A 2-liter bag of dialysate should normally take 15 minutes or less to run into the peritoneal cavity. If inflow has stopped or significantly slowed, mechanical causes should be suspected. After checking to ensure that the tubing and catheter are not kinked, that all clamps or rollers are open to the inflow position, and that any frangible seal is fully broken, the catheter should be flushed vigorously with 20 ml of heparinized saline. If the catheter is cleared, heparin should be added (500 U/l) to the next few cycles because the cause of the blockage is often a fibrin plug. Should the catheter remain blocked, a plain abdominal radiograph is required. If this shows that the catheter is in a satisfactory position in the pelvis, an attempt to restore patency should be made with a thrombolytic agent (urokinase, 5000 U or tissue plasminogen activator [tPA], 2 mg in 40 ml of normal saline),[5] which can be instilled into the PD catheter for approximately 1 hour before being withdrawn. If inflow is restored, heparin should be added to the dialysate for the next few cycles. We no longer recommend the use of an endoscopic brush because of safety concerns.

If the radiograph shows the catheter to be malpositioned, an attempt should be made to reposition the catheter tip into the pelvis (Fig. 97.1). This can be done under radiologic guidance with a sterile guidewire inserted into the catheter, alternatively the catheter can be repositioned at laparotomy or with the laparoscope. Sometimes the catheter becomes wrapped in omentum, suggested usually by complete inflow and outflow failure. This requires a partial omentectomy or an omental hitch, a surgical procedure in which the omentum is temporarily held away from the catheter by a dissolvable suture (omentopexy). The value of laparoscopy in this context is that it can provide a diagnosis as to the cause of catheter flow failure and provide a solution—for example, by repositioning the catheter, removing an omental wrap, or performing a limited omentectomy.

Catheter Function: Outflow

The most common reason for outflow failure is constipation, although causes of inflow failure discussed previously also should be considered. Loading of the bowel with fecal material is often obvious on a plain radiograph, but treatment for constipation should be initiated without recourse to this investigation because it is so common. Constipation should be treated with oral laxatives or an enema. Subsequently, bowel action should be kept regular by increasing the fiber in the diet and, if necessary, adding a mild laxative. Slow outflow can be a problem in patients using automated peritoneal dialysis (APD), resulting in excessive machine alarms. This can be managed by switching to tidal APD and using a relatively large residual volume, for example, 25% to 50% of the fill volume. Recently concerns have been raised about the risk for excessive intraperitoneal dialysate volume that might occur during tidal PD, and, as a precaution, cycler algorithms have been altered to incorporate a complete drain into the treatment schedule.

Fibrin in the Dialysate

The mesothelial cells of the peritoneal membrane have a range of physiologic functions, including the production of fibrinolytic agents such as tPA. This process is disrupted during peritonitis when the appearance of fibrin in the dialysate is common. If fibrin causes restriction of dialysate flow, heparin (500 U/l) should be added to each bag. A small number of patients have fibrin formation in the absence of peritonitis. Immediately on drainage the bag may appear cloudy, but on standing the fibrin will aggregate and the fluid becomes clear. The first time this happens, a sample must be sent to the microbiology laboratory to exclude infection. If the results of this testing prove negative, the patient can be reassured.

FLUID LEAKS

Fluid leaks occur in which dialysate leaks out of the peritoneal cavity—which can be either visible externally or not. It is recommended that after PD catheter surgery, patients be allowed to heal sufficiently before use (2 weeks) to minimize this risk. If the catheter must be used early, low volumes should be used (start with 1 liter) in the supine position (e.g., APD with a dry day), with the patient instructed not to mobilize while dialysate is in the peritoneal cavity during the first 2 weeks after catheter insertion. Although PD catheters can be used successfully as the primary approach to manage late-presenting patients or for acute

kidney injury, the incidence of leaks is higher under these conditions unless precautions are taken.[6,7]

External Leaks

On occasion, fluid may leak from the exit site or even the incision used to insert the catheter into the peritoneal cavity. A leak of dialysate, which is confirmed by measuring glucose concentration in the leaking fluid, is a risk factor for infection. It is important that PD catheters be adequately immobilized if used for early-start PD to reduce the risk for tugging and leak.

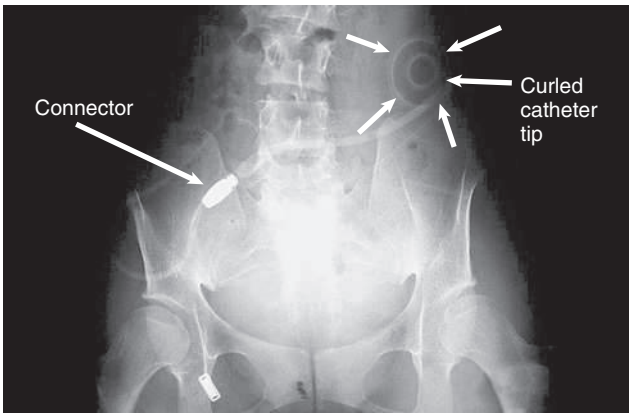

Fig. 97.1 Catheter malposition. Plain radiograph of the abdomen with curled catheter *(arrows)* misplaced in the upper left abdomen.

Internal Leaks

Isolated edema of the abdominal wall suggests an internal leak from the peritoneal cavity, either spontaneously or in association with a surgical hernia. In contrast, genital edema suggests an inguinal hernia or patent processus vaginalis. On occasion, both can be present. The site of the leak can be visualized on computed tomography (CT) scanning after intraperitoneal instillation of contrast material or on magnetic resonance imaging without the use of contrast. It may be necessary for the patient to stand or perform other maneuvers to increase intra-abdominal pressure before the leak is demonstrated (Fig. 97.2A). An alternative diagnostic test is to perform scintigraphy after injection of a compound such as technetium Tc-99m–labeled diethylenetriamine-pentaacetic acid (^{99m}Tc-DTPA; see Fig. 97.2B). A surgical repair will be required if a major leak is visualized and should always be considered when there is a hernia. Most leaks, however, will heal after resting or with APD, using dry days, or temporary HD.

Hydrothorax

A pleural effusion can occur with generalized fluid overload or local lung disease, but it is occasionally caused by a leakage of dialysate through the diaphragm (Fig. 97.3A). This occurs more commonly on the right side. A leak is most simply indicated by aspirating a sample of the effusion and demonstrating that its glucose concentration is higher than the patient's blood glucose concentration, which can be confirmed by scintigraphy after intraperitoneal instillation of isotope, usually ^{99m}Tc-DTPA (see Fig. 97.3B). If one can be confident that the pleural effusion is not caused by the PD, then PD can be continued while the effusion is investigated and managed. Although there are

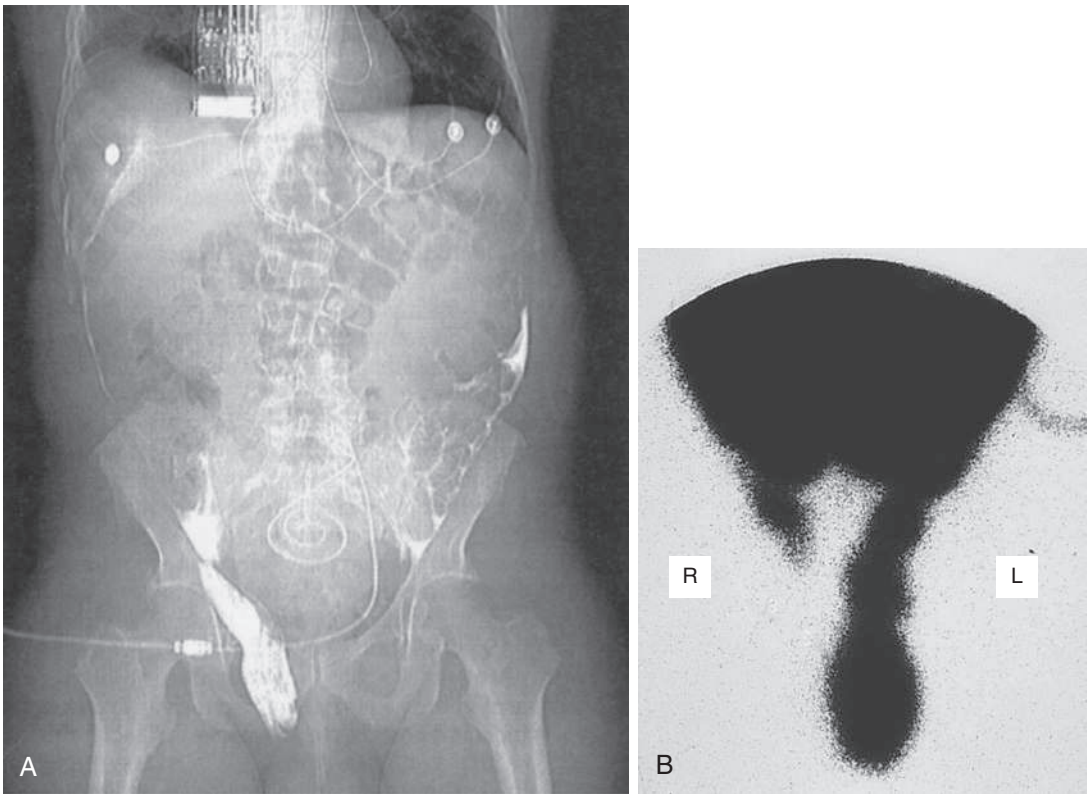

Fig. 97.2 Inguinal hernia during peritoneal dialysis. (A) CT scan after intraperitoneal injection of contrast material in a male patient showing dialysate flowing into a right inguinal hernia. (A from reference 43.) (B) Peritoneal scintigram of a male patient on peritoneal dialysis showing bilateral inguinal hernias. The left hernia extends into the scrotum; the right hernia is less extensive.

(B) Scintigram in a peritoneal dialysis patient showing isotope in the right hemithorax *(arrows)* confirming a right pleural effusion.

reports that repairing pleural leaks allows subsequent PD, the best advice is to transfer the patient to HD unless there are very strong reasons not to do so.

PAIN RELATED TO PERITONEAL DIALYSIS

Inflow Pain

Soon after starting PD, patients may experience pain during fluid inflow, and occasionally pain affects the shoulders and is pleuritic, possibly because of diaphragmatic irritation, which usually resolves over the following days. Slowing the rate of fluid inflow will often reduce the symptoms, and peritonitis should be excluded and treated. A small number of individuals have persistent inflow pain, and the use of bicarbonate-lactate–buffered dialysate at physiologic pH improves symptoms in such patients.[8]

Outflow Pain

Some patients have discomfort or pain when the fluid is drained out, which can be experienced in the genital area or rectum and is commonly a result of pelvic irritation related to the catheter tip. This emptying sensation is abolished when the next cycle runs in and is best treated by leaving a small residual volume of fluid in the peritoneal cavity at the end of the drain, for example, by using tidal APD. Tidal APD is where a residual volume is left in the peritoneal cavity at the end of each dialysis cycle (e.g., 20% of the drain volume). To reduce the risk for intraperitoneal volume overload the treatment algorithm includes at least one complete drain during and at the end of treatment.

Blood-Stained Dialysate

Blood-stained dialysate is uncommon. It is rarely serious but causes considerable alarm to the patient. There is sometimes a clear history of trauma to the abdomen or of unexpected strain. A range of rare conditions are associated with this complication[9]; a few female patients relate the episode to their time of ovulation or menstruation. The treatment is to flush the abdomen with a few cycles of dialysate containing heparin (500 U/l) to minimize the chances of clotting in the catheter. The problem usually resolves spontaneously and often is visible only in one outflow. It is unusual for the blood-stained dialysate to be associated with infection, although it is wise to have the fluid cultured. Routine use of antibiotics is not necessary.

INFECTIOUS COMPLICATIONS

Peritonitis

There are wide variations in peritonitis rates both between and within countries. Reducing peritonitis rates requires a multifaceted, multidisciplinary approach based on the use of preventive measures around the time of catheter insertion, the use of modern disconnect systems, exit site management, and education of patients and health care professionals.[10] This should be supported by regular local audit of peritonitis rates including causative organisms and local sensitivities, which is increasingly important because of the emergence of resistant organisms, and the requirement to use antibiotics effectively. Root cause analysis (e.g., inquiring about breaches in sterile technique) should be performed after each episode of PD peritonitis, with retraining as appropriate. Guidelines for the diagnosis and management of PD

peritonitis are published by the International Society for Peritoneal Dialysis (ISPD; www.ispd.org) (Box 97.1).[10] The spectrum of peritonitis and its management in children have also recently been described in detail.[11] The reader is directed to a detailed review on reducing peritonitis risk.[12]

Diagnosis of Peritonitis

Peritonitis should be suspected in any patient who develops abdominal pain or a cloudy bag when PD fluid is drained; patients with these symptoms should be advised to contact their dialysis center immediately. Fever may be present but is not a universal feature. Samples of the dialysate should be taken for cell count and microbiologic examination. The diagnosis is confirmed by finding more than 100 white blood cells/mm^3 (1×10^7 cells/l). A Gram stain of the spun deposit should be performed to help identify the type of causative organism, although initial treatment will usually be empiric pending culture and sensitivity results. Various culture techniques have been proposed, but white cell lysis and inoculation into blood culture media is often helpful in increasing the yield of a positive growth.

The dialysate leukocyte count will be affected by dwell length, and this needs to be considered in APD patients. In short dwells, the count will be lower, and under these circumstances, if the proportion of cells that are neutrophils exceeds 50%, empiric treatment of peritonitis should be commenced. Conversely, if the patient has had a dry abdomen during the day, the initial drain on connection may be cloudy. This will clear within one or two cycles, and most of the cells found will be mononuclear leukocytes.

Treatment of Peritonitis

The empiric treatment of peritonitis will vary according to center and should be developed in close collaboration with the local microbiology service, taking into account sensitivity patterns and infection control policy. Initial regimens must cover both gram-positive and gram-negative organisms; the latest ISPD guidelines (www.ispd.org) give examples of appropriate antibiotics and their doses, including vancomycin, cephalosporins, and aminoglycosides. Antibiotic regimens are adjusted as soon as culture results are available, usually after about 48 hours.[10] The preferred route of administration is intraperitoneal (IP) unless the patient has features of systemic sepsis. IP gentamicin can be administered as daily intermittent dosing at a dose of 0.6 mg/kg/day (aiming to maintain the trough serum concentration of <2 mg/l); IP vancomycin also can be administered intermittently every 5 to 7 days, at a dose of 15 to 30 mg/kg, aiming to maintain the serum vancomycin level above 15 µg/ml. IP cephalosporin be administered either continuously (in each exchange) or on a daily intermittent basis.[10]

Dosage regimens will depend on whether the patient is on CAPD or APD. For CAPD, the antibiotic is administered as a loading dose in the first bag and then as a maintenance dose in subsequent bags. The intermittent IP dose can be given in the day dwell of APD patients; however, APD results in a higher peritoneal clearance of antibiotics than CAPD, and therefore extrapolation of data from CAPD to APD may result in underdosing.

Once the culture result is available, the regimen should be modified accordingly (Table 97.1). If the organism is methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin will be continued as part of the regimen. If the culture is negative, empiric therapy should be continued for 2 weeks, assuming there is a clinical response. If a gram-negative organism is identified, the subsequent management will depend on the sensitivity (Fig. 97.4). The isolation of multiple organisms with or without anaerobes strongly suggests perforation of the small or large intestine or biliary system. Metronidazole should be added to the regimen to cover anaerobic organisms, antibiotic therapy augmented to intravenous administration, and prompt surgical review obtained with necessary imaging (CT scan if appropriate).

TABLE 97.1 Antibiotic Regimens for Bacterial Peritoneal Dialysis Peritonitis

Culture	Antibiotic
Gram positive: Based on sensitivities	Vancomycin or other appropriate antibiotic
Coagulase-negative staphylococci	Treat for 14 days
*Staphylococcus aureus**	Treat for 21 days: Screen for carriage
Enterococci	Treat for 21 days
Other streptococci	Treat for 14 days
Gram-negative bacilli or mixed bacterial growth	Continue gram-negative coverage based on sensitivities Consider switching to third- or fourth-generation cephalosporins
*Pseudomonas** or *Stenotrophomonas* spp.	Two antibiotics based on sensitivity, treat for 21-28 days
Other gram-negative bacilli	Treat for 21 days Mixed gram-negative or gram negative + gram-positive, consider metronidazole and ampicillin/vancomycin.

From reference 10.
*Examine for exit site or catheter tunnel infection.
Suggested antibiotic regimens when dialysate fluid culture is available. Except for culture-negative episodes, empiric treatment is stopped once the sensitivities are known. All antibiotic regimens should be adjusted for local microbiologic practices.

A wide variety of antibiotics other than those cited have been used with success, and these are documented in the ISPD 2016 guideline.[10] A commonly used strategy is to include an oral quinolone, such as ciprofloxacin. There is debate surrounding the role of aminoglycosides—advantages being simplicity of use and good coverage for gram-negative organisms; however, there are concerns regarding ototoxicity and nephrotoxicity, the former of which is irreversible. Reports regarding the impact of these agents on residual renal function are inconsistent, but serious episodes of peritonitis tend to adversely affect residual renal function. It is, however, advisable to avoid recurrent or protracted courses of aminoglycosides, with an early switch to alternative agents (e.g., third-generation cephalosporins) if they are used as empiric first-line treatment. There is evidence for the use of concomitant *N*-acetylcysteine, which should be considered to block the ototoxicity.[13] Current recommendations are that for gram-positive organisms, therapy should be for 14 days except in the case of *S. aureus,* for which 21 days is suggested. For culture-negative episodes, 14 days of therapy should suffice. The same is true in the case of single-organism gram-negative peritonitis.

Many patients can be treated successfully as outpatients. It is extremely important, however, that they be followed either in the clinic or by telephone. In most patients, clinical resolution (as judged by the clearing of the bags) starts within 48 hours. If there is no improvement within 96 hours despite use of the correct antibiotic, as judged by sensitivity tests, the fluid must be retested by cell count, Gram stain, and culture. The ISPD recommends that the catheter be removed if there is no improvement in 5 days; however, in a severe infection this should be done earlier, and in a more indolent case the period of observation can be longer. A specific recommendation is that the catheter should be

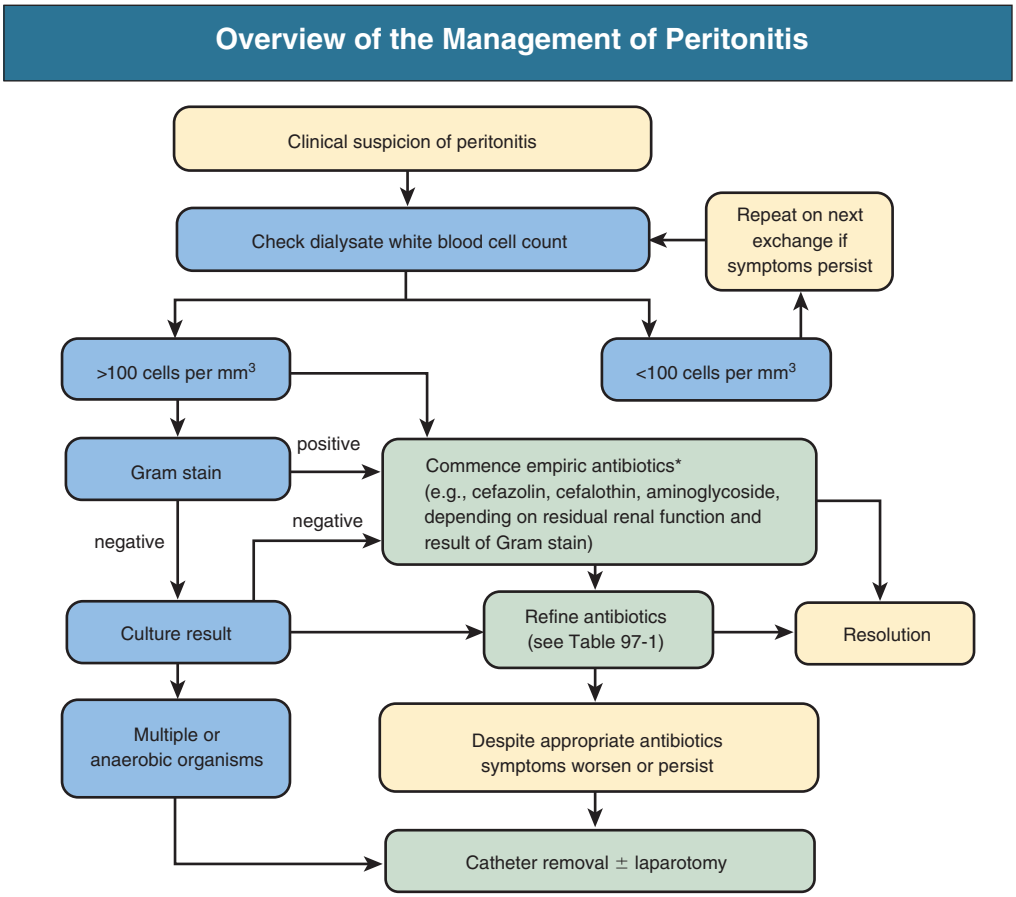

Fig. 97.4 Overview of the management of peritonitis.

removed where a *Pseudomonas* or *S. aureus* peritonitis occurs in conjunction with an exit site or tunnel infection.[10] In addition, the possibility of intraabdominal or gynecologic disease or the presence of unusual organisms such as mycobacteria should be considered. Under these circumstances, a mini-laparotomy should be performed to exclude intraabdominal disease, and if mycobacterial infection is suspected, a peritoneal biopsy specimen should be obtained for culture.

Fungal Peritonitis

If peritonitis is caused by yeasts or fungi, the peritoneal catheter should be removed promptly. This should be combined with treatment with an appropriate antifungal for at least 2 weeks after catheter removal. Fungal peritonitis is a serious complication of PD, commonly requiring hospitalization and transfer to hemodialysis (HD), with a high associated mortality. It is essential to review the appropriate antifungal agent with the local microbiologic team; options are described in some detail in the 2016 peritonitis update from the ISPD.[10] Amphotericin B should not be given intraperitoneally because it causes chemical peritonitis and pain. Appropriate antifungal therapy should be continued for at least 2 weeks after catheter removal.

Relapsing Peritonitis

Relapsing peritonitis is defined as infection caused by the same organism as the original infection occurring within 4 weeks, whereas *recurrent peritonitis* is defined as a different organism within 4 weeks of completion of an appropriate course of antibiotics. In general, the advice is to treat as for a primary infection but to try to establish an underlying cause. For example, recurrence of *S. aureus* infection should trigger a search for pericatheter infection. If enterococci or gram-negative organisms are the cause of a relapse, the possibility of intraabdominal disease or an abscess should be considered (although these organisms are frequently water-borne). If a patient has other gastrointestinal symptoms, such as change in bowel habit, appropriate investigation should be conducted. Some organisms (including coagulase-negative staphylococci) produce biofilm that can lead to a relapse of the infection. Consideration should be given to changing the PD catheter once the infection has been treated; of course, the catheter will need to be removed if the infection does not respond to treatment. Current practice in most units is to allow up to 3 weeks of treatment before a new catheter is inserted.

Culture-Negative Peritonitis

Culture-negative peritonitis is associated with increased risk for treatment failure. Commonly the cause relates to the sampling technique or the microbiologic approach; alternatively, concurrent antibiotic use may be responsible. It is important to be aware of the possibility of fastidious organisms (e.g., atypical mycobacteria, suspicious of contaminated water sources, or yeasts). In addition, other causes of peritoneal inflammation may responsible; these include the presence of an intraabdominal malignancy or surgical pathology or eosinophilic reactions—for example, in the case of vancomycin allergy or some fungal infections. Chylous effluent is a rare finding in PD; the cause is often unclear, but if recurrent, conditions affecting lymphatic drainage should be considered.

Exit Site Infection

Exit site infection (ESI) is an important complication of long-term PD. The diagnosis is suspected on clinical grounds, usually by the presence

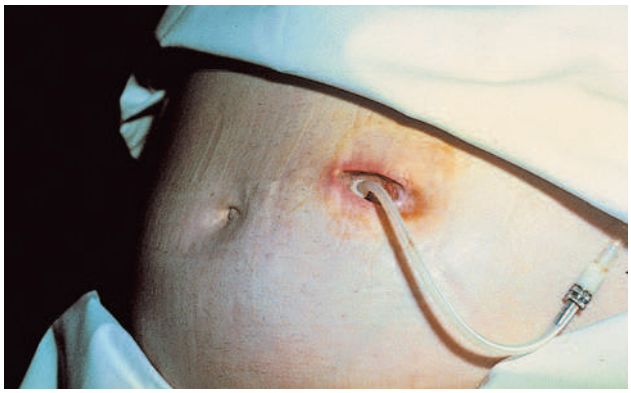

Fig. 97.5 Exit site infection. A severe exit site infection that has exposed the outer cuff of the catheter.

of marked erythema or discharge from the exit site (Fig. 97.5). A scoring system for exit sites has been developed to determine the likelihood of infection and grade its severity, with points assigned for crusting, swelling, pain, and discharge according to severity; if the discharge is purulent, this mandates treatment.[14] Extension of the infection into the tunnel may be assessed either clinically or by ultrasound. The most common infecting organism is *S. aureus.* There is evidence for the use of prophylactic topical antibiotics at the exit site, the strongest being for mupirocin for the prevention of ESI caused by *S. aureus.*[14] There is also evidence for the use of topical gentamicin, although there were some reports of an increase in ESI caused by Enterobacteriaceae, *Pseudomonas* spp., and probably nontuberculous mycobacteria after a change of prophylactic protocol from topical mupirocin to gentamicin.[10]

All suspected infected exit sites should be swabbed; routine swabbing of healthy exit sites should be avoided, and incidental bacterial growth does not require treatment. Unless there is prior evidence that the patient carries MRSA or *Pseudomonas,* initial treatment should be with an antibiotic effective against *S. aureus*—such as a penicillinase resistant penicillin (e.g., dicloxacillin or flucloxacillin—it is important to be aware of the risk for associated hepatotoxicity with the latter) or a first-generation cephalosporin if the patient is allergic to penicillin. In most patients, the drug can be given orally; but if the individual is systemically ill, the antibiotics should be administered intravenously until clinical improvement occurs. Hospitalization, parenteral antibiotics, and often urgent catheter removal are required if there is evidence of spread into the tunnel. If the infection is with MRSA, eradication therapy should be attempted with systemic vancomycin, as for peritonitis. Should the culture grow a gram-negative organism, ciprofloxacin (500 mg twice daily orally) will be effective empiric treatment in most patients. ESIs caused by *Pseudomonas* spp. are particularly difficult to treat and often require prolonged therapy with two antibiotics.

Treatment is recommended for a minimum of 2 weeks, extended to 3 weeks in *Pseudomonas* infections. In gram-positive infections, if there is no improvement within 7 days, ultrasound of the catheter tunnel should be performed because a collection of fluid around the catheter signifies a tunnel infection. If complete healing does not take place after 4 weeks of therapy, further measures should be considered, such as exteriorizing and shaving the outer cuff because it may be involved in the infection. If the infection persists or relapses, catheter removal must be considered because there is a high risk that the ESI will lead to peritonitis. It is important that the new exit site be formed in a different part of the anterior abdominal wall.

REDUCED ULTRAFILTRATION AND ULTRAFILTRATION FAILURE

Definition and Significance of Ultrafiltration Failure

There are two complementary approaches to defining ultrafiltration (UF) failure. The first is based solely on the net fluid removal (termed *ultrafiltration capacity*) from a standard 4-hour peritoneal equilibration test (PET). The conduct and interpretation of the PET are further discussed in Chapter 97. Account should be taken of the overfill of dialysis bags by the manufacturers, which can be as much as 200 ml. A net UF capacity below 400 ml with a hypertonic glucose exchange (3.86%) is indicative of an inadequate membrane,[15] bearing in mind that this may not be clinically relevant in a patient with well-preserved residual renal function. If a middle-strength glucose solution is used (2.27%), the equivalent value is 0 ml (again excluding overfill). Although this definition is clear enough, the main limitation is that it relies on a single measurement of UF capacity, which is subject to significant error (coefficient of variation is up to 25%). The second approach to defining UF failure is more holistic in that it considers patient factors that affect fluid status (e.g., comorbid conditions) and an acceptable glucose exposure required to maintain adequate hydration. Many clinicians now take the view that regular use of hypertonic solutions is not acceptable unless the life expectancy is shorter than the likely time to development of severe membrane failure and its complications, unusual before 5 years.

UF failure is a significant cause of technique failure[16]; it results in low UF, which in turn increases the risk for mortality in anuric patients[17,18] and is also a risk factor for encapsulating peritoneal sclerosis (EPS).[19] Although it is impossible to set a fluid removal goal that applies to all patients, the European Automated Peritoneal Dialysis Outcomes Study (EAPOS) found that anuric patients who failed to reach an UF target of more than 750 ml/day had less efficient membranes (specifically lower osmotic conductance, see later) and higher mortality.[18] Patients whose total fluid removal is less than 1 l/day because of poor UF should have their membrane function assessed.

Establishing the Causes of Ultrafiltration Failure

Failure of the membrane to ultrafiltrate needs to be distinguished from other causes of inadequate peritoneal fluid removal such as catheter dysfunction, leak, or excessive fluid reabsorption.[20] The latter can occur if the intraperitoneal cavity pressure is too high, suspected if the UF falls after an increase in dialysate volume. If there is doubt, a dialysate sodium concentration below 125 mmol/l 1 hour into a PET using 3.86% glucose, an indicator of preserved sodium sieving (see later) suggests that UF is preserved.

There are two main causes of UF failure: a *fast peritoneal solute transport rate* (fPSTR) or low membrane UF efficiency despite a preserved osmotic gradient, termed *reduced osmotic conductance.* Both can exist at the start of PD or can be acquired with time on therapy, although it is rare for a patient to develop reduced osmotic conductance without also having rapid transport.

Fast Peritoneal Solute Transport Rate–Related Ultrafiltration Failure: Diagnosis and Management

With the 4-hour PET, a dialysate–plasma creatinine ratio greater than average (0.64) could contribute to poor UF. This is because more rapid diffusion of small solute across the membrane leads to earlier dissipation of the osmotic gradient driving UF. Furthermore, once the gradient is lost, membranes with a larger diffusive area will reabsorb fluid more rapidly. In continuous ambulatory PD patients, fPSTR is associated with increased mortality, technique failure, and hospitalization,[21] whereas this association is attenuated or possibly reversed when APD is used.[22,23]

Thus both theoretically and empirically the short exchanges used in APD prescription are associated with better outcomes in fPSTR-associated poor UF. Prevention of fluid reabsorption during the long day or night exchange is also required in these patients, and this can be achieved by use of icodextrin (polyglucose solution), which also improves the fluid status[24] and reduces episodes of fluid overload.[25] The main determinant of fPSTR is increased intraperitoneal inflammation, which is independent of systemic inflammation.[26] Only the latter is an independent predictor of mortality.

Low Osmotic Conductance–Related Ultrafiltration Failure: Diagnosis and Management

This problem should be suspected if UF failure persists despite adjustment of the prescription to accommodate the peritoneal solute transport rate (PSTR). Osmotic conductance is a measure of the efficiency of the peritoneal membrane to ultrafiltrate for a given osmotic agent, typically glucose. Reduced osmotic conductance can be demonstrated quite easily in the clinic. Sodium sieving is the consequence of free water entering the peritoneal cavity via the transcellular endothelial aquaporin pathway, resulting in a drop resulting from dilution in the dialysate sodium concentration; it is independent of the sodium-coupled UF that occurs across endothelial tight junctions. Thus the absence of a fall in the dialysate sodium concentration 1 hour after using a high glucose exchange indicates the lack of sodium sieving, which implies reduced free water UF. This can be combined with the double–mini-PET,[20] which requires back-to-back 1-hour exchanges using low (1.36%) and high (3.86%) glucose concentrations; a difference of less than 400 ml net UF between the two exchanges indicates poor osmotic conductance. The two causes so far identified are reduced aquaporin function, possibly constitutive and thus present at the start of treatment, and progressive fibrosis of the membrane as a result of acquired membrane injury. There is no specific treatment, so clinical effort should focus on prevention (see next section) and timely switch to HD or transplantation.

CHANGES IN PERITONEAL STRUCTURE AND FUNCTION

It is widely assumed that alterations in peritoneal function, a combination of an increased PSTR and loss of osmotic conductance, are related to structural changes in the peritoneal membrane.[27] There is accumulating evidence that continuous exposure to dialysis solution components and repeated episodes of bacterial peritonitis are the main drivers of this process (Fig. 97.6). The relationship between structure and function is becoming clearer: increased PSTR is likely to reflect a greater vascular surface area, whereas loss of osmotic conductance requires an additional mechanism that is associated with progressive membrane fibrosis and an increased risk for EPS. The submesothelial collagenous zone shows progressive increase in thickness with time on PD (Figs. 97.7 and 97.8), and this is associated with progressive changes to the structure of small venules ranging from subtle thickening of the subendothelial matrix to complete obliteration of vessels (Fig. 97.9).[28,29] This process is accompanied by a reduction in sodium sieving, implying reduced free water transport, but no change in aquaporin expression, suggesting that the fibrosis is the main cause of UF failure.[30]

Preventing Membrane Injury

The main clinical factors associated with more rapid and severe membrane injury are early loss of residual renal function, recurrent or severe peritonitis, and the earlier use of higher glucose–containing solutions (often associated with loss of diuresis but an independent risk factor).[31] Hypertonic solutions may induce injury because of direct glucose toxicity; glucose degradation products (GDPs) manifest as a result of the sterilization process, or both. The prevention of membrane injury should focus on all of these drivers and include (1) preservation of residual renal function by avoiding both volume depletion and the use of angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs); (2) use of loop diuretics to maintain urine volume and delay use of hypertonic exchanges; (3) use of icodextrin in the long exchange; (4) avoidance of peritonitis; and (5) use of low-GDP neutral pH solutions.[32] The balANZ study shows that the increase in PSTR over the first 2 years of PD is prevented by use of ultralow-GDP dialysis fluid. More importantly, this study showed that achievement of less UF, lower use of hypertonic glucose, and in particular low-GDP solutions early in the course of PD, now confirmed in meta-analyses of several trials is associated with preservation of residual kidney function.[25,33] This, combined with trial evidence that fluid status is stable in patients with residual kidney function,[34] supports the main strategy clinicians should adopt in preserving the membrane—prescribing to maintain adequate but not excessive UF, which will only drive thirst and increase the risk for volume depletion.

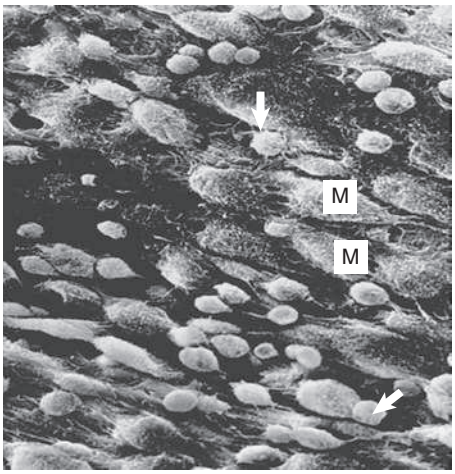

Fig. 97.6 Peritonitis. Scanning electron micrograph of the peritoneum from a patient receiving peritoneal dialysis who has peritonitis. The small round cells *(arrows)* are phagocytes, which are widely distributed among the mesothelial cells *(M)*. (Magnification, ×1800.)

Encapsulating Peritoneal Sclerosis

A minority of patients on PD develop EPS, in which the bowel is enveloped in a thick cocoon of fibrous tissue, causing intestinal obstruction (Fig. 97.10).[19] It is variable in severity but may be life-threatening, causing death from malnutrition or intraabdominal catastrophe; but with experienced management by a multidisciplinary team, overall survival compares well with that of matched controls. Diagnosis of this syndrome requires both clinical signs and symptoms of bowel obstruction leading to weight loss and malnutrition (with or without features of systemic inflammation) combined with either typical features on imaging (CT scanning) or confirmation of fibrous cocooning at laparotomy. Although UF failure is a risk factor for EPS (especially when there is also loss of osmotic conductance), EPS appears to be a different pathologic process that predominantly affects the visceral membrane, is usually associated with another trigger (such as severe peritonitis or interruption of PD), and frequently has a systemic inflammatory phase (biopsy material more often shows inflammation and fibrinous exudates).

The single most important risk factor for EPS is time on PD; at 5 years the incidence is 2% to 3%, whereas by 10 years, this rises to 6% to 20%.[19] Recent reports from Japan[35] and the Netherlands suggest that the incidence of EPS is decreasing, possibly because of a better

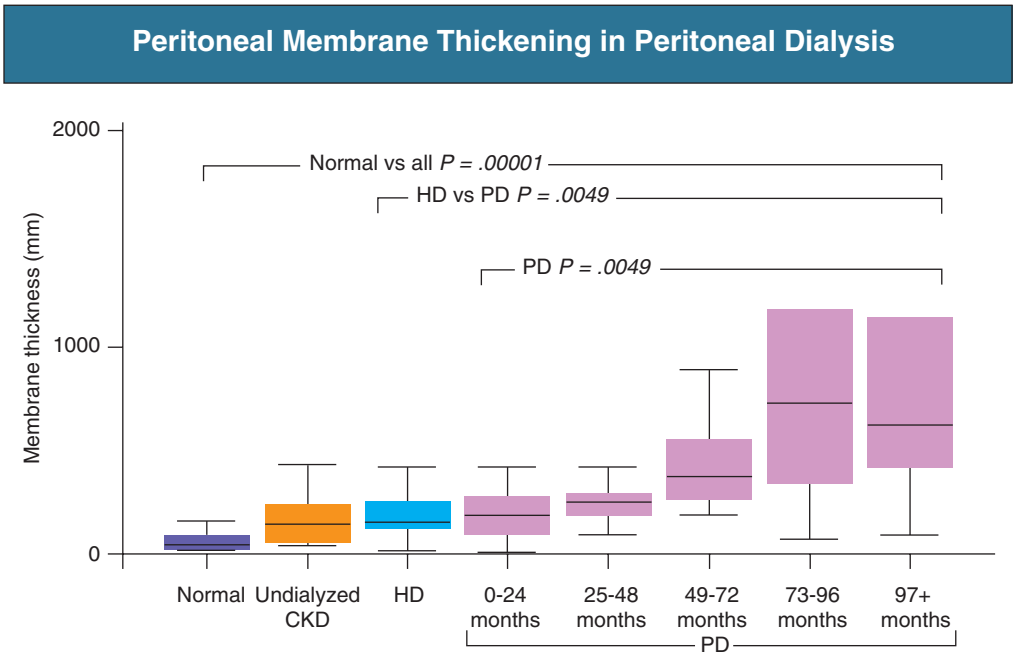

Fig. 97.7 Peritoneal membrane thickening in peritoneal dialysis *(PD).* The thickness of the submesothelial collagenous zone of the peritoneal membrane in normal individuals, in undialyzed patients with advanced chronic kidney disease *(CKD),* patients with uremia, in patients receiving hemodialysis *(HD),* and in those who have received PD for different periods. Membrane thickness is significantly increased in all uremic and dialysis patients compared with normal individuals. Membrane thickness increases significantly with duration of PD and is increased in PD patients as a group compared with HD patients.

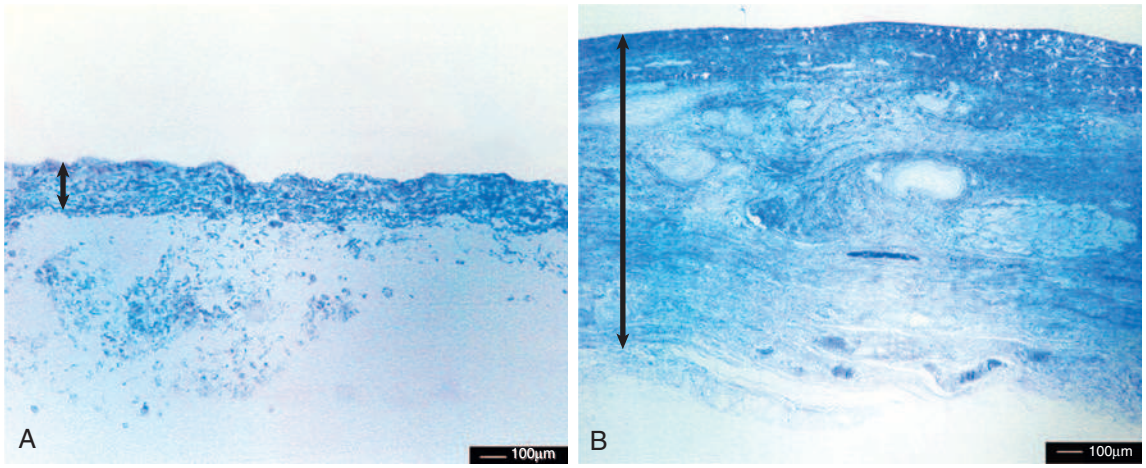

Fig. 97.8 Morphologic changes in the parietal peritoneal membrane. (A) Normal. (B) A patient who has been on peritoneal dialysis (PD) for 10 years. Note the marked thickening of the submesothelial compact zone *(arrows).* (Toluidine blue stain.)

understanding of the management of risk factors. There is increasing evidence that surgical treatment (extensive adhesion lysis and excision of the peritoneum while avoiding enterotomy) is most effective, especially when there are obstructive symptoms. This should be undertaken by an experienced surgical team, which can achieve cure rates of 70% to 80%. Parenteral nutrition can be used as a preparation for surgery and occasionally as a long-term solution. In about 50% of patients, symptoms are less severe and gradually resolve. There is no role for preemptive screening by CT scanning, but this is helpful in diagnosis. Most commonly, EPS develops after transfer from PD to either HD or transplantation; but if it develops in a patient on PD, the consensus is that PD should be stopped to avoid continued exposure to nonphysiologic dialysis solutions. Other strategies, such as continued irrigation, dual-modality treatment with PD and HD, and use of antifibrotic drugs such as tamoxifen, are practiced, but an evidence base for such management is lacking.

NUTRITIONAL AND METABOLIC COMPLICATIONS

Undernutrition

Cross-sectional surveys of patients receiving PD show that about 40% have evidence of mild and 8% severe protein-calorie depletion as judged

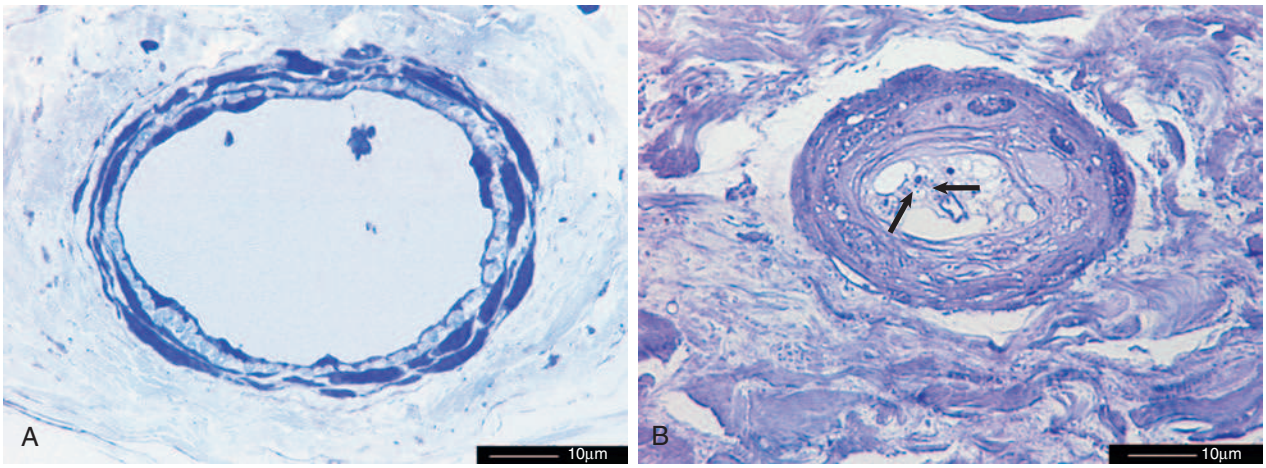

Fig. 97.9 Blood vessels in the parietal peritoneum: transverse sections of peritoneal arterioles. (A) Normal. (B) Vasculopathy in a patient on peritoneal dialysis; the vascular lumen *(arrows)* is occluded by connective tissue containing fine calcific stippling.

by the subjective global assessment of nutritional state. Malnutrition is a risk factor for morbidity and mortality of patients on PD and often associated with systemic inflammation. The assessment and management of malnutrition are discussed further in Chapter 86. One obvious contributing factor is protein loss through the peritoneum, which averages 8 g/day. Protein loss is proportional to effective membrane area and so is most marked during peritonitis and in patients with fast peritoneal transport. The ensuing hypoalbuminemia exacerbates the extravascular extracellular fluid expansion in these patients.[36] Therefore it has been recommended that PD patients should consume daily at least 1.2 to 1.3 g of protein per kilogram of body weight. In practice, many patients take only about 0.8 g/kg/day, and nitrogen balance is maintained partly as a result of calories from dialysate. However, especially once patients are anuric, there is a progressive loss in lean body mass.[34] Despite concerns over hypoalbuminemia in peritoneal dialysis patients, the association with mortality is not worse than for HD patients.[37]

PD patients have abnormal eating behavior with smaller meals, slow eating, and impaired gastric emptying, which causes nausea, especially in patients with diabetes. This is worst when using more hypertonic glucose and least severe with icodextrin. Amino acid–based dialysate improves nitrogen balance in malnourished patients, but the long-term nutritional benefit is marginal.[38]

Acid-Base Status

Correction of acidosis is best achieved by use of dialysate with higher levels of potential buffer,[39] but if necessary, oral bicarbonate may be added. There is evidence that correction of acidosis, by whatever means, to within the upper half of the normal range for serum bicarbonate reduces protein catabolism, resulting in weight gain and increased midarm muscle circumference.[38] The use of amino acid–containing dialysate fluid can worsen acid-base status, requiring close monitoring.

Lipids and Obesity

PD results in significant daily glucose absorption, which may range from 80 to 200 g/day (300 to 800 kcal). Therefore PD patients tend to develop features of metabolic syndrome: central obesity, hyperglycemia, dyslipidemia, and hyperinsulinemia; they may even develop frank diabetes, although there is no evidence that this or worsening obesity is more common than in HD patients.[40] These problems can be reduced by use of icodextrin and amino acid solutions in place of glucose with better glycemic control in diabetics.[41] Blood glucose monitoring in diabetic patients using icodextrin must not use glucose dehydrogenase pyrroloquinoline quinone (GDH-PQQ) test strips because this will lead to falsely high estimates and risk for severe hypoglycemia.

Despite these concerns, there is no evidence to suggest that PD should be avoided in obese patients even though the survival advantage seen in HD associated with a higher body mass index is not seen with PD.[42]

SELF-ASSESSMENT QUESTIONS

1. Regarding catheter function, which of the following statements is/are false?
   - **A.** Introducing the routine use of laparoscopic technique for catheter insertion will improve early catheter survival more than carefully audited standard methods used by an experienced surgeon.
   - **B.** Slow catheter drainage is most commonly a result of constipation.
   - **C.** Pain on draining in ("inflow pain") is best solved by use of tidal peritoneal dialysis (PD).
   - **D.** Pain on draining out is best solved in automated PD (APD) patients by use of tidal PD.
   - **E.** Poor drainage associated with edema in the genital area indicates an inguinal hernia or patent processus vaginalis.
2. Regarding peritonitis and infection, which of the following statements is/are *false*?
   - **A.** Treatment of suspected peritonitis should always commence with antibiotics covering both gram-positive and gram-negative organisms.
   - **B.** Fungal peritonitis usually can be successfully treated with intraperitoneal agents without requiring catheter removal.
   - **C.** Redness and pain at the exit site always should be treated immediately with oral antibiotics.
   - **D.** Prophylactic use of mupirocin or gentamicin at the exit site has been shown to reduce the chances of peritonitis.
   - **E.** Culture of more than one organism in a patient with peritonitis should raise serious concerns of a perforated viscus and lead to mini-laparotomy as well as catheter removal.
3. Regarding membrane function, which of the following statements is/are *false*?
   - **A.** Regular use of hypertonic glucose exchanges is associated with an increased risk for acquired membrane injury.
   - **B.** There should be a minimum target of 1 liter of ultrafiltration (UF) per day.
   - **C.** Rapid solute transport contributes to poor UF but can be addressed by use of APD and icodextrin such that it no longer is associated with increased mortality.
   - **D.** Routine computed tomography (CT) scanning to look for progressive membrane thickening and calcification is the best way to screen for encapsulating peritoneal sclerosis (EPS).
   - **E.** Progressive loss of osmotic conductance is thought to represent increasing fibrotic damage, may predispose to EPS, and is a reason for switching to hemodialysis.

