate of 84%. Alternatively, surgical lipectomy or liposuction can be performed to facilitate cannulation of deeply located fistulas.[10]

Elbow and Upper Arm Cephalic Vein Arteriovenous Fistula

The brachiocephalic and antecubital configurations can be used for AV anastomoses in the elbow region. If possible, the anastomosis can be created between the cephalic, cubital, or perforating vein and the brachial artery 2 cm distal to the elbow, which optimizes opportunities for cannulation along the cephalic vein in the upper arm (Fig. 91.2). The outcome of the brachiocephalic AVF is usually good, with a high primary function rate and good long-term patency; studies show a 10% early failure rate caused by nonmaturation and an 80% 1-year patency rate.[11,12] Two-year primary, assisted primary, and secondary patency rates were 40%, 59%, and 67%, respectively. (Primary patency is functioning access without any intervention; assisted primary patency is functioning access after preemptive intervention for flow decline; secondary patency is functioning access after intervention for thrombosis.) Predictors of failure include diabetes mellitus and a history of contralateral forearm AV graft (AVG; indicating poor vessels). Therefore the primary patency of brachiocephalic fistulas is comparable to that of radiocephalic fistulas. The early failure and 1-year patency rates of brachiocephalic AVFs are shown in Table 91.2.[11-15]

Upper Arm Basilic Vein Arteriovenous Fistula

The upper arm basilic vein is usually inaccessible for dialysis cannulation because of its medial and deep position. Therefore the basilic vein needs to be superficialized and transposed to an anterolateral position. The original technique of brachiobasilic AVF construction is a two-step approach. First, a brachiobasilic anastomosis is constructed, and in the second operation, usually after 6 weeks, the arterialized vein is mobilized into a subcutaneous position, becoming accessible for needling

Options for the Creation of Elbow AV Fistulas

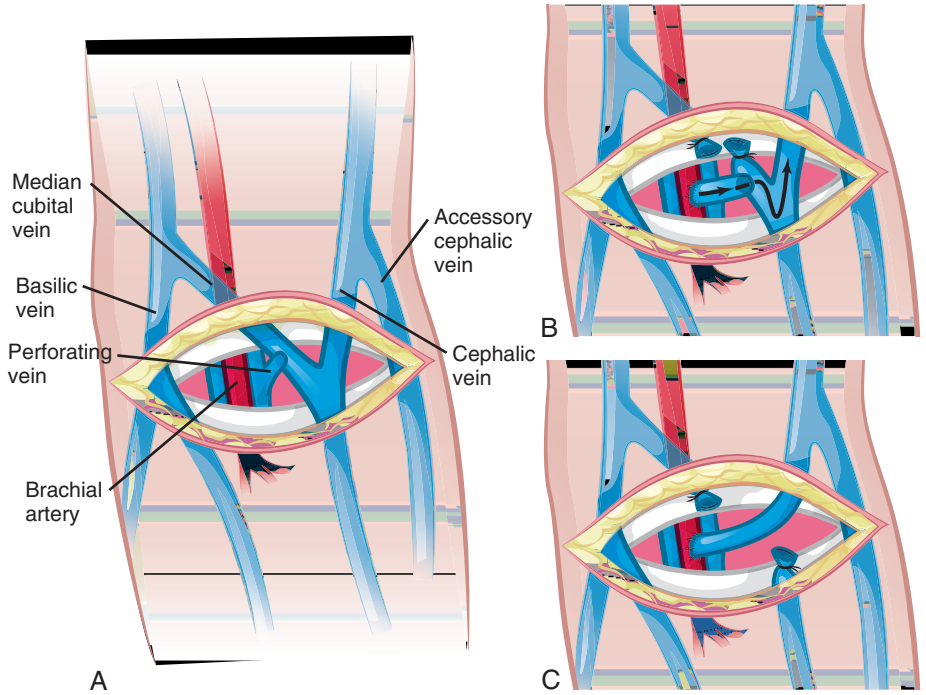

Fig. 91.2 Options for the creation of elbow arteriovenous fistulas (AVFs). (A) Anatomy of arterial and venous vessels in the elbow. (B) Brachio-perforating vein AVF with ligation of proximal cubital vein. (C) Brachiocephalic AVF.

Syed et al[17]	2012	106	19	86

(Fig. 91.3). However, the brachiobasilic AVF creation may be performed as a one-stage surgical procedure, with elevation or transposition of the vein to a subcutaneous and anterolateral position at the time of creation of the AV anastomosis. A nonrandomized study comparing the different techniques of brachiobasilic AVF creation reported 86% to 90% 1-year patencies in all groups, with only 5% to 7% nonmaturation rates.[16] Primary failure rates are 2% to 26% with 1-year secondary patencies varying from 66% to 89% (Table 91.3).[13,15,17-20] In comparison with brachiocephalic fistulas, brachiobasilic AVFs are more likely to mature, although they are more susceptible to late thrombosis. However, studies showed similar patencies of brachiocephalic and brachiobasilic AV fistulas.[13,15]

The technique of subcutaneous placement of the basilic vein has several advantages over forearm or upper arm graft implantation, with less infection and thrombosis. A meta-analysis found that brachiobasilic AVFs have superior primary and secondary patency compared with prosthetic grafts, and the former should therefore be used preferentially in difficult access cases.[21]

NONAUTOGENOUS PROSTHETIC VASCULAR ACCESS

When autogenous AVF creation is impossible, graft implantation should be considered as a vascular access conduit. Xenografts such as the ovine sheep graft (Omniflow) are popular materials as an alternative access conduit, with acceptable patency and low infection rates. The most frequently used implants are prosthetic grafts made of either polyurethane (Vectra) or polytetrafluoroethylene (PTFE). These prosthetic

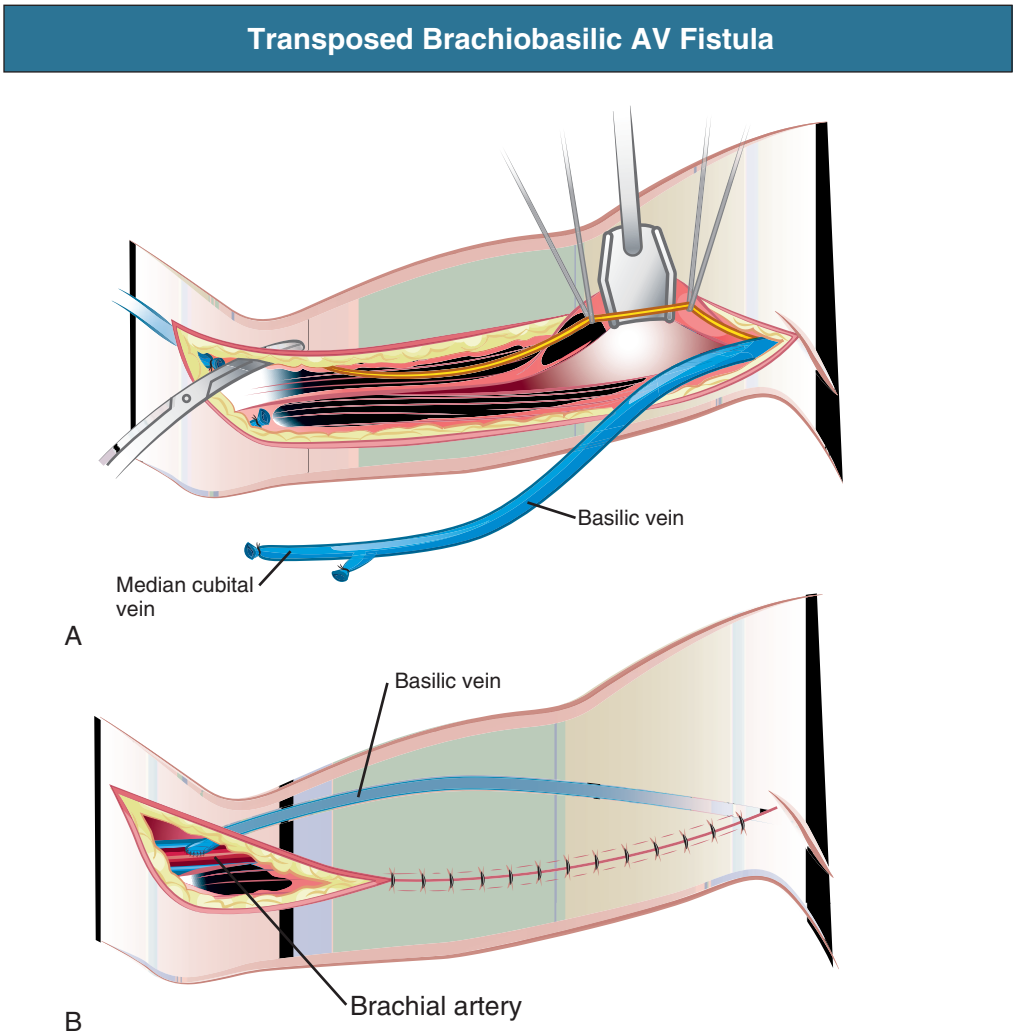

Fig. 91.3 Transposed brachiobasilic arteriovenous fistula (AVF). (A) Dissection of the basilic vein. (B) Anterolateral transposition and brachial artery anastomosis.

grafts can be implanted in a wide variety of locations and configurations in the upper limb (Fig. 91.4). At present, early cannulation of PTFE grafts (within 24 hours of surgery) is feasible because of newer graft compositions. Short-term functional patency is usually good, but stenosis (mostly at the graft-vein anastomosis) may lead to thrombotic occlusion within 12 to 24 months. The primary patency rates of prosthetic AVGs vary from 60% to 80% at 1 year and from 30% to 40% at 2 years of follow-up. Secondary patency ranges from 70% to 90% and from 50% to 70% at 1 and 2 years, respectively.[22-25] Intimal hyperplasia, with smooth muscle cell migration and proliferation and matrix deposition, is the major cause of stenosis formation and thrombosis. The cause of the intimal hyperplasia is uncertain, although the high wall shear stress, caused by the access flow, may denude the endothelial cell layer, resulting in platelet adhesion and initiation of a cascade of proteins that stimulate the smooth muscle cells to proliferate and to migrate.

Measures to Improve Graft Patency

Numerous studies have defined the influence of graft material and design on AVG patency. Modulating the geometry of the arterial inlet or venous outlet of the graft may have a beneficial effect on intimal hyperplasia. Clinical studies using tapered (at the arterial side of the graft) grafts did not improve patency rates, nor did cuff implantation at the venous anastomosis.[26,27] However, primary patency did improve with the use of a cuff-shaped prosthesis (Venaflo).[28] Grafts such as polyurethane, which are more distensible, could in principle influence intimal hyperplasia by the better matching of the stiff prosthesis with the compliant vein at the anastomotic site; however, in clinical studies, this feature was not of proven benefit.[29]

Because PTFE AVGs are prone to thrombosis, infection, and intimal hyperplasia at the venous anastomosis, tissue-engineered vascular grafts have been developed as a potential solution to these limitations in dialysis access. Preliminary results of human studies suggest these grafts provide safe and functional HD access and warrant further study in RCTs.[30]

PHARMACOLOGIC APPROACHES FOR ACCESS PATENCY

Meta-analysis of three studies suggests that ticlopidine as an adjuvant treatment may increase the patency of AVFs and AVGs, but the duration of follow-up was only 1 month. There was insufficient evidence to determine if there was a difference in graft patency between placebo and other treatments such as aspirin, fish oil, clopidogrel, dipyridamole, warfarin, and sulfinpyrazone. However, the quality of the evidence was low because of short follow-up periods, the small number of studies

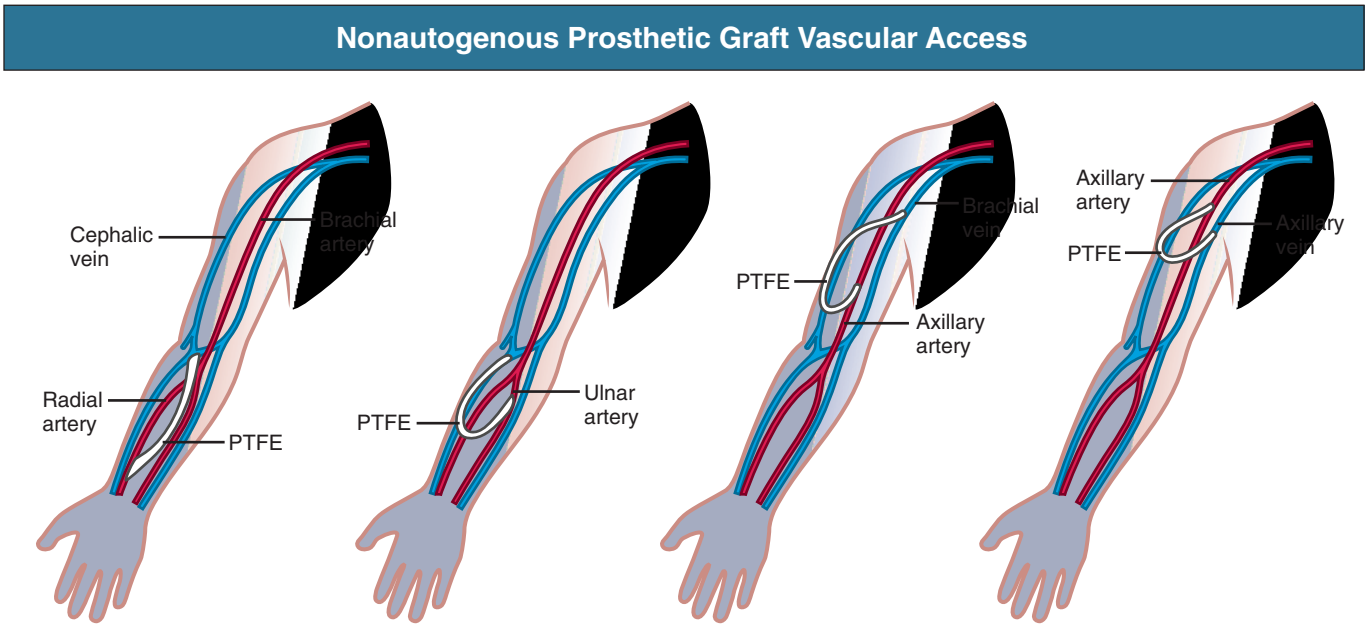

Fig. 91.4 Nonautogenous prosthetic graft (polytetrafluoroethylene *[PTFE]*) vascular access. Straight and loop configuration in upper limb.

for each comparison, heterogeneity among trials, and moderate methodologic quality of the studies as a result of incomplete reporting.[31] Warfarin reduces AVG thrombosis but increases the risk for hemorrhage and vascular calcification.[32] A large trial showed that dipyridamole plus aspirin had a significant but modest effect in reducing the risk for stenosis and improving the duration of primary unassisted patency of newly created AVGs.[33] In a large randomized study, clopidogrel improved primary radiocephalic fistula patency but not functional maturation.[34]

There have been suggestions that other drugs such as calcium channel blockers and angiotensin-converting enzyme inhibitors might be associated with improved AVF patency, but this requires confirmation with randomized studies.[35] Fish oil reduced AVG thrombosis in one randomized trial.[36] Clinical trials in patients undergoing AVF and AVG creation, who had perivascular biodegradable collagen wraps with sirolimus placed at the anastomosis, demonstrated safety and feasibility of the sirolimus wrap. An ongoing phase III RCT is assessing the safety, efficacy, and patency outcomes of a perivascular sirolimus-eluting implant placed at the AVF anastomosis in HD patients receiving new AVFs.[37]

LOWER LIMB VASCULAR ACCESS

Probably the only indication for lower limb vascular access is bilateral central venous or caval obstruction, which endangers the outflow of upper limb AVFs. Saphenous and superficial femoral vein transposition is a primary option for thigh AVFs, although this carries a relatively high risk for distal ischemia. If clinical evaluation indicates incipient ischemia, primary flow reduction by tapering of the anastomosis is indicated to prevent complications. Prosthetic graft implantation in the thigh bears a high risk for infection and septicemia.[38]

VASCULAR ACCESS COMPLICATIONS

Nonmaturation of Arteriovenous Fistulas

Fistulas that fail immediately do so as a consequence of poor selection of vessels, poor surgical technique, or postoperative hemodynamic instability. Vascular abnormalities, including stenoses, occlusions, and accessory veins, will be identified in virtually all early failures, and more than half of the stenoses are in the perianastomotic area of nonmatured fistulas. Arterial inflow stenoses of more than 50% vessel diameter reduction coupled with poor flows are seen in less than 10% of nonmaturing fistulas, but if identified, they should undergo angioplasty. Anastomotic and swing segment (in which the vein has been mobilized and swung over to the artery) stenosis may be treated percutaneously or surgically, depending on local expertise.

The diameter of the angioplasty balloon is chosen to correspond to the diameter of the vessel next to the stenotic or occlusive lesion and is usually not smaller than 5 mm for venous stenoses and not smaller than 4 mm for arterial or anastomotic stenoses. Ultra-high-pressure balloons inflatable up to 36 atm are used when necessary to abolish the waist of the stenosis on the balloon. Apart from local infection, contraindications to balloon angioplasty are anastomotic stenoses in fistulas less than 4 to 6 weeks after surgical construction, which increases the risk for anastomotic disruption at angioplasty. Percutaneous balloon angioplasty is further discussed in Chapter 92.

When a surgical approach is selected, matured fistulas that fail should be reconstructed, usually under regional or local anesthesia. The anastomosis is exposed and ligated; the vein then can be divided, mobilized proximally, and reanastomosed to the proximal radial artery. A prospective nonrandomized study of 64 patients showed that outcomes were similar with angioplasty or surgery.[39] Restenosis rates were significantly higher after angioplasty, but overall costs of treatment were similar.

Nonmatured fistulas are rescued by angioplasty of stenoses or occlusions, ligation of accessory veins, or both. Accessory veins can be obliterated through coil embolization, percutaneous ligation, or surgical ligation. The use of coils with a diameter of 1 mm in excess of the target vessel diameter will prevent coil dislocation. In predialysis patients the risk for renal function deterioration as a result of radiocontrast load can be overcome by performance of ultrasound-guided angioplasty of the nonmatured fistula.[40]

Stenosis and Thrombosis

Vessel stenosis in both autogenous AVFs and prosthetic AVGs is usually initiated by intimal hyperplasia caused by migrating and proliferating

vessel smooth muscle cells, which form extracellular matrix. Progressive stenosis leads to access flow deterioration and subsequently thrombotic occlusion. Prophylactic repair of access stenoses may prevent thrombosis and prolong access patency.

Autogenous Fistula Stenosis or Thrombosis

AVF stenosis should be suspected if the vessel diameter is reduced by more than 50% and is accompanied by a reduction in access flow (25% flow decline between measurements or absolute flow below 500 ml/min) or in measured dialysis dose. Other indications for diagnostic testing are difficulties in cannulation and prolonged bleeding time after decannulation, indicating high intraaccess pressure caused by outflow vein stenosis. Venous pressure above 250 mm Hg with a blood flow of 200 ml/min is also suggestive of stenosis. In AVFs, 55% to 75% of the stenoses are close to the AV anastomosis, 25% in the venous outflow tract, and 15% in the arterial inflow. In brachiocephalic and brachiobasilic AVFs, the typical location for stenosis (other than the anastomosis) is at the junction of the cephalic with the subclavian vein (cephalic arch) and the basilic with the axillary vein (junctional stenosis). Initial evaluation of suspected access stenosis is by ultrasound; angiography is used subsequently when intervention is planned.

Endovascular treatment by percutaneous transluminal angioplasty (PTA) is the first option for arterial inflow and venous outflow stenoses and junctional stenoses, with the option of stent placement.[41] These techniques are discussed further in Chapter 92. Some stenoses may not be sufficiently dilated by conventional balloons (12 to 16 atm), and in these patients, cutting balloons or ultra-high-pressure balloons (up to 36 atm) may be applied. Drug-eluting balloons may prevent restenosis; however, outcome data for this approach are not yet available. Anastomotic stenoses in forearm and upper arm fistulas are primarily treated with PTA; however, surgical revision with a more proximal reanastomosis for swing segment stenosis is indicated after failed PTA of a radiocephalic AVF.

Fistula thrombosis should be treated as soon as possible because timely declotting allows immediate use of the access without the need for a CVC. Fistula salvage usually requires intervention within 6 hours (grafts may be salvaged up to 24 hours). The duration and site of AVF thrombosis, as well as the type of access, are important determinants of treatment outcome. Thrombi become progressively fixed to the vein wall, which makes surgical removal more difficult. When the clot is localized at the anastomosis in radiocephalic and brachiocephalic fistulas, the outflow vein may remain patent because of continuing flow in its tributaries, making it possible to create a new proximal anastomosis.[42]

Thrombolysis can be performed mechanically or pharmacomechanically. Whereas the immediate success rate is higher in AVGs than in autogenous AVFs (99% vs. 93% in forearm fistulas), the primary patency rate of the forearm AVF at 1 year is much higher (49% vs. 14%). One-year secondary patency rates are 80% in forearm and 50% in upper arm AVFs.[43]

Arteriovenous Graft Stenosis or Thrombosis

The most common cause of graft dysfunction and thrombosis is venous anastomotic stenosis. Because grafts should be implanted only in patients with exhausted peripheral veins, vein-saving procedures such as PTA or patch angioplasty are preferred to graft extensions to more central venous segments. When a stent or a patch fails, graft extension is still possible. Graft monitoring by access flow measurement is recommended; with preemptive endovascular treatment, this may diminish graft thrombosis but does not extend graft patency.

Intragraft (or midgraft) stenoses are found in the cannulation segment of grafts. They result from excessive ingrowth of fibrous tissue through puncture holes. These stenoses can be treated by PTA, graft curettage, or segmental graft replacement. When only a part of the cannulation segment is replaced, the access can be used immediately for HD without the need for a CVC. When restenosis occurs in a nonexchanged part of the graft, this can be replaced after healing of the new segment.

Prosthetic graft thrombosis can be treated with various percutaneous techniques and tools, including combinations of thromboaspiration, thrombolytic agents such as tPA, and mechanical thrombectomy. An initial success rate of 73% and primary patency rates of 32% and 26% at 1 and 3 months, respectively, are reported.[43] It is important to perform thrombolysis as soon as possible to avoid the need for a CVC and as an outpatient procedure to decrease costs, whenever possible. Postprocedural angiography to detect and correct inflow, intraaccess, or venous outflow stenosis is mandatory.

When endovascular treatment fails or is not possible, surgical thrombectomy may be performed with a Fogarty catheter after venotomy, with correction of the underlying obstruction. On-table angiography should be performed after completion of thrombectomy of both the arterial and venous limbs of the graft.

Central Venous Obstruction

In the majority of patients, central vein obstruction is a result of previously inserted CVCs or pacemaker wires. In 40% of patients with subclavian vein and 20% with jugular vein catheters, venous stenosis or occlusion will develop. Chronic swelling of the access arm is the most important sign, usually with prominent superficial collateral veins around the shoulder. The indications for intervention by PTA and stent placement are severe and disabling arm swelling, finger ulceration, and pain or inadequate HD. Contrast angiography of the access and complete venous outflow tract must be performed; ultrasound is not suitable for examining the central veins because of their retroclavicular location.

Endovascular Intervention

Endovascular intervention is the first treatment option for central venous obstruction. PTA alone results in patency rates of only 10% or less at 1 year, and numerous restenoses may develop. Primary or additional stent implantation gives a much better outcome, with 1-year patency rates up to 56% or higher.[44,45] Reinterventions are usually required to maintain patency and achieve long-term clinical success.

Stent placement should avoid overlapping the ostium of the internal jugular vein because this vein is essential for future placement of CVCs. Similarly, a stent placed in the innominate vein should not overlap the ostium of the contralateral vein; otherwise, contralateral stenosis may occur and preclude future use of the contralateral limb for access creation.

Surgical Intervention

When interventional treatment of central venous obstruction fails, surgical revision with bypass grafting is indicated. Surgical bypass to the ipsilateral jugular vein or contralateral subclavian or jugular vein is the first option in these patients. Alternative surgical approaches for upper limb vascular accesses with compromised venous outflow are axillary vein to femoral, saphenous, or popliteal vein and right atrial bypasses.[46] In case of bilateral obstruction of the mediastinal veins, including the superior vena cava, it will not be possible to sustain upper limb access and lower limb access will be required.

Ultimately, ligation of the upper limb access can be considered, which will relieve local symptoms but sacrifices a valuable dialysis access.

Vascular Access–Induced Ischemia

Vascular access–induced upper limb ischemia is a serious complication that without prompt intervention may lead to amputation. The

incidence of symptomatic ischemia varies from 2% to 8% of the HD population.[47] Elderly patients, diabetics, patients with prior ipsilateral AV access, and those with peripheral or coronary arterial occlusive disease are most at risk for ischemia. Access-induced ischemia occurs more often with proximally located fistulas and high flow rates; such AVFs can induce a steal phenomenon with lowering of distal perfusion pressures, and when collateral circulation is inadequate, symptoms may occur. Pain during HD is a characteristic early symptom. A grade 1 to 4 classification for access-induced ischemia can be used to outline the severity of the disease; this ranges from minor symptoms to finger necrosis.[48]

- *Grade 1:* Pale and blue or cold hand without pain
- *Grade 2:* Pain during exercise or HD
- *Grade 3:* Ischemic pain at rest
- *Grade 4:* Ulceration, necrosis, and gangrene

For grades 1 and 2, conservative treatment of ischemia is advocated. With grades 3 and 4, interventional treatment is mandatory.

Diagnosis of Ischemia

Physical examination, including observation and palpation of peripheral vessels, may be inadequate and misleading for the diagnosis of symptomatic ischemia. Additional noninvasive testing with measurement of digital pressures and calculation of the digit-brachial index, transcutaneous oximetry ($TcPo_2$), ultrasound of forearm arteries, and access blood flow measurement are important steps in the diagnosis and decision making process.[49] Finally, contrast angiography with visualization of the upper extremity arterial tree from the proximal subclavian artery to the distal palmar arches with and without AVF compression to enhance distal flow is obligatory to outline the strategy for treatment and determine whether interventional or surgical options are preferred.

Endovascular and Surgical Management of Ischemia

The treatment strategy depends on the cause of the ischemia. Inflow arterial obstruction and distal arterial lesions are recanalized with small-caliber balloons or stent placement[50]; high-flow AVFs are suitable for flow-reducing procedures such as access banding and arterial inflow reduction by an interposition graft to a smaller forearm artery (revision using distal inflow) (Fig. 91.5).[51,52] Steal in itself may be cured by ligation of the artery distal to the AV anastomosis (distal radial artery ligation). In most patients, it is necessary to add a saphenous vein or prosthetic graft bypass to the forearm arteries to augment distal hand perfusion (distal revascularization–interval ligation [DRIL] procedure) (Fig. 91.6). The results of these procedures are usually good, with relief of symptoms and preservation of the access site (Table 91.4).[53-57] A simpler alternative to the DRIL procedure is the proximal AV anastomosis technique, in which the AV anastomosis at the elbow is disconnected and moved to the axilla, with anastomosis to the axillary artery by means of a graft interposition.[58] The minimally invasive limited ligation endoluminal-assisted revision procedure has been described; this procedure uses a minimally invasive percutaneous technique with banding of the access over a 4-mm balloon.[59]

Intraoperative digital pressure measurement (or $TcPo_2$) is mandatory to guarantee an adequate surgical intervention with acceptable outcome. A digital-brachial pressure index above 0.60 or $TcPo_2$ above 40 mm Hg is indicative of sufficient distal hand perfusion. In some patients, AVF ligation and transition to chronic catheter dialysis access

or a change in renal replacement modality to peritoneal dialysis may be the only solution.

CENTRAL VENOUS CATHETER ACCESS

CVCs are widely used as vascular access for HD despite practice guidelines to the contrary. Data from the Dialysis Outcomes and Practice Patterns Study (DOPPS)[60] indicate that 15% of HD patients in the United States are dialyzed with catheters; in other countries the use of catheters is even more common (Canada, 45%; Belgium, 38%; United Kingdom, 16%). CVCs are the preferred vascular access only for patients who present with acute kidney injury and patients with CKD without permanent AV access or with failed vascular access. Two types of catheters are used in practice: nontunneled catheters for short-term dialysis, with a limited use and high morbidity, and tunneled cuffed catheters, which can be used for up to several months with lower morbidity. The physical characteristics (i.e., design and geometry) not only influence the performance (blood flow rate, recirculation, and resistance) but also affect the overall efficiency of the HD therapy and morbidity risk (infection, thrombosis).

Distal Revascularization-Interval Ligation (DRIL) for Ischemia in an Upper Arm Vascular Access

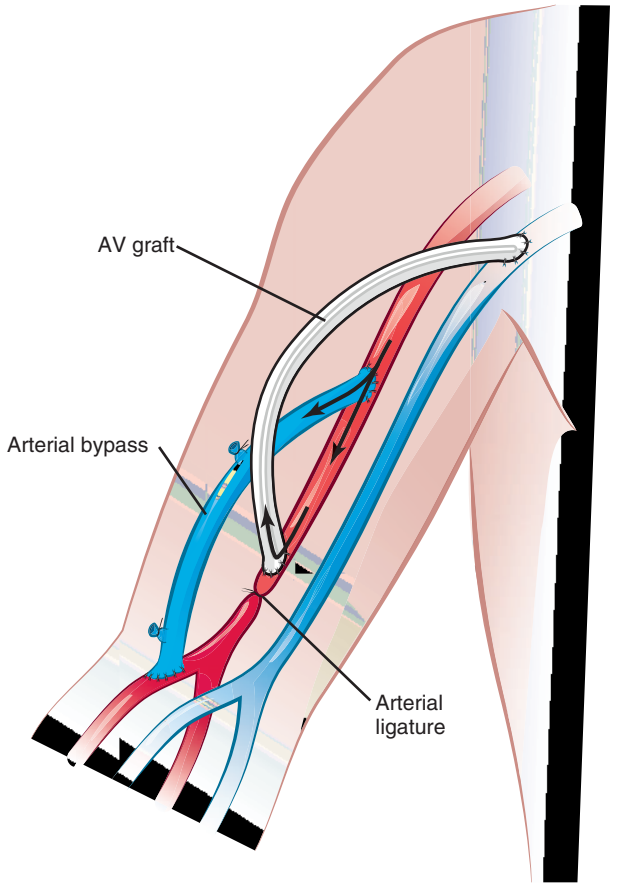

Fig. 91.6 Distal revascularization–interval ligation for ischemia in an upper arm vascular access. *AV,* Arteriovenous.

Nontunneled Catheters

Single- or double-lumen catheters are usually made of polymers (polyethylene, polyurethane), enabling a simple and direct implant possibility. The length of the catheter must be chosen in accordance with the insertion site. The femoral route requires catheters of 30 to 35 cm in length for the distal tip to be located in the inferior vena cava. The internal jugular vein route needs shorter catheters of 20 to 25 cm in length, with tip location at the inferior vena cava and right atrium junction. The subclavian vein should not be used because of the very high risk for subsequent venous stenosis. For sufficient blood flow rates to be achieved, the diameter of these catheters must be ideally 12 to 14 French. It is recommended that the use of nontunneled catheters not exceed 7 days.

Tunneled Catheters

Tunneled CVCs have two lumens, each having a length of 40 cm, 10 cm of which is tunneled under the skin; the cannulae are made of synthetic polymer with a large internal lumen and a Dacron cuff to ensure subcutaneous anchoring. The catheter characteristics rely on the type of polymer, design, and geometry (double-lumen catheters, dual catheters, split catheters). The use of tunneled CVCs is associated with reduced morbidity as well as better and constant performance compared with uncuffed catheters.[61]

Both tunneled and nontunneled catheters are inserted percutaneously by the Seldinger technique with ultrasound guidance. These techniques are described in Chapter 92. The internal jugular vein and femoral vein routes are preferred because of ease of implantation and low risk for complications, such as central vein stenosis (Fig. 91.7).

Catheter Infection

Catheter-related bloodstream infections are a significant cause of morbidity and mortality in HD patients. Results of the Hemodialysis (HEMO) study indicate that CVC use is associated with a relative risk for mortality

TABLE 91.4 Results of the Distal Revascularization–Interval Ligation Procedure for Vascular Access–Related Ischemia

NS, Not stated.

of 3.4 compared with patients with AVFs. Switching from CVCs to AVFs decreases the relative mortality risk to 1.4.[62] The most likely explanation for this increased mortality risk is infection and sepsis related to the CVC, including exit site infection. Typical infection rates are three episodes of infection per 1000 tunneled catheter–days and higher with nontunneled catheters.[63] These localized infections can progress to metastatic complications of osteomyelitis, septic arthritis, epidural abscess, and endocarditis. Various societies have issued recommendations for the management of catheter infections.[64] A recommended treatment algorithm is shown in Fig. 91.8.

Tunneled Cuffed Double-Lumen Central Venous Catheter Inserted in the Right Internal Jugular Vein

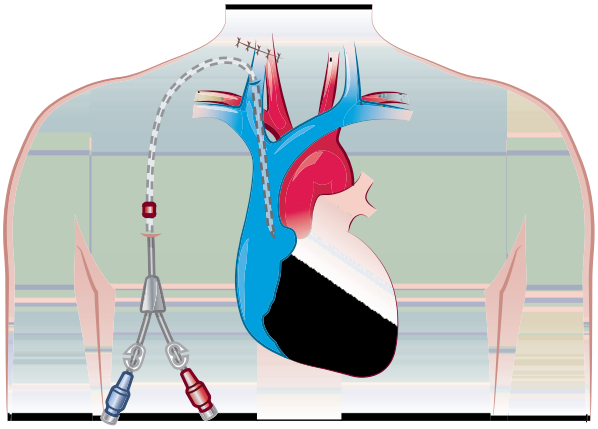

Fig. 91.7 Tunneled cuffed double-lumen central venous catheter inserted in the right internal jugular vein.

Infections Involving Temporary Catheters

When a temporary dialysis catheter becomes infected, it should always be removed. There is no role for trying to salvage temporary catheters.[64]

Exit Site Versus Tunnel Tract Infections

An exit site infection is a localized cellulitis confined to the 1 to 2 cm where the catheter exits the skin. The majority of these infections respond well to systemic antibiotics and meticulous exit site care, and the removal of the catheter is generally not required.[64] However, exit site infections can progress to tunnel tract infections, which involve the potential space surrounding the catheter more than 2 cm from the exit site (Fig. 91.9). Patients with a tunnel tract infection sometimes but not always have an associated exit site infection; untreated, they can rapidly develop bacteremia. Patients with a tunnel tract infection present with fever as well as local signs of pain, swelling, fluctuance, and erythema along the tract of the catheter. Because tunnel tract infections involve a potential space, in an area with limited vascular supply, and an implanted synthetic material, they respond poorly to antibiotics alone and require catheter removal.[64]

Catheter-Associated Bacteremia

When a patient with a dialysis catheter has a fever, catheter infection always must be considered. If the patient does not have a clear and convincing alternative explanation for the fever, blood culture specimens should be obtained peripherally as well as through the catheter, and the patient should be started on antibiotic therapy, which is subsequently adjusted on the basis of culture results.[64] The most common organism is *Staphylococcus aureus,* although a wide range of gram-positive and gram-negative organisms have been reported (Table 91.5). The percentage of patients with methicillin-resistant *S. aureus* (MRSA) varies greatly across centers, with higher rates associated with greater antibiotic use. An aminoglycoside or a cephalosporin is a good choice for gram-negative coverage; however, local microbiologic epidemiology must be taken into consideration, especially with regard to antibiotic resistance.

Management of Central Venous Dialysis Catheter Infections

Numbers do not add up to 100% because 16% of infections were polymicrobial.

Catheter Removal

The decision to remove a tunneled cuffed dialysis catheter because of an episode of catheter-associated bacteremia is not straightforward. The clinical condition of the patient and response to initial therapy, the presence of metastatic complications, the infecting organism, and the availability of other vascular access sites must be taken into consideration before a treatment plan is selected (see Fig. 91.8).

The conventional approach is to remove the catheter with interval replacement at a different site after the infection has resolved. Although this is effective, it leads to an additional temporary catheter if dialysis is needed before the catheter can be replaced. Attempts to salvage an infected catheter with systemic antibiotic therapy lead to resolution of infection in only about 30% of patients. Another treatment option is to combine systemic antibiotics with antibiotic "lock" solutions. Many different combinations of antibiotics mixed with either heparin or citrate have been tested; a popular regimen is vancomycin 2.5 mg/ml, gentamicin 1 mg/ml, and heparin 2500 U/ml. Infection clearance rates of 50% to 70% are reported with antibiotic locking.