Extracorporeal Therapies for Drug Overdose and Poisoning

Nigel Suren Kanagasundaram, Andrew Lewington

Poisoning and drug overdose, whether intentional or accidental, is a common medical emergency, accounting for around 170,000 hospital admissions per year in the United Kingdom—as many as for myocardial infarction.[1] Most exposures do not require hospitalization, with nearly 70% of U.S. cases in 2014 being managed in a non–health care facility, usually at the site of the incident.[2] Overall exposure-related mortality remains relatively low, with approximately 1400 fatalities recorded in nearly 2.2 million exposures in this same U.S. report.[2] Poisoning, however, remains a significant cause of death in young people.[3]

The spectrum of agents ingested is wide, ranging from overdose of prescribed and nonprescribed medicinal drugs to poisoning with nonpharmacologic substances and recreational drugs. The pattern of toxin ingestion has changed over the years and varies according to geographical location. Frequently implicated agents in industrialized societies include analgesics (acetaminophen, opioids, and salicylates), antidepressants, sedatives, and antipsychotics. Pesticides remain a frequent cause of poisoning in areas of the developing world.[3] Legislation has been used to reduce the availability of potential toxins; in the United Kingdom, for instance, paraquat was withdrawn from sale in July 2008, although occasional exposures continue as a result of residual stored product.[1] Similarly, U.K. legislation limiting pack size of paracetamol (acetaminophen) in 1998 was followed by a significant reduction in the number of deaths from paracetamol overdose.[4]

The mainstays of management of poisoning include hemodynamic, respiratory, and other supportive care, prevention of further poison absorption (through oral activated charcoal in specific patients), neutralization of toxicity (e.g., with intravenous *N*-acetylcysteine after significant acetaminophen overdose or digoxin immune Fab [Digibind]), and enhancement of endogenous toxin elimination (e.g., through urinary alkalinization). These aspects of management are well described by resources such as Toxbase in the United Kingdom (www.toxbase.org) and via the American Association of Poison Control Centers website (www.aapcc.org). Other local and regional poison information services are linked through the website of the European Association of Poisons Centers and Clinical Toxicologists (www.eapcct.org).

Extracorporeal techniques for poison elimination include renal replacement therapies (RRTs) and other modalities such as hemoperfusion or therapeutic plasma exchange. However, they are only occasionally needed; in the United States in 2014, for instance, only around 2500 patients were treated, mostly through hemodialysis (HD).[2] Only 43 patients were recorded as receiving hemoperfusion, reflecting a long-term decline explained partly by the increasing rarity of theophylline and barbiturate overdose (historically, the main indications for this technique) but also by the increased use of high-efficiency, high-flux HD, allowing removal of toxins previously regarded as being nondialyzable.[5,6]

Extracorporeal treatment has long been used to manage poisoning,[5] but common practices are often not supported by high-quality evidence, at least partly because of the practical and ethical barriers to randomized controlled trials.[5] Despite these barriers the EXTRIP (EXtracorporeal TReatments in Poisoning) consensus group (www.extrip-workgroup.org)[6] has created several useful resources for clinicians, endorsed by various national and international stakeholder societies.

WHEN SHOULD EXTRACORPOREAL REMOVAL BE CONSIDERED?

Extracorporeal treatment is most commonly used for lithium, toxic alcohol, and salicylate ingestions[7]; other potential indications are shown in Table 98.1. Extracorporeal elimination should be considered when it is evident that other treatments (e.g., activated charcoal; specific antidotes) will not reduce poison levels below toxic thresholds. It is important, therefore, to understand the general principles underpinning the use of extracorporeal treatment to make decisions about management of poisonings, particularly for those for which no consensus or evidence base exists.

Extracorporeal removal is appropriate for only a small proportion of poisonings. Against the potential advantages of therapy must be balanced with the risks that are generic to all extracorporeal techniques (e.g., acute transfer to a specialist center, vascular access, anticoagulation[8,9]) and those specific to its use in poisoning (as discussed later under individual modalities). Factors that help determine whether extracorporeal therapy might be helpful are summarized in Box 98.1. It should be noted that effective clearance does not necessarily prevent ongoing end-organ toxicity[5] and a fatal outcome, as may occur in cases of paraquat poisoning.[10]

Molecular Weight

Most ingested poisons have a molecular weight (MW) in the 100 to 1000 Da range and would therefore be amenable to removal by HD,[11] which is the modality of choice for clearance of small solutes. Higher flux membranes extend the range of dialyzable solutes up to approximately 10,000 Da, particularly if performed for long hours, and allow removal of toxins such as theophylline and carbamazepine, for which hemoperfusion might historically have been indicated.[11] Molecules toward the upper end of this range and up to about 40 kDa are more effectively removed using modalities with a significant convective component such as hemofiltration (HF) or hemodiafiltration (HDF). Even larger solutes may be removed by non–RRTs such as plasma exchange or one of the albumin-dialysis techniques used for liver support.

Protein Binding

Diffusive and convective modalities (HD, HF, HDF; either intermittent or continuous) are generally unsuitable for removing poisons with protein binding greater than 80%.[11] However, certain toxins (e.g.,

salicylate, valproate) are highly protein-bound under normal circumstances, but saturate protein-binding sites during poisoning, leading to high (and therefore dialyzable) serum concentrations of free agent.[5] In addition, easy dissociation of protein-toxin complexes may allow significant diffusive removal, as with phenytoin.[5] Agents with very high (>90%) protein binding and that are not amenable to diffusive or convective elimination may be removed by plasma exchange (e.g., L-thyroxine and cisplatin).[11]

The interplay between MW and protein binding and their impact on modality choice are graphically illustrated in Fig. 98.1.

TABLE 98.1 Some Poisonings for Which Extracorporeal Removal May Be Indicated*

Agent	Preferred Modality	Other, Acceptable Modalities
Acetaminophen	IHD	IHP, CRRT, Ex
Long-acting barbiturates	IHD	HP, CRRT
Carbamazepine	IHD	IHP, CRRT
Ethylene glycol	IHD	CRRT
Lithium	IHD	CRRT*
Metformin	IHD	CRRT*
Methanol	IHD	CRRT
Phenytoin	IHD	IHP
Salicylates	IHD	IHP, CRRT, Ex
Thallium	IHD	IHP, CRRT
Theophylline	IHD	HP, CRRT, Ex
Valproate	IHD	IHP, CRRT

See reference 6.
*After initial treatment, both IHD and CRRT are equally acceptable. Other agents that may be amenable to removal by extracorporeal techniques include β-blockers, meprobamate, deferoxamine, aminoglycosides (with high flux membranes), pentoxyfilline, sodium edetate, *Amanita phalloides* toxin and paraquat.
CRRT, Continuous renal replacement therapy; *Ex,* exchange transfusion in neonates; *IHD,* intermittent hemodialysis; *IHP,* intermittent hemoperfusion.

Volume of Distribution

The efficacy of toxin removal is also influenced by the theoretical volume of distribution (V_D). Substances confined to the bloodstream will have a low V_D (~0.07 l/kg body weight), those distributed in the extracellular space, a V_D of approximately 0.2 l/kg, and those confined to total body water, approximately 0.6 l/kg. Higher distribution volumes are often found in those substances with avid tissue binding, lipophilicity, or sequestration. As V_D increases, more solute must be removed for achievement of a particular blood level. The ideal solute would therefore have a low distribution volume and would be located within a single, well-mixed compartment that is directly accessible by extracorporeal treatment. There are exceptions; carbamazepine, metformin, and thallium all have high distribution volumes but are amenable to extracorporeal removal.[11]

Solute Compartmentalization

Solutes are often distributed across one or more body compartments that may not be directly accessible by extracorporeal therapy (Fig. 98.2). If there is any resistance to solute movement between the accessible

BOX 98.1 Factors Affecting Toxin Removal by Extracorporeal Therapy*

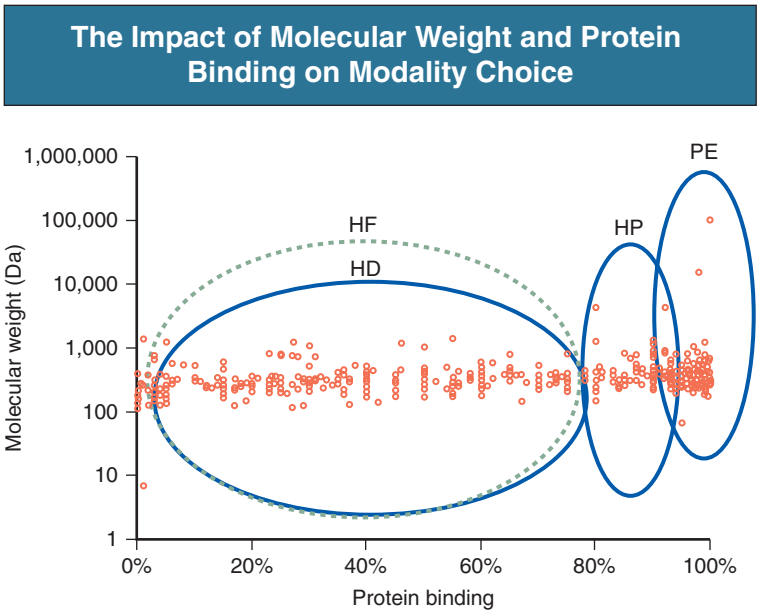

Fig. 98.1 The impact of molecular weight and protein binding on modality choice. *Circles* indicate for which poisons a specific modality might be most useful. *HD,* Hemodialysis; *HF,* hemofiltration; *HP,* hemoperfusion; *PE,* plasma exchange. (With permission, from reference 11). The decline in use of hemoperfusion in many parts of the world means that it may be unavailable as a treatment option. In these circumstances, plasma exchange, which is widely available, may be used.

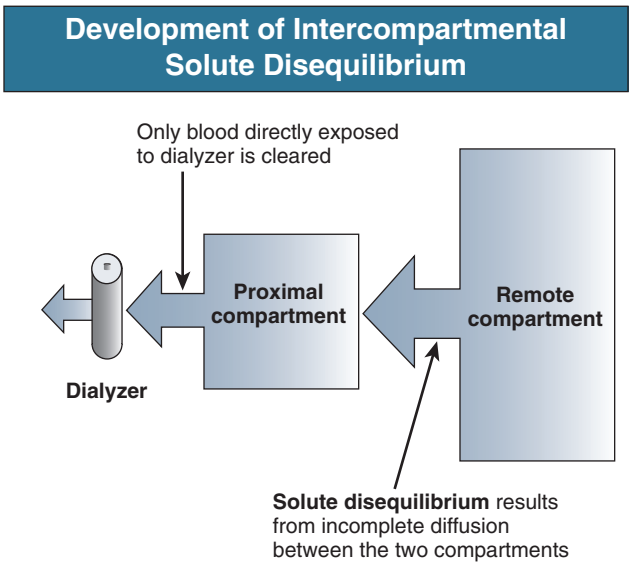

Fig. 98.2 Intercompartmental solute disequilibrium. Access of dialyzer to toxin is limited by disequilibrium, which retains toxin in the remote compartment.

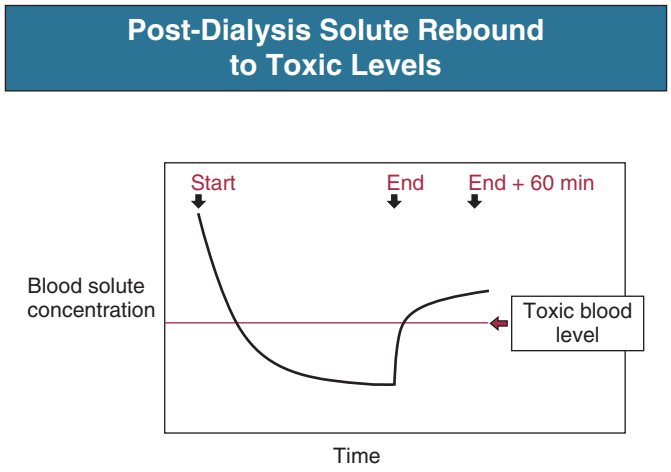

Fig. 98.3 Postdialysis rebound. Falling solute concentration during dialysis with rapid postdialysis rebound to toxic levels.

proximal and the remote compartments, disequilibrium will develop during an extracorporeal treatment, reducing the overall efficiency of toxin removal, and potentially leading to a large postsession rebound in toxin blood levels. Potentially toxic post-treatment levels may be missed if the immediate postdialysis blood level is used to estimate elimination (Fig. 98.3). After extracorporeal treatment for lithium poisoning for instance it is recommended that levels be rechecked after 6 to 12 hours to detect clinically significant rebound.[12] Vigilance for rapidly rising levels is also important if ongoing toxin absorption is suspected and may require earlier and more frequent monitoring.

High clearance techniques (i.e., intermittent HD or HDF) rapidly reduce blood solute levels but are more likely to result in intercompartmental disequilibrium. Extending sessions beyond 4 hours can ameliorate rebound but intermittent HD and the diffusive component of intermittent HDF are inherently inefficient processes that depend on the solute concentration presented to the dialyzer. Most solute removal will therefore occur at the start of dialysis so any gains in solute removal will be disproportionately lower as dialysis time extends. Increasing treatment frequency can mitigate the risk for significant rebound to toxic blood levels.

Compartmentalization need not preclude HD-/HDF-mediated toxin removal, but the total body burden of extremely compartmentalized toxins (e.g., digoxin; tricyclic antidepressants [TCAs]) cannot be effectively reduced by HD even though blood levels are rapidly reduced. Therefore extracorporeal treatment is not recommended in digoxin or TCA poisonings[6] despite occasional reports of successful clearance of TCAs with dialysis.[5]

Contribution of Extracorporeal Toxin Relative to Endogenous Clearance

Even toxins that may be readily cleared by extracorporeal therapy may not require such treatment if endogenous clearance rates are high. It is proposed that extracorporeal therapy is justified if it increases total body clearance by at least 30%[13] or if endogenous clearance is less than 4 ml/min/kg body weight.[14] Unfortunately, these thresholds can be difficult to estimate at the bedside, although an indication of endogenous clearance rates are available for some drugs (see www.medicines.org.uk/emc/) and estimates of dialyzer clearances can be obtained from the product insert. For HF, an estimate of clearance can be provided by the ultrafiltration rate. Maximal clearances for the extracorporeal therapies are approximately 240 ml/min (for intermittent HD/HF/hemoperfusion), 50 ml/min (for continuous RRTs [CRRTs] and plasma exchange) and 10 ml/min (for exchange transfusion).[11]

However, endogenous elimination in the setting of poisoning may be markedly lower than in health. High endogenous clearances of approximately 2000 ml/min (e.g., for cocaine, labetalol, toluene, verapamil)[11] would appear to obviate the need for extracorporeal treatment. However, if these elimination routes are limited by end-organ dysfunction (e.g., by renal or liver failure), extracorporeal therapy may be life-saving.

These considerations are summarized in Fig. 98.4.

TREATMENT MODALITIES

The range of extracorporeal techniques employed for toxin elimination with parameters that might be manipulated to enhance toxin clearances are shown in Box 98.2. Generic considerations, including the basics of physical process, nomenclature, and vascular access (and its care) are detailed, elsewhere.[8,9]

Intermittent Hemodialysis, Hemofiltration, and Hemodiafiltration

Diffusion against a steep concentration gradient (as in intermittent HD) encourages the rapid removal of smaller solutes, including most poisons. Clearances can be enhanced by increasing dialyzer efficiency (indicated by the KoA, the urea mass transfer area coefficient) or membrane surface area. Larger solute removal can be enhanced by increasing dialyzer flux (Kuf) when intermittent HD is used (for toxins with MW between 500 Da and 10,000 Da, e.g., deferoxamine, aminoglycosides) or by introducing convective removal (with HF or HDF), which can allow removal of toxins up to approximately 40,000 Da.

Intermittent HD is usually the first-choice extracorporeal modality because of its common availability, the rapidity of toxin removal, and the low MW of common poisons. The role of other renal replacement modalities is less clear because of a lack of published data.

Peritoneal Dialysis

Peritoneal dialysis is not an "extracorporeal" technique, per se, and is rarely used to treat poisoning because of the comparatively slow rate of clearance, the risks associated with acute peritoneal dialysis catheter

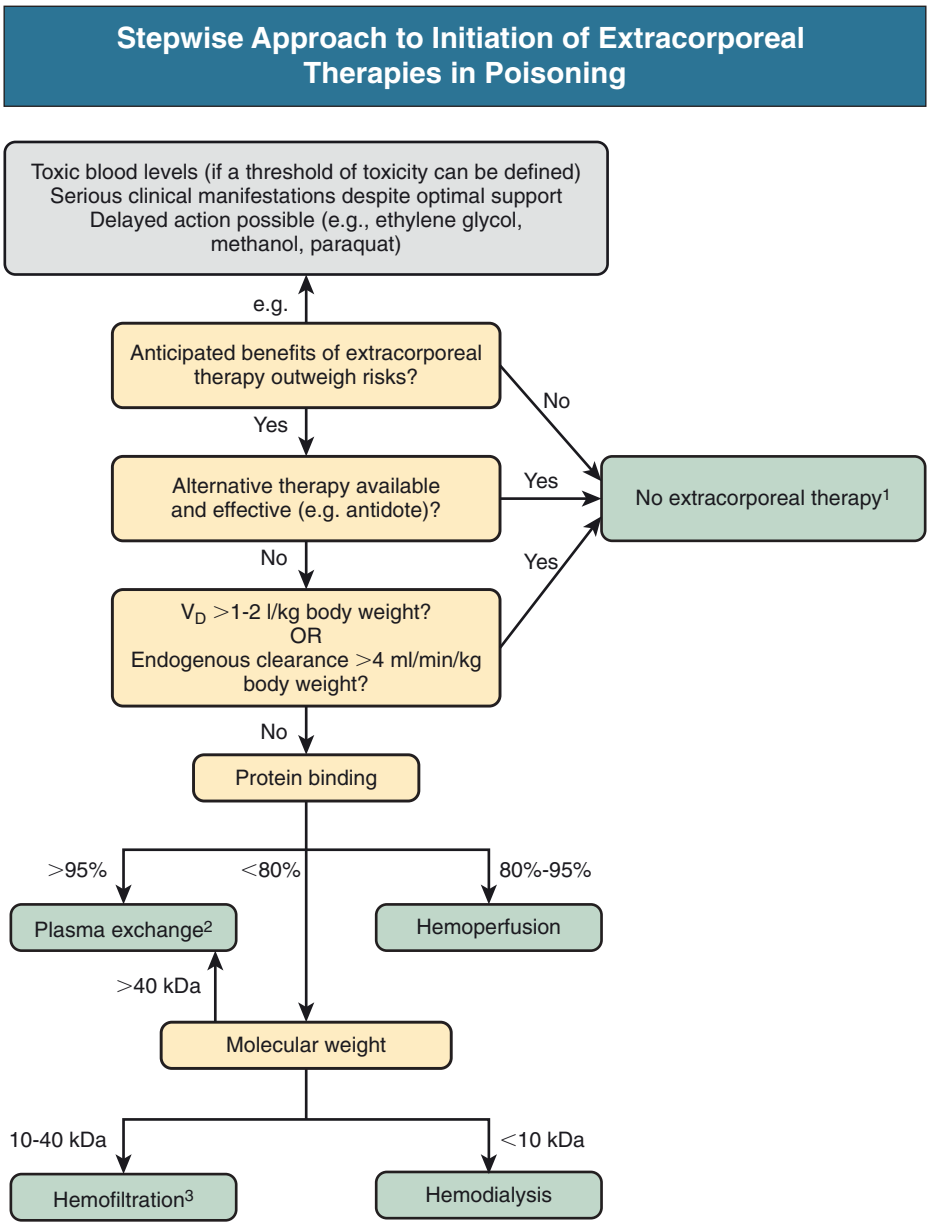

Fig. 98.4 Stepwise approach to the initiation of extracorporeal techniques for enhanced elimination in poisoned patients. [1]Unless other indication (e.g., acute kidney injury [AKI] (e.g., from acetaminophen overdose), severe metabolic acidosis, severe liver failure, hypothermia or hyperthermia). Choice of technique will depend on the indication (e.g., one of the renal replacement therapies for AKI). [2]Or albumin dialysis if available. [3]Or hemodialysis with high cut-off membrane, if available (pore size cut-off ~65 kDa). V_D = Solute volume of distribution. Modified with permission from reference 11.

insertion, and the widespread availability of other modalities, at least in the industrialized world. It may have a role in the treatment of poisoning in childhood because its lower clearance may be sufficient for the smaller solute distribution volumes in children and because of technical challenges associated with HD in very young children.

Continuous Renal Replacement Therapy

CRRT may be used when intermittent HD is not immediately available or when more rapid solute removal would be compromised by significant intercompartmental disequilibrium. For small-solute clearances, continuous HF and continuous HD have near kinetic equivalence. Full saturation of dialysate effluent in continuous HD, because of its slow flow rates, gives a small-solute concentration similar to both the ultrafiltrate from HF and plasma water as it leaves the hollow-fiber device. CRRT gives better solute clearances when applied over the course of several days but elimination is not as rapid as with intermittent HD. Delivered small-solute clearances of CRRT can be maximized by combining diffusion and convection in continuous HDF. If it is logistically possible, an ideal combination may be initial use of intermittent HD for rapid reduction of toxin levels, with continuous therapy then used to ameliorate any postdialysis rebound when this is anticipated.

Although small-solute clearances are similar in continuous HF and continuous HD, the former should be used in preference to remove larger toxins.

Because RRT modalities are often applied for drug elimination in the absence of renal dysfunction or serious electrolyte disturbance,

BOX 98.2 Practical Considerations in Prescribing Extracorporeal Therapy for Poisonings

Intermittent hemodialysis:

- Maximize Qb and dialyzer membrane surface area
- Aim for Qb/Qd ratio of ≥2.5:1 (although diminishing benefits gained from increasing Qd beyond ~600 ml/min)[33]
- Maximize treatment times to at least 4 hours
- Use high-flux (Kuf), high-efficiency (KoA) dialyzer, particularly if middle molecular weight solutes (>1000 Da) are to be cleared

Intermittent hemofiltration/filtrative component of intermittent hemodiafiltration:

- Aim for postdilution fluid replacement to maximize efficiency with high-flux membrane
- Maximize Quf according to filtration fraction*

Continuous renal replacement therapies†:

- Aim for high convective clearances (i.e., postdilutional CVVH with high-flux membrane) for larger solutes (>1000 Da)
- Aim for high diffusive clearances (i.e., CVVHD) for small solutes (≤1000 Da)
- For CVVH, maximize Quf according to filtration fraction*
- For CVVHD, CVVHDF, maximize Qd up to at least 2.5 l/ h‡ for small solutes;
  - for larger solutes (e.g., of an equivalent size to β_2-microglobulin; MW 11,800) there may be little gain from a Qd >1.5 l/h.[34]

Hemoperfusion:

- Limit Qb to ~100 to 250 ml/min (see section on hemoperfusion)
- Change cartridge every 3 to 4 hours
- Consider benefits of charcoal vs resin cartridges depending on poison[15]

Plasma exchange:

- Aim for two plasma volume exchanges per day
- Modify replacement fluid according to poison (see text for details)

*The chief risk with postdilutional fluid replacement is hemoconcentration. This can be minimized by keeping the filtration fraction (FF) ≤50%.

The minimum Qb to achieve this can be calculated from the following formula[35]:

Minimum Qb = Quf/(05 * [1 – Hematocrit])

Alternatively, the maximum Quf would solve as:

Quf = Qb * 05 * (1 – Hematocrit)

In addition, transmembrane pressures should be kept <400 mm Hg to help prevent membrane fiber rupture.

†Aiming for conventional effluent flow rates (i.e., 25 ml/kg/h[36]) for support of the patient with acute kidney injury may fail to maximize potential poison clearances.

‡For small solutes at Qb 150 ml/min, there appears to be a direct linear relationship between increasing clearances and Qd to flow rates of at least 2.5 l/h.[34] It would seem reasonable, therefore, to maximize Qd as machine hardware, dialyzer specifications, and practicalities (fluid availability, nursing workload) allow.

Qb, extracorporeal blood flow; *Qd*, dialysate flow; *Quf*, ultrafiltration rate; *CVVH*, continuous venovenous hemofiltration; *CVVHD*, continuous venovenous hemodialysis; *CVVHDF*, continuous venovenous hemodiafiltration.

Adapted from reference 33, with permission.

careful monitoring for evolving biochemical abnormalities is required. Hypokalemia can be corrected by adjusting the dialysate or replacement fluid composition and by supplementation. Hypophosphatemia can be addressed with standard supplements. At least for intermittent HD, the risk of developing metabolic alkalosis can be attenuated in patients with normal kidney function and baseline serum bicarbonate by using a dialysate bicarbonate concentration at the lower end of the deliverable range. Because the bicarbonate concentration of premanufactured replacement or dialysate fluid in CRRT cannot be manipulated, intermittent HD against a low bicarbonate dialysate may be preferable if severe metabolic alkalosis is present.

Fig. 98.5 A charcoal hemoperfusion cartridge.

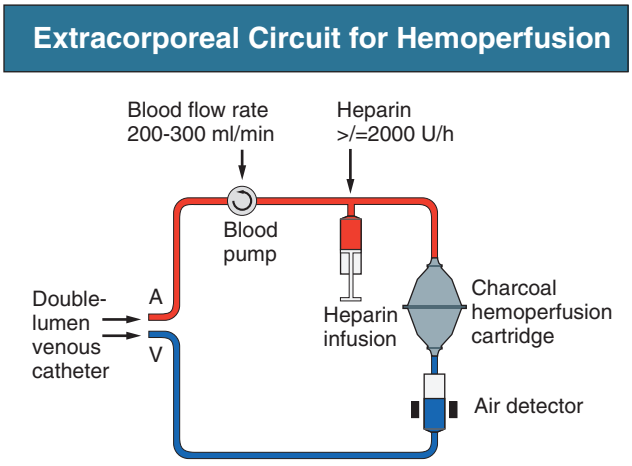

Fig. 98.6 Extracorporeal circuit for hemoperfusion.

Hemoperfusion

The technique involves the extracorporeal circulation of blood through a hemoperfusion cartridge (Fig. 98.5) containing an adsorbent material such as activated charcoal or a resin. Hemoperfusion removes substances that bind to the adsorbent material. It is effective at removing uncharged molecules through competitive binding, especially those that are significantly plasma protein bound and lipophilic, although those toxins exceeding about 5000 to 10,000 Da are less well removed.[15] As with other modalities, the likely proportional contribution to total toxin elimination should be considered before hemoperfusion is begun along with the availability of other, potentially safer techniques such as long-hours, high-flux dialysis (see later).

Other than the cartridge and the lack of dialysate and other replacement fluid circuits, the disposables and hardware are those used for intermittent HD (Fig. 98.6). Blood flows should be limited to approximately 100 to 250 ml/min to minimize the risk of hemolysis during passage through the cartridge.[16]

Standard anticoagulation protocols may be insufficient for hemoperfusion because heparin is also adsorbed. A larger initial bolus and maintenance dose of unfractionated heparin is usually required (e.g., ≥2000 U/h), with adjustments guided by regular monitoring of clotting times during the procedure. The manufacturer's instructions should

be reviewed carefully, because some cartridges require priming with dextrose solution to prevent hypoglycemia. Other complications include hypocalcemia, hypophosphatemia, charcoal embolization, leukopenia, thrombocytopenia (usually uncomplicated and self-limiting), pyrogenic reactions, and adsorption of coagulation factors.[15]

The charcoal sorbent particles may be coated with a polymer or other substance to increase biocompatibility and reduce the risk of embolization. Pretreatment of cartridges with albumin, plasma, or heparin to improve biocompatibility and reduce removal of endogenous molecules is of uncertain benefit.[15]

Saturation of the adsorbent material limits the duration of treatment with any individual hemoperfusion cartridge. It is usually recommended that cartridges are changed approximately every 3 to 4 hours, but treatments of this length are usually adequate for a significant lowering of toxin blood levels.[15]

If a toxin is equally removed by intermittent HD and hemoperfusion, intermittent HD should be used preferentially, because it is less risky and also allows correction of fluid balance, electrolyte status, and other metabolic abnormalities.

Decreasing familiarity with hemoperfusion and increasing scarcity of the requisite cartridges, coupled with the ready availability of alternative treatment (long-hours, high-flux renal support) is likely to propagate this decline in the Western world, although the modality continues to be employed in China, India, and elsewhere.[15]

Other Modalities

Some of the advantages of both continuous and intermittent RRTs are combined in the hybrid modalities, such as sustained low-efficiency dialysis (SLED), but these require further evaluation.

There are a few reports of the use of plasma exchange and the molecular adsorbent recirculating system (MARS) in poisoning. In principle, both should be useful for toxins that are strongly protein bound but not lipid soluble, are tissue bound, or have a large V_D outside the blood compartment.[17] Plasma exchange is most commonly used in *Amanita phalloides* poisoning but also has been reported to prevent limb loss in snake envenomation and reduce toxic levels of biologic therapeutic agents (e.g., monoclonal antibodies).[17] Plasma exchange can clear the red cell fragments and free hemoglobin that result from poisoning with sodium chlorate or other agents that can cause hemolysis. The replacement fluid used in plasma exchange warrants some consideration because the plasma free fraction of toxins that are highly albumin-bound may rebound after treatment if insufficient albumin is administered.[17] Some toxins have a greater affinity for other plasma proteins such as α1-acid glycoprotein than for albumin (e.g., dipyridamole, quinidine, imipramine, propranolol, and chlorpromazine) arguing for the use of plasma- rather than albumin-based replacement in these situations.[17] Plasma replacement may be preferable where there is a significant coagulopathy, such as in certain instances of snake envenomation.[17] One to two plasma volume exchanges per day is likely to be sufficient until toxic manifestations and tissue release have subsided.[17]

Exchange transfusion may be useful in neonates and small children who have been poisoned with toxins that have a low volume of distribution (e.g., theophylline, salicylates).[11]

EXTRACORPOREAL THERAPY FOR SPECIFIC DRUGS AND POISONS

Alcohols

Ethylene glycol (MW 62 Da) and methanol (MW 32 Da) can be found in antifreeze, de-icing solutions, and windscreen cleaning fluid. The ingestion of as little as 1 g/kg body weight of either methanol or ethylene glycol is potentially lethal. Toxicity results from the metabolism of ethylene glycol and methanol by alcohol dehydrogenase to glycolic acid and formic acid, respectively, and may result in optic nerve damage, seizures, coma, and ultimately death. Poisoning should be suspected in any patient presenting with nausea, vomiting, abdominal pain, impaired consciousness, severe metabolic acidosis, and acute kidney injury (AKI).

Early recognition of ethylene glycol or methanol poisoning may allow treatment with ethanol or fomepizole to inhibit hepatic alcohol dehydrogenase. Fomepizole has now replaced ethanol as first-line therapy[18,19] because it is safe and is better tolerated.

Fomepizole should be prescribed if there is a clear history of ethylene glycol and/or methanol ingestion, if the osmol gap is greater than 10 mOsm/kg, or the ethylene glycol/methanol blood level is greater than 20 mg/dl (3.2 mmol/l for ethylene glycol and 6.2 mmol/l for methanol). Fomepizole is administered as a loading dose of 15 mg/kg intravenously (IV). This is followed by 10 mg/kg every 12 hours for 4 doses and then 15 mg/kg every 12 hours until the metabolic acidosis has resolved and the serum concentration of ethylene glycol and methanol is less than 20 mg/dl (or <10 mg/dl in the presence of end-organ damage). Patients who have ingested methanol also should receive folinic acid 50 mg IV every 6 hours to enhance the metabolism of formic acid. The administration of thiamine 100 mg IV or pyridoxine 50 mg IV should be considered in patients with poor nutritional status after ethylene glycol ingestion. If fomepizole is not available, intravenous 10% ethanol should be administered as a loading dose of 800 mg/kg followed by an infusion of 80 to 160 mg/kg/h to achieve a serum ethanol concentration of 1 to 1.5 g/l. Ethanol should be administered until no ethylene glycol or methanol is detectable in the blood. Intravenous sodium bicarbonate should be considered to help correct any associated metabolic acidosis.

Ethylene glycol and methanol have low MWs, limited protein binding, single-compartment kinetics, and a limited volume of distribution. Immediate HD is recommended if ingestion of ethylene glycol or methanol is confirmed with a serum concentration greater than 50 mg/dl (8.1 mmol/l for ethylene glycol and 15.6 mmol/l for methanol) in the setting of coma, seizures, severe metabolic acidosis (pH 7.15), or the presence of end-organ damage such as AKI or visual disturbance. Because fomepizole is removed by HD, a maintenance infusion of 1 to 1.5 mg/kg/h should be prescribed for the duration of the HD session after administration of the loading dose. Similarly, ethanol doses should be doubled during the dialysis session.

To achieve optimal clearance the dialyzer should have a large surface area (>1.5 m^2) and the blood flow rate should be greater than 300 ml/min. Bicarbonate buffer should be used and serum concentrations of ethylene glycol and methanol should be measured 2 hours after the treatment to take account of rebound. HD should continue until the pH has normalized and the concentration of ethylene glycol or methanol is below 25 mg/dl (4.0 mmol/l for ethylene glycol and 7.8 mmol/l for methanol). Patients who have ingested large quantities of ethylene glycol and methanol may require further HD treatment.

The EXTRIP workgroup recommends intermittent HD as the modality of choice; continuous modalities are acceptable if intermittent HD is not available, although they are not as effective at removing methanol.[20]

β-Blockers

β-Blocker overdose will manifest with bradycardia and hypotension and may also include altered mental state, seizures, bronchospasm, hypoglycemia, and cardiogenic shock. Extracorporeal removal is rarely required unless patients have not improved despite maximal medical therapy. Extracorporeal treatment is only effective for hydrophilic, minimally protein-bound drugs such as atenolol, sotalol, nadolol, and acebutolol. Propranolol, timolol, and metoprolol are not removed. Intermittent HD is recommended in hemodynamically stable patients. CRRTs may be considered in patients who are hemodynamically unstable.

Lithium

Severe lithium poisoning may manifest with arrhythmias, hypotension, confusion, coma, or seizures. Lithium (MW 7 Da) is removed easily by HD because of its low MW and negligible protein binding. The clearance of lithium by HD is superior to that achieved by the kidneys, which is limited by significant proximal tubular reabsorption. HD is recommended if the serum lithium concentration is greater than 4 mmol/l or greater than 2.5 mmol/l in a patient with central nervous system manifestations.[12] Lithium equilibrates relatively slowly between the extracellular and intracellular compartments; thus postdialysis rebound may be significant[21] and extended or frequent HD treatment may be needed to minimize its impact. Serum lithium levels should be checked 6 hours postdialysis to guide further therapy. CRRT may complement intermittent HD by helping mitigate the impact of the postdialysis rebound.

Metformin

Patients who have taken an overdose of metformin (MW 166 Da) may present with tachypnea, nausea, abdominal pain, tachycardia, hypotension, and, in the setting of AKI, severe lactic acidosis. Metformin is normally excreted unmetabolized by the kidneys and has negligible protein binding. Metformin causes lactic acidosis by inhibiting hepatic gluconeogenesis from lactate and promoting the conversion of glucose to lactate in the small intestine. Medical management involves supportive measures and the intravenous administration of sodium bicarbonate. Extracorporeal therapy is recommended in patients who are unresponsive to medical management.[22] Both intermittent HD and CRRT can provide effective extracorporeal removal.

Salicylates

The clinical manifestations of salicylate overdose include fever, sweating, tinnitus, epigastric pain, nausea, vomiting, diarrhea, vertigo, and blurring of vision. Severe overdoses may progress to depression of mental state, noncardiogenic pulmonary edema, and death. Salicylate intoxication initially results in hyperventilation and respiratory alkalosis. This is followed by metabolic acidosis secondary to the accumulation of lactic acid and ketoacids. Therefore patients may present with either respiratory alkalosis or mixed respiratory alkalosis–metabolic acidosis. Diagnosis is based on the presenting history and clinical examination and confirmed with plasma salicylate levels.

Increased salicylate tissue penetration and toxicity can occur with only small decreases in pH as a result of increased concentration of nonionized salicylate. Intravenous sodium bicarbonate should be given to decrease tissue penetration and facilitate the excretion of salicylate through the kidneys unless the patient has oliguric AKI, pulmonary edema, or cerebral edema.

Although salicylate (MW 180 Da) is 90% protein-bound, saturation of protein binding in significant poisoning and its limited volume of distribution makes it amenable to removal by dialysis. Extracorporeal therapy is recommended in patients with severe salicylate poisoning, reflected by altered mental state, the acute respiratory distress syndrome, and failure to respond to medical management irrespective of salicylate levels. Extracorporeal therapy is also indicated, regardless of signs and symptoms, at levels greater than 100 mg/dl (7.2 mmol/l). Lower thresholds are applied for patients with AKI. Intermittent HD carries advantages over hemoperfusion because the former allows rapid correction of associated electrolyte abnormalities and acidemia. CRRT is acceptable if intermittent HD is not available.[23]

Theophylline

Theophylline (MW 180 Da) overdose manifests with nausea, vomiting, diarrhea, gastrointestinal hemorrhage, hypokalemia, seizures, arrhythmias, and hypotension. Overdose may be acute or chronic. Theophylline is readily cleared by either HD or hemoperfusion because of its low volume of distribution and minimal protein binding. Extracorporeal therapy is recommended for severe acute theophylline poisoning (theophylline level >100 mg/l [555 μmol/l], or the presence of seizures, life-threatening arrhythmias, shock, or failure of standard therapy). In chronic poisoning, extracorporeal therapy is suggested if theophylline levels are greater than 60 mg/l (333 μmol/l) or greater than 50 mg/l (278 μmol/l) and the patient is older than 60 years of age. High-flux, high-efficiency HD is more effective in removing theophylline than hemoperfusion and is associated with fewer side effects. Continuous venovenous HF can be used but requires a more sustained period of treatment.[24]

Valproate

Although valproate (MW 144 Da) is highly protein bound, saturation of protein binding after significant poisoning makes it amenable to removal by extracorporeal therapy. Overdose may manifest with mild confusion, lethargy, nausea, vomiting, tachycardia, hypotension, metabolic acidosis, and electrolyte disturbances (hyponatremia and hypocalcemia). Extracorporeal therapy is recommended for severe overdose (valproate level >1300 mg/l [9000 μmol/l], cerebral edema, or shock). Extracorporeal therapy can be considered for valproate concentrations above 900 mg/l (6250 μmol/l), coma or respiratory depression requiring ventilation, acute hyperammonemia, or pH less than 7.10. HD is preferred to hemoperfusion because it not only clears unbound drug but also reverses associated metabolic abnormalities.[25]

Tricyclic Antidepressant Drugs

Extracorporeal therapy is not likely to have any clinical benefit for patients who have experienced an overdose with TCA drugs.[26]

Thallium

Thallium (MW 204 Da) poisoning continues to be reported where it is used as a rodenticide and a contaminant of herbal and illicit drug products (see reference list in reference 27). It is absorbed extensively through almost all routes of exposure and is widely distributed across multiple body compartments. Toxicity is caused by thallium replacing potassium as a stimulator or inhibitor of a variety of intracellular electrochemical and enzymatic processes. Despite a lack of high-quality evidence and as a result of the severe toxicity of thallium and a lack of alternative therapies, extracorporeal therapy is strongly recommended.[27] Intermittent HD is preferable, but hemoperfusion and CRRT are valid alternatives.

Barbiturates

Although barbiturate overdose is less common, it is still a significant cause of fatal poisoning. It is recommended that extracorporeal therapy be restricted to cases of severe long-acting barbiturate poisoning with clinical features including prolonged coma, respiratory depression requiring ventilation, shock, and a failure to treat effectively with multiple-dose activated charcoal; intermittent HD is the preferred mode of therapy.[28]

Acetaminophen

There is a paucity of high-quality evidence for the extracorporeal removal of acetaminophen (MW 46 Da), although it may have a role in the rare cases when *N*-acetylcysteine has not been effective; intermittent HD is the preferred modality.[29]

Carbamazepine

Carbamazepine (MW 236 Da) is moderately well dialyzed, with intermittent HD being the favored modality for severe poisoning (coma,

respiratory depression requiring ventilation, or carbamazepine levels that do not respond to standard therapy with activated charcoal). If HD is not available, hemoperfusion or CRRT can be considered.[30]

Phenytoin

Phenytoin (MW 252 Da) has a large volume of distribution and is extensively protein bound (90%) but dissociates easily and is amenable to extracorporeal removal. However, phenytoin poisoning rarely causes permanent organ damage or death, and so extracorporeal therapy is recommended only in very severe cases of poisoning that have been resistant to standard therapy.[31] Enteral absorption of phenytoin is slow and unpredictable, so vigilance should be maintained for the delayed effects of poisoning.

Digoxin

Digoxin (MW 781 Da) has variable absorption from the gut depending on the size of the ingestion. Although it is 20% to 30% protein bound, it also has a large volume of distribution and an effective antidote (digoxin immune Fab) so extracorporeal therapy is not useful in the management of overdose.[32]

SELF-ASSESSMENT QUESTIONS

1. Which one of the following statements is *true* regarding ethylene glycol toxicity?
   - **A.** Ethylene glycol is metabolized to glycolic acid.
   - **B.** Ethylene glycol is metabolized to formic acid.
   - **C.** Ethylene glycol is metabolized by alcohol hydrogenase.
   - **D.** Urinalysis demonstrates uric acid crystals.
   - **E.** Ethylene glycol toxicity is associated with a normal anion gap
2. Which one of the following is not associated with a raised osmolar gap?
   - **A.** Ethylene glycol intoxication
   - **B.** Methanol intoxication
   - **C.** Isopropanol intoxication
   - **D.** Diabetic ketoacidosis
   - **E.** Acute kidney injury
3. Intermittent hemodialysis (HD) is not effective for removal of which of the following in overdose?
   - **A.** Lithium
   - **B.** Ethylene glycol
   - **C.** Metoprolol
   - **D.** Atenolol
   - **E.** Methanol
4. Which one of the following statements is true:
   - **A.** Hemoperfusion remains the 1st choice treatment for removal of theophyllines.
   - **B.** If endogenous clearance rates of toxins are < 10 ml/min/kg body weight, extracorporeal treatment should be considered.
   - **C.** Highly protein-bound toxins are not suitable for extracorporeal treatment.
   - **D.** When continuous veno-venous hemofiltration is used, solely, for poison removal, conventional doses used for patients with AKI should be utilized.
   - **E.** Toxin rebound after intermittent hemodialysis may be mitigated by frequent scheduling of treatment or adjunctive therapy with one of the continuous renal replacement therapies.

Plasma Exchange

Jeremy Levy

Over the last 10 years, it has become clearer how best to use plasma exchange (plasmapheresis) in the management of renal disease, but the quality of published data is relatively poor, with less than 1% of relevant literature in the form of randomized controlled trials (RCTs). Plasma exchange came into widespread clinical use after early reports of beneficial effects in Goodpasture disease in the mid-1970s. It is used to remove many large molecular weight (MW) substances from plasma, including pathogenic antibodies, cryoglobulins, and lipoproteins. Newer techniques allow more selective removal of plasma components, such as double-filtration plasma exchange, cryofiltration, and immunoadsorption with or without immobilized ligands. The most common renal indications recorded in the Canadian Apheresis Registry in 2014 (in order of frequency) were thrombotic thrombocytopenic purpura/hemolytic-uremic syndrome (TTP/HUS), renal transplantation (antibody-mediated rejection and for desensitization either for anti-ABO blood group antibodies or anti–human leukocyte antigen [HLA] antibodies), antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis, cryoglobulinemia, recurrent focal segmental glomerulosclerosis (FSGS), and anti–glomerular basement membrane (anti-GBM) antibody disease.

TECHNIQUES

Plasma exchange can be carried out either by centrifugal cell separators or (more commonly in renal units) with hollow-fiber plasma filters and standard hemodialysis (HD) equipment (Figs. 99.1 and 99.2). Centrifugal devices allow withdrawal of plasma from a bowl with either synchronous or intermittent return of blood cells to the patient.[1] There is no upper limit to the MW of proteins removed by this method. The bowls and circuits are single use and disposable and require relatively low blood flow rates (50 to 150 ml/min) that can be delivered through large-bore peripheral cannulae. Platelet counts can decrease by as much as 50%, with centrifugal devices, although this has improved with newer technologic approaches and is usually less than 10%. Membrane plasma filtration uses highly permeable hollow fibers with membrane pores 0.2 to 0.5 μm. Plasma readily passes through the membrane while the cells are simultaneously returned to the patient. All immunoglobulins will cross the membrane (immunoglobulin G [IgG] slightly more efficiently than IgM), and molecules up to 3 million d are cleared. Hemolysis can occur if transmembrane pressures are too high (a rare complication). The blood flow rates required for membrane plasma filtration are higher than for centrifugal cell separators (100 to 300 ml/min) and require central venous access or a fistula; there is no increase in rate of plasma filtration at blood flows greater than 300 ml/min, but there is an increased risk for hemolysis. Membrane exchange takes slightly longer than centrifugal techniques for the same plasma volume removal. Membranes used in plasma filters are polysulfone, polypropylene, cellulose diacetate, polymethylmethacrylate, and polyacrylonitrile.[1] It has been suggested that the adsorptive properties of the membrane for cytokines and other biomolecules may account for some of the beneficial effects of plasma filtration. There have been occasional reports of mild adverse reactions in patients taking angiotensin-converting enzyme inhibitors when plasma is filtered with ethylene vinyl alcohol or acrylic copolymer membranes. Reuse of plasma filters is not advised because of potential risks resulting from loss of filtration capacity and to staff from cleaning procedures, but performance data do not indicate a major loss of function during routine plasma exchange. For patients with severe renal failure, sequential HD and plasma exchange can easily be performed with plasma filtration.

Vascular access is usually achieved using standard central venous catheters, but existing arteriovenous fistulas (AVFs) can be used if available. Sometimes plasma exchange can be done using large-bore, short intravenous cannulas placed in the antecubital fossa, especially with centrifugal devices. Single-needle access using an AVF is also relatively easy to accommodate, especially for centrifugal plasma exchange, in which the blood removal and return can be asynchronous, but also for membrane filtration. Anticoagulation must be carefully managed in patients at higher bleeding risk (e.g., thrombotic microangiopathy [TMA], recent or ongoing pulmonary hemorrhage, or a recent renal biopsy). Citrate is used for anticoagulation with centrifugal plasma exchange and heparin for membrane plasma filtration; however, citrate is superior for patients at higher bleeding risk in view of its lack of systemic anticoagulation.[1] When heparin is used, higher doses may be needed than in HD as a result of increased losses during the procedure (heparin is protein bound). Bolus doses of unfractionated heparin of 2000 to 5000 U are given initially and then 500 to 2000 U/h. Anticoagulant is administered prefilter. Increasingly low molecular weight heparin (LMWH) is also used with a single bolus dose at initiation of exchange.

Both methods of plasma exchange require large volumes of colloid replacement. A single plasma volume exchange will lower plasma macromolecule levels by approximately 60%, and five exchanges over 5 to 10 days will clear 90% of the total body immunoglobulin (Fig. 99.3).[1,2] For most patients, this is achieved by removing 50 ml of plasma per kilogram body weight at each procedure (~4 liters for a 75-kg person). Daily plasma exchange more rapidly depletes total body load of immunoglobulins, but there is no good evidence that intensity of exchanges has a major effect on outcomes except in patients with HUS with poor prognostic markers (see later discussion). Indeed, alternate-day exchanges are of proven efficacy in ANCA-associated diseases. Replacement solely with crystalloid is contraindicated because of the need to maintain colloid oncotic pressure. Synthetic gelatin–based plasma expanders or hydroxyethyl starch (Hespan) can be used as part of a replacement regimen but have been reported to cause a coagulopathy in patients with sepsis and have a shorter half-life than

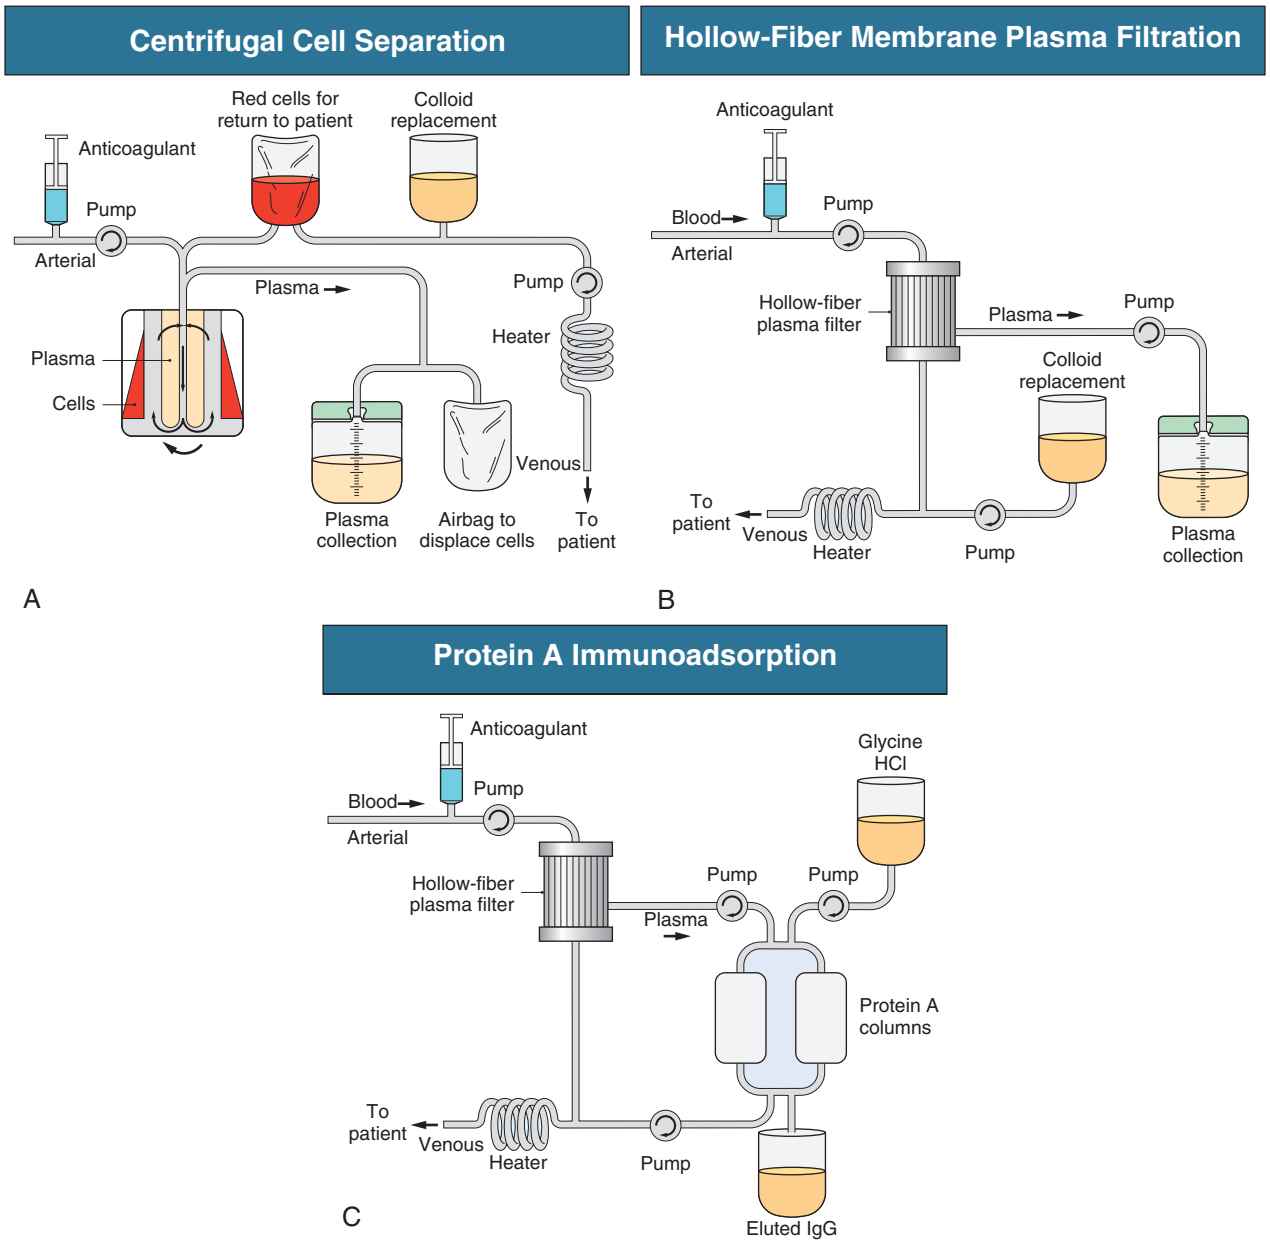

Fig. 99.1 Plasma exchange and immunoadsorption techniques. Techniques include centrifugal cell separation (A), hollow-fiber membrane plasma filtration (B), and protein A immunoadsorption (C). *IgG,* Immunoglobulin G.

human albumin, which is the main replacement fluid. The major disadvantage of albumin solutions is the lack of clotting factors, with the potential development of depletion coagulopathy after plasma exchange. Fresh-frozen plasma (FFP) should be given, usually in addition to human albumin solution, in patients at particular risk for bleeding. If partial replacement is with FFP, this should be given late during the exchange so the constituents are not removed by the ongoing plasma exchange. However, almost all the serious complications of plasma exchange (hypotension, anaphylaxis, citrate-induced paresthesia, urticaria) have been reported in patients receiving FFP rather than albumin (see later discussion).[1,3] Both human products carry a tiny risk for transmission of infectious diseases, especially viral. Standard regimens for plasma exchange are summarized in Table 99.1. Human albumin solution (4% to 5%) should be used for all exchanges except in TMAs (in which plasma should provide the total exchange), and FFP should form part of the exchange when bleeding risk is high (ongoing pulmonary hemorrhage or within 48 hours of biopsy or surgery). If fibrinogen levels decrease to below 1.25 to 1.5 g/l or prothrombin time is increased 2 to 3 seconds above normal, FFP should be administered (Table 99.2).

Double-filtration plasma exchange (or cascade filtration) uses membrane filtration to separate cells from plasma and then a secondary plasma filtration (pore size 0.01 to 0.03 μm) to remove plasma solutes based on molecular size. Most albumin is therefore returned to the patient, together with lower MW proteins, reducing the need for replacement fluids. Cryofiltration uses a similar principle but exposes the filtrate

TABLE 99.1 Practical Regimens for Plasma Exchange in Renal Disease

Indication	Anti–Glomerular Basement Membrane Antibody (anti-GBM) Disease	Small-Vessel Vasculitis	Cryoglobulinemia	Recurrent FSGS After Transplantation	HUS/TTP
Duration of treatment	Daily, at least 14 days until anti-GBM antibodies 20% of baseline	Daily or alternate daily, 7-10 days depending on clinical response	At least 7-10 days or until clinical response	Daily, at least 10 days initially, then continuing less frequently, often for months	Daily for 7-10 days or until platelet count 80-100 $\times 10^9$/l (sometimes needed twice daily)
Exchange volume	50 ml/kg each treatment	As for anti-GBM disease	As for anti-GBM disease	As for anti-GBM disease	As for anti-GBM disease
Replacement fluid	Human albumin 5% (unless bleeding risk)	As for anti-GBM disease	As for anti-GBM disease	As for anti-GBM disease	Fresh-frozen plasma (FFP) or cryo-poor FFP
Additions to replacement fluid	20 ml 10% calcium gluconate (occasionally more), 3 ml 15% KCl if not dialysis dependent, heparin 2000-5000 U bolus, then 500-2000/h, (LMWH an alternative with bolus only) *or* citrate anticoagulation	As for anti-GBM disease	As for anti-GBM disease	As for anti-GBM disease	As for anti-GBM disease (may need more calcium because of increased volume of FFP-containing citrate)
Immunosuppression	See Chapter 24	See Chapter 25	See Chapter 21	See Chapter 29	See Chapter 29
Variations	FFP 5-8 ml/kg at end of exchange volume if hemorrhage risk (renal biopsy in last 48 h, lung hemorrhage, platelets <40 $\times 10^9$/l, fibrinogen <1.5 g/l); immunoadsorption may be as effective	As for anti-GBM disease Immunoadsorption may be as effective	As for anti-GBM disease	As for anti-GBM disease; may need to include replacement immunoglobulins if continuing long term; immunoadsorption may be as effective	

FSGS, Focal segmental glomerulosclerosis; *HCV,* hepatitis C virus; *HUS,* hemolytic-uremic syndrome; *TTP,* thrombotic thrombocytopenic purpura.

TABLE 99.2 Investigations To Be Undertaken Before Every Plasma Exchange Session

Investigation	Action To Be taken
Platelet count	Caution with undertaking plasma exchange if platelet count less than 40×10^9/L unless disease itself associated with thrombocytopenia (e.g., aHUS/TTP), and use FFP as part of replacement fluid.
Plasma fibrinogen	If <150 mg/dl, should use FFP as part of exchange fluid.
Prothrombin time	If prolonged more than 2-3 seconds, use FFP as part of exchange fluids.
Serum calcium	If <2.1 mmol/l (<8.4 mg/dl), increase amount being provided with replacement albumin/FFP.
Serum potassium	Can be very variable depending on changing renal function in addition to plasma exchange treatment; adjust potassium replacement according to serum potassium.

aHUS, Atypical hemolytic-uremic syndrome; *FFP,* fresh-frozen plasma; *TTP,* thrombotic thrombocytopenic purpura.

to 4° C during the procedure, with the aim of precipitating cryoproteins. These techniques are not widely available.

Selective and specific immunoadsorption techniques are increasingly available. Protein A immunoadsorption has been used to remove immunoglobulin alone from plasma, without the need for replacement fluids and without depletion of clotting factors and complement (see Fig. 99.1C). Protein A selectively binds the Fc domains of immunoglobulin molecules, and the immunoadsorption columns can be repeatedly regenerated. Columns have been used for 1 year for a single patient on up to 30 occasions; however, the repeated acid stripping during regeneration reduces the efficacy of antibody binding. This technique has been used to treat conditions in which autoantibodies are thought to be important and usually in place of plasma exchange (e.g., Goodpasture disease, rheumatoid arthritis, lupus, or systemic vasculitis) and to remove anti-ABO or anti–HLA antibodies in highly sensitized transplant recipients. In general, the reported efficacy has been equal to that of plasma exchange, although if used over the long term, immunoadsorption can be much more cost-effective in single patients because there is no requirement for replacement albumin or plasma. Specific ligands also have been immobilized onto columns for more specific removal of potentially pathogenic serum factors; ligands used include anti–human IgG, C1q, phenylalanine, hydrophobic amino acids, acetylcholine receptor, β-adrenoreceptor peptides, and blood group–related oligosaccharides. Immunoadsorption of all varieties is not widely available because the initial column costs are high and few centers have much clinical experience. Costs of all other plasma exchange modalities are dominated by the costs of replacement albumin and plasma; equipment costs do not vary much among modalities, and all require skilled and trained nursing staff. Plasma filtration requires minimal extra support or training for dialysis nurses because the equipment is very similar to normal HD machines.

COMPLICATIONS

The complication rate of plasma exchange is not high.[3] The Swedish registry reported no fatalities during 20,485 procedures and an overall adverse incidence rate of only 4.3% of all exchanges (0.9% for severe adverse events) of which 27% were paresthesias, 19% transient hypotension, 13% urticaria, and 8% nausea.[4] The Canadian Apheresis Registry collected data on 144,432 apheresis procedures since 1981 and reported adverse events occurring in 12% of procedures (mostly minor) and overall in 40% of patients. Severe events occurred in only 0.4% of procedures. Three deaths were probably related directly to the procedure: one from a transfusion-related acute lung injury and two from complications from central venous catheters.[5] An overall complication rate of 1.4% has been reported in more than 15,000 treatments in patients receiving albumin and 20% in patients receiving FFP.[1,3,5,6] Plasma exchange by centrifugation had a lower risk for adverse events than by filtration.

Other complications directly attributable to plasma exchange include citrate-induced hypocalcemia (presenting with perioral tingling and paresthesias) and citrate-induced metabolic alkalosis. Citrate is usually present in FFP (up to 14% by volume) or is administered in the extracorporeal circuit as an anticoagulant; it binds free calcium in plasma. Symptomatic hypocalcemia can be averted by infusing 10 to 20 ml of 10% calcium gluconate during each plasma exchange. Alkalosis is rare and is caused by metabolism of citrate to bicarbonate and failure to excrete the latter in patients with renal impairment.

Plasma exchange predictably increases the risk for bleeding by depleting coagulation factors in patients receiving albumin as sole replacement colloid. Prothrombin time is increased by 30%, and partial thromboplastin time by 100% after a single plasma volume exchange. Patients at risk for bleeding (pulmonary hemorrhage, postbiopsy, postoperative) should receive FFP (300 to 600 ml) with replacement fluids. Dilutional hypokalemia is avoided by replacing potassium according to daily blood testing. An increased incidence of infection secondary to hypogammaglobulinemia has not been confirmed in recent series.[3-6] Sepsis related to intravenous access is the most common infectious complication of plasma exchange. Hypotension can occur for a variety of reasons related to extracorporeal circuits, sepsis, and allergic reactions, but also if saline is used for exchanges with a concomitant reduction in serum oncotic pressure during the procedure. Cascade filtration can lead to hemolysis (in up to 20% patients) but rarely necessitates transfusion.

MECHANISMS OF ACTION

The pathogenicity of autoantibodies in anti-GBM disease (Goodpasture disease) provided the impetus for development of plasma exchange therapy, but it is now clear that antibodies, although necessary, are not alone sufficient to cause the necrotizing glomerulonephritis (GN) in that disease. Plasma exchange, however, removes all large MW substances from the plasma in addition to antibodies, including complement components, immune complexes, endotoxin, lipoproteins, and von Willebrand factor (vWF) multimers. In animal studies, for example, complement depletion abrogates anti-GBM GN very effectively. Therefore plasma exchange may well have benefits in addition to clearance of autoantibodies.

The clearance of antibodies from patients is variable and depends on several factors, including the rate of equilibration of macromolecules between the intravascular and extravascular compartments. IgM antibodies are cleared more effectively than other classes of immunoglobulin because they are retained in the vascular compartment almost wholly. A rebound increase in antibody production will occur unless there is concomitant immunosuppression to prevent resynthesis.

Plasma exchange has been shown to remove immune complexes, which may have clinical significance in cryoglobulinemia and systemic lupus, and fibrinogen and complement components. There is no good evidence that removal of cytokines has any clinical significance. Plasma

exchange reduces plasma viscosity, with consequent improved blood flow in the microvasculature. There is also some evidence for improvement in monocyte/macrophage function, alteration in lymphocyte function, and sensitization of antibody-producing cells to immunesuppressive drugs after plasma exchange.

INDICATIONS FOR PLASMA EXCHANGE

Evidence to support specific indications for plasma exchange is variable in quality. Direct comparison among RCTs can be unsatisfactory because of variations in dose and frequency of plasma exchange and in immunosuppressive and other adjunctive therapy. The American Society for Apheresis (ASFA) reviewed all indications for plasma exchange most recently updated in 2016 and summarized available trial data.[7,8] In this chapter, evidence from available randomized trials is discussed alongside observational data. The indications are summarized in Tables 99.3 and 99.4.

Anti–Glomerular Basement Membrane Antibody Disease (Goodpasture Disease)

Most patients can be depleted of pathogenic anti-GBM antibodies after 7 to 10 plasma volume exchanges if further antibody synthesis is inhibited by the concurrent use of cyclophosphamide and corticosteroids. Before plasmapheresis, the mortality from Goodpasture disease was higher than 90%, and only 11% of patients who were not dialysis-dependent at presentation survived with preserved renal function. The use of plasma exchange improved the outcome considerably: 70% to 90% of patients now survive. However, only 50% of survivors retain independent renal function and no more than 10% of those who are dialysis dependent at presentation. There has been only one small controlled trial of plasma exchange in the treatment of Goodpasture disease, which used a low intensity of plasma exchange.[7,9] A total of 17 patients were randomized to receive corticosteroids and cyclophosphamide, with or without plasma exchange. Only 2 of the 8 who received plasma exchange developed end-stage renal disease (ESRD) compared with 6 of the 9 who received drugs alone.

Long-term data from 71 patients with Goodpasture disease confirmed the benefit of a treatment regimen including plasma exchange because most patients with mild to moderate renal failure retained independent renal function over 10 to 25 years,[10] and renal recovery was possible even in some of those with the most severe renal disease. Very similar results were identified in the largest reported series from China. Combining all the available published data for patients with Goodpasture disease, 76% of patients presenting with serum creatinine below 5.5 to

TABLE 99.3 Conditions for Which There Is Strong Evidence for the Benefit of Plasma Exchange

Indication	Randomized Controlled Trials (No. Patients)	Controlled Trials (No. Patients)	Case Series (No. Patients)	Replacement Fluid	Comments
ANCA-associated systemic vasculitis	8 (300)	1 (26)	22 (347)	Albumin unless pulmonary hemorrhage or need to prevent coagulopathy	Proven benefit only in dialysis-dependent patients. Should consider daily exchanges in fulminant cases or with pulmonary hemorrhage.
Anti–glomerular basement membrane antibody disease	1 (17)	0	9 (468)	Albumin unless pulmonary hemorrhage or need to prevent coagulopathy	Minimum course 14 days to remove antibodies effectively. Especially beneficial in nonoliguric patients predialysis. Patients with creatinine >5.5 mg/dl (500 μmol/l) unlikely to benefit.
Cryoglobulinemia	1 (57) (and 1 using immunoadsorption; 17 patients)	0	24 (302)	Albumin	Long-term maintenance treatment needed in some patients. Ensure blood warmer on return lines or warm replacement fluids.
Thrombotic thrombocytopenic purpura	7 (301)	2 (133)	38 (1541)	Plasma or cryo-poor plasma	Daily. Often with corticosteroids. The only treatment that has improved mortality.
ABO-incompatible kidney transplantation	0	0	>21 (>750)	Albumin ± plasma (compatible with donor and recipient or AB)	Used pretransplant to reduce titers of antibodies and often continued for a few days after surgery to allow successful transplantation.
Antibody-mediated kidney transplant rejection	3 (61)	8 (342)	37 (727)	Albumin	Daily or alternate day. Usually with IVIG and sometimes enhanced immunosuppression
HLA desensitization for transplantation (in highly sensitized patients)	0	5 (441)	29 (466)	Albumin	Always in combination with immunosuppression and usually IVIG, and continued until cross-match negative. Usually five plasma exchanges are needed to reduce Ab levels sufficiently.

ANCA, Antineutrophil cytoplasmic antibody; *HLA,* human leukocyte antigen.

TABLE 99.4 Conditions for Which There Is Some Evidence for Plasma Exchange

Indication	Randomized Controlled Trial (No. of Patients)	Controlled Trials (No. of Patients)	Case Series (No. of Patients)	Replacement Fluid	Comments
Catastrophic antiphospholipid antibody syndrome	0	0	6 (109)	Plasma	Should be done daily. Combination of plasma exchange or IVIG, heparin, and corticosteroids (from registry data) gives best outcomes.
Recurrent FSGS after transplantation	0	3 (48)	49 (224)	Albumin	Sometimes in combination with rituximab. May need long-term maintenance treatment.
Atypical hemolytic-uremic syndrome	0	0	10 (200)	Plasma or cryo-poor plasma	Daily plasma exchange initially. Eculizumab preferred treatment if available.
Myeloma	5 (182)	0	8 (102)	Albumin	Daily or alternate day for 7-10 exchanges. Despite negative randomized trial in 2005, plasma exchange might be considered if high light-chain load, severe renal failure, and oliguria and light chains not depleted with urgent chemotherapy.
Rapidly progressive glomerulonephritis (may include patients with ANCA-associated disease in older literature)	7 (196)	0	21 (295)	Albumin	No good evidence for benefit in immune complex disease of any cause. Small case series of benefit in crescentic IgA vasculitis (Henoch-Schonlein purpura) with RPGN.
Scleroderma	0	3 (75)	7 (70)	Albumin	No good evidence for benefit, but some patients have reported improvement.
Systemic lupus (not nephritis)	1 (20)	1 (4)	14 (128)	Albumin	For cerebritis, lupus-associated TTP, severe hemolysis, or pulmonary hemorrhage.

ANCA, Antineutrophil cytoplasmic antibody; *FSGS,* focal segmental glomerulosclerosis; *IVIG,* intravenous immunoglobulin; *RPGN,* rapidly progressive glomerulonephritis; *TTP,* thrombotic thrombocytopenic purpura.

6.8 mg/dl (500 to 600 µmol/l) will retain renal function if treated with plasma exchange, in contrast to only 8% of those who are dialysis dependent at presentation. Diffuse alveolar hemorrhage, which occurs in up to 50% of patients and can be life threatening, is an independent indication for plasma exchange regardless of renal function.

Recommendation

All patients who are not dialysis-dependent at presentation should receive intensive plasma exchange with daily 4-liter exchanges initially for 14 days (regimen shown in Table 99.2). For dialysis-dependent patients, we recommend plasma exchange with immunosuppression only for those who have biopsy or clinical evidence of recent-onset disease. Pulmonary hemorrhage is an independent indication for plasma exchange. Treatment of Goodpasture disease is discussed further in Chapter 24.

Small-Vessel Vasculitis

The majority of patients with rapidly progressive glomerulonephritis (RPGN), other than anti-GBM disease, have small-vessel vasculitis with ANCA detectable in their serum, and there is increasing evidence that these autoantibodies are pathogenic. Plasma exchange was initially introduced in such patients because of the similarity of the histologic changes to those seen in Goodpasture disease and the supposition that removing ANCA itself may be of benefit. Several trials of plasma exchange in non–anti-GBM RPGN have been reported.[7,11] Most of the early trials included patients with a variety of diseases, used a low intensity of plasma exchange, and often excluded those with oligoanuria. These trials showed no overall benefit of plasma exchange in addition to conventional immunosuppression; however, those patients with the most severe disease did seem to benefit. Combining the results of the controlled trials, 31 of 42 (74%) dialysis-dependent patients treated with plasma exchange recovered renal function compared with only 8 of 25 (32%) treated with drugs alone. The most recent RCT (MEPEX Methylprednisolone or Plasma Exchange in severe ANCA-associated vasculitis) randomized 137 patients with ANCA-associated systemic vasculitis and serum creatinine above 5.5 mg/dl (500 µmol/l) to plasma exchange or intravenous methylprednisolone in addition to oral corticosteroids and cyclophosphamide.[11] Sixty-nine percent of patients recovered renal function when treated with plasma exchange compared with 49% of those receiving intravenous methylprednisolone, and significantly more patients were dialysis independent at the trial end-point, although this difference was not maintained at 3 years. MEPEX was the largest study in a meta-analysis of 387 patients, with creatinine levels ranging from 3.2 to 13.5 mg/dl. The addition of plasma exchange to standard immunosuppression in MEPEX was associated with reduced risk for ESRD or death. Patients with both ANCA and anti-GBM antibodies (so-called double-positive patients) and RPGN do not seem to respond well to plasma exchange and rarely, if ever, recover renal function.[12]

Recommendation

We perform plasma exchange in patients with small-vessel vasculitis who present with severe renal failure (serum creatinine >5.5 mg/dl [~500 µmol/l] or dialysis dependent) or pulmonary hemorrhage. The regimen is shown in Table 99.2.

Other Crescentic Glomerulonephritis

Crescent formation is a common histologic finding in a number of other patterns of GN, including postinfectious GN, GN associated with infective endocarditis, IgA nephropathy (IgAN), membranoproliferative glomerulonephritis (MPGN), and membranous nephropathy. Such patients were often included in studies of treatment of RPGN, and plasma exchange has been used in the treatment of a number of these conditions. Over 400 patients with such diseases have been treated with plasma exchange with no good evidence for any benefit in crescentic GN not caused by anti-GBM disease or vasculitis.[7,8] In crescentic IgAN, there are anecdotal reports of short-term benefit in patients with severe renal impairment, but longer term follow-up has proved disappointing. A single recent report showed some benefit of 5 to 10 plasma exchanges in preventing or reversing dialysis dependency in 12 patients with crescentic IgAN manifesting with RPGN, with measured decreases in circulating plasma IgA-IgG complexes.[13]

Recommendation

We reserve plasma exchange in IgAN and other GNs for patients with rapidly deteriorating renal function and extensive fresh crescents in the biopsy specimen.

Focal Segmental Glomerulosclerosis

Plasma exchange and protein A immunoadsorption have been used to treat patients with primary FSGS or recurrent disease after transplantation. The results have been less good in primary disease because less than 40% of patients achieve either partial or complete remission,[7,8,14] and we do not recommend plasma exchange in this setting. Plasma exchange for recurrent disease is discussed later and in Chapter 108.

Thrombotic Microangiopathies

In both HUS and TTP, endothelial activation leads to TMA, but through distinct mechanisms.

Infection-Associated Hemolytic-Uremic Syndrome

Infections leading to HUS are most recognized after enteropathogenic *Escherichia coli* from Shiga toxin production (Stx-associated HUS) and more recently described after *Streptococcus pneumoniae* (pHUS). The prognosis is generally good, especially in childhood. Most children will recover fully with supportive care and management of fluid and electrolyte imbalance and hypertension. Two controlled trials of plasma infusion (at least 10 ml/kg/day) in childhood HUS complicated by dialysis-dependent renal failure showed no clinical benefit (as determined by hypertension, renal dysfunction, and proteinuria) in either short- or medium-term follow-up.[15] There has been no study of plasma exchange in childhood Stx-associated HUS. Plasma exchange and infusion have not been subjected to any controlled trials in adult Stx-associated HUS, but uncontrolled observations suggest possible benefit.[7,16] The 2011 outbreak of enterohemorrhagic and Stx-producing *E. coli* O104:H4 in Europe led to 855 confirmed cases of HUS, but despite severe illness in many patients a retrospective analysis of 491 treated patients did not support any major benefit of plasma exchange in addition to intensive supportive care.[17]

Thrombotic Thrombocytopenic Purpura

Patients with TTP usually have a defective vWF cleaving protease (ADAMTS13), an enzyme that normally degrades large vWF multimers. The defect is typically due to an inherited deficiency or autoantibodies directed against the protease. Accumulation of vWF multimers leads to systemic platelet activation under conditions of high shear stress (the microcirculation) and thrombosis. The rationale for plasma infusion and plasma exchange in TTP is therefore to replenish vWF cleaving protease, to remove antibodies against the protease, and to remove the large vWF multimers from circulation. There are well-designed RCTs in the treatment of TTP.

The first prospective, controlled trial compared plasma infusion with plasma exchange (1 to 1.5 plasma volumes at least seven times in the first 9 days).[18] All patients received aspirin and dipyridamole. Of patients receiving plasma exchange, 47% had a platelet count exceeding 150×10^9 cells/l and no new neurologic features, compared with only 25% of those receiving plasma infusion over the first 2 weeks. At 6 months, survival was substantially better in those given plasma exchange (50% vs. 78%). More recent series using plasma exchange have reported mortality rates as low as 15%,[7] and there may be an association of reduced early mortality with more intensive plasma exchange. Renal impairment is not an independent predictor of poor outcome in TTP and does not in itself warrant more intensive therapy; clinical course does not correlate with ADAMTS13 activity. Fever, age older than 40 years, and hemoglobin below 9 g/dl have been associated with a worse outcome. Whether FFP or its cryosupernatant fraction is better as replacement fluid remains unclear.

TTP may also be induced by drugs, including ticlopidine, clopidogrel, mitomycin C, cyclosporine, tacrolimus, gemcitabine, and quinine, and the evidence for benefit of plasma exchange in this context is poor, with the exception of ticlopidine-induced TTP in which ADAMTS13 activity is severely depressed.[7]

Atypical Hemolytic Uremic Syndrome

The less common forms of HUS in which there is no clear diarrheal prodrome (atypical HUS [aHUS]) are now known to be commonly caused by mutations, polymorphisms, or acquired dysregulation of the complement pathway (including the development of autoantibodies), especially of factor H, factor I, and membrane cofactor protein, leading to uninhibited activation of complement. Other causes include infections or drugs that cause platelet or leukocyte activation and complement activation and consumption. Direct activation of endothelial cells also may be a cause. Plasma exchange and infusion have not been evaluated in controlled trials in aHUS, but uncontrolled series suggest benefit and current guidelines recommend early initiation of plasma exchange with FFP (see Chapter 29), both to remove potential complement inhibitors or autoantibody and to replace absent or defective complement regulators.[7] The introduction of the complement inhibitor eculizumab, a humanized anti-C5 monoclonal antibody, has revolutionized the treatment of aHUS and should now be the mainstay of management after urgently excluding other diagnoses and can replace plasma exchange. If eculizumab is not available, plasma exchange should be continued. TMA occurring after renal transplantation has also responded to plasma exchange.

Recommendation

We use plasma exchange in all adults with TTP or atypical HUS and perform all exchanges against FFP or cryo-poor FFP. In aHUS, plasma exchange continues until we can initiate eculizumab therapy.

Systemic Lupus

Plasma exchange has been used extensively in patients with lupus. Most studies have included patients with diverse patterns of disease, often with only mild renal involvement. A randomized, prospective trial could show no benefit of plasma exchange over conventional immunosuppression for renal, serologic, or clinical outcomes, both in the short and long term.[19] However, patients with crescentic lupus nephritis and

those with the most severe renal dysfunction (dialysis dependency) were excluded. Anecdotal evidence suggests that plasma exchange may benefit patients with systemic lupus and crescentic GN, pulmonary hemorrhage, cerebral lupus, catastrophic antiphospholipid syndrome, severe antibody-induced hemolysis, lupus-associated TTP, or severe lupus unresponsive to conventional drugs or in patients for whom cytotoxic therapy has been withdrawn because of bone marrow suppression or other toxicity. Immunoadsorption may be more successful in the severe forms of lupus nephritis. A variety of techniques have been used, including standard protein A and antiimmunoglobulin absorption, and also phenylalanine, tryptophan, and dextran sulfate ligands, all of which bind immunoglobulin, rheumatoid factors, and immune complexes to varying degrees and all of which have been reported to induce remission in patients with severe disease after failure of conventional therapy.

Recommendation

We reserve plasma exchange for lupus patients with rapidly progressive renal failure and class IV lupus nephritis with crescents, for patients with severe neurologic involvement or severe hemolysis, for patients with myelosuppression who are thought unable to tolerate cyclophosphamide, and for those with catastrophic antiphospholipid syndrome or severe macrophage activation syndrome. The treatment of lupus is further discussed in Chapter 26.

Cryoglobulinemia

In type I cryoglobulinemia, usually associated with myeloma or lymphoma, a monoclonal immunoglobulin causes hyperviscosity and cryoprecipitation. Such antibodies are easily removed by plasma exchange, often with immediate clinical benefit. Cytotoxic agents are used simultaneously to inhibit further paraprotein production. There are no controlled trials of plasma exchange, but symptoms are closely related to the presence of the cryoimmunoglobulin, and hence treatment with plasma exchange appears effective.[7]

Patients with type II (mixed essential) cryoglobulinemia develop a monoclonal antibody (usually IgM) with specificity for a second, usually polyclonal, immunoglobulin. Type II cryoglobulins occur most commonly in association with hepatitis C virus (HCV) infection and lymphoma. The resulting immune complexes can be deposited in the microcirculation and are particularly associated with MPGN (see Chapter 21). Plasma exchange is effective at clearing the immune complexes, although the cryoglobulins often recur, and sustained benefit has not been clearly demonstrated. However, many of the acute features of cryoglobulinemia resolve with plasma exchange, particularly arthralgia, skin lesions, and digital necrosis, and patients with RPGN can recover renal function. Concomitant treatment with rituximab may prevent resynthesis of the cryoproteins, although some patients require long-term intermittent plasma exchange to control symptoms. Patients with HCV-associated cryoglobulinemia should now be treated with the newer antiviral agents, which are extremely effective in curing the viral infection, after which cryoglobulins usually disappear. A single RCT in 17 patients with HCV-associated cryoglobulinemia added immunoadsorption apheresis (with dextran sulfate) to antivirals and immunosuppression and showed significant clinical improvements, but this was from an era before the current antiviral agents.[20]

Cryofiltration apheresis (in which a normal plasma filter is used to separate plasma, which is then cooled to precipitate the cryoglobulin before return to the patient) selectively removes cryoglobulins, avoids large volumes of replacement fluids, and avoids deficiency of clotting factors, but needs to be combined with immunosuppression to prevent synthesis of further cryoglobulin. Few centers currently perform this technique, especially because of the widespread introduction of rituximab for cryoglobulinemia.

Myeloma

Plasma exchange almost certainly does not provide benefit in myeloma with either cast nephropathy or light-chain renal toxicity, and the most important therapy seems to be urgent initiation of chemotherapy, especially thalidomide, lenalidomide, or bortezomib. A large prospective, controlled trial randomized 97 patients with myeloma and progressive acute kidney injury (creatinine >200 μmol/l [2.3 mg/dl] with an increase >50 μmol/l over the previous 2 weeks despite conventional management) to receive plasma exchange (five to seven sessions of 50 ml/kg over 10 days) in addition to chemotherapy (vincristine, adriamycin, and dexamethasone [VAD] or melphalan and prednisolone).[21] This study showed no benefit of plasma exchange on mortality or recovery of renal function. However, patients had a wide degree of renal dysfunction and relatively few had a renal biopsy performed to confirm cast nephropathy. A retrospective review suggested that those with myeloma and high light-chain loads or severe renal failure may benefit if plasma exchange reduces light chains rapidly.[22] More recently a variety of studies in patients with renal disease and myeloma, especially using bortezomib-based regimens, have shown significant improvements even in patients with dialysis-requiring renal failure but without plasma exchange. An RCT of HD using novel membranes allowing the removal of large MW molecules and lengthy dialysis sessions (6 to 8 hours) failed to show any benefit (for survival or recovery of renal function) when added to modern chemotherapeutic regimens, which depleted light chains rapidly in the absence of plasma removal.

Recommendation

We no longer use plasma exchange in patients with myeloma but ensure effective chemotherapy is urgently initiated.

TRANSPLANTATION

Antibody-Mediated Rejection

A review of 157 patients included in five trials did not demonstrate any significant difference in the outcome of acute vascular rejection in patients treated with or without plasma exchange.[7,8] More recently, at least 11 trials including more than 400 patients with more clearly defined antibody-mediated rejection and case series of more than 700 patients have suggested that plasma exchange, combined with intravenous immunoglobulin (IVIG) and/or rituximab, but sometimes antithymocyte globulin, may effectively reverse 55% to 100% of such rejection episodes.[7]

There is no convincing evidence that plasma exchange has any role in the treatment of chronic rejection.

Anti–Human Leukocyte Antigen Antibodies

Highly sensitized patients with preformed anti-HLA antibodies have been treated before and after transplantation with plasma exchange or immunoadsorption to reduce cytotoxic antibody levels, often with high-dose IVIG.[7] Patients usually received intensive immunoadsorption or plasma exchange before transplantation to ensure a current negative crossmatch immediately before transplantation; some received longer term immunoadsorption or plasma exchange in combination with immunosuppressive therapies in the months preceding transplantation. Most recent studies have shown that donor-specific antibody titers of less than 1:32 are often depleted completely with preoperative plasma exchange, allowing successful renal transplantation. Such patients have

an increased risk for antibody-mediated rejection—approximately 40%—but despite this, 90% have 1-year graft survival.

ABO-Incompatible Renal Transplantation

Plasma exchange is widely used to remove natural anti-A or anti-B blood group antibodies from the recipient before living donor transplantation from an ABO-incompatible donor. Various protocols are in use, but all rely on depletion of specific antibody over 2 to 5 days before transplantation by exchanging a single plasma volume for human albumin solution (in addition to routine immunosuppression, sometimes including rituximab and IVIG). Plasma exchange is sometimes continued for one or two sessions after transplantation or if antibody-mediated rejection occurs.[23] One-year graft survival rates of over 90% have been reported with such protocols, and although rejection episodes are more common than in ABO-compatible transplants, overall graft survival is similar. Patients with increasingly high antibody titers are being treated in this way. Immunoadsorption using synthetic A- or B-oligosaccharide epitopes linked to Sepharose has been developed, which specifically remove anti-A or anti-B antibodies, but any clinical benefit remains uncertain and the costs are high.

Recurrent Focal Segmental Glomerulosclerosis

Plasma exchange, double-filtration plasma exchange, and protein A immunoadsorption have been used to treat nephrotic syndrome after transplantation in patients with recurrent FSGS.[7,24,25] An incompletely defined circulating factor causing increased permeability of glomerular capillaries can be found in most patients with recurrent FSGS. There are no controlled trials of plasma treatments in recurrent FSGS, and most series are small. One study demonstrated an 82% reduction in urinary protein excretion in eight patients with recurrent nephrosis during plasma protein adsorption; however, the effect was transient and persisted for less than 2 months in seven of the eight patients.[24] Other investigators have obtained remissions (complete and partial) in up to 80% of patients and a significant reduction in graft loss resulting from recurrent disease compared with historic controls.[25] More intensive treatment regimens have led to more persistent remissions. All three apheresis modalities have been used prophylactically in patients deemed to be at high risk for recurrence, with variable success.

Recommendations

We recommend use of plasma exchange for patients with recurrent FSGS, initially daily for 7 to 10 days. If proteinuria is successfully reversed, this may need to be continued less frequently (weekly, then every other week, then monthly) for 2 to 3 days on each occasion. Management of recurrent FSGS is discussed further in Chapter 108.

SELF-ASSESSMENT QUESTIONS

1. A patient with anti–glomerular basement membrane disease, serum creatinine 250 μmol/l, and pulmonary hemorrhage is being treated with plasma exchange and immunosuppression. Which complication can occur as a direct result of the plasma exchange?
   A. Hypernatremia
   B. Hyperviscosity
   C. Hypocalcemia
   D. Pulmonary embolism
   E. Thrombocytosis
2. A 52-year-old woman presented with acute kidney injury and evidence of hemolysis and thrombocytopenia.
   Investigations:
   Hemoglobin: 86 g/l (115-165)
   White cell count: 4.2×10^9/l (4.0-11.0)
   Platelet count: 35×10^9/l (150-400)
   Serum creatinine: 238 μmol/l (60-110)

The results of remaining investigations are awaited. Which one of these diagnoses should lead to urgent initiation of plasma exchange?
   A. Atypical hemolytic-uremic syndrome (HUS)
   B. Infection-associated HUS
   C. Myeloma
   D. Scleroderma renal crisis
   E. Systemic lupus
3. A 42-year-old man received a cadaveric kidney transplant under standard immunosuppression. Six weeks later his renal function deteriorated, an ultrasound scan was normal, and a kidney biopsy was performed. Which finding might lead to initiation of plasma exchange?
   A. Antibody-mediated rejection
   B. CD4-positive staining on the biopsy
   C. Cyclosporine-induced microangiopathy
   D. Recurrent membranous nephropathy
   E. T cell–mediated cellular rejection

Immunologic Principles in Kidney Transplantation

Karl L. Womer

Important to an effective immune response is the ability of T cells to recognize a wide variety of nonself antigens, which allows for restrained immune activation and subsequent antigen-specific killing. This task is accomplished through the generation of a diverse repertoire of T cells in a single individual with specificity for an enormous number of potential foreign antigens presented as peptides on the surface of major histocompatibility complex (MHC) molecules. Variations in MHC structure among individuals increase the variety of peptides that can be presented to T cells, which protects the species as a whole by ensuring adequate T cell responses to a given foreign organism. Although slight, these MHC polymorphisms expressed in the donor kidney are recognized as foreign after kidney transplantation between nongenetically identical humans and induce alloresponses that in the absence of immunosuppression result in rejection of the allograft (see Box 100.1 for graft terminology). In this chapter, basic immunologic principles important to the field of kidney transplantation are reviewed.

ISCHEMIA/REPERFUSION INJURY

The immunologic responses after kidney transplantation occur in well-defined stages[1] (Fig. 100.1). Initial insults to the graft during donor organ procurement and subsequent transplantation into the recipient are referred to as ischemia/reperfusion injury (IRI). The pathogenesis of IRI involves biochemical, cellular, vascular endothelial, and tissue-specific factors, with inflammation as a common feature.[2] Acute ischemia leads to tissue damage and endothelial cell activation, which initiates the innate, or antigen-nonspecific, immune response. Innate immunity occurs rapidly, with limited specificity and without memory and includes both cellular elements (neutrophils, monocyte/macrophages, dendritic cells [DCs], and natural killer [NK] cells) as well as molecular components (pathogen-associated pattern recognition receptors [PRRs], complement proteins, cytokines, and chemokines [chemoattractant cytokines]).

PRRs expressed on innate immune cells enable them to recognize not only pathogen-associated molecular patterns but also endogenous markers of tissue injury or damage-associated molecular patterns (DAMPs) released by cells during IRI.[3] The sensing of DAMPs by PRRs results in release of cytokines, including tumor necrosis factor (TNF), interleukin (IL)-6, IL-1, type I interferons, chemokines, and the rapid expression of P-selectin (CD62P) by endothelial cells.[3] These events identify the transplant as a site of injury and inflammation, which stimulates the migration of donor-derived antigen-presenting cells (APCs) from the transplant to recipient lymphoid tissue and triggers the recruitment of inflammatory leukocytes into the graft. Neutrophil accumulation is the prime cellular mediator of microvascular plugging and local tissue destruction in IRI. In the next phase, monocyte/macrophage infiltration occurs and likely contributes to extension of early injury, as well as repair.[4]

These events contribute to delayed graft function and trigger the adaptive, or antigen-specific, phase of transplantation immunity (T cells and antibody-producing B cells) that can negatively affect long-term graft survival. NK cells likely also function as a bridge between innate and adaptive immunity in IRI, in part through bidirectional cross-talk between NK cells and DCs that plays a relevant role in the mechanisms leading to activation/maturation of DCs.[5] Likewise, although activation of the complement system plays an important role in IRI as a manifestation of the innate immune system, complement also regulates adaptive immune responses. T and B cells constitute the primary arms of the adaptive immune response, but they also play an important role in the acute and possibly healing phases of IRI.[2] These described immunologic events are not specific to allografts because they also occur in syngeneic grafts during IRI. However, innate immune responses alone are only rarely able to reject an allograft.

ANTIGEN PRESENTATION

Antigen-Presenting Cells

APCs are specialized cells capable of activating T cells. Antigen is endocytosed by APCs and then displayed by MHC molecules on their surface. T cells recognize and interact with the antigen:MHC complex to become activated. DCs, macrophages, and B cells are considered "professional APCs," although DCs are the most potent at antigen presentation. Alloimmune responses are initiated by activation of APCs (mostly DCs) through innate immune recognition systems when there is a genetic difference between donor and recipient. DCs are highly versatile, determining whether the environment indicates that antigen should lead to an immune response or alternatively to tolerance.[6] In the graft and surrounding tissues after transplantation, DCs of either donor or host

BOX 100.1 Graft Terminology

Autograft (autologous graft): A graft from one part of the body to another. Examples include skin and vascular grafts. No rejection occurs.

Isograft (isogenic or syngeneic graft): A graft from one member of a species to a genetically identical member of the same species. Examples include grafts between identical twins and between members of the same inbred rodent strain. No rejection typically occurs.

Allograft (allogeneic graft): A graft between nonidentical members of the same species. Examples include grafts between unrelated or related nonidentical humans and between members of different inbred rodent strains. Rejection occurs by lymphocytes reactive to alloantigens on the graft (i.e., alloresponse).

Xenografts (xenogeneic grafts): A graft between members of different species. Examples include pig or baboon to human, and rat to mouse. Rejection occurs by lymphocytes reactive to xenoantigen on the graft (i.e., xenoresponse).

origin become activated and move to T cell areas of secondary lymphoid organs (SLOs).

The trafficking pattern of naïve T cells is restricted to SLOs, such as the lymph node and spleen, but also possibly to tertiary lymphoid structures formed in tissues after inflammation, including those in allografts.[7] They traverse from blood to lymphoid organs, where they pass through the T cell areas and become activated on encounter with donor antigen (alloantigen) presented by activated DCs in the context of MHC molecules. The movement of DCs and naïve T cells is coordinated to bring them into contact in the T cell areas of SLOs, which appears essential for effective priming.[8] Once activated, T cells leave SLOs via lymph vessels and enter the blood and peripheral tissues, particularly into sites of inflammation. B cells are activated when antigen engages their antigen receptors, initially in the border of T and B cell areas of SLOs, where helper T cell function is provided.[9]

Antigen-experienced memory cells may be activated by other APCs, such as graft endothelium.[10] Patients normally have no preexisting immunoreactivity to alloantigen, unless they have been exposed to alloantigen through pregnancy, blood transfusion, or prior transplantation. However, microbial antigens that cross-react with alloantigens (molecular or antigenic mimicry) may generate alloantigen-specific memory cells through a process termed *heterologous immunity*.[11]

T Cell Ontogeny and Major Histocompatibility Complex Specificity

Allografts induce alloimmune responses by the recognition of nonself antigens (e.g., MHC) from the graft by recipient T cells. During T cell ontogeny in embryogenesis, multilineage bone marrow precursors migrate to the thymus, where ultimate rearrangement of the T cell receptor (TCR) gene occurs, resulting in irrevocable T cell commitment. TCR gene rearrangement is random and ensures that a diverse repertoire of T cells exists to respond to the enormous number of potential foreign antigens.[12] The mature T cell repertoire is determined in the thymus by two processes, positive and negative selection. Positive selection depends on a certain degree of antigen-specific T cell affinity to self-MHC molecules expressed on thymic cortical epithelial cells. This process ensures that mature T cells will interact effectively with MHC to allow recognition of foreign antigen in the context of self-MHC. Negative selection occurs by deletion of T cells with excessively high affinity for self-peptide and MHC, thereby preventing release of high-affinity T cells with autoimmune potential.

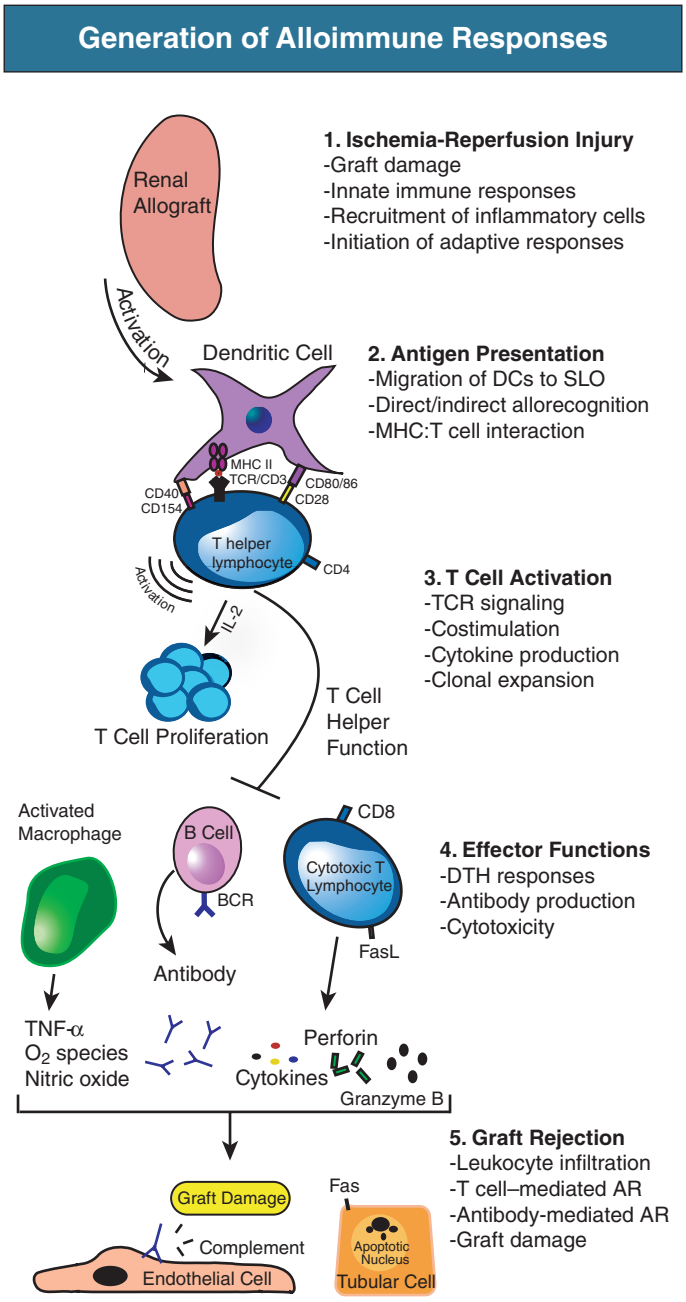

Fig. 100.1 Generation of alloimmune responses. Immunologic responses after renal transplantation represent a series of well-defined stages that result in rejection of the allograft in the absence of exogenous immunosuppression. Graft damage following ischemia/reperfusion injury during procurement and transplantation activates innate (antigen-nonspecific) immune responses, which recruit inflammatory cells and initiate adaptive (antigen-specific) immune responses. After activation, dendritic cells *(DCs)* of donor (direct pathway) or recipient (indirect pathway) origin migrate to secondary lymphoid organs *(SLO),* where they present alloantigen to T cells through major histocompatibility complex *(MHC)* structures on their cell surface. After T cell receptor *(TCR)* signaling and appropriate costimulation, T cells become activated to produce large amounts of cytokine and undergo clonal expansion. CD4 T cells provide help to B cells, CD8 T cells, and macrophages for the production of alloantibody, cellular cytotoxicity, and delayed-type hypersensitivity *(DTH)* responses, respectively. These effector functions result in destruction of the graft by acute rejection, which may be T cell- and/or antibody-mediated. *AR,* Acute rejection; *BCR,* B cell receptor; *IL-2,* interleukin 2; *TCR,* T cell receptor.