Several studies have reported that exchange of the catheter over a guidewire after 48 hours of antibiotic treatment is more effective than treatment with antibiotics alone and is as effective as removal of the catheter and delayed replacement, with the advantages of only one invasive procedure and preservation of the venous access site.[65] There are no published randomized trials of antibiotic locking or catheter exchange over a guidewire.

Prevention of Infection

The most important measure to prevent catheter infection is meticulous handling of the catheter at all times. The catheter should be inserted with use of maximal sterile precautions. The dialysis nurses need procedures for accessing the catheters under strict sterile conditions, and it is of the utmost importance that these catheters never be accessed by untrained personnel. Compared with unfractionated heparin, citrate catheter locking solutions appear to reduce bleeding and may reduce bacteremia in patients undergoing HD with a CVC. However, it is unclear whether citrate alone has the same protective effect against systemic infection as it does when combined with other antimicrobial agents.[66] Topical application of mupirocin ointment to tunneled exit sites has been reported to reduce the incidence of catheter-associated bacteremia.

Catheter Obstruction

Catheter obstruction may be caused by endoluminal fibrin deposits, restricting the catheter lumen or obstructing catheter side holes at the tip, or external fibrin sleeves surrounding the catheter, resulting in inadequate flow and excessive extracorporeal blood pressure alarms during the dialysis session. Depending on the location of the fibrin clot (arterial or venous line), there may be high negative arterial pressure (obstruction at the arterial catheter line) or high positive venous pressure (obstruction at the venous catheter line).

Prevention of clot formation in the catheter tip during the interdialytic period is crucial. This is achieved by installing an antithrombotic lock solution (trisodium citrate 30%).[67] Catheter malfunction might be treated with regularly urokinase locking. A certain amount of the antithrombotic lock solution may leak into the circulation through side and central catheter holes, facilitating catheter clot formation while increasing risk for hemorrhage. Regular use of low-dose warfarin or antiplatelet agents has failed to improve catheter function in dialysis patients in randomized trials.

To correct catheter dysfunction, it is recommended that the catheter lumen be cleaned periodically by application of a fibrinolytic agent (urokinase) as a lock solution or by continuous infusion into both arterial and venous lines. Occluded catheters are reopened either by a mechanical method (brush) or pharmacologically (urokinase). Removal of the fibrin sleeve may be achieved by Lasso wire stripping or infusion of a fibrinolytic solution (urokinase) for 3 to 6 hours. Alternatively, the catheter may be exchanged over a guidewire.

SELF-ASSESSMENT QUESTIONS

1. Arteriovenous fistulas (AVFs) are preferable to arteriovenous grafts (AVGs) because of:
   A. Lower early failure rate
   B. Improved ease of cannulation
   C. Better long-term patency
   D. Lower risk of ischemia
2. Ischemia in elbow fistulas with normal access flow (800 ml/min) is best treated by:
   A. Access banding
   B. Distal revascularization–interval ligation (DRIL) procedure
   C. Revision using distal inflow (RUDI) procedure
   D. Distal radial artery ligation
3. Tunneled cuffed central vein catheters are preferred over nontunneled catheters because of:
   A. Ease of insertion
   B. Lower occlusion rate
   C. Higher dialysis flows
   D. Lower infection rate
4. AVFs have a better long-term survival because of:
   A. Lower thrombosis rate
   B. Lower infection rate
   C. Higher access flow
   D. Less frequent aneurysm development
5. The primary treatment option for symptomatic central vein occlusion is:
   A. Percutaneous transluminal angioplasty
   B. Stent placement
   C. Surgical bypass
   D. Vascular access ligation

Diagnostic and Interventional Nephrology

W. Charles O'Neill, Haimanot Wasse, Stephen R. Ash

A variety of procedures are essential to the care of nephrology patients and include ultrasound, renal biopsy, insertion of hemodialysis (HD) and peritoneal dialysis (PD) catheters, creation of arteriovenous fistulas (AVFs), and diagnostic and interventional procedures to maintain HD access function. These procedures have traditionally been performed by other specialists, but an increasing number of nephrologists perform these procedures. The field of diagnostic and interventional nephrology is most developed in the United States, where the American Society of Diagnostic and Interventional Nephrology (ASDIN) (www.asdin.org) has established training standards and certification procedures. This chapter covers ultrasound, insertion of dialysis catheters, and interventions in vascular access, focusing on the applications of these procedures and their performance by nephrologists. Renal biopsy is covered in Chapter 6, and placement of AVFs and arteriovenous grafts (AVGs) in Chapter 91.

ULTRASOUND

An important reason for nephrologists to be involved in ultrasound procedures is that many of the findings on ultrasound are not specific and require clinical correlation. The role and interpretation of ultrasound are further covered in Chapter 5.

Applications and Limitations of Ultrasound

Ultrasound is an excellent tool for examination of the kidneys and urinary tract. Under optimal conditions, both kidneys, the renal artery and vein, the proximal and distal ureter (when enlarged), and the bladder can be visualized. The ureter is usually apparent only when it is dilated. The middle portion of the ureter is usually obscured by overlying bowel but still may be visible when it is very dilated. In transplanted kidneys, the entire ureter can be visualized, even when it is not markedly dilated, because of the proximity to the probe and the lack of overlying bowel. In very ill patients who cannot be optimally positioned, cannot control their breathing, or have abdominal wounds or distention, views of the kidneys may be limited, but it is still usually possible to determine whether hydronephrosis is present.

Chronic Kidney Disease

Ultrasound is indicated in any patient with chronic kidney disease (CKD) to establish renal size and rule out polycystic kidney disease or urinary tract obstruction. Small, echogenic kidneys indicate severe irreversible disease, eliminating the need for a biopsy.[1]

Acute Kidney Injury

Although the diagnostic yield is very low in patients in whom the basis for renal failure is likely to be acute tubular necrosis or prerenal causes, ultrasound is still indicated in certain patients to rule out obstruction and identify preexisting CKD.[2]

Renal Transplantation

Ultrasound is indicated when there is an acute decline in renal transplant function, because urinary obstruction is common in this setting.[3] In the immediate post-transplantation period, Doppler evaluation of renal blood flow should also be performed to rule out thrombosis. Additional indications in transplant patients are pain, swelling, ipsilateral leg edema, and infection. Another important indication in both native and transplanted kidneys is guidance for percutaneous biopsy, nephrostomy, or drainage of fluid collections.

Renal Biopsy

Ultrasound is the method of choice to guide percutaneous renal biopsy.[4] Computed tomography usually offers no advantages over ultrasound[5] and results in unnecessary irradiation. This is discussed further in Chapter 5.

Urinary Bladder

Ultrasound is the procedure of choice for measurement of postvoid residual volume because it is simple, painless, and sufficiently accurate.[6] Additional indications include checking the location and patency of Foley catheters and examination of the distal ureters. Placement of the catheter in the proximal urethra is uncommon but not rare, and obstruction of catheters is frequent, so examination of the bladder always should be considered when urine output decreases. Prostatic hypertrophy, prostatitis, bladder carcinoma, mucosal edema, blood clots, stones, stents, and other foreign bodies can be recognized with ultrasound, but transabdominal ultrasound is not the appropriate test to rule out bladder cancer (which requires cystoscopy) or prostatic cancer (which requires transrectal ultrasound and biopsy).

Hemodialysis Access

Ultrasound is essential in the management of vascular access, including guidance of catheter insertion, evaluation of fistula dysfunction, preoperative vein mapping, and monitoring of access flow. Of these, the first two can be readily performed by nephrologists. Guidance of catheterization is best performed with a dedicated scanner but can be done with any scanner that has a vascular probe because Doppler imaging is not required. Examination of dysfunctional fistulas is also straightforward and does not necessarily require Doppler analysis. Vessel mapping and monitoring of access flow are both best performed by an experienced vascular technician. Sonography can be very useful in guiding cannulation of fistulas and grafts and in training patients for self-cannulation.[7]

Renovascular Ultrasound

Doppler ultrasound of renal arteries and veins is a difficult study requiring an experienced operator and is not usually practical for nephrologists. Tracings from segmental arteries are more easily obtained and can be useful in diagnosis of renal artery stenosis and vein thrombosis. However, measurement of resistive index can be unreliable and nonspecific because it is influenced by external factors such as systemic blood pressure and heart rate[8] and is of questionable usefulness in the evaluation of acute kidney injury either in native kidneys or transplanted kidneys. Doppler ultrasound is useful in distinguishing between cystic and vascular lesions and between renal vein and ureter.

Equipment

Important considerations in the choice of equipment are image quality, probe type and frequency, cost, size, portability, and output. Image quality is difficult to quantify and is related to the number of elements (crystals) in the probe and the number of channels that can be processed. Probes should be electronic and in the frequency range of 2.0 to 6.0 MHz (up to 7.5 MHz for pediatric use) for abdominal imaging. Preferably, these should be variable-frequency, curvilinear probes. Probes for vascular imaging are usually linear probes with a frequency of 10 to 12 MHz. For grayscale renal ultrasound, portable, lightweight scanners with good image quality are available; Doppler capability is increasingly being offered as a standard feature. Larger and more expensive scanners are difficult to maneuver and have additional features that are of little use to the nephrologist. Controls on the scanner allow adjustment of scanning depth, focal length, time-gain compensation, sound intensity, and grayscale. Although this seems a daunting number of variables, adjustment is usually straightforward and mostly empiric. Images can be printed directly or stored digitally.

Procedure

Description of the scanning procedures cannot substitute for hands-on training because scanning is an acquired skill that requires practice. Ideally, the patient should be fasting for abdominal scanning to minimize interference from intestinal gas, but this is not essential for examination of kidneys and is of no consequence for examination of the bladder or transplanted kidneys. There must be an airtight connection between the probe and the skin, which is accomplished by placing gel on the probe or skin and applying firm pressure against the skin. To avoid compression of the vessels, minimal pressure should be applied for vascular examinations, with the use of more gel. Gel specifically designed for ultrasound should be used because other gels, such as lubricating gel, give poorer image quality. Ambient light should be dimmed to optimize viewing of the monitor.

The patient should be flat in the supine or lateral decubitus position with imaging through the abdomen for examination of native kidneys. Initial attempts should be made with the patient in the supine position before resorting to the lateral decubitus position. Imaging through the back is not recommended for diagnostic imaging because of sound attenuation by muscle and fascia and limitations on angling of the probe. Placement of the ipsilateral arm over the head, removal of pillows from under the head, and deep inspiration aid in moving overlying ribs superiorly. Transplanted kidneys and the urinary bladder are examined with the patient in the supine position, but he or she need not be completely flat.

Initially, longitudinal images should be obtained to determine maximal kidney length. On the right side, this view should be obtained through the liver if possible (Fig. 92.1A). The probe should be oriented so the upper pole is toward the left side of the image. The probe should then be rotated 90 degrees counter-clockwise to obtain transverse views (see Fig. 92.1B), and the kidney is scanned from pole to pole to ensure visualization of the entire kidney. Examination of each kidney should include longitudinal images with adjacent liver or spleen if possible, as well as transverse images through the mid-kidney and each pole.[9] Measurements other than length are not clinically useful, and measurements of kidney volume are inaccurate and no better than length in judging kidney size.[10] Sagittal and transverse views of the urinary bladder are obtained with the probe just superior to the symphysis pubis and angled inferiorly (see Fig. 92.1C and D). Volume is obtained by multiplying the two transverse dimensions and the sagittal length by 0.523.[6] Although there is significant error in this measurement, it is rarely clinically significant. The technique for renal biopsy is discussed in Chapter 6.

Training and Certification

There are no data on what constitutes adequate training for renal ultrasound. Training is required for both performance and interpretation and should include didactic, hands-on, and supervised components. The last can vary considerably, depending on case volume and particularly type because any quantity of studies will be inadequate if the findings are all normal. Thus the number of studies required for competence is inversely related to the frequency of pathology. Minimal qualifications for physician-sonographers have been established by the American Institute of Ultrasound in Medicine[11] and the American College of Radiology,[6] but neither organization has developed guidelines for limited abdominal ultrasound. ASDIN (www.asdin.org) has established training standards for ultrasound limited to kidneys and bladder that specify 50 hours of training and 125 studies (at least 80 being supervised and the remaining having confirmatory follow-up).[11] Because renal ultrasound is not usually a formal component of nephrology training, a course for nephrologists has been established in the United States (http://medicine.emory.edu/renal-medicine/education/ultrasonography-nephrologists.html).[9] Training and certification are available in vascular ultrasound but are not limited to applications specific to nephrology. Such training is important for vascular studies of kidneys but is not necessary for examination of dysfunctional AVFs and AVGs (unless flow is measured) because this does not require Doppler analysis. There are currently no guidelines or training established for vascular ultrasound related to nephrology.

PERITONEAL DIALYSIS CATHETERS

Successful PD depends on proper catheter insertion and management. The feasibility, safety, and success of these procedures when they are performed by nephrologists have been well documented,[13-15] and this can facilitate use of PD. Tenckhoff catheters remain the most popular chronic peritoneal access devices, over 50 years since their description. These catheters are constructed of silicone rubber with a 5-mm external diameter and internal diameters of 2.6 to 3.5 mm and numerous intraperitoneal side-holes. The intraperitoneal portion can be straight, straight with perpendicular silicone disks, or curled have been Several, design modifications were developed to attempt to diminish outflow obstruction, including a version sold in Europe with a weighted tip. The subcutaneous portion is either straight or bent and has one or two extraperitoneal Dacron cuffs that prevent fluid leaks and bacterial migration around the catheter, although one catheter has a silicone ball and Dacron disc at the parietal peritoneal surface. The subcutaneous catheter shapes all provide a lateral or downward direction of the exit site. An upwardly directed exit site collects debris and fluid, increasing the risk for exit site infection. The method of catheter placement has more effect on the outcome than catheter choice does.

Catheter Insertion

The four techniques for PD catheter insertion are dissection (surgical), the Seldinger technique (blind or with fluoroscopy), peritoneoscopic,

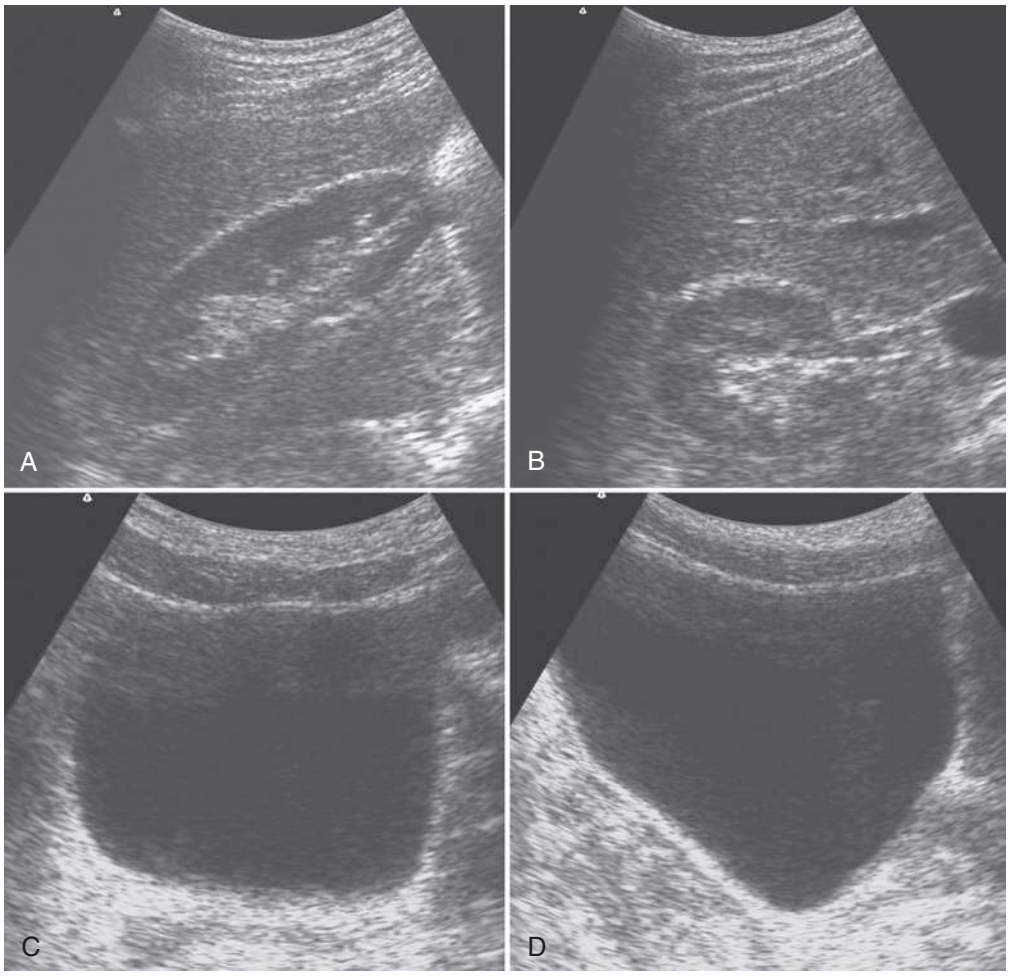

Fig. 92.1 Imaging planes for renal and bladder sonography. (A) Longitudinal image of right kidney. Upper pole should be on left side of the image. (B) Transverse image of right kidney through the renal hilum. (C) Transverse image of urinary bladder. Anteroposterior and mediolateral dimensions are obtained in this plane. (D) Sagittal image of the urinary bladder. Superior portion of the bladder is to the left. Superoinferior dimension is obtained in this plane.

and laparoscopic.[16] The Seldinger and peritoneoscopic techniques are most frequently used by nephrologists. Peritoneoscopic insertion is a single-puncture technique using a small (2.2-mm diameter) optical peritoneoscope for direct inspection of the peritoneal cavity and identification of a suitable site for the optimal intraperitoneal portion of the catheter. Peritoneoscopic placement is usually performed with local anesthesia (sometimes with conscious sedation) and manual infusion of about 1 liter of air. Laparoscopic techniques are performed with the patient under general anesthesia, with larger scopes, multiple insertion sites, and automated gas infusion. Both peritoneoscopic and laparoscopic techniques allow direct visualization of intraperitoneal structures.

The choice of technique must take into account the local experience with complications (pericatheter leakage, outflow failure, exit site and tunnel infection) and long-term catheter function associated with each technique, costs, ease and timely insertion of the catheter, and factors contributing to mortality risk (local vs. general anesthesia). Both randomized and nonrandomized studies have documented that the peritoneoscopic and fluoroscopic Seldinger techniques result in fewer catheter complications (infection, outflow failure, pericatheter leak) and improved catheter survival compared with surgical placement.[14,17] The superior results with peritoneoscopic placement may relate to direct visualization of the abdominal cavity, less tissue dissection, and avoidance of general anesthesia. Because tissue dissection for intermittent peritoneal dialysis is minimal, the catheter can be used immediately (after 36 hours), although a 2- to 3-week delay is recommended.[18]

For peritoneoscopic insertion (Fig. 92.2), a small skin incision (2 to 3 cm) is made and dissection is carried down only to the subcutaneous tissue.[19] The anterior rectus sheath is identified but not incised. A preassembled cannula with trocar and a spiral sheath is then inserted at a 40- to 50-degree angle into the abdominal cavity through the rectus muscle (see Figs. 92.2A and 92.3). The trocar is then removed and replaced by the peritoneoscope to confirm the intraabdominal position of the cannula (see Fig. 92.2B). Air is then infused (600 to 1000 ml) to separate visceral and parietal peritoneum. Alternatively, a Veress needle can be used.[20] Bowel loops, the dome of the bladder, and any intra-abdominal adhesions are identified. The cannula and spiral sheath are advanced into the pelvis (see Fig. 92.2C). The cannula and the peritoneoscope are then removed, the spiral sheath is dilated to 6-mm diameter (see Fig. 92.2D), and the catheter is inserted through the sheath by a stylet (see Fig. 92.2E). The deep cuff is implanted into the rectus muscle with use of an implanter tool without dissection of the anterior rectus sheath or the muscle (see Fig. 92.2F). A tunnel and an exit site are created and the superficial cuff is implanted into the subcutaneous tissue. The subcutaneous tissue is sutured with absorbable material,

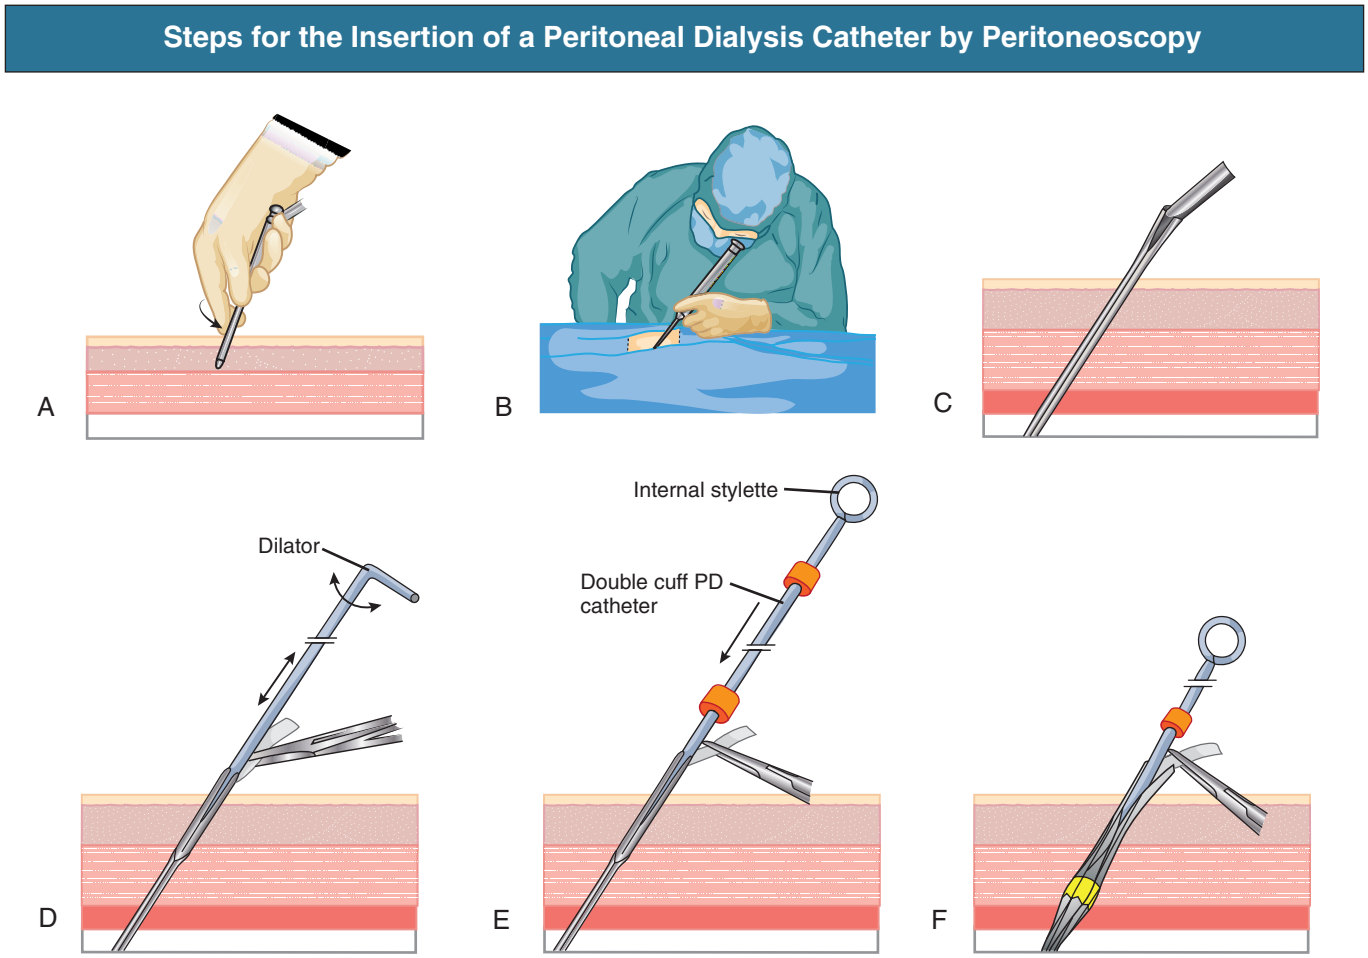

Fig. 92.2 Steps for the insertion of a peritoneal dialysis *(PD)* catheter by peritoneoscopy. (A) A trocar and cannula with a sheath are inserted into the abdominal cavity. (B) A peritoneoscope is passed through and locked into the cannula. (C) The sheath has been passed into the abdominal cavity and the peritoneoscope and cannula removed sequentially. (D) The sheath is secured with forceps while it is being dilated. (E) A PD catheter (with double cuff) is passed through the dilated sheath by use of an internal stylet. (F) The deep cuff is implanted into the rectus muscle. (Redrawn from Y-Tec Instructions: *Laparoscopic and Peritoneoscopic Placement of Peritoneal Dialysis Catheters.* Oswego, IL: Medigroup Inc. [division of Janin Group, Inc.]; 2004:1-5.)

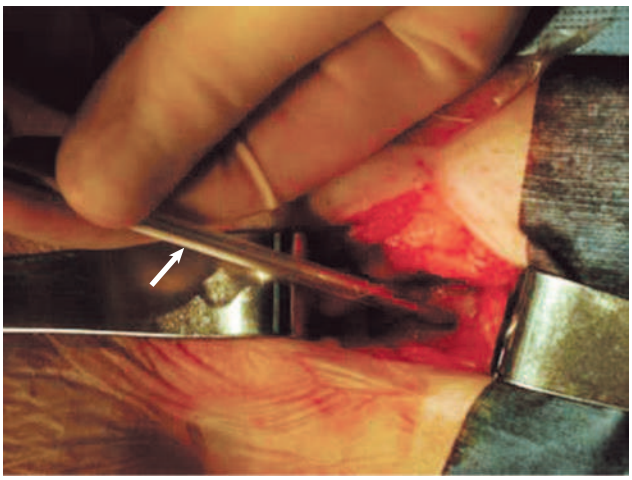

Fig. 92.3 Peritoneoscopic insertion of a peritoneal dialysis catheter. During peritoneoscopic insertion of a peritoneal dialysis catheter, a Quill guide trocar and cannula *(arrow),* with its wrapped spiral sheath, is being inserted through the rectus muscle under local anesthesia.

and the skin is closed with nylon. No sutures are placed on the external rectus sheath or at the skin exit site.

The Seldinger technique using fluoroscopy begins with blunt dissection down to the level of the lateral border of the rectus sheath. An 18-gauge needle with internal blunt stylet or a 22-gauge needle from a 5-French micropuncture set is inserted at an angle of 45 degrees, directed toward the lower pelvis into the peritoneum (ultrasound is helpful to identify thickness of the rectus muscle and presence of adhesions to the parietal peritoneum).[21] The location of the needle within the peritoneal cavity is confirmed by injecting 1 to 5 ml of contrast material, which forms a classic "spider web" appearance as dye moves into small spaces between bowel loops and parietal peritoneum (Fig. 92.4A).[21] If the tip of the needle is in the preperitoneal space, the dye collects around the tip of the needle, forms an outline of the parietal peritoneum, and appears static over a minute or so (Fig. 92.4B). Advancing the needle under fluoroscopic visualization allows the tip to penetrate the parietal peritoneal surface. If a micropuncture needle is used, an 0.018-inch wire is then inserted through the needle under fluoroscopy. Once the wire is in the lower pelvis, a 5-French catheter is placed over the wire. Contrast material can again be injected through the catheter

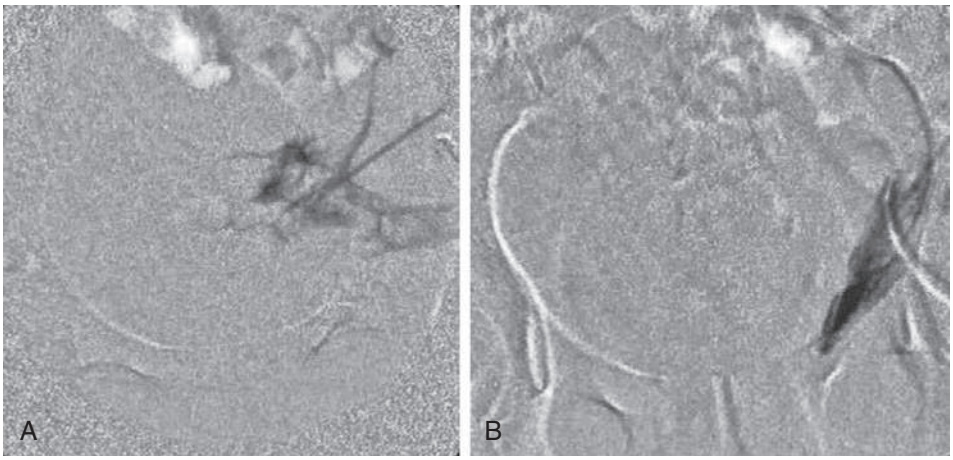

Fig. 92.4 (A) Fluoroscopic image after injecting a few milliliters of radiopaque dye through an 18-gauge needle after insertion through the rectus muscle and into the peritoneal space. Dye moves quickly away from the needle, and the image is not static. (B) Image after injecting a few milliliters of dye into an 18-gauge needle after insertion through the rectus muscle, with the tip of the needle in the preperitoneal space. Dye collects around the tip of the needle, at least one flat surface outlines the parietal peritoneum, and image changes very little with time. (With permission, from reference 21.)

Fig. 92.5 Subcutaneous tunnel being created for a peritoneal dialysis catheter. With use of a disposable tool, a subcutaneous tunnel is created for the catheter. The superficial cuff shown will be implanted in the subcutaneous tunnel.

to confirm the position. If an 18-gauge needle is used, a 0.035-inch guidewire is passed directly through the needle and dilators are advanced sequentially up to the final 18-French dilator and peel-away sheath. The guidewire is removed, and the PD catheter is inserted over a metal stylet through the sheath, splitting the sheath as the deep Dacron cuff advances. This cuff is pushed into the rectus muscle while the sheath is in place, and the sheath is then removed around the cuff and catheter. The catheter is tunneled laterally with a tunneling tool (Fig. 92.5).[22,23]

Burying (Embedding) the Peritoneal Dialysis Catheter

If the catheter will not be used immediately, it can be embedded (buried) under the skin for weeks to months before it is tunneled to the outside and used. The catheter is placed in the usual manner, filled with dilute heparin solution in saline (100 U/ml), blocked with a plug, and tunneled through a small skin exit site. The tip is then directed into the exit site and tunneled through the subcutaneous space in a direction toward midline, caudal to the umbilicus. In some centers the catheter is tied off with silk suture and coiled into a pouch under the exit site. The primary incision and exit site are then closed over the catheter. Embedding the catheter allows ingrowth of tissue into the cuffs of the catheter with less chance of bacterial colonization and diminishes the incidence of early pericatheter infections and peritonitis.[24,25] Exteriorization of the catheter is done by making a small incision (1 cm) through the original exit site. Catheters buried in this fashion have been successfully exteriorized and used more than 1 year after insertion.[26] We recommend embedding the catheter when the catheter will not be used for at least a month.

Complications of Peritoneal Dialysis Catheter Insertion

Bowel perforation is the most feared complication of catheter insertion. The incidence is 1% to 1.4% with surgical insertion[14,15] but 0% to 0.8% with the peritoneoscopic insertion.[13,15] The diagnosis is established by direct peritoneoscopic visualization of bowel mucosa, bowel contents, or hard stool or return of fecal material or emanation of foul-smelling gas through the cannula. Whereas some investigators suggest this complication should be treated with surgical intervention,[27] successful conservative management of bowel perforation with bowel rest and intravenous antibiotics also has been reported.[22,28] To minimize the risk for perforation, a needle (such as a Veress needle) that is smaller and has a blunt, self-retracting end can be used instead of a trocar to gain access to the abdominal cavity.[20] Previous abdominal surgery is mentioned as a relative contraindication to PD because of intraperitoneal adhesions.[29,30] However, with careful ultrasound examination before needle placement an area free of adhesions can be identified. Peritoneoscopy is especially valuable for patients at high risk for adhesions. The scope can be used to identify intraperitoneal adhesions, assess their extent, and locate another site more suitable for catheter placement. With either fluoroscopic or peritoneoscopic techniques, the incidence of bowel perforation is no higher than during surgery, for patients with or without prior abdominal surgery, and the early success rate of catheters exceeds 95%.[11,13]

Catheter Repositioning

Migration of the PD catheter to the upper abdomen is a frequent cause of catheter failure. A variety of techniques have been used for repositioning, including guidewire or stylet insertion, Fogarty catheters, and laparoscopy, and many of the techniques are feasible for nephrologists.

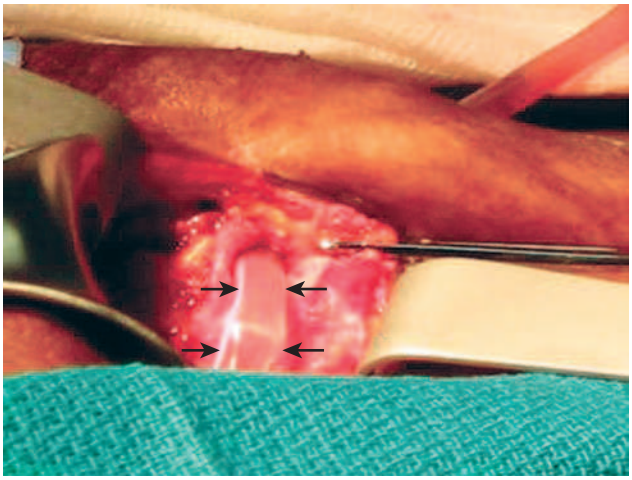

Fig. 92.6 Peritoneal dialysis catheter removal. The catheter (*arrows* show lateral margins of catheter) has been exposed by dissection of the subcutaneous tunnel.

The long-term success rate of repositioned catheters is only 27% to 48%,[31,32] probably because the migration of the catheter is the result of adhesion of omentum to the catheter. Thus insertion of a new catheter is required in many patients. Fogarty catheter manipulation is perhaps the most cost-effective, safe, and simple method for catheter reposition. A Fogarty catheter is advanced into the PD catheter, and the balloon is inflated. Manipulation is performed by tugging movements to reposition the catheter into the pelvic area. Infusion and drainage of dialysate and fluoroscopy are performed to determine patency and position of the PD catheter, respectively. Peritoneal catheters can be repositioned using stiff guidewires or stylets. Fluoroscopic images are very helpful in determining the degree of catheter entrapment and the progress of the repositioning procedure.[21]

Removal of Peritoneal Dialysis Catheters

A Tenckhoff curled or straight PD catheter can be safely removed without need for an operating room or general anesthesia.[18] Local anesthetic is infiltrated at the site of the original primary incision, and it is incised. Dissection is carried down to the subcutaneous portion of the catheter, which is elevated while the surrounding fibrous sheath is opened. The catheter is clamped with a hemostat, a nylon suture is placed in the catheter beyond the hemostat as a tag, and the catheter is cut between tag and hemostat. Dissection is continued toward the deep cuff by incising the fibrous tunnel adjacent to the catheter (Fig. 92.6). Additional anesthetic is infiltrated around the deep cuff. For catheters that have been in place for less than a month, blunt dissection is usually sufficient to free the deep cuff. Older catheters require sharp dissection. Exposure of the deep cuff and the anterior rectus sheath is required. Once the deep cuff is separated from the surrounding tissue, the intraperitoneal portion of the catheter is gently withdrawn from the peritoneal cavity and the defect in the rectus sheath closed with an absorbable purse-string suture. The nylon tag is then pulled to expose the remaining subcutaneous portion of catheter segment, and dissection is performed in the direction of the superficial cuff. Once the superficial cuff is free, this portion of the catheter is removed through the primary incision site or the exit site. Absorbable suture material in the dermis is used to close the skin incision subcutaneous tissue; and nylon sutures or sterile adhesive strips are applied to reinforce the skin closure. The exit site is not sutured.

Training and Certification

The ASDIN has established training guidelines and criteria for certification of physicians in the insertion of PD catheters (www.asdin.org).[12] In addition to appropriate didactic training, there should be two practice insertions (into models, animals, or human cadavers), observation of two insertions into patients, and then six successful insertions into patients as primary operator.