Mature T cells expressing their clone-specific TCRs exit the thymus as either CD4 or CD8 T cells. The TCRs of CD4 T cells (also called *T helper cells*) are selected to interact with class II MHC molecules, whereas the TCRs of CD8 T cells (precursors of cytotoxic T lymphocytes [CTLs]) interact with class I MHC molecules. A fundamental principle of immunology is that T cells do not recognize intact foreign proteins directly, but instead as peptides presented by self-MHC on APCs. However, allelic variation among MHC molecules from individual to individual is quite small, resulting in similarities between donor and recipient MHC structure. Thus unique to the transplant setting, recipient TCRs have a strong affinity for intact donor MHC molecules and can recognize them directly, which explains in large part the high proportion of T cells responding to alloantigen.[13] In fact, only $1/10^5$ to $1/10^6$ of T cells will respond to any given foreign antigen (e.g., peptide derived from tetanus toxin or influenza hemagglutinin). However, the frequency of T cells that respond to foreign MHC molecules (alloantigens) is 100-fold to 1000-fold higher (up to 5% to 10% of all T cells) because the thymus does not select for or against T cells to recognize the many MHC alleles not expressed by the graft recipient.[14]

Pathways of Allorecognition

Recipient T cells encounter alloantigen by either direct, semidirect, or indirect pathways of allorecognition (Fig. 100.2). As previously alluded to, direct antigen presentation involves recipient T cell recognition of donor MHC peptides in the peptide groove of intact donor MHC molecules on the surface of donor APCs. By this mechanism, donor APCs migrate from the graft to recipient lymphoid organs and activate alloreactive recipient T cells to initiate the alloimmune response. The best evidence of the potential importance of direct allorecognition to the alloresponse is the strong in vitro response generated in the mixed lymphocyte response, where lymphocytes are cultured with allogeneic APCs. It has been suggested that the direct pathway may be active only early after transplantation, when a large number of donor APCs are present in the allograft. However, direct antigen presentation also may occur later when recipient T cells recognize intact donor MHC molecules on cells of the graft (e.g., endothelium). Likewise, semidirect antigen presentation can occur through the transfer of intact donor MHC:peptide complexes contained in extracellular vesicles derived from the surface of donor APCs or from the graft to the surface of recipient APCs for presentation to recipient T cells, a process called *cross-dressing* or *cell nibbling*.[14] B cells also recognize intact donor MHC antigen via their B cell receptors.

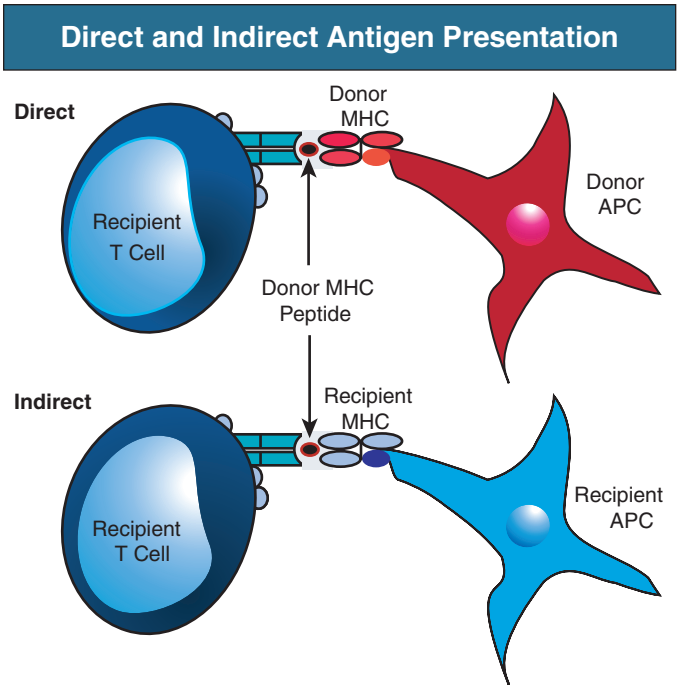

Fig. 100.2 Direct and indirect antigen presentation. In direct allorecognition, donor antigen *(shown in red)* is presented to recipient T cells as a peptide in the context of intact donor major histocompatibility complex *(MHC)* molecules on the surface of donor antigen-presenting cells *(APC)*. In indirect allorecognition, the donor antigen is processed by recipient APCs and presented as a peptide in the context of recipient MHC molecules.

Indirect antigen presentation is the physiologic mechanism of foreign antigen recognition. Foreign antigen is taken up by APCs, processed intracellularly, and then presented as peptides on MHC molecules. During indirect allorecognition after allotransplantation, donor MHC molecules and minor histocompatibility antigens (discussed in later section) are shed from the graft and processed by recipient APCs, where they are presented as peptides to recipient T cells in the context of recipient MHC molecules.[15] Donor MHC molecules are continually shed from the graft and presented by recipient APCs; thus indirect allorecognition may play a larger role in the late alloresponse, including during chronic rejection. However, the relative contribution of the direct, semidirect, and indirect allorecognition pathways to the alloresponse at different time points after transplantation remains the subject of debate.

Major Histocompatibility Complex

Class I and II MHC molecules are designed for presentation of antigen from different sources for different purposes (Fig. 100.3). The class I system is designed to sample cytosolic proteins to detect tumors or intracellular pathogens, such as virus and intracellular bacteria. Class I molecules are recognized by CD8 T cells and provide a surveillance mechanism to target infected or malignant cells for destruction by CTLs. The class II system is designed to sample extracellular proteins that have been taken up and processed by APCs. Class II molecules are recognized by CD4 T helper cells and allow for the generation of immune responses to invading pathogens that are phagocytosed by APCs. Cross-presentation is a process by which certain APCs take up, process, and present extracellular antigen on class I molecules to CD8 T cells.[16] This mechanism is necessary for immunity against tumors and viruses that do not infect APCs. MHC products also play other important roles, including the positive and negative selection of developing T cells described earlier, stimulation of naïve and memory T cells that is necessary for their survival (homeostatic proliferation), the induction of T cell tolerance and anergy (discussed later), and interaction with NK cells and other inhibitory/activating receptors.

The MHC gene locus (in humans, HLA) maps to the short arm of chromosome 6 and is divided into three regions: the class II region, the class III region, and the class I region. Only the class I and II regions encode proteins involved in antigen presentation. The key MHC genes are the class I genes (HLA-A, -B, and -C) and the class II genes (HLA-DP, -DQ, and -DR). The class I and II proteins share structural homology but are functionally different[17] (see Fig. 100.3).

Class I proteins are expressed on virtually all nucleated cells, although the amount expressed varies. Class II proteins have a more restricted cell distribution, generally limited to bone marrow–derived "professional" APCs, including DCs, B cells, macrophages, and Langerhans cells, but also other cells, including activated parenchymal and endothelial cells. Both class I and II antigens can be induced on a variety of cells by interferon (IFN)-γ in synergy with other cytokines during rejection episodes.

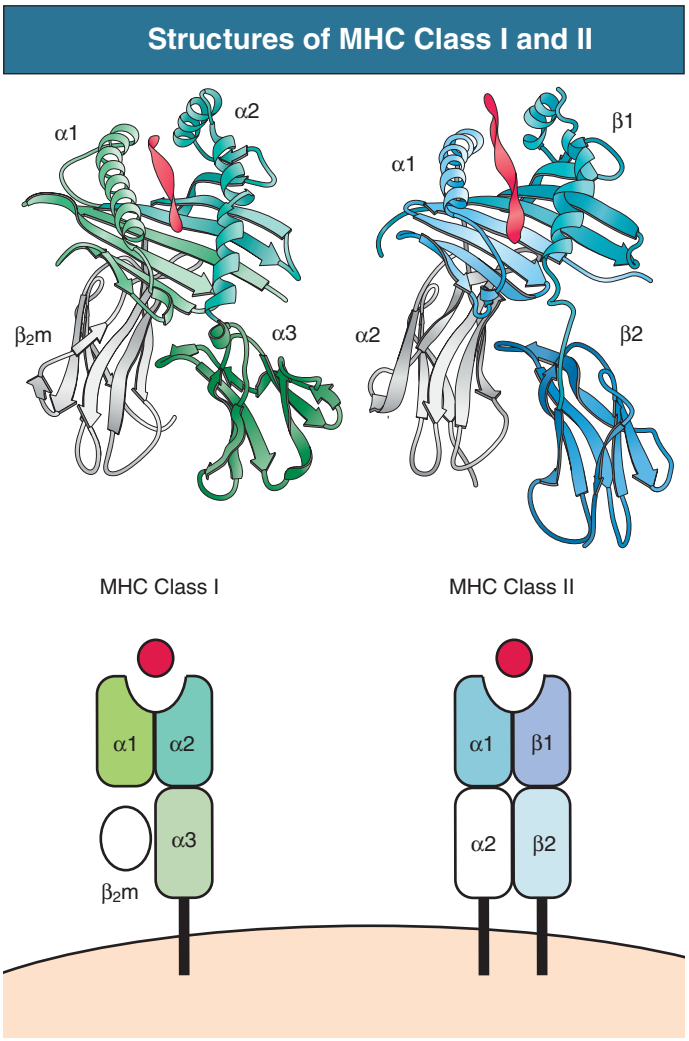

Fig. 100.3 Structures of major histocompatibility complex *(MHC)* classes I and II. MHC class I is composed of a heavy chain divided into α1, α2, and α3 domains noncovalently associated with β_2-microglobulin (β_2m). The α1 and α2 domains each form a long α helix and β sheet to make up the floor and walls of the peptide-binding groove *(peptide indicated by red ribbon).* MHC class II is a dimer composed of α and β chains. Each chain is divided into two domains, with α1 and β_1 domains forming the two α helices and β-pleated sheet that surround the peptide-binding groove.

Human Leukocyte Antigen Typing and Transplantation

MHC class I and II genes are highly polymorphic in the regions that encode the peptide-binding groove. These polymorphisms help ensure survival of the species by increasing the variety of peptides that can be presented to T cells.[18] However, these polymorphisms also predispose to allograft rejection because the antigen-presenting structures of one individual, though very similar, are still regarded as foreign by another nonidentical individual.

Originally, polymorphisms were defined by HLA serologic (antibody) typing using sera from multiparous women or persons who had received blood transfusions. The development of molecular biology techniques (polymerase chain reaction [PCR] sequencing) has allowed the analysis of the HLA allelic sequence diversity at the DNA level. By DNA typing, many more polymorphisms (alleles) have been identified: currently 3657 for HLA-A, 4459 for HLA-B, and 2208 for HLA-DR, with an increasing number of sequences added each year. An updated source for HLA alleles can be identified at www.ebi.ac.uk/imgt/hla.

Human Leukocyte Antigen Inheritance

HLA genes are inherited in a mendelian codominant fashion, meaning that a copy of each HLA gene (i.e., one haplotype) is inherited from each parent and expressed as antigens. HLA typing identifies the specific alleles carried by a person. The term *HLA matching* means assigning a donor kidney to a recipient with as few mismatches as possible. In kidney transplantation, efforts are made to match HLA-A, -B, and -DR genes and proteins. It can be predicted that siblings from the same set of parents will have a 25% chance of having zero mismatches, 50% chance of one haplotype mismatch, and 25% chance of two haplotype mismatches (Fig. 100.4).

Non–Major Histocompatibility Antigens

Minor histocompatibility antigens are normal proteins that are polymorphic within a given species. Even when a transplant donor and recipient are identical with regard to MHC genes, amino acid differences in these minor proteins can lead to rejection. Minor antigens are encoded by a large number of chromosomes and are presented only as peptides in the context of recipient MHC (indirect allorecognition). Minor antigens are responsible for the need for immunosuppression after donation between HLA matched but nonidentical twin siblings. The prototypic minor histocompatibility antigen, the male or H-Y antigen, is derived from a group of proteins encoded on the Y chromosome. Alloresponses to this antigen are responsible for rejection of male mouse skin grafts by otherwise identical female recipients and may explain observations of reduced long-term graft survival in human male-to-female donations.

MHC I–related chain A (MICA) antigens are surface glycoproteins with functions related to innate immunity. Exposure to allogeneic MICA during transplantation can elicit antibody formation.[19] ABO blood group glycolipids expressed on endothelial and red blood cells are other notable non-MHC antigens. Finally, immune responses to autoantigens have been associated with allograft damage.[20]

T CELL ACTIVATION

T cells are required for allograft rejection. Alloreactive T cells can be found in the naïve and memory T cell populations, but both require recognition of nonself MHC molecules to become activated. Reactions mediated by naïve T cells take longer to develop than those mediated by memory T cells, which can be generated more quickly and with higher numbers of cells (secondary response). During allograft rejection, both populations are activated simultaneously.

T Cell Receptor

Each T cell bears about 30,000 identical antigen-receptor molecules. Each receptor consists of two different polypeptide chains, termed the TCR α and β chains, which are linked by a disulfide bond. The genes encoding the TCR chains are members of the immunoglobulin supergene family, which are found on B, T, and NK cells. The α:β heterodimers are very similar in structure to the Fab fragment of an immunoglobulin molecule and account for antigen recognition by most T cells (Fig. 100.5). In contrast to the immunoglobulin receptors of B cells, TCRs do not recognize antigen in its native state, but instead recognize a composite ligand of a peptide bound to an MHC molecule. A minority of T cells bear an alternative, but structurally similar, receptor composed of a different polypeptide heterodimer (γ:δ).

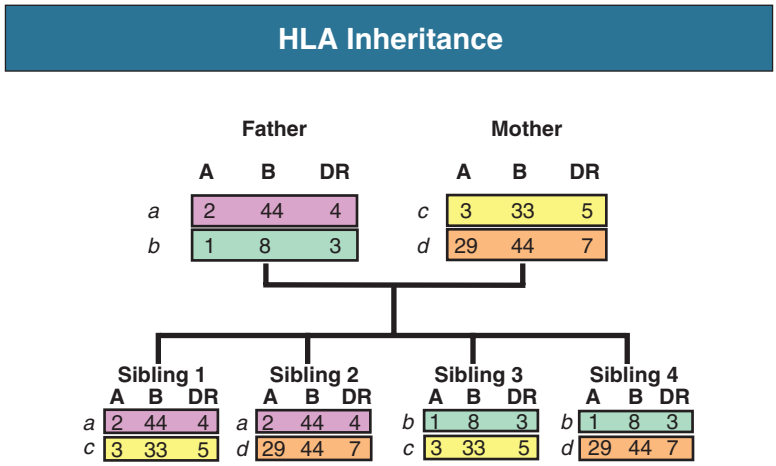

Fig. 100.4 Human leukocyte antigen (HLA) inheritance. HLA antigens are inherited and expressed in a mendelian codominant fashion, whereby one copy of each HLA gene called a *haplotype* (e.g., *a, b, c, d*) is inherited from each parent. Efforts are made to match both class I (HLA-*A* and -*B*) and class II (HLA-*DR*) antigens.

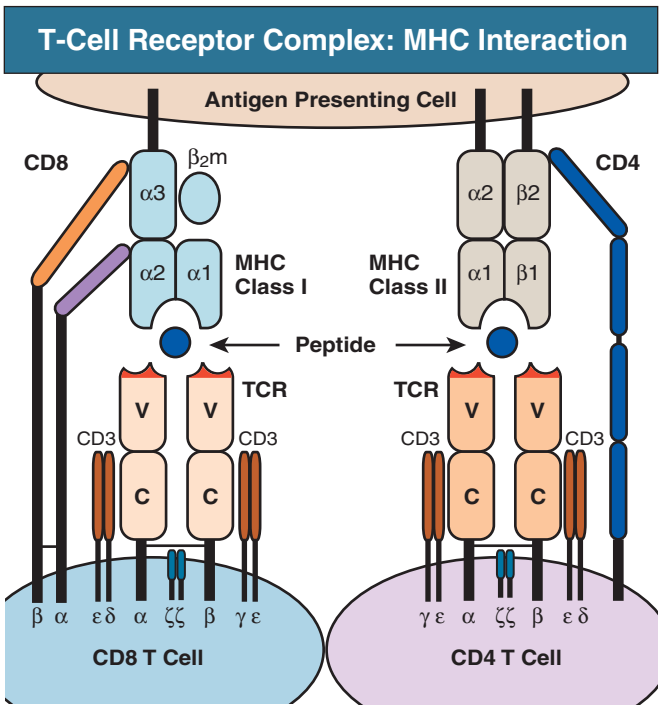

Fig. 100.5 T cell receptor complex: Major histocompatibility complex (MHC) interaction. Each T cell receptor *(TCR)* consists of an α and β chain linked by a disulfide bond. The α:β heterodimers are similar in structure to the Fab fragment of immunoglobulin molecules (Fig. 100.7), including variable *(V)* and constant *(C)* regions. Diversity in the T cell repertoire is encoded in the V domains of the α and β chains in three complementarity-determining regions (CDRs) that form the antigen binding site at the end of the TCR *(highlighted in red)*. CD8 is a disulfide-linked α:β heterodimer or α:α homodimer, with each chain containing a single immunoglobulin-like domain linked to the membrane by a polypeptide chain. CD8 binds to the conserved region of the α3 domain of the class I MHC molecule on antigen-presenting cells (APCs), but also interacts with the class I MHC α2 domain probably through the α chain. CD4 is composed of four immunoglobulin-like domains and binds to a conserved site on the β_2 domain of the class II MHC molecule on APCs. Triggering of the TCR by antigen initiates a signaling cascade started by the signaling complex made up of CD3 γ, ε, and δ chains, as well as the ζ chain homodimer.

CD4 and CD8 Coreceptors

T cells fall into two major classes with different effector functions, distinguished by the expression of the cell-surface proteins CD4 and CD8 (Fig. 100.5). Both CD4 and CD8 have a cytoplasmic tail that can associate with signaling proteins important in T cell activation. CD4 and CD8 binding to MHC are required to make an effective response. Thus these molecules are called coreceptors.

T Cell Receptor Engagement of Antigen: Signal 1

The TCR α:β heterodimer recognizes and binds its peptide:MHC ligand[21] but cannot signal to the cell that antigen has bound. In the functional receptor complex, α:β heterodimers are associated with a complex of four other signaling chains (two ε, one δ, one γ) collectively called CD3 (see Fig. 100.5). Engagement of the TCR by MHC, along with the other required receptor engagements, initiates the signaling process from the CD3 complex, leading to cell proliferation and differentiation.[22]

T Cell Costimulation: Signal 2

Binding of the TCR:CD3 complex to the peptide:MHC complex on APCs delivers a signal that can induce the clonal expansion of naïve T cells only when the appropriate costimulatory signal is delivered (signal 2). CD8 T cells require a stronger costimulatory signal, and their clonal expansion is aided by CD4 T cells interacting with the same APC (i.e., T helper function). Costimulation is likely a checkpoint developed by the immune system to prevent the activation of self-reactive T cells that escaped negative selection in the thymus. Antigen binding to the TCR in the absence of costimulation not only fails to activate the T cell but also leads to a state called *anergy,* in which T cells become refractory to subsequent activation, or even undergo apoptosis (programmed cell death). Thus costimulation removes this inhibition and determines whether a T cell will proceed with clonal expansion and the development of effector functions. It is now clear that costimulatory molecules can provide positive or negative signals to T cells (Fig. 100.6). It is the integration of both positive and negative costimulatory signals during and after initial T cell activation, dictated by their temporal and spatial expression patterns, that ultimately determines the fate and functional status of the T cell response.[23]

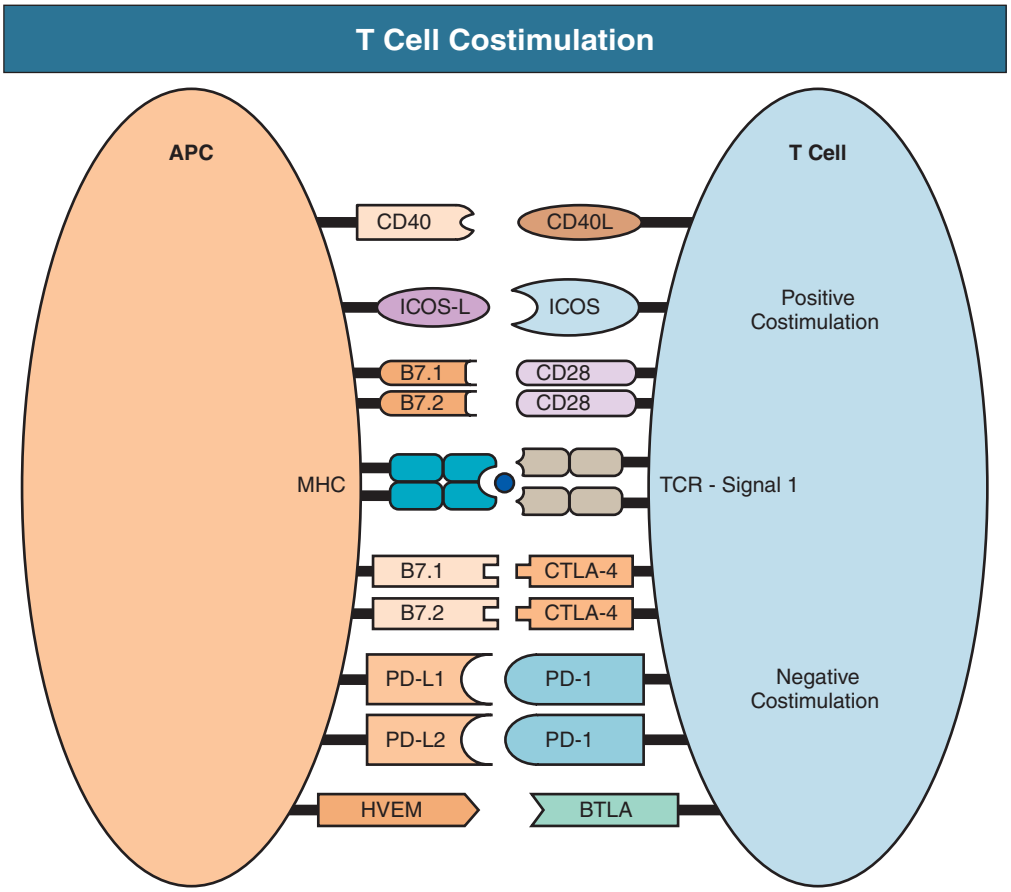

Fig. 100.6 T cell costimulation. Binding of the T cell receptor *(TCR):CD3* complex to the peptide:major histocompatibility complex on antigen-presenting cells *(APCs)* delivers a signal that can induce the clonal expansion of naïve T cells only when the appropriate costimulatory signal is delivered (Signal 2). CD28 and its ligands, B7.1 (CD80) and B7.2 (CD86), are the best-characterized costimulatory molecules and are members of the immunoglobulin superfamily. Ligation of CD28 by B7 molecules is required for clonal expansion of naïve CD4 T helper cells. Once activated, T cells express increased levels of CTLA-4 (CD152). CTLA-4 has an affinity 10 to 20 times greater than that of CD28 for B7 molecules and thus binds most or all of the B7 molecules, effectively shutting down the proliferative phase of the response. B and T lymphocyte attenuator *(BTLA)* and programmed death-1 (PD-1) are two other costimulatory molecules of the immunoglobulin superfamily that when engaged by their ligands (herpes virus entry mediator [HVEM] and PD-L1/PD-L2, respectively) provide inhibitory signals to T cells. Activated T cells express a number of proteins that contribute to sustaining or modifying the costimulatory signal to drive clonal expansion and differentiation. The inducible costimulatory molecule (ICOS) is a CD28 homologue, but unlike CD28 is not constitutively expressed on naïve T cells. Rather, ICOS is induced only after T cell activation. Engagement of ICOS by B7H enhances T cell proliferation, cytokine production, and survival. Costimulatory molecules of the tumor necrosis factor (TNF) and TNF-R superfamily include CD40 ligand (CD40L, CD154) on T cells and its receptor CD40 on APCs, such as B cells, DCs, macrophages, and endothelial cells. Binding of CD40 by CD40L, which is upregulated by CD28 signaling, transmits activating signals to the T cell but also activates the APCs to secrete proinflammatory molecules and to express B7 molecules, thus stimulating further T cell proliferation.

T Cell Clonal Expansion and Differentiation

In most instances, the number of T cells that react to a given antigen is quite small. Therefore effective immune responses require clonal expansion and differentiation of T cells. These processes are driven by cytokines, including IL-2, which acts on the T cell in an autocrine fashion or by paracrine secretion to neighboring T cells. Activated T cells produce the alpha subunit (CD25) of the IL-2 receptor (IL-2R), enabling a fully functional signaling receptor composed of α, β, and γ subunits that can bind IL-2 with high affinity, which in turn initiates another pathway mediated in part through the protein mammalian target of rapamycin (mTOR). New proteins are then translated, allowing the cell to progress from the G1 phase to the S phase of the cell cycle, resulting in proliferation. Table 100.1 lists selected cytokines involved in allograft rejection, their sources, and their effects.

CD4 and CD8 T cells have different roles during immune responses. CD4 T cells are both effectors and regulators and have heavy cytokine secretion. After prolonged stimulation, CD4 T cells tend to express groups (signatures) of several cytokines, probably depending on the local environment, nature of the antigen, and type and activation status of the APC. These different T helper (Th) subsets, each with unique transcription factor and cytokine signatures, are referred to as Th1,

TABLE 100.1 Cytokines Involved in Allograft Rejection

Cytokine	Source	Biologic Activity
IL-1	Macrophages, DCs, ECs, NK cells	Proinflammatory, adhesion molecule expression on ECs, NK cell function
IL-2	Activated T cells	T cell proliferation, CTL and NK cell function, Treg maintenance, immunoglobulin production by B cells, AICD of activated T cells
IL-4	Activated T cells	Activated T and B cell proliferation, Th2 differentiation, allergic responses, MHC II upregulation on B cells
IL-6	T cells, macrophages, ECs	Proinflammatory and antiinflammatory, acute-phase responses
IL-10	T cells, macrophages, DCs	Antiinflammatory, suppression of APC function, NK cell inhibition
IL-12	Macrophages, DCs	Proinflammatory, Th1 differentiation, NK cell and CTL activity, IFN-γ and TNF-α production by NK and T cells
IL-15	Epithelial cells, stromal cells, macrophages	NK cell proliferation, T cell proliferation, memory T cell survival
IL-17	T cells	Proinflammatory and allergic responses, Th17 function, cytokine production from many cell types
IFN-γ	Activated Th1 cells, CTLs, DCs, NK cells	MHC expression by EC, macrophage function, Th1 differentiation, Th2 suppression, adhesion and binding of T cells to ECs, NK cell activity
TGF-β	T and B cells, macrophages, platelets	Antiinflammatory, wound healing, fibrosis
TNF-α	Macrophages, T and B cells, ECs, NK cells	Proinflammatory, acute phase responses, cytotoxicity

AICD, Activation-induced cell death; *CTL,* cytotoxic T lymphocytes; *DC,* dendritic cells; *EC,* endothelial cells; *IL,* interleukin; *NK,* natural killer; *Treg,* regulatory T cells; *Th,* T helper (cell); *IFN-γ,* interferon-γ; *TNF-α,* tumor necrosis factor-α; *TGF-β,* transforming growth factor-β.

Th2, Th9, Th17, and Tfh (follicular help) populations. The Th1 clones produce IL-2, IFN-γ, and lymphotoxin, and Th2 clones produce IL-4, IL-5, and IL-10. Th1-derived cytokines are growth and maturation factors for CTLs (especially IL-2) and macrophages (particularly IFN-γ), whereas Th2-derived cytokines act similarly on B cells. Th2 cells also mediate B cell class switching to differentiation to Th9 cells requires TGF-beta and IL-4. These clones secrete IL-9 and recruit mast cells. T helper 17 (Th17) cells are a subset of T helper cells stimulated by TGF-β and a number of other cytokines and produce IL-17, IL-21, and IL-22.[24] Th17 cells and IL-17–producing CD8 T cells have the capacity to play a role in rejection, particularly in the absence of a Th1 response. Tfh cells are found in lymph nodes and are important for B cell maturation, possibly playing a role in antibody-mediated rejection. CD8 T cells are usually cytotoxic but can be divided into Tc1 and Tc2 subsets, in addition to IL-17–producing CD8 T cells.[3]

In addition to T cells that promote immune responses, there are populations that regulate or control immune responses termed *regulatory T cells* (Tregs). Tregs are thymus-derived T cells that can be induced in the periphery and exhibit sustained expression of the transcription factor, Foxp3.

Memory Cells

Although there is limited knowledge of how memory T cells are generated or maintained, these cells are an important component of the immune response to infectious pathogens. In clinical transplantation, previous sensitization to alloantigen with formation of memory cells is associated with increased risk for rejection and premature graft failure. Memory responses to alloantigen frequently occur at the time of blood transfusion, pregnancy, and transplantation. However, alloantigen memory responses can develop as a result of antigen cross-reactivity during response to infection (heterologous immunity), but also by normal proliferation in response to lymphopenia induced by leukocyte-depleting agents in transplant recipients.

The principle of immunologic memory is that the immune response to a previously encountered antigen is swifter and more effective than the response to a new antigen. Memory cells are more easily activated than naïve T cells, with lower requirement for costimulation, and in addition, produce more cytokines. Furthermore, there is an increase in antigen-specific T cell frequency after exposure to a given antigen. Finally, exposure to antigen leads to a refinement of the antibody repertoire, resulting in a more effective memory response. Effector memory T cells are specialized for quickly entering inflamed tissues because they can rapidly mature into effector T cells and secrete larger amounts of cytokines after restimulation. Central memory T cells likely remain in the SLOs and do not produce as much cytokine.[25] Memory cells are believed to persist after an initial immune response through expression of the antiapoptotic genes *Bcl-2* and *Bcl-xL,* which are induced primarily by IL-2 and CD28 stimulation, although IL-15 also may provide survival signals. Long-term memory cell survival is likely a function of periodic interactions with self-MHC:peptide complexes on APCs (i.e., homeostatic proliferation).

EFFECTOR FUNCTIONS

Once activated and expanded, T cells exert effector functions that result in destruction of graft tissue. Although T cells are essential for acute organ allograft rejection, the precise mechanisms by which they mediate graft injury are uncertain. CD4 T helper cells may release numerous cytokines that affect the alloimmune response. For example, they may promote delayed-type hypersensitivity (DTH) responses that involve stimulating production of nitric oxide, reactive oxygen species, and TNF-α by macrophages. T cell cytokines may act directly on parenchymal cells or indirectly through effects on the endothelium and vascular supply. TNF-α and TNF-β exert local cytotoxic effects on receptors on the graft, including endothelial cells (TNF-R1) and tubular cells (TNF-R2). IFN-γ, the prototypical Th1 cytokine, is released by both CD4 and CD8 T cells during rejection. IFN-γ induces MHC class II expression on endothelium and MHC class I expression on vascular endothelial cells, epithelial cells, and parenchymal cells in the graft. The precise role of class II expression by donor cells in the graft remains controversial because mouse kidney grafts lacking class II are rejected more vigorously. Although IFN-γ is strongly associated with rejection, it probably has other signaling roles that actually help stabilize the graft. As cytokine production by CD8 T cells is generally lower than that of

CD4 T cells, production of cytokines such as IL-2 by CD4 T cells provides help for the generation of CTLs from their CD8 T cell precursors. CD4 T cells may themselves become cytolytic T cells, by mechanisms similar to those used by CD8 CTLs (described later). CD4 T cells also provide help to B cells to enhance their production of alloantibodies. Finally, Tregs have important roles in suppressing immune responses and maintaining tolerance.

Cytologic T Lymphocyte Differentiation and Function

With rare exceptions, virtually all CTLs are MHC class I–restricted CD8 T cells. Activated CTLs possess two mechanisms to kill target cells that require cell-to-cell contact.[26] First, they release perforin and granzyme B from specialized lytic granules of most CTLs and NK cells. Perforin, like activated complement, has the ability to induce transmembrane pores. The granzyme B–perforin complex enters the cell through the mannose 6-phosphate receptor, and, after internalization, perforin allows granzyme B to enter the cell through the vesicle surface to induce programmed cell death through apoptosis.[27] A third cytotoxic protein, granulysin, also induces apoptosis in target cells. The second mechanism is by Fas/Fas ligand (FasL) interactions. Fas (CD95) is a member of the TNF-R family and is the surface mediator of a pathway that when activated by FasL on activated CTLs, induces the target cell to undergo apoptosis. Both pathways induce apoptosis through activation of the caspase cascade in target cells. As previously alluded to, CD8 CTLs also release several cytokines that exert direct cytotoxic effects, including IFN-γ, TNF-α, and TNF-β.[28] Effector CD4 T cells that can mediate class II–restricted cytotoxicity to minor antigens also have been detected.

Macrophage Activation

Macrophages are recruited to the graft in response to proinflammatory cytokines, such as IL-1 and IL-6. The activated macrophage is an important mediator of DTH responses, which leads to localized tissue destruction. Resting macrophages must be activated to exert full inflammatory and cytopathic effects. Th1 cells provide help for this activation by interaction of CD40L with CD40 on the macrophage and by production of IFN-γ, which sensitizes the macrophage to respond to IFN-γ. It is possible that T cell membrane–associated TNF-α and TNF-β can substitute for CD40L. CD8 T cells also produce IFN-γ and can activate macrophages. Production of TNF-α, oxygen radicals, and nitric oxide by activated macrophages are important for their cytopathic effects. Activated macrophages also can produce IL-12, which directs the differentiation of activated naïve CD4 T cells into Th1 effector cells. Macrophage activation is inhibited by cytokines such as transforming growth factor-β (TGF-β) and IL-10, many of which are produced by Th2 cells.

The Humoral Immune Response

The extracellular spaces of the body are protected by the humoral immune response, in which antibodies produced by B cells cause the destruction of extracellular microorganisms and prevent the spread of intracellular infections. Membrane-bound immunoglobulin on the B cell surface serves as the antigen receptor and is known as the *B cell receptor* (BCR) (Fig. 100.7). It is associated with antigen-nonspecific signaling molecules, Igα and Igβ. Immunoglobulin of the same specificity is then secreted as antibody by terminally differentiated B cells (i.e., plasma cells). B cells develop in the bone marrow and undergo sequential rearrangement of immunoglobulin gene segments to generate a diverse repertoire of antigen receptors that can interact with antigen in their environment. In a process similar to that for developing T cells in the thymus, immature B cells that are strongly self-reactive at this stage are inactivated by negative selection. In contrast to T cells, new B cells are continually produced in adulthood.

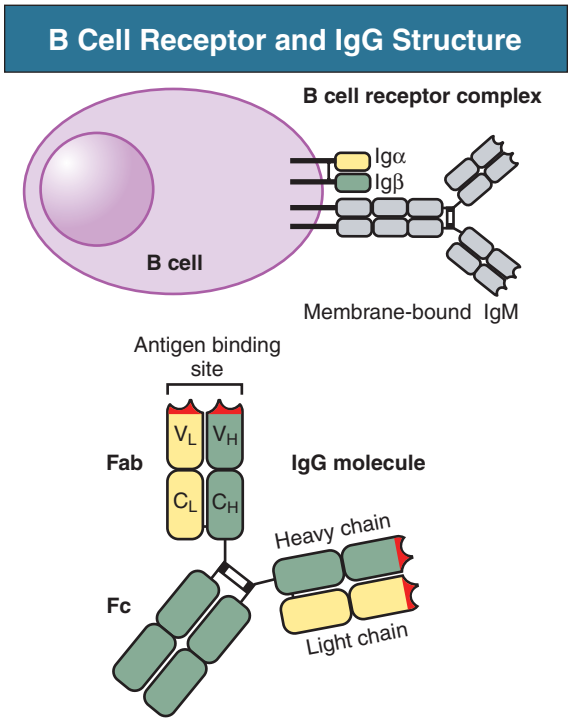

Fig. 100.7 B cell receptor and immunoglobulin G *(IgG)* structure. B cell surface membrane-bound immunoglobulin M *(IgM)* associated with antigen-nonspecific signaling molecules, Igα and Igβ, forms the B cell receptor complex. The IgG molecule is made up of four polypeptide chains, comprising two identical light (L) chains *(yellow)* and two identical heavy (H) chains *(green)*. Each of the four chains has a variable *(V)* region at its amino terminus (Fab portion), which contributes to the antigen binding site, and a constant *(C)* region (Fc portion), which determines the isotype. The V domains contain hypervariable regions that determine antigen specificity called *complementarity-determining regions (highlighted in red)*.

B cell activation requires binding of antigen to the BCR. Although some polysaccharides and polymeric proteins activate B cells directly, antibody responses to most proteins require both binding of the antigen to the BCR and interaction of the B cell with antigen-specific helper T cells. Helper T cells recognize peptide fragments derived from the antigen that are internalized and presented as peptide:MHC class II complexes on the B cell surface. Helper T cells stimulate B cells through the binding of CD40L with CD40 on B cells, through interaction of other TNF:TNF-R family ligands and by the directed release of cytokines. Although these helper T cells are generally of the Th2 subset, Th1 cells also can assist with B cell activation. Activated B cells also provide signals to T cells via B7 family molecules that promote their continued activation.

Secretion of antibodies, which bind pathogens or their toxic products, is the main effector function of B cells in adaptive immunity. The antibody molecule has two separate functions: one is to bind specifically to molecules from the pathogen that elicited the immune response, and the other is to recruit other cells and molecules to destroy the pathogen bound by the antibody. The five major classes of antibodies are IgM, IgD, IgG, IgA, and IgE. IgG is by far the most abundant immunoglobulin and has several subclasses (IgG1, 2, 3, and 4). The IgG molecule is made up of two identical light (L) and two identical heavy (H) chains that form a flexible Y-shaped structure (see Fig. 100.7). Each of the four chains has a variable (V) region at its amino terminus (Fab portion), which contributes to the antigen binding site, and a constant

(C) region (Fc portion), which determines the isotype. The V regions of a given antibody contain hypervariable segments that determine antigen specificity by forming a surface complementary to the antigen referred to as *complementarity-determining regions* (CDRs).

After appropriate activation and help from T cells, previously naïve B cells proliferate, secrete IgM, and then undergo differentiation into memory B cells or antibody-secreting plasma cells. During this process, the antibody isotype can change (to IgA, IgG, or IgE) in response to cytokines released by helper T cells, and the antigen-binding properties of the antibody can change by somatic hypermutation of the V region genes. T helper cells selectively activate higher affinity mutants, resulting in high-affinity plasma cells and memory B cells. Antibodies function in several different ways once bound to their target antigen. These mechanisms include fixation of complement, opsonization for phagocytosis by Fc receptor (FcR)-positive cells (including B lymphocytes, NK cells, macrophages, and neutrophils), opsonization for cell lysis by cells capable of antibody-dependent cellular cytotoxicity (NK cells, macrophages, neutrophils, and eosinophils), and induction of eosinophil degranulation.

Natural Killer Lymphocytes

NK cells are a subset of peripheral lymphocytes that share developmental and functional features with CD8 T lymphocytes.[29] Unlike T or B cells, NK cells do not possess a clonotypically distributed, antigen-specific cell surface receptor that is generated by gene recombination. Instead, NK cells use receptors that recognize the loss of HLA class I molecules on susceptible targets. Thus NK cells can recognize when self-MHC class I is absent, the so-called "missing self," which triggers their activation. Peripheral NK cells are mature, do not require costimulation and differentiation as with T cells, and immediately release cytotoxic granules and inflammatory cytokines such as TNF-α and IFN-γ on detection of relevant targets. Given the strong cytolytic function and potential for autoreactivity, NK cell activity is tightly regulated. Mechanisms of activation include cytokines, binding of antibody to FcRs, and binding of ligands to activating and inhibitory receptors. The role NK cells play during rejection is still being investigated.[30,31]

Termination of the Immune Response

Mechanisms are also in place to terminate the immune response. Once the source of antigen is destroyed, there are still preexisting effector cells that can cause antigen-specific tissue damage and must be deactivated. Several mechanisms accomplish this task. Once terminally mature, DCs switch cytokine production from IL-12 to IL-10, favoring the generation of regulatory mechanisms that suppress the function of effector T cells. As mentioned previously, induction of CTLA4 after T cell activation provides regulatory feedback to provide inhibitory signals to T cells that induce anergy. In the absence of continued cytokine production, T cells lack the necessary growth factors and undergo passive cell death. Finally, activated T cells undergo activation-induced cell death (AICD) by the expression of Fas and FasL on their surface. Engagement of Fas by its ligand triggers a death signal, leading to apoptosis of the cell. Although IL-2 is important for the clonal expansion of T cells, it is also essential for AICD, as well as the proliferation of Tregs, which are important in maintaining self-tolerance after removal of effector T cells.[32]

ALLOGRAFT REJECTION

Allograft rejection is defined as tissue injury produced by the effector mechanisms of the alloimmune response, leading to deterioration of graft function.[33] There are two types of rejection: T cell–mediated rejection (TCMR) and antibody-mediated rejection (AMR). Both types of rejection can be early or late, fulminant or indolent, and isolated or concomitant and can share pathologic features on biopsy.[3]

Recruitment of Cells into the Interstitium of Kidney Allografts

Allograft rejection is caused by several cellular elements of the immune system, including T cells, macrophages, B cells, plasma cells, eosinophils, and neutrophils. Although there are a variety of target cells in the graft, endothelial and tubular cells are particularly affected by these mediators. T cells serve as the main effectors and regulators of the alloimmune response, and macrophages serve as possible effectors but also aid in the removal of apoptotic cells. B cells and plasma cells serve in the production of alloantibodies, and neutrophils likely cause significant damage, particularly during AMR.

A three-step model has been proposed to explain the entry of cellular infiltrates into the allograft: tethering, adhesion, and transmigration. Table 100.2 lists several of the proteins involved in this process. The endothelium of postcapillary venules in the graft serves as the entry

TABLE 100.2 Proteins Involved in the Recruitment of Leukocytes into Allografts

Protein Type	Name	Ligand	Function
Selectins	CD62L (L-selectin)	Sialylated glycoproteins	Initial rolling of leukocytes on endothelium
	CD62L (P-selectin)		
	CD62L (E-selectin)		
Chemokines	MCP-1/CCL2	CCR2	Recruitment of monocytes, immature DCs, T cells, and NK cells
	MIP-1α/CCL3	CCR1	Recruitment of monocytes, immature DCs, T cells, and neutrophils
	RANTES/CCL5	CCR1, CCR4, CCR5	Recruitment of monocytes, DCs, T cells, NK cells, and neutrophils
	IL-8/CXCL8	CXCR1, CXCR2	Recruitment of neutrophils
	MIG/CXCL9	CXCR3	Recruitment of activated memory T cells
	IP-10/CXCl10	CXCR3	Recruitment of activated memory T cells
	Lymphotactin/XCL1	XCR1	Recruitment of T cells
Immunoglobulin superfamily	CD54/ICAM-1	LFA-1	Tight adhesion of leukocytes to endothelium
	CD102/ICAM-2	LFA-1	Tight adhesion of leukocytes to endothelium (not as strong as ICAM-1)
	CD50/ICAM-3		
	CD106/VCAM-1	VLA-4	Rolling and tight adhesion of leukocytes to endothelium
	CD31/PECAM-1	CD31	Extravasation of leukocytes across endothelium

DCs, Dendritic cells; *ICAM,* intercellular adhesion molecule; *LFA-1,* leukocyte function–associated antigen 1; *NK,* natural killer; *PECAM,* platelet endothelial cell adhesion molecule; *VCAM,* vascular cell adhesion molecule; *VLA-4,* very late antigen-4.

point of recipient leukocytes from the bloodstream. Selectins cause leukocytes to roll along the vessel wall, a process called *tethering*. Leukocytes slowed by selectins come into more prolonged contact with the endothelium and are stimulated by chemokines. As chemokines bind to receptors on leukocytes, they activate the adhesion function of integrins.

The best characterized integrin, LFA-1, is expressed on most leukocytes. The ligands for LFA-1, including intercellular adhesion molecule (ICAM)-1, -2, and -3 (immunoglobulin superfamily gene members), are expressed weakly on resting endothelium, but are induced by activation with cytokines, such as IL-1 and TNF-α. Likewise, LFA-1 transitions to a high-affinity state for ICAM, resulting in tight adhesion of the leukocyte to the endothelium. This adhesion contributes to antigen recognition, and, through a process called *haptotaxis,* leukocytes are induced to move along the vessel wall by an adhesion gradient.

Transmigration is the final step in the process of cellular entry into the allograft. Rapidly after integrin engagement of their ligands, leukocytes flatten and then undergo diapedesis through gaps between endothelial cells. Leukocyte secretion of proteases degrades the basement membrane, allowing their escape from the vessel. Once in the interstitium, secretion of matrix metalloproteinases allows leukocytes to digest extracellular matrix to move through the tissue on a chemokine gradient by a process called chemotaxis. Once confronted with foreign antigen in the allograft, previously activated T cells are capable of releasing proinflammatory cytokines (helper T cells) or directly killing foreign cells (cytotoxic T cells).

Acute T Cell–Mediated Rejection

Tubulitis, invasion of the tubular epithelium by infiltrating T cells and myeloid cells of the monocyte, macrophage, and DC series, is a characteristic feature of acute TCMR (Fig. 100.8). Deterioration of renal function during TCMR correlates with tubulitis and arterial inflammation (endothelialitis), which is much less common. The precise mechanisms by which T cells orchestrate damage to the allograft are not clear. CTLs can kill target cells by release of cytotoxic molecules (perforin, granzyme B, and granulysin) or engagement of Fas on target cells by FasL. Human gene expression studies show an increase in mRNA for CTL-associated transcripts, including granzyme B, perforin, and FasL, as well as T-bet, a master transcription factor for effector Th1 lymphocytes, during rejection episodes. Moreover, lymphocytes expressing mRNA and perforin

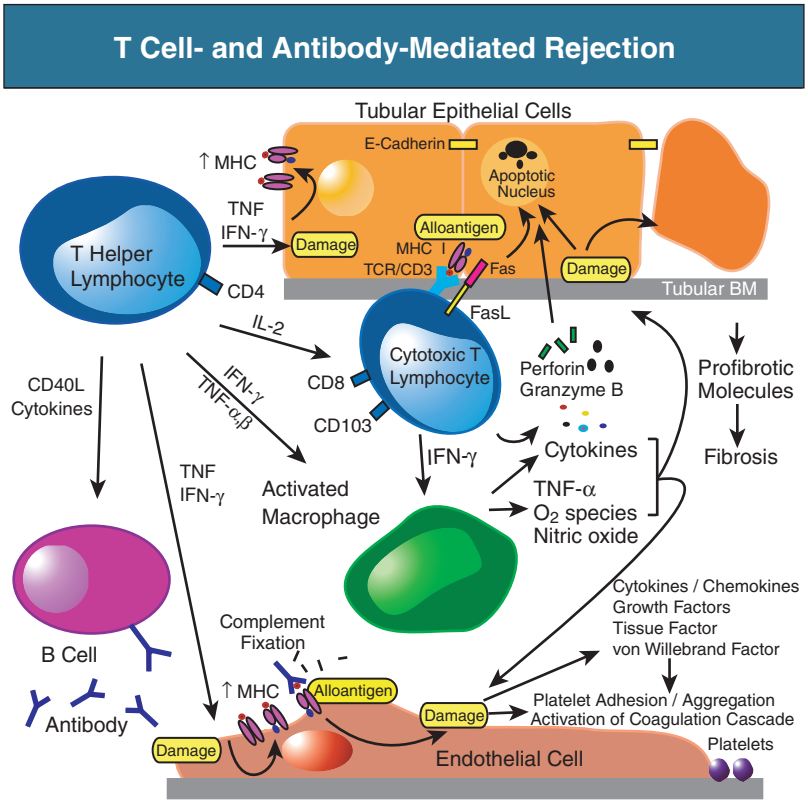

Fig. 100.8 T cell–mediated and antibody-mediated rejection. CD4 T cells induce epithelial and endothelial cell damage directly by secretion of cytokines but also indirectly by activation of cytotoxic T lymphocytes (CTLs) and macrophages. CTLs may cause apoptosis by releasing cytolytic granules containing granzymes and perforin or by exposure of Fas ligand (FasL) on the T cell surface. The integrin component CD103 is postulated to help retain T cells in epithelial layers by binding to E-cadherin, expressed most strongly in the distal nephron. Macrophages induce local tissue damage through secretion of cytokines, oxygen species, and nitric oxide (delayed-type hypersensitivity response). CD4 T cells secrete cytokines, which induce upregulation of major histocompatibility complex *(MHC)* molecules on epithelial and endothelial cells. CD4 T cells also provide help to B cells for production of alloantibody by engagement of CD40L and production of cytokines. Antigraft antibody is usually directed at MHC molecules, followed by activation of complement. Damaged endothelial cells secrete factors that activate coagulation systems and result in formation of microthrombi. Exposure of tubular cells and glomerular capillary loops to alloimmunity over time results in interstitial fibrosis, tubular atrophy, and glomerulosclerosis. *IFN,* Interferon; *TCR,* T cell receptor; *TFN,* tumor necrosis factor.

protein are closely associated with tubular epithelial cells. Some studies suggest that tubulitis may involve a specific subset of CTLs expressing the integrin CD103, which binds to its ligand E–cadherin on epithelial cells, resulting in retention of T cells in the tubules.