TUNNELED HEMODIALYSIS CATHETERS

Central venous catheters are used as a temporary HD access, as a bridge to AVF or AVG use, and when all other permanent access sites have been exhausted. Nontunneled catheters are used when a limited number of dialysis sessions is anticipated or there are contraindications to tunneled catheters (systemic infection, risk for bleeding) and are appropriate for use only in the inpatient setting. Tunneled catheters can be placed in both inpatient and outpatient settings, can be inserted at multiple vein locations, are relatively low in cost, and provide immediate access. However, there are significant disadvantages, including morbidity from infection and thrombosis and the risk for central vein stenosis or occlusion.[33,34] The role of the tunneled dialysis catheter in the provision of vascular access for HD is discussed further in Chapter 91.

Tunneled Catheter Insertion

The right internal jugular vein is the preferred catheter location compared with the left internal jugular and subclavian vein sites; it provides a straight route to the right atrium, thereby reducing the risk for central vein stenosis. Catheters also may be placed in the femoral veins.

Catheter insertion is performed in a sterile setting, ideally in an operating room environment with fluoroscopy available or at a minimum in a dedicated procedure room with cardiac monitoring. Before cannulation the vein should be located by ultrasound to detect anatomic variation or venous thrombosis. The patient's neck is then prepared and draped in sterile fashion; under ultrasound guidance, the vein is cannulated with a micropuncture needle (18 to 22 gauge), and a micropuncture guidewire is inserted and positioned in the superior vena cava. The needle is then removed, and the micropuncture dilator is inserted over the guidewire so it can be replaced with a standard guidewire. The use of the smaller needle rather than the standard 15-gauge needle minimizes trauma to the vein. A small subcutaneous incision is made adjacent to the dilator or guidewire, additional dilation is performed, and the catheter is placed over the guidewire, with care taken to hold the guidewire in place. If a tunneled catheter is to be placed, a catheter exit site is selected inferior to the clavicle and sufficiently lateral to the venotomy to avoid a kink in the catheter. A 1-cm superficial incision is made at this point, and a subcutaneous tract adjacent to the venotomy is infiltrated with lidocaine. A double-lumen catheter, generally 24 or 28 cm in length, is attached to the tunneling device and pulled through the subcutaneous tunnel in a curved path. A guidewire is passed through the dilator and into the inferior vena cava. The venotomy site is then serially dilated over the guidewire. The catheter can then be inserted over the guidewire through the venous port. When a split-tip catheter is used, the guidewire is passed in and out of the two venous ports and through an arterial port or through a hollow intracatheter stiffener. Alternatively, a peel-away sheath is placed over the guidewire and the catheter inserted through the sheath after the removal of the guidewire; however, this method has greater potential for blood loss and air embolism. Fluoroscopy is used to confirm tip placement at the level of the right atrium, with the arterial port facing away from the atrial wall, and to ensure there are no kinks in the catheter (Fig. 92.7). Each port of the catheter is then flushed with saline and locked with the appropriate amount of heparin based on catheter length and priming volume designation, followed by placement of the catheter hub caps.

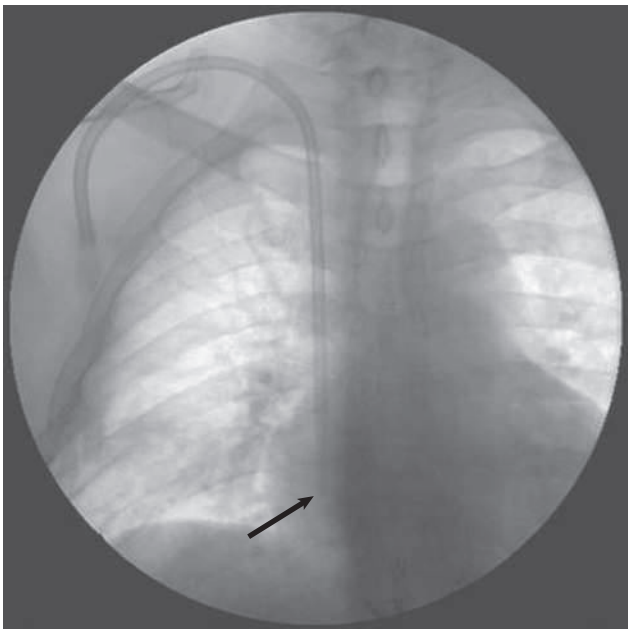

Fig. 92.7 Insertion of a venous catheter for hemodialysis. Chest radiograph confirming that the tip of the catheter *(arrow)* is at the junction of the superior vena cava and the right atrium.

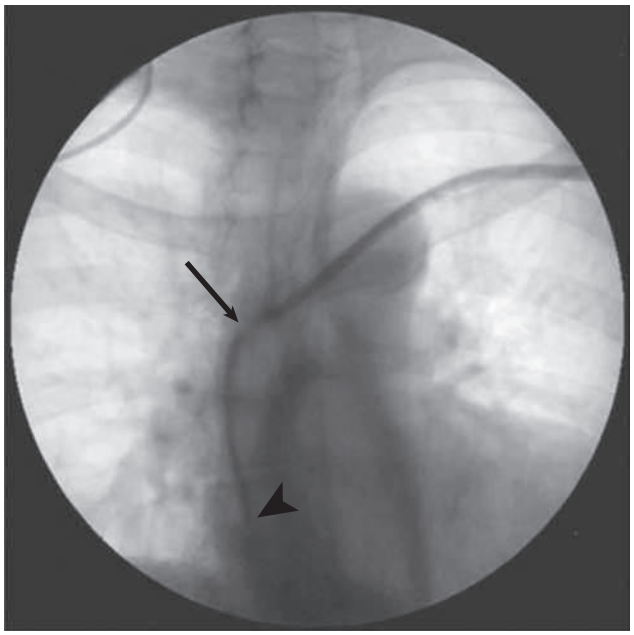

Fig. 92.8 Fibrin sheath on a tunneled venous catheter. Contrast material has been injected into a tunneled catheter after the tip *(arrow)* has been pulled back into the innominate vein. The contrast material fills a sheath that extends from the catheter tip as far as the *arrowhead*.

Catheter Dysfunction

Catheter dysfunction is defined as the failure to maintain a blood flow sufficient to perform HD without significantly extending treatment time; this is usually 300 ml/min or greater for conventional dialysis.[35] Causes of immediate dysfunction include a kink in the catheter, incorrect position or orientation (e.g., arterial port against the vessel wall), and errant venous cannulation. These problems should be ascertained and corrected at the time of catheter placement. Catheter thrombosis is the most common cause of late dysfunction. Extrinsic thrombosis is less common than intrinsic thrombosis and is caused by central vein, mural, or right atrial thrombosis. Intrinsic obstruction results from thrombus within the catheter lumen or tip or most commonly from a fibrin sheath. Fibrin sheaths typically develop weeks to months after catheter insertion and result when a sleeve of connective tissue forms at the venotomy site and extends and encases the catheter tip, creating a flap-valve. First-line treatment of catheter thrombosis includes forceful flush of the catheter with saline. If flow is not restored, a fibrinolytic agent should be instilled. Tissue plasminogen activator (tPA) is commonly used and appears more effective than urokinase in restoring patency and adequate flow.[36,37] Typically, 2 mg of tPA is instilled per occluded catheter lumen with 0.9% sodium chloride without preservative to fill the internal volume of each lumen and is allowed to dwell 30 minutes. If this fails, the catheter should be exchanged. Strategies to minimize dialysis catheter thrombosis are discussed in Chapter 91.

Catheter Exchange and Fibrin Sheath Removal

Catheter exchange over a guidewire is useful in the setting of catheter thrombosis or bacteremia and allows the preservation of the venotomy, tunnel, and exit sites. The tunnel and exit sites must appear free of infection if the same sites are to be used. Catheter exchange should take place within 72 hours of the initiation of antibiotic therapy.[35] Under sterile conditions, the exit site is anesthetized and the cuff is freed. Once the catheter is pulled back 8 to 10 cm, contrast material is injected through the catheter under fluoroscopy to check for a fibrin sheath (Fig. 92.8). To obliterate a sheath, a guidewire is passed down the venous port of the catheter and into the inferior vena cava. The catheter is then removed, and a balloon catheter is inserted over the guidewire to the sheath location and inflated to disrupt the sheath. A new catheter is then inserted over the guidewire. When the catheter tip is beyond the venotomy site, near the superior vena cava, contrast material can be injected again to check for sheath removal before proceeding with catheter insertion.

Training and Certification

The American Society of Diagnostic and Interventional Nephrology guidelines for HD vascular access procedure certification specify formal didactic training in central venous anatomy, sonographic examination of central veins, fluoroscopy, and catheter design and complications. In addition, practical training for certification includes satisfactory insertion of 25 tunneled long-term catheters. More information may be obtained at www.asdin.org.

PROCEDURES ON ARTERIOVENOUS FISTULAS AND GRAFTS

The most common indications for intervention are inadequate flow during dialysis, thrombosis, and failure of AVFs to mature. Specific interventions include angiography, thrombectomy, angioplasty, and stenting. All of these procedures require a dedicated facility, either inpatient or outpatient, with fluoroscopy, monitoring equipment, and staff to assist with the procedures and deliver conscious sedation. There are many different techniques for AV access procedures and few data to indicate superiority of one method over the other, so the choice is generally one of personal preference and cost. However, the first step always should include careful physical and ultrasound examination of the access. An examination will generally identify the problem and allow detection of access infection, an absolute contraindication to intervention. Appropriate intervention then can be planned. Monitoring and management of vascular access to minimize stenosis, thrombosis, and failure are discussed further in Chapter 91.

Percutaneous Balloon Angioplasty

Stenosis in AVGs and AGFs is routinely managed by percutaneous balloon angioplasty, which causes minimal discomfort and allows immediate use of the access. Not all stenotic lesions are responsive, however, and some require repeated treatment. In fistulas, the stenosis is most commonly located at the "swing point," including the portion of the native vein mobilized during creation of the AV anastomosis (Fig. 92.9), or during vein transposition, or at the cephalic arch; in grafts, the venous anastomosis is the most common site of stenosis.[38-42] Angioplasty is indicated if the stenosis is 50% or more and is associated with clinical or physiologic abnormalities.[35] Treatment of stenosis increases access blood flow and longevity and reduces access thrombosis and access-related hospitalization.[42,43,44] A relative contraindication to angioplasty is a newly created access (<4 to 6 weeks old).

The access is cannulated with an introducer needle, a sheath is inserted, and initial angiography is performed. This should include views of the access, draining veins (peripheral and central), and arterial anastomosis and is used to confirm the location and degree of stenosis. Unless contraindicated, short-acting sedation and analgesia are given once a lesion has been identified on initial angiography, because angioplasty is painful.

A guidewire is passed through the sheath and across the stenosis. An angioplasty balloon catheter is passed over the guidewire, positioned at the stenotic site, and inflated with a syringe or inflation device (Fig. 92.10). A variety of sheaths, guidewires, balloon sizes, and maximum pressures are available. The guidewire is left in place, and angiography is repeated to identify residual stenosis or any complications. Angioplasty is repeated for residual stenosis or when multiple lesions are present and may require a second cannulation of the access in the opposite direction for inflow stenoses. After removal of all devices, hemostasis at the cannulation site is achieved by manual pressure or suture placement. There is no evidence to support the use of antiplatelet agents or anticoagulation after intervention. According to Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines, a successful angioplasty is achieved when there is no more than 30% residual stenosis and physical indicators of stenosis have resolved.[35]

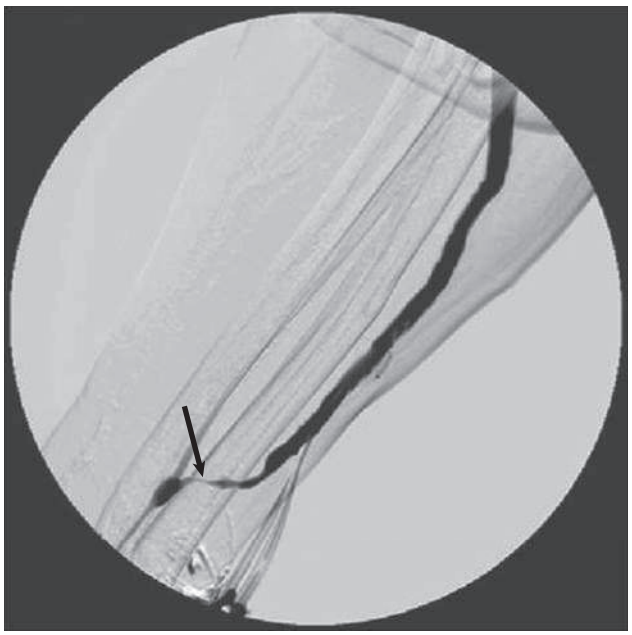

Fig. 92.9 Juxtaanastomotic stenosis in a radiocephalic arteriovenous fistula. Contrast material was injected at the arterial anastomosis *(bottom left of image)* and demonstrates a narrowing in the initial portion of the fistula *(arrow)*.

Percutaneous Thrombectomy

A variety of techniques are used for thrombus removal. In thromboaspiration—the least costly method, and as effective and efficient as mechanical and pharmacomechanical thrombolysis—low-dose tPA is instilled into the thrombosed access, the clot is manually macerated, flow returns, and angioplasty is used to dilate access stenoses.[45] Thrombectomy by thromboaspiration combines angiography with balloon angioplasty and thrombectomy by clot aspiration. Absolute contraindications to thromboaspiration include access infection and known right-to-left cardiac shunt; relative contraindications include a large clot burden and long-standing access occlusion.

The access is cannulated in an antegrade direction, and a guidewire is passed to the level of the central veins. A straight catheter is inserted over the wire to the central veins, and angiography is performed to confirm central venous patency. Anticoagulation and short-acting sedative and analgesic medications are administered in the central circulation. An angiogram is then obtained as the catheter is pulled back to identify the location of stenosis. The guidewire is then inserted beyond the stenotic lesion, followed by an angioplasty balloon catheter. The balloon catheter is insufflated by hand with a syringe or inflation device, and the stenotic lesion is dilated. The access is then cannulated in the retrograde direction, a sheath is inserted, and a Fogarty catheter is passed across the arterial anastomosis, inflated, and pulled back through the entire length of the access while clot fragments are aspirated. On return of flow through the access, angiography is performed to evaluate the inflow and the arterial anastomosis, and angioplasty is repeated if necessary. Hemostasis is achieved by manual pressure or a suture at the cannulation sites.

Stents

Stents are considered in the setting of failed balloon angioplasty (an elastic lesion), when there are few remaining access sites, if the patient is not a surgical candidate for a new access, or when an outflow vein ruptures after balloon angioplasty (Figs. 92.11 and 92.12).[50,51] Results of randomized studies designed to demonstrate stent graft noninferiority to conventional angioplasty for AVG venous anastomotic stenosis show

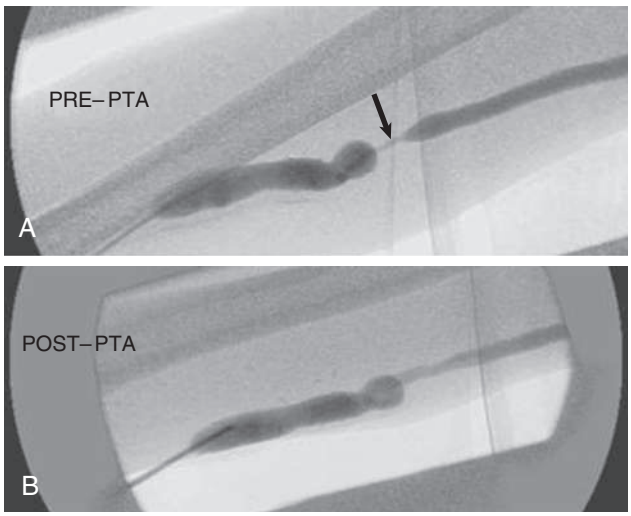

Fig. 92.10 Arteriovenous graft stenosis. (A) Stenosis in the outflow vein of an upper arm arteriovenous graft *(arrow)*. (B) Angiogram performed immediately after percutaneous angioplasty. *PTA,* Percutaneous transluminal angioplasty.

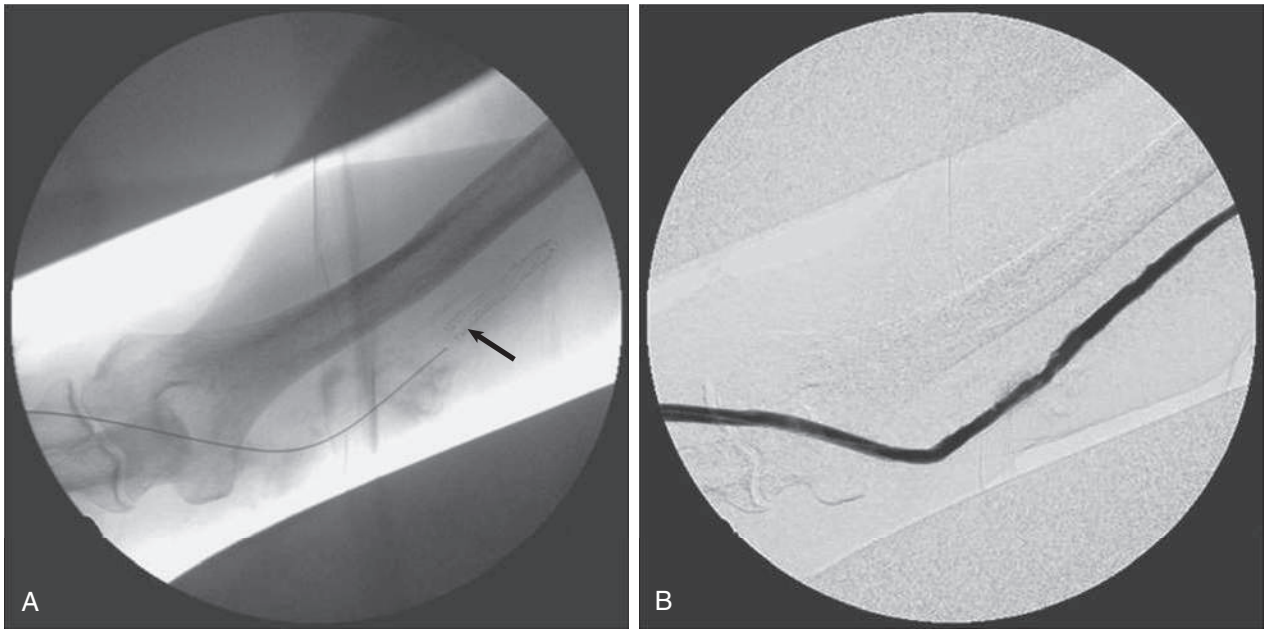

Fig. 92.12 Treatment of vein rupture with an intraluminal stent. (A) Placement of the stent *(arrow).* (B) An angiogram obtained after stent placement showing that venous outflow has been reestablished. (Courtesy Dr. G. Beathard, Austin, Texas.)

an increased primary patency for stent grafts.[52-54] Further, data suggests improved patency with stent grafts used to treat outflow vein re-stenosis in AVG, AVF and central veins. Remove work 'bare-metal'.[46-49,55] Finally, a stent may be useful in the setting of an expanding pseudoaneurysm.[56,57]

Despite these encouraging findings, stents should be used judiciously, particularly when surgical options may provide greater enduring patency. Stents should be avoided in situations in which their use will not extend the life of the access.

Training and Certification

The ASDIN guidelines for HD vascular access procedure certification specify didactic training in venous anatomy, fluoroscopy, procedural equipment, and sedation and analgesia. Requirements for practical training include 125 procedures in both fistulas and grafts of each of the following: angiography, angioplasty, and thrombectomy as primary operator (refer to www.asdin.org for more information). In general, several hundred procedures as secondary operator will be required before one can become a primary operator.

SELF-ASSESSMENT QUESTIONS

1. Tissue plasminogen activator (tPA) is generally effective in treating poor blood flow in tunneled central venous catheters resulting from fibrin sheath formation.
   A. True
   B. False
2. A 57-year-old male patient with end-stage renal disease with a mature, left brachiocephalic arteriovenous fistula (AVF) is referred for evaluation of prolonged bleeding from his AVF on removal of the dialysis needles. His AVF is pulsatile on examination and does not collapse when the left arm is raised above the heart. An angiogram identifies a 75% stenosis at the cephalic arch, and an angioplasty is performed. According to National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines, what defines a successful percutaneous angioplasty of an AV access?
   A. Less than 10% residual stenosis at the angioplasty site
   B. Ability to receive eight uncomplicated, consecutive dialysis sessions after the procedure
   C. Less than 30% residual stenosis and resolution of physical indicators of stenosis
   D. A and B
   E. B and C
3. Embedding (or burying) a newly placed peritoneal dialysis (PD) catheter under the skin:
   A. Allows ingrowth of tissue into the cuffs of the catheter without an opportunity for bacterial colonization
   B. Diminishes the incidence of early pericatheter infections
   C. Results in better catheter function in the future
   D. A and B
   E. Is of no benefit other than cosmetic
4. Which of the following statements about ultrasound of the renal and urinary tract is *false?*
   A. For examination of the kidneys a renal ultrasound is always indicated in the workup of chronic kidney disease.
   B. A renal ultrasound is not indicated in every patient with acute kidney injury.
   C. Ultrasound is not useful in the diagnosis of bladder outlet obstruction.
   D. The ureters are usually visible only when dilated.
5. Which of the following are commonly used techniques for insertion of PD catheters?
   A. Laparoscopy
   B. Surgical dissection
   C. Peritoneoscopy
   D. The guidewire (Seldinger) technique

Hemodialysis
Principles and Techniques

Peter Kotanko, Martin K. Kuhlmann, Christopher Chan, Nathan W. Levin

Hemodialysis (HD) has existed for more than 50 years and has extended the lives of millions of patients with renal failure worldwide. Although the basic principles of HD are still being applied today, dialysis technology has improved markedly.

DIALYSIS SYSTEM

The aim of the HD system is to deliver blood in a fail-safe manner from the patient to the dialyzer, enable the efficient removal of uremic toxins and excess fluid, and deliver the cleared blood back to the patient. The main components of the dialysis system are the extracorporeal blood circuit, the dialyzer, the dialysis machine, and the water purification system.[1]

HD has conventionally been delivered in three treatment sessions per week. This developed as a practical compromise between the physiologic benefits of replacing renal function by HD and the practicalities of delivering HD. Treatment times of 3 to 5 hours per session are now typical (for a detailed discussion of outcomes related to treatment time and frequency see Chapter 94).

DIALYZER DESIGNS AND MEMBRANES

The dialyzer provides countercurrent transfer of solutes and fluid across a semipermeable membrane. The semipermeable dialysis membrane separates the blood compartment from the dialysate compartment (Table 93.1). The original membrane material was cellulose. In cellulose acetate, most hydroxyl groups are replaced by acetate radicals. Synthetic tertiary amino compounds are added to form cellulosynthetic membranes. The current generation of membranes is made of entirely synthetic materials that are considered more biocompatible, such as polyacrylonitrite, polysulfone, polycarbonate, polyamide, and polymethylmethacrylate.

Transport of molecules across the dialysis membrane is due to (1) the concentration gradient (diffusive transport) and (2) the hydrostatic pressure gradient across the membrane (convective transport) and depends on membrane pore size. Dialyzer efficiency increases with surface area (usually 0.8 to 2.1 m^2). The dialyzer mass transfer area coefficient (KoA) for urea is a measure of the theoretically maximal possible urea clearance (milliliters per minute). Dialyzer efficiency can be categorized based on KoA for urea as low (<500 ml/min), moderate (500 to 700 ml/min), and high (>700 ml/min). High-flux dialyzers have pores large enough to allow the passage of larger molecules such as β_2-microglobulin (molecular weight 11,800 d). Water permeability is defined by the ultrafiltration coefficient (Kuf) that describes the transmembrane ultrafiltration volume per hour and unit of hydrostatic transmembrane pressure in millimeters of mercury. In high-flux dialyzers Kuf can be as high as 80 ml/h/mm Hg. During high-flux HD, backfiltration of dialysate into the blood as a result of higher hydrostatic pressure on the dialysate side occurs at the distal end of the dialyzer blood compartment and may result in a transfer of 5 to 10 liters of dialysate into the blood during a treatment; it is compensated for by an increased blood water removal at the proximal part of the dialyzer. Therefore water quality is of paramount importance when high-flux dialyzers are used (see later). The ultrafiltration rate is controlled precisely by a volumetric control system.

SAFETY MONITORS

Safety monitors are integral parts of the dialysis machine.

Pressure monitors are in most machines integrated to monitor the system pressure in critical positions (Fig. 93.1)[1]:

- Between the arterial side and the blood pump (prepump arterial pressure) to assess the suction pressure; overly negative values may signal reduced arterial inflow and access problems.
- Between the blood pump and the dialyzer inlet (postpump) to assess the dialyzer inflow pressure; a high pressure may signal dialyzer clotting.
- Between the dialyzer outlet and the air trap (venous pressure) to control the return pressure; a high pressure may point toward an obstruction in the venous limb; it is important to realize that in the event of venous needle displacement, with external bleeding, the venous pressure will remain positive because of the needle's flow resistance and a pressure alarm may not occur.

A *venous air detector* and *air trap* are located downstream of the venous pressure monitor. A positive signal at the air detector automatically clamps the venous line and stops the blood pump.

A *blood leak detector* is placed in the dialysate outflow line. Dialysate temperature is constantly monitored. Dialysate is produced by a proportioning system that mixes acid and bicarbonate concentrates with highly purified water. The osmolality of the dialysate translates into conductivity, which is measured by the dialysis conductivity monitor.

ANTICOAGULATION

Either unfractionated or low molecular weight heparin (LMWH) is used to prevent blood clotting in the extracorporeal circuit. Constant infusion of heparin, repeated boluses of heparin, or a single bolus of LMWH is used. Alternatives are available for patients at high risk for bleeding or who have contraindications to heparin, such as saline flushes, regional citrate anticoagulation, prostacyclin, danaparoid, argatroban (direct thrombin inhibitor), and lepirudin (recombinant hirudin).

TABLE 93.1 Dialysis Membrane Properties

Membrane	Membrane Name (Example)	High or Low Flux	Biocompatibility
Cellulose	Cuprophane	Low	Low
Semisynthetic cellulose			
Cellulose diacetate	Cellulose acetate	High and low	Intermediate
Cellulose triacetate	Cellulose triacetate	High	Good
Diethylaminoethyl-substituted cellulose	Hemophane	High	Intermediate
Synthetic polymers			
Polymethylmethacrylate	PMMA	High	Good
Polyacrylonitrile methacrylate copolymer	PAN	High	Good
Polyacrylonitrile methallyl sulfonate copolymer	PAN/AN-69	High	Good
Polyamide	Polyflux	High and low	Good
Polycarbonate-polyether	Gambrane	High	Good
Ethylene vinyl alcohol copolymer	EVAL	High	Good
Polysulfone	Polysulfone	High and low	Good

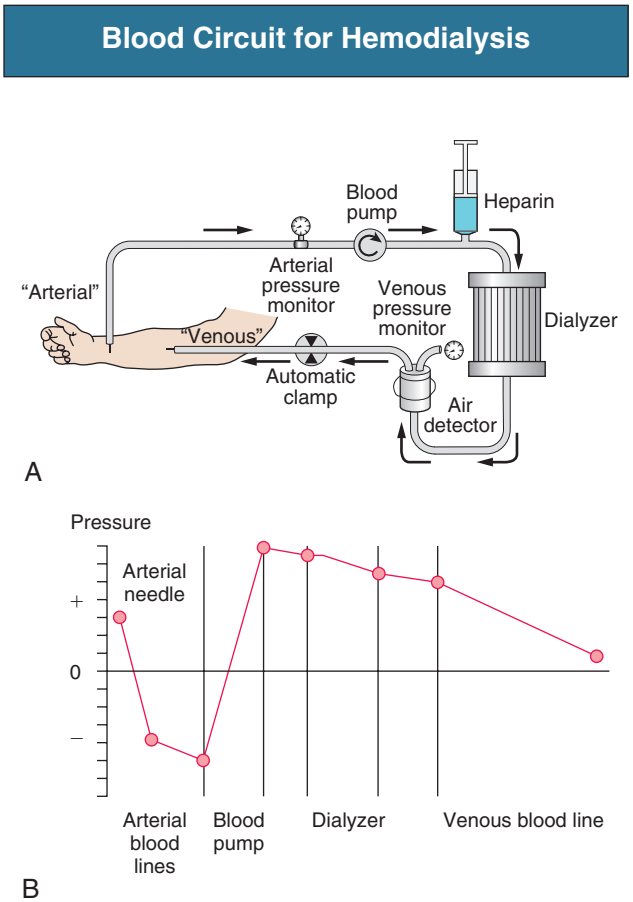

Fig. 93.1 Blood circuit for hemodialysis. (A) The blood circuit. (B) The pressure profile in the blood circuit with an arteriovenous fistula as the vascular access.

Lepirudin has the disadvantage of a very prolonged half-life in dialysis patients. In some institutions, regional citrate anticoagulation is used routinely, especially in patients with recent surgery, coagulopathies, thrombocytopenia, active bleeding, pericarditis, or heparin-associated side effects (heparin-induced thrombocytopenia type 2, pruritus, rapidly progressive osteoporosis, alopecia). Heparin requirements may be reduced with the use of citrate-containing dialysate.[2]

A typical routine prescription of constant infusion heparin is to administer an initial bolus of 2000 IU followed by a heparin infusion (800 to 1200 IU/h) which is stopped 30 to 60 minutes before the end of the session. Applying the repeated-bolus method, an initial heparin bolus (e.g., 4000 IU) is followed by a second bolus (e.g., 1000 to 2000 IU) after 2 hours. LMWH has become the anticoagulant of choice in many centers, usually given as a bolus at the beginning of the session. Routine monitoring of whole-blood partial thromboplastin time, activated clotting time, or factor Xa is usually not necessary.

DIALYSATE FLUID

Water and Water Treatment

A standard 4-hour HD session exposes the patient to 120 to 160 liters of water. Therefore water quality is of paramount importance to the patient's well-being. A typical water purification plant is shown in Fig. 93.2. Water from municipal sources is filtered to remove particulate matter. Activated carbon adsorbs substances such as endotoxins, chlorine, and chloramines. Downstream water softeners use a resin coated with sodium ions, which are exchanged for calcium and magnesium ions before the water enters the reverse osmosis (RO) system. During RO, water is pumped at high pressure (15 to 20 bar) through a tight membrane. The small pore size of these membranes (0.5 to 0.5 nm) provides an absolute barrier for molecules larger than 100 to 300 d. This process rejects over 99% of all bacteria, viruses, pyrogens, and organic materials. Optional ultraviolet irradiation upstream of a filter is used to further protect against contamination with bacteria.

Standards for chemical quality of water are widely accepted, but there is less consensus regarding acceptable levels of bacterial and endotoxin contamination. The microbiologic standards for HD water, dialysis fluid, and substitution fluid vary across countries (Table 93.2).[3] Endotoxin concentrations below 0.25 endotoxin units (EU)/ml are suggested, and many support the use of 0.06 EU/ml or lower. Municipal water supplies may contain a variety of contaminants that are toxic to HD patients. Substances added to the water supply such as aluminum and chloramines cause significant morbidity. Aluminum accumulation may result in a severe neurologic disorder, bone disease, and erythropoietin-resistant anemia. Is it recommended to measure plasma aluminum concentration regularly in situations in which aluminum exposure of the patient is likely to occur. Levels should be below 1 µmol/l, and levels above 2 µmol/l should prompt the search for excessive exposure. Chloramines have been associated with hemolysis

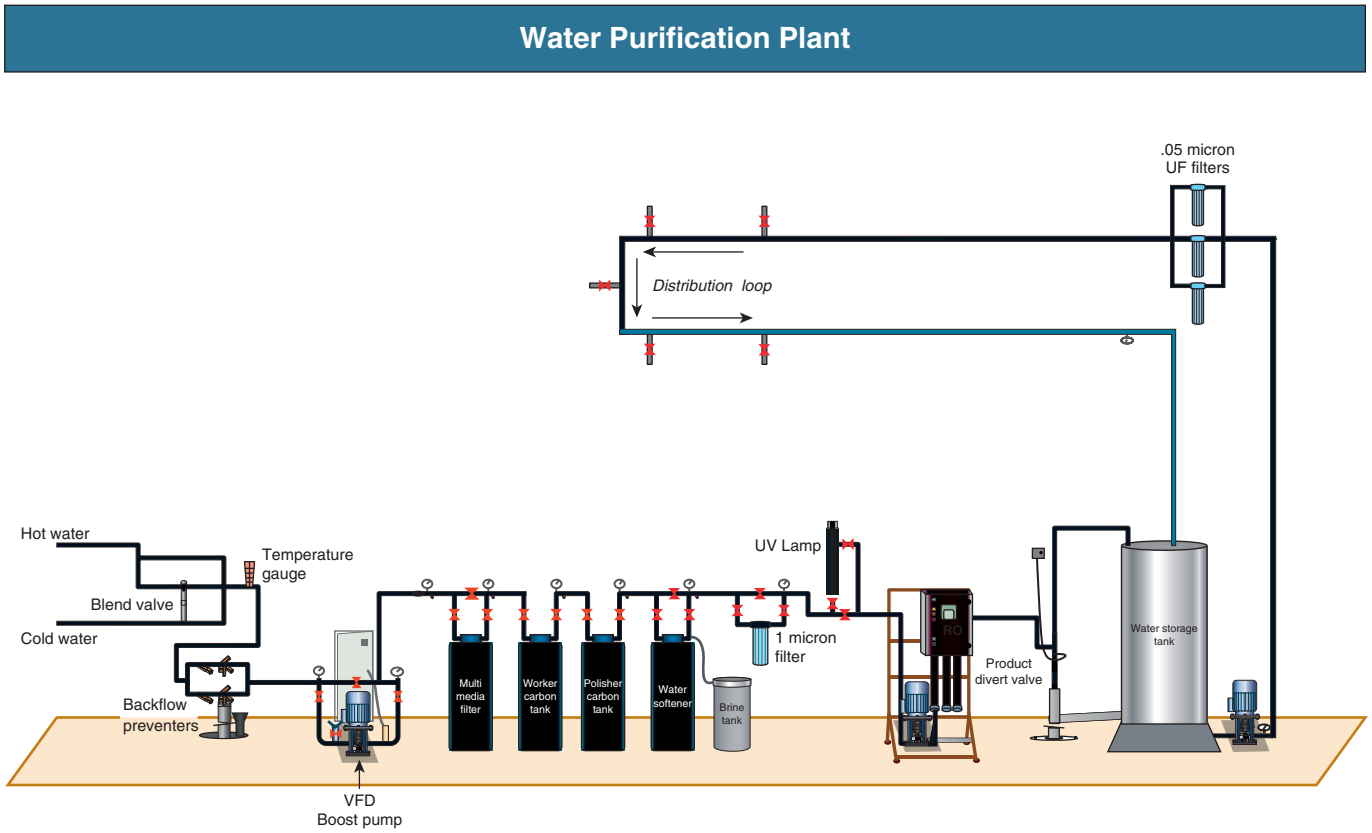

Fig. 93.2 Water purification plant. The four main functional domains are water supply, water pretreatment, primary purification, and delivery to the loop. A series of filters and water softeners are the key technical pretreatment components, whereas reverse osmosis is the main component of the primary purification. Note that several features are optional, for example, the water storage tank. *UF,* Ultrafiltration; *UV,* ultraviolet light; *VFD,* variable frequency drive. (Original artwork courtesy of Rob Levin and Randy Hux, New York, NY.)

and methemoglobinemia. Copper and zinc may leach from plumbing components and may cause hemolysis. Lead has been associated with abdominal pain and muscle weakness. Nitrate and nitrite may cause nausea and seizures. High concentrations of calcium may cause the hard water syndrome, characterized by acute hypercalcemia and hypomagnesemia, hemodynamic instability, nausea, vomiting, muscle weakness, and somnolence.

Gram-negative bacteria produce endotoxins, and fragments of these endotoxins may be responsible for some dialysis-related symptoms. Exposure to bacteria and endotoxin is associated with rigors, hypotension, and fever. Low levels of microbiologic contaminants may be a major cause of chronic inflammation in HD patients. Use of a polysulfone or polyamide filter in the dialysate line may be adequate to remove endotoxins, but smaller molecules, including bacterial DNA fragments, may pass through the dialyzer and stimulate immune cells. In the absence of routine hot water disinfection of the machine and the connections to the water loop, the only way endotoxin concentration can be kept low is by frequent measurement and disinfection of the entire system when concentration exceeds accepted standards. Liquid bicarbonate dialysis fluid concentrate distributed in a central distribution system may be a source of bacterial growth and should be replaced daily; acid concentrates in canisters and bicarbonate powder represent no bacterial growth risk.

Ultrapure water is recommended by international guidelines for use with high-flux dialyzers. Water used for online hemodiafiltration (HDF) has to be virtually sterile and nonpyrogenic, thus fulfilling the criteria for ultrapure water. To ensure chemical and microbial purity, water is treated by microfiltration and activated charcoal followed by two RO modules in series. Ultrapure water is delivered to dialysis machines for the production of ultrapure dialysate, which undergoes cold sterilization using additional sterilizing ultrafilters. A sterile and nonpyrogenic replacement fluid is generated online by filtering dialysis fluid through bacteria- and endotoxin-retentive filters before it is infused into the patient.

Dialysate Solution

Dialysis fluid can be considered as a drug to be adjusted to the individual patients' needs (Table 93.3). Dialysate is made by mixing two components, which may be provided as liquid or dry (powder) concentrates. The *base concentrate* contains sodium bicarbonate and sodium chloride. The *acid concentrate* typically contains chloride salts of sodium, calcium, magnesium, and potassium, glucose monohydrate, and an organic acid, the latter in the form of acetic acid, citric acid, or lactic acid. The acid concentrate may contain the salt of an organic acid, such as sodium acetate. The purpose of the acid is to lower the dialysate pH to below 7.3 so that calcium and magnesium do not precipitate when bicarbonate is added. Base and acid components are mixed simultaneously with purified water to make the dialysate. Dialysate proportioning pumps ensure proper mixing. One typical mixing relationship is 1 : 1.72 : 42.28 (acid concentrate:base concentrate:water; also known as *45X preparation*). The relative amounts of water, bicarbonate, and acid component define the final dialysate composition. It is important to note that some dry acid concentrates contain sodium diacetate (8 mmol/l), which is made up of equal parts of acetic acid and sodium acetate. After mixing

Glucose	0-11 (0-200 mg/dl)	5.5 (100 mg/dl)

with bicarbonate, the final dialysate contains 8 mmol/l sodium acetate.[4] Dialysate composition can be modified by small changes in the mixing ratio and adding salt solutions; potential advantages and disadvantages of dialysate modifications are shown in Table 93.4

BIOCOMPATIBILITY

The contact of blood with some lines and membranes triggers an inflammatory response. Although many components of the dialysis procedure contribute to the degree of biocompatibility, it is the membrane itself that is most important. Biocompatibility is especially important when cellulose membranes are used, whereas synthetic and reused membranes activate complement to a much lesser extent (Fig. 93.3). Activation of complement peaks at 15 minutes after the start of dialysis and lasts up to 90 minutes.

HEMOFILTRATION AND HEMODIAFILTRATION

Hemofiltration (HF) and HDF involve the removal of large fluid volumes from the patient, with the removed fluid replaced by substitution fluid. It is the use of substitution fluid that sets these techniques apart from simple ultrafiltration.

Hemofiltration (HF; Fig. 93.4) is a convective elimination technique by which water and solutes from the blood compartment are driven solely by positive hydrostatic pressure across the dialyzer membrane into the filtrate compartment without the use of dialysate. As a result of solvent drag effects, small and larger solutes are eliminated at a rate depending on membrane characteristics.

Hemodiafiltration (HDF; Fig. 93.5) combines diffusive (HD) and convective (HF) solute transport using a high-flux membrane. Fluid is removed by ultrafiltration, and the volume of filtered fluid exceeding the volume to achieve target weight loss is replaced by ultrapure, nonpyrogenic infusion solution. *Online* HDF refers to the online production by the dialysis machine of nearly unlimited amounts of ultrapure, nonpyrogenic dialysate, which is also used as infusion solution. *High-volume* HDF refers to an effective convection volume of at least 20% of the total blood volume processed.

Modes of Hemofiltration and Hemodiafiltration

Modes of HDF are differentiated depending on the site in relation to the dialyzer, with through which replacement fluid is infused into the patient's blood.

Postdilution Hemodiafiltration

Ultrafiltration is enforced on the undiluted blood with the replacement fluid being infused to the patient downstream of the dialyzer. Filtration is limited by hemoconcentration. Postdilution HDF is most efficient in terms of increasing solute removal.

Predilution Hemodiafiltration

Replacement fluid is added upstream of the dialyzer, which results in dilution of the patient's blood. Although filtration rates up to 100% of blood flow rate are possible, the efficiency of this mode is lower than postdilution HDF because of dilution of solute blood concentrations and thus the transmembrane gradient.

Mixed Dilution Hemodiafiltration

Replacement fluid is infused both upstream and downstream of the dialyzer. The ratio of upstream and downstream infusion rates can be varied to achieve the optimal compromise between maximizing clearance and avoiding the consequences of a high transmembrane pressure and hemoconcentration.

TABLE 93.4 Advantages and Disadvantages of Modifications in the Dialysate Composition

Component	Advantage	Disadvantage
Sodium		
Increased	Hemodynamic stability	Postdialytic thirst; increased postdialytic serum sodium levels; increased intradialytic weight gain; high blood pressure
Decreased	Reduced osmotic stress in the presence of predialytic hyponatremia	Intradialytic hemodynamic instability
Potassium		
Increased	Fewer arrhythmias in digoxin intoxication with hypokalemia; may improve hemodynamic stability	Hyperkalemia
Decreased	Increased dietary potassium intake	Arrhythmias; risk for sudden death
Calcium		
Increased	Suppresses PTH, increased hemodynamic stability	Hypercalcemia, vascular calcification, adynamic bone disease resulting from PTH suppression
Decreased	Permits more liberal use of calcium-containing phosphate binders	Stimulation of PTH, reduced hemodynamic stability
Bicarbonate		
Increased	Acidosis control improved	Postdialytic alkalosis; increased mortality
Decreased	No postdialytic alkalosis	Promotes acidosis; increased mortality
Magnesium		
Increased	Hemodynamic stability, fewer arrhythmias, suppresses PTH	Altered nerve conduction, pruritus, renal bone disease
Decreased	Permits use of magnesium-containing phosphate binders; improved bone mineralization; less bone pain	Arrhythmias, muscle weakness and cramps, elevated PTH
Glucose		
Decreased	Avoidance of intradialytic hyperglycemia and hyperinsulinemia	Increased risk for disequilibrium (rare), hypoglycemia
Increased	Lower risk for disequilibrium	Intradialytic hyperglycemia and hyperinsulinism
Citrate	Heparin-sparing effect	High blood citrate levels in liver failure

PTH, Parathyroid hormone.

Middilution Hemodiafiltration

Replacement fluid is infused within specifically designed dialyzers partway down the blood pathway so that the first part of the blood circuit is operated in postdilution and the second part in predilution mode.

UREMIC TOXINS AND THEIR REMOVAL BY HEMODIALYSIS

Uremic toxins have been traditionally categorized based on their molecular weight and binding properties (Table 93.5). The list of uremic toxins is steadily growing.[5] Recent research has identified the gut, in particular the colon, as an important source of uremic toxins and their precursors. These colon-derived toxins are products of bacterial metabolisms, such as phenols, indoles, and amines.[6]

Low molecular weight compounds not bound to protein: These include urea, and guanidines such as asymmetric dimethylarginine (ADMA), which are structural metabolites of arginine, purines, pyrimidines, oxalate, phosphorus, and uric acid. Modern dialysis membranes achieve maximal removal of these compounds. However, clearances are usually lower than that of urea, which is explained by their higher molecular weights (within the 500 d limit) and multicompartmental distribution increasing transfer time.

Low molecular weight compounds bound to protein: To varying degrees, these include major uremic toxins indoxyl and cresyl compounds, advanced glycation end-products, tumor necrosis factor-α, and phenolic compounds. Clearances of the unbound fraction may be increased by use of HDF, especially postdilutional modes. "Leaky" dialysis membranes increase the clearance of such substances bound to plasma proteins decreasing with total molecular weight of the bound substance in relationship to the pore size of the membrane.

Middle molecule compounds: Traditionally, middle molecules encompass substances with a molecular weight between 5 and 32 kDa. Their removal by low-flux dialyzers is poor. The diffusive removal of these compounds can be improved by the use of high-flux dialyzers, and their convective removal is further improved by high-volume HDF.[7] The potential advantages in increasing the removal of specific middle molecule toxins have not been evaluated yet in appropriate clinical trials.

ADDITIONAL DEVICES AND TECHNOLOGIES

Relative Blood Volume Monitoring

Blood volume monitors provide continuous noninvasive monitoring of relative changes in blood volume by continuous measurement of plasma protein concentration by ultrasound or hematocrit by optical scattering. A decline in relative blood volume occurs when the ultrafiltration rate exceeds the plasma refilling rate. A sharp decline in relative blood volume may precede intradialytic hypotension. In the randomized controlled Crit-Line Intradialytic Monitoring Benefit (CLIMB) study, mortality was higher in patients using relative blood volume monitoring compared with conventional monitoring. However, because of an atypically low mortality rate in the conventional monitoring group, the authors pointed out that these findings should be generalized to the U.S. HD population with caution.[8] In some dialysis machines the rate of blood volume change is used to automatically adjust ultrafiltration rates and dialysate sodium concentration (feedback control). This

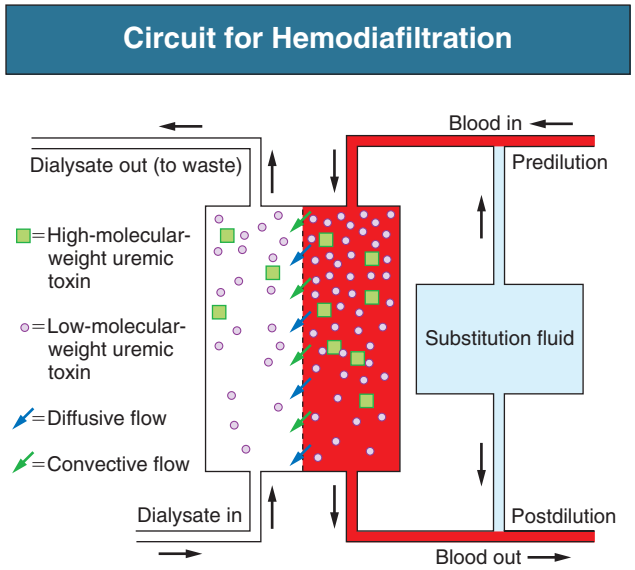

Fig. 93.5 Circuit for hemofiltration.

approach has been shown to reduce the frequency of symptomatic intradialytic hypotension.[9,10]

Ultrafiltration Profiling

The ultrafiltration rate is usually kept constant, but can be changed during the dialysis session in a preprogrammed manner (ultrafiltration profiling). It may be advantageous to remove a large proportion, for example, two thirds of the prescribed total ultrafiltration volume in the first half of the HD session. Because of a high initial plasma refilling rate, severely fluid-overloaded patients may tolerate a higher ultrafiltration rate in the early stages and normal fluid status may be reached more easily. The clinical benefits of ultrafiltration profiling are under debate.

Sodium Profiling

Normally, the dialysate sodium concentration is kept constant throughout the dialysis treatment. The variable sodium option allows dynamic changes of the dialysate sodium concentration during the treatment (sodium profiling). Some patients with hemodynamic instability may benefit from this option in which the initial sodium concentration is kept high and then slowly reduced to avoid sodium loading. In a recent meta-analysis, stepwise profiling was shown to be effective in reducing intradialytic hypotensive episodes.[11] Care is needed to ensure a significant amount of sodium is not added to the circulation.

Online Clearance Monitoring

Sodium and urea clearances are identical for practical purposes. The conductivity of the dialysate is largely a function of the dialysate sodium concentration, and online clearance monitors can use this feature to compute the urea clearance (K) of a dialyzer during a dialysis treatment. The conductivity clearance is equivalent to urea clearance, and Kt is easily calculated. Together with estimates of V (total body water), Kt/V can be determined during each treatment.

Blood Temperature Monitoring and Dialysate Cooling

In most patients, HD exerts a net positive thermal balance that may affect hemodynamic stability. "Cool" dialysate has been shown to improve vascular stability during dialysis. The core temperature can be controlled by blood temperature monitoring, which adapts the dialysate temperature according to the desired core temperature. A meta-analysis of 22 studies concluded that intradialytic hypotension occurred 7.1 times less frequently with cool dialysis[12] without reduction in urea clearance. A recent prospective randomized trial showed cardiac and brain white matter protection with individualized cooling at 0.5°C below body temperature.[13,14]

Intradialytic Oxygen Measurement

Blood coming from a functioning arteriovenous access resembles arterial blood. Some devices and dialysis machines measure predialyzer

TABLE 93.6 Home Hemodialysis Prescription and Practices

	Conventional	Short Daily	Nocturnal	Low Dialysate Flow Systems
Treatments per week	3	6	5-6	6
Treatment time (hours)	4	2-3	6-8	2.5-3.5
Blood flow rate (ml/min)	400	400	200	400
Dialysate flow rate (ml/min)	500	800	300	130

blood oxygen saturation. There is some indication that hypoxemia is associated with episodes of intradialytic hypotension. In an observational study, patients with prolonged intradialytic hypoxemia showed greater morbidity and mortality.[15]

Bioimpedance

Bioimpedance devices are increasingly used to determine fluid status in HD patients. In a prospective randomized trial the use of whole-body bioimpedance resulted in a reduction of fluid overload by 2 liters in fluid-overloaded patients without increasing the occurrence of intradialytic adverse events. This reduction of fluid overload was associated with reduction in systolic blood pressure and antihypertensive medication.[16]

HOME HEMODIALYSIS

Home HD (HHD) offers several clinical benefits compared with conventional renal replacement therapies, such as better survival, enhanced blood pressure control and left-ventricular geometry, normalization of phosphate balance, augmentation of kidney-specific quality of life scores, and improved fertility.[16] HHD also provides greater patient autonomy in a cost-effective manner.[17] There are variations in HHD prescription and practices (see Table 93.6). Additionally, conventional HD platforms and low dialysate flow systems may be used in the home.

Several considerations should be addressed before commencing patients on HHD. Routinely, a home visit should be conducted before starting home dialysis to assess for feasibility and potential renovations and modifications.

DIALYSIS MACHINE CHOICE AND OTHER EQUIPMENT

The choice of machine should be tailored to the patient's individual requirements and preference, and it will also determine the ease of dialysis fluid preparation. Additionally, the availability of appropriate water, electrical supply, and space may influence the choice of HD machine. Conventional HD platforms will require water filtration systems, whereas others (i.e., low-dialysate flow systems) may use prepackaged dialysate or generate online dialysis solutions. Premixed bags are available with bicarbonate-buffered or lactate-buffered dialysate. All types of vascular accesses may be used for HHD. Registry data suggest that permanent vascular access has superior outcomes compared with tunneled HD catheters. Moreover, the use of buttonhole cannulation (compared with stepladder technique) is associated with higher infectious complications.

WATER PREPARATION, STANDARDS, AND PLUMBING

As for in-center HD, prevailing standards for water quality should be adhered to (see previous discussion). Depending on the local water conditions and regulations, water softener, backflow preventers, and blending devices may be necessary in the home. In certain circumstances, feeder tanks may be necessary to provide the water pressure necessary for the RO unit and dialysis machine to function properly.

SAFETY

All dialysis machines are equipped with monitors, as described earlier. Leak and moisture detectors should be placed around vascular access cannulation sites, under the dialysis machine, and at the water treatment system. For central venous catheters, special connectors or catheter safety lock boxes can be used. Telemonitoring systems have been employed for HHD, though they are not a prerequisite. Practically, most HHD users continue to rely on an "on-call" system for troubleshooting. Typically, arterial and venous pressure alarms are the most common type of alarms. The average number of alarms per night decreased significantly over time as patients gained experience with HHD (from a maximum of 1.98 ± 3.31 alarms/night to a low of 0.74 ± 1.63 alarms/night) according to the London Ontario experience.[18]

WEARABLE ARTIFICIAL KIDNEY

Wearable artificial kidneys (WAKs) have been successfully tested in clinical trials, proving the concept that this technology is safe and a potential future form of renal replacement therapy.[19] The WAK is light, small, and ergonomic enough to be worn as a belt, allowing patients to ambulate and perform activities of daily life while the WAK delivers sufficient rates of fluids and solutes removal. The dialysate is recirculated through a series of sorbent cartridges containing urease, zirconium resins, and charcoal. These purify and regenerate the dialysate so it can be recirculated back into the dialyzer continuously. As a result, the WAK requires only 400 ml of dialysate. At their current stage, though, WAKs are not yet suitable for routine use, facing formidable challenges such as anticoagulation, toxin clearance, and fluid removal.

SELF-ASSESSMENT QUESTIONS

1. Which statement is correct?
   - **A.** Bacterial endotoxin in the hemodialysis (HD) fluid cannot pass through the dialysis membrane.
   - **B.** An increase in HD fluid sodium concentration will always raise the serum sodium level.
   - **C.** HD fluid buffers include anions such as bicarbonate diacetate, chloride, and citrate.
   - **D.** HD fluid potassium concentrations of 1 mEq/l are safer than 3 mEq/l.
2. Which statement is correct?
   - **A.** A high-protein diet will eventually reduce the level of uremic toxins in the blood.
   - **B.** Urea is considered a powerful uremic toxin.
   - **C.** Some uremic toxins are synthesized in the colon and absorbed into the bloodstream.
   - **D.** Hemodiafiltration (HDF) is highly efficient in removing protein-bound uremic toxins.
3. Which statement is correct?
   - **A.** Heparin should not be used as an anticoagulant when dialyzing patients with autoimmune diseases.
   - **B.** Thanks to biocompatible dialysis membranes, aluminum intoxication is no longer a concern.
   - **C.** Predilution HDF is most efficient in terms of increasing solute removal.
   - **D.** Dialysate cooling is an effective means to increase hemodynamic stability.
4. Which statement is correct?
   - **A.** Intradialytic hypoxemia is associated with poor outcomes.
   - **B.** Sodium profiling is a preferred way to treat patients with intradialytic hypertension.
   - **C.** In patients with predialysis serum potassium levels above 6.2 mEq/l, a dialysate potassium concentration of 0 mEq/l is warranted.
   - **D.** Home HD is not advised in patients with diabetes mellitus.
5. Which statement is correct?
   - **A.** A positive venous pressure is a reliable indicator of correct needle placement.
   - **B.** Water treatment is key to the preparation of adequate dialysis fluid.
   - **C.** Intradialytic hypoxemia is associated with poor outcomes.
   - **D.** Modern dialyzer membranes combine polysulfone with cellulose.

Hemodialysis: Dialysis Prescription and Adequacy

Martin K. Kuhlmann, Peter Kotanko, Nathan W. Levin

From an idealistic perspective an adequately treated hemodialysis (HD) patient is physically active, well nourished, euvolemic, and normotensive with a maintained good quality of life and a life expectancy comparable to that of similarly aged persons with normal kidney function. The HD treatment retains a core position among the many different aspects of the multifactorial management necessary to achieve these goals. Adequacy of HD treatment today encompasses more than just the replacement of excretory kidney function (dialysis dose) and extends to the prevention of intradialytic and interdialytic complications, particularly the maintenance of hemodynamic stability and organ perfusion. Elderly patients, the largest group of prevalent and incident dialysis patients worldwide, because of their compromised vascular status and multiple comorbid diseases, are especially vulnerable to hemodynamic effects of the dialysis treatment and therefore require a special approach in dialysis prescription.

ASSESSMENT OF DIALYSIS DOSE

Markers of Uremic Toxin Removal by Renal Replacement Therapy

Urea Removal

Among all potential uremic toxins, only urea, a 60-d small water-soluble compound, is established as a marker of uremic solute retention and removal. Urea, which itself shows little toxicity, is a metabolite of amino acid metabolism; urea generation therefore depends on protein intake and the balance between protein anabolism and catabolism. Urea removal was originally considered to be representative of the removal of other water-soluble solutes with a higher pathogenic impact, but it is now clear that urea removal does not closely parallel that of other small water-soluble compounds, protein-bound solutes, or middle molecules. Urea is most easily transferred across cell membranes by diffusion or specific urea transporters, thus allowing rapid equilibration of urea concentration within whole-body water after dialytic removal of urea from the blood compartment. For almost all other small and middle molecular weight uremic toxins, many of which are highly protein bound, the intercompartmental transfer rate is much slower, leading to protracted equilibration between the various compartments. Nevertheless, knowledge of urea kinetics is essential for the general understanding of the physics and basic principles of solute accumulation and of removal during dialysis.[1]

Similarly to native kidney function, the delivered dose of dialysis is conventionally assessed by the rate of removal of selected uremic toxins from the patient's body. For more than two decades urea removal from the body has been expressed either by the urea reduction ratio (URR), or by the treatment index *Kt/V*. The urea clearance of the dialyzer itself is a marker of dialyzer efficiency but not of dialysis dose. Although urea has shortcomings as a marker of dialysis adequacy, its removal is still the standard measure to quantify dialysis treatment. The dialysis dose ideally should be evaluated in conjunction with residual renal function (RRF) measurement using the same uremic toxin.

Intradialytic Urea Kinetics

Dialyzers are highly efficient at removing urea from the blood, reducing plasma urea concentration during one dialyzer passage by more than 90%. Intradialytic plasma urea kinetics is satisfactorily described by a two-compartment model in which the intravascular blood compartment is replenished with urea through redistribution from extravascular body water compartments. Because intercompartmental redistribution is not immediate, the intradialytic urea concentration in the blood compartment is always lower than in the extravascular compartments and postdialysis blood urea concentration rebound occurs within 30 to 60 minutes after the end of the dialysis treatment until full equilibration between all compartments is reached. The dynamics of urea redistribution depend on the urea concentration gradient between blood water and extravascular water, but also on blood flow in the various tissue regions. Accordingly, intradialytic urea kinetics are best described by "equilibrated" models that consider the various compartments (Fig. 94.1, *solid line*). In contrast, the classic single-compartment (single-pool) urea kinetic model (UKM) assumes that full equilibration between blood and tissue compartments occurs immediately. In such idealized models, the change in serum urea follows first-order kinetics, with a linear decline and no urea rebound (see Fig. 94.1, *dashed line*).

Current methods for assessment of dialysis dose are based on the predialysis and postdialysis difference in serum urea and include URR, single-pool *Kt/V* (*spKt/V*), equilibrated double-pool *Kt/V* (*eKt/V*), and weekly standard *Kt/V* (*d-Kt/V*).

Urea Reduction Ratio

URR refers to the treatment-related reduction of serum urea concentration and is computed as:

$$\text{URR}\,(\%) = (1 - C_t/C_0) \times 100\%$$

where C_t is postdialysis and C_0 is predialysis serum urea concentration.

URR is a simple but rather imprecise way to quantify dialysis dose because it does not take into account intradialytic urea generation and convective urea removal by ultrafiltration and is a single-pool measurement. Despite these limitations, URR correlates well with dialysis outcome and is an accepted method for assessment of dialysis dose. A minimum URR of 65% to 70% can be considered an adequate dialysis dose.

Single-Pool Kt/V (spKt/V) and Equilibrated Double-Pool Kt/V (eKt/V)

The treatment index *Kt/V* is the most widely used parameter to assess dialysis dose. *Kt/V* is a dimensionless number representing the total plasma volume cleared (*K*×*t*, in liters) in relation to the individual volume of distribution (*V*, in liters). The concept of *Kt/V* may be applied to any substance but in clinical practice is almost exclusively used for urea, where *K* is the dialyzer blood water urea clearance (liters per hour), *t* is dialysis session length (hours), and *V* is the distribution volume of urea (liters), which equates closely to total body water. A delivered *Kt/V* of 1.0 implies that the volume of plasma cleared of urea (*K*×*t*) during a dialysis session is equal to urea distribution volume (*V*). However, because of the multicompartment kinetics of urea equilibration, and its constant formation, clearing a plasma volume equivalent to 1 unit of total body water (V) does not mean that all urea has been removed from body water.

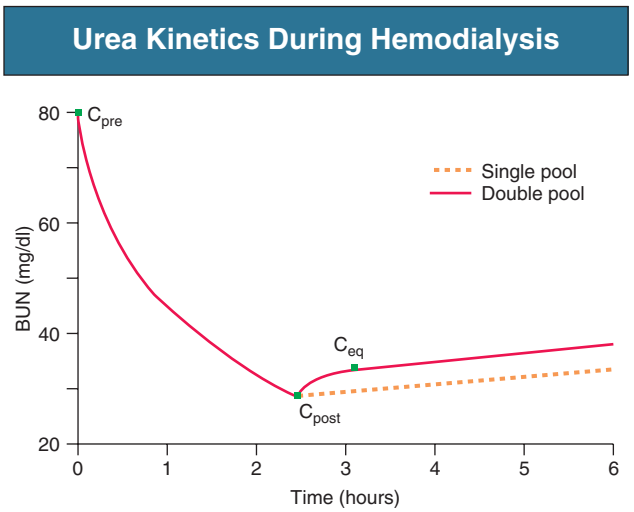

Fig. 94.1 Urea kinetics during hemodialysis. Urea kinetics is determined by the difference between predialysis (C_{pre}) and postdialysis (C_{post}) blood urea nitrogen *(BUN)*. The single-pool Kt/V model assumes no relevant change in BUN concentration after termination of dialysis except for a slow constant increase as a result of BUN generation *(yellow dashed line)*. The double-pool Kt/V model *(red line)* more accurately describes the in vivo situation, in which intercompartmental urea redistribution leads to a urea rebound until full equilibration between blood and tissue compartments is reached. Equilibrated postdialysis BUN concentration (C_{eq}) can be mathematically predicted from postdialysis BUN (C_{post}).

In daily clinical practice and in the absence of availability of formal UKM, single-pool Kt/V (spKt/V) is computed from the Daugirdas equation, which is based on URR but also accounts for intradialytic urea generation and ultrafiltration volume.[2] The Daugirdas equation is validated for a *Kt/V* range between 0.8 and 2.0 and is widely used because of its simplicity and accuracy.

$$spKt/V = -\ln(R - 0.008 \times t) + (4 - 3.5 \times R) \times UF/W$$

where *ln* is the natural logarithm, *R* is the postdialysis/predialysis serum urea ratio, *t* is treatment time (hours), *UF* is ultrafiltration volume (liters), and *W* is the patient's postdialysis body weight (kilograms).

Single-pool Kt/V regularly overestimates the delivered dialysis dose because nonequilibrated post-HD urea concentration is used for computation. A more accurate estimate of delivered dialysis dose is achieved by using the equilibrated post-HD urea concentrations. The difference between equilibrated and nonequilibrated urea concentration depends on the intensity of dialysis; the shorter and more intense a treatment, the higher is the rebound. The more accurate equilibrated double-pool Kt/V is directly computed from spKt/V and improves the accuracy of dialysis dose assessment. Because equilibrated post-HD serum urea concentrations are higher than nonequilibrated concentrations, *eKt/V* is lower than *spKt/V* for any treatment. By applying these equations the volume of distribution does not need to be measured separately (Table 94.1).

Correct assessment of *Kt/V* requires accurate timing of blood collections. Predialysis blood samples must be collected right at the start of the treatment and postdialysis samples immediately before termination of treatment after slowing the blood flow rate to reduce any potential effect of recirculation. Blood sampling procedures should be standardized (for recommendations see reference 3). URR, sp*Kt/V*, or *eKt/V* should be assessed monthly, and the dialysis prescription adjusted accordingly. In large observational studies, mortality was higher at *spKt/V* of less than 1.2, and a target *spKt/V* of 1.4 is recommended for conventional thrice-weekly dialysis schedules.[3]

A very accurate form for prescribing dialysis dose is a software-based formal UKM, in which spKt/V is modeled from prescribed dialyzer clearance (K), blood and dialysate flow rates, ultrafiltration volume, treatment time, and initial assumed urea distribution volume. By comparing modeled Kt/V to delivered Kt/V, problems in the delivery of dialysis dose (such as vascular access recirculation) can be readily identified. Besides dialysis dose, the mathematical models integrated in UKM allow the estimation of protein catabolic rate (PCR) or protein equivalent of nitrogen appearance (PNA), a measure of the balance between protein catabolism and protein synthesis, including dietary protein intake. Most modern HD machines provide the option to monitor urea clearance

TABLE 94.1 Computation of Dialysis Dose*

Results Derived From Different Model Equations

Formula	Result	Comment
$URR = (1 - C_t/C_0) \times 100\%$	67%	Urea rebound, urea generation, and ultrafiltration not taken into account
$Kt/V = \ln(C_0/C_t)$	1.10	Urea rebound, urea generation, and ultrafiltration not taken into account
$spKt/V = -\ln(R - 0.008 \times t) + (4 - 3.5\,R) \times UF/W$	1.33	Single-pool model; urea rebound not taken into account
$eKt/V = spKt/V - 0.6 \times spKt/V/t + 0.03$	1.16	Double-pool model for arteriovenous access, including urea rebound
$eKt/V = spKt/V - 0.47 \times spKt/V/t + 0.02$	1.20	Double-pool model for central venous access, including urea rebound

*Calculations based on dialysis duration *(t)* = 4 hours.
Predialysis blood urea nitrogen (BUN) (C_0) = 90 mg/dl; nonequilibrated postdialysis BUN (C_t) = 30 mg/dl; ultrafiltration volume *(UF)* = 3 liters; postdialysis body weight *(W)* = 72 kg; $R = C_t/C_0$.
URR, Urea reduction ratio.

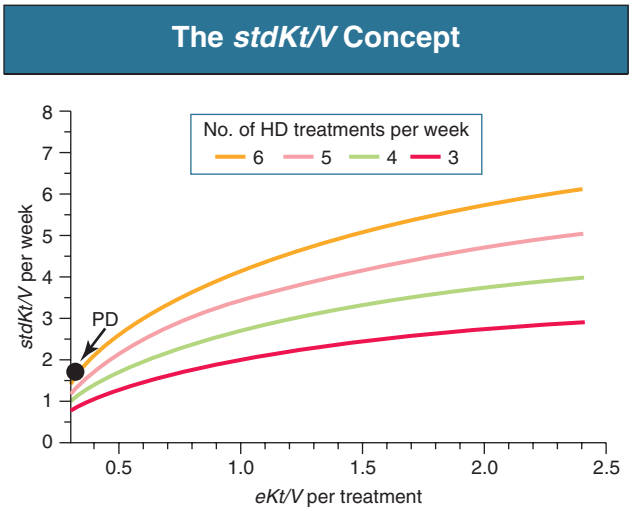

Fig. 94.2 The weekly *std-Kt/V* concept. The weekly *std-Kt/V* for any hemodialysis *(HD)* frequency is derived by plotting *eKt/V* of a representative dialysis session onto the respective frequency curve. *PD,* Peritoneal dialysis.

online during dialysis and assess sp*Kt/V* during each single dialysis session without the need for blood sampling. However, a weakness of the online method lies in the inability to measure the volume of urea distribution directly.

Weekly Dialysis Dose and Weekly Standard: *Kt/V* (*stdKt/V*)

A useful way to compare native kidney function with dialysis dose across a wide variety of dialysis modes and frequencies is by looking at an average clearance (in milliliters per minute) of any given solute achieved over a unifying period, such as 1 week. The established parameter developed for this comparison is the weekly standard Kt/V for urea (weekly stdKt/V). With this concept, a thrice-weekly *intermittently* provided dialysis urea clearance (e.g., 250 ml/min for 4 hours thrice weekly and 0 ml/min for the remaining 6.5 days per week) is converted to an equivalent *continuous* extracorporeal urea clearance (in milliliters per minute) related to urea distribution volume *V* (ml).[4] The resulting dimensionless *stdKt/V* value is directly compatible with the continuous native residual renal clearance (GFR or renal Kt/V) and peritoneal clearance (*weekly peritoneal Kt/V)*. The principle of *weekly stdKt/V* is visualized in Fig. 94.2, in which on the x-axis the *eKt/V* of a representative dialysis session is plotted onto a curve representing the prescribed treatment frequency, and the resulting stdKt/V is then derived from the intercept with the y-axis. The frequency curves are not linear because the decreasing transmembrane urea gradient over time results in decline of the efficiency in dialysis urea mass removal. A maximum *stdKt/V* of 3.0/week can be achieved with conventional thrice-weekly dialysis independent of treatment time. To further increase weekly dialysis dose, treatment frequency needs to be modified. Continuous RRF, expressed as *renal Kt/V,* is added directly to dialysis *std-Kt/V*. Independent of the treatment schedule, a minimum target *stdKt/V* of 2.3/week with a minimum delivered stdKt/V of 2.1 including *renal Kt/V* is recommended for all patients.[5] In anuric patients this is achieved with a standard thrice-weekly schedule and delivered dialysis dose of *spKt/V* of 1.2 per treatment.

MIDDLE MOLECULE REMOVAL

It is widely held that retention solutes of middle molecular size may play an important role in the pathogenesis of uremia and contribute significantly to the high mortality of dialysis patients. Because of higher membrane porosity, high-flux dialyzers can remove larger amounts of middle molecules than low-flux dialyzers, and this may be further increased by the use of convective dialysis strategies, such as hemodiafiltration (HDF). Because of slower intercompartmental equilibration rates, middle molecule removal is limited during conventional 4-hour dialysis sessions. Serum β_2-microglobulin, a surrogate for uremic middle molecules, can be effectively removed only by high-flux dialysis. Predialysis β_2-microglobulin levels were found to be related to mortality in patients treated randomly with high-flux or low-flux dialyzers.[5] Certain subgroups of dialysis patients, such as diabetics, and incident patients with serum albumin levels below 40 g/l, may benefit most from high-flux dialysis.[6,7] The European Best Practice Guidelines recommend the use of synthetic high-flux membranes to reduce cardiovascular risk and improve control of hyperphosphatemia and anemia.[8]

High-volume online HDF has the potential to provide the largest removal of the widest range of low and middle molecular size solutes. Diffusive and convective solute elimination are maximized to the benefit of the removal of larger molecular size solutes. Because diffusive urea clearance during standard HD treatment is already high and does not increase by more than 10% when convective clearance is added, urea removal is not an adequate marker of treatment dose in convective dialysis modes. In HDF, mass removal of middle molecules is directly related to ultrafiltration volume, which is also referred to as *convection volume* (CV) (see Chapter 93). The *effective* CV is used as key quantifier for HDF dosing, where the term *effective* principally relates to the undiluted blood water volume removed by filtration. Thus, in postdilution mode, the *effective* CV is identical to total CV whereas in predilution or mixed-dilution mode, the *effective* CV is considerably lower than total CV.

Three randomized controlled studies (CONTRAST Study, the Turkish HDF Study, and the ESHOL trial)[9-11] failed to demonstrate convincingly that survival with postdilution high-volume HDF is superior to conventional low-flux or high-flux HD. However, in each trial, patients receiving the highest CV had a significantly lower mortality risk compared with those receiving a lower HDF dose. An individual patient data analysis of these online HDF trials demonstrated a significantly reduced risk for mortality for patients receiving more than 23 liters of effective CV normalized to a body surface area of 1.73 m^2 in postdilution HDF mode.[12] Adjustment of target HDF dose to some measure of body size makes sense in view of the fact that both generation rate and distribution volume of uremic toxins are related to body mass.