Most experimental evidence with perforin/granzyme, Fas/FasL, and CD103 knockouts indicates that any one of these individual cytolytic pathways is dispensable because acute rejection still occurs with these deficiencies in fully mismatched combinations.[34] These studies argue against cytoxicity as a primary mechanism to explain graft epithelial cell deterioration. Likewise, CD103:E-cadherin interactions may not be responsible for creating the lesions of tubulitis, but rather may reflect damaged cells that lose the ability to exclude inflammatory cells. Thus tubulitis may not be the cause of tubular cell deterioration but instead a sign that is has occurred.

T cells may mediate rejection instead through the secretion of cytokines, either through their direct effects or through their ability to activate macrophages to organize a DTH response.[35] DTH responses involve the release of reactive oxygen species, proteolytic enzymes, eicosanoids, and other products. These products may act directly on tubular epithelium and interstitial matrix or indirectly via effects on endothelium and the vascular supply.

Endarteritis is detected in a minority of biopsy specimens taken for acute TCMR and often responds only to anti–T cell therapies, arguing for a pathogenic role for T cells. Endarteritis is not always associated with interstitial inflammation, arguing for a T cell pathway distinct from that of tubulointerstitial rejection. Glomerulitis is an occasional feature of acute TCMR, and cells are typically a mixture of T cells and macrophages. Why the glomerulus becomes the target in only a minority of cases is not currently known. Foxp3 + CD4 Tregs are concentrated in tubules during rejection, although their role during TCMR continues to be debated.

Acute Antibody-Mediated Rejection

Acute AMR may occur with or without a component of TCMR (see Fig. 100.8). Although typically a response to donor HLA antigens expressed on endothelial cells, AMR can occur to non-HLA antigens. Examples include ABO blood group antigens and the putative endothelial alloantigens, as suggested by the rare occurrence of AMR in HLA-matched nonidentical sibling grafts. Autoantibodies also have been implicated, including to angiotensin II type 1 receptors. The kidney typically shows an accumulation of T cells, neutrophils, and monocytes in peritubular and glomerular capillaries (microvascular inflammation), although the infiltrate can be quite sparse.[36] Tubulitis is generally minimal, unless a component of TCMR is present. Foxp3 + Tregs are more rare in the AMR infiltrate than that of TCMR,[37] perhaps relevant to the poorer prognosis. Hyperacute rejection, which is due to the presence of preformed antidonor HLA antibody in sensitized recipients or of antibodies to mismatched ABO blood group loci, is a form of AMR that can result in immediate graft failure. This type of AMR is rare now that crossmatching practices and/or desensitization protocols are routinely employed by transplant centers.

Alloantibodies are cytotoxic through their ability to activate complement. Only the classical pathway has been shown to participate in acute or chronic AMR. C4d is an inactive fragment of C4b, an activation product of the classical pathway. C4b (and C4d) contains an occult sulfhydryl group that forms a covalent thioester bond with nearby proteins bound in the tissue after activation by immunoglobulin and C1. No functional role for C4d is known, but it remains in the tissue for several days after immunoglobulin and C1 have been released. C4d deposition is strongly associated with circulating antibody to donor HLA class I or II antigens and is currently the best single marker of complement-fixing circulating antibodies to the endothelium.

The acute effects of complement include chemoattraction of neutrophils and macrophages via C3a and C5a, vasospasm through the release of prostaglandin E2 from macrophages, and edema through the release of histamine from mast cells. C3a and C5a increase endothelial adhesion molecules and various cytokines and chemokines.[38] The membrane attack complex, C5b-9, causes lysis of endothelial cells. Alloantibodies also may induce cell damage through complement-independent pathways by recruitment of leukocytes with Fc receptors (CD16 most common), including NK cells and macrophages (antibody-dependent cellular cytotoxicity).[39]

A common feature of all types of AMR is the presence of microthrombi. As a result of antibody-mediated damage, von Willebrand factor is released from the endothelium, leading to platelet aggregation.[40] Animal models indicate that clotting activation is a direct consequence of complement fixation. Activation of endothelial protease-activated receptors by coagulation proteases, including thrombin, leads to the secretion of many proinflammatory cytokines.[41]

The current diagnostic criteria for acute/active AMR are: histologic evidence of acute tissue injury (in the absence of other possible causes), immunopathologic evidence of current/recent antibody interaction with vascular endothelium (e.g., C4d staining or microvascular inflammation), and evidence of circulating antibody reactive to the donor (HLA or other antigen).

Chronic Rejection

Late allograft dysfunction is due to both alloimmune mechanisms (i.e., chronic rejection) and alloimmune-independent mechanisms, including hypertension, calcineurin inhibitor toxicity, and recurrent disease.[42] Chronic rejection may occur by either cellular or humoral mechanisms, or both. Histologic features characteristic of chronic rejection are transplant glomerulopathy, peritubular capillaropathy (see later), transplant arteriopathy, and, less specifically, tubular atrophy and interstitial fibrosis.

Transplant glomerulopathy is defined by the widespread duplication or multilamination of the glomerular basement membrane (GBM), sometimes accompanied by mesangial expansion and accumulation of mononuclear cells in glomerular capillaries. GBM duplication may be caused by insults to the allograft glomerulus, including recurrent or de novo immune complex glomerular disease and thrombotic microangiopathy. However, it is believed that chronic antibody-mediated injury predominates, because the majority of cases of transplant glomerulopathy are associated with circulating antibody to donor class II MHC antigens (sometimes class I antigens), and approximately 30% to 50% of these cases have C4d deposition in the peritubular capillaries (PTCs).[43] Absence of C4d deposition in the remainder of cases may represent intermittent antibody involvement or antibodies directed at non-MHC antigens that do not fix complement.

Multilamination of peritubular capillaries can be demonstrated by electron microscopy (peritubular capillaropathy). Repeated episodes of antibody-mediated injury to the endothelium may result in repair mechanisms characterized by duplication of the basement membrane. What leads to episodic antibody injury is unknown, but fluctuating donor-specific antibody levels are observed in some patients. Neointimal thickening can be observed in either C4d positive or negative chronic rejection. Known as *transplant arteriopathy,* this lesion is characterized by thickening of the arterial intima. Macrophages and T cells may sometimes be demonstrated within the thickened intima, providing evidence of cell-mediated immunologic activity. Although not specific for rejection, interstitial fibrosis with tubular atrophy is another important histologic feature of chronically rejected allografts.

The current criteria for chronic active AMR are histologic evidence of chronic injury (in the absence of other possible causes),

immunopathologic evidence of antibody action (e.g., C4d staining), and evidence of circulating antibody reactive to the donor (HLA or other antigen).[36] The first event in chronic AMR is alloantibody production (stage I), followed by antibody interaction with alloantigens resulting in the deposition of C4d in the PTCs and glomeruli (stage II), followed by pathologic changes (stage III), and finally graft dysfunction (stage IV). Although the factors promoting progression from stage 1 to stage IV are not currently understood, the hypothesized stages provide a useful organizing structure for ongoing clinical trials designed to intervene in the earlier stages (I or II).

TRANSPLANTATION TOLERANCE

Transplantation tolerance is a state characterized by the absence of a destructive immune response in the recipient toward a well-functioning donor allograft, with a fully intact immune system and no exogenous immunosuppression.[44,45] As with self-tolerance, transplantation tolerance is achieved through control of T cell reactivity by both central and peripheral mechanisms. Central tolerance involves thymic deletional mechanisms that eliminate T cells with reactivity against self-antigens (or donor antigens in the case of transplantation tolerance) and positive selection of T cells without such reactivity. In experimental transplant models, central tolerance is achieved by elimination of the preexisting mature T cell population by irradiation and/or cytotoxic agents, followed by infusion of donor hematopoietic progenitor cells. Reconstituted donor antigen "reeducates" the thymus to delete developing T cells with antidonor reactivity, leading to a state of chimerism, in which both donor and recipient cells coexist. Translating this approach to the clinical setting, however, requires a functional thymus, which may not be present in the adult human.

Peripheral tolerance mechanisms include deletion, anergy, and regulation. With self-tolerance, these mechanisms prevent deleterious autoimmune responses from T cells that escape central deletion. Various approaches to induce peripheral transplant tolerance with the goal of inhibiting deleterious alloimmune responses are currently under investigation, including costimulatory blockade, pharmacologic manipulation of DCs, and the induction of donor antigen-specific Tregs. A hurdle to the development of clinical tolerance strategies is the lack of reproducible immune monitoring assays for tolerance, which would determine when immunosuppressive medications could be safely withdrawn. Although transplantation tolerance is not yet a clinical reality, progress in the field is being made.[46,47]

SELF-ASSESSMENT QUESTIONS

1. Which of the following is *not* true regarding human leukocyte antigen (HLA) genes?
   - **A.** HLA genes are inherited in a mendelian codominant fashion.
   - **B.** It is predicted that siblings from the same parents will have a 50% chance of having zero HLA mismatches.
   - **C.** In kidney transplantation, efforts are made to match HLA-A, -B, and -DR genes.
   - **D.** One haplotype of HLA genes is inherited from each parent.
2. Which of the following is *true* regarding allograft rejection?
   - **A.** Chronic rejection may occur by either cellular or humoral mechanisms.
   - **B.** Acute antibody-mediated rejection may occur with or without a component of cellular-mediated rejection.
   - **C.** Tubulitis is a characteristic feature of acute cellular-mediated rejection.
   - **D.** All of the above.
   - **E.** None of the above.
3. Sensitization to an alloantigen can occur during which of the following conditions?
   - **A.** Pregnancy
   - **B.** Blood transfusion
   - **C.** Transplantation
   - **D.** Infection
   - **E.** All of the above
   - **F.** None of the above
4. Which of the following is *not* true regarding alloantigen presentation to T cells?
   - **A.** T cells recognize alloantigen via direct or indirect pathways.
   - **B.** Class II major histocompatibility complex (MHC) molecules are recognized by CD4 T cells.
   - **C.** The MHC class I system is designed to present extracellular proteins taken up and processed by antigen presenting-cells.
   - **D.** T cells recognize alloantigen as peptides presented by MHC molecules.

Immunosuppressive Medications in Kidney Transplantation

Kawther F. Alquadan, Karl L. Womer, Michael J. Casey

Much of the success of kidney transplantation is a result of advances in immunosuppressive medications used during the induction and maintenance phases and for treatment of acute rejection.[1] The term *maintenance immunosuppression* is usually used to describe drug regimens consisting of small-molecule agents that are administered to stable kidney transplant recipients. Increasingly, physicians outside specialist transplant centers are involved in the care of stable kidney transplant recipients. In contrast, biologic agents that are used as induction immunosuppression before the maintenance stage or for the treatment of acute rejection episodes are usually managed by specialist transplant physicians.

SMALL-MOLECULE DRUGS

Corticosteroids

Corticosteroids have been a cornerstone of transplant immunosuppression for the past 50 years, both as maintenance immunosuppression and for treatment of acute rejection.

Mechanism of Action

Corticosteroids suppress production of numerous cytokines and vasoactive substances, including interleukin (IL)-1, IL-2, tumor necrosis factor-α (TNF-α), major histocompatibility complex class II, chemokines, and proteases. Corticosteroids also cause neutrophilia (often with a left shift), but neutrophil chemotaxis and adhesion are inhibited. They also affect nonhematopoietic cells, including endogenous renal cells. Corticosteroids act as agonists of glucocorticoid receptors but at higher doses have receptor-independent effects. Corticosteroid receptors (CRs) belong to a family of ligand-regulated transcription factors called *nuclear receptors* and are normally present in the cytoplasm in an inactive complex with heat shock proteins. The binding of corticosteroids to the CRs dissociates heat shock protein and forms the active corticosteroid-CR complex, which migrates to the nucleus and dimerizes on palindromic DNA sequences in many genes; this action is called the *corticosteroid response element.* The binding of CR in the promoter region of the target genes can lead to either induction or suppression of gene transcripts (e.g., of cytokines). CRs also exert effects by interacting directly with other transcription factors independent of DNA binding. Corticosteroids influence immune responses by regulation of the transcription factors activator protein 1 (AP-1) and nuclear factor-κB (NF-κB). Normally, NF-κB is present as an inactive complex with inhibitor of nuclear factor κB (IκB), but it can be released by IκB kinase. Corticosteroids limit inflammation by stimulating IκB, which then competes with the IκB–NF-κB complex for degradation by IκB kinase. Corticosteroids also stimulate lipocortin, which inhibits phospholipase A_2, thereby inhibiting production of leukotrienes and prostaglandins. Also, recent animal data suggest that there may be direct corticosteroid effects on renal glomerular cells separate from its immunosuppressive effects.[2] The net effect of corticosteroids involves immunosuppressive effects on cytokines, adhesion molecules, apoptosis, and inflammatory cells, as well as possible direct effects on renal glomerular cells.

Pharmacokinetics

The major corticosteroids used are oral prednisone (or prednisolone) and intravenous methylprednisolone. The oral agents have good bioavailability and short pharmacokinetic half-lives (60 to 180 minutes) but long biologic half-lives (18 to 36 hours). Corticosteroids are eliminated by hepatic conjugation and are excreted by the kidneys as inactive metabolites. Coadministration of inducers of cytochrome P-450 enzymes that metabolize corticosteroids (e.g., phenytoin, rifampin) decrease corticosteroid half-life, whereas concomitant use of P-450 3A4 inhibitors (e.g., ketoconazole) has the opposite effect. Because corticosteroid levels are not routinely monitored, dosage adjustment during concurrent therapy with these medications is problematic. For treatment of acute rejection, pulse doses of 250 to 1000 mg of methylprednisolone are typically used.

Side Effects

Side effects of corticosteroid therapy are common and associated with significant morbidity, particularly cataracts, osteoporosis, and avascular necrosis of the femoral head (Table 101.1). Other side effects include hypertension, increased appetite with weight gain, hyperglycemia, hyperlipidemia, cushingoid features, psychiatric disturbances, sleep disorders, peptic ulcer disease, pancreatitis, colonic perforation, growth retardation, and myopathy. Infection risk is also increased and is excessive if high-dose pulse therapy is prolonged. Interestingly, corticosteroids are not associated with an increased incidence of malignancy. Although corticosteroids are generally considered safe in pregnancy, fetal adrenal suppression has been reported. Rapid corticosteroid reduction protocols with low maintenance doses (5 to 10 mg/day of prednisone) can improve corticosteroid tolerability by ameliorating many of these side effects. In clinical trials of kidney transplant recipients, low-dose maintenance corticosteroids were still associated with lipid abnormalities and weight gain, but they were not associated with more infections or new-onset diabetes.[3,4]

Calcineurin Inhibitors

Calcineurin inhibitors (CNIs), including cyclosporine and tacrolimus, are fungus-derived lipid-soluble small molecules that are the mainstays of current maintenance immunosuppression. Considerable variability exists in their pharmacokinetics, interactions, and side effect profiles, which raises the question of which agent to use in the individual patient. Cyclosporine is a cyclic, lipophilic undecapeptide with several *N*-methylated amino acids, which may explain its resistance to

TABLE 101.1 Side Effects of Small-Molecule Immunosuppressive Medications

	Cyclosporine	Tacrolimus	Mycophenolate	Azathioprine	Corticosteroids	mTOR Inhibitors	Leflunomide
Renal	Nephrotoxicity, type 4 RTA, HTN, diuretic resistance, hyperkalemia, hypomagnesemia, hypophosphatemia	Nephrotoxicity, type 4 RTA, HTN, diuretic resistance, hyperkalemia, hypomagnesemia, hypophosphatemia			HTN, hypokalemia, diuretic resistance	Synergistic nephrotoxicity with CNIs, delayed recovery from ATN, proteinuria, hypokalemia, HTN	
Gastrointestinal		Diarrhea, abdominal pain	Diarrhea, nausea and vomiting, gastritis, esophagitis, oral and colonic ulcers	Nausea and vomiting, hepatotoxicity, pancreatitis	Peptic ulcers, gastritis, esophagitis, diarrhea, colonic perforation	Diarrhea	Nausea, diarrhea, hepatitis
Hematologic	Thrombotic microangiopathy	Thrombotic microangiopathy	Anemia, leukopenia, thrombocytopenia	Anemia, leukopenia, thrombocytopenia	Leukocytosis, polycythemia	Thrombotic microangiopathy, anemia, thrombocytopenia	Anemia, leukopenia
Metabolic	Hyperlipidemia, hyperuricemia, gout, glucose intolerance	New-onset diabetes			Hyperlipidemia, hyperuricemia, hyperglycemia, osteoporosis, avascular necrosis, increased appetite and weight gain	Hyperlipidemia	
Dermatologic	Gingival hyperplasia, coarsened facial features	Alopecia			Hirsutism, acne, cushingoid facies, buffalo hump	Impaired wound healing, oral ulcers	Alopecia Rash
Neurologic	Encephalopathy, insomnia, myopathy, tremors	Encephalopathy, insomnia, myopathy, tremors	Progressive multifocal leukoencephalopathy		Psychosis, insomnia, myopathy	Reflex sympathetic dystrophy	
Other	Edema	Myocardial hypertrophy	Viral infections, pulmonary edema in elderly		Cataracts	Lymphocele, interstitial pneumonitis, rash, edema	

ATN, Acute tubular necrosis; *CNIs,* calcineurin inhibitors; *HTN,* hypertension; *mTOR,* mammalian target of rapamycin; *RTA,* renal tubular acidosis.

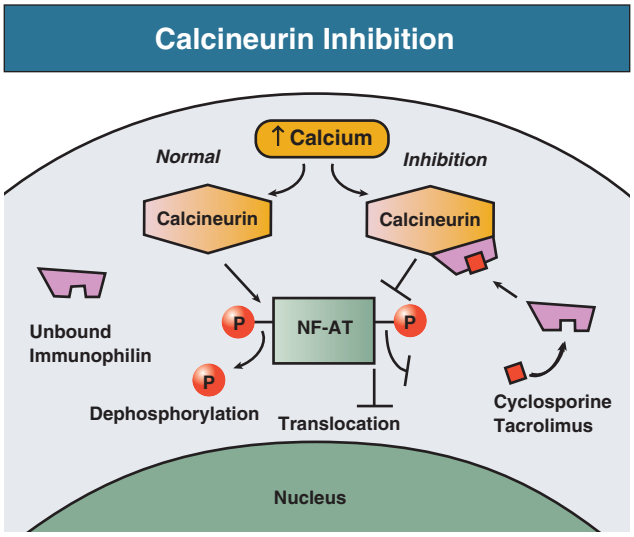

Fig. 101.1 Calcineurin inhibition. During normal T cell activation, calcium release activates calcineurin's phosphatase activity, causing dephosphorylation of the transcription factor, nuclear factor of activated T cells *(NF-AT),* and subsequent translocation to the nucleus. Cyclosporine and tacrolimus form a complex with immunophilins (cyclophilin or FK-binding protein 12, respectively), which bind calcineurin and sterically inhibit the phosphatase activity, preventing dephosphorylation and nuclear translocation of NF-AT.

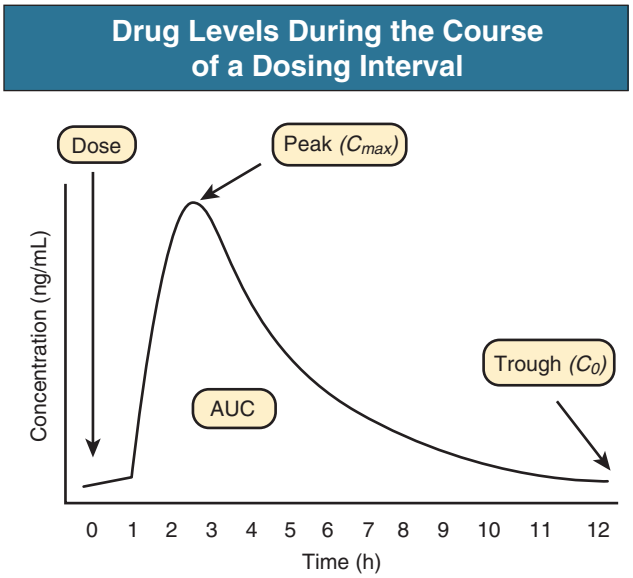

Fig. 101.2 Drug levels during a dosing interval. The drug concentration is lowest just before the dose is taken *(C_0),* then rises to a peak concentration at a certain time after the dose *(C_{max}).* The area under the concentration-time curve *(AUC)* describes total drug exposure during the entire administration interval.

inactivation in the gastrointestinal (GI) tract. Tacrolimus is a macrolide lactone antibiotic.

Mechanism of Action

CNIs exert their effect by binding to cytoplasmic proteins called *immunophilins* (Fig. 101.1). Cyclosporine binds to cyclophilin, and tacrolimus binds to FK-binding protein 12 (FKBP12).[5] Such binding enhances immunophilin affinity for and subsequent inhibition of calcineurin, which is a calmodulin-activated serine phosphatase important for dephosphorylation of inactive nuclear factor of activated T cells (NF-AT). Nuclear translocation of dephosphorylated (active) NF-AT, in association with other transcription factors, initiates downstream events leading to T cell activation. The tacrolimus-FKBP12 complex inhibits calcineurin with greater molar potency than the corresponding cyclosporine complex. Cyclosporine and tacrolimus can interfere with activation of calcineurin on substrates other than NF-AT, which likely explains many of their side effects. Treatment with CNIs also causes upregulation of the cytokine transforming growth factor-β (TGF-β), which has significant immunosuppressive properties but also promotes production of matrix proteins and tissue fibrosis. CNIs also can suppress the immune response by calcineurin-independent pathways, likely by blocking intracellular signaling pathways specific for T cells. The ability of these agents to interfere with two distinct mechanisms of T cell activation contributes to their highly specific immunosuppressive properties.

Pharmacokinetics, Monitoring, and Drug Interactions

After a dose of CNI, there is an initial absorptive phase, during which blood concentrations reach a peak level (C_{max}).[6] Typically, C_{max} occurs during the first 2 to 3 hours after the dose and corresponds to the time of maximum calcineurin inhibition. Drug levels then fall because of metabolism (also known as the *elimination phase*) until they are at the trough level (C_0) immediately before the next dose. The total drug exposure throughout the period from one dose until the next is the area under the concentration-time curve (AUC; Fig. 101.2).

For both CNIs, most of the interpatient and intrapatient variability occurs in the absorption rather than in the elimination phase. The oil-based formulation of cyclosporine requires solubilization in bile and is plagued by highly variable and unpredictable bioavailability. The microemulsion preparation of cyclosporine (modified) has enhanced bioavailability and less dependence on bile secretion. In blood, cyclosporine resides primarily in erythrocytes (60% to 70%) and leukocytes, with some binding to lipoproteins and, to a lesser extent, other plasma proteins. Cyclosporine is metabolized primarily by CYP3A4, a member of the cytochrome P450 superfamily. Metabolism occurs mostly in the liver. Interindividual differences in CYP3A4 activity and the large number of exogenous and endogenous substances capable of altering its function and expression explain the wide variation in clearance rates. One factor is the multidrug resistance 1 gene product, P-glycoprotein, which is variably expressed in the intestine and reduces the absorption of several xenobiotics, including CNIs, by transport out of intestinal epithelial cells. The average half-life of cyclosporine is about 19 hours, with excretion primarily in bile. Generic formulations of modified cyclosporine exist, although they may not have identical pharmacokinetics and therefore may not be readily interchangeable.

The absorption of tacrolimus, like that of cyclosporine, is highly variable, with bioavailability ranging from 5% to 67%. Absorption is not bile dependent but does depend on GI transit time and is affected by the presence or absence of food and the lipid content of food. Clearance appears to be faster in children, necessitating higher or more frequent dosing. African Americans and Latin Americans also require higher doses than Whites to achieve equivalent therapeutic levels, likely because of differences in subtypes of CYP3A, such as CYP3A5.[7] Similarly, higher tacrolimus dose requirements were reported for non-White Brazilian transplant recipients as well as Black transplant recipients in the United Kingdom.[8,9]

In blood, tacrolimus distributes primarily to erythrocytes, with whole-blood concentrations 10 to 30 times higher than in plasma. In contrast to cyclosporine, no lipoprotein binding occurs. Tacrolimus has 20- to 30-fold higher potency than cyclosporine on a molecular weight basis. Like cyclosporine, metabolism occurs through the CYP3A4 system,

BOX 101.1 Drugs and Other Substances That Interact With Calcineurin Inhibitors

with pharmacokinetics also affected by intestinal P-glycoprotein. Both CNIs are generally administered twice daily, but daily formulations for tacrolimus are also available in many countries. Because of the narrow therapeutic index for CNIs, the variability of concentrations among patients after a dose, and the potential for drug interactions, monitoring of drug levels is required to ensure both safety and adequacy.

Both cyclosporine and tacrolimus bind to cells and plasma components (primarily lipoproteins for cyclosporine and albumin for tacrolimus) and therefore must be assayed in whole blood. Four assays are currently used to monitor levels of CNIs in the blood: high-performance liquid chromatography (HPLC), monoclonal radioimmunoassay (RIA), monoclonal and polyclonal fluorescent polarization immunoassays, and the specific enzyme-multiplied immunoassay. Cyclosporine trough levels measured by HPLC or RIA are comparable because both measure only the parent compound. However, these concentrations are one-third lower compared with techniques that detect the parent compound plus its metabolites.

Given the complementary influence of both CYP3A4 and P-glycoprotein on the pharmacokinetic profiles of CNIs, it is assumed that CNI-drug interactions on both CYP3A4 and P-glycoprotein have similar complementary effects on CNI pharmacokinetics. Drugs that competitively inhibit CYP3A4 activity, such as ketoconazole, usually also inhibit P-glycoprotein, thereby increasing the bioavailability of CNIs, with potential for toxicity. Likewise, drugs such as phenytoin that increase CYP3A4 levels tend to upregulate P-glycoprotein, decreasing overall bioavailability. In this case the likelihood of rejection increases. Despite similar drug interactions, the age-related and ethnic differences in pharmacokinetics between the two CNIs are likely to influence the degree and importance of such interactions. Common interactions are presented in Box 101.1.

Side Effects

Cyclosporine and tacrolimus have similarities and differences in their toxicity profiles (see Table 101.1). Both can cause nephrotoxicity, hyperkalemia, hypomagnesemia and hypophosphatemia (secondary to urinary loss), type 4 renal tubular acidosis, hypertension, diabetes, and neurotoxicity. Gingival hyperplasia, hirsutism, hypertension, hyperuricemia, and hyperlipidemia, are more common with cyclosporine, whereas tremor and glucose intolerance are more common with tacrolimus. Cyclosporine also may be associated with coarsening of facial features, especially in children, and bone pain responsive to calcium channel blockers. Tacrolimus, especially in combination with mycophenolate mofetil (MMF), has been suspected of inducing more BK virus nephropathy. The most common and vexing problem with CNIs is nephrotoxicity, with its importance evident from heart and liver transplant recipients, in whom CNIs were associated with progression to end-stage renal disease. Both reversible hemodynamic and irreversible structural components underlie the nephrotoxicity of CNIs. Reversible vasoconstriction is caused by direct vascular effects but is also due to activation of the renin-angiotensin system (RAS), endothelin, thromboxane, and the sympathetic nervous system. Over time, chronic renal injury occurs characterized by afferent arterial hyalinosis and tubulointerstitial fibrosis, presumably as the result of prolonged renal vasoconstriction with ischemia. Experimentally, chronic cyclosporine nephropathy is exacerbated by sodium restriction and volume depletion, which stimulates the RAS, and can be ameliorated by angiotensin-converting enzyme inhibitors or angiotensin receptor blockers. Cyclosporine toxicity and to a lesser extent tacrolimus toxicity are potentiated in combination with mammalian target of rapamycin (mTOR) inhibitors such as sirolimus and everolimus. Finally, CNIs can cause thrombotic microangiopathy (TMA), probably by direct endothelial cell injury and dysfunction.

Mycophenolate

MMF and enteric-coated mycophenolate sodium (EC-MPS) are important components of immunosuppressive regimens that are associated with some of the most successful outcomes in kidney transplantation.[10] Because of its well-documented efficacy and acceptable side effect profile, MMF is by far the most frequently used antiproliferative agent and is commonly used in combination with CNIs.

Mechanism of Action

The immunosuppressive effects of mycophenolate are likely mediated through the active metabolite mycophenolic acid (MPA). MMF is a morpholinoethyl ester of MPA, a potent reversible inhibitor of inosine monophosphate dehydrogenase (IMPDH), isoform 2. EC-MPS is a salt that combines an acid—MPA—with a base—sodium. The enteric coating delays MPS release so that the MPA is absorbed in the small intestine rather than in the stomach. MPA noncompetitively inhibits IMPDH, which is the rate-limiting enzyme in the de novo synthesis of guanosine monophosphate (GMP). Inhibition of IMPDH creates a relative deficiency of GMP and a relative excess of adenosine monophosphate (AMP). GMP and AMP levels act as a control on de novo purine biosynthesis; therefore MPA, by inhibiting IMPDH, blocks de novo purine synthesis, which selectively interferes with proliferative responses of T and B cells. Some other cell types such as GI epithelial cells use the de novo pathway. Thus MPA may inhibit replication of GI epithelial cells, leading to the disruption of fluid absorption and diarrhea. However, most other cell types depend primarily on the alternative pathway for DNA synthesis and cell division and thus are relatively spared from toxicity.

Pharmacokinetics

MMF, being a prodrug of MPA, is absorbed rapidly and completely from the GI tract and undergoes extensive presystemic deesterification

to become MPA, the active form. Food intake can delay the rate of MMF absorption but does not affect the extent. However, coadministration of antacids or cholestyramine decreases absorption by approximately 20% and 40%, respectively. EC-MPS has shown bioavailability equivalence as well as similar efficacy to that of MMF despite reaching higher levels with the use of proton pump inhibitors. MPA undergoes enterohepatic circulation, and its plasma concentration shows a secondary peak at 6 to 12 hours after intravenous or oral administration. The mean contribution of enterohepatic circulation to the overall AUC of MPA is 37% (range 10% to 61%). Most MPA is metabolized in the liver through a phase II glucuronidation process.

The major metabolite of MPA is the pharmacologically inactive 7-*O*-glucuronide metabolite (MPAG), although two other metabolites, MPA-acylglucuronide (AcMPAG) and MPA-phenyl-glucoside (glucoside-MPA), are isolated from the plasma of renal transplant patients. AcMPAG has shown in vitro pharmacologic activity (inhibition of IMPDH) as well as proinflammatory effects and potentially is responsible for the GI toxicity of MPA. The glucuronide metabolites are excreted into the bile, a process mediated by the multidrug resistance–related protein 2 (MRPR2), then undergo deglucuronidation back to MPA by enzymes that are produced by colonic bacteria. Blockade of MRPR2 by an inhibitor, such as cyclosporine but not tacrolimus, decreases the biliary excretion of MPAG and increases plasma MPAG levels. This eventually leads to lower plasma levels of MPA because the glucuronide metabolites no longer can be reabsorbed as MPA by enterohepatic cycling. Thus tacrolimus-treated patients have higher exposure to MPA than cyclosporine-treated patients. The ultimate elimination pathway for the glucuronide metabolites is through the kidney, and more than 95% of an administered dose eventually is found in the urine as glucuronide metabolites. For the most part, MMF and EC-MPS have been used in a fixed-dose regimen. However, studies have established a strong association of MPA AUC and its pharmacologic effects, specifically prevention of acute rejection. Furthermore, considerable interpatient variability is found in MPA AUC and trough concentrations in patients who receive a fixed dose of MMF. These data lend support to efforts to evaluate the role of therapeutic drug monitoring in increasing the therapeutic potential and minimizing adverse effects of MMF and EC-MPS.

Side Effects

MMF and EC-MPS have similar side effect profiles, including GI toxicity, bone marrow suppression, and increased infections, especially those of viral cause (see Table 101.1). GI disturbances include oral ulcerations, esophagitis, gastritis, nausea, vomiting, diarrhea, and colonic ulcers. Diarrhea and leukopenia frequently necessitate a dose reduction that could precipitate a rejection. Because the metabolites of MPA appear to play a major role in the GI disturbances associated with MMF, there is little rationale for enteric coating of the prodrug to reduce these symptoms. In fact, randomized controlled trials (RCTs) have found no significant difference in GI adverse events between MMF and EC-MPS.[11,12] MMF is not routinely used during pregnancy because of its teratogenicity in experimental animal models and clinical reports of major fetal malformations.

Azathioprine

The use of azathioprine has decreased dramatically in kidney transplantation since the introduction of MMF. Azathioprine is metabolized in the liver to 6-mercaptopurine and further converted to the active metabolite thioinosinic acid by hypoxanthine-guanine phosphoribosyltransferase. Because allopurinol (a xanthine oxidase inhibitor) increases levels of thioinosinic acid and can lead to life-threatening bone marrow suppression, the dose of azathioprine must be substantially reduced or azathioprine substituted with another agent—commonly MMF—in patients taking concurrent allopurinol. Azathioprine suppresses the proliferation of activated T and B cells and reduces the number of circulating monocytes by arresting the cell cycle of promyelocytes in the bone marrow. The antiproliferative effect is mediated by the metabolites of azathioprine, including 6-mercaptopurine, 6-thiouric acid, 6-methylmercaptopurine, and 6-thioguanine. These compounds are incorporated into replicating DNA and halt replication. They also block the de novo pathway of purine synthesis by formation of thioinosinic acid; this effect confers specificity of action on lymphocytes that lack a salvage pathway for purine synthesis. The major side effect of azathioprine is bone marrow suppression, leading to leukopenia, thrombocytopenia, and anemia (see Table 101.1) with potential life-threatening complications arising from the concurrent use of azathioprine and xanthine oxidase inhibitors such as allopurinol. The mean cell volume is commonly increased in patients taking azathioprine, and red cell aplasia occasionally can occur. The hematologic side effects are dose related and usually reversible on dose reduction or temporary discontinuation of the drug. Other common side effects are increased risk for malignancy (especially of skin cancers), hepatotoxicity, pancreatitis, and hair loss.

Mammalian Target of Rapamycin Inhibitors

mTOR inhibitors are proliferation signal inhibitors with immunosuppressive activity. Sirolimus, also known as *rapamycin,* was the first mTOR inhibitor used in transplantation and is a macrolide product of a soil fungus discovered on Easter Island.[13] Everolimus is a rapamycin analogue with a similar mechanism of action, immunosuppressive properties, and side effect profile. Although initially used in drug regimens with the intent of minimizing exposure to CNIs with its known side effects, the mTOR inhibitors have been associated with their own set of toxicities that have prevented their widespread use.

Mechanism of Action

Sirolimus has a structural similarity to tacrolimus and binds to immunophilin FK-binding protein 12 (FKBP12). The affinity of sirolimus for FKBP12 is higher than that of everolimus. mTOR inhibitors do not inhibit calcineurin or the calcium-dependent activation of cytokine genes but instead inhibit cytokine receptor–mediated signal transduction and cell proliferation that block lymphocyte responses to cytokines and growth factors. The sirolimus-FKBP12 or everolimus-FKBP12 complex binds with high affinity to the kinase enzyme mTOR, which is a serine-threonine kinase of the phosphatidylinositol 3–kinase pathway that acts during costimulatory and cytokine-driven pathways. mTOR inhibits a translation repressor protein (4E-BP1) and activates a ribosomal enzyme (p70-S6 kinase), both of which are important for translation of the mRNAs for certain proteins needed for progression from the G1 phase to the S phase of DNA synthesis. mTOR has been identified as the principal controller of cell growth and proliferation. The sirolimus-FKBP12 complex inhibits mTOR-mediated signal transduction pathways by blocking postreceptor immune responses to costimulatory signal 2 during G0 to G1 transition and to cytokine signaling during G1 progression. It also inhibits IL-2– and IL-4–dependent proliferation of T and B cells, leading to suppression of new ribosomal protein synthesis and arrest of the G1-S phase of the cell cycle. Proliferation of nonimmune cells, such as fibroblasts, endothelial cells, hepatocytes, and smooth muscle cells, is also impaired by inhibition of the growth factor–mediated responses (e.g., basic fibroblast growth factor, platelet-derived growth factor, vascular endothelial cell growth factor, and TGF-β). In addition, mTOR contributes to several protein synthesis pathways that could be involved in oncogenesis.

Pharmacokinetics

The oral bioavailability of sirolimus is poor (10% to 16%), with significant interindividual and intraindividual variability. Peak concentrations occur

approximately 1 to 2 hours after an oral dose, and sirolimus distributes extensively into tissues, including blood cells. The oral bioavailability of everolimus is higher than that of sirolimus. High-fat meals increase sirolimus levels while decreasing everolimus levels. Because sirolimus has a relatively long half-life (~62 hours), it is reasonable to wait 1 week (~three half-lives to achieve steady state) before monitoring sirolimus blood levels after initiation or dose adjustment. Sirolimus is metabolized by the P-450 3A4 isoenzyme and P-glycoprotein system and thus has interactions similar to those described for CNIs (see Box 101.1).

When an mTOR inhibitor is administered simultaneously with cyclosporine, the C_{max} and AUC for both compounds are increased. Also, cyclosporine clearance may be reduced during concurrent therapy. Because of the risk for acute CNI nephrotoxicity, it is recommended that concurrent CNI and mTOR inhibitor therapy be avoided.

Side Effects

The mTOR inhibitors have a wide variety of toxicities (see Table 101.1). The most common adverse effects associated with sirolimus are dose-dependent hypertriglyceridemia, anemia, thrombocytopenia, and leukopenia. Other adverse effects include impaired wound healing and dehiscence, formation of lymphoceles, oral ulcers, reduced testosterone levels, diarrhea, and pneumonitis. Although not inherently nephrotoxic, the mTOR inhibitors result in renal graft damage through several mechanisms. When used in combination with full-dose cyclosporine (and probably tacrolimus), sirolimus potentiates CNI-induced nephrotoxicity. In patients with renal impairment, sirolimus is associated with marked yet potentially reversible proteinuria and worsening of established proteinuria. Sirolimus also can cause delayed recovery from acute tubular necrosis. Finally, cases of TMA have been reported, and there is concern that higher doses of sirolimus may inhibit endothelial cell growth. Interestingly, sirolimus-based regimens have been associated with a reduced incidence of post-transplantation malignancy. Some physicians regard sirolimus as the preferred immunosuppressive agent in transplant patients who develop malignancy, but this is based on data limited to kidney transplant recipients with squamous cell skin cancer.[14,15] Sirolimus is not routinely used during pregnancy because of its teratogenicity in animal models, although successful pregnancies have been reported.

Dihydroorotate Dehydrogenase Inhibitors

Leflunomide and its derivative FK778 are pyrimidine synthesis inhibitors with immunosuppressive as well as antiproliferative effects. These agents inhibit dihydroorotate dehydrogenase, which is a key rate-limiting enzyme in de novo pyrimidine synthesis. Unlike other cell types, activated lymphocytes expand their pyrimidine pool by nearly eightfold during proliferation, whereas purine pools increase only twofold. Thus inhibition of dihydroorotate dehydrogenase prevents lymphocytes from accumulating sufficient pyrimidines to support DNA synthesis. Leflunomide tablets are 80% bioavailable. After oral administration, leflunomide is metabolized to teriflunomide, which is responsible for essentially all of the activity in vivo and is monitored during therapy. Metabolism occurs in the liver, with excretion in the urine and bile. Because of its very long half-life (~2 weeks), a loading dose of 100 mg for 3 days is generally used to reach steady-state levels quickly. Side effects include GI symptoms, alopecia, bone marrow suppression, severe hepatitis, interstitial lung disease, peripheral neuropathy, and life-threatening skin reactions. Leflunomide use is not safe during pregnancy, and unless female leflunomide users receive cholestyramine therapy to eliminate the drug from the body, pregnancy must be avoided for 2 years after discontinuation. Additionally, male-mediated teratogenicity is a concern with leflunomide, so males wishing to father a child should undergo an accelerated leflunomide elimination procedure. Although it is not approved for use in kidney transplantation, leflunomide has been assigned orphan drug status for the prevention of rejection in solid organ transplantation, largely because of modest antiviral activity in vitro against BK virus and cytomegalovirus. However, the efficacy and safety of leflunomide have not been completely assessed in well-controlled studies. Furthermore, the manufacturers of FK778 discontinued development because of a lack of benefit over current options with regard to prevention of rejection and treatment of BK virus nephropathy.

BIOLOGIC AGENTS

Biologic agents in the form of polyclonal antibodies and monoclonal antibodies (mAbs) are frequently used in kidney transplantation either as induction therapy or for the treatment of rejection. Polyclonal antibodies are derived from horses or rabbits; historically, mAbs have been murine in origin. However, because foreign proteins can elicit an immune response, there has been an attempt to replace murine monoclonal products with humanized or chimeric mAbs (Fig. 101.3). Humanized antibodies are produced by merging the DNA that encodes the antigen-binding portion of a monoclonal mouse antibody with human antibody–producing DNA. Mouse hybridomas are then used to express this DNA to produce hybrid antibodies that are not as immunogenic as the murine variety. Chimeric antibodies use the same strategy but for the entire variable region and thus are more immunogenic than humanized antibodies. Polyclonal antibodies and mAbs can be depleting agents or immune modulators.

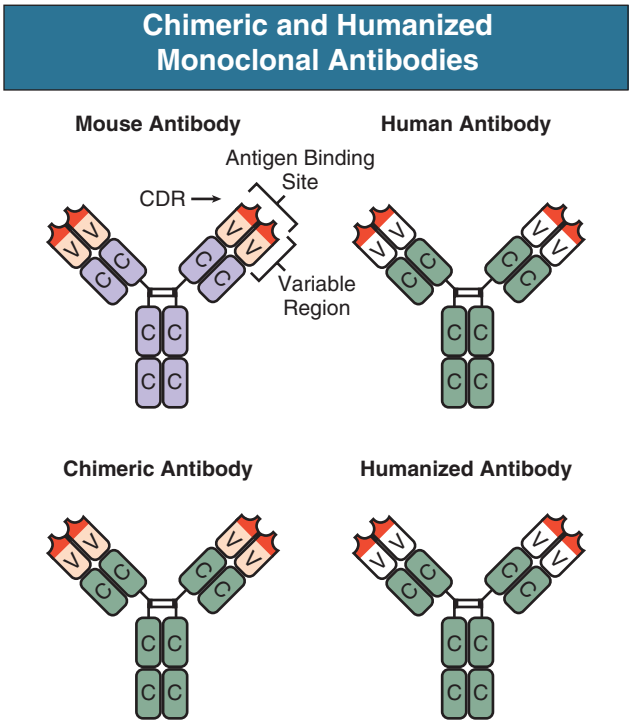

Fig. 101.3 Chimeric and humanized antibodies. Chimeric antibodies consist of human constant *(C)* regions and mouse variable *(V)* regions. A chimeric antibody therefore retains the antigen binding site of the mouse antibody but with fewer amino acid sequences foreign to the human immune system than a standard mouse antibody. Humanized monoclonal antibodies retain only the minimum necessary parts of the mouse antibody for antigen binding, the complementarity-determining region *(CDR, highlighted in red),* and therefore are even less immunogenic in the human host.

Polyclonal Antilymphocyte Sera

Polyclonal antilymphocyte agents are produced by immunizing animals with human thymus–derived lymphoid cells. Although rabbit antithymocyte globulin (ATG) is currently the preferred preparation, equine preparations historically have been used. Most regimens involve daily intravenous administration of ATG for 4 to 7 days either as induction therapy or for treatment of corticosteroid-resistant rejection. ATG contains antibodies that react against a variety of targets, including red blood cells, neutrophils, dendritic cells, and platelets. ATG binds to multiple epitopes on the surface of T cells and induces a rapid lymphocytopenia by several mechanisms, including complement-dependent cytolysis, cell-dependent phagocytosis, and apoptosis. ATG is a potent immunosuppressive, and T- and B-lymphocyte counts can remain depressed up to 24 hours after administration. The lack of specificity coupled with marked immunosuppression increases the risk for infection and malignant neoplasms. Because polyclonal agents are xenogeneic proteins, they may elicit a number of side effects, including fever and chills. The initial lysis and activation of T cells that follow ATG administration may generate significant side effects after the first dose with the release of TNF-α, interferon-γ (IFN-γ), and other cytokines. Less commonly, ATG can induce a serum sickness–like syndrome and, rarely, acute respiratory distress syndrome.

Humanized Monoclonal Anti-CD52 Antibody

Alemtuzumab is a humanized IgG1 mAb directed against CD52, a glycoprotein found on circulating T and B cells, monocytes, macrophages, natural killer cells, and granulocytes. Alemtuzumab was originally approved for the treatment of B cell chronic lymphocytic leukemia, but it has been used off label as an induction agent in renal transplantation. Treatment results in a rapid and effective depletion of peripheral and central lymphoid cells, which may take months to return to pretransplantation levels. Side effects of alemtuzumab include first-dose reactions, neutropenia, anemia, and rarely, pancytopenia and autoimmunity (e.g., hemolytic anemia, thrombocytopenia, and hyperthyroidism). The risks for immunodeficiency complications such as infection and malignant neoplasia with alemtuzumab are still not clear, and additional controlled trials are necessary to establish dosing, safety, and efficacy.

Monoclonal Anti-CD25 Antibody

The alpha subunit of the IL-2 receptor (CD25) is upregulated on activated T cells and leads to the expression of high-affinity IL-2 receptors. The engagement of IL-2 receptors by IL-2 triggers the activated T cell to undergo proliferation. Basiliximab is a chimeric mAb with a specificity for CD25; it induces relatively mild immunosuppression and is used as an induction agent to prevent rejection but not to treat established rejection.[16,17] Although the exact mechanism of action is not fully understood, it is clear that significant depletion of T cells does not play a major role. Saturation of the IL-2 receptor alpha subunit persists for up to 25 to 35 days after treatment with basiliximab. Although saturation is important as a determinant of minimal blood concentrations, it is not predictive of rejection. No major side effects have been associated with anti-CD25 induction compared with transplant recipients receiving no anti-CD25 induction.