Phosphate Removal

Hyperphosphatemia is a major problem in HD (see Chapter 85).[13] Management of hyperphosphatemia is based on phosphate removal by dialysis, dietary phosphate restriction, and intestinal phosphate binding with use of phosphate binder medication. Despite its low molecular weight, the effective molecular size of phosphate (as a result of rather stable coating with several water moieties) is much bigger than that of other low molecular weight solutes, which impairs intercompartmental and transmembrane phosphate transport during dialysis. Intradialytic phosphate kinetics resembles much more those of middle molecules, with serum phosphate levels steeply falling during the first 90 to 120 minutes into dialysis as a result of removal primarily from plasma and extracellular volumes and stabilizing thereafter (Fig. 94.3). This intradialytic plateau is explained by phosphate mobilization from various compartments at a rate similar to that of dialyzer phosphate removal. Phosphate removal can be improved by high-flux HD and HDF, by the use of larger dialyzer surface area, and, most dramatically, by longer or higher frequency dialysis schedules, such as short daily or daily nocturnal HD. Long, frequent dialysis schedules may even result in

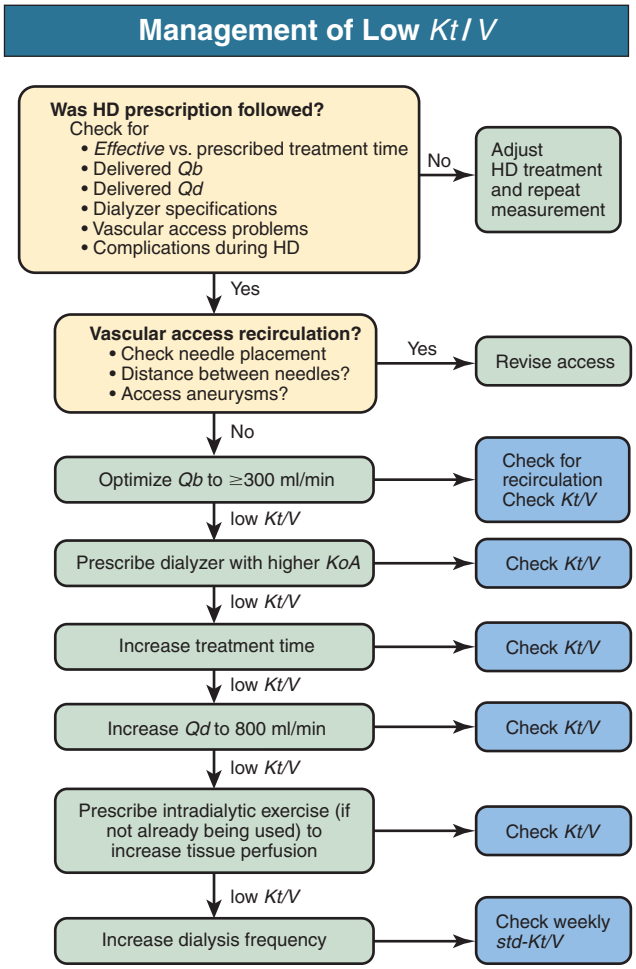

Fig. 94.3 Management of low and inadequate *Kt/V*. *HD,* Hemodialysis; *KoA,* the dialyzer urea mass transfer area coefficient; *Qb,* blood flow rate; *Qd,* dialysate flow rate.

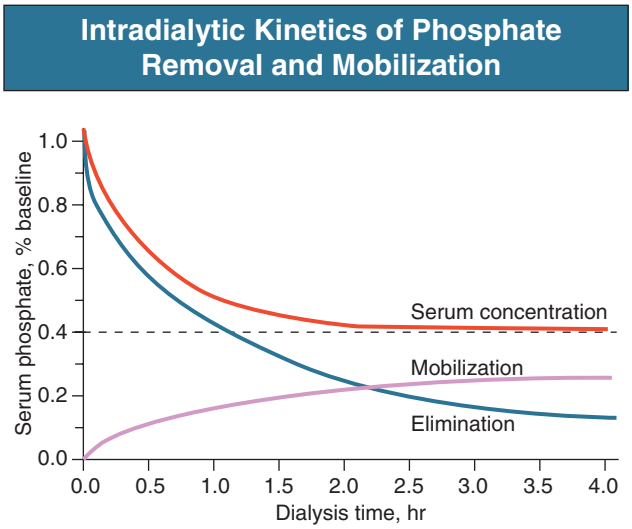

Fig. 94.4 Intradialytic kinetics of phosphate removal and mobilization.

hypophosphatemia so that phosphate has to be added to the dialysate. In all patients, predialysis serum phosphate levels should be lowered toward the normal range.

PRESCRIPTION OF HEMODIALYSIS

Hemodialysis Dose

The National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines recommend a target spKt/V of 1.4 per HD session for patients treated thrice weekly, with a minimum delivered spKt/V of 1.2. In patients with significant residual native kidney function, the dose of HD may be reduced provided RRF is measured periodically to avoid inadequate dialysis. For HD schedules other than thrice weekly, a target stdKt/V of 2.3 volumes per week is provided with a minimum delivered dose of 2.1 using a method of calculation that includes the contributions of ultrafiltration and residual kidney function.[3]

Delivered dialysis dose depends on dialyzer efficiency (Kd), effective treatment time (t), and distribution volume (V). Dialyzer clearance Kd depends on the flow rates within the blood and dialysate compartments (Qb and Qd), dialyzer KoA, effective membrane surface area, hematocrit, and anticoagulation. Effective treatment time t is essential for reaching the Kt/V target and can be substantially shorter than prescribed treatment time because of intermittent pump stops or patient demand. Distribution volume V does not substantially change during a single HD session but may change over time. Therefore the dialysis dose needs to be adjusted when lean body mass, which closely correlates with V, increases. On the contrary, if there is a loss in muscle mass, which is associated with a decrease in V, Kt/V should not be reduced but rather based on a higher (ideal) patient V to support gains in body mass.[3]

A standard dialysis prescription should consist of a high-flux dialyzer, a minimum treatment time of 4 hours, a blood flow rate of at least 250 ml/min, and a dialysate flow rate of 500 to 800 ml/min. The prescription is then adjusted to meet the target *spKt/V* of 1.4. In severe and long-standing uremia, the target dose is approached slowly over the course of several sessions to avoid the dialysis disequilibrium syndrome. Confronted with an inadequate URR or *Kt/V,* it is sensible to check whether the studied session was representative of the average session, because unusual problems may have occurred (e.g., shortened time, vascular access recirculation, single-needle HD). Frequent causes of inadequately low delivered dialysis dose with recirculation are vascular access problems particularly of arterial supply. Blood sampling errors also should be considered because delayed post-HD blood sampling results in falsely low *Kt/V* results. If a low *Kt/V* remains unexplained, treatment time should be increased and a more efficient dialyzer and higher blood and dialysate flow rates should be considered (Fig. 94.4). Active or passive muscle stimulation before or during dialysis improves *Kt/V* by increasing blood supply to poorly perfused muscle tissue and facilitates urea and phosphate removal.[14] In selected patients, physical exercise before or during HD treatment will be a way to improve dialysis dose. Delivered *Kt/V* should be checked whenever the dialysis prescription has been modified substantially.

Hemodiafiltration Dose

The two major aims governing the prescription of high-volume online-HDF dose are adequate delivery of the target effective CV and the prevention of excess hemoconcentration. High-flux membranes offering high hydraulic permeability as well as high middle-molecule clearance are required for adequate HDF. Hydraulic permeability is reflected by the membrane ultrafiltration coefficient, whereas membrane permeability is defined by the sieving coefficients for selected middle molecules. For high-volume HDF a high-flux membrane with an ultrafiltration coefficient greater than 20 ml/h/mm Hg/m^2 and a sieving coefficient for β_2-microglobulin of 0.6 is recommended.[15]

The major determinants of achieving a prescribed target CV in postdilution HDF are blood flow rate (Qb), ultrafiltration rate (UFR),

and treatment time (T). Because ultrafiltration is applied to undiluted blood, hemoconcentration necessarily occurs together with a lowering of blood flow rate within the dialyzer. Under certain circumstances this leads to the deposition of plasma proteins on the membrane surface, clogging of membrane pores, and occlusion of dialyzer capillaries. To prevent excessive hemoconcentration, UFR and Qb need to be individually adjusted so that the filtration fraction (FF), which is defined as the ratio of UFR to Qb, does not exceed 25%. Higher FF up to 30% can be safely achieved only with modern HD machines designed to optimize filtration rate based on constant assessment and optimization of transmembrane pressure. Effective treatment time in high-volume HDF with a fixed target CV will thus always depend on achievable Qb and UFR.

Treatment Time and Frequency

The European best practice guidelines recommend that dialysis should be delivered at least 3 times per week and the total duration should be at least 12 h per week, unless supported by significant residual RRF.[8]

Conventional thrice-weekly dialysis remains the standard of care in most countries, where treatment time is typically governed by dialysis dose (Kt/V), with the consequence of longer dialysis in patients with higher urea distribution volumes. Acknowledging the difficulties in removing adequate amounts of fluid and low and middle molecular size uremic solutes during short dialysis sessions, a minimum treatment time of 4 hours per HD session is recommended in various countries. The argument that longer treatment time improves survival is confounded by factors such as body size, (smaller patients having higher mortality), lack of compliance, differences in sodium intake and therefore in interdialytic weight gain (IDWG), and frequently lack of successful postdialytic weight reduction.[16] More frequent in-center dialysis and longer dialysis hours delivered by in-center or home HD are increasingly used alternatives to conventional thrice-weekly treatment. Both modalities offer the opportunity for improved solute clearance and complete removal of IDWG with fewer intradialytic problems, particularly hypotension.

Several retrospective epidemiologic studies in larger patient populations suggest a survival advantage for patients treated with extended time and/or frequency dialysis schedules, such as daily nocturnal or thrice-weekly nocturnal HD, over conventional HD.[17-19] The randomized controlled Frequent Hemodialysis Network (FHN) Study[20] demonstrated that short daily in-center HD yielded favorable effects on the coprimary composite outcomes of death, change in left ventricular mass and death, or change in self-reported physical health. Analysis of patient survival over a median of 3.6 years after randomization suggested that short daily in-center HD reduced long-term mortality. Of note, a post-trial observational study of the FHN nocturnal trial with a median follow-up of 3.7 years, for reasons unknown thus far, indicated a higher mortality rate in patients randomly assigned to nocturnal HD compared with those randomly assigned to conventional dialysis.[21,22] In summary, current data suggest that short daily dialysis appears the most favorable for survival followed by thrice-weekly nocturnal and thrice-weekly HD.

Dialysate Composition

During a standard HD treatment session, a patient's blood is exposed to 120 to 200 liters of dialysate. The several ingredients of dialysate composition should therefore be prescribed with great care. Generation of near sterile dialysate and prescription of dialysate temperature are addressed in Chapter 93.

Sodium

A positive sodium balance is a typical feature of end-stage renal disease (ESRD) and an important factor in the pathogenesis of hypertension and fluid overload in HD patients. Judicious control of sodium balance is effective in normalizing blood pressure (BP), and dietary sodium intake should be restricted to approximately 6 g salt (2300 mg or 100 mmol sodium) per day. Sodium is mainly removed through ultrafiltration; but depending on the ratio of dialysate to plasma water sodium concentration, it will be additionally removed from or delivered to the patient by diffusion. To avoid a positive diffusive sodium balance, dialysate and serum sodium concentrations should be aligned or care should be taken that dialysate sodium does not exceed the patient's average predialysis serum sodium concentration by more than 2 to 3 mmol/l. There is clear indication that a positive sodium gradient— a dialysate sodium concentration exceeding the patient's serum sodium level—is associated with higher ultrafiltration volumes and possibly higher BP. The associations between serum and dialysate sodium levels, morbidity, and mortality are controversial.[23]

Nonosmotic tissue sodium storage has been documented in HD patients, and HD has the ability to clear some of the tissue sodium. More recently in patients with chronic kidney disease an association between left ventricular hypertrophy and tissue sodium has been demonstrated.[24,25]

Potassium

Potassium removal during dialysis ideally should be equal to the amount accumulated during the interdialytic period. The dialysate potassium concentration has to be set at a level that avoids pre-HD hyperkalemia as well as intradialytic hypokalemia, which may provoke dialysis-induced arrhythmia. The typical dialysate potassium concentration is set between 2.0 and 4.0 mmol/l. Prescription of potassium dialysate concentrations less than 2.0 mmol/l has been associated with an increased risk for tachyarrhythmia and sudden cardiac death and should therefore be avoided.[26]

Calcium

In light of accelerated vascular calcification in ESRD, intradialytic calcium delivery to the patient should be avoided. In patients using calcium salts as phosphate binders, a negative intradialytic calcium mass balance is desirable.[27] A standard dialysate calcium concentration of 1.25 to 1.50 mmol/l is recommended by Kidney Disease: Improving Global Outcomes (KDIGO), but some patients will be in positive balance even at 1.25 mmol/l.[28] These and higher dialysate calcium concentrations may be associated with tissue calcium accumulation, whereas lower dialysate calcium will stimulate parathyroid hormone (PTH) secretion. In most patients a dialysate calcium concentration of 1.25 mmol/l is now used.

Bicarbonate

Chronic metabolic acidosis is associated with decreased protein synthesis and increased protein catabolism and contributes to mineral and bone disorders. Normalized pre-HD bicarbonate levels in the range of 20 to 23 mmol/l are associated with improved survival. Dialysate bicarbonate concentration is typically set between 35 and 40 mmol/l to generate a transmembrane concentration gradient favoring bicarbonate delivery to the patient. Data from the Dialysis Outcomes and Practice Patterns Study (DOPPS) indicate that both high (>27 mmol/l) and low (<17 mmol/l) predialysis serum bicarbonate levels are associated with increased risk for mortality and hospitalization.[29]

Magnesium

In the past, dialysate magnesium levels of 1.5 mmol/l were used frequently. Current recommended levels are between 0.5 and 1.0 mmol/l. Two recent observational studies in Japanese and U.S. HD patients showed an inverse association between serum magnesium levels and mortality.[30] It is unclear to what extent dialysate magnesium levels have a sustained effect on serum levels.

Fluid Status and Ultrafiltration Rate

Fluid overload is an established risk factor for the development of left ventricular hypertrophy and cardiovascular mortality. Adequate HD aims to normalize body water homeostasis and extracellular volume to a level comparable with that of patients of similar age and normal renal function. This ideal postdialysis body weight, which is representative of normal fluid status, is frequently termed *dry weight,* which often differs substantially from the target weight prescribed by the physician. Because of the difficulties in detecting fluid overload of 2 to 3 liters clinically, technical methods, such as bioimpedance, relative blood volume monitoring, and imaging (ultrasound, chest x-ray) for assessing volume status should be applied regularly.[31] UFRs above 10 ml/kg/h are associated with higher odds of intradialytic hypotension and a greater risk for mortality.[32]

With exception of habitual overdrinkers, salt intake governs water intake from thirst. Dietary salt restriction to 6 g salt per day is recommended to prevent high IDWG and the development of arterial hypertension and congestive heart failure. This often requires constant education including the family. A successful approach used has been the gradual and small reduction in postdialysis weight until BP is in the normal range.[33] Predialysis extracellular fluid depletion as determined by bioimpedance is associated with increased mortality.[34] It is important to realize that IDWG and fluid overload are not synonymous and that fluid depletion can result in high IDWG.[35]

DIALYSIS ADEQUACY

Dialysis adequacy used to be defined as prescribing and delivering a dialysis dose that is associated with the best long-term outcome. However, after many decades of intense international research it has become evident that not only mortality but also morbidity and quality of life of HD patients cannot be influenced by single measures but depend on a multitude of factors. Therefore dialysis adequacy in modern terms along with dialysis dose and dialysis prescription also includes several other measures, including prevention of intradialytic and interdialytic complications, particularly the maintenance of hemodynamic stability and organ perfusion during HD treatment.

Prevention of Intradialytic Hypotension

Intradialytic hypotension occurs in 20% to 30% of treatments and is associated with well-proven damage to the brain, gut, heart, and kidney and poor outcome. Intradialytic hypotension is often due to high rates of ultrafiltration occasioned by the necessity to remove large IDWGs in an often arbitrarily defined short dialysis time.[36] In addition, an individual inability to preserve organ perfusion in the face of dialysis-related hypotension or intravascular hypovolemia (e.g., secondary to uremic and/or diabetic autonomic dysfunction) may lead to short-term changes such as intradialytic cardiac stunning and long-term consequences, such as heart failure and cardiac mortality outcomes.[37] Prevention of high IDWG through dietary counseling in regard to sodium intake as well as lengthening of dialysis duration, dialysate cooling, use of α-sympathetic agonists such as midodrine, and avoidance of food during dialysis may be useful. In addition, prevention and management of postural hypotension immediately after dialysis is essential to prevent falls. Intradialytic hypotension is also discussed in Chapter 96.

Preservation of Residual Renal Function

Most patients starting dialysis still have considerable RRF, but by the end of the first year, the majority have lost RRF completely. Only 10% to 20% of patients still have RRF after more than 3 years of dialysis. RRF of urea clearance of 2 to 3 ml/min contributes significantly to the elimination of uremic toxins.[38] For a patient with an estimated total body water of 40 liters, a residual urea clearance of 2 to 3 ml/min is equivalent to a *stdKt/V* of 0.5 to 0.75/week. This translates into lower serum β_2-microglobulin, phosphate, potassium, urea, creatinine, and uric acid levels, as well as maintained endocrine, metabolic, and antioxidative stress functions; higher hemoglobin concentration; enhanced nutritional status; better quality of life scores; and a reduced need for dietary and fluid restrictions. Loss of RRF, in contrast, is associated with left ventricular hypertrophy. Risk factors for the loss of RRF include activation of the immune system by cellulose-based membranes and dialysate water impurities; intradialytic hypotension and renal hypoperfusion; use of angiotensin-converting enzyme inhibitors or nephrotoxic agents, such as radiocontrast media, aminoglycosides, and nonsteroidal antiinflammatory drugs; and hypercalcemia. Loss of RRF may be delayed by adequate target post-HD weight prescription and prevention of intradialytic hypotensive episodes.

Maintenance or Improvement of Nutritional Status

HD patients are at risk for malnutrition secondary to protein-energy wasting, decreased appetite, infection, intercurrent illnesses, hospital admissions, and missed meals after dialysis.[39] The recommended daily intake of 1.2 g protein per kilogram of ideal body weight and 30 to 35 kcal per kilogram of ideal body weight are often not met. The nutritional status of dialysis patients should be assessed regularly by clinical and biochemical means, including measurement of PCR (or PNA), and technical means such as bioimpedance. Observational data indicate a beneficial effect of monitored intradialytic oral nutritional supplements in patients with albumin levels of 3.5 g/dl or greater.[40] Vitamin intake should be according to needs. Nutrition in HD patients is also discussed in Chapter 86.

Dialysis Adequacy in the Elderly

Patients older than 75 years of age represent the largest incident and fastest growing prevalent patient population in HD worldwide, and the unique medical and social needs of these patients requires consideration. Studies in this elderly patient population show that not the classic parameters of HD dose such as Kt/V and treatment time but other factors, such as cardiovascular comorbidity, nutritional status, functional capacity, and falls, are predictive of outcome.[41] Therefore the focus of dialysis adequacy in elderly patients should shift from assessment of dialysis dose to the use of a more multidimensional measure.[42]

Elderly dialysis patients with multiple comorbidities tolerate HD treatments less well than younger patients. Typical complications, such as intradialytic hypotension, cramps, trial fibrillation, and postdialysis fatigue contribute to the rapid loss of independence occurring in this vulnerable patient population. The underlying etiology is reduced tolerance to intravascular volume reduction during dialysis, which is at least partially caused by impaired cardiovascular hemodynamic responses in combination with uremic and/or diabetic autonomic neuropathy (Fig. 94.5). Significant reductions in organ perfusion occurring in the gut, liver, kidneys, heart, and brain contribute to the development of inflammation, malnutrition, heart failure, loss of RRF, frailty, depression, and dementia.[43] To protect vulnerable elderly patients from the dramatic short- and long-term consequences of intradialytic tissue hypoxia, the HD prescription can be individually adjusted. The following list provides some interventions that may help make HD treatments more tolerable in elderly patients, with the goal to reduce cardiovascular complications, sustain nutritional status, and slow the development of frailty.

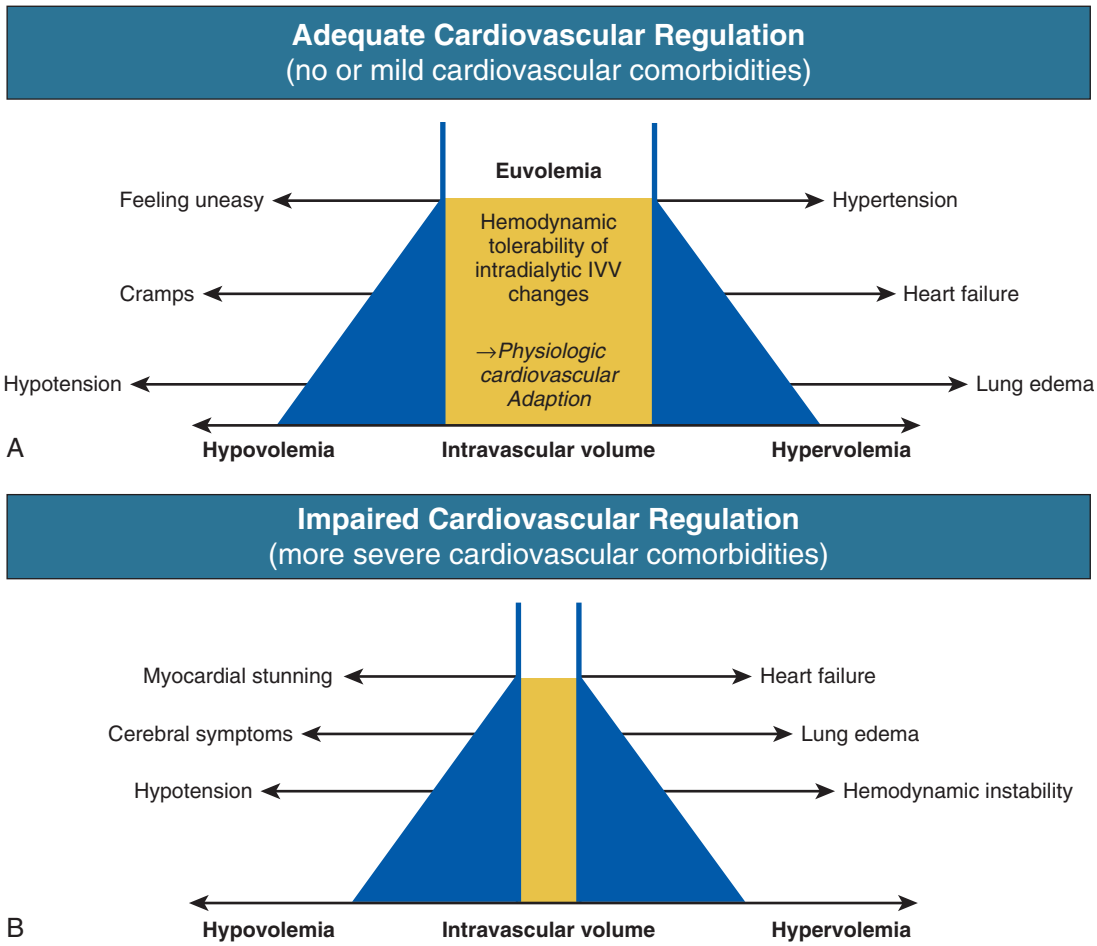

Fig. 94.5 Intradialytic vulnerability. The occurrence of complications *(arrows)* in response to intradialytic changes in intravascular volume *(IVV)* (x-axis) depends on the functionality of physiologic cardiovascular (CV) adaptation mechanisms, such as an increase in heart rate and constriction of arterioles and venous capacity vessels. The individual hemodynamic tolerability of intradialytic IVV changes *(yellow field)* is higher in patients on hemodialysis (HD) with no or mild CV comorbidities and intact CV responses (A) than in typically older and multimorbid HD patients with impaired cardiovascular regulation (e.g., secondary to diabetic autonomous neuropathy) (B). (Modified from reference 44.)

- Carefully evaluate individual susceptibility to intradialytic hypotension in relation to UFR.
- Assess vascular refilling capacity by monitoring intradialytic changes in blood volume.
- Individualize maximum UFR (ideally <10 ml/kg body weight/h).
- Consider ultrafiltration profiling and/or the use of dialysis machines with biofeedback control of UFR.
- Lower dialysate temperature to prevent the intradialytic increase in body core temperature associated with an increased risk for intradialytic hypotension.
- Reduce IDWG (dietary counseling regarding salt intake, prescribe adequately dosed diuretics).
- Avoid intradialytic positive sodium balance (individualize dialysate composition).
- Increase dialysis frequency in case the patient does not tolerate a long interdialytic interval.
- Reduce β-blocker medication to allow cardiac compensation for changes in intravascular volume.
- Reduce or pause antihypertensive medication before dialysis in hypotension-prone patients.
- Assess the effect of food intake during dialysis on hemodynamic stability.
- Regularly adjust postdialysis target weight (bioimpedance).
- If hypertensive, gradually reduce postdialysis weight, avoiding intradialytic hypotensive episodes.
- Consider supine position during dialysis.
- Consider online HDF.
- Consider peritoneal dialysis in patients with otherwise intractable intradialytic hypotension (IDH).
- Treat intradialytic hypoxia by intradialytic oxygen application.
- Ensure three meals per day, including the dialysis day.
- Prescribe oral nutritional supplements during and between dialysis treatments.
- Prevent immobilization by early rehabilitation and physical therapy.

SELF-ASSESSMENT QUESTIONS

1. Which of the following factors related to the hemodialysis prescription in a patient without much residual renal function is likely to result in the *worst* outcome?
   A. *Kt/V* of 1.15 over months
   B. Use of low-flux dialysers
   C. 3-Hour dialysis times
   D. Dialysate potassium of 2 mEq/l
2. Hypertension is very common in dialysis patients. Which factor alone is *least* likely to reduce blood pressure (BP)?
   A. Use of antihypertensive drugs
   B. Longer dialysis times with fluid removal
   C. Postdialysis weight reduction
   D. Dietary sodium restriction
3. Which action is *not* useful when the BP falls frequently during dialysis?
   A. Decrease dialysate temperature
   B. Apply abdominal pressure
   C. Reduce the ultrafiltration rate
   D. Increase postdialysis target weight
4. The recommended target convective volume in online hemodiafiltration (HDF) is 23 l/1.73 m^2/treatment. Which of the following actions is *not* useful to increase the convective volume?
   A. Increase ultrafiltration rate (UFR)
   B. Increase filtration fraction (FF)
   C. Increase blood flow rate (Qb)
   D. Increase dialysate flow rate (Qd)
   E. Increase treatment time (T)
5. In patients with residual kidney function, an intrinsic urea clearance of 3 ml/min is approximately equivalent to a weekly standard *KtV* of:
   A. 0.10
   B. 0.25
   C. 0.75
   D. 1.05
   E. 1.50

Acute Complications During Hemodialysis

Kevan R. Polkinghorne, Peter G. Kerr

Although technical advances in hemodialysis (HD) have made the procedure increasingly safe and well tolerated, there are still important acute complications that will be encountered by physicians responsible for patients receiving HD in both acute and chronic clinical settings. These complications with their causes and management are discussed in this chapter.

CARDIOVASCULAR COMPLICATIONS

Intradialytic Hypotension

Intradialytic hypotension occurs in 10% to 30% of treatments, and ranges from asymptomatic episodes to marked compromise of organ perfusion resulting in myocardial ischemia, cardiac arrhythmias, vascular thrombosis, loss of consciousness, seizures, or death.[1] Furthermore, in patients with acute kidney injury, intradialytic hypotension may induce more renal ischemia and retard recovery of renal function. Recurrent HD-induced ischemic cardiac injury (myocardial stunning) is a prominent cause of intradialytic hypotension and is more common at higher ultrafiltration rates and less frequent with longer and more frequent dialysis treatments.[2] Like intradialytic hypotension and postdialysis orthostatic hypotension, myocardial stunning is an independent risk factor for mortality.[3] The pathogenesis of intradialytic hypotension is complex and is summarized in Fig. 95.1. Most commonly, however, intradialytic hypotension results from the need to deal with excessive fluid weight gain between dialysis treatments. The subsequent rate of fluid removal required exceeds the achievable rate of intravascular filling, resulting in relative intravascular volume depletion. Recent data demonstrate an increased risk for death as the ultrafiltration rate increases, regardless of the threshold used.[4]

The immediate treatment for intradialytic hypotension is to restore the circulating blood volume by placing the patient in the Trendelenburg position, reducing or stopping ultrafiltration, and infusing boluses of 0.9% isotonic saline (≥100 ml, as necessary). Salt-poor albumin and other hypertonic solutions offer no advantage over isotonic saline and are more expensive. Blood flow rate should not be routinely reduced to manage hypotension, because this has not been shown to be beneficial and will compromise solute clearance. Of course, in the setting of excessive weight gain, the administration of boluses of saline or cessation of ultrafiltration, makes achieving the target dry weight more difficult. Because cardiac factors can precipitate intradialytic hypotension, the clinician should maintain a high index of suspicion for cardiac ischemia, especially if hypotension is accompanied by chest pain or dyspnea, and an electrocardiogram and serum troponin values should be obtained. Similarly, recurrent and unexplained episodes of hypotension might warrant echocardiography to rule out pericarditis or pericardial effusion.

Preventive strategies include correction of anemia and hypoalbuminemia and treatment of congestive heart failure or arrhythmias, avoidance of antihypertensive drugs before dialysis, and avoidance of food before and during dialysis. Patients should be counseled to avoid excessive interdialytic weight gain because this is the predominant cause of intradialytic hypotension, and accurate assessment of the patient's dry weight is required. Particular attention should be given to ensuring minimal salt intake. Midodrine, an oral selective α_1-agonist, 5 to 10 mg before dialysis, can be a useful preventive therapy.

Preventive strategies through modification of the dialysis procedure include in the first instance use of bicarbonate dialysate, volumetric control of ultrafiltration, and sodium modeling. Subsequently, reducing the ultrafiltration rate by increasing either treatment time or the frequency of dialysis can be tried.[5] Online blood volume monitoring and biofeedback techniques have been developed in an attempt to improve intradialytic cardiovascular (CV) stability.[6] Although online blood volume devices decrease the incidence of intradialytic hypotension in an at-risk population, there is limited evidence that blood volume monitoring can predict intradialytic hypotension in individual patients or produce a long-term morbidity and mortality benefit, especially in the wider HD population.[6] Cooling of dialysate to 35.5° to 36° C (95.9° to 96.8° F), a measure that induces release of catecholamines, resulting in vasoconstriction or at least preventing vasodilation, may lessen hypotension. Modulation of dialysate temperature is achieved by measuring the blood temperature in the arterial and venous circuits and feeding back the information to the arterial and venous thermostats in the dialysis machine. The machine can be programmed to allow a constant body temperature and a negative overall energy transfer, so-called *isothermic* or *thermoneutral* HD, which aims to prevent energy transfer between the dialysate and extracorporeal blood. A recent systematic review of the randomized controlled trials using biofeedback-modulating dialysate temperature demonstrated significant reductions in the incidence of intradialytic hypotension compared with conventional dialysis.[7] However, large multicenter, randomized trials are needed to determine whether reduced temperature dialysis reduces CV events and patient death.

Across Europe and many other countries, hemodiafiltration (HDF) has become a common mode of dialytic therapy. Although claims of improved mortality with this modality remain a matter of debate, most accept that HDF is associated with improved intradialytic CV stability and less frequent hypotension, although this is also disputed by some.[8]

Intradialytic Hypertension

Intradialytic hypertension occurs in 8% to 30% of treatments.[9] Hypertension during or immediately after HD constitutes an important risk factor for CV mortality. Moreover, an intradialytic increase in systolic blood pressure (BP) is associated with an increased risk for hospitalization or death.[10]

In most circumstances, an intradialytic elevation of BP indicates significant volume overload. However, in a number of patients, BP remains elevated despite fluid removal, a syndrome called *dialysis-refractory*

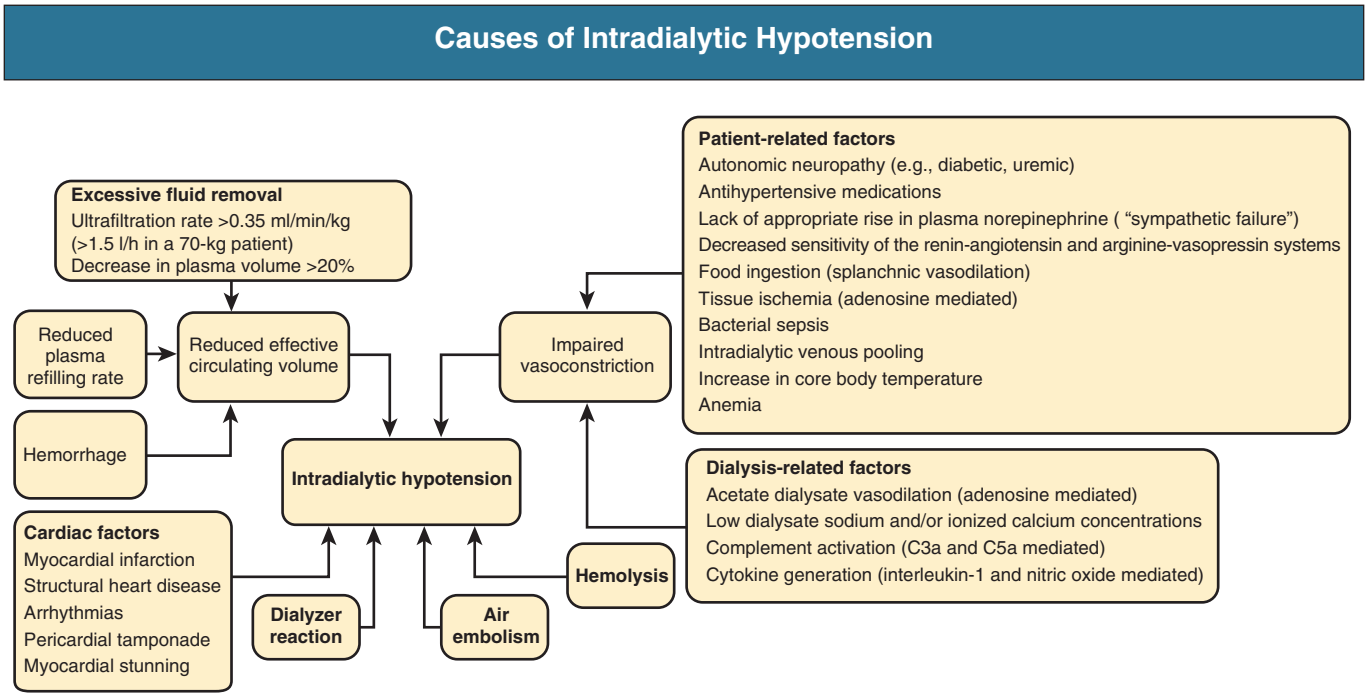

Fig. 95.1 Pathogenesis and causes of intradialytic hypotension.

hypertension. These patients are usually young, with preexisting hypertension, and have excessive interdialytic weight gain and a hyperactive renin-angiotensin system in response to fluid removal.[11] In these patients the hypertension is still mediated by the previous volume expansion, but there is often a lag of days to 2 or more weeks before the BP becomes normal after reduction of the dry target weight (known as the dialysis "lag phenomenon"). Often patients can discontinue most of their antihypertensive agents once this occurs.

Erythropoietin (EPO) and other erythropoiesis-stimulating agents have been associated with a 20% to 30% incidence of new-onset or exacerbation of hypertension. Furthermore, among patients receiving intravenous (not subcutaneous) EPO, elevated levels of endothelin-1 (a potent vasoconstrictor) have been shown to correlate with increased BP. Predominantly, such EPO-induced rises in BP are associated with a rapid rise in hemoglobin and can be avoided by a more conservative approach to correcting the hemoglobin.

Intradialytic hypertension can be precipitated by the use of high-sodium dialysate, which is intended to mitigate the intradialytic decrease in serum osmolality that occurs with the diffusive removal of urea and sodium.[12] Although this approach stabilizes BP during dialysis by improving intravascular filling, high-sodium dialysate results in a positive intradialytic sodium balance and is associated with increased postdialysis thirst, resulting in significant weight gain in the interdialytic period. To circumvent these problems, sodium modeling has been adopted as an approach that uses variable sodium concentrations in the dialysate, generally with sodium reduced in a continuous or stepwise manner from an initial level of 150 to 154 mmol/l to 138 to 142 mmol/l. Although sodium modeling has been widely promoted, results from both randomized and nonrandomized cross-over studies do not suggest any definitive benefit.[13] Other hypothesized mechanisms of intradialytic hypertension include hyperactivity of the sympathetic nervous system[14] and increased cardiac output resulting from fluid removal, particularly in patients with cardiomyopathy.[15] Clinicians also should be aware of possible dialytic removal of certain antihypertensive drugs, such as angiotensin-converting enzyme (ACE) inhibitors and β-blockers.