B Cell–Depleting Monoclonal Anti-CD20 Antibody

Rituximab is an engineered chimeric mAb that contains murine heavy- and light-chain variable regions directed against CD20 plus a human IgG1 constant region.[18] The CD20 antigen, a transmembrane protein, is found on immature and mature B cells and on malignant B cells. CD20 mediates proliferation and differentiation of B cells. Rituximab directly inhibits B cell proliferation and induces apoptosis and lysis by complement-dependent cytotoxicity, antibody-dependent cell cytotoxicity, and activation of tyrosine kinases as a direct effect of the antibody binding to its CD20 ligand. Rapid and sustained depletion of circulating and tissue-based B cells occurs after intravenous administration, and recovery does not begin until approximately 6 months after treatment. Although plasma cells are usually CD20 negative, many are short lived and require replacement from CD20-positive precursor cells. In addition, CD20-positive B cells can act as secondary antigen-presenting cells (APCs), thereby enhancing T cell responses. Thus by targeting CD20 on precursor B cells, rituximab decreases the production of activated B cells and limits their antibody production as well as antigen presentation capability. Most adverse events are first-infusion effects, such as fevers and chills, and are generally of mild severity, becoming less frequent with subsequent infusions. Viral infections, including reactivation of hepatitis B virus and JC virus have been reported, although it is not known whether these events are specific to the agent or instead reflect the overall state of immunosuppression. Antichimeric antibodies develop in some patients, but their true incidence and therapeutic significance are uncertain. Rituximab has been used in kidney transplantation to treat antibody-mediated rejection, as well as in combination with intravenous immunoglobulin (IVIG) to reduce high-titer anti–human leukocyte antigen (anti-HLA) antibodies in highly sensitized patients awaiting renal transplantation.[19] Rituximab is also used as induction therapy after desensitization therapy for ABO blood group–incompatible and high-risk positive crossmatch kidney transplantation. Finally, rituximab is often used to treat post-transplantation lymphoproliferative disease.

Intravenous Immunoglobulin

IVIG products are known to have powerful immunomodulatory effects in inflammatory and autoimmune conditions. The mode of action of IVIG is not well understood. In renal transplantation, the most important effect appears to be a reduction of alloantibodies through inhibition of antibody production and increased catabolism of circulating antibodies. Additional potential mechanisms include inhibition of complement-mediated injury, inhibition of inflammatory cytokine generation, and neutralization of circulating antibodies by antiidiotypes. Side effects related to IVIG administration include minor self-limited reactions, such as flushing, chills, headache, myalgia, and arthralgia. Rarely, anaphylactic reactions may occur. Delayed reactions include severe headache and aseptic meningitis, which respond to analgesics. More recently, severe thrombotic events have been linked to the administration of IVIG products. Osmotic injury of the proximal tubular epithelium can occur after administration of sucrose-containing IVIG preparations. This tubular injury is self-limited and can be minimized or avoided by use of sucrose-free preparations. In combination with plasma exchange, IVIG appears to offer significant benefits in the desensitization of positive-crossmatch and ABO-incompatible patients to allow successful transplantation as well as in the treatment of antibody-mediated rejection. Alone or in combination with rituximab, IVIG has been successful in the desensitization of highly sensitized wait-listed patients to increase the chances of finding a compatible donor.

Belatacept

Costimulation blockade is an immunosuppression alternative for kidney transplant recipients. Belatacept, a first-in-class costimulation blocker, is a fusion protein that binds to CD80 and CD86 on APCs to prevent T cell activation and proliferation (Fig. 101.4). The drug affects the CD28 pathway as well as the cytotoxic T-lymphocyte antigen 4 (CTLA-4) pathway, the latter being required for the function of T regulatory cells (Tregs) and tolerance of transplanted tissue. Belatacept was initially

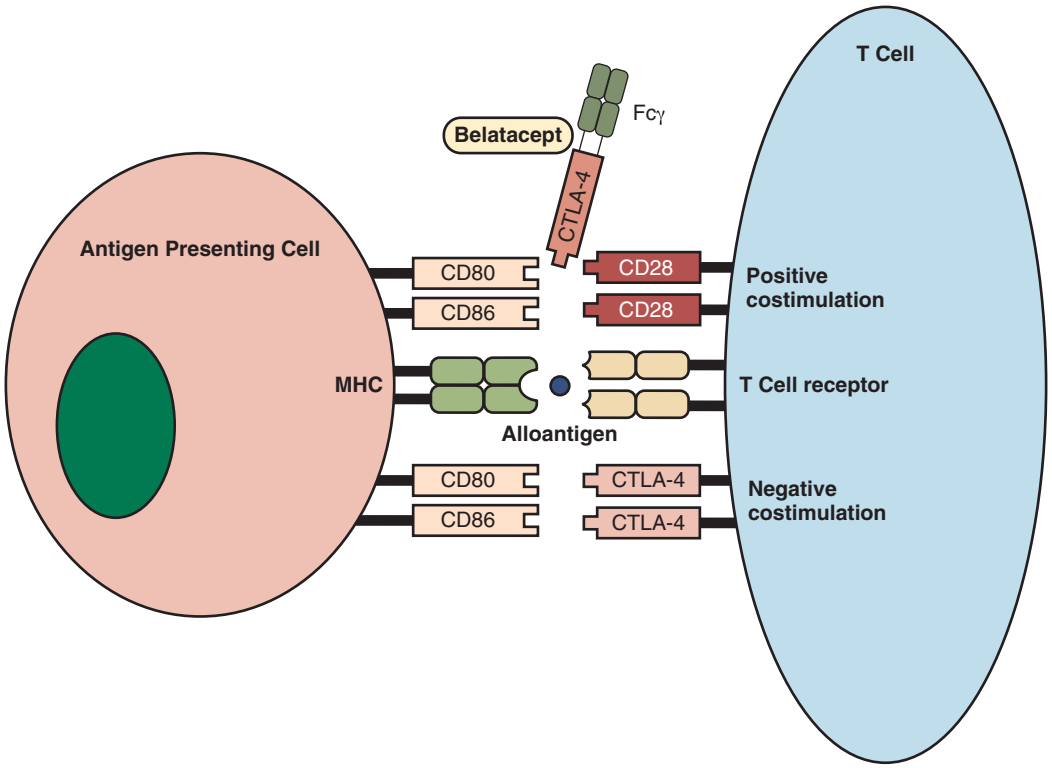

Fig. 101.4 Costimulation blockade. Lymphocyte T cell activation requires two signals with the first signal mediated by the major histocompatibility complex (MHC) and the T cell receptor, and the second signal (positive costimulation) mediated by CD80/CD86 on the antigen-presenting cell *(APC)* and *CD28* on the T cell. Negative costimulation is mediated by the cytotoxic T lymphocyte–associated protein 4 *(CTLA-4)* on activated T cells that binds to *CD80/CD86* on the APC and suppresses T cell responses (negative costimulation). Belatacept is a CTLA-4 fusion protein that binds CD80/CD86 and blocks positive costimulation via the CD28 pathway, thus preventing T cell activation.

approved by the U.S. Food and Drug Administration for de novo kidney transplantation only in Epstein-Barr virus (EBV)-seropositive adult patients because of concerns that administering belatacept might increase the risk for early post-transplant lymphoproliferative disorder (PTLD) in EBV-seronegative patients. Also, it has been used off label for conversion from CNIs after renal transplantation. Common side effects include anemia, leukopenia, and GI symptoms, as well as hypokalemia or hyperkalemia. Rare but serious side effects include progressive multifocal leukodystrophy and PTLD.

In the phase III BENEFIT trial, belatacept showed significantly better glomerular filtration rate (GFR) despite higher rates of early acute rejection compared with cyclosporine.[20] Belatacept-treated patients also had better blood pressure and lipid control compared with cyclosporine controls. The 7-year follow-up data showed that the composite endpoint of graft and patient survival was better with belatacept, but the individual graft survival and patient survival were separately not statistically different compared with cyclosporine.[21] Belatacept continued to show better 7-year renal function with no increased risk for late PTLD in EBV seropositive patients.

Other studies looked at patients who were not included in the BENEFIT trial. The BENEFIT-EXT trial included patients who received a kidney transplant from an expanded criteria donor, donation after cardiac death donor, or a donor with long cold ischemia time.[22] This trial also found that patient and graft survival with belatacept were not inferior, but unlike in the BENEFIT trial, the acute rejection rate and GFR were similar between belatacept and cyclosporine. More recently a retrospective study of the Scientific Registry of Transplant Recipients database compared the 1-year outcomes between belatacept and tacrolimus.[23] Similar to the BENEFIT trial, this study showed no difference in graft survival, but better renal function despite a greater risk for acute rejection was seen with belatacept compared with tacrolimus. Also, a lower risk for new-onset diabetes after transplantation was observed with belatacept. In summary, belatacept seems to better preserve GFR and have a better metabolic profile compared with CNIs, but it is unclear whether more acute rejection early on might affect long-term renal graft survival.

Other Agents Used in Transplantation

Bortezomib

Bortezomib is an antineoplastic agent originally approved for the treatment of plasma cell dyscrasias such as multiple myeloma and several types of lymphomas. It inhibits proteasomes, which are enzyme complexes that regulate protein homeostasis. Specifically, bortezomib reversibly inhibits chymotrypsin-like activity at the 26S proteasome, leading to activation of signaling cascades, cell-cycle arrest, and apoptosis. It targets mature rapidly proliferating antibody-producing plasma cells, but also interferes with T cell function and interleukin and TNF production. Bortezomib has been used off label for both primary and refractory antibody-mediated rejection, experimental desensitization protocols, and induction immunosuppression in patients who are highly sensitized with HLA antibodies.[24-26] Also, the BORTEJECT study is an ongoing phase 2 RCT investigating the impact bortezomib might have on treating late antibody-mediated rejection.[27] Bortezomib is administered intravenously and is metabolized by the liver. GI symptoms are common, but thrombocytopenia and peripheral neuropathy limit its use. Herpes zoster prophylaxis is required.

Eculizumab

Eculizumab is a humanized monoclonal antibody directed against complement protein C5 that prevents cleavage into C5a and C5b, thus blocking the subsequent formation of the terminal complex C5b-9 or membrane attack complex. Eculizumab prevents antibody-dependent complement-mediated cytotoxicity; therefore it has been used as an off label treatment for antibody-mediated rejection. However, because of its experimental use and extreme cost, eculizumab is usually reserved as a rescue therapy for allografts resistant to other antirejection therapies. Preliminary data using eculizumab in acute antibody-mediated rejection appears promising, but its role in treating chronic antibody-mediated rejection remains unproven.[28-30] As a result of increased incidence of meningococcal infections associated with eculizumab, meningococcal vaccine and antibiotic prophylaxis are required before starting therapy.

SELF-ASSESSMENT QUESTIONS

1. What is the most common and vexing problem with cyclosporine and tacrolimus in kidney transplantation?
   A. Nephrotoxicity
   B. Hypertension
   C. Thrombotic microangiopathy (TMA)
   D. Alopecia
2. Belatacept offers patients a non-CNI alternative to maintenance immunosuppression and works by which mechanism of action?
   A. Blocks complement C5 cleavage
   B. Blocks CD25 on the IL-2 receptor
   C. Blocks CD28 mediated costimulation of T cells
   D. Inhibits B cell proliferation by targeting CD20
3. Which immunosuppressive agent has been associated with teratogenicity in experimental animals and major fetal malformations?
   A. Tacrolimus
   B. Azathioprine
   C. Corticosteroids
   D. Mycophenolate
4. The following agents commonly have been used in the treatment of acute rejection *except:*
   A. Antithymocyte globulin
   B. Basiliximab
   C. Rituximab
   D. Intravenous immunoglobulins

Evaluation and Preoperative Management of Kidney Transplant Recipient and Donor

William R. Mulley, John Kanellis

Kidney transplantation provides superior long-term outcomes compared with dialysis, in both quantity and quality of life, although the benefit gained varies among individuals.[1] The better outcomes associated with transplantation coupled with the shortage of available organs has led to an expansion of donor criteria and an increasing tendency for centers to accept marginal donor kidneys. In this chapter, we review current recommendations for the evaluation and preoperative management of both the kidney transplant recipient and the donor.

RECIPIENT EVALUATION

Many transplant centers now accept patients who were previously excluded from transplantation, such as those with human immunodeficiency virus (HIV) infection, obesity, and diabetes. This is because of the availability of newer treatment options for some conditions, a greater understanding of the impact of these conditions on patients and graft survival, and changing societal attitudes regarding equality of access to transplantation. Some absolute contraindications to transplantation remain (Box 102.1), including current infection or malignancy, noncompliance or substance abuse, and any condition likely to severely limit life expectancy (<1 to 2 years).[2-4]

Whereas the application of guidelines for transplant suitability may be relatively straightforward for patients with a single comorbidity, it is not as simple for those with multiple medical conditions, who represent a growing group of potential transplant recipients. Determination of suitability in such patients often requires input from specialists in a variety of medical and surgical disciplines along with allied health professionals. The final decision needs to be made by clinician and patient together after full discussion of the likely risks and benefits followed by regular reassessment of suitability while the patient awaits transplantation.

A summary of guidelines published by national and international transplantation associations[2-4] is presented in Box 102.2. Some of the important areas to consider in evaluating the transplant recipient are discussed here.

Cardiovascular Disease

Cardiovascular disease is common in patients with end-stage renal disease (ESRD) and is a major cause of death in transplant recipients. Hence, cardiovascular evaluation is critical in the evaluation of the potential transplant recipient.

Coronary Heart Disease and Left Ventricular Dysfunction

Chronic kidney disease (CKD) is a major risk factor for coronary heart disease (CHD). However, the vascular lesion, clinical features, and response to treatment may be quite different in patients with ESRD compared with the normal population. The role of pretransplantation screening and intervention for CHD is controversial. However, given the high incidence of cardiac events in the peritransplantation period and its major contribution to post-transplantation mortality, we favor aggressive evaluation and intervention in at-risk patients while avoiding unnecessary tests and procedures in low-risk candidates. Patients may be stratified into risk groups on the basis of history and examination, resting electrocardiography, and chest radiography. Further evaluation is unnecessary in asymptomatic patients without risk factors because of a very low incidence of coronary events.[5] Further investigation is recommended in patients with abnormal test results or significant risk factors, such as previous cardiac ischemic events, diabetes, smoking, age older than 50 years, hypertension, prolonged dialysis duration (>2 years), or a family history of CHD.[2-4]

Symptomatic patients should proceed directly to coronary angiography; noninvasive functional testing should be used to evaluate the need for angiography in asymptomatic patients.[5,6] Exercise echocardiography or myocardial perfusion scintigraphy are preferred; however, pharmacologically driven testing may be necessary if exercise is not impossible. Whereas a normal result does not exclude CHD, both testing modalities have negative predictive values for myocardial infarction or cardiac death in excess of 90% in patients with renal failure.[7] If significant CHD is identified, treatment before transplantation is required. Treatment consists of medical management, including aggressive risk factor modification, angioplasty, and stenting or coronary artery bypass grafting in patients with significant stenoses.[5,6] A suggested approach is presented in Fig. 102.1.

In patients with clinical or radiologic evidence of left ventricular dysfunction, transthoracic echocardiography should be performed to assess the severity and nature of the dysfunction. A cause should be sought and treated when possible. Severe left ventricular dysfunction may improve significantly after transplantation, so is not an absolute contraindication to transplantation. However, because it is associated with reduced post-transplantation survival it represents a contraindication in patients with significant comorbidities, unless combined heart and kidney transplantation is appropriate.[2-4]

Cerebrovascular Disease

Patients with a history of recent transient ischemic attack or stroke are at greatest risk for recurrence early after the primary event; and because stroke after transplantation is associated with a high rate of mortality,[8] a waiting time of 6 months is recommended. Meanwhile, aggressive risk factor modification is required to limit the likelihood of further stroke. Risk factors for de novo stroke post-transplantation include

BOX 102.1 Contraindications to Renal Transplantation

Current Absolute Contraindications to Transplantation

- Active sepsis
- Current uncontrolled malignancy
- Uncontrolled psychosis
- Active drug dependence
- Any medical condition with a severely shortened life expectancy (<1 to 2 years)
- Positive T cell CDC crossmatch

Historical Contraindications to Transplantation*

- HIV infection
- Hepatitis B and C infection
- Obesity
- Mood disorders
- Age older than 60 years
- Previous malignancy
- Blood group incompatibility

*These conditions are now acceptable under certain circumstances (see text).
CDC, Complement-dependent cytotoxicity; *HIV,* human immunodeficiency virus.

BOX 102.2 Recipient Evaluation Checklist

History and Examination

- Cause of renal failure and risk for recurrence
- Sensitization (transfusion, pregnancy, previous transplant)
- Past and current infections (TB, hepatitis, HIV)
- Immunization (especially hepatitis B)
- Malignancy
- Cardiovascular risks (smoking, hypertension, diabetes)
- Pulmonary, gastrointestinal disease
- Genitourinary tract
- Psychiatric, psychological history
- Surgical issues (weight, iliac vessels, abdomen, previous surgery)

Laboratory and Radiologic Investigations

- Viral serology (HIV, CMV, EBV, hepatitis B and C)
- Liver function tests
- Bone-related issues (PTH, calcium, phosphate)
- Chest radiograph
- Electrocardiogram
- Prostate-specific antigen (for men older than 50 to 60 years)
- Mammogram or breast ultrasound (women older than 50 years or with family history of breast cancer)
- Pap smear (sexually active women)

Immunologic Investigations

- ABO blood group and HLA typing
- Screening for HLA antibodies and autoreactive antibodies
- Crossmatching

CMV, Cytomegalovirus; *EBV,* Epstein-Barr virus; *HIV,* human immunodeficiency virus; *HLA,* human leukocyte antigen; *PTH,* parathyroid hormone; *TB,* tuberculosis.

older age, diabetes, and atrial fibrillation, although transplantation is associated with a reduced risk for stroke relative to remaining on the waiting list or maintenance dialysis. Routine testing for cerebrovascular disease is not advocated in asymptomatic patients except for those with a carotid bruit who should proceed to carotid endarterectomy if a significant stenosis is found. Patients with polycystic kidney disease with additional risks for cerebral aneurysm rupture (e.g., personal or family history of cerebral hemorrhage) should be evaluated for cerebral aneurysm before transplantation. Risk for cerebral aneurysm in polycystic kidney disease is discussed further in Chapter 44.

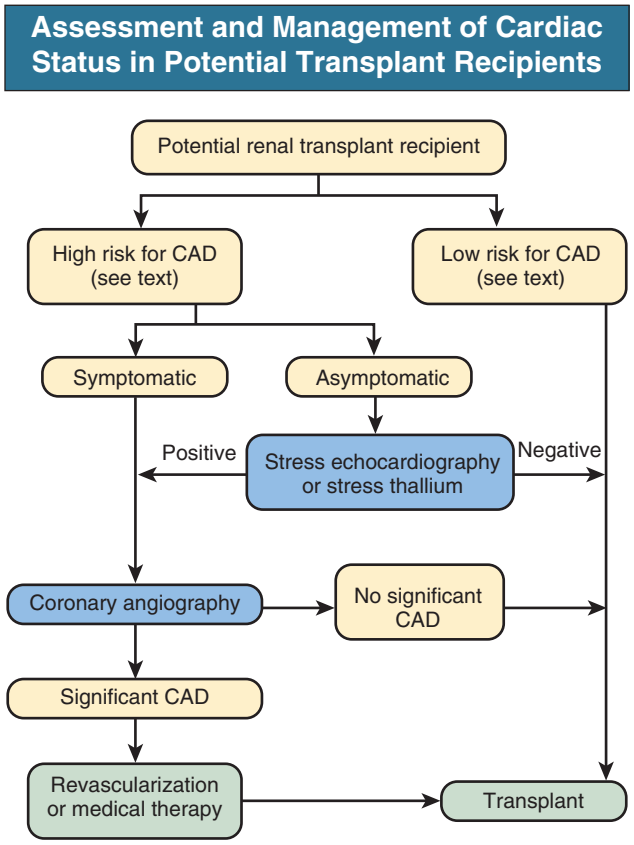

Fig. 102.1 Assessment and management of coronary artery disease in potential transplant recipients. *CAD,* Coronary artery disease.

Peripheral Vascular Disease

Asymptomatic patients with strong femoral and peripheral pulses generally require no further investigation. Patients with diabetes, history of claudication, or reduced pulses require vascular imaging beginning with Doppler ultrasound. Significant disease involving the iliac vessels may make transplantation difficult or impossible and may worsen ischemia in the distal leg. Although it is not an absolute contraindication to transplantation, peripheral vascular disease is associated with increased mortality and should be considered in conjunction with the patient's other comorbidities.

Cancer

Cancer is a major cause of death in renal transplant recipients. Further increases in the incidence of malignancy are likely with increased graft survival and acceptance of older recipients. The incidence of malignancy is also increased in transplant recipients compared with the general population.[9] However, the effect of transplantation on different types of cancer is not uniform, nor is the effect of different immunosuppressive agents.[10] Some cancers, such as nonmelanoma skin cancers (61% to 82% at 20 years) and lymphoma, have a markedly increased incidence in transplant recipients compared with the general population, in contrast to breast and prostate adenocarcinoma, which are not as substantially increased. In patients with previous malignancy, guidelines for

BOX 102.3 Guidelines for Transplantation in Patients With Previous Malignancy

Usual Wait Time of 2 Years
- Most cancers

No Wait Time Necessary
- Incidental renal carcinoma
- In situ carcinoma
- Focal neoplasm (defined as a localized tumor without metastases)
- Low-grade bladder cancer
- Basal cell skin cancer

Wait Time of More Than 2 Years May Be Necessary
- Melanoma
- Breast cancer
- Colorectal cancer
- Uterine cancer

BOX 102.4 Screening Tests for Occult Infection

Routine Serology
- Cytomegalovirus
- Epstein-Barr virus
- Hepatitis B virus
- Hepatitis C virus
- HIV

Where Indicated, Tests for the Following Conditions and Infections
- HTLV
- Human herpesvirus 8
- Malaria
- Schistosomiasis
- *Strongyloides stercoralis*
- *Trypanosoma cruzi*
- Tuberculosis

Other Routine Investigations
- Chest radiograph
- Urine culture

HIV, Human immunodeficiency virus; *HTLV,* human T-lymphotropic virus.

recommended waiting time are based on the likelihood of recurrence after transplantation (Box 102.3). In general, the longer the cancer-free interval before transplantation, the smaller the recurrence risk. For most malignancies, a period of 2 to 5 years is recommended.[2-4] There are several exceptions. A longer waiting time (≥5 years) is recommended for breast cancer with nodal involvement, melanoma, and colorectal cancer worse than Dukes stage B1; no waiting time is thought necessary for nonmelanocytic skin cancers confined to the skin, in situ cancers of bladder and cervix, focal microscopic low-grade prostate cancer, and small (<7 cm) incidentally discovered and surgically removed renal cell carcinomas. Given the heterogeneity of malignant neoplasms, waiting periods before transplantation need to be individualized, taking into account the patient's other comorbidities.

Chest radiography is performed as part of the routine assessment. Although extensive screening of all potential recipients is not warranted, potential recipients should be evaluated for breast, cervical, prostate, and colorectal cancer. More comprehensive and targeted evaluation is recommended in patients with a strong family history or suggestive clinical features of malignancy or conditions associated with an increased risk for malignant disease, such as renal imaging in patients with acquired cystic disease of the kidney for possible renal cell carcinoma.[2,3]

Infectious Complications

All patients are screened for previous exposure to Epstein-Barr virus and cytomegalovirus (CMV) to assess the risk for infection, either primary or reactivation. This guides the appropriate use of prophylactic antiviral agents. For example, patients who are negative for CMV immunoglobulin G (IgG) who receive a kidney from a CMV-positive donor are at the highest risk for infection and may benefit from prolonged prophylaxis compared with the lower risk CMV-negative donor to a CMV-negative recipient (see Chapter 105). Screening for other infections should be tailored to geographical location; a guide for screening is presented in Box 102.4. All potential recipients should be immunized against hepatitis B virus (HBV). Immunization against encapsulated organisms (pneumococci, *Hemophilus influenzae,* and meningococci) should be considered in patients at high risk for antibody-mediated rejection in case rescue therapy (e.g., splenectomy) or complement inhibition with eculizumab is required.

Since the introduction of highly active antiretroviral therapy centers experienced in managing HIV infection and transplantation have reported excellent patient and graft survival in carefully selected recipients.[11] In the absence of an acquired immunodeficiency syndrome (AIDS)-defining illness, patients with sustained CD4 counts above 200/ml and undetectable HIV viral loads can be considered for transplantation.[2] Patients with HBV infection may be considered for renal transplantation if there is no evidence of active viral replication (HBV DNA or HBV early antigen [HBeAg] negative), advanced liver disease or cirrhosis (as determined by liver biopsy), or hepatocellular carcinoma.[2-4] Immunosuppression can increase HBV replication; hence, treatment before transplantation is indicated in patients with active disease, and although data to support prophylactic antiviral therapy after transplantation are scarce, treatments such as entecavir are commonly used while immunosuppression is at its highest (initial 12 to 24 months). Early reports suggest that mortality may be increased in HBV-positive patients after transplantation compared with HBV-negative recipients.[12] The significance of these findings is unclear in the current era with more effective treatment options and if only patients with inactive disease undergo transplantation. Frank disclosure of possible risks involved is recommended.[2-4]

Patients with hepatitis C should be assessed by measurement of hepatitis C virus (HCV) viral load and a liver biopsy. In patients without cirrhosis, transplantation should not be delayed by treatment because direct-acting antivirals can be safely used to treat HCV after transplantation[13] and mortality in HCV-positive patients is reduced by transplantation compared with remaining on dialysis.[14] With informed consent, HCV-positive patients may receive a kidney from an HCV-positive donor because any possible increased risk for the latter is offset by a significantly reduced waiting time. Patients with HBV and HCV infection should be screened every 12 months for hepatocellular carcinoma by liver ultrasound and serum α-fetoprotein. Those with cirrhosis may be considered for combined kidney-liver transplantation.

Patients at high risk for tuberculosis (TB) reactivation after transplantation (previous TB, abnormal chest radiograph, or positive tuberculin skin test result; residence in an endemic area) who have not been previously treated should receive prophylactic isoniazid after transplantation (see Chapter 105). Interferon-γ (IFN-γ) ELISPOT assays may replace or supplement the tuberculin skin test because they appear

more sensitive for detecting latent TB infection.[15] The need to evaluate patients for TB is determined by the likelihood of previous exposure.

Previous graft loss caused by polyoma (BK) viral nephropathy is not a contraindication to repeated transplantation. Waiting for serum and urine BK polymerase chain reaction test results to become negative appears to be preferable,[16] whereas the value of graft nephrectomy before repeated transplantation is unclear. Vigilant evaluation for recurrence is recommended.[4]

Obesity

Transplantation in obese patients (body mass index [BMI] >30 kg/m^2) generally improves survival compared with matched waiting list controls, but inferior outcomes for patient and graft survival, delayed graft function and wound healing, and infective complications have been reported compared with nonobese patients, particularly those with a BMI above 36 kg/m^2.[17,18] The association of obesity with reduced graft and patient survival is less marked after adjustment for comorbidities.[19] Nevertheless, the overweight or obese patient is more likely to develop new-onset diabetes after transplantation, which can adversely affect graft and patient survival, so such individuals should be advised to lose weight before transplantation.

Recurrent Disease

The risk for disease recurrence should be discussed as part of the informed consent process, particularly in primary renal diseases with a high risk for recurrence (e.g., focal segmental glomerulosclerosis).[20] Recurrent disease accounts for more than 5% of graft loss[20] and becomes an increasingly important cause of graft dysfunction with increasing time post-transplantation. The risks and management of recurrent disease are discussed in Chapter 108.

Gastrointestinal Disease

Screening for gastrointestinal disease is not warranted in the asymptomatic patient.[3,4] Patients with active acute or chronic pancreatitis should not undergo transplantation until they have been clear of symptoms for 12 months. Patients with active peptic ulcer disease should be treated before transplantation with proton pump inhibitors, and this should be continued to prevent ulceration after transplantation. Patients with symptomatic diverticular disease require colonoscopy and potential colonic resection in severe cases before transplantation because they are at increased risk for perforation on immunosuppressive medications.[3] Whereas symptomatic cholecystitis should be treated surgically before transplantation, asymptomatic cholelithiasis does not require surgery before transplantation because cholecystectomy after transplantation is required in less than 10% of these patients and results in no increased mortality or morbidity compared with pretransplantation cholecystectomy and has no deleterious effects on graft function.[21]

Genitourinary Disorders

Screening for genitourinary tract disorders before transplantation is indicated in those with a history or renal ultrasound suggestive of urinary obstruction, especially in children, in whom urologic problems are a major cause of ESRD. If obstruction is found, urologic assessment, which may include voiding cystourethrography and urodynamic studies, is indicated to determine the best course of action to ensure bladder emptying and limit bladder pressures after transplantation; this may involve bladder augmentation, urinary diversion, or self-catheterization.

Native nephrectomy before transplantation should be considered in patients with recurrent or persistent renal sepsis, particularly in the setting of nephrolithiasis. Very large polycystic kidneys may need to be removed to accommodate the transplant kidney. Whether previous grafts should be removed before repeated transplantation is controversial. Nephrectomy of a failed graft is commonly performed on withdrawal of immunosuppression in patients with early graft failure (<12 months) to alleviate symptoms such as pain, fever, and weight loss.[22] Other indications include graft sepsis and allowance of room for the new graft. However, unless there is a convincing reason to remove the graft, it is generally left in situ. In these circumstances the patient may need to stay on minimal immunosuppression, such as prednisolone for 3 to 6 months, to minimize graft tenderness and inflammation. Graft nephrectomy may be associated with an increased risk for human leukocyte antigen (HLA) sensitization,[22] but this is not a universal finding. Another advantage of leaving the previous transplant in situ is preservation of any residual renal function and urine output.

Pulmonary Disease

Initial assessment by physical examination and chest radiography is indicated for all potential recipients; pulmonary function tests or computed tomographic (CT) scanning are performed if clinically indicated. Guidelines suggest that patients with a short life expectancy associated with pulmonary disease, such as cor pulmonale, uncontrolled asthma, and severe obstructive lung disease (FEV_1 <25% of predicted or Po_2 <60 mm Hg [8 kPa] on room air), or those needing home oxygen should be excluded from transplantation.[4] Many centers require patients to cease smoking before acceptance because smokers have an increased risk for death and graft loss. Cessation of smoking demonstrates positive lifestyle behavior and good adherence, suggesting these factors will optimal after transplantation.

Psychosocial Issues

Psychosocial issues can have a major impact on transplant outcomes. Patients should be evaluated by a health professional experienced in judging capacity to consent and assessing likely adherence with a transplant medication regimen. Adherence with the post-transplantation treatment regimen is vital to minimize premature graft loss. Predicting adherence can be challenging and may be based on pretransplantation adherence, such as to dialysis management regimens. Transplantation should not proceed if medical, psychiatric, psychological, and social work assessment suggests that adherence is unlikely.[2-4]

Cognitive impairment is not an absolute contraindication to transplantation if appropriate supports and proxy arrangements are in place. Patients with psychiatric illnesses, including depression, bipolar affective disorder, and psychosis, require assessment by a psychiatrist to determine transplant suitability and devise a management plan to cope with possible consequences of immunosuppressive medications such as corticosteroids.[2-4] Drug and alcohol addiction should be addressed with rehabilitation and demonstrated abstinence before the patient is listed for transplantation.

Presence of Multiple Comorbidities

Increasingly, patients with multiple comorbidities are referred for consideration of transplantation. Each morbidity in itself often is not an absolute contraindication, but taken together they may mean the patient has significantly reduced overall survival prospects. Controversially, some societies have suggested that patients must have specified long-term survival prospects—for example, an 80% chance of surviving 5 years—to be accepted for transplantation from a deceased donor. In addition, risk calculators have been devised based on registry data to allow such predictions (e.g., https://optn.transplant.hrsa.gov/resources/allocation-calculators/epts-calculator/.[23]

Reevaluation of Patients on the Waiting List

Patients may wait several years on the transplant list before an opportunity to undergo transplantation. It is vital that when their opportunity

BOX 102.5 Potential Recipient Re-Evaluation While Awaiting Transplantation

- Stress echocardiogram or thallium scan
- Angiography if indicated (see Fig. 102.1)

Cancer Surveillance Relevant to Age, Sex, and Risk Factors

Cardiac reevaluation every 1 to 2 years depending on risk factors (e.g., diabetes).

comes, they are still suitable candidates. A targeted reassessment of waiting list patients therefore should be conducted at regular intervals (Box 102.5). General measures, such as cancer screening (e.g., skin, prostate, breast, and cervical), should be continued as indicated. Reassessment of cardiac status is advocated based on risk. Diabetic and other high-risk patients should be reassessed every 1 to 2 years.[5] The value of reassessing low-risk patients is more questionable, but given that CKD is a strong risk factor for cardiac disease, repeated stress testing by exercise or pharmacologically driven echocardiography or myocardial perfusion scintigraphy at least every 3 years seems appropriate. Patients with preexisting medical conditions (e.g., HIV infection or viral hepatitis) require regular specialist reviews, with any issues arising brought to the attention of the transplant team. Surgical reassessment may be needed in patients with peripheral vascular disease, if patients gain weight, or if a complication such as peritonitis occurs while the patient awaits transplantation. Patients should be temporarily removed from the waiting list if they develop a serious infection or other illness until it is resolved.

DONOR EVALUATION

Donor kidneys can be obtained from both deceased and living donors.

Deceased Donors

Classification of the Deceased Donor

Deceased donors can be classified as either heart-beating donors with loss of brainstem function (donation after brain death [DBD]) or non–heart beating donors (donation after cardiac death [DCD]). In recent years the proportion of DCD donors has been increasing in many countries as a result of policies aiming to maximize the opportunities for donation.[24]

DBD donors can be further divided into standard criteria donors (SCDs) and expanded-criteria donors (ECDs). The definition of ECD varies; in the United States, for example, it refers to heart-beating donors older than 60 years or 50 to 59 years old with two or three of the following criteria: a history of hypertension, elevated serum creatinine at donation (>1.5 mg/dl or 130 μmol/l), or death from a cerebrovascular accident. In some jurisdictions, the term *marginal donor* is loosely used to describe donors who are less than optimal for some reason such as significant underlying disease (hypertension, diabetes, vascular disease, renal impairment) or advanced age (older than 65 years). In recent years the United Network for Organ Sharing (UNOS) in the United States has adapted a new system for classifying and allocating kidneys using a quality index.[25] The Kidney Donor Risk Index (KDRI) is a score that combines various donor factors, including clinical parameters to summarize the perceived quality of deceased donor kidneys relative to other deceased donor kidneys. Factors in the calculation include age, creatinine, mode of death, donor pathway (brain death vs. circulatory death), history of hypertension or diabetes, race (African American) and risk for HCV infection. A raw index score is converted to a percentile producing the Kidney Donor Profile Index (KDPI), rating from 0 (best) to 100 (worst).

BOX 102.6 Classification of Donation After Cardiac Death Donors

As per Maastricht classification[23] (also known as non–heart-beating donors)

Uncontrolled

Category I: Dead on Arrival to Hospital

Cause of death is usually obvious (e.g., severe head injury), and no resuscitation is given.

Category II: Unsuccessful Resuscitation

The patient is brought to the emergency department while being resuscitated, but this is not effective. Alternatively, cardiac arrest occurs in hospital and the patient cannot be resuscitated.

Controlled

Category III: Awaiting Cardiac Arrest

Severe brain injury without brain death. Patients are usually ventilator dependent. Cardiac arrest occurs once support is withdrawn.

Category IV: Cardiac Arrest While Brain Dead

Patient suffers cardiac arrest after being declared brain dead. Alternatively, this occurs during brain death testing and the patient is not successfully resuscitated.

Category V: Unexpected Cardiac Arrest in a Critically Ill Patient

Example: Unsuccessful resuscitation after unexpected cardiac arrest in intensive care.

From reference 45.

The Maastricht classification defines donors after cardiac death as controlled or uncontrolled (Box 102.6).[26] Controlled donors are those who experience cardiac arrest after withdrawal of support or after brain death. Uncontrolled donors are those who are deceased on arrival to the hospital or who had unsuccessful cardiopulmonary resuscitation. From a practical point of view, a system that uses controlled donors is easier to implement than one using uncontrolled donors. This is largely related to factors surrounding ethical considerations and the consent process involving relatives of the donor.

The survival of kidneys from expanded-criteria donors and from some categories of DCD donors is generally inferior to that of kidneys retrieved from standard criteria donors.[26] Many matching schemes attempt to allocate these less ideal grafts to recipients who are predicted to have a lower than average overall survival, but practice varies considerably across countries.

Evaluation of the Deceased Donor

In most circumstances, organ donor coordinators screen potential deceased donors after referral from intensive care units (ICUs) or emergency departments (EDs). Patient records are assessed and relatives are interviewed about important aspects of the clinical history. The assessment focuses on general health (including history of infections and cancer), social history (especially drug use and sexual history), and laboratory evidence of renal impairment or other diseases (Box 102.7).

BOX 102.7 Deceased Donor Evaluation Checklist

Medical History
- Hypertension, diabetes
- Malignancy
- Infections: Past and current (TB, hepatitis, HIV)
- Transfusions
- Trauma
- Surgical history
- Hospitalizations

Social History
- Intravenous drug use
- Alcohol, smoking
- Sexual behavior
- Tattoos, acupuncture
- Overseas travel
- Incarceration

Examination
- Blood pressure
- Cardiac, vascular
- Lymphadenopathy
- Abdominal

Laboratory and Technical
- Serum creatinine
- Urinalysis, urine culture
- Liver function tests
- Coagulation profile, complete blood count
- Blood culture
- *Virology, depending on geographical region: Antibodies to CMV, EBV, HSV-1 and HSV-2; HHV-6, HHV-7, HHV-8; HCV, HBV (including HBsAg, anti-HBcAg, IgG, and IgM), HIV, West Nile virus, rabies, HTLV-1
- Parasites, depending on geographical region: Malaria, babesiosis, toxoplasmosis, Chagas disease, syphilis
- Fungi in appropriate regions: *Coccidioides, Histoplasma*
- Tuberculosis (depending on geographical region)
- Chest radiograph
- Electrocardiogram
- Biopsy if there is concern for chronic kidney disease

Operating Room Evaluation
- Intraabdominal examination to detect occult malignancy

*Choice of virologic investigations according to local risks.
Macroscopic appearance of kidneys
CMV, Cytomegalovirus; *EBV,* Epstein-Barr virus; *HBcAg,* hepatitis B core antigen; *HBsAg,* hepatitis B surface antigen; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *HHV,* human herpesvirus; *HIV,* human immunodeficiency virus; *HSV,* herpes simplex virus; *HTLV,* human T cell lymphotropic virus; *TB,* tuberculosis.

Patients with sepsis, acute hepatitis, or HIV infection are excluded from donation, as are those with a history of malignancy. Nonmelanoma skin cancers do not lead to exclusion, nor do primary brain tumors unless they are of a high grade or the donor has received chemotherapy or had a craniotomy or cerebral shunt inserted.[27] In some centers, donors potentially carrying HBV or HCV are accepted only for recipients who are seropositive for these viruses. The risk for an unknown donor malignant neoplasm is approximately 1.3%; however, the risk for transmitting a donor malignant neoplasm is lower at approximately 0.2%.[28]

Evaluation of renal function is determined by history, urinalysis, and serum creatinine concentration. In some patients a biopsy (often performed at retrieval) may provide useful information, particularly with ECDs or donors with a high KDPI. Serum creatinine concentration at admission should be in the near-normal range (estimated glomerular filtration rate [eGFR] >60 ml/min/1.73 m^2), but a temporary decline in renal function is acceptable if function is expected to recover. Proteinuria (>0.5 g/day) may indicate structural renal damage and is a valid reason for nonacceptance.

The use of kidneys from very small donors varies among centers. Donors younger than 5 or 6 years are generally associated with high risk for failure, especially from vascular thrombosis.[29] For this reason, some centers occasionally transplant two kidneys in the one recipient en bloc, using the aorta and inferior vena cava as conduits.[30]

Deceased Donor Management Before Transplantation

In the brain-dead donor, maintenance of adequate blood pressure (BP) and oxygenation are important to prevent warm ischemic renal injury. The use of pressor agents, volume resuscitation, and other conditioning strategies is complex and has been the subject of several guideline documents (see the Intensive Care Society website, www.ics.ac.uk). In this category of donor, the kidneys are generally not subject to significant warm ischemia at the time of organ retrieval unless the donor experiences prolonged hemodynamic compromise.

In DCD, once death is certified and deemed irreversible, either rapid surgical exposure of the great vessels with cooling of the organs followed by prompt retrieval is required, or, alternatively, the kidneys are cooled in situ by insertion of perfusion catheters through the femoral vessels (see also Chapter 103). Surgical retrieval can then take place after the following occur, as required: family counseling, donor assessment, or relocation from one hospital area to another (e.g., from the ICU or ED, to the operating theater). DCD is inevitably associated with warm ischemic renal injury. This is responsible for the higher rate of delayed graft function that is seen in this group. The need for dialysis after transplantation is approximately 50% but varies from 30% to 90%, depending on the Maastricht category of donor.[26]

Living Donors

Live kidney donation is currently accepted in most countries based on the demand for deceased donor organs—which far outweighs the supply—as well as the apparent very low level of risk to the majority of healthy donors.[31] Added to this are the detrimental effects for the recipient of waiting on dialysis and the excellent, generally superior results obtained through use of living donors.

Living donors may be related, unrelated, altruistic, or part of a donor exchange or list-exchange program. In many countries with well-established transplant programs, half or more of all transplants are now performed with living donors. In Japan, Brazil, and the Middle East, more than 80% of transplants use living donors. The superior outcomes of transplantation from living donors compared with that from deceased donors has supported the development of living donor paired exchange, in which living donors who are incompatible with their intended recipients are exchanged between recipients. Another

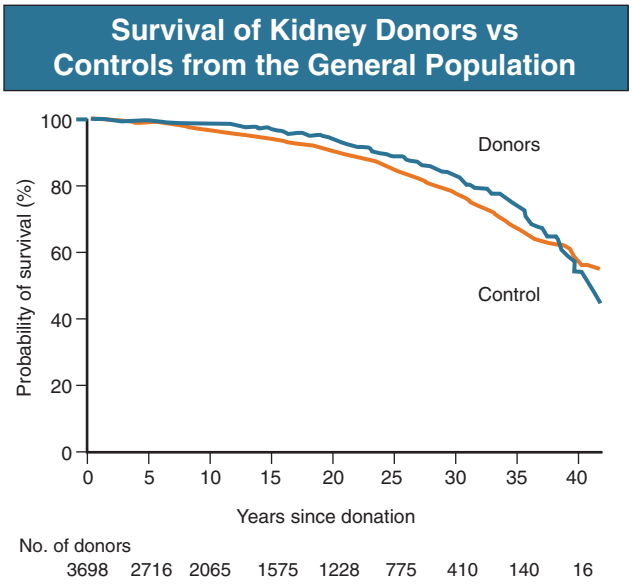

Fig. 102.2 Survival of living kidney donors. The survival of living related donors is similar to the survival among controls from the general population. Error bars at 5-year intervals indicate 95% confidence intervals for the probability of survival among kidney donors. (Modified with permission from reference 31.)

approach is living donor–deceased donor exchange, in which the donor donates to the wait list in exchange for the intended recipient receiving priority on the list.[33]

In some countries, either a state-organized or a free-market system results in the purchase of living donor kidneys; this is a highly controversial area.[33] The Declaration of Istanbul and the World Health Organization both condemn the exploitation of living donors who are vulnerable (illiterate, impoverished, undocumented immigrants, prisoners, and political or economic refugees).[34]

In recent times, many centers have extended their selection of donors to include patients who are mildly hypertensive, overweight, or hyperlipidemic or who have other abnormalities (such as isolated microhematuria or previous nephrolithiasis).[35] Whereas donation appears to be safe in the short to medium term for most of these patients, longer term medical or psychological risks have not been adequately assessed.

Mortality and Morbidity

Mortality related to living donation is a catastrophic and unexpected event (Chapter 104). Registry data and institutional surveys suggest the perioperative risk for donor death is approximately 3 in 10,000.[4,36] In the longer term, survival of donors appears to be similar to that of controls in the general population (Fig. 102.2).

Case series report that physical and psychological function in living donors is higher than the community norm. Physical issues reported by donors after donation frequently include a temporary decrease from baseline in energy; some note a longer time to full recovery than anticipated and incision pain (after open nephrectomy) that lasts longer than expected. Psychological factors usually include an improved relationship with the recipient, an improved self-image, and frequently a positive effect on the donor's life. Longer-term psychological morbidity appears minimal; however, some series have reported an association with anxiety, depression, or other psychological issues in a small proportion of the patients.[37] Even though most donors have a positive experience, a small number for a variety of reasons regret the decision to donate (0% to 5%).[38] Psychological evaluation before donation is therefore extremely important, as is the need to provide support and counseling after donation. This issue is particularly important when the transplant does not go as well as anticipated.

BOX 102.8 Living Donor Evaluation Checklist: History and Examination

History

- Hypertension
- Diabetes (including gestational)
- Infections
- Cancer (including skin lesions)
- Vascular disease
- Renal calculi
- Gout
- Urinary tract
- Family history
- Medications (including NSAIDs, herbs)
- Smoking
- Illicit and intravenous drug use
- Sexual history
- Vocation, sport interests
- Level of physical activity, exercise
- Psychiatric history, psychological factors
- Willingness to donate
- Relationship with recipient

Examination

- Blood pressure
- Weight and height, BMI
- Joints, skin
- Cancer (including skin lesions, breast)
- Lymph nodes
- Vascular disease
- Heart and lungs
- Abdomen

BMI, Body mass index; *NSAIDs,* nonsteroidal antiinflammatory drugs.

Evaluation of the Living Donor

Several groups have developed guidelines for the evaluation of the living donor, including Kidney Disease: Improving Global Outcomes (KDIGO), the Amsterdam forum[39] and consensus guidelines published by several U.S. transplant centers.[40] An outline of the usual donor evaluation is shown in Boxes 102.8 and 102.9. It includes a thorough history and examination, blood and urine screening tests, chest radiography, electrocardiography, age and family history, electrocardiography, cardiac stress test, and radiographic assessment of the kidneys and vessels. An assessment of relevant anatomy may be achieved by CT angiography or magnetic resonance angiography, depending on the center. Renal arteriography is not usually necessary, given the anatomic detail available from noninvasive techniques.

Assessment of Renal Function

Most centers use GFR of 80 ml/min/1.73 m^2 as the lower limit for donors. It is accepted that this threshold may be too low for donors younger than 40 years and too high for donors older than 60 to 65 years. An alternative approach is to consider the age-specific GFR and accept donors only if they fall within the average for this age-range. This method has been recommended by the British Transplantation Society (guidelines available at www.bts.org.uk) and is presented in Fig. 102.3. An alternative approach uses the life expectancy of the donor.[41] Based on these calculations, a 30-year-old donor would require a GFR of

BOX 102.9 Living Donor Evaluation Checklist: Investigations

Laboratory and Radiologic Investigations

- Urinalysis (blood, protein)
- Urine microscopy and culture (blood, organisms)
- Serum electrolytes, urea, and creatinine
- Liver function tests
- Full blood examination
- Fasting blood glucose and/or oral glucose tolerance test
- Fasting lipids
- 24-Hour urine, creatinine clearance, or GFR measurement by iothalamate, Cr-EDTA, DTPA clearance, 24-hour urine protein, or protein excretion by other methods (e.g., protein-creatinine ratio)
- Serum uric acid, calcium, phosphate
- Viral screening: HBV, HCV, HIV, CMV, EBV serology
- Syphilis screening (RPR)
- TB screening (PPD)
- Electrocardiogram
- Chest radiograph
- Females: Pap smear, mammography (according to age and family history)
- Males: Prostate-specific antigen (according to age and family history)
- Additional cardiac investigations (where indicated by age, history, risk factors)
  - Stress test
  - Echocardiography
  - Ambulatory blood pressure

Renal Imaging (According to Local Expertise)

- Computed tomographic angiography
- Magnetic resonance imaging angiography
- Catheter angiography

CMV, Cytomegalovirus; *Cr-EDTA,* chromium-labeled ethylenediaminetetraacetic acid; *DTPA,* diethylenetriaminepentaacetic acid; *EBV,* Epstein-Barr virus; *GFR,* glomerular filtration rate; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *HIV,* human immunodeficiency virus; *PPD,* purified protein derivative test; *RPR,* rapid plasmin reagent; *TB,* tuberculosis.