Increasing hypertension during a dialysis session requires intervention if systolic BP is greater than 180 mm Hg. This is best treated with a centrally acting agent such as clonidine or a short-acting ACE inhibitor such as captopril. Successful treatment of hypertension for a longer period requires an accurate determination of the patient's dry weight and its achievement by gradual ultrafiltration over several weeks of dialysis. Once dry weight is achieved, optimization of antihypertensive drug therapy is warranted, potentially including the use of minimally dialyzable or nondialyzable medications such as angiotensin receptor blockers, calcium channel blockers, clonidine, and carvedilol. However, use of antihypertensive agents may make achievement of dry weight difficult because of induced intradialytic hypotension. Evidence from the Dry-Weight Reduction in Hypertensive Hemodialysis Patients (DRIP) trial[16] suggests that optimal control of BP in HD patients is via control of extracellular fluid volume (salt and water) not the use of antihypertensive agents. One common error in management is to treat dialysis hypertension with increasing BP medications as opposed to opting to achieve dry weight. The use of vasodilator drugs (hydralazine, minoxidil) can lead to increased fluid retention that worsens volume overload. Minoxidil also can cause pleural and pericardial effusions and should be avoided in dialysis patients if at all possible.

Cardiac Arrhythmias

Intradialytic arrhythmias are common and are often multifactorial in origin.[17,18] Left ventricular hypertrophy, congestive cardiomyopathy, uremic pericarditis, silent myocardial ischemia, and conduction system calcification are frequently encountered in adult dialysis patients. In addition, polypharmacy coupled with the constant alterations in fluid, electrolyte, and acid-base homeostasis may precipitate intradialytic arrhythmias. The range of electrocardiographic abnormalities that may be encountered in renal failure is shown in Table 95.1. QTc dispersion,

TABLE 95.1 Electrocardiographic Abnormalities in Renal Failure

Function	Abnormality Seen in Renal Failure
PR interval	Usually normal; prolongation in long-term HD. Calcification of mitral valve annulus may involve His bundle, resulting in complete heart block.
QRS interval	
Amplitude	Increases during ultrafiltration (correlates with reduction in left ventricular [LV] dimensions). LV hypertrophy (LVH) on voltage criteria found in up to 50%.
Duration	Prolonged (within normal range) by hemodialysis. Late potentials increased only in patients with preexisting coronary heart disease. Prolonged in hyperkalemia.
ST segment	Depression during HD does not predict coronary artery disease. Depression or elevation may occur in hyperkalemia. Depression during ambulatory monitoring poorly predictive of coronary artery disease.
QTc interval	Increases during HD (correlates with reduction in K^+ and Mg^{2+}). Increased QT dispersion reported in patients on dialysis.
T wave	Peaking or inversion may occur in hyperkalemia. Inversion in anterolateral leads in LVH with strain pattern.
Rhythm	Bradycardia and asystole in long intradialytic break and during HD. Atrial and ventricular arrhythmias during HD.

Risk factors include left ventricular dysfunction, wall motion abnormalities, known coronary artery disease, abnormal perfusion scans (even without coronary artery disease), use of cardiac glycosides, and low dialysate potassium concentration.
HD, Hemodialysis.

the difference between maximum and minimum QTc interval on a standard 12-lead electrocardiogram, is prolonged after HD and has been proposed as a prognostic indicator of cardiac complications in dialysis patients.

Preventive measures include the use of bicarbonate dialysate and careful attention to dialysate potassium and calcium levels. There are very few trials of the most appropriate dialysate potassium level, although recent observational evidence suggests that dialysate potassium levels below 2 mmol/l should be avoided in most patients.[19] Zero potassium dialysate should be avoided in the hyperkalemic individual because of its arrhythmogenic potential, particularly in patients receiving digoxin, because serum potassium levels can fall to less than 3.5 mmol/l during dialysis. Serum digoxin levels should be regularly monitored and the need for the drug regularly reassessed.

Sudden Death

Cardiac arrest occurs in 7 per 100,000 HD sessions and is more common in the elderly, patients with diabetes, and patients using central venous catheters.[20] Sudden deaths during dialysis are observed more frequently after the 3-day (classically weekend) interdialytic interval in patients receiving dialysis three times per week.[21,22] The etiology is complex but likely related to cardiac structural abnormalities related to long-standing hypertension and uremia coupled with the more marked fluid and solute accumulation seen in the long interdialytic period. Both peritoneal dialysis patients and patients undergoing frequent long-hours HD do not show this high event rate on a particular day of the week.[22] Recent analysis of data from implantable cardiac monitors in HD patients with sudden cardiac death found that the vast majority were due to bradycardia and asystole, rather than malignant ventricular arrhythmias raising uncertainty regarding β-blocker use in this population.[23]

Although coronary heart disease increases the risk for sudden death, other catastrophic intradialytic events need to be ruled out. The prompt recognition and treatment of hyperkalemia, as a reversible cause of cardiac dysfunction, is imperative. Profound generalized muscle weakness may be a warning sign of imminent life-threatening hyperkalemia.

When cardiopulmonary arrest occurs during dialysis, an immediate decision must be made as to whether the collapse is the result of an intrinsic disease or technical errors, such as air embolism, unsafe dialysate composition, overheated dialysate, line disconnection, or sterilant in the dialyzer. Air in the dialysate, grossly hemolyzed blood, and hemorrhage caused by line disconnection can be easily detected. However, if no obvious cause is identifiable, blood should not be returned to the patient, particularly if the arrest occurred immediately on initiation of dialysis. A patient exposed to formaldehyde may have reported earlier burning at the access site; fortunately this agent is rarely used today. If the possibility of a problem with dialysate composition is remote, blood may be returned to the patient. However, blood and dialysate samples should be immediately sent for electrolyte analysis, the dialyzer and blood lines saved for later analysis, and the dialysis machine replaced until all its safety features have been thoroughly evaluated for possible malfunction. It should be standard practice to have defibrillators in dialysis units. The management of cardiopulmonary arrest during dialysis should follow the standard principles of cardiopulmonary resuscitation; the diagnosis and management of technical errors are discussed later. All dialysis units should have established protocols for managing cardiac arrest and other common dialysis emergencies.

Prevention of sudden cardiac death in HD patients, including the role of implantable defibrillators, is discussed further in Chapter 81.

Pericarditis

The management of pericarditis in dialysis patients is discussed in Chapter 81.

Dialysis-Associated Steal Syndrome

The construction of an arteriovenous fistula (AVF) or arteriovenous graft (AVG) may result in reduction of blood flow to the hand. Although clinically significant ischemia does not usually result, symptoms are by no means rare, particularly in diabetic or elderly patients with peripheral vascular disease. Dialysis-associated steal syndrome is more common in upper arm AVFs (~4%) compared with both AVGs and forearm AVFs (~1%). The clinical presentation, differential diagnosis, and evaluation of dialysis-associated steal syndrome are summarized in Box 95.1 and are discussed further in Chapter 91.[24]

Treatment depends on the clinical severity of ischemia and vascular access anatomy.[24] Severe ischemia can cause irreparable injury to nerves within hours and must be considered a surgical emergency. Mild ischemia, manifested by mild pain during HD, subjective coldness, and paresthesias, and objective reduction in skin temperature but with no loss of sensation or motion, is common and generally improves with time.[25] Patients with mild ischemia should undergo symptom-specific therapy (e.g., wearing a glove) and frequent physical examination, with special attention to subtle neurologic changes and muscle wasting. Failure to improve may necessitate surgical or radiologic intervention (see Chapter 91). Persistent symptoms after an apparently successful correction of the vascular access flow should alert the clinician to other unrelated causes.

BOX 95.1 Dialysis-Associated Vascular Steal Syndrome

Clinical Presentations (Symptoms Often Aggravated on Dialysis)

- Hand numbness, pain, or weakness
- Coolness of distal arm
- Diminished pulses
- Acrocyanosis, gangrene

Differential Diagnosis

- Dialysis-associated cramp
- Polyneuropathy: Diabetes, uremia
- Entrapment neuropathy: β_2-microglobulin–derived amyloidosis
- Reflex sympathetic dystrophy
- Calciphylaxis

Evaluation of Steal Severity

- Pulse oximetry
- Plethysmography
- Doppler flow
- Angiography

Treatment Options (Depending on Severity)

- Symptomatic (e.g., gloves)
- Surgical, with preservation of vascular access: banding to reduce flow, distal revascularization–interval ligation (DRIL) procedure (see Fig. 91.6)
- Surgical, with loss of vascular access: ligation

NEUROMUSCULAR COMPLICATIONS

Muscle Cramps

Muscle cramps occur in 5% to 20% of patients late during dialysis and frequently involve the legs. They account for 15% of premature discontinuations of dialysis.[26] Electromyography shows increased tonic muscle electrical activity throughout dialysis, and serum creatine kinase may be elevated.

Although the pathogenesis is unknown, dialysis-induced volume contraction and hypoosmolality appear to be common predisposing factors. Indeed, the onset of muscle cramps may give an indication that the target weight has been reached. However, hypomagnesemia and carnitine deficiency also may play a role.

The acute management is directed at increasing plasma osmolality. Cessation of ultrafiltration is not useful. Parenteral infusion of 23.5% hypertonic saline (15 to 20 ml), 25% mannitol (50 to 100 ml), or 50% dextrose in water (25 to 50 ml) is equally effective. However, hypertonic saline may result in postdialytic thirst, and both hypertonic saline and mannitol cause transient warmth and flushing during the infusion. Furthermore, large and repetitive infusions of mannitol may lead to increased thirst, interdialytic weight gain, and fluid overload. Overall, dextrose in water is preferred, particularly in nondiabetics.

Preventive measures include dietary counseling about excessive interdialytic weight gain. In patients without clinical signs of fluid overload, it is reasonable to increase the dry weight by 0.5 kg and to observe the clinical response. Quinine sulfate (250 to 300 mg) or oxazepam (5 to 10 mg) given 2 hours before dialysis also may be effective. Although the U.S. Food and Drug Administration regards quinine sulfate as unsafe and ineffective for the prevention of cramps, this drug works well in some patients and is used freely in most parts of the world. Some reports also promote the use of vitamin E in this role.[27] The use of sodium gradients during dialysis may have some benefit as well. Proposed strategies include starting with a dialysate sodium concentration of 145 to 155 mmol/l and a linear decrease to 135 to 140 mmol/l by the completion of the treatment. A comparison of sodium modeling with an exponential, linear, or step program has yielded similar results.[13,28] In anecdotal reports, 5 mg of enalapril twice weekly may be effective, presumably by inhibiting angiotensin II–mediated thirst. Stretching exercises, magnesium, creatine monohydrate (12 mg before dialysis), and L-carnitine supplementation (20 mg/kg per dialysis session) also may be beneficial. An intradialytic blood volume biofeedback control system has been shown to reduce the incidence of muscle cramps.[29]

Restless Legs Syndrome

Restless legs syndrome is common in dialysis patients. The typical report is of crawling sensations in the legs that occur with inactivity, and symptoms may worsen during dialysis. The etiology, prevention, and management of restless legs syndrome are discussed in Chapter 85.

Dialysis Disequilibrium Syndrome

Despite a decline in its incidence, dialysis disequilibrium syndrome (DDS) is still observed sporadically in patients who are initiated on HD on high-flux dialyzers with large surface areas and short dialysis time. Risk factors include young age, severe uremia, rapid and marked intradialytic falls in urea at dialysis initiation, low dialysate sodium concentration, and preexisting neurologic disorders (see Chapter 85).

DDS commonly manifests with restlessness, headache, nausea, vomiting, blurred vision, muscle twitching, disorientation, tremor, and hypertension. More severe manifestations include obtundation, seizures, and coma. DDS usually develops toward the end of dialysis but may be delayed for up to 24 hours. Although cerebral edema is a consistent finding on computed tomographic scanning, DDS remains a clinical diagnosis because laboratory tests, including electroencephalography, are nonspecific. It is usually self-limited, but full recovery may take several days.

The pathogenesis of DDS is still a subject of debate. The reverse urea effect theory, which proposes that a transient osmotic disequilibrium occurs during dialysis as a result of a more rapid removal of urea from blood than from cerebrospinal fluid, has been disputed.[30] In animals undergoing rapid dialysis, despite the correction of systemic acidosis, a paradoxical cerebrospinal fluid acidosis develops that is aborted by slower dialysis. An additional mechanism is the intracerebral accumulation of idiogenic osmoles, such as inositol, glutamine, and glutamate.

In high-risk patients, preventive measures include the use of volumetric-controlled machines, bicarbonate dialysate, sodium modeling, earlier recognition of uremic states, and stepped initiation of dialysis (short initial treatment times with lower blood pump speeds). In addition, short and more frequent dialysis treatments are recommended with use of small surface area dialyzers and reduced blood flow rates. The target reduction in blood urea should initially be limited to 30%. The prophylactic use of mannitol or anticonvulsants is not recommended.

An extension of this syndrome may be one that mimics osmotic demyelination syndrome—similar to that seen with rapid correction of hyponatremia. Several cases have been reported in association with dialysis initiation, with clinical manifestations similar to those of the locked-in pontine picture of central demyelination. The difference is that with the dialysis-related condition, patients appear to recover over the ensuing 5 to 7 days and the condition seems to be related to edema rather than demyelination.[31]

Seizures

Intradialytic seizures occur in less than 10% of patients and tend to be generalized but easily controlled. However, focal or refractory seizures warrant evaluation for focal neurologic disease, particularly intracranial

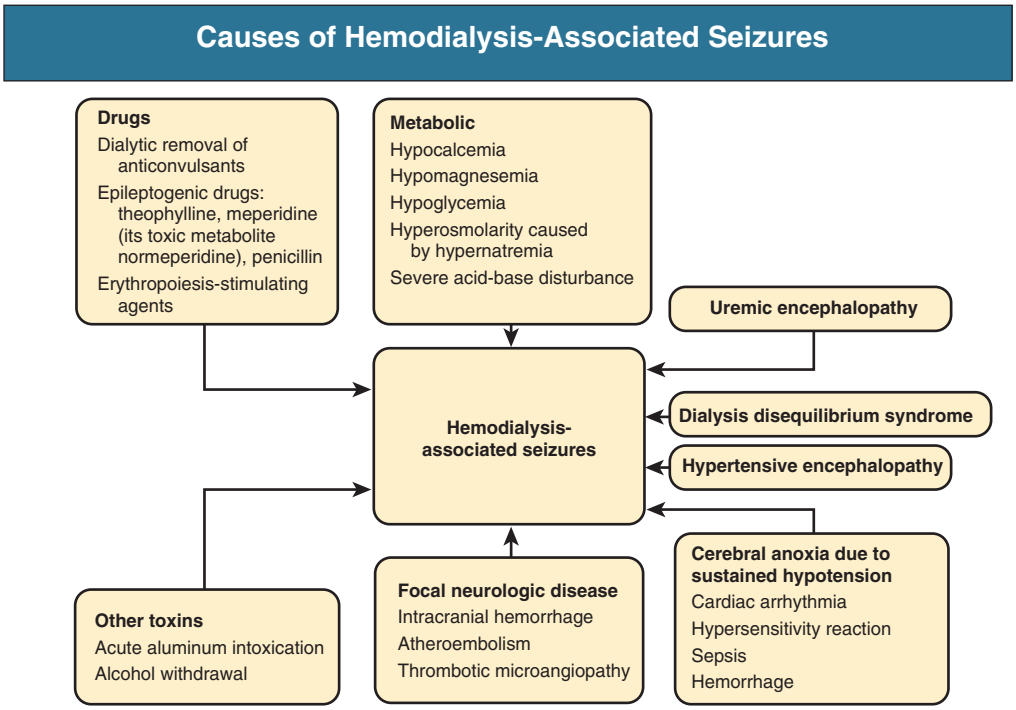

Fig. 95.2 Causes of hemodialysis-associated seizures.

hemorrhage. Causes of seizures are summarized in Fig. 95.2 and are discussed further in Chapter 85.

Treatment of established seizures requires cessation of dialysis, maintenance of airway patency, and investigation for metabolic abnormalities. Intravenous diazepam, alprazolam, or clonazepam, and phenytoin may be required. Intravenous 50% dextrose in water should be administered promptly if hypoglycemia is suspected.

Headache

Dialysis headache is common and typically consists of a bifrontal discomfort that develops during dialysis and may become intense and throbbing, accompanied by nausea and vomiting. It is usually aggravated by the supine position, but there are no visual disturbances.[32]

Although its cause is unknown, dialysis headache may be a subtle manifestation of DDS or may be related to acetate, which is present in low concentrations (3 to 4 mmol/l) in almost all dialysate fluid. A role for nitric oxide also has been postulated. Alternatively, it may be a manifestation of caffeine withdrawal caused by dialytic removal of caffeine.

Management consists of oral analgesics (e.g., acetaminophen [paracetamol]). Preventive measures include slow dialysis with reduced blood flow rates, change to bicarbonate dialysate, sodium, and ultrafiltration modeling, coffee ingestion during dialysis, and use of reprocessed dialyzers. Attention should also be paid to adequate flushing of the lines and dialyzer before commencement of dialysis. Changing the dialyzer (especially to a synthetic membrane or an alternative synthetic membrane) is sometimes useful in refractory cases.

HEMATOLOGIC COMPLICATIONS

Complement Activation and Dialysis-Associated Neutropenia

During dialysis with unsubstituted cellulose dialyzers, which are now infrequently used, the free hydroxyl groups present on the membrane cause activation of the alternative pathway of complement.[33] This results in activation and increased adherence of circulating neutrophils to the endothelial capillary pulmonary vasculature, leading to transient neutropenia that reaches a nadir after 15 minutes of dialysis, followed by a rebound leukocytosis 1 hour later. Complement activation and neutropenia also have been detected with other more widely used dialyzer membranes, including cellulose acetate and polysulfone, but to a lesser degree. Although the long-term clinical relevance of this phenomenon remains speculative, its contribution to acute intradialytic morbidity is discussed later.

Intradialytic Hemolysis

Acute hemolysis can be caused by faulty dialysis equipment, chemicals, drugs, toxins, or patient-related factors (Fig. 95.3).[34] With the advent of better dialysis equipment design and the widespread use of reverse osmosis and/or deionization systems and carbon filters, traumatic red blood cell (RBC) fragmentation caused by poorly designed blood pumps and methemoglobinemia caused by water contamination with chloramine or copper are rarely seen today. However, nitrate or nitrite intoxication causing methemoglobinemia still occurs sporadically in patients on home HD who use well water contaminated with urine from domesticated animals. Furthermore, during dialyzer reprocessing, formaldehyde retention can result in hemolysis by inducing formation of cold agglutinins or inhibiting RBC metabolism.

The diagnosis of acute hemolysis is evident when grossly translucent hemolyzed blood is observed in the tubing. Patients with methemoglobinemia have nausea, vomiting, hypotension, and cyanosis, and oxygen therapy does not improve the black blood present in the extracorporeal circuit. Copper contamination should be suspected in the presence of skin flushing and abdominal pain or diarrhea.

Evaluation should include reticulocyte count, haptoglobin, lactate dehydrogenase, blood smear, Coombs test, and measurement of methemoglobin. Chromium 51 (^{51}Cr)-labeled RBC survival and bone marrow examination may occasionally be indicated if there is recurrent hemolysis.

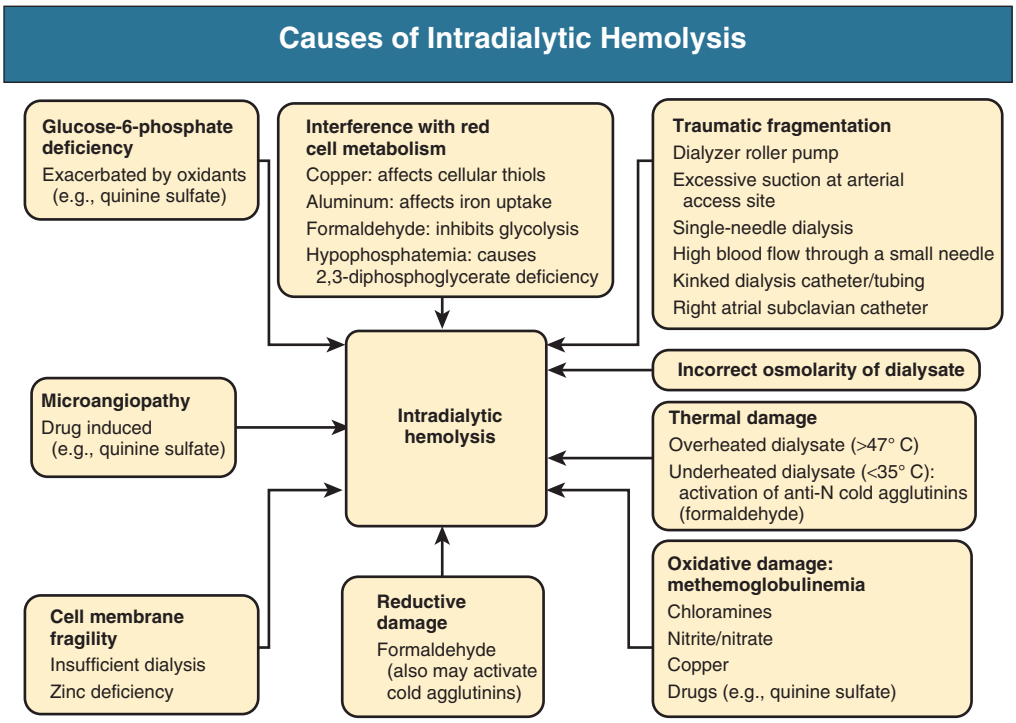

Fig. 95.3 Causes of intradialytic hemolysis.

More important, analysis of tap water for chloramines and assessment of the status of charcoal filtration (which removes chloramines) and metal contaminants and thorough analysis of the dialysis equipment for clues of increased blood turbulence are recommended.

Hemorrhage

Bleeding complications are commonly related to the use of intradialytic anticoagulation, which exacerbates the uremic bleeding diathesis (see Chapter 83). In addition, dialysis patients are prone to spontaneous bleeding at specific sites, such as gastrointestinal arteriovenous malformations; subdural, pericardial, pleural, retroperitoneal, and hepatic subcapsular spaces; and the ocular anterior chamber. Despite its limitations, the bleeding time remains the best indicator of hemorrhagic tendency.

In addition to specific measures directed to the site of hemorrhage, reversal of uremic platelet dysfunction is imperative. Strategies include the use of erythropoiesis-stimulating agents or RBC transfusions to achieve a hematocrit above 30% to improve rheologic platelet–vessel wall interactions, intravenous conjugated estrogens at 0.6 mg/kg/day for 5 consecutive days, intravenous or subcutaneous 1-deamino-8-D-arginine vasopressin (DDAVP) at 0.3 mcg/kg administered over 15 to 30 minutes, and intravenous infusion of cryoprecipitate (see Box 83.2). For patients experiencing severe bleeding, it is advisable to consider heparin-free dialysis with use of normal saline flushes every 15 to 30 minutes with ultrafiltration adjustments. Other alternatives may include regional heparin or citrate anticoagulation, and in the long term the use of low molecular weight heparin, heparin modeling, or prostacyclin may be considered. More recently, the use of heparin-bound dialyzers (such as hemophan or AN69ST)[35] or citrate-containing dialysate have been advocated in patients at risk for bleeding, although they may not decrease the need for routine circuit anticoagulation.[36] In patients scheduled for elective surgery or invasive procedures, cessation of aspirin should be considered a week in advance, the dose of anticoagulant reduced to a minimum, and the hematocrit maintained above 30%. In some patients, intravenous DDAVP to reverse the uremic platelet defect also may be required. Tranexamic acid, a potent fibrinolytic inhibitor, can be used as an adjuvant treatment to control hemorrhage in dialysis patients.[37]

Thrombocytopenia

An increasingly important cause of thrombocytopenia in dialysis patients is heparin-induced thrombocytopenia. The diagnosis and management, including alternative strategies for anticoagulation for HD, are discussed in Chapter 83.

PULMONARY COMPLICATIONS

Dialysis-Associated Hypoxemia

In most patients, the arterial Pao_2 decreases by 5 to 20 mm Hg (0.6 to 4.0 kPa) during dialysis, reaching a nadir at 30 to 60 minutes, and resolves within 60 to 120 minutes after discontinuation of dialysis. This decrease is usually of no clinical significance to patients unless there is preexisting chronic cardiopulmonary disease.

Hypoventilation is the main implicated factor and is primarily central in origin as a result of a decrease in carbon dioxide production after acetate metabolism (specific to acetate dialysate), loss of carbon dioxide in the dialyzer (with both acetate and bicarbonate dialysate), and rapid alkalinization of body fluids (particularly with large surface area dialyzers).[38] In addition, acetate-induced respiratory muscle fatigue can lead to hypoventilation, especially in acutely ill patients. Furthermore, a commonly observed ventilation-perfusion mismatch may be caused by pulmonary leukocyte agglutination (in part resulting from complement activation) or impaired cardiac output (resulting from acetate-induced myocardial depression).

In high-risk patients with fluid overload, preventive measures consist of using intradialytic oxygen supplementation, conventional bicarbonate dialysate, and biocompatible membranes. Optimizing hematocrit values

and performing sequential ultrafiltration followed by HD may further reduce the likelihood of hypoxemia.

TECHNICAL MALFUNCTIONS

Air Embolism

The most vulnerable source of air entry into the extracorporeal circuit is the prepump tubing segment, in which significant subatmospheric pressures prevail. However, other sources need to be considered, including intravenous infusion circuits especially with glass bottles, air bubbles from the dialysate, and (especially uncuffed) dialysis catheters. High blood flow rates may allow rapid entry of large volumes of air despite small leaks.

Clinical manifestations depend on the volume of air introduced, the site of introduction, the patient's position, and the speed at which air is introduced.[39] In the sitting position, air entry through a peripheral vein bypasses the heart and causes venous emboli in the cerebral circulation. The acute onset of seizures and coma in the absence of precedent symptoms such as chest pain and dyspnea is highly suggestive of air embolism. In the supine position, air introduced through a central venous line will be trapped in the right ventricle, where it forms foam, interferes with cardiac output, and, if it is large enough, leads to obstructive shock. Dissemination of microemboli to the pulmonary vasculature results in dyspnea, dry cough, chest tightness, or respiratory arrest. Furthermore, passage of air across the pulmonary capillary bed can lead to cerebral or coronary artery embolism. In the left Trendelenburg position, air emboli migrate to the lower extremity venous circulation, resulting in ischemia as a result of increased outflow resistance. Foam may be visible in the extracorporeal tubing, and cardiac auscultation may reveal a peculiar churning sound.

The immediate management of clinically suspected air embolism is summarized in Fig. 95.4. Prevention depends primarily on dialysis machines equipped with venous air bubble traps and foam detectors located just distal to the dialyzer and a venous pressure monitor at the venous end. The detector is attached to a relay switch that simultaneously activates an alarm, shuts off the blood pump, and clamps the venous blood line if air is detected. Therefore dialysis should never be performed in the presence of an inoperative air detection alarm system. Glass bottles should be avoided because they create vacuum effects that can permit air entry into the extracorporeal system. Dialysis catheters should be aspirated and flushed with saline before connection. Dialyzer rinsing, before use, should expand all compartments to remove residual air bubbles.

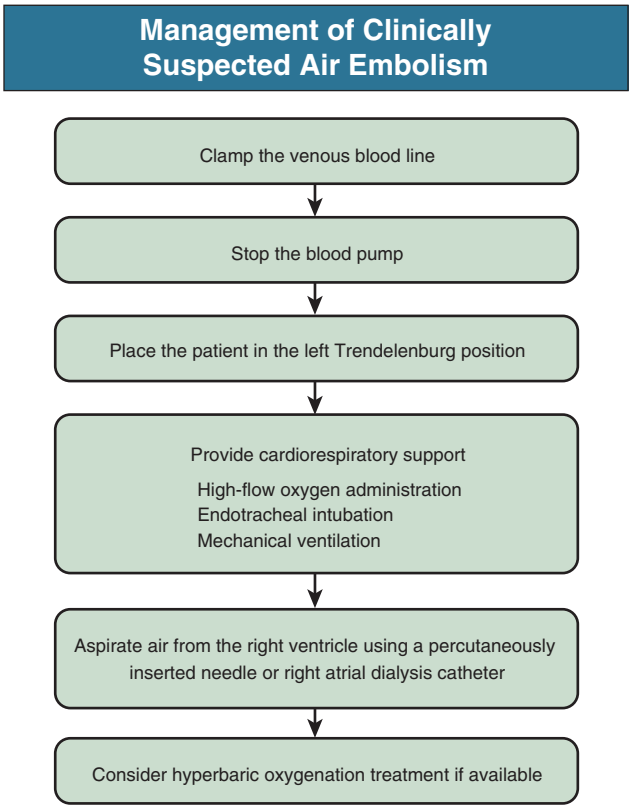

Fig. 95.4 Management of clinically suspected air embolism.

Incorrect Dialysate Composition

Incorrect dialysate composition results from technical or human errors. Because the primary solutes constituting the dialysate are electrolytes, the dialysate concentration will be reflected by its electrical conductivity. Therefore proper proportioning of concentrate to water can be achieved by the use of a meter that continuously measures the conductivity of the dialysate solution as it is being fed to the dialyzer. Life-threatening electrolyte and acid-base abnormalities are avoidable if the conductivity alarm is functioning properly and the alarm limits are set correctly. However, in dialysis machines that are equipped with conductivity-controlled mixing systems, the system automatically changes the mixing ratio of the concentrates until the dialysate solution conductivity falls within the set limits. This may inadvertently lead to dialysate without any bicarbonate, with apparently acceptable conductivity. Therefore, if conductivity-controlled systems are used, it is safer to also check the dialysate pH before dialysis. Conductivity monitors can fail or can be improperly adjusted by human error. Therefore it is important to add human monitoring of dialysate composition before every treatment, whenever a machine has been sterilized or moved about, or whenever a new concentrate is used. Furthermore, many nonstandardized solutions are available, some of which may be used with an inappropriate proportioning system. Therefore it is also essential that the supplies match the machine-proportioning ratio for which they were prepared for the appropriate final dialysate composition to be obtained. Double checking of concentrate variations (e.g., potassium, calcium, and phosphate concentration) should be practiced, as it is for intravenous drug administration.

Hypernatremia

Hypernatremia occurs when concentrate or the ratio of concentrate to water is incorrect and the conductivity monitors or the alarms are not functioning properly. Hyperosmolality results in intracellular water depletion. Clinical manifestations include thirst, headache, nausea, vomiting, seizures, coma, and death. Aggressive treatment is mandatory and includes cessation of dialysis, hospitalization, and infusion of 5% dextrose in water. Dialysis should be resumed with a different machine; the dialysate sodium level should be 2 mmol/l lower than the plasma level, and isotonic saline should be concurrently infused. Dialysis against a sodium level 3 to 5 mmol/l lower than the serum level may increase the risk for disequilibrium. Ultrafiltration with equal volume replacement with normal saline is another option.

Hyponatremia

Failure to add concentrate, inadequate concentrate-to-water ratio, or conductivity monitor or alarm malfunction can cause hyponatremia. Hyponatremia also can occur during the course of dialysis with a proportioning system if the concentrate container runs dry and the conductivity set limits are inappropriate. Acute hypoosmolality causes hemolysis with hyperkalemia and hemodilution of all plasma constituents.

Symptoms include restlessness, anxiety, pain in the vein injected with the hypotonic hemolyzed blood, chest pain, headache, nausea, and occasional severe abdominal or lumbar cramps. Pallor, vomiting, and seizures may be observed. Treatment consists of clamping the blood lines and discarding the hemolyzed blood in the extracorporeal circuit. High-flow oxygen and cardiac monitoring are imperative because of hyperkalemia and potential myocardial injury. Dialysis should be restarted with a new dialysate batch containing low potassium, and high transmembrane pressure should be applied to remove excess water. Correction of serum sodium concentration should be achieved by no more than 1 to 2 mmol/l/h. Anticonvulsants are indicated for seizures and blood transfusions for severe anemia. Successful correction of severe hyponatremia has been reported in a single 3-hour HD session with a dialysate sodium concentration of 135 mmol/l without any adverse neurologic consequences despite a serum sodium correction rate of 3 mmol/l/h.[40] This suggests that elevated blood urea levels might protect uremic patients from the development of demyelinating syndromes when hyponatremia is rapidly corrected.

Metabolic Acidosis

Although acute intradialytic metabolic acidosis can be a manifestation of improper mixing of concentrates or failure of pH monitors, other causes need to be ruled out, including diabetic or alcoholic ketoacidosis, lactic acidosis, toxic ingestions, and dilutional acidosis.[41] The diagnosis is usually suggested by the acute onset of hyperventilation during HD and confirmed by laboratory evaluation. In most circumstances, correction of the underlying cause and use of bicarbonate dialysate at the appropriate concentration (32 to 35 mmol/l) are adequate measures.

Metabolic Alkalosis

Severe intradialytic metabolic alkalosis is rare and may be caused by error in dialysate concentrates, reversed connection of bicarbonate and acid concentrate containers to the entry ports of the dialysis machine, pH monitor malfunction, or use of regional citrate anticoagulation. The most common cause, however, is hydrochloric acid loss as a result of vomiting or nasogastric suction. Attention should also be directed to identification of sources of added alkali.[42]

Acute treatment is rarely necessary unless a technical error has occurred. Removal of the alkali source is usually sufficient, and H_2-antagonists or proton pump inhibitors may be successful if there is gastric acid loss. The administration of sodium chloride to anephric patients with chloride-sensitive alkalosis will not repair the alkalosis. If a more rapid reduction in serum bicarbonate is desired, modification of the dialysate bath by replacement of alkali with chloride, substitution of bicarbonate with acetate dialysate, use of acid dialysate, and infusion of hydrochloric acid are effective but cumbersome measures. The use of conventional or low-bicarbonate (25 to 30 mmol/l) dialysate is probably as effective.

Temperature Monitor Malfunction

Malfunction of the thermostat in the dialysis machine can result in the production of excessively cool or hot dialysate. Whereas cool dialysate is not dangerous and may have beneficial hemodynamic effects (see discussion regarding intradialytic hypotension), overheated dialysate can cause immediate hemolysis and life-threatening hyperkalemia, particularly if the dialysate temperature increases to more than 51° C. In such an event, dialysis must be stopped immediately and blood in the system discarded. The patient should be monitored for hemolysis and hyperkalemia. Dialysis should be resumed to cool the patient by use of a dialysate temperature of 34° C to treat hyperkalemia and allow blood transfusions if necessary. Visual and audible alarms are mandatory to prevent this complication.

Blood Loss

Intradialytic blood loss can result from arterial or venous needle disengagement from the access, separation of the venous or arterial line connections, femoral or central line dialysis catheter perforation or dislodgment, or rupture of a dialysis membrane with or without malfunction of the blood leak detector. Clinical findings include hypotension, loss of consciousness, and cardiac arrest. In addition, after traumatic insertion of a dialysis catheter, blood loss can result in pain or mass from a rapidly expanding hematoma; chest, shoulder, or neck pain from intrapericardial blood loss; back, flank, groin, or lower abdominal pain or distention from retroperitoneal bleeding; or hemoptysis from pulmonary bleeding. Acute management includes the discontinuation of HD, pressure application for local hemostasis, reversal of anticoagulation (e.g., protamine sulfate for heparin), hemodynamic support, oxygen administration, and surgical intervention if needed.

In the home dialysis setting, especially nocturnal HD, venous needle dislodgement is potentially catastrophic. A number of devices have been developed for early detection of blood leak resulting from needle dislodgment, including bed-wetting incontinence pads, Red-Sense and HEMOdialert blood detectors and other proprietary techniques. However, the most important component is prevention by repeated patient education about adequate taping of needles and dialysis lines.

Clotting of Dialysis Circuit

Clotting of the extracorporeal circuit during dialysis is a common practical problem, has many underlying causes, and warrants a thorough investigation. Technical factors include an inadequate or poor priming technique, resulting in retention of air in the dialyzer, and lack of or inadequate priming of the heparin infusion line. Such operator-induced errors are corrected through ongoing staff education and competency assessment. Incorrect heparin loading dose, insufficient time lapse after loading dose of heparin for systemic anticoagulation to occur, incorrect pump setting for constant heparin infusion, delayed start of the heparin pump, and failure to release the heparin line clamp are important correctible causes of clotting that also should be considered. Low molecular weight heparin is often used as a single bolus at the commencement of dialysis but may not maintain anticoagulation for extended hours of treatment (e.g., nocturnal dialysis). Vascular access–related problems from inadequate blood flow caused by needle or catheter positioning or clotting, excessive access recirculation, and frequent interruption of blood flow also can result in clotting. Immediate management requires prompt recognition of the underlying cause and implementation of corrective actions, including ongoing heparin dose adjustment and, if indicated, vascular access revision.

Heparin-free dialysis is sometimes medically indicated, such as in an actively bleeding patient or postoperatively. Although traditional approaches to avoid circuit clotting in this circumstance involve frequent saline flushes, an alternative approach is to employ predilution HDF.

DIALYSIS REACTIONS

During HD, blood is exposed to surface components of the extracorporeal circuit, including the dialyzer, tubing, sterilization processes, and other foreign substances related to the manufacturing and reprocessing procedures. This interaction between the patient's blood and the extracorporeal system can lead to various adverse reactions (Fig. 95.5).

Anaphylactic and Anaphylactoid Reactions

Clinical Presentation

Anaphylaxis is the result of an immunoglobulin E (IgE)-mediated acute allergic reaction in a sensitized patient, whereas anaphylactoid reactions

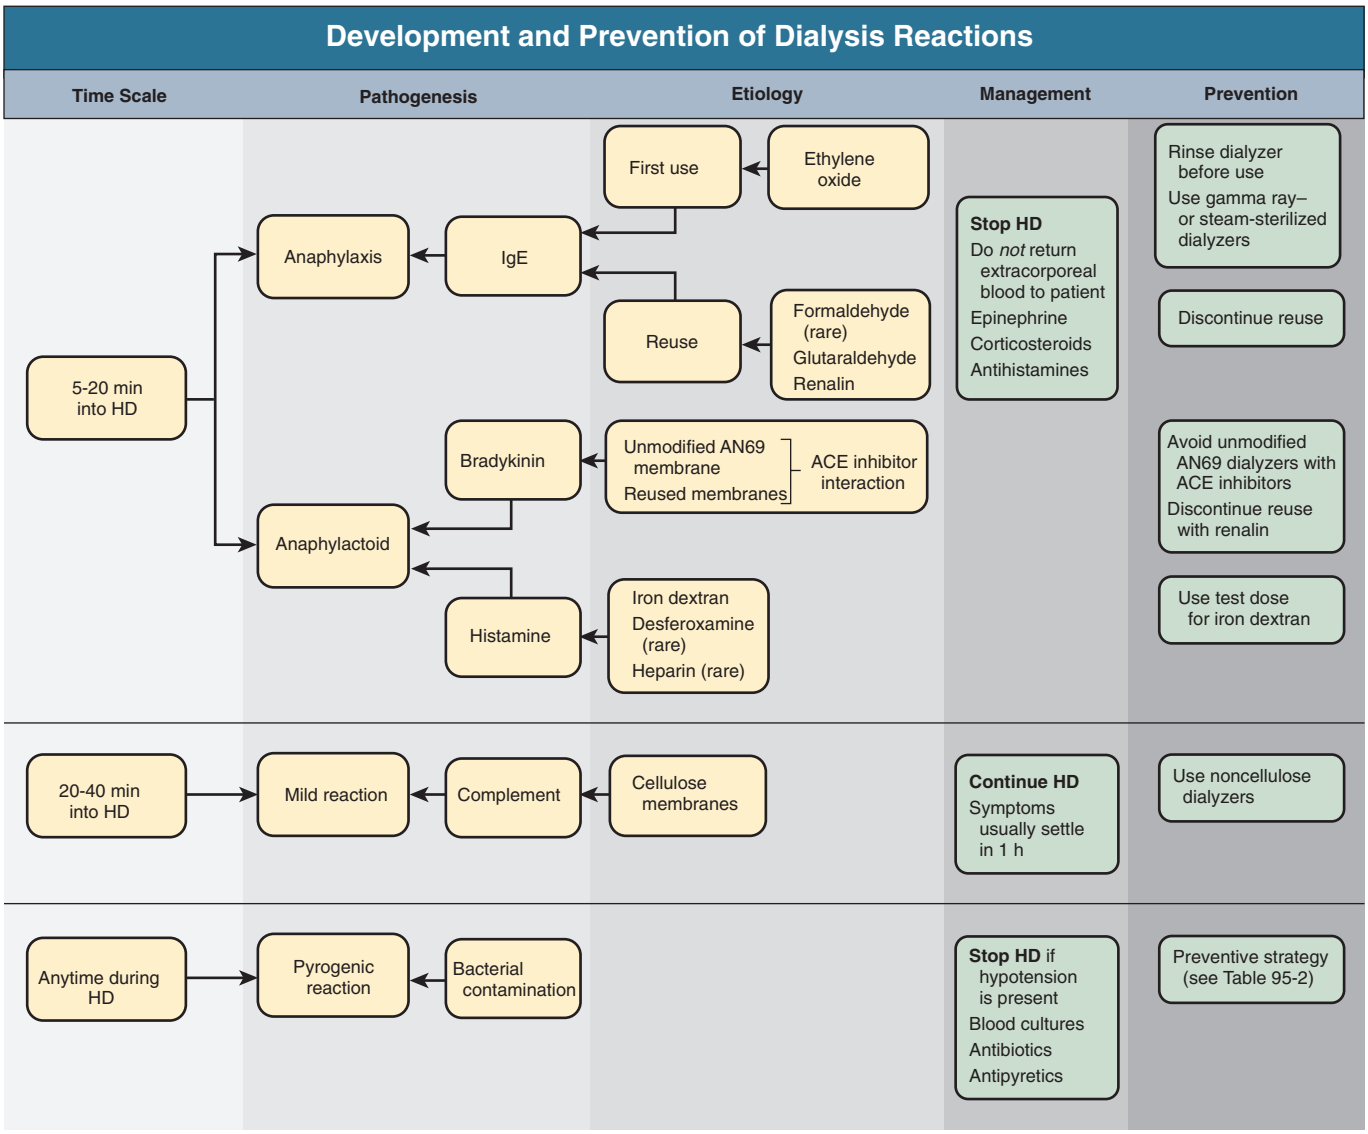

Fig. 95.5 Development and prevention of dialysis reactions. *ACE,* Angiotensin-converting enzyme; *HD,* hemodialysis.

result from the direct release of mediators by host cells. Symptoms usually develop within the first 5 minutes of dialysis, although a delay of up to 20 minutes is possible. Symptoms vary from subtle to severe and include burning or heat throughout the body or at the access site; dyspnea, chest tightness, and angioedema or laryngeal edema; paresthesias involving the fingers, toes, lips, or tongue; rhinorrhea, lacrimation, sneezing, or coughing; skin flushing; pruritus; nausea or vomiting; abdominal cramps; and diarrhea. Predisposing factors include a history of atopy, elevated total serum IgE, eosinophilia, and the use of ACE inhibitors. The etiology of dialysis reactions is diverse, and a thorough investigation is required.

First-Use Reactions

The majority of first-use reactions were ascribed to the manufacturer's dialyzer sterilant ethylene oxide (ETO), which is now rarely used. The potting compound that anchors the hollow fibers in the dialyzer housing acts as a reservoir for ETO and may impede its washout from the dialyzer, leading to sensitization. When it is conjugated to human serum albumin (HSA), ETO acts as an allergen. By use of a radioallergosorbent test (RAST), specific IgE antibodies against ETO-HSA are detected in two thirds of patients with such reactions. However, 10% of patients with no history of dialysis reactions have a positive RAST result.

Reuse Reactions

Because most residual ETO is washed out of the dialyzer during first use, reuse reactions are likely to be a result of the disinfectants used for dialyzer reprocessing. These agents include formaldehyde, glutaraldehyde, and peracetic acid–hydrogen peroxide (Renalin); in allergic patients, specific IgE antibodies against formaldehyde are occasionally detectable.

Bradykinin-Mediated Reactions

In the early 1990s, anaphylactoid reactions appeared in Europe among patients dialyzed with modified acrylonitrile (AN69) dialyzers who were also taking ACE inhibitors. Investigation of these incidents revealed that binding of factor XII to this sulfonate-containing, negatively charged membrane resulted in the formation of kallikrein and release of bradykinin, which in turn led to the production of prostaglandin and

histamine, with subsequent vasodilation and increased vascular permeability. ACE inactivates bradykinin, and therefore ACE inhibitors can prolong the biologic activities of bradykinin.[43] These membranes have since been chemically modified, thereby reducing this risk.

Anaphylactoid reactions also have been observed in patients taking ACE inhibitors who were dialyzed with membranes that had been reprocessed with Renalin; these reactions abated once reprocessing was discontinued, despite continued use of ACE inhibitors. It has been speculated that Renalin may oxidize cysteine-containing proteins that are adsorbed on the dialyzer membrane, leading to the formation of cysteine sulfonate and contact activation of factor XII.

Drug-Induced Reactions

Anaphylactoid reactions to parenteral iron dextran occur in 0.6% to 1% of HD patients. Significantly higher rates of anaphylactoid reactions have been observed among users of higher molecular weight compared with lower molecular weight iron dextran. In vitro, dextran produces a dose-dependent basophil histamine release. The National Kidney Foundation's Clinical Practice Guidelines recommend that resuscitative medication and personnel trained to evaluate and resuscitate anaphylaxis should be available whenever a dose of iron dextran is administered.[44] Alternative preparations of iron provoke fewer anaphylactoid reactions than iron dextran and are discussed further in Chapter 82.

Hypersensitivity to heparin formulations is rare and usually responds to substitution of beef with pork heparin or vice versa. An alternative is to substitute low molecular weight heparin. A nationwide outbreak in the United States of severe adverse reactions in HD patients was attributed to vials of heparin contaminated with oversulfated chondroitin sulfate.[45]

Treatment and Prevention

Treatment of anaphylactic and anaphylactoid reaction requires the immediate cessation of HD without returning the extracorporeal blood to the patient. Epinephrine, antihistamines, corticosteroids, and respiratory support should be provided, if needed. Specific preventive measures include rinsing the dialyzer immediately before first use, substituting ETO with dialyzers sterilized with gamma ray or steam, avoiding unmodified AN69 membranes in patients taking ACE inhibitors and discontinuing reprocessing procedures in selected patients.

Mild Reactions

Mild reactions particularly occur 20 to 40 minutes after initiation of dialysis, predominantly with first use of unsubstituted cellulosic dialyzers, and consist of chest or back pain. Dialysis can be continued because symptoms usually abate after the first hour, suggesting a relation to the degree of complement activation. Indeed, these reactions decrease with the use of substituted and reprocessed unsubstituted cellulose membranes. Administration of oxygen and analgesics is usually sufficient. Preventive measures include automated cleansing of new dialyzers and use of noncellulose dialyzers.

Fever and Pyrogenic Reactions

Fever during dialysis can be due to infection or excessive microbial contamination of the dialysis apparatus. The latter, known as *pyrogenic reaction,* is usually a diagnosis of exclusion. Several factors during dialysis place patients at risk for exposure to bacterial products, including contaminated water or bicarbonate dialysate, improperly sterilized dialyzers, use of central venous dialysis catheters, and cannulation of infected AVFs or AVGs.[46] Soluble bacterial products such as endotoxin fragments can diffuse across the dialyzer into the blood, resulting in cytokine production and, consequently, pyrogenic reactions. Whereas high-flux dialyzers have larger pores that may potentially allow larger fragments to cross from the dialysate to the patient, the synthetic high-flux membranes have a thick wall that tends to be very adsorptive for endotoxin fragments, thus mostly preventing this phenomenon.[47] Similarly, although HDF potentially has a higher risk for pyrogenic reactions because of the infusion of 10 to 25 liters of dialysate, the customary use of two serial ultrafilters in the dialysate circuit make this an uncommon occurrence. Strategies for the prevention of pyrogenic reactions are summarized in Table 95.2.[48]

When fever develops during HD, the first step is to address hemodynamic stability. If the patient is hypotensive, administration of fluids, cessation of ultrafiltration, and discontinuation of dialysis are often required, and refractory hypotension suggesting severe sepsis should trigger hospitalization.

The next step is to identify a potential source of infection. The dialysis vascular access should be carefully examined. If an infectious

TABLE 95.2 Strategies to Prevent Bacterial Contamination

Type of Fluid	Microbial Count (cfu/ml)	Endotoxin (EU)
Water products	<100	<0.25
Dialysate	<100	<0.50
Ultrapure dialysate (e.g., for HDF)	<0.1	<0.03
Reprocessed dialyzers	No growth	—
Use appropriate germicide: 4% formaldehyde* 1% formaldehyde heated to 40° C*,† Glutaraldehyde† Hydrogen peroxide–peracetic acid mixture (Renalin)*,† Heat sterilization (105° C for 20 hours) for reprocessing of polysulfone membranes†		
Wash and rinse the vascular access arm with soap and water.		
Before cannulation, inspect vascular access for local signs of inflammation.		
Scrub the skin with povidone-iodine or chlorhexidine and allow to dry for 5 minutes before cannulation.		
Record temperature before and after dialysis.		
When central delivery system is used: Clean and disinfect connecting pipes regularly. Remove residual bacteria or endotoxin by additional filtration.		
When single-patient proportioning dialysis machine is used: Freshly prepare bicarbonate dialysate on a daily basis. Discard unused solutions at the end of each day. Rinse and disinfect containers with fluids that meet AAMI standards. Air dry containers before dialysate preparation.		
Follow manufacturer's guidelines for use of preservative-free medications.		

From reference 48.
*A minimum of 11- or 24-hour exposure to peracetic acid or formaldehyde is required, respectively.
†These germicides are equivalent or superior to 4% formaldehyde. The action level for the total viable microbial count in the product water and conventional dialysate is 50 cfu/ml, and the action level for the endotoxin concentration is 50% of the relevant standard. Strict adherence to aami/iso 11663:2014 standards.

source related to non–vascular access is identified, specific therapy should be instituted on the basis of the working diagnosis. Nontunneled and tunneled central venous dialysis catheters always should be suspected as a likely cause of infection, even in the absence of local signs of infection such as erythema and exit site drainage. Catheters with evident signs of infection at the insertion site should be removed and the tip cultured.

Antipyretics should be administered, and blood culture specimens should be obtained before initiation of antibiotic therapy; this should include cultures from temporary access devices. The initial choice of antibiotics should include gram-positive and gram-negative bacterial coverage, and the regimen should be adjusted according to the culture results and local guidelines.

In the presence of a dialysis catheter, paired blood culture specimens should be obtained from a peripheral vein and the catheter lumen, and a broad-spectrum antibiotic regimen should be initiated. Catheter lock solutions that use either antibiotics or sterilants such as calcium citrate have been demonstrated to significantly reduce the rate of catheter-related bacteremia.[49,50] In the case of catheter-related bacteremia, removal of the dialysis catheter is strongly indicated, as is transesophageal echocardiography to rule out endocarditis, particularly with staphylococcal sepsis. A regimen of at least 14 days of antibiotic therapy after removal of the catheter is also recommended.

An outbreak of bacteremia among several dialysis patients involving a similar organism should prompt a thorough search for bacterial contaminants in the dialysis equipment.[46] Attention should also be paid to multiuse vials that are punctured several times, such as vials of EPO, which has been linked to an outbreak of bloodstream infection. Single-use vials are preferred, when available.

Investigation of a Dialysis Pyrogenic Outbreak

Although causes of dialysis outbreaks are usually easily identifiable, often the reason for the outbreak is less clear, such as water contamination with bacterial toxins,[51] medication chemical impurities,[45] bacterial contaminants, systemic embolization of degraded dialyzer membrane polymer after prolonged or improper storage,[52] and hemolysis from faulty blood tube sets.[53] Investigation of a dialysis outbreak requires a methodical approach, including a critical review of the medical records and the various steps of the dialysis procedure (Box 95.2).

BOX 95.2 Investigation of Dialysis Pyrogenic Outbreak

Review of Medical Records

- Demographics
- Underlying diseases
- Dialysis schedule
- Dialysis machine
- Dialyzer used
  - Membrane
  - Type
  - Manufacturer's sterilization method
  - Reuse germicide (if applicable)
- Medication history
- Signs and symptoms of illness
- Laboratory tests
- Interview of medical staff caring for patient during incident

Procedural Review

- Water treatment systems and practices
  - Disinfection
  - Distribution
  - Storage procedures
- Disinfection and maintenance of reprocessed dialyzers
- Disinfection and maintenance of dialysis machines
- Review of patient's dialysis sessions

MISCELLANEOUS COMPLICATIONS

Postdialysis Fatigue

An ill-defined "washed out" feeling or malaise during or after HD is a common nonspecific symptom that is observed in about one third of patients and has multifactorial origins. Reduced cardiac output, peripheral vascular disease, depression, poor conditioning, postdialysis hypotension, hypokalemia or hypoglycemia, mild uremic encephalopathy, myopathy caused by carnitine deficiency, and membrane bioincompatibility through cytokine production have all been incriminated. The use of bicarbonate dialysate with or without additional glucose (5 to 10 mmol/l) and L-carnitine supplementation (20 mg/kg/day) have been shown to improve postdialysis well-being. A trial of thrice-weekly L-carnitine at 20 mg/kg for 6 months resulted in a marked decrease in C-reactive protein level, which was paralleled by an increase in body mass index.[54] To date, however, there is no conclusive evidence that L-carnitine improves quality of life in unselected dialysis patients.[44]

Compared with thrice-weekly HD, more frequent dialysis, including short daily and nocturnal HD, has been associated with a marked shortening in the time it takes for patients to recover from a dialysis session and to resume their daily activities, which is a surrogate for postdialysis fatigue.

Pruritus

Pruritus is common and can be a very troubling symptom. The cause is often multifactorial, including xerosis, hyperparathyroidism, neuropathy, derangements in the immune system, and inadequate dialysis. In many patients, pruritus is more severe during or after dialysis and may be a manifestation of an allergic reaction to heparin, ETO, formaldehyde, acetate, or the dialysis membrane. In this subgroup of patients, use of gamma ray–sterilized dialyzers, discontinuation of formaldehyde use, switching to bicarbonate dialysate, and use of low-dialysate calcium and magnesium might result in cessation of itching. Eczematous reactions to antiseptic solutions, rubber gloves or puncture needle components, puncture needles, or adhesive tapes used to secure dialysis needles also should be considered.[55]

The management of uremic pruritus is discussed further in Chapter 87 (see Fig. 88.3).

Genitourinary Problems

Priapism occurs in less than 0.5% of male HD patients. It is not related to sexual activity and occurs while the patient is on dialysis. The patient is usually awakened from sleep by a painful erection. Although the majority of cases are idiopathic, secondary causes include hyperviscosity; high hematocrit from androgen or epoetin therapy; dialysis-induced hypoxemia and hypovolemia from excessive ultrafiltration, particularly in men with sickle cell disease; and use of α-blockers, such as prazosin, or an antidepressant, such as trazodone.[56]

Urgent urologic referral is mandatory. Acute treatment consists of corporal aspiration and irrigation. Although surgical bypass provides venous egress from the corpora cavernosa, secondary impotence commonly develops but may be effectively treated by a penile prosthesis.

An unusual case of testicular angina occurring during excessive ultrafiltration has been described. The patient was diabetic and had extensive vascular calcification evident on imaging. He eventually required orchidectomy.[57] A similar mechanism for this type of "angina" also has been described for the mesentery and right colon.

Hearing and Visual Loss

Intradialytic hearing loss may be caused by bleeding in the inner ear as a consequence of anticoagulation or cochlear hair cell injury from edema.

Intradialytic visual loss is rare but can be caused by central retinal vein occlusion, retinal hemorrhage secondary to heparin exposure in diabetics, precipitation of acute glaucoma, ischemic optic neuropathy secondary to hypotension, or Purtscher-like retinopathy secondary to leukocyte embolization.

SELF-ASSESSMENT QUESTIONS

1. The most common cause of intradialytic hypotension is:
   A. New-onset sepsis
   B. Cardiac ischemia
   C. Intravascular volume depletion
   D. Altered thermal balance
   E. Use of antihypertensive medications
2. The most appropriate preventive strategy to avoid intradialytic hypotension is:
   A. Isothermic dialysis
   B. Sodium modeling
   C. Hematocrit-controlled volume removal
   D. Avoidance of excessive interdialytic weight gains
   E. Use of agents such as midodrine
3. Intradialytic hemolysis may be caused by all of the following *except:*
   A. Copper in the dialysate
   B. Residual formaldehyde
   C. Chloramine spillover
   D. Faulty dialysis pumps
   E. Heparin exposure
4. Severe dialyzer reactions may occur as a result of exposure to:
   A. New synthetic dialysis membranes
   B. Potting compound
   C. Sterilant effects related to steam or gamma radiation
   D. Angiotensin-converting enzyme inhibitors
   E. Peracetic acid
5. Management options for intradialytic cramps include:
   A. Intravenous hypertonic saline
   B. Oral magnesium salts
   C. Oral carnitine supplementation
   D. Intravenous 50% dextrose
   E. All of the above

96

Peritoneal Dialysis: Principles, Techniques, and Adequacy

Bengt Rippe[†]

Peritoneal dialysis (PD) is used by approximately 200,000 end-stage renal disease (ESRD) patients worldwide, representing approximately 7% of the total dialysis population.[1] In PD the peritoneal cavity is used as a container for 2 to 2.5 liters of sterile, usually glucose-containing, dialysis fluid, which is exchanged four to five times daily by permanently indwelling catheter. The dialysis fluid is provided in plastic bags. The peritoneal membrane, via the peritoneal capillaries, acts as an endogenous dialyzing membrane. Across this membrane, waste products diffuse into the dialysate and excess body fluid is removed by osmosis induced by the glucose or another osmotic agent in the dialysis fluid (ultrafiltration [UF]). PD is usually provided 24 h/day and 7 days/wk in the form of continuous ambulatory peritoneal dialysis (CAPD). Approximately one third of the patients in most centers receive automated peritoneal dialysis (APD; sometimes also referred to as continuous cycling peritoneal dialysis [CCPD]), in which nightly exchanges are delivered via an automatic PD cycler. The use of PD as a modality for ESRD treatment varies widely among countries, mostly because of nonmedical factors such as the reimbursement policy.

ADVANTAGES AND LIMITATIONS OF PERITONEAL DIALYSIS

If patients or their caregivers are competent to undertake PD, the only absolute contraindications are large diaphragmatic defects, excessive peritoneal adhesions, surgically uncorrectable abdominal hernias, or acute ischemic or infectious bowel disease. These and other relative contraindications are discussed further in Chapter 97. PD is best used for patients with some residual renal function, although anuric patients may do very well. Most patients who start PD will eventually, after several years, transfer to other modalities of renal replacement therapy (RRT), such as hemodialysis (HD), if adequacy cannot be maintained or as a result of other complications, such as recurrent peritonitis or exit site or catheter problems. Only rarely do HD patients transfer to PD, most commonly because of failure to maintain adequate vascular access.

PD offers several advantages over HD, at least during the first 2 or 3 years of treatment. First, PD represents a slow, continuous, physiologic mode of removal of small solutes and excess body water, associated with relatively stable blood chemistry and body hydration status. Second, there is no need for vascular access. The absence of vascular access and the absence of the blood-membrane contact of HD make catabolic stimuli less prominent in PD than in HD. Furthermore, residual renal function is somewhat better preserved in PD patients than in HD patients. Because of its continuous nature, PD provides a standardized weekly *Kt/V* similar to that of thrice-weekly HD despite less efficient small-solute clearance.

PD also has potential disadvantages, including increased workload for patients and families, an increased risk for dyslipidemia, a relatively high glucose load when glucose-based solutions are used, and a tendency to mild chronic volume overload. In addition, not all patients are able to safely perform PD, although this can be mitigated by using professional or nonprofessional dialysis assistants. The issue of dialysis modality selection is discussed in Chapter 90.

PD is a home-based therapy, and most patients are trained to do the exchanges themselves. In general, home dialysis patients have a better quality of life than those on other types of dialysis. The number of hospital visits is reduced, and the ability to travel is increased. Furthermore, several studies have shown a lower incidence and severity of delayed graft function in PD patients after transplantation.[2] In children, PD (usually APD) is the preferred dialysis modality because it is noninvasive and socially acceptable, reducing hospital visits and allowing the child to attend school. Advocates of PD often recommend that RRT should ideally begin with PD according to the patient's choice and then proceed, as required when residual renal function declines, to HD or transplantation. PD should thus be regarded as part of an integrated RRT program, together with HD and transplantation.[3]

PRINCIPLES OF PERITONEAL DIALYSIS

Three-Pore Model

The major principles governing solute and fluid transport across the peritoneal membrane are diffusion, driven by concentration gradients, and convection (filtration or UF), driven by osmotic or hydrostatic pressure gradients. The capillary wall and the interstitium together serve to separate the plasma in the peritoneal capillaries from the fluid in the peritoneal cavity. For the transport of fluid (UF) and large solutes, the capillary wall is by far the dominating transport barrier. However, for small-solute diffusion the interstitium accounts for approximately one third of the transport (diffusion) resistance; the mesothelium lining the peritoneal cavity is of much less significance. The permeability of the capillary wall can be described by a three-pore model of membrane transport (Fig. 96.1).[4] In the capillary wall the major route for small-solute and fluid exchange between the plasma and the peritoneal cavity is the space between individual endothelial cells, the interendothelial clefts. The functional radius of the permeable pathways in these clefts, denoted *small pores,* is 40 to 50 Å, slightly larger than the radius of albumin (36 Å). The size of these pores markedly impedes the transit of albumin and completely prevents the passage of larger molecules (e.g., immunoglobulins and α_2-macroglobulin). However, larger proteins can transit via very rare large pores (radius ~250 Å) in capillaries and postcapillary venules. The large pores constitute only 0.01% of the total

[†]Deceased.

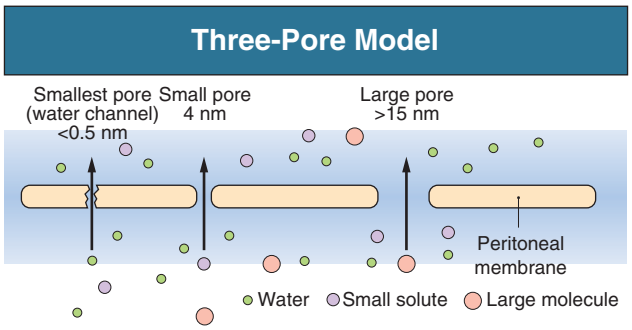

Fig. 96.1 Three-pore model. The small pores (4 nm) represent the major pathway across the peritoneum through which small solutes move by diffusion and water by convection driven by hydrostatic, colloid osmotic, and crystalloid osmotic pressure differences. Across large pores (>15 nm), macromolecules move out slowly by convection from plasma to the peritoneal cavity. The smallest pores (<0.5 nm) are represented by aquaporins permeable to water, but impermeable to solutes. Water moves here exclusively by crystalloid osmotic pressure.

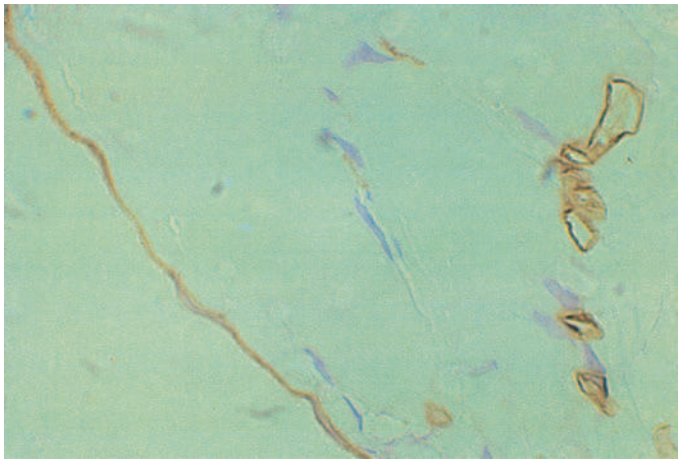

Fig. 96.2 Light microscopic section of a peritoneal membrane with capillaries and venules *(to the right)* in an "amorphous" interstitium. The peritoneum is lined by a thin layer of mesothelium *(to the left)*. Capillaries and venules, as well as the mesothelium, are immunocytochemically stained for aquaporin-1 (AQP1) *(brownish color)*. (From reference 51.)

number of capillary pores, and the transport across them occurs by hydrostatic pressure–driven unidirectional filtration from the plasma to the peritoneal cavity. In addition, the capillary wall has a high permeability to osmotic water transport via aquaporin-1 (AQP1) channels in the endothelial cell membranes (Fig. 96.2).[5]

Fluid Kinetics

Under normal (non-PD) conditions, most transport occurs via the small pores. Only 2% of peritoneal water transport occurs via AQP1. In PD, fluid removal is markedly enhanced by infusion of a hyperosmolar dialysate into the peritoneal cavity. The type of osmotic agent used markedly affects the mechanism of osmosis. Glucose will induce fluid flow through both AQP1 (~45%) and small pores (~55%), whereas large molecules, such as polyglucose (icodextrin) will remove fluid mainly via small pores (~90%). Thus glucose osmosis will result in a rapid dilution of the peritoneal dialysate, as reflected by a fall in sodium concentration (sodium sieving) during the first 2 hours of the dialysate dwell, caused by relatively large transport via the water-only AQP1 channels; this tends to correct later as diffusion across the small pores eventually increases the sodium concentration to that in the plasma.

Glucose is usually available at three concentrations that vary somewhat among manufacturers: low (1.36% or 1.5%), intermediate (2.27% or 2.5%), and high (3.86% or 4.5%). Fig. 96.3A demonstrates the intraperitoneal fluid kinetics, computer simulated using the three-pore model, over 12 hours of dwell time with these three solutions. Glucose is an intermediate-size osmolyte with a low osmotic efficiency (osmotic reflection coefficient [σ] = 0.03) across small pores, whereas glucose is 100% efficient as an osmotic agent across AQP1 (σ = 1). For that reason, glucose will markedly (30-fold) boost the transport of fluid through AQPs and thus redistribute fluid transport away from the small pores toward AQP1, resulting in significant sodium sieving. For example, for 3.86% glucose in the PD solution, the dialysate Na^+ concentration will drop from 132 mmol/l to 123 mmol/l in 60 to 100 minutes, which later increases toward serum Na^+ concentration (see Fig. 96.3B). On the other hand, icodextrin, with an average molecular weight of 17 kDa, has a high osmotic efficiency (σ ~0.5) across small pores and in relative terms is rather inefficient across AQPs. Hence, during icodextrin-induced osmosis only a very minor fraction of the UF will occur through AQP1, producing insignificant sodium sieving (see Fig. 96.4B).

In addition to the size of the osmotic agent, the degree of sodium sieving depends on the presence and quantity of AQP1, total rate of net UF (which is mainly determined by the glucose concentration), and diffusion capacity of Na^+. A high rate of small-solute transport (and thereby of sodium diffusion) in fast transporters will manifest as rapid equilibration of small solutes (creatinine and glucose) in the peritoneal equilibration test (PET; see later) and will also reduce sodium sieving.

In the absence of an osmotic agent in the PD fluid, the dialysate would be reabsorbed into the plasma within a few hours, mainly driven by the difference in colloid osmotic pressure between plasma and the peritoneum. This absorption will to a major extent occur via small pores, whereas approximately 30% of the peritoneal fluid will be removed by lymphatic absorption. The partial fluid flows in the peritoneal membrane modeled across different fluid conductive pathways in the three-pore model (for 3.86% glucose) are shown in Fig. 96.5. It is the presence of relatively high concentrations of glucose in the peritoneal fluid that prevents the reabsorption of fluid into the plasma during the first few hours of the dwell.

Patients who have a high rate of sodium diffusion (fast transporters) also have rapid transport of glucose out of the peritoneal cavity. Therefore the glucose gradient favoring UF dissipates more rapidly, and it is harder to achieve effective fluid removal compared with "slow transporters." In fast transporters the maximum UF volume is reduced and UF occurs earlier. There is usually also a more rapid reabsorption of fluid in the late phase of the dwell. The mechanism of fluid loss from the peritoneum is controversial, because some authors claim that the peritoneal fluid loss occurring in the late phase of the PD dwell is dominated by lymphatic absorption.[6]

Effective Peritoneal Surface Area

The functional surface area of the peritoneum reflects the effective surface area of the peritoneal capillaries.[7] The transport of small solutes, such as urea, creatinine, and glucose, is partly limited by the degree of perfusion of these capillaries—the "effective" peritoneal membrane blood flow. Furthermore, as mentioned earlier, some of the diffusion resistance for the smallest solutes (urea and creatinine) is located in the interstitium. The number of effectively perfused capillaries is increased

by arteriolar vasodilation and reduced by vasoconstriction. These alterations often occur without large changes in the fluid permeability (hydraulic conductance [L_pS]) of the peritoneum. Thus, during vasodilation or vasoconstriction, there is usually a dissociation between changes in the permeability–surface area product (PS) for small solutes and in the L_pS of the membrane. Vasodilation, with recruitment of capillary surface area, occurs early in the dwell when glucose is used as the osmotic agent, causing early, transient increases in PS.[8]

Peritonitis is also associated with marked vasodilation, again leading to increases in small-solute PS, in the absence of large changes in L_pS, during the first 60 to 100 minutes of the dwell. However, in some patients with peritonitis, an increase in L_pS will result in relative increased fluid transport across the small pores. Furthermore, there is usually an opening of large pores in the capillaries (and postcapillary venules), resulting in enhanced leakage of macromolecules (e.g., albumin and immunoglobulins) from plasma to peritoneum. Peritonitis may thus result in relative difficulty in removing fluid (because of rapid dissipation of intraperitoneal glucose), a reduced sodium sieving (because of the reduced UF and increased Na^+ diffusion), and a markedly increased leakage of proteins to the dialysate.

The contact area between the dialysate and the peritoneal tissue varies as a result of posture and fill volume. Adult patients usually tolerate 2 to 2.5 liters of instilled volume, with larger volumes typically possible at night when the patient is supine. An intraperitoneal hydrostatic pressure (IPP) of less than 18 cm H_2O (supine position) is usually tolerated.[9] At higher pressures (>18 cm H_2O) the patient usually feels some discomfort. At intraperitoneal volumes of less than 2 liters there is a reduction in small-solute PS, whereas PS is only moderately increased at high fill volumes. Overall, an increased fill volume implies a more efficient exchange with regard to both small-solute exchange and UF, the latter being much more pronounced for hypertonic solutions.[10] For a long time it was thought that increased fill volumes would directly

affect peritoneal fluid reabsorption by the hydrostatic pressure effect (increases in IPP). However, because 80% of any increase in IPP is transmitted via vein compression back to the capillaries, the actual changes in the transcapillary hydrostatic pressure gradient, which governs UF, will be rather small.[11] Thus the impact of IPP on fluid absorption is moderate.[12]

PERITONEAL ACCESS

The key to successful chronic PD is a safe and permanent access to the peritoneal cavity (Fig. 96.6). Catheter-related complications cause significant morbidity, sometimes forcing the removal of the catheter. Catheter-related problems are a cause of permanent transfer to HD in up to 20% of all patients. Most catheters are derived from that originally devised by Tenckhoff and Schechter.[13] The Tenckhoff catheter is a Silastic tube with side holes along its intraperitoneal portion. There are usually one or two Dacron cuffs, allowing tissue ingrowth, which secures the catheter in place and prevents pericatheter leakage and infection. The Tenckhoff catheter is straight, having one cuff lying on the peritoneum with the catheter tip pointing in the caudal direction; the outer cuff is close to the skin exit. Several centimeters of the catheter is thus located transcutaneously. Intraperitoneal and transcutaneous catheter modifications continue to appear, indicating that no single design is perfect (Fig. 96.7). Although several studies report less frequent catheter drainage failures with use of the arcuate "swan neck" catheter (see Fig. 96.7) compared with straight catheters, there is no hard evidence that any of the modified catheters on the market are actually superior to the original (one- or two-cuff) Tenckhoff catheter.[14]

Ideally, catheters should be inserted in the operating room under sterile conditions by an experienced and appropriately trained operator. Presurgical assessment for the presence of herniation or any weakness of the abdominal wall is essential. If present, it may be possible to correct these at the time of catheter insertion. Before the operation, eradication of nasal carriage of *Staphylococcus aureus* with locally applied antibacterial agents (such as mupirocin) significantly reduces exit site infection rates. A single preoperative intravenous dose of a first- or second-generation cephalosporin is also recommended. To avoid development of vancomycin-resistant enterococcus, vancomycin should not be used as a prophylactic agent. Several placement techniques have been described and practiced: surgical mini-laparotomy and dissection,

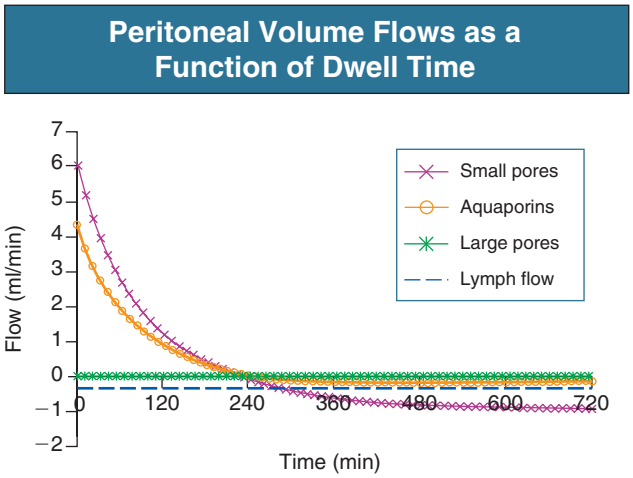

Fig. 96.5 Peritoneal volume flows as a function of dwell time. Peritoneal volume flows as a function of dwell time for 3.86% glucose partitioned among aquaporins, small pores, large pores, and lymphatic absorption. The small-pore volume flow is initially approximately 60% of total volume flow and becomes negative after peak time (220 min). The aquaporin-mediated water flow becomes slightly negative after approximately 250 min. The large-pore volume flow is negligible and remains constant throughout the dwell, as does lymphatic absorption (0.3 ml/min). (Modified from reference 52.)

blind placement using the Tenckhoff trocar, blind placement using a guidewire (Seldinger technique), mini-trocar peritoneoscopy placement, and laparoscopy. These techniques are discussed further in Chapter 92.