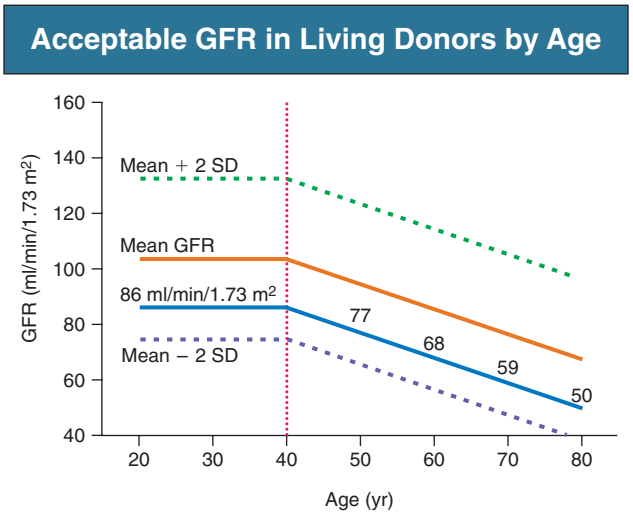

Fig. 102.3 Acceptable glomerular filtration rate *(GFR)* in living donors by age. Diagram explaining the minimum acceptable age-associated GFR in living donor candidates. The *solid orange line* shows the variation with age of mean GFR. The *outer dashed lines* show the +2 and –2 population standard deviation (SD) limits. GFR is constant up to the age of 40 years and then declines at the rate of 9 ml/min/1.73 m^2 per decade. The reference plot is based on an analysis of data for 428 living renal transplant donors who had chromium-51–labeled ethylenediaminetetraacetic acid (^{51}Cr-EDTA) GFR measurements. The *solid blue line* shows the acceptable lowest GFR for young adults, declining to 50 ml/min/1.73 m^2 at age 80 years. For transplant donors with preoperative GFR values above the solid blue line, the GFR of the remaining kidney will still be above 37. 5 ml/min/1.73 m^2 at age 80 years. (Modified with permission from the revised British Transplantation Society/Renal Association U.K. guidelines for living donor kidney transplantation, available at www.bts.org.uk/.)

123 ml/min/1.73 m^2; the required GFR for a 70-year-old person would be 68 ml/min/1.73 m^2.

Hypertension and Proteinuria in the Living Donor

Donation may be acceptable for some hypertensive individuals if BP is well controlled, GFR is as expected for donation and age, and there are no features of end-organ involvement from hypertension.[39,40] The evaluation for hypertension should include BP measurements on three separate occasions. Borderline elevated levels should be further evaluated with ambulatory BP monitoring. If elevated BP is detected and the prospective donor is still under consideration, echocardiography (looking for left ventricular hypertrophy), ophthalmologic evaluation (looking for hypertensive retinal changes), and assessment for microalbuminuria (suggesting hypertensive renal damage) should be undertaken. The prospective donor should be excluded if any of these features are present.

KDIGO recommends using the ratio of albumin to creatinine from a random urine sample with confirmation using an albumin excretion rate (AER) to assess donors for significant albuminuria (www.kdigo.org/guidelines/).[42] An acceptable AER is less than 30 mg/day, with 30 to 100 mg/day requiring an individualized approach. An AER greater than 100 mg/day should exclude potential donors. Previous recommendations referred mostly to total urinary protein excretion rather than albuminuria, with a level of 300 mg/day being used as the cut-off for exclusion. These newer recommendations are more consistent with our improved understanding of the early changes seen with underlying renal and systemic microvascular pathology signifying an increased cardiovascular risk.

Obesity and Abnormal Glucose Tolerance in the Living Donor

Although many centers accept obese living donors, several issues must be addressed. These include the impact of obesity on perioperative complications, future renal function, and cardiovascular health. In one study, obese (BMI >30) patients had an increased rate of proteinuria and renal impairment 10 to 20 years after nephrectomy.[43] Obese individuals may therefore be more prone to development of renal disease after donation, but this issue has not been carefully studied.

Future risk for diabetes is another important consideration. In addition to close assessment of those who are overweight, prospective donors with an abnormal fasting glucose concentration, a history of gestational diabetes, or a first-degree relative with diabetes should be evaluated with an oral glucose tolerance test. An abnormal glucose tolerance test result is a contraindication to donation. Patients often lose weight and otherwise change their lifestyle (exercise, diet), leading to an improvement in their results and eventual acceptance as donors. It is important that these lifestyle and risk modifications be sustained after donation occurs.

Renal Abnormalities in the Living Donor

As well as factors identified in the history (e.g., previous calculi, urinary tract infections, prostatic disease), a variety of previously unidentified renal abnormalities can be encountered in prospective donors during

their assessment. These include microhematuria, renal scarring (e.g., polar distortion suggesting reflux nephropathy), renovascular abnormalities, and renal masses and cysts.

Isolated microhematuria in a prospective donor necessitates consideration of thin basement membrane nephropathy, Alport syndrome (carrier status in women may cause minor or moderate abnormalities), and IgA nephropathy, as well as urinary tract infection, malignancy, and nephrolithiasis. Persistent microhematuria is relatively common and is evident in approximately 3% of the general population.[44] Among the possible disorders, IgA nephropathy is generally a contraindication to live donation, whereas thin basement membrane nephropathy may not necessarily be so.[45] The implications of isolated mesangial IgA without other manifestations of glomerulonephritis requires further research, and donation should be decided in the context of family history, absolute renal function, presence of interstitial disease, and age. If persistent isolated asymptomatic microhematuria is detected during living donor evaluation, a workup should include cystoscopy and urinary cytology. A renal biopsy also should be considered because glomerular hematuria cannot otherwise be excluded. If there is a possibility of familial disease (e.g., Alport syndrome, IgA nephropathy), this also helps clarify the prospective donor's future risk for progressive renal disease.[44]

Those with a history of bilateral or recurrent stones and those with systemic conditions associated with recurrent stone disease should not donate. An asymptomatic potential donor with a current single stone is suitable if the donor does not have a high risk for recurrence, if the stone is smaller than 1.5 mm, and especially if the stone is potentially removable during transplantation.[45] The evaluation of an asymptomatic donor with a single prior episode of nephrolithiasis should include evaluation of serum calcium, creatinine, albumin, and parathyroid hormone levels; spot urine for cystine; urinalysis and urine culture; spiral CT scan; chemical analysis of the stone, if available; and 24-hour urine measurement of oxalate, uric acid, and creatinine.

Atherosclerotic renal vascular disease is a relative contraindication to living donation. If it is discovered, the donor should be normotensive, have normal renal function, and have only unilateral disease. Careful evaluation for CHD and peripheral vascular disease should be undertaken, given the significant association of renovascular disease with atherosclerosis elsewhere. Fibromuscular dysplasia is found in 2% to 4% of prospective donors. Donors with severe and diffuse disease should not be accepted for donation. The age of the prospective donor should be considered, with the outcome in donors older than 50 years more predictable and benign than in younger donors.[45]

Malignancy

A history of certain malignancies is a contraindication to live kidney donation. These include melanoma, testicular cancer, renal cell cancer, bronchial and breast cancer, choriocarcinoma, hematologic malignant neoplasm, and multiple myeloma.[39] A history of malignancy may be acceptable for donation if prior treatment does not decrease renal reserve, place the donor at increased risk for renal disease, or increase the operative risk for nephrectomy. A history of malignancy may be acceptable if the specific cancer is curable and transmission of the cancer can be reasonably excluded; consultation with an oncologist may be required. Examples of cancers with low risk for transmission include certain mild forms of prostate, bladder, and cervical cancer. Consent to receive a renal transplant must include a discussion with the donor and the recipient regarding the fact that risk for transmission of malignancy cannot be completely excluded.

Cardiovascular and Pulmonary Disease

In prospective donors, the cardiac assessment should be based on the history, risk factors, examination, and electrocardiographic findings. An exercise or pharmacologic stress test and echocardiography may be warranted in certain circumstances. Individuals with myocardial dysfunction or coronary ischemia are at increased perioperative risk and should generally not donate. Pulmonary contraindications to donation include chronic lung diseases that significantly increase the anesthetic risk. If indicated by history and examination, pulmonary function testing, echocardiography, or sleep studies should be performed. All donors should cease smoking for at least 8 to 12 weeks before surgery to minimize the risk for postoperative pneumonia.

COMPATIBILITY AND IMMUNOLOGIC CONSIDERATIONS

Blood Group Compatibility

Traditionally, transplantation across incompatible blood groups has been avoided because of the risk for hyperacute rejection mediated by preformed anti-A or anti-B antibodies to the carbohydrate blood group antigens, expressed by endothelial cells as well as by red blood cells. In recent years, ABO-incompatible transplantation has become more widespread, largely based on excellent outcomes described initially by Japanese centers.[46] "Desensitizing" the recipient can avert hyperacute rejection. This involves removal of blood group antibodies by plasma exchange or immunoadsorption to achieve target titers. Preemptive splenectomy or rituximab administration (anti-CD20 monoclonal antibody) also is often used; however, the need for these measures is not clear. Rejection is predicted by high initial antibody titers and high rebound titers early after transplantation.[47] A further period of plasma exchange or immunoadsorption after transplantation is commonly instituted, whereas other centers determine the need for these therapies preemptively based on post-transplantation antibody titers. With use of this protocol, patient and graft survival appears to be equivalent to that of blood group–compatible transplantation for the short to medium term (up to 9 years).[46] Longer term results are awaited. A comprehensive overview and summary of current approaches relating to antibody-incompatible transplants is available at the British Transplantation Society website (www.bts.org.uk).

Human Leukocyte Antigen Compatibility

Tissue typing of recipient and donor determines their HLA match. HLA antigens are coded on chromosome 6, with half (one haplotype) inherited from each parent. The major histocompatibility class I HLA-A and HLA-B and class II HLA-DR antigens are routinely determined, because rejection responses are thought to most commonly stem from mismatches at these alleles. There is an increasing awareness of the importance of immune responses to other HLA antigens, and many centers now look for the presence of antibodies to HLA-C, HLA-DQ, and HLA-DP. A six-antigen (HLA-A, HLA-B, and HLA-DR) match confers a graft survival advantage compared with zero antigen matches for both deceased and living donor transplantation of 10% at 10 years.[48] In addition to determination of the HLA compatibility, crossmatching and screening for anti-HLA antibodies are performed to assess the risk for rejection.

Assessing Human Leukocyte Antigen Sensitization

The principle of screening for antibodies against HLA antigens using panel reactivity is shown in Fig. 102.4. IgG antibodies against class I (HLA-A and HLA-B) antigens are highly associated with acute rejection. IgM antibodies against HLA antigens also may predict rejection if present in current but not past sera; however, as their presence is less clinically relevant, they are usually removed by treatment of sera with dithiothreitol to aid in the interpretation of the test (Table 102.1). Autoantibodies (such as may occur in lupus) also may give false-positive

TABLE 102.1 Interpretation of the Crossmatch Test

	CROSSMATCH (NORMAL PROCEDURE)		CROSSMATCH (IgM DEPLETED*)		
Antibody to MHC Class	**T Cells**	**B Cells**	**T Cells**	**B Cells**	**Risk for Antibody-Mediated Graft Damage**
IgG against class I	+	+	+	+	Yes
IgM against class I	+	+	–	–	Yes; IgM class I antibodies may be harmless if present in old sera only but not in the current serum
IgG against class II	–	+	–	+	Yes
IgM against class II	–	+	–	–	Unknown
IgM autoantibodies	+	+	–	–	No

Ig, Immunoglobulin; *MHC,* major histocompatibility complex.
*Dithiothreitol is used to deplete IgM antibodies (see text).

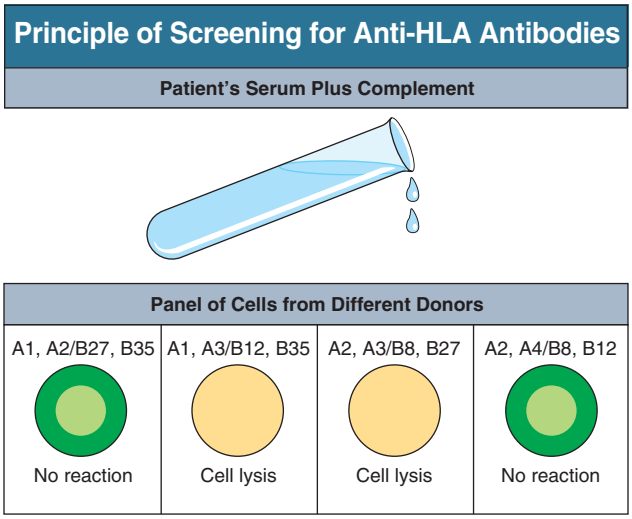

Fig. 102.4 Principle of screening for anti–human leukocyte antigen (HLA) antibodies. The patient's serum is tested with a panel of cells of known HLA types. The most common HLA antigens are represented in such panels. In this example, the A3 antigen is the only antigen present in the two lysed cell populations and absent from the nonlysed samples. Therefore the patient's serum contains anti-HLA A3 antibodies.

results and can be determined by prior absorption with autologous lymphocytes.

Sensitization to HLA antigens generally occurs through blood transfusion, pregnancy, or prior transplantation. Presence in the recipient of antibodies to donor-specific HLA antigens can result in hyperacute rejection. Crossmatching of donor lymphocytes with recipient serum allows screening for this possibility. Terasaki and coworkers pioneered the complement-dependent cytotoxicity (CDC) crossmatch.[49] This assay determines the presence of antibodies thought to be of clinical significance by mixing donor T or B lymphocytes with recipient serum in the presence of complement. The sensitivity of the assay can be augmented by the addition of anti-human globulin. Presence of a positive T cell CDC crossmatch to the donor is highly predictive of hyperacute rejection,[49] whereas a B cell CDC crossmatch is more subject to false-positive results but should prompt a search for donor-specific antibodies.[50] A positive T cell crossmatch is an absolute contraindication to transplantation.

The flow crossmatch is more sensitive than the CDC in detecting antibody capable of binding to donor T or B lymphocytes. Binding of antibody from donor serum is detected by flow cytometry after probing with a fluorescein-labeled antiimmunoglobulin antibody. The predictive value of a positive flow crossmatch for rejection is less than that of a CDC crossmatch because of its increased sensitivity, and it does not assess the ability of the antibody to fix complement. In most centers, it is not routinely performed before deceased donor transplants, but it is commonly performed in a living donor transplant workup. A positive-flow crossmatch (with a negative CDC crossmatch) is not an absolute contraindication to proceeding; however, it may lead to alteration of the immunosuppressive regimen (e.g., use of a desensitization protocol) to decrease the risk or severity of antibody-mediated rejection.

Determination of the presence of anti-HLA antibodies in the recipient's serum is increasingly used as a means of predicting rejection. This virtual crossmatch compares the specificity of the antibodies identified with the prospective donor's HLA typing. Donor-specific anti-HLA antibodies are correlated with worse graft survival even in the setting of a negative crossmatch.[51] Antibodies can be detected through panel reactive antibody testing, by enzyme-linked immunosorbent assay, or with more sensitive antigen-coated bead techniques. Beads coated with a single HLA antigen are mixed with recipient serum and probed with a fluorescein-labeled antiimmunoglobulin antibody. Beads that bind antibody are therefore identified by fluorescence. The decision on whether to proceed with transplantation in the context of this information is complex. Recommendations for detection and characterization of clinically relevant antibodies in solid organ transplantation are summarized by the British Society of Histocompatibility and British Transplantation Society and are available at www.bts.org.uk. A more recent set of guidelines was also published after a Consensus Conference on Antibodies in Transplantation, held in 2012.[52]

SELF-ASSESSMENT QUESTIONS

1. Which of the following recipient factors is an absolute contraindication to transplantation?
   - **A.** Active sepsis
   - **B.** HIV infection
   - **C.** Obesity
   - **D.** Age older than 70 years
   - **E.** Previous malignancy
2. In predicting the risk for cardiac death in potential kidney transplant recipients, stress echocardiography performs best in terms of which of the following parameters?
   - **A.** Sensitivity
   - **B.** Specificity
   - **C.** Positive predictive value
   - **D.** Negative predictive value
   - **E.** A and B equally
3. Which of the following brain-dead donors meets the definition for an expanded-criteria deceased donor (as previously used in the United States)?
   - **A.** A previously well 53-year-old person with a serum creatinine at donation of 1.7 mg/dl (150 µmol/l)
   - **B.** A 48-year-old person with diabetes, hypertension, vascular disease, and smoking history
   - **C.** A 48-year-old person with hypertension and death from a cerebrovascular accident
   - **D.** A 62-year-old person with no significant medical history
   - **E.** A 58-year-old person with hepatitis
4. Which of the following investigations would you *not* routinely perform on a 67-year-old man to assess his suitability to donate a kidney to his wife?
   - **A.** Urine microscopy
   - **B.** Colonoscopy
   - **C.** Hepatitis serology
   - **D.** Electrocardiogram
   - **E.** Renal imaging
5. Which of the following will *best* identify a high risk for hyperacute rejection?
   - **A.** Recipient tissue typing
   - **B.** Positive flow crossmatch
   - **C.** Positive T cell cytotoxicity–dependent crossmatch
   - **D.** Positive virtual crossmatch
   - **E.** Donor O blood group

Kidney Transplantation Surgery

Adam D. Barlow, Michael L. Nicholson

SOURCES OF KIDNEYS FOR TRANSPLANTATION

The usual and most frequent source of kidneys for transplantation has been donation after brain death (DBD), formerly known as donation from a heart-beating cadaveric donor. The increasing worldwide discrepancy between the availability of and the need for renal allografts[1] has led to the increasing use of alternative sources of organs, including donation after cardiac death (DCD) donors (previously known as non–heart-beating donors) and living donors. The evaluation and selection of donors are discussed in Chapter 102. Here we discuss surgical aspects of retrieval and transplantation of kidneys.

DONATION BEFORE CARDIAC DEATH DONORS

The potential DBD donor is maintained by artificial ventilation in a critical care setting until death has been diagnosed by brainstem death criteria,[2] the consent of the next of kin for donation has been given, and the necessary legal and institutional approvals have been obtained.

In the operating room some dissection is undertaken initially to define any aberrant anatomy and increase the speed and safety of organ retrieval after perfusion (warm dissection). Cannulation of the aorta and inferior vena cava is performed while the heart is still beating. This allows perfusion of the organs with cold preservative solution immediately before cardiac arrest, minimizing warm ischemia. The priorities of the organ retrieval team are influenced by the range of organs being donated. Heart, lung, liver, and pancreas retrieval take priority over kidney retrieval, which may significantly lengthen the ischemic time. The kidneys are removed with a cuff of aorta (Carrel patch) attached to the renal artery, with the maximum achievable length of renal vein, and 10 to 15 cm of ureter. The length of the right renal vein should be maximized by including a portion of inferior vena cava in continuity. Care is taken to avoid damage to polar and other accessory arteries, especially the lower pole artery, which may supply the ureter. Stripping of adventitial tissue from the ureter must also be avoided, because this also may compromise its blood supply.

The kidneys are flushed with ice cold preservation fluid until the effluent is clear and then are stored for transport in crushed ice or on a perfusion machine (see the discussion of renal preservation).

DONATION AFTER CARDIAC DEATH DONORS

Before consensus was reached regarding the definition of brainstem death, DCD donors were the main source of transplant organs. These donors were intensive care unit based and had suffered head injuries or cerebrovascular accidents deemed irrecoverable, but organ retrieval could proceed only after cardiorespiratory death. This changed with the introduction of brainstem death legislation, but the use of DCD kidneys has recently increased again in response to the shortage of suitable organs for transplantation. An international consensus has defined categories of DCD donors[3] to facilitate legal and ethical discussion and to highlight possible differences in organ viability (see Chapter 102, Box 102.6). DCD kidneys sustain a period of warm ischemia, the period between cardiac arrest and the time that in situ cold perfusion is started. The duration of ischemia correlates with rates of primary nonfunction, delayed graft function, acute rejection, allograft, and patient survival. The main requirement of organ procurement from DCD donors is therefore to achieve rapid in situ perfusion of the kidneys to limit warm ischemia. This requires an emergency response team of surgeons and transplant coordinators, with considerable on-call and logistic commitments.

DCD donors may be either uncontrolled (Maastricht categories I and II) or controlled (Maastricht categories III through V). In controlled donors, cardiac arrest is expected, and it is therefore possible to reduce the warm ischemia time to only a few minutes because the surgical retrieval team will be on standby. Unexpected donor cardiac arrest may result in prolonged warm ischemia times. The duration of reversible warm ischemia time that the human kidney can sustain is unknown, but DCD kidneys with warm ischemia exceeding 60 minutes are considered by many to be of marginal suitability.

Donation After Cardiac Death Protocol

Centers involved with DCD donation should adhere to the Maastricht protocol,[4] which includes the following principles:

- Approval by the local medical ethics committee
- Diagnosis of death by doctors who are independent of the transplantation team
- 5-Minute rule (after declaration of cardiac death, the body is left untouched for a period of at least 5 minutes before intervention)
- Rapid in situ cooling with use of a catheter inserted into the aorta
- Organ retrieval by standard surgical techniques

Uncontrolled Donation After Cardiac Death Donors

After a period of unsuccessful resuscitation, confirmation of cardiac death, and observation of the 5-minute rule, cardiac massage and ventilation with 100% oxygen are recommenced in an attempt to deliver oxygenated blood to the kidneys. A mechanical resuscitation device may be used. In situ renal cooling is effected by placing a double-balloon, triple-lumen perfusion catheter into the aorta via a femoral artery cutdown (Fig. 103.1) with instillation of preservation solution. Alternatively, the donor can be moved to an operating room as soon as death has

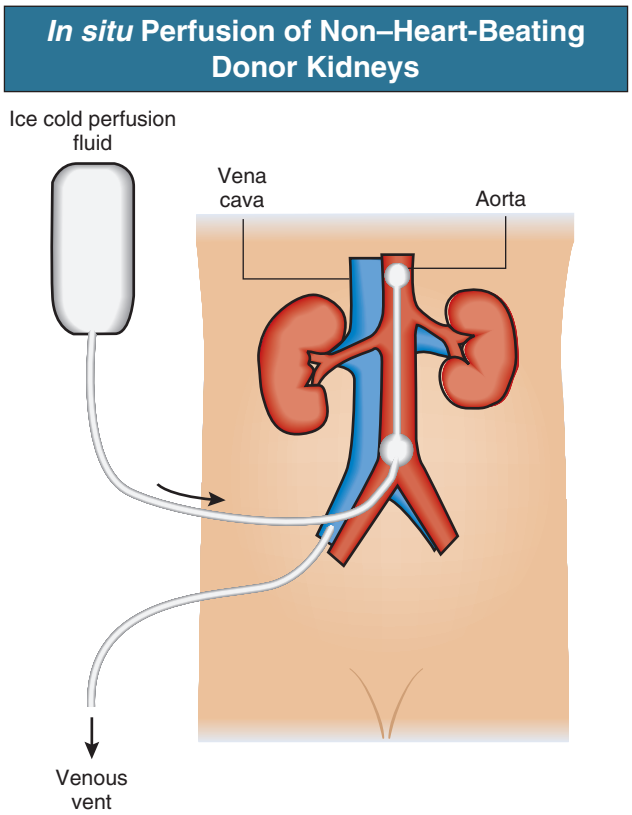

Fig. 103.1 Technique for in situ perfusion of donation after cardiac death kidneys. A double-lumen, double-balloon arterial catheter is introduced through the femoral artery and the lower balloon inflated at the aortic bifurcation and the upper balloon above the renal arteries. Ice-cold perfusion fluid is introduced and vented through the femoral vein until the effluent becomes clear.

occurred, and the aortic perfusion catheter placed directly at laparotomy rather than via a femoral artery cut-down.

Controlled Donation After Cardiac Death Donors

For controlled DCD donors, the transplantation team awaits cardiac arrest; after confirmation of death, the 5-minute rule is observed and then the perfusion catheter is inserted via the femoral artery. Alternatively, the patient can be taken to the operating room before cardiac death if the next of kin gives consent.

LIVING KIDNEY DONORS

In the United States in 2014, 30% of renal transplants were from living donors,[5] compared with 34% in the United Kingdom.[6] After a rapid increase in living donor transplantation at the beginning of this decade, rates have become more static. Superior recipient post-transplantation outcome compared with use of kidneys from deceased donors,[7] the potential for preemptive transplantation before dialysis, and the ability to plan the procedure (allowing optimization of recipient condition) are major advantages and justify continued efforts to expand use of living donors. The medical evaluation of the living donor is discussed in Chapter 102 (see Boxes 102.8 and 102.9).

Preoperative Imaging

Preoperative imaging of living donors confirms the presence of two functioning kidneys, indicates pathology that would preclude donation, and provides anatomic information necessary for planning the procedure. Imaging assumes paramount importance before minimal access donor nephrectomy because of the reduced operative exposure and particular difficulties in the identification of complex vascular anatomy. The location, size, and number of renal arteries and veins needs to be accurately described preoperatively. Angiography combined with excretion urography is now obsolete. For preoperative description of the main renal artery and vein anatomy, magnetic resonance angiography and computed tomographic angiography are comparable,[8] but computed tomographic angiography is more sensitive and specific for complex vascular anatomy and provides excellent correlation between imaging and surgical findings[9] (Fig. 103.2).

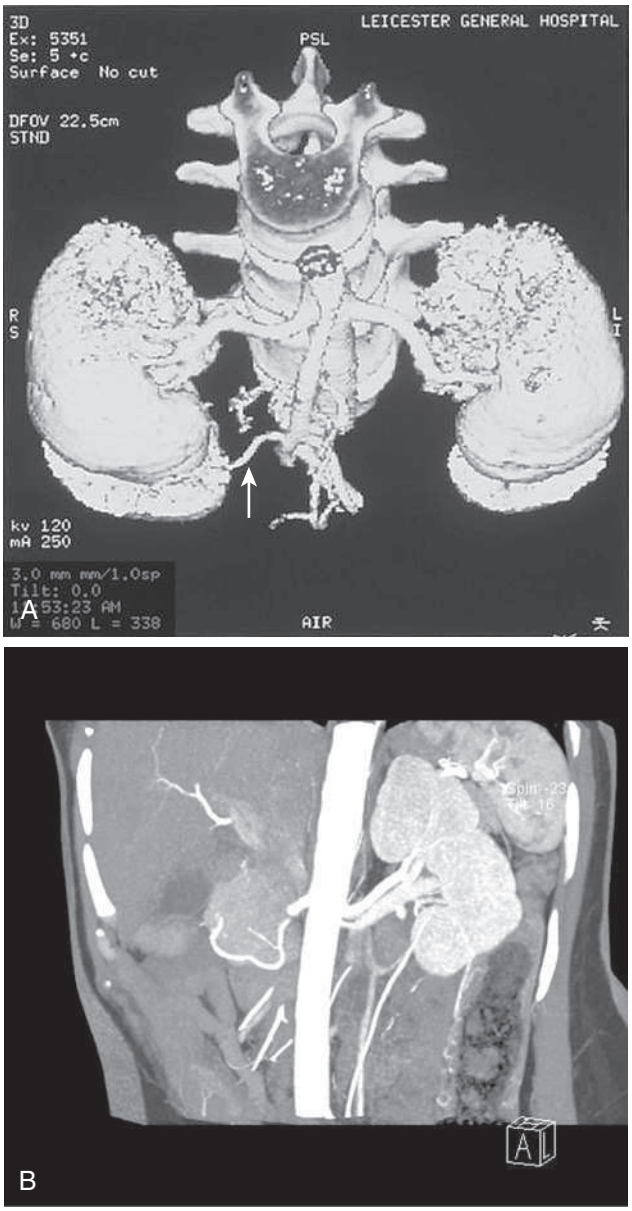

Fig. 103.2 Living donor preoperative computed tomographic angiogram. (A) Three-dimensional reconstruction of arterial supply. Note the lower pole artery to the right kidney *(arrow),* which may supply the ureter as well as the lower pole parenchyma. (B) Conventional image showing single artery and vein to the left kidney.

Minimal Access (Laparoscopic) Donor Nephrectomy

Living donor nephrectomy has traditionally been performed through an open incision, necessitating a prolonged period of recovery. This

Fig. 103.3 Flank wound from open nephrectomy.

BOX 103.1 Donor Benefits of Minimally Invasive Donor Nephrectomy

- Shorter incisions
- Less pain
- Shorter hospital stay
- Shorter recovery
- Better cosmetic appearance

and the cosmetic implications of a large flank wound may discourage potential donors (Fig. 103.3). To reduce such disincentives, there has been a move toward minimally invasive donor nephrectomy, first performed as a transperitoneal laparoscopic procedure (laparoscopic donor nephrectomy [LapDN]).[10] LapDN is associated with decreased severity and duration of postoperative pain, shorter inpatient stay, quicker return to work and normal activities, and improved cosmetic result compared with open donor nephrectomy[11] (Box 103.1). Furthermore, the overall societal cost of LapDN is lower[12] and recipient quality-of-life scores are higher.[13] The procedure is, however, technically demanding, and there is potential for damage to the renal parenchyma, vessels, and ureter during dissection. It takes longer than open nephrectomy and exposes the allograft to a longer period of warm ischemia.[11]

Nevertheless, retrospective data suggest that minimal access donor nephrectomy not only offers postoperative advantages to the donor, but also increases the number of transplants performed by reducing donor disincentives; estimates range from a 25% to a 100%[14] increase in transplantation activity. The widespread introduction of LapDN at the beginning of this decade saw an initial dramatic increase in the number of live kidney donors. However, rates have been static in both the United States and the United Kingdom over the last 5 years, suggesting that we may have seen the maximum benefits of this effect. Three minimal access approaches have been described: transperitoneal, extraperitoneal, and hand-assisted living donor nephrectomy.

Transperitoneal Laparoscopic Donor Nephrectomy

Pneumoperitoneum is established, and four laparoscopic ports are usually required (Fig. 103.4). After laparoscopic dissection a Pfannenstiel incision is made through which the kidney is brought out within an endoscopy retrieval bag after control and division of the artery vein and ureter.

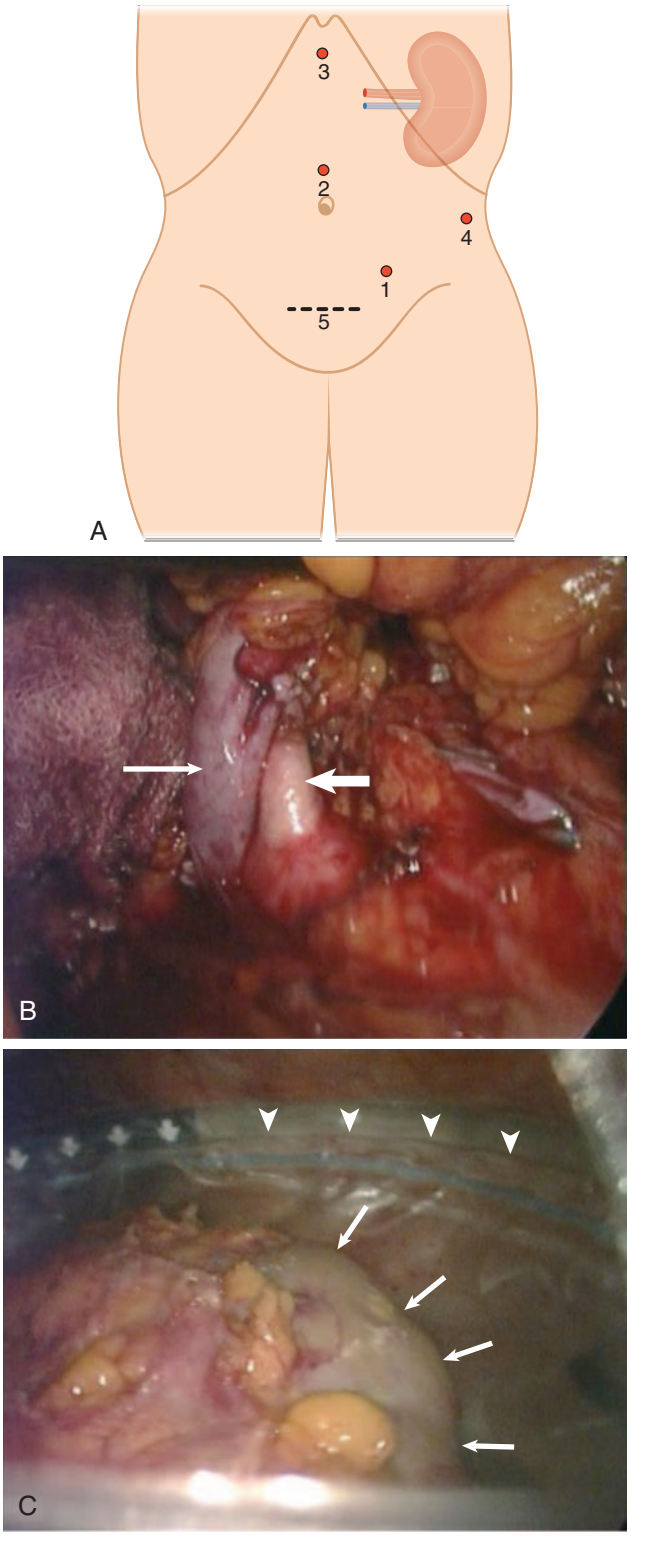

Fig. 103.4 Technique for laparoscopic donor nephrectomy. (A) Positions for four laparoscopic ports (*1* to *4*) and Pfannenstiel incision *(5)* through which the kidney is removed. (B) Intraoperative view showing left renal artery *(short arrow)* and vein *(long arrow)* prepared for control and division. (C) Intraoperative view showing the kidney (*arrows* mark lateral margin) placed in the endoscopic retrieval bag *(arrowheads mark the edge of the bag).*

Hand-Assisted Laparoscopic Donor Nephrectomy

The hand-assisted technique allows tactile sense to facilitate dissection, retraction, and exposure. It is said to be easier to learn and can be safely and efficiently performed by surgeons with less laparoscopic experience. The hand-assist device allows the operator's nondominant hand to enter the abdomen through an airtight system.

Retroperitoneoscopic Operative Technique

The retroperitoneal approach avoids breaching the peritoneum, displays the renal anatomy in a very different manner, and may be easier for retrieving the full length of the vessels, especially on the right side. The disadvantage is that a more limited operating space is available than with the transperitoneal or hand-assisted laparoscopic techniques.

Contraindications to Minimal Access Donor Nephrectomy

There are no absolute contraindications other than those applying to the open operation. The relative contraindications are dictated by donor factors and the experience of the surgeon. The donor must be fit for anesthesia, including the physiologic stress of pneumoperitoneum. Obesity is a relative contraindication for both open and laparoscopic surgery, and the hand-assisted approach may be better suited in such patients. Previous abdominal surgery is a further relative contraindication because of the potential for adhesions. Multiplicity of renal vessels should not hinder LapDN.

Effect of Pneumoperitoneum

Transient intraoperative oliguria secondary to decreased renal blood flow is a frequent occurrence during laparoscopic procedures. Proposed mechanisms include decreased cardiac output, renal vein compression, ureteral obstruction, renal parenchymal compression, and systemic hormonal effects. Intracranial pressure increases during pneumoperitoneum, with release of vasoconstrictor agents that decrease renal blood flow. Use of a lower pressure reduces the adverse effects of pneumoperitoneum on renal perfusion. In donor nephrectomy, impaired renal blood flow may compromise early allograft function and compound the damaging effects of warm and cold ischemia and operative manipulation of the kidney. Laparoscopically derived donor kidneys have higher serum creatinine up to 1 month post-transplantation compared with open surgery, but thereafter graft function is equivalent.[15] The pioneers of LapDN used high volumes of crystalloid preoperatively and intraoperatively to maintain renal perfusion in the presence of pneumoperitoneum. We have seen two episodes of unilateral pulmonary edema in the dependent lung, and we now recommend volume loading the donor with 2 liters of crystalloid the night before surgery and only using replacement fluid during surgery. This protocol has led to no apparent detriment to graft function.

Graft Function and Acute Rejection

There is no consistent evidence that graft function differs among kidneys retrieved by open, laparoscopic, or hand-assisted donor nephrectomy. The exception is that rates of delayed graft function and acute rejection may be higher in pediatric recipients, especially the 0 to 5-year age group.

Pretransplantation ischemia could, in theory, render the donor kidney more immunogenic by inducing major histocompatibility complex (MHC) class II expression. However, despite the longer warm ischemia time, acute rejection rates and severity of rejection are not higher in laparoscopic than in openly retrieved living donor kidneys.

Technical Issues

Ureteral ischemia was more common in early experience of LapDN but can be avoided if care is taken to ensure that sufficient periureteral tissue is taken and that the dissection does not occur too close to the renal pelvis.

Multiple arteries need not be a barrier to successful use of grafts from laparoscopic donors. In open donor nephrectomy, the right kidney is retrieved in 20% to 30% of procedures, whereas LapDN uses the right kidney in less than 10%,[16] reflecting concern over the operative safety of the right-sided laparoscopic operation, principally the difficulties involved in obtaining an adequate length of renal vein. It has been argued that this practice has led to compromise of the principle that the better kidney should remain with the donor.

Postoperative Recovery

After uneventful open nephrectomy, the donor can expect to be discharged from the hospital in 5 or 6 days and is able to return to work after 3 to 6 weeks, although return to work has been shown to be 2 to 3 weeks later in open nephrectomy compared with LapDN.[11] After LapDN the donor usually leaves hospital in 2 to 4 days and can return to work in 3 to 6 weeks.

Choice of Donor Operative Technique

The choice of operative procedure depends on the local expertise of the surgeons. There is accumulating evidence that the laparoscopic operation removes some of the disincentives to donation, and this approach is likely to be adopted widely in the future.

RENAL PRESERVATION

Preservation of deceased donor organs is crucial to allow time for matching, sharing of organs, and preparation of the recipient. Damage from hypothermia and reperfusion must be minimized. There is little standardization of the type of preservation solution used. Marshall's hyperosmolar citrate solution and histidine-tryptophan-ketoglutarate are popular choices in Europe, but University of Wisconsin (UW) solution is more commonly used in the United States because extended preservation times are more often required.

Organs can be preserved by cold storage (kept in crushed ice after flushing with preservation solution) or by machine-driven pulsatile perfusion. The proposed benefits of machine perfusion come from allowing aerobic function through provision of oxygen and substrate and removal of metabolic end-products. Although machine perfusion has been used for many years, there is still no consensus about its superiority to cold storage nor about the best perfusion parameters. Recent randomized trials have yielded conflicting results; a U.K. trial of DCD kidneys showed no benefit,[17] whereas a European trial demonstrated reduced delayed graft function in deceased donor transplants after machine perfusion.[18]

A novel approach to kidney preservation, only recently introduced into clinical practice, is *ex vivo* normothermic perfusion. Early results are promising,[19] but the technique needs to be studied in larger clinical trials, one of which is ongoing in the United Kingdom.

Decisions on the use of a kidney from a marginal donor can be supported by data from machine or normothermic perfusion; high perfusion pressures are associated with primary nonfunction and delayed graft function.

RENAL TRANSPLANTATION PROCEDURE

The transplanted kidney is placed heterotopically in one or another iliac fossa. The inferior epigastric vessels are ligated, as is the round ligament of the uterus in female patients. Occasionally the inferior epigastric artery may be preserved and used for revascularization of small polar arteries. In male patients the spermatic cord is mobilized

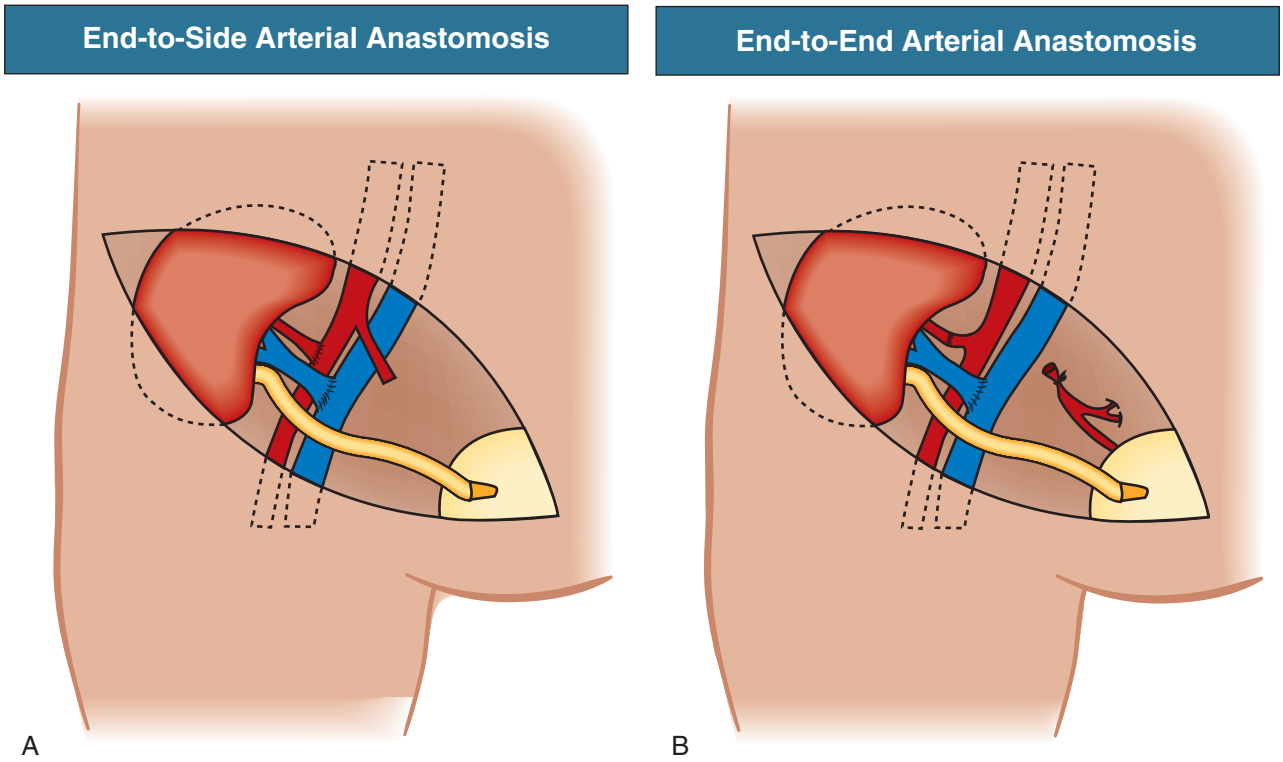

Fig. 103.5 Vascular anastomosis techniques for renal transplantation. (A) End-to-side anastomosis to the external iliac artery. (B) End-to-end anastomosis to the divided internal iliac artery, suitable for living donor transplantation in which no aortic patch is available.

and preserved. The peritoneum should not be breached, but instead swept superiorly to reveal the extraperitoneal bed into which the transplanted kidney will be placed. The iliac blood vessels are then mobilized, with care taken to meticulously ligate all the associated lymphatic channels to reduce the risk for post-transplantation lymphatic leak.

Vascular Anastomosis

The renal vein is anastomosed end to side to the external iliac vein. The arterial anastomosis can be performed either end to side to the external iliac artery or end to end to the divided internal iliac artery (Fig. 103.5). The end-to-side anastomosis is technically easier and is the usual method used in cadaveric transplantation, where it is possible to include a Carrel aortic patch with the renal artery.

With living donor kidneys it is not possible to include a Carrel patch, and occasionally a cadaveric kidney may be provided without a useable patch. In these circumstances the options are to anastomose the renal artery end to end to the divided internal iliac artery or end to side to the external iliac artery. Use of an aortic punch to create a circular arteriotomy may facilitate the latter technique. For living donor kidneys most surgeons use the external iliac artery. It is our experience that positioning the kidney is often easier if the internal iliac artery has been used for the anastomosis, but this does risk buttock claudication and potentially increases the risk for erectile dysfunction in male recipients.

After completion of the vascular anastomoses, the kidney must sit in such a position that the renal vessels are not kinked. The transplanted kidney can be placed laterally in the iliac fossa or may be placed in a subrectus pouch fashioned specifically for the purpose.[20] In the latter case the renal vessels run laterally from the kidney, and this should be noted when a post-transplantation biopsy is performed. An operative diagram of the position of the kidney and vessels is therefore an important component of the clinical notes.

If there are multiple renal vessels, the number of anastomoses should be minimized. This usually can be achieved by careful bench surgery before implantation. If there are two or more renal arteries, their aortic patches are joined in such a way that a single arterial anastomosis is required. If necessary, recipient iliac artery or saphenous vein is used to facilitate reconstruction. Occasionally, small polar arteries will be recognized only after a kidney has been retrieved, and it is particularly important to reanastomose lower polar arteries accurately because these may provide all the ureteral blood supply. In the case of double renal veins, the most common course of action is simply to ligate the smaller vein; the larger one is usually sufficient to drain the whole kidney. If there are two equally sized veins, both may need to be anastomosed separately to the external iliac vein.

Urinary Drainage

The traditional method of ureteral anastomosis is the Politano-Leadbetter technique, involving a transvesical ureteroneocystostomy with creation of a submucosal antireflux tunnel. The end of the transplanted ureter is drawn through a submucosal tunnel from outside to inside and sutured to the bladder mucosa. The majority of surgeons now prefer the technically simpler extravesical ureteroneocystostomy onlay in which the spatulated end of the ureter is anastomosed to the cystostomy and the divided muscle layer is then resutured over the ureter to create a short antireflux muscle tunnel. The onlay method has the advantage of being possible with only a short length of ureter. The shorter the ureter, the less likely it is that there will be an inadequate blood supply to the distal end, thereby reducing the risks for ischemic ureteral leaks or stenosis. A temporary double-J ureteral stent is usually placed. Stents reduce the impact of small technical errors while the ureter is leaking and reduce major urologic complications to an incidence of 1.5%.[21] However, they are a potential source of urinary tract infection, can become

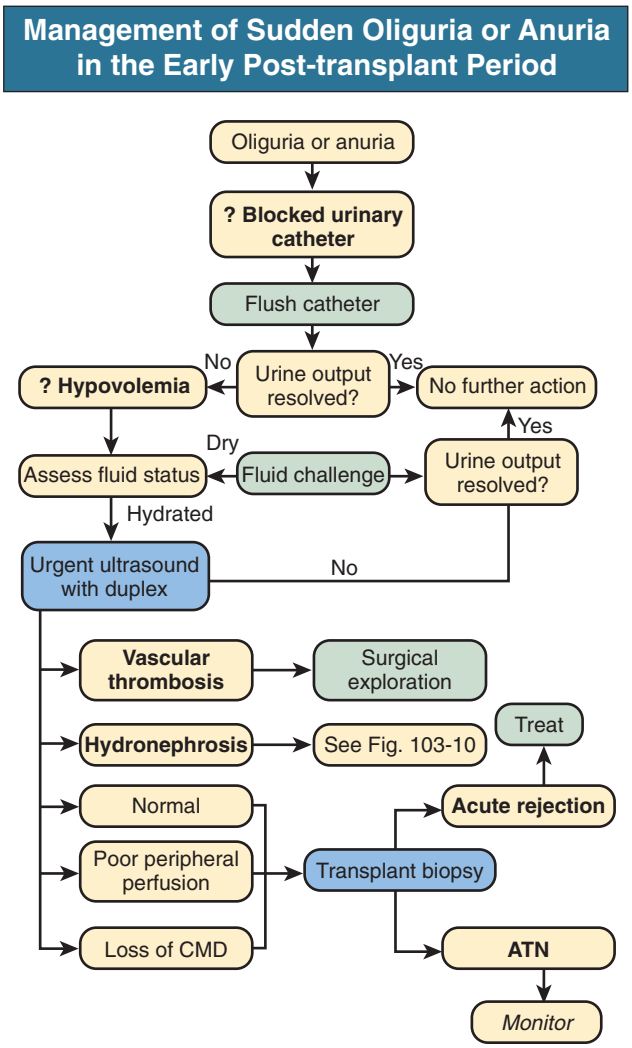

Fig. 103.6 Management of sudden oliguria or anuria in the early post-transplant period. *ATN,* Acute tubular necrosis; *CMD,* corticomedullary differentiation.

encrusted or blocked by debris, and can migrate or fragment. Nevertheless, antibiotic prophylaxis is not justified because it increases the risk for infection with multiresistant organisms. A further danger is the forgotten stent that has not been removed, which should always be considered in patients with unexplained and persistent lower urinary tract symptoms after transplantation. Stents are usually removed 4 to 6 weeks post-transplantation, and this can be performed without general anesthesia with use of a flexible cystoscope.

Alternative Techniques of Urinary Reconstruction

Renal transplantation is quite commonly performed in patients who have abnormal bladders. In many patients it is possible to anastomose the transplanted ureter to the bladder in the hope that the bladder can be rehabilitated, if necessary, with use of post-transplantation intermittent self-catheterization. Nonetheless, some patients require urinary diversion with an ileal conduit. The conduit should be fashioned at least 6 weeks before transplantation, but it may have been present for many years. If so, a contrast study (a conduitogram) should be performed before transplantation to exclude the development of conduit stenosis, although this is rare. The transplanted kidney is best placed in the ipsilateral iliac fossa to avoid tension in the ureter, and it may be preferable to deliberately place the transplanted kidney upside down so that the ureter runs cranially and has a more direct route to the conduit. After revascularization, the peritoneum is opened and the ureter is anastomosed to the conduit over a double-J stent. Excellent long-term results have been achieved with this technique.[22]

Drainage and Wound Closure

Both the transplant bed and the subcutaneous tissues may be drained to prevent the accumulation of serosanguineous fluid or lymph around the transplanted kidney, although many surgeons no longer routinely place drains. The skin is best closed with a subcuticular absorbable suture and then dressed with a clear adhesive dressing so ultrasound scanning can be performed early without disturbing the wound. For this reason, metal clips are rarely used for the skin.