TECHNIQUES OF PERITONEAL DIALYSIS

In CAPD, 2 to 2.5 liters of dialysis fluid is instilled into the peritoneal cavity four or five times daily. In 4 to 5 hours there is 95% equilibration of urea and approximately 65% equilibration of creatinine, whereas the glucose gradient has dissipated to approximately 40% of the initial value. For glucose as an osmotic agent, 4 to 5 hours is a suitable dwell time. For night dwell exchanges, longer dwell times can be accepted (8 to 10 hours). Furthermore, there is room for individual exchange schedules that can be adjusted to suit individual patient convenience. Dwell times shorter than 4 to 5 hours can be performed with use of a machine (cycler). This technique can be used to maintain adequate dialysis when

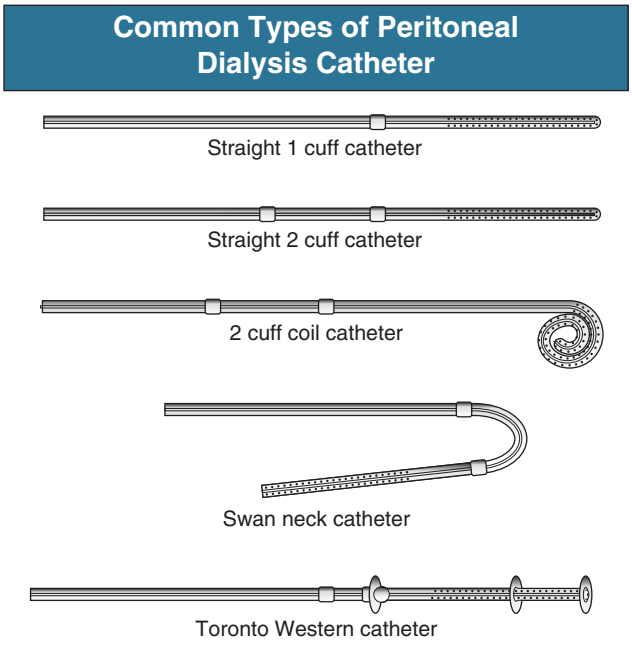

Fig. 96.7 Common types of peritoneal dialysis catheter.

more frequent, lower volume exchanges are needed—for example, to minimize leakage in conjunction with catheter insertion, hernia repair, or abdominal operations. Rapid exchanges also may be required during treatment for peritonitis or in patients with fluid overload when the patient's hydration status needs to be corrected rapidly.

Today, double-bag systems (so-called Y systems) are in general use according to the principle "flush before fill." The double-bag system contains the unused dialysis fluid connected to an empty sterile drain bag via a Y-set tubing system. After the patient has connected the system and flushed the connection (for 2 to 3 seconds), a frangible (breakable) pin to the drain bag is opened, and the peritoneal cavity is drained over 10 to 15 minutes to fill the drain bag. Then this bag is clamped, and the fresh bag opened, to fill the peritoneal cavity over another 10 to 15 minutes. The time for exchange (instillation and drainage), if the catheter is in good order, should not exceed a total of 30 minutes. Usually the first 1.6 to 1.8 liters will drain rapidly (at ≥200 ml/min), whereas the last 200 to 300 ml will drain much more slowly. The breakpoint between the rapid and the slow phase may vary markedly from individual to individual.

APD is usually performed with use of a cycler overnight (8 to 10 hours), during which large volumes (10 to 20 liters) can be exchanged. During daytime the APD patient usually has a so-called wet day—that is, a long dwell, usually with icodextrin as the osmotic agent in the dialysis fluid. Some patients with nightly APD perform one daily exchange so that there are two long (6 to 8 hours) daily dwells. Most cyclers can be programmed to vary inflow volume, inflow time, dwell time, and drain time. Cyclers usually warm the fluid before inflow, and they also monitor outflow volume and the excess drainage (UF volume). Current APD machines have alarms for inflow failure, overheating, and poor drainage. Some cyclers interrupt drainage at the breakpoint between the fast and slow phases to make the exchange more efficient. Another way to accelerate exchanges is to allow a considerable sump volume in the peritoneal cavity by not letting all the fluid drain; subsequent inflow volumes are proportionally reduced, and after multiple cycles complete drainage occurs. This technique is called *tidal peritoneal dialysis* (TPD).

The exchange volume should be adjusted according to the patient's size. Adult patients weighing less than 60 kg should start with 1.5-liter

bags. The average patient (60 to 80 kg) should receive 2-liter exchanges, and for patients weighing more than 80 kg, 2.5 liters should be used. If pressure monitoring systems are available, the IPP may inform the choice of exchange volume. In the supine position, most patients have an IPP of 12 cm H_2O.

PERITONEAL DIALYSIS FLUIDS

The majority of PD fluids used today have the composition of a lactate-buffered, balanced salt solution devoid of potassium, with glucose (1.36% or 1.5%, 2.27% or 2.5%, 3.86% or 4.5%) as the osmotic agent. The K^+ concentration in PD fluids is zero to aid control of potassium balance.

Lactate is used as a buffer instead of bicarbonate, because bicarbonate and Ca^{2+} may precipitate (to form calcium carbonate) during storage. With the advent of newer multichambered PD delivery systems, it is possible to replace lactate with bicarbonate and make a number of other solution modifications that previously were not feasible. However, the higher cost of the newer more physiologic fluid formulations should be borne in mind. For example, in the United Kingdom, icodextrin solution costs approximately 80% more per unit volume than glucose-based solutions.

Electrolyte Concentration

In current PD fluids the concentrations of Na^+, Cl^-, Ca^{2+}, and Mg^{2+} are selected to be close to the serum concentration. The removal of these ions across the peritoneum is therefore a result of the low diffusion gradient, more or less completely dependent on convection. For every deciliter of fluid removed in a 4-hour dwell, approximately 10 mmol of Na^+[15] and 0.1 mmol of Ca^{2+} are removed, provided that serum Na^+ and Ca^{2+} are within the reference ranges.[11]

The frequent use of calcium-containing phosphate binders requires an understanding of Ca^{2+} kinetics for various types of dialysis fluids to avoid hypercalcemia. The calcium concentration of current PD solutions is usually 1.25 to 1.75 mmol/l. However, because Ca^{2+}, like Na^+ and Mg^{2+}, has a UF-dominated transport, 1.25 mmol/l may be considered appropriate only for 1.36% glucose, to achieve a zero (neutral) peritoneal calcium removal. For example, UF-driven Ca^{2+} loss will occur during a 4-hour dwell with 3.86% glucose solution. With use of a three-compartment system for the PD bags, it would be possible to adapt the dialysis fluid Ca^{2+} concentration to obtain net zero peritoneal Ca^{2+} transport across the peritoneum, or to reach a preset calcium removal target, for each PD fluid glucose concentration used.[16] However, in currently available PD solutions, Ca^{2+} concentration is not variable as a function of glucose concentration; therefore 1.25 mmol/l Ca^{2+} is recommended when patients use calcium-containing phosphate binders. It should be noted that net peritoneal calcium removal with 1.25 mmol/l Ca^{2+} level can be achieved only by PD fluids containing 2.27% or 3.86% glucose.

The Mg^{2+} concentration commonly used in current PD solutions is 0.25 to 0.75 mmol/l. For 1.36% glucose, 0.25 mmol/l would be appropriate for zero Mg^{2+} transport during the dwell, whereas for higher dialysis fluid glucose concentrations there will be net Mg^{2+} losses.

Osmotic Agents

Glucose is the principal osmotic agent used for fluid removal (UF) in PD. Alternative commercially available osmotic agents are amino acids and icodextrin. Icodextrin is a polydisperse glucose polymer with an average molecular weight of 17 kDa.[17] However, because of the polydispersity of icodextrin, approximately 70% of the molecules have a molecular weight of 3 kDa or less.[10] Icodextrin is available as a 7.5% solution with essentially the same electrolyte composition as glucose-based dialysates. The osmolality of the glucose polymer solution, unlike that of 1.36% glucose (osmolality 350 mOsm/kg) dialysis fluid, is within the same range, or actually slightly lower, than that of normal serum. The presence of larger molecules in the icodextrin solution, compared with those in glucose-based solutions, improves the osmotic efficiency markedly across the small pores ($\sigma = 0.5$) and also reduces dissipation of the osmotic gradient over time. This yields a sustained UF over 8 to 12 hours (see Fig. 96.4A). Therefore icodextrin is preferable for long dwell exchanges, for example, overnight, and particularly for patients who tend to absorb glucose rapidly (fast transporters, see later). Icodextrin is slowly absorbed into serum and degraded (circulating α-amylase) to oligosaccharides, such as maltose, which may give false-positive results for glucose, leading to erroneous measures of hyperglycemia and inappropriate use of glucose-lowering agents.[18]

Another alternative osmotic agent that is commercially available is a 1.1% amino acid mixture having the same osmolality as 1.36% glucose.[19] According to some studies, regular use of this dialysate may increase certain nutritional indices, although there is also some evidence that amino acid solutions increase acidosis and raise plasma urea. Both icodextrin-based and amino acid–based solutions may be used to reduce the glucose exposure of the peritoneal membrane and total glucose load to the patient.

Until recently, conventional PD solutions have had a low pH and a high concentration of glucose degradation products (GDPs). GDPs are reactive carbonyl compounds that form during heat sterilization and/or storage of glucose-based solutions. GDPs are toxic to a variety of cells in vitro and also potentially toxic in vivo.[20] By the use of multicompartment systems reconstituted immediately before infusion, it has been possible to compose new solutions with much lower concentrations of GDPs and a neutral pH and also to use bicarbonate or bicarbonate-lactate mixtures as buffers.[21-23] Solutions using bicarbonate or bicarbonate-lactate mixtures result in significantly less infusion pain and are as effective as lactate at correcting acidosis, when used at the same total buffer ion concentration.[24] In prospective, randomized studies these fluids have been associated with improvement in dialysate effluent markers of peritoneal membrane integrity, particularly cancer antigen 125 (CA-125), a measure of peritoneal mesothelial cell mass.[21-23] There also have been some indications of improved residual renal function in patients with PD solutions low in GDPs,[23] although this was not confirmed in recent prospective, randomized studies.[25,26] One of those studies, however, the balANZ study,[26] suggested that biocompatible PD solutions may delay the onset of anuria and reduce the incidence of peritonitis compared with conventional solutions.

ASSESSMENTS OF PERITONEAL SOLUTE TRANSPORT AND ULTRAFILTRATION

Small-Solute Removal

The net removal of solutes and fluid during PD, in excess of residual renal excretion, can be measured by evaluating the drained dialysate. For this purpose the concentrations of urea and creatinine are measured in dialysate and plasma. The dialysate-plasma concentration ratios (D/P) of either of these solutes multiplied by the daily drain volume gives the 24-hour clearance. Weekly creatinine and urea clearances are obtained by multiplying these figures by 7. For comparison among patients, creatinine clearance is conventionally standardized to body standard surface area (1.73 m^2), and urea clearance (mostly for comparison with HD) is expressed as Kt/V (where Kt is the weekly clearance and V the volume of distribution of urea). In PD, routine assessment of V is imprecise, in contrast to the situation in HD, in which V can be mathematically derived directly from urea kinetics. V should preferably be determined by direct techniques, such as from the dilution of isotopic

water (total body water); in practice, however, *V* is usually approximated from standard tables using BW and height as anthropometric parameters together with gender.[27] Criticism of the *Kt/V* concept in PD is based on the uncertainty of determining a correct value for *V*. In those who are markedly underweight or overweight the ideal body weight should be used for calculating *V*.[28]

Large-Solute Removal

For more insight into peritoneal transport, the clearance of larger solutes such as β_2-microglobulin, as well as markers for transport across the large pores, such as albumin, immunoglobulins and α_2-macroglobulin, can be measured. Although many centers assess the daily peritoneal removal of total protein and/or albumin, measurements of most other solutes are not made in routine clinical practice.

Ultrafiltration

UF can be assessed with a 24-hour collection. Even if done accurately, there is a considerable dwell-to-dwell and day-to-day variability in UF depending on drainage conditions, posture, and varying levels of residual (sump) intraperitoneal volume. Reasonably accurate estimations of daily UF volume can be obtained by averaging collections of all fluid over a period of several days. In clinical practice, the patient's own daily dialysis records also should be examined with respect to dwell-to-dwell UF volumes and the number of hypertonic bags used per day. For a 3.86% glucose dwell a UF volume less than 400 ml will indicate insufficient UF—that is, ultrafiltration failure (UFF). UF volume also can be determined by the PET, as described later. In a routine 2.27% glucose PET, less than 200 ml of UF in 4 hours signals UFF. More accurate determination of intraperitoneal volume can be achieved as a function of time with use of a marker, such as iodine-125 (^{125}I)–human serum albumin or dextran 70. This is not required in routine clinical practice but as a research tool allows more precise UF volume estimations.

Peritoneal Membrane Function

Peritoneal Equilibration Test

The PET yields approximate estimations of the rate of peritoneal transport of small solutes and of UF capacity.[9] The rate of small-solute transport depends on the effective peritoneal surface area, which is essentially dependent on the number of effectively perfused capillaries available for exchange (and the blood flow). The volume ultrafiltered in 4 hours is a function of the osmotic conductance to glucose (OCg; the peritoneal UF coefficient multiplied by the reflection coefficient for glucose) and the rate of dissipation of the glucose osmotic gradient (the rate of small-solute transport). In general, when the rate of glucose disappearance is high, UF volume is low.

The PET procedure is summarized in Box 96.1. After an overnight dwell (8 to 12 hours) the dialysate fluid is drained, and a 2-liter 2.27% glucose bag is infused for 10 minutes with the patient in the supine position (rolling from side to side every 2 minutes). After 10 minutes—that is, at completion of the infusion—200 ml is drained into the drainage bag and mixed, and a zero time dialysate sample taken. At the end of the 4-hour dwell period, dialysate is drained out and measured. The net volume is noted. Concentrations of glucose and creatinine in the outflow and plasma are measured, as well as the concentration of glucose in the zero sample. The results are expressed as the dialysate-plasma (D/P) solute concentration ratio and as the dialysate glucose at 4 hours–dialysate glucose at time zero (D/D_0) concentration ratio. The higher the D/P ratio for creatinine, the faster the rate of transport for small solutes. According to D/P ratios for creatinine or D/D_0 for glucose, patients can be divided into slow, slow average, fast average, or fast transporters (Fig. 96.8); transport status remains stable in approximately 70% of patients at 1 year and approximately half of patients at 2 years.

BOX 96.1 Peritoneal Equilibration Test

1. Two liters (warm) 2.27% fluid instilled for 10 minutes with the patient supine and rolling from side to side every 2 minutes.
2. Exactly at 10 minutes after start of the infusion, 200 ml is drained into the bag. Draw 5 ml (discard); the next 5 ml taken for creatinine and glucose determination.
3. After 2 hours, new samples collected as in 3.
4. After 4 hours (exactly), collect drainage over 20 minutes. Note total bag weight. Subtract empty bag weight. Take samples (after mixing) for creatinine and glucose.
5. Glucose D/D_0 (the ratio of dialysate glucose at 4 hours and at time zero) and creatinine D/P (the ration of dialysate and serum creatinine at 4 hours) are plotted versus time (as shown in Fig. 96.8). Record the total drain volume.

The night bag (8 to 12 hours) must be 1.36% or 2.27% glucose, drained for 20 minutes with patient sitting.

It should, however, be emphasized that D/P measurements give only an approximate estimation of small-solute transport rate. Additional information can be obtained by variations, including the modified PET (instilling a 3.86% solution and draining after 4 hours),[30] the mini-PET (instilling a 3.86% solution and draining after 1 hour), and the double–mini-PET (instilling sequentially a 1.36% solution and a 3.86% solution, draining each after 1 hour).

Mini–Peritoneal Equilibration Test

In the mini-PET, a 3.86% glucose solution is instilled and completely drained after 1 hour. The Na^+ concentration in the drained dialysate assesses the degree of sodium sieving and hence gives a measure of AQP-mediated ("free") water flow.[31,32] The fraction of "free" water transport can be evaluated in the early phase of the dwell from the 1-hour drained volume minus the 1-hour peritoneal Na^+ clearance (i.e., the drained Na^+ – the instilled Na^+ ÷ the serum Na^+ concentration). In the first hour when Na^+ diffusion is negligible, the peritoneal clearance of sodium (across small pores) will directly reflect the peritoneal small-pore fluid clearance (UF). This value is then subtracted from the total (1-hour) UF volume to yield an estimate of the free (AQP-mediated) water transport. Reductions in this parameter usually occur over time on PD, and marked reductions in free water transport are assumed to reflect peritoneal fibrosis.[33,34]

Double–Mini–Peritoneal Equilibration Test

The OCg can be measured with a double–mini-PET—that is, a 1-hour dwell with 1.36% glucose and also a 1-hour dwell with 3.86% glucose solution. The calculation of OCg is based on the difference in the 1-hour drained volume between the 3.86% and 1.36% glucose solutions.[35] In long-term PD, increases in D/P-creatinine and reductions in D/D_0-glucose are usually seen, eventually resulting in UFF. These changes are often combined with moderate reductions in OCg, the latter perhaps coupled with peritoneal fibrosis.[36] Marked reductions in OCg may signal imminent development of peritoneal sclerosis.[37]

Residual Renal Function

In PD, residual renal function is important for patient and technique survival. Residual renal function is somewhat better preserved over treatment time in PD than in HD.[38] Residual renal function can be assessed by collecting all urine over a day and assessing the urine concentrations of urea and creatinine and total urine volume. Because renal creatinine clearance, as a result of tubular secretion, yields an

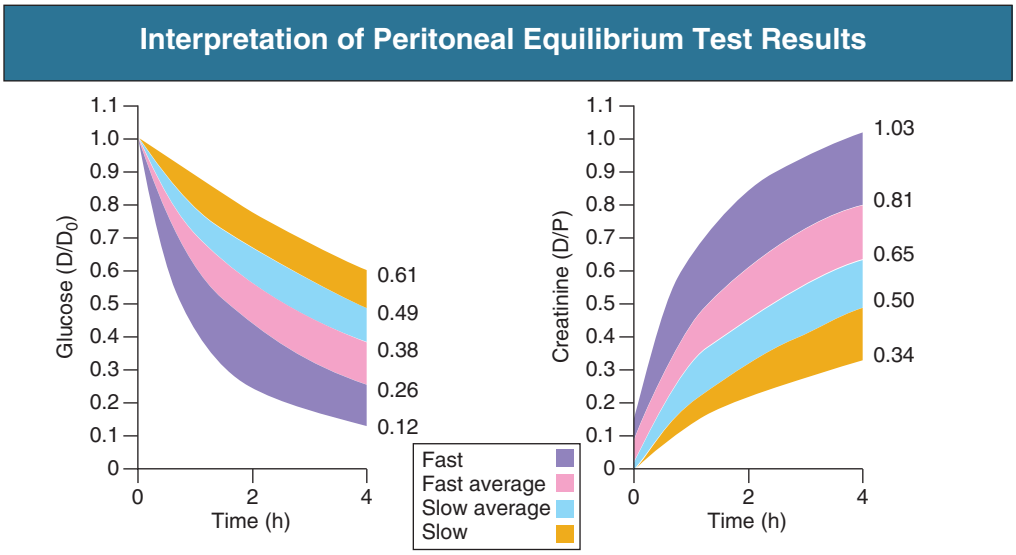

Fig. 96.8 Interpretation of peritoneal equilibration test (PET) results. Changes in solute concentration during a PET allow classification into different transport types. (Modified from reference 29.)

overestimate of the glomerular filtration rate (GFR) (by 1 to 2 ml/min) when the GFR is 10 ml/min or lower, and renal urea clearance yields an underestimate of GFR (by 1 to 2 ml/min) in the same interval of (reduced) GFR, a good estimate of actual GFR can be calculated as the average of renal creatinine clearance and urea clearance. However, if the daily urine volume is less than 200 ml, residual renal function will be too small to be measured accurately.

ADEQUACY

The most important measure of dialysis adequacy is the general clinical state of the patient, as manifested by a good nutritional status (maintained muscle mass) and the absence of anemia, edema, hypertension, electrolyte and acid-base disturbances, neurologic symptoms, pruritus, and insomnia. Management of anemia and bone disease in ESRD patients is discussed in Chapters 82 and 84, respectively. Some criteria for PD adequacy are given in Table 96.1.

Small-Solute Clearance

Few prospective randomized studies define adequate PD. From a clinical point of view it hasbeen suggested that a weekly *Kt/V* above 1.7 and a weekly creatinine clearance above 50 l/1.73 m^2 would be (minimally) adequate for patients on CAPD. In a large prospective study (CANUSA), the outcome for a cohort of 680 patients starting CAPD was studied with an average follow-up of 2 years.[39] Patients who maintained a high *Kt/V* or creatinine clearance over time did better than those who did not. An increase of 0.1 unit of *Kt/V* (peritoneal + renal) per week was associated with a 5% decrease in relative risk for death, and an increase of 5 l/1.73 m^2 of creatinine clearance per week (peritoneal + renal) was associated with a 7% decrease in the relative risk for death. Further analysis of the CANUSA study findings indicated that the survival advantage of patients with higher total small-solute clearance was entirely attributed to the residual renal function. For each increase of 250 ml of urine output per day, there was a 36% decrease in the relative risk for death. In the Adequacy of Peritoneal Dialysis in Mexico (ADEMEX) study,[40] a large randomized controlled trial (RCT) designed to test the value of increasing peritoneal small-solute clearance, there was no survival advantage of increasing the peritoneal clearance to obtain a total weekly creatinine clearance above 60 l/1.73 m^2 at an average peritoneal *Kt/V* of 2.12 (intervention group) compared with a clearance above 50 l/1.73 m^2 at an average peritoneal *Kt/V* of 1.56 (control group). However, although overall mortality, hospitalization, withdrawal, and technique survival were similar in the two groups, the causes of withdrawal were different. Relatively more patients in the control group withdrew because of uremia, hyperkalemia, and acidosis and died from congestive heart failure than in the intervention group.

From these studies it seems that renal and peritoneal clearance are not mutually comparable. High residual renal function is of greater survival advantage than high peritoneal solute transport capacity. The fact that the survival of PD patients is equal to or supersedes that of HD patients during the first 2 to 3 years of dialysis (see later), despite the fact that PD provides approximately 50% of the total *Kt/V* of HD,

TABLE 96.1 Criteria for Peritoneal Dialysis Adequacy Criteria for Peritoneal Dialysis Adequacy

Clinical	Patient feels well and has stable lean body mass No symptoms of anorexia, asthenia, nausea, emesis, insomnia Stable nerve conductance velocity
Small-solute clearance	Weekly *Kt/V* urea >1.7 (renal + peritoneal) Weekly creatinine clearance >50 l/1.73 m^2
Large-solute clearance	Albumin clearance <0.15 ml/min
Fluid balance	No edema No hypertension No postural hypotension
Electrolyte balance	Serum potassium <5 mmol/l
Acid-base balance	Serum bicarbonate >24 mmol/l
Nutrition	Daily protein intake ≥1.2 g/kg Daily calorie intake >35 kcal/kg/day Serum albumin >3.5 g/l BMI 20-30 kg/m^2 Stable midarm muscle circumference

BMI, Body mass index.

indicates that the benefit of PD goes beyond the clearance of small solutes. In a European multicenter study of APD, the European Automated Peritoneal Dialysis Outcomes Study (EAPOS), small-solute clearance did not correlate with survival in anuric patients.[37] On the contrary, total volume removal and hydration state were important factors. Still, there is reasonably good evidence that a weekly *Kt/V* above 1.7 and a weekly creatinine clearance above 50 l/1.73 m^2 are adequacy targets that should be reached and maintained in a majority of patients. Lower values of *Kt/V* and creatinine clearance have been found to be associated with more clinical problems and higher consumption of erythropoiesis-stimulating agents in a large RCT. [41]

Commercially available computer programs can predict urea and creatinine clearances and peritoneal UF performance and provide suggestions for treatment options, based on drained volumes and on plasma and dialysate creatinine and urea values. These parameters are often obtained by PET or standardized schedules for specified dwell exchanges. Some of the programs yield an estimate of peritoneal albumin clearance, which to a great extent depends on the filtration occurring across large pores, being increased in "inflammation." Recommended dialysis schedules based on the categorization of the PET are given in Table 96.2.

Fluid Balance

As in all types of RRT, long-term maintenance of adequate fluid and electrolyte balance is crucial for the survival of patients on PD. As already mentioned, the outcome of PD is directly related to residual renal function, particularly a high urine output. Furthermore, patients with fast transport in the PET (a more rapid absorption of glucose and a more rapid loss of the osmotic gradient) have a reduced technique survival. It seems evident that after 2 or 3 years of PD, when residual renal function is low, most patients on PD are fluid overloaded.[42,43] It is likely that volume overload not only aggravates hypertension but also leads to progression of left ventricular hypertrophy, often already present at the start of PD. However, during the first year of PD there is often a fall in blood pressure (BP) and a reduced need for antihypertensive agents. Unfortunately, with time on PD, BP usually rises and the number of antihypertensive drugs needed usually again increases.[44] In patients with evidence of volume overload, PET tests can clarify the mechanism and guide adjustments to the dialysis regimen, if required. Therefore it is advisable to regularly assess dialytic fluid removal in such patients over time, at least every 6 months, with a modified PET (4-hour 3.86% glucose dwell, in conjunction with a standard 2.27% 4-hour PET).

TABLE 96.2 Typical Peritoneal Dialysis Regimens Required for Achievement of Adequate Solute Clearances

	PERITONEAL SOLUTE TRANSPORT CHARACTERISTICS: D/P CREATININE AT 4 HOURS			
Patient Body Surface Area (m2)	Slow (<0.5)	Slow Average (0.5 to <0.65)	Fast Average (0.65-0.82)	Fast (>0.83)
<1.7	CAPD/APD 10-12.5 l	CAPD/APD+ 10-12.5 l	APD+* 10-12.5 l	APD* 10-12.5 l
1.7-2.0	CAPD+/APD 12.5-15 l	APD+ 12.5-15 l	APD+* 12.5-15 l	APD+* 12.5-15 l
>2.0	CAPD+, HD	APD+ 15-20 l	APD+* 15-20 l	APD+* 15-20 l

*The use of glucose polymer (icodextrin) solution for the long exchange will enhance both solute clearance and ultrafiltration. Typical peritoneal dialysis regimens required to achieve adequate solute clearance according to patient size and membrane characteristics in anuric patients. The total volume of dialysate fluid required increases with body size, with use of 2.5- or even 3.0-liter exchanges. As solute transport increases, the use of automated peritoneal dialysis (APD) with shorter overnight exchanges is favored over continuous ambulatory peritoneal dialysis (CAPD). Both CAPD and APD may have to be augmented by the use of an additional exchange (denoted by +); This is given by way of an additional afternoon exchange in CAPD patients or by use of an exchange device that delivers a single additional exchange at night.
D/P, Dialysate-plasma concentration ratios; *HD,* hemodialysis.

Management of Fluid Overload

As total urinary water (and sodium) excretion and peritoneal UF volume decline, it is advisable to instruct patients to restrict salt and water intake. In view of the difficulty in compliance with salt restriction, the use of PD solutions with lower sodium concentration has been advocated. Preliminary studies of low-sodium PD solutions have been promising with regard to reducing the need for BP-lowering drugs to control hypertension[45]; however, low-sodium solutions are not yet commercially available. Loop diuretics such as furosemide 250 to 500 mg/day can be used to maintain urine volumes but do not maintain renal clearance. If salt and water restriction and diuretics are not effective in maintaining UF, it can be enhanced by increasing the dialysis glucose concentration. Patients with alterations in peritoneal membrane function, appearing over the first few years of PD, usually have increased small-solute transport combined with only a moderate change in peritoneal UF capacity,[36] and there is an increased reabsorption of fluid in the late phase of the dwell. These patients can benefit from switching to APD and the use of icodextrin for one of the (daily) exchanges. RCTs using icodextrin for the long daytime dwell in APD have demonstrated an improved UF and a reduced extracellular fluid volume.[46] Patients who have been on PD for several years may have a reduced UF capacity (reduced OCg).[35,36] These patients would (theoretically) benefit less from switching to icodextrin because of the reduced UF capacity.[10]

Nutrition

During their first year of treatment, CAPD patients typically have evidence of net anabolism; the average weight gain may exceed 5 kg without any clinical signs of fluid overload. Contributing to this weight gain is the peritoneal glucose reabsorption (on average 100 to 150 g/day), which adds 400 to 600 kcal of energy intake daily and results in metabolic syndrome in approximately 50% of prevalent PD patients.[47] As residual renal function declines, the nutritional and metabolic abnormalities in CAPD become increasingly manifest, with reductions in lean body mass. The main cause of protein-energy malnutrition and wasting, apart from poor food intake, is the impaired metabolism of protein and energy in uremia. Despite glucose absorption, many patients on long-term CAPD have signs of energy malnutrition, a major component of the uremic wasting syndrome. Contributing factors are (low-grade) inflammation associated with carbonyl and oxidative stress and with accelerated atherosclerosis, the malnutrition inflammation atherosclerosis syndrome.[48] It is important that CAPD patients be prescribed an adequate amount of protein (>1.2 g protein/kg/day) and energy (total energy intake >35 kcal/kg/day) and a sufficient dose of dialysis, enabling the patient to ingest this diet. It should be noted that the daily losses of protein to the dialysate are not negligible, but approximately 5 to 7 g daily, of which approximately 4 to 5 g is albumin. This is comparable to the losses occurring in nephrotic range proteinuria. The nutritional

management of PD patients should include frequent assessments of their nutritional status, and, if inadequate, referral for HD (or transplantation) should be considered. Nutrition in dialysis patients is discussed further in Chapter 86.

OUTCOME OF PERITONEAL DIALYSIS

Registry data have indicated a lower risk for death in patients treated with PD during the first 3 years of treatment compared with those treated with HD, although overall the mortality of patients on PD compared with HD is not significantly different.[49] Survival differences seem to vary substantially according to the underlying cause of ESRD, age, and baseline comorbidity. In a study based on U.S. Medicare registry data,[50] HD was associated with a higher risk for death among diabetic patients with no comorbidity and among younger patients (age 18 to 44), whereas PD was associated with a higher risk for death among patients aged 45 to 64. In patients with mortality rates adjusted for comorbidity at start of dialysis, there were no differences between HD and PD among nondiabetic patients and among younger diabetic patients (ages 18 to 44), but mortality was higher on PD for older diabetic patients with baseline comorbidity. Limited data address comparative survival for HD versus PD in patients older than 70, but small studies from the NTDS study (in the United Kingdom) and the REIN study (in France) suggest that the risk for serious outcomes such as hospitalization and death are similar, regardless of the modality selected. In summary, it appears that dialysis modality does not substantially affect major adverse clinical outcomes, provided patients are appropriately selected.

SELF-ASSESSMENT QUESTIONS

1. In peritoneal dialysis (PD), the fraction of aquaporin (AQP) (ultrasmall pore)-mediated water flow is much higher for glucose than for icodextrin (ICO) as osmotic agent. Why?
   - **A.** Glucose will induce more initial vasodilation and recruitment of exchange vessel surface area than ICO.
   - **B.** The glucose molecules are smaller than the ICO molecules and therefore are relatively "inefficient" as osmotic agents in small pores, but relatively more efficient across AQP.
   - **C.** Glucose, but not ICO, will regularly induce increases in the number of AQPs.
   - **D.** Glucose, but not ICO, can increase the peritoneal capillary filtration coefficient (L_pS).
   - **E.** Oncotic agents such as ICO cannot pull fluid across AQP at all.
2. Which of the following PD catheters has a superior clinical outcome?
   - **A.** The Toronto Western catheter
   - **B.** The Swan neck catheter
   - **C.** The straight one-cuff (original) Tenckhoff catheter
   - **D.** The straight two-cuff (original) Tenckhoff catheter
   - **E.** None of the catheters above shows significant clinical superiority.
3. Long-term changes in peritoneal transport parameters usually involve:
   - **A.** Increases in the mass transfer of small solutes (e.g., PET_{creat}) and marked increases in the peritoneal ultrafiltration (UF) coefficient (L_pS)
   - **B.** Reductions in small-solute mass transport (PET_{creat}) and increases in the peritoneal UF coefficient (L_pS)
   - **C.** Increases in small-solute transport (PET_{creat}) combined with no or only moderate increases in the UF coefficient (L_pS)
   - **D.** Increases in large-solute transport together with increases in UF coefficient (L_pS)
   - **E.** Increases in large-solute transport combined with reductions in the UF coefficient (L_pS)
4. Glucose-based dialysis fluids for PD, low in glucose degradation products, have the following advantages:
   - **A.** They prevent peritoneal fibrosis and encapsulating peritoneal sclerosis.
   - **B.** They preserve residual renal function.
   - **C.** They prevent increases in small-solute transport over treatment time.
   - **D.** They produce higher concentrations of the dialysate effluent marker CA-125.
   - **E.** They increase peritoneal UF capacity.
5. Which of the following is true about icodextrin as a high molecular weight osmotic agent?
   - **A.** Icodextrin is monodispersed.
   - **B.** Icodextrin is polydispersed, but with 100% of the molecules being larger than 3 kDa.
   - **C.** Icodextrin is polydispersed, but with 80% of the molecules being larger than 3 kDa.
   - **D.** Icodextrin is polydispersed, but with 50% of the molecules being larger than 3 kDa.
   - **E.** Icodextrin is polydispersed, but with 30% of the molecules being larger than 3 kDa.
6. Net fluid reabsorption from the peritoneal cavity occurs via lymphatic reabsorption plus backfiltration through:
   - **A.** Small pores
   - **B.** Aquaporin-1
   - **C.** Large pores
   - **D.** Larges pores + aquaporin-1
   - **E.** Small pores + large pores

Complications of Peritoneal Dialysis

Simon J. Davies, Martin E. Wilkie

CATHETER MALFUNCTION

Optimal Timing and Placement of the Peritoneal Dialysis Catheter

Catheter dysfunction adversely affects patient outcome by preventing commencement of the chosen dialysis modality, as well as by being disruptive to training schedules and increasing health care costs. Published literature does not give a strong indication that one insertion technique is better than another, although a recent meta-analysis suggested an advantage of the laparoscopic compared with the open surgical insertion technique.[1] It is clear that the enthusiasm and experience of the operator are key determinants of catheter outcome,[2] and international guidelines describe the optimal conditions for catheter insertion.[3] Timing is also important; patients randomized to the late start arm of the Initiating Dialysis Early and Late (IDEAL) study (estimated glomerular filtration rate [eGFR] 5 to 7 ml/min), were less likely to start on PD than those starting early (eGFR 10 to 14 ml/min), despite PD being their preferred treatment.[4] Early catheter problems are more difficult to manage in the absence of residual kidney function. For optimized catheter function it is necessary that each center audit its success with catheter placement against internationally agreed-on standards as part of local quality improvement.[2,3]

Catheter Function: Inflow