Postoperative Course

The recipient is nursed in a general ward with standard precautions and no need for reverse barrier nursing. There is no benefit to continuing prophylactic antibiotics beyond a single dose given at induction of anesthesia. Prophylaxis against thromboembolic disease is in the form of thromboembolic deterrent stockings and low molecular weight heparin (LMWH) is continued until discharge. Oral fluids and diet are commenced as tolerated immediately after surgery. Maintenance immunosuppressive agents are given orally, except in the presence of a prolonged postoperative ileus with high volumes of nasogastric drainage, when they should be administered intravenously. If recovery is straightforward, the bladder catheter and wound drains are usually removed by day 5, and the recipient is fit for discharge after 7 to 10 days to be kept under close outpatient monitoring.

SURGICAL COMPLICATIONS OF RENAL TRANSPLANTATION

There is a small but significant incidence of technical complications, which can be minimized by avoiding damage to the kidneys at the time of the retrieval. Nonetheless, the presence of multiple renal vessels and donor atherosclerotic disease does increase the likelihood of technical problems in the recipient, as do recipient obesity, atherosclerosis, and previous transplantation. Algorithms to aid in the management of complications in the early post-transplant period can be found in Figs. 103.6 and 103.7.

Wound Infection

The use of preoperative prophylactic antibiotics, commonly amoxicillin–clavulanic acid, has reduced the incidence of wound infection to less than 1%. If a wound infection does occur, treatment is with antibiotics, guided by microbiologic wound swabs, and drainage of collections as necessary.

Wound Dehiscence

The risk for wound dehiscence is increased in obese and diabetic patients and those receiving sirolimus. Identification and treatment of any infection are mandatory. Resuturing of the wound is rarely justified. Large areas of dehiscence often benefit from vacuum-assisted closure, but the majority require only frequent dressing.

Vascular Complications

Transplant vascular thrombosis is a feared complication that may cause early and irreversible graft failure. Although there are also significant hemorrhagic risks, routine perioperative prophylaxis should be given with subcutaneous LMWH, and some units prescribe aspirin for the first few postoperative months.

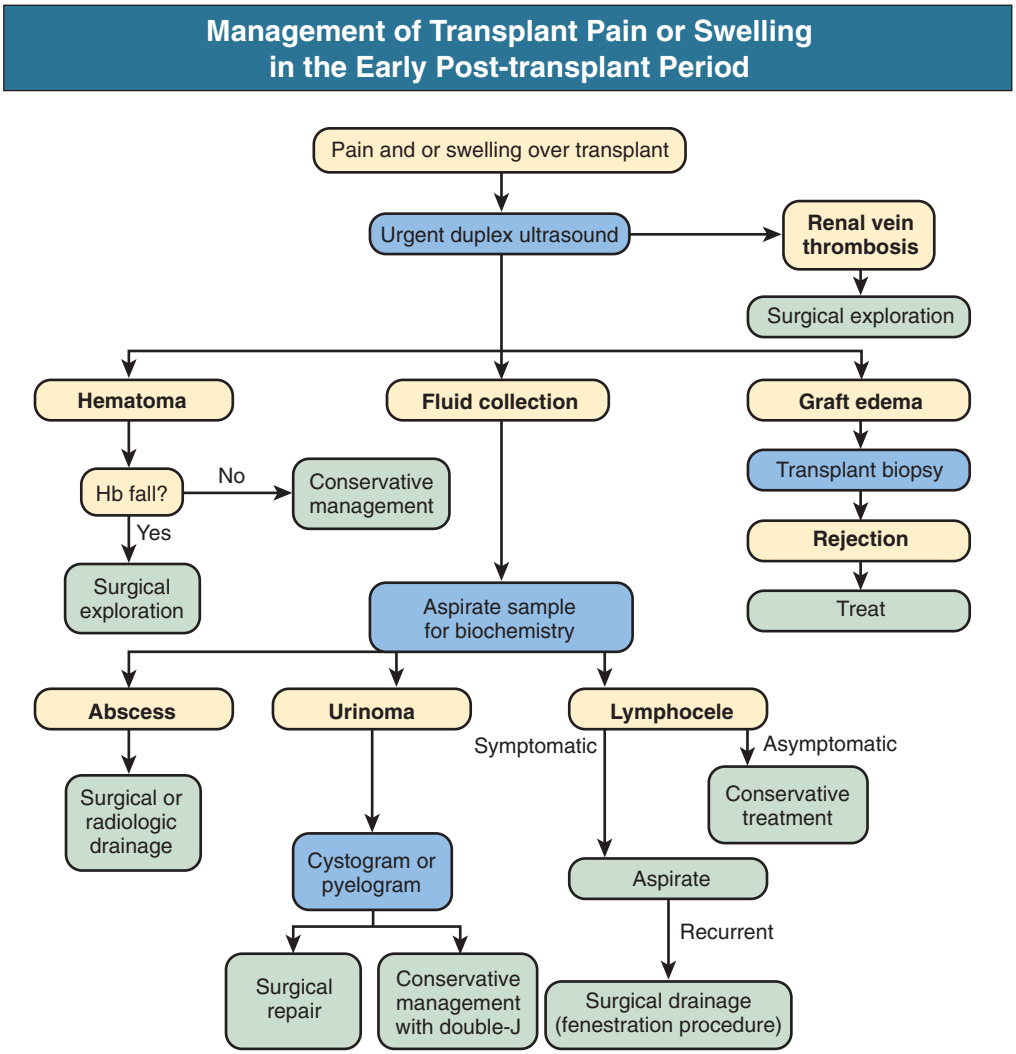

Fig. 103.7 Management of transplant pain or swelling in the early post-transplant period. *Hb,* Hemoglobin.

Bleeding From Vessels in the Renal Hilum

Careful postoperative observation and regular hemoglobin and hematocrit measurements are crucial for the early detection of bleeding. Output from the transplant drains may give an early indication of heavy blood loss. Unsecured small vessels in the renal hilum may not be obvious during surgery, but they may start bleeding postoperatively. This form of blood loss can be slow, persistent, and serious. If the patient's condition allows, urgent imaging may be performed to secure a diagnosis, but the best course of action is usually emergency exploration of the transplant under general anesthesia.

Anastomotic Hemorrhage

Anastomotic hemorrhage is a rare occurrence, usually caused by a technical surgical error, and is more common with multiple arteries and the use of antiplatelet agents.[23,24] Early after transplantation, the patient may report pain over the graft. This symptom always should be taken seriously. There also may be pain in the back or the rectum caused by a tension hematoma in the retroperitoneum or pelvis. Significant hemorrhage will be attended by circulatory collapse, with tachycardia and hypotension. There will be a decrease in the hemoglobin and hematocrit, sometimes to alarmingly low levels. The patient must be returned to the operating room immediately and the transplant reexplored.

Hemorrhage also can occur some weeks after transplantation because of the development of a mycotic aneurysm of the renal artery. In the rare case of a ruptured mycotic aneurysm, an immediate graft nephrectomy is required, but the mortality is high.

Renal Artery Thrombosis

Renal artery thrombosis is a rare event, occurring in less than 1% of transplants. The usual outcome is loss of the kidney. Acute arterial thrombosis may occur intraoperatively or during the first days or weeks after transplantation. Potential causes include hyperacute rejection or a procoagulant state, but most cases are caused by a technical error during the anastomosis of small or atheromatous vessels.[24] Successful vascular anastomosis requires that the vessels are not under tension and that there is a smooth transition between the two endothelial surfaces; sutures must be placed through all layers of the vessel walls so an intimal flap is avoided. Vascular adventitia is thrombogenic and must be excluded from the lumen of the anastomosis. The risk for renal artery thrombosis is increased in the presence of atherosclerosis, persistent hypotension, volume depletion (e.g., diarrhea, excessive preoperative dialysis), and prothrombotic states, including diabetes.

Renal arterial thrombosis manifests with sudden anuria, the differential diagnoses being a blocked urinary catheter, dehydration, acute tubular necrosis, or a urologic complication. A high index of suspicion

is required to make this diagnosis, particularly in the immediate postoperative period. The only worthwhile investigation is an urgent duplex ultrasound scan, but if the diagnosis is seriously entertained, the only hope of saving the transplant is to reexplore it immediately in the hope that a correctable cause can be found. The reality is that unless the acute arterial thrombosis occurs during surgery, there is little chance of saving the transplanted kidney. Acutely thrombosed grafts must nevertheless be explored and removed to avoid the development of sepsis in a necrotic graft, a potentially fatal complication.

Renal Vein Thrombosis

Renal vein thrombosis is more common than arterial thrombosis and occurs in 1% to 6% of renal transplants.[24,25] Although it may result from a technical error at the time of surgery, its cause is usually less certain. The renal vein can certainly be twisted or kinked if it is not correctly placed after completion of the vascular and ureteral anastomoses. The peak incidence of renal vein thrombosis is 3 to 9 days after transplantation[26]; transplant patients with good initial graft function will have a sudden loss of urine output, which is often markedly blood stained, associated with severe pain arising from swelling and (very rarely) rupture of the allograft. The ipsilateral leg may swell if there is involvement of the iliac venous system. Renal vein thrombosis also may be occult and is one differential diagnosis of delayed graft function. Duplex ultrasound scanning is the best investigation. In an established renal vein thrombosis this may show an obviously swollen allograft with surrounding hematoma and an absence of renal perfusion. Lesser degrees of thrombosis, or indeed incipient thrombosis, may be highlighted by an absence of arterial flow in diastole. An even later development is a reversal of flow in diastole.

As with arterial thrombosis, if this diagnosis is entertained, the best course of action is to reexplore the transplant as an emergency. The renal vein anastomosis can be opened to allow clot to be extracted, and the venotomy is then closed and the kidney observed for improvement. A more radical alternative is to immediately explant the kidney by taking down the arterial, venous, and ureteral anastomoses. The kidney can then be reflushed with cold perfusion fluid on the back table and held in preservation fluid at 4° C. This allows much more time to assess the cause of the venous thrombosis, and if the kidney remains viable, the transplant operation can be repeated. If the transplant is already infarcted or cannot be adequately flushed with preservation fluid, the organ will need to be discarded anyway and nothing is lost by immediate explantation. Successful emergency surgical exploration with subsequent long-term function is rare. Interventional radiographic techniques offer an alternative to surgery. The renal vein can be selectively catheterized via the ipsilateral femoral vein, and graft thrombolysis then may be attempted. This technique is particularly useful when renal vein thrombosis occurs late after transplant and the risk for systemic anticoagulation is low. The use of various thrombolytic agents has been reported, including heparin, urokinase, streptokinase, and tissue plasminogen activator, with no consensus as to which is the most appropriate.

Transplant Renal Artery Stenosis

Transplant renal artery stenosis is a later complication occurring 3 to 48 months after transplantation. Not all stenoses are of functional or clinical significance, as shown by studies in which all functioning transplants have undergone angiography.[27] Causal factors include donor and recipient atherosclerosis, factors associated with surgical technique, and severe acute rejection.[28] The presentation and management of transplant renal artery stenosis are discussed in Chapter 41.

Lymphocele

Small, clinically insignificant lymphatic collections can be demonstrated by ultrasound scan in up to 50% of renal transplants.[29] Larger lymphoceles that cause complications or require treatment occur in 2% to 10% of patients.[30] The source of peritransplant lymph leaks is the lymphatic channels around the iliac arterial system rather than the lymphatics of the transplanted kidney itself.[31] Therefore, during the dissection of the iliac arterial system, all the surrounding lymphatic channels must be meticulously secured with nonabsorbable ligatures or metals clips. Wound suction drains should not be removed postoperatively until less than 30 ml of fluid is produced on 2 consecutive days. It is safe to leave drains in place for several weeks post-transplantation to allow a low-volume lymphatic leak to seal by gradual fibrosis. Despite the theoretical risk for infection, this does not seem to be a problem in practice. If necessary, the patient can be discharged from the hospital with the drain in situ.

Compression of the transplanted ureter leading to renal dysfunction is produced only by very large lymphoceles (volume >300 ml). The peak incidence is at 6 weeks, but a lymphatic collection may manifest 2 weeks to 6 months after transplantation.[29] Most lymphatic collections are found anterior to the iliac vessels and lying between the transplant and the bladder (Fig. 103.8). Presenting features may include wound or ipsilateral thigh swelling in association with suprapubic discomfort and urinary frequency caused by bladder compression. Other presentations include pain over the transplanted kidney, sometimes associated with fever, ureteral obstruction with graft dysfunction, and ipsilateral thrombophlebitis. However, the vast majority are asymptomatic and manifest as an incidental finding during an ultrasound scan being performed for another reason. It is important to aspirate all peritransplant fluid collections under ultrasound control to aid diagnosis. Macroscopic

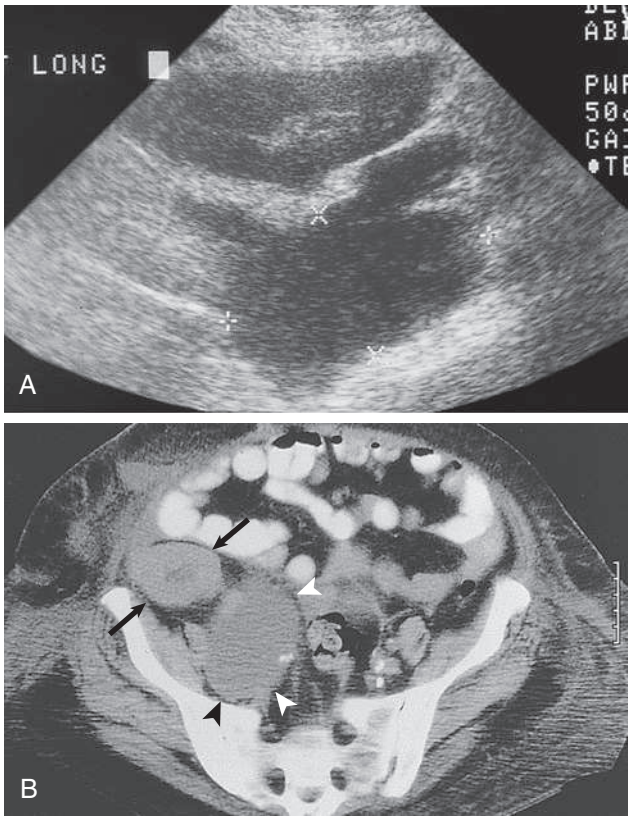

Fig. 103.8 Post-transplantation lymphocele. (A) Ultrasound appearance. A large echolucent lymphocele can be seen inferior to the transplanted (marked by *crosses*). (B) Computed tomography appearance. A 5- × 5-cm lymphocele *(arrowheads)* is present under the transplanted kidney *(arrows)*.

findings are usually sufficient to differentiate infected from noninfected lymph, and biochemical analysis of the fluid allows a urine leak to be excluded. Computed tomography or magnetic resonance imaging is an essential investigation if surgery is being contemplated, particularly if a laparoscopic procedure is planned. This allows accurate definition of the relationship between the lymphocele and the transplanted ureter. If the ureter is bow-strung across the superior surface of the lymphocele, it could be damaged during a laparoscopic fenestration procedure.

Many small lymphoceles are asymptomatic and will resolve spontaneously given enough time. If action is deemed necessary, first-line treatment is aspiration under ultrasound control. If there is a recurrence, further aspirations can be performed or an external drain can be placed with ultrasound guidance. If these simple measures fail, open or laparoscopic surgical drainage may be required. A 5-cm-diameter disk of the lymphocele wall is removed to create a large opening into the peritoneal cavity, allowing reabsorption of the lymph through the abdominal lymphatic drainage system. These peritoneal fenestrations have a tendency to heal before the lymphocele is completely reabsorbed, leading to early recurrence; a metal or omental plug may prevent this.

Urologic Complications

Urinary tract complications are relatively common after renal transplantation, with an incidence of 5% to 14%.[32] Although they can be difficult to manage, they only rarely cause graft loss or mortality. The relatively high incidence of urologic problems is a consequence of the tenuous blood supply of the transplanted ureter. After kidney retrieval, the only ureteral blood supply that is preserved is derived from the renal artery near the hilum of the kidney, and this can be easily damaged during retrieval.

Urinary Leaks

Urinary leaks most commonly occur because of ischemic necrosis in any part of the transplanted urinary collecting system. The distal ureter has the poorest blood supply and is therefore the most common site. Less commonly, leaks occur from the renal pelvis or the midportion of the ureter, which may be a result of unrecognized direct damage to the ureter during organ retrieval. Urinary leaks tend to occur in the first few days after transplantation but can manifest much later. The usual presentation is with straw-colored fluid leaking directly from the transplant wound or accumulating in the drains in association with oliguria. Alternatively, extravasating urine may accumulate as a peritransplant fluid collection. This manifests as a painful swelling of the wound, and the patient may have a fever. In either case, the extravasated fluid must be differentiated from lymph by biochemical analysis of the fluid and a simultaneous serum sample. Urine will have markedly elevated urea and creatinine levels compared with the patient's serum, whereas lymph will have a similar biochemical profile.

The presence of a urinary fistula should be confirmed by antegrade or retrograde pyelography. Both of these techniques present challenges. Antegrade puncture of a nondilated pelvicaliceal system is technically difficult but usually possible. Retrograde cannulation of the transplanted ureteral orifice can be attempted with a flexible cystoscope. This is also a difficult maneuver because the transplanted ureter is implanted into the dome of the bladder rather than at its base. If the urine leak is contained as a urinoma, ultrasound will demonstrate a fluid collection between the transplanted kidney and the bladder, which can be sampled by needling or drained by the placement of a suitable percutaneous catheter.

The management of urinary leaks has changed significantly in recent years. The former practice of early reexploration and surgical reconstruction[33] is no longer always necessary. Interventional radiographic techniques offer an alternative, at least for initial treatment. The aim is to place a double-J (pigtail) ureteral stent across the region of damage via an antegrade nephrostomy; this may allow time for the urinary fistula to heal.[34] This technique, however, is unlikely to be successful if there is significant ischemic necrosis of the ureter, in which case, surgery still has a role. Reexploration of kidney transplants is straightforward in the early postoperative period but may be a considerable challenge later because of the development of an intense peritransplant fibrotic reaction. The choice of operative procedure for a necrotic distal ureter depends on the length of remaining viable ureter. If there is sufficient length after excision of the necrotic distal portion, the transplanted ureter may simply be reimplanted into the bladder. If this is not possible, the urinary tract should be reconstructed with use of the patient's native ureter. Depending on length of viable transplanted ureter, there is a choice between anastomosing the native ureter to the transplanted ureter proximal to the ischemic segment (ureteroureterostomy) or to the transplanted renal pelvis (ureteropyelostomy; Fig. 103.9). Whichever technique is chosen, the anastomosis should be protected with a double-J stent. Although these techniques require the native ureter to be ligated proximally, there is usually no need to perform an ipsilateral nephrectomy.[35] Postoperatively, the antegrade nephrostomy can be left in situ so a contrast study can be performed after 7 to 10 days to confirm healing of the new anastomosis. If the transplant recipient has undergone an ipsilateral nephrectomy in the past or the native ureter is too diseased to be used for reconstruction, a Boari bladder flap can be used to reconstruct the urinary tract.

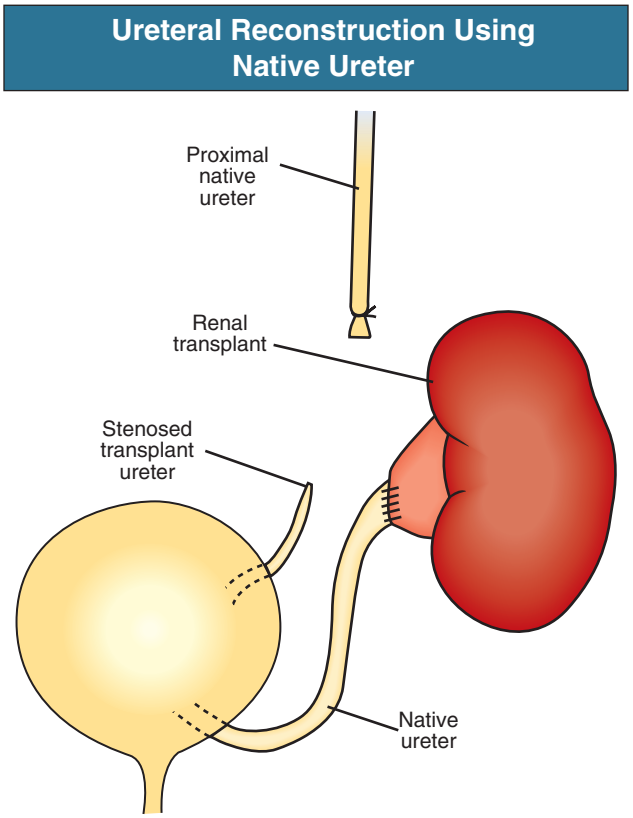

Fig. 103.9 Ureteral reconstruction using native ureter.

Ureteral Obstruction

Obstruction of the transplanted ureter may occur at any time after transplantation. It should always be considered in the differential diagnosis of acute transplant dysfunction and excluded by ultrasound examination. The management of transplant ureteral obstruction is

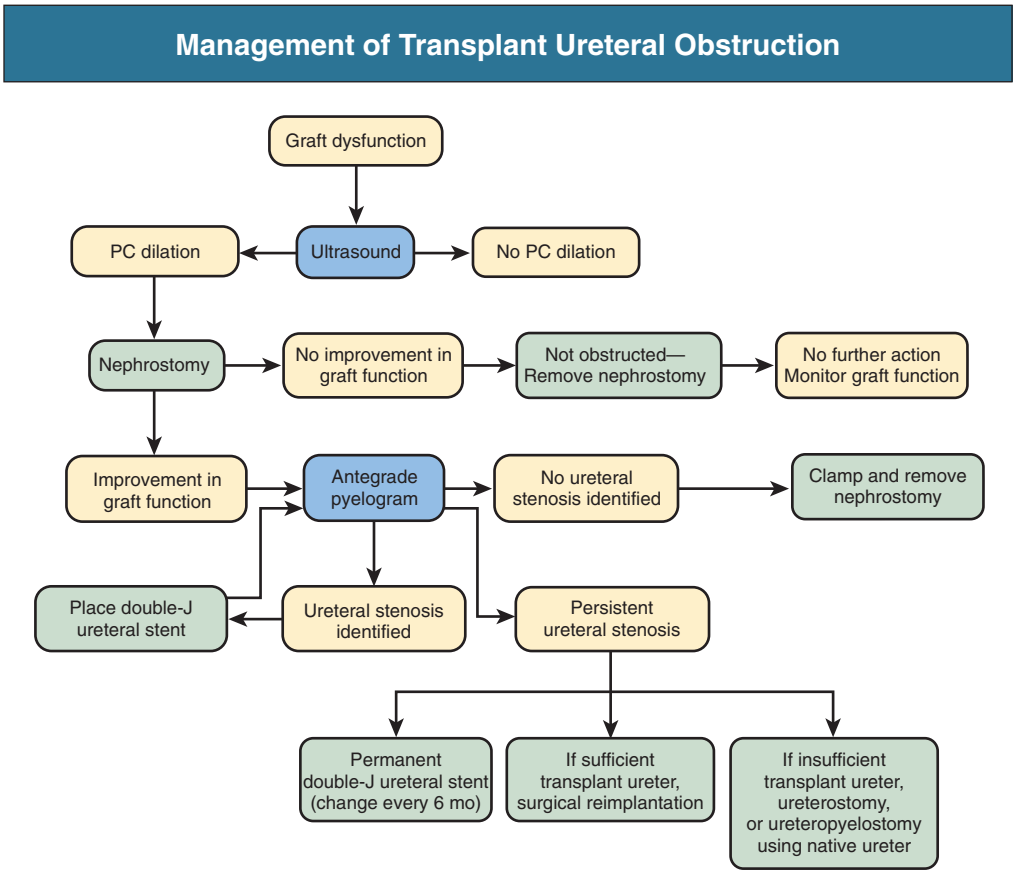

Fig. 103.10 Management of transplant ureteral obstruction. *PC,* Pelvicaliceal.

summarized in Fig. 103.10. Early obstruction is uncommon and suggestive of a technical error, such as creating a submucosal bladder tunnel that is too tight, kinking of a redundant length of ureter, and incorrect suture placement during anastomosis. Early obstruction may be caused by a blood clot in the ureter, bladder, or catheter. Bleeding may occur from the ureterovesical anastomosis or cystostomy or after a transplant biopsy. It is common practice to drain the urinary bladder using a three-way irrigating catheter because small-diameter two-way Foley catheters are easily blocked by blood clot.

Late ureteral obstruction may occur at the vesicoureteral or pelviureteral junctions. Ischemia that is not severe enough to cause necrosis is presumed to be the cause of most vesicoureteral obstructions.[36] Renal transplants invariably excite a pronounced perigraft fibrotic response, and this is more likely to be the cause of an obstruction at the level of the pelviureteral junction. It is also possible that acute rejection episodes contribute to subsequent fibrosis.[34] BK polyoma virus also can cause late ureteric obstruction because of hypertrophy of ureteric epithelial cells in combination with infiltration of inflammatory cells.

An ultrasound scan will demonstrate a dilated pelvicaliceal system. However, long-standing kidney transplants may have quite marked pelvicaliceal dilation without being obstructed. This most commonly causes uncertainty in assessment of whether obstruction may be contributing to chronic allograft dysfunction in a patient with biopsy-proven chronic allograft nephropathy. Further investigation is needed to confirm or refute the presence of obstruction and define its anatomy. Retrograde pyelography has a low success rate because of the difficulty of catheterizing the transplanted ureteral orifice at cystoscopy. Therefore percutaneous nephrostomy followed by antegrade pyelography is the investigation of choice in suspected transplant ureteral obstruction. The nephrostomy is performed under antibiotic cover using ultrasound control, and the nephrostomy tube should be left in place for a few days. If serum creatinine decreases during this period, obstruction is confirmed. If there is no improvement in renal function, significant obstruction can be confidently excluded. This simple observation avoids the need for an antegrade pressure study (Whittaker test), which may be difficult to interpret in transplanted kidneys. After external decompression of the transplanted kidney for a few days, an antegrade pyelogram is obtained to accurately define the anatomy of the obstructing lesion.

Nonoperative approaches for the treatment of transplant ureteral stricture are often preferred.[37] The simplest approach is to place a double-J stent across the stricture via a percutaneous nephrostomy. This may require initial balloon dilation.[38] The stent can be removed after 6 weeks, but the restenosis rate is high. An alternative is long-term stenting, changing the stent every 6 months. The disadvantage of this method is a high incidence of urinary tract infection, with potential severe consequences for immunosuppressed patients, and long-term antibiotic prophylaxis is a sensible precaution. Open surgical management still has a place in the management of ureteral obstruction. The operation performed depends on the site of obstruction and remaining length of healthy transplanted ureter proximal to the obstruction (see discussion of urinary leaks). Not all cases of obstruction require intervention. When there is a mild degree of obstruction not associated with urinary tract infection and in a long-standing kidney that is affected by chronic allograft nephropathy, it may be better to simply monitor transplant function, reserving intervention for a later date should it become necessary.

Complications in the Transplant Bed

A number of nerves may be encountered in the retroperitoneal dissection required for kidney transplantation. These include the lateral femoral cutaneous nerve and the femoral, obturator, and sacral nerves. Each of these may be damaged by a traction injury, particularly when modern fixed wound retraction systems are used, because these can exert a great deal of pressure on the surrounding tissues. Patients with such neurapraxias should recover completely, but this may take some months, and the condition can be very disabling.

In male transplant recipients, the spermatic cord must be mobilized during the dissection to gain access to the retroperitoneal space. Damage to the testicular artery in the cord can result in testicular atrophy.

TRANSPLANT NEPHRECTOMY

The optimal management strategy for patients with a failed renal transplant remains unclear, with a lack of good-quality evidence. Transplant nephrectomy is mandatory for early graft failure caused by vascular thrombosis, capsular rupture, and irreversible rejection. However, the management of a renal transplant that has chronically failed is more challenging. The options are transplant nephrectomy or leaving the graft in situ, with or without continuation of immunosuppression. Mortality from both infection and cardiovascular disease has been shown to be higher in patients with failed grafts continuing immunosuppression.[39] However, weaning and discontinuation of immunosuppression also have been shown to increase the risk for transplant nephrectomy and allosensitization.[40]

If the graft remains in situ without immunosuppression, signs and symptoms such as pain, fever, hematuria, and thrombocytopenia may prompt transplant nephrectomy, although the patient also can be treated initially with corticosteroids.

Historically, transplant nephrectomy was advocated to remove antigenic stimulation for anti–human leukocyte antigen (anti-HLA) antibody production, which might adversely affect the possibility of retransplantation. However, there is some evidence that transplant nephrectomy, particularly late after transplantation, may actually increase allosensitization.[41] The suggestion is that the graft may act as an "immunologic sponge" to absorb antibody or may regulate the production of antidonor antibody by the recipient's immune system.

Early graft nephrectomy is straightforward, but after the first few weeks kidney transplants usually develop quite intense perigraft fibrosis, and this can make late allograft nephrectomy a difficult technical challenge. A subcapsular dissection is preferred, and after removal of the kidney, the hilum is sutured, leaving a cuff of donor vessels in place. Careful hemostasis is required, and the whole raw capsular bed should be cauterized. The wound is usually closed without drains.

SELF-ASSESSMENT QUESTIONS

1. Which of the following is/are *false* regarding organ donation and retrieval?
   - **A.** For donation after brain death the aorta is cannulated after cardiac arrest.
   - **B.** Donation after cardiac death kidneys sustain a period of warm ischemia during retrieval.
   - **C.** Approximately 35% of renal transplants in the United Kingdom are currently from living donors.
   - **D.** Laparoscopic donor nephrectomy is contraindicated with multiple renal arteries.
   - **E.** The usual hospital stay after laparoscopic donor nephrectomy is 2 to 4 days.
2. Which of the following is/are *true* regarding the renal transplant surgical procedure?
   - **A.** The kidney is placed in an extraperitoneal position in one or the other iliac fossa.
   - **B.** For cadaveric renal transplants the renal artery is usually anastomosed to the internal iliac artery.
   - **C.** Lower pole renal arteries can be sacrificed without increasing the risk for ureteral complications.
   - **D.** The transplant ureter is anastomosed directly to the bladder.
   - **E.** Transplant ureteral stents should remain in place for 3 months.
3. Which of the following is/are *not* risk factors for transplant renal artery thrombosis?
   - **A.** Atherosclerosis
   - **B.** Dehydration
   - **C.** von Willebrand disease
   - **D.** Diabetes
   - **E.** Protein C deficiency
4. Which of the following is/are *true* regarding urologic complications after renal transplantation?
   - **A.** Urologic complications are less common than vascular complications.
   - **B.** Urologic complications invariably manifest early.
   - **C.** Urine leaks are diagnosed by markedly raised urea and creatinine levels in the fluid compared with serum.
   - **D.** Reexploration and surgical reconstruction are always required for urine leaks.
   - **E.** Transplant ureteral stenosis is associated with BK polyoma virus infection.
5. Which of the following is/are *true* regarding transplant nephrectomy?
   - **A.** Transplant nephrectomy is mandatory for early graft failure caused by thrombosis.
   - **B.** Transplant nephrectomy reduces allosensitization.
   - **C.** Mortality is higher in patients with failed grafts weaned from immunosuppression.
   - **D.** Graft nephrectomy, particularly late after transplantation, is straightforward.
   - **E.** All failed renal transplants should be removed.

Prophylaxis and Treatment of Kidney Transplant Rejection

James E. Cooper, Erik Stites, Alexander C. Wiseman

The clinical presentation of the immune response to transplanted tissue (referred to as *rejection*) became apparent in 1960 when, after successful proof-of-principle kidney transplants were performed in identical twins, kidney transplantation was attempted between immunologically dissimilar individuals.[1] Eleven patients underwent lymphoid irradiation to prevent rejection after kidney transplant from nonidentical donors. Although 10 of 11 died of overwhelming infection, illustrating the potential consequences of immunosuppression, the lone surviving patient from this series subsequently experienced two episodes of acute rejection, both of which were treated with corticosteroids, and recovered good graft function. Thus began the development of immunosuppressive agents that could prevent and treat rejection while not inducing severe life-threatening side effects. As a result of the development of newer immunosuppression medications, the incidence of acute rejection in the first year after transplant has significantly decreased over time and is now approximately 10% to 15%[2] (Fig. 104.1). However, the management of chronic rejection has remained a challenge, with continued attempts to better define the nature of injury and methods to prevent or reverse this process. As attention shifts to limiting the toxicity of immunosuppression medications (e.g., withdrawal of corticosteroids or calcineurin inhibitors [CNIs]) and attempts to increase access to transplant (e.g., performing transplants across human leukocyte antigen [HLA] and blood type barriers), management of acute rejection continues to be an important clinical issue.

DEFINITION

Rejection (both acute and chronic) is defined by histologic findings after kidney transplant biopsy. A biopsy considered adequate for analysis contains at least 10 glomeruli and 2 small arteries, stained for hematoxylin and eosin (HE), periodic acid–Schiff (PAS) or methenamine silver, and Masson trichrome, and a biopsy with 7 to 9 glomeruli and 1 artery is considered of marginal adequacy. When performed for clinical indications (renal dysfunction), two separate cores should be obtained because the findings of rejection are often patchy in distribution (Fig. 104.2).[3]

The Banff Working Classification of Renal Allograft Pathology forms the basis of the histologic definition of rejection and is updated biannually (Box 104.1). First developed in 1993 with a primary focus on T cell–mediated acute inflammatory infiltrates to classify the degree of rejection, updates in the classification differentiated humoral (antibody-mediated) and T cell responses and further distinguished a chronic humoral form of injury previously classified as chronic allograft nephropathy (see Chapter 107).[4] This was based on the indirect identification of antibody-mediated injury by evidence of complement (C4d) deposition. C4d is a fragment of C4b that is generated after immunoglobulin G (IgG) and IgM binding to host antigens with activation of the classical complement pathway. C4b/C4d forms a covalent bond with proteins on tissue such as capillary endothelial cells via a sulfhydryl group and remains bound to tissue after immunoglobulin and other complement products have been released.[5] Staining for C4d, either by immunohistochemistry or immunofluorescence, indicates that an antibody-mediated process may be involved.

Although the detection of C4d remains a specific marker for antibody-mediated graft pathology, significant limitations in sensitivity have led to the recognition of C4d-negative antibody–mediated rejection.[6] Studies of endothelial-associated transcript (ENDAT) expression[7,8] and C4d-negative histologic findings from protocol biopsy studies in patients with microvascular inflammation[9] helped identify the clinical importance of C4d-negative antibody–mediated rejection, which led to these updated Banff criteria.

Antibody-Mediated Rejection

Acute antibody-mediated (humoral) rejection occurs in 5% to 7% of all transplants and is present in 20% to 30% of episodes of acute rejection[10] in patients at lower immunologic risk, occurring typically within the first few weeks of transplantation or in association with a change in immunosuppression. Although patients who have preexisting donor-specific HLA alloantibodies (donor-specific antibodies) are at higher risk for acute humoral rejection, the identification of de novo donor-specific antibodies at the time of graft dysfunction is common. The diagnosis of acute humoral rejection requires (1) evidence of circulating donor-specific antibodies, (2) evidence of current/recent antibody interaction with vascular endothelium, and (3) evidence of tissue injury (Fig. 104.3).[6] Patterns of injury associated with acute humoral rejection range from acute tubular cell injury suggestive of acute tubular necrosis to thrombotic microangiopathy, but neutrophils and/or macrophages are typically present in peritubular capillaries. The requirement for evidence of antibody/endothelial interaction has been expanded beyond C4d staining and now includes at least moderate microvascular inflammation or evidence of increased ENDAT expression if using a validated assay.

Chronic active antibody-mediated rejection has been identified as a leading cause of late allograft loss[7,11] and is likely the result of an indolent alloimmune response that can result in transplant glomerulopathy and microcirculatory inflammation. Although transplant glomerulopathy is often associated with circulating donor-specific antibodies and C4d deposition, these diagnostic markers are not detected in 30% to 50% of cases.[12] One possibility is that these lesions are not solely due to a humoral response. Alternatively, the failure to detect these

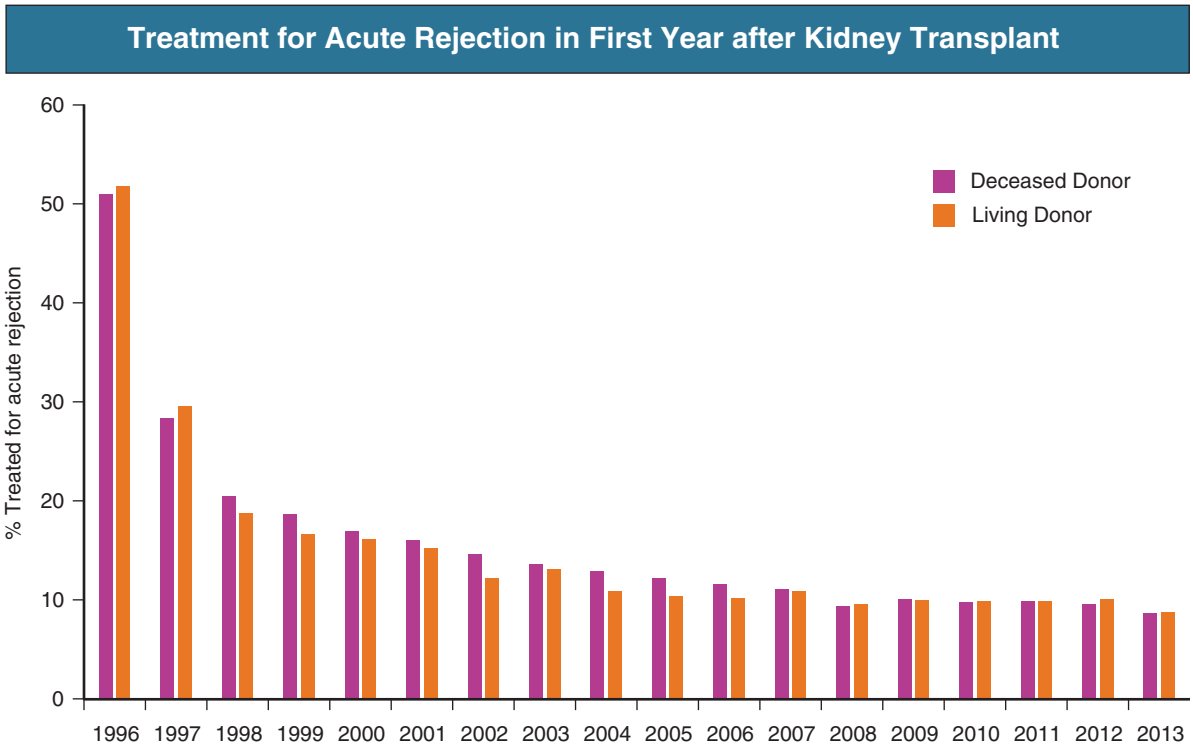

Fig. 104.1 Treatment for acute rejection within 1 year of transplant in the United States, 1996 to 2013. (From 2015 U.S. Renal Data System [USRDS] data report.)

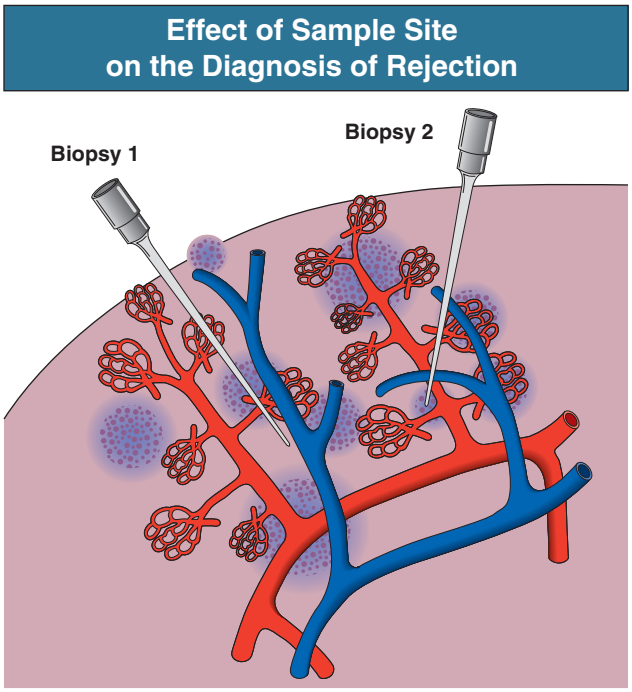

Fig. 104.2 Biopsy technique. Acute rejection begins as patchy, focal infiltrates and becomes homogeneous only in advanced stages. The intensity of mononuclear infiltrate seen on biopsy sample would differ between core 1 and core 2. Routinely taking two core biopsy samples can help decrease the sampling errors, which can affect the histologic interpretation of rejection.

markers could be due to non–complement-fixing antibodies and/or the waxing/waning nature of the humoral response.

The current Banff diagnostic criteria for chronic humoral rejection require (1) evidence of donor-specific antibodies, (2) evidence of current/recent antibody interaction with vascular endothelium, and (3) evidence of chronic tissue injury such as transplant glomerulopathy, multilamination of the peritubular capillary basement membrane, and/or arterial intimal fibrosis (Fig. 104.4).

T Cell–Mediated Rejection

The original pathologic description of rejection is now referred to as *T cell–mediated rejection*. The classification of acute T cell–mediated rejection (acute cellular rejection [ACR]) is based on the degree and location of mononuclear cell inflammation. Because interstitial inflammation and tubulitis are frequently present immediately beneath the renal capsule (subcapsular inflammation) in stable allografts, this finding is not considered when interpreting an allograft biopsy result for the presence of rejection. When severe, interstitial inflammation may extend into tubules via injury to the tubular basement membrane (tubulitis). The predominant phenotype of these infiltrates is a mixture of $CD4^+$ and $CD8^+$ T cells; however, B cells, eosinophils, and macrophages also may be present. Less commonly, endarteritis (endothelialitis) may be present in which T cells and macrophages extend under the arterial endothelium, a phenomenon that may or may not be accompanied by interstitial inflammation or tubulitis. The finding of interstitial infiltrates and tubulitis in a kidney transplant biopsy is not specific to ACR and other causes such as viral nephropathy (BK virus, less commonly cytomegalovirus), pyelonephritis, or post-transplant lymphoproliferative disease should be considered. In contrast, the histologic finding of endothelialitis is pathognomonic of ACR.

Acute T cell–mediated rejection is histologically classified in the Banff criteria by endothelialitis, the degree of interstitial inflammation, and the quantity of cells infiltrating into tubules. Type I ACR is

BOX 104.1 Banff Classification of Rejection

Antibody Mediated

Acute/Active

I. Acute tissue injury with one or more of the following:
   a. Microvascular inflammation (g>0, ptc>0)
   b. Intimal arteritis (v>0)
   c. Acute thrombotic microangiopathy
   d. Acute tubular injury

II. Evidence of current/recent antibody interaction with vascular endothelium with one or more of the following:
   a. Linear peritubular capillary C4d staining
   b. Moderate microvascular inflammation (g+ptc≥2)
   c. Increased expression of endothelial injury-associated gene transcripts in biopsy tissue

III. Serological evidence of donor specific antibodies

Chronic Active

I. Acute tissue injury with one or more of the following:
   a. Transplant glomerulopathy (cg>0)
   b. Severe peritubular capillary basement membrane multilayering
   c. Arterial intimal fibrosis

II. Evidence of current/recent antibody interaction with vascular endothelium with one or more of the following:
   a. Linear peritubular capillary C4d staining
   b. Moderate microvascular inflammation (g+ptc≥2)
   c. Increased expression of endothelial injury-associated gene transcripts in biopsy tissue

III. Serological evidence of donor specific antibodies

T Cell Mediated

Acute

Mononuclear cell interstitial inflammation and tubulitis and/or arteritis

IA: More than 25% interstitial infiltration, 4 to 10 mononuclear cells/tubular cross section

IB: More than 25% interstitial infiltration, greater than 10 mononuclear cells/tubular cross section

IIA: Intimal arteritis, mild to moderate (0% to 25% of luminal area)

IIB: Intimal arteritis, severe (>25% of luminal area)

III: Transmural arteritis and/or fibrinoid change and necrosis of medial smooth muscle cells with accompanying lymphocyte inflammation

Chronic

Arterial intimal fibrosis with mononuclear cell infiltration in fibrosis, formation of neointima

Borderline

Presence of 10% to 25% interstitial infiltration, fewer than 4 mononuclear cells/tubular cross section

Modified from reference 6.
cg, Chronic glomerulopathy; *g,* glomerulitis; *ptc,* peritubular capillaritis; *v,* vasculitis.

characterized by the absence of endothelialitis, with interstitial inflammation of at least 25% of the parenchyma, and tubulitis (Fig. 104.5). Type II ACR is characterized by vascular involvement/endothelialitis (Fig. 104.6). Type III ACR is characterized by vascular inflammation that extends to the media (transmural) and may be accompanied by fibrinoid change and necrosis of the smooth muscle cells (Fig. 104.7). Types II and III ACR may or may not be associated with elements of type I ACR; thus the pathologic description of rejection should not be viewed as a pathogenic continuum. However, types II and III ACR often require different therapeutic interventions and carry different prognostic implications than type I ACR (see later sections).

Chronic active T cell–mediated rejection is a histologic diagnosis that refers to arterial intimal fibrosis specifically with evidence of mononuclear cell infiltration and formation of neointima (Fig. 104.8). This is distinguished from chronic humoral rejection by the location of vascular injury and lack of evidence of pathogenic antibody; it is distinguished from other nonimmunologic processes that may lead to vascular and interstitial fibrosis by the presence of persistent infiltrating cells within vessels. This is covered in greater detail in Chapter 107.

Borderline Rejection

The finding of inflammation in 10% to 25% of the interstitium with tubulitis of less than four mononuclear cells per tubular cross-section is classified as borderline rejection, which remains a pathologic definition without clear clinical significance. When identified in the setting of graft dysfunction or with other findings such as glomerulitis, the risk for progression to clinical rejection on subsequent biopsies is increased and thus treatment may be considered.[13]

CLINICAL MANIFESTATIONS

The clinical presentation of acute rejection is common to both T cell–mediated and antibody-mediated rejection. Patients typically present with a rapid rise in serum creatinine and in severe cases may have decreasing urine output, weight gain, fever, or graft tenderness. The clinical findings are commonly nonspecific and other etiologies of graft dysfunction should be considered at the time of presentation (Box 104.2) in the context of an individual's risk for the development of acute rejection (Box 104.3). As a result of the increase in the number of patients who undergo transplant despite a risk factor for humoral rejection (e.g., presensitization; known donor-specific antibody in desensitization protocols; and ABO-incompatible transplants), approximately 25% of acute rejection episodes now have a humoral component. In acute humoral rejection there may be features of thrombotic microangiopathy with anemia, evidence of hemolysis, and thrombocytopenia. If there is immediate cyanosis of the graft on revascularization (hyperacute rejection) or an abrupt decline in urine output and graft tenderness 3 to 14 days after transplant (delayed hyperacute or accelerated rejection), donor-specific antibody is implicated. Typically there is type III ACR and interstitial hemorrhage on biopsy.

PROPHYLAXIS AND PREVENTION

Prophylaxis

The primary goal of transplant management is prevention of immunologic graft loss in the early period after transplant. Over time, the risk for acute rejection diminishes and the approach to immunosuppressive therapy shifts toward considerations of adverse effects of the therapy and risks for other events such as cardiovascular (CV) disease and malignancy. Therefore clinical practice follows a strategy of intensive immunosuppression and monitoring in the first months after transplant with a reduction in the intensity of treatment thereafter.

Prevention of Acute T Cell–Mediated Rejection: Induction Therapy

A brief course of potent immunosuppression at the time of transplant (referred to as *induction therapy*) is now commonly used to prevent acute rejection in transplant recipients, regardless of immunologic risk. According to the Scientific Registry of Transplant Recipients, approximately 85%

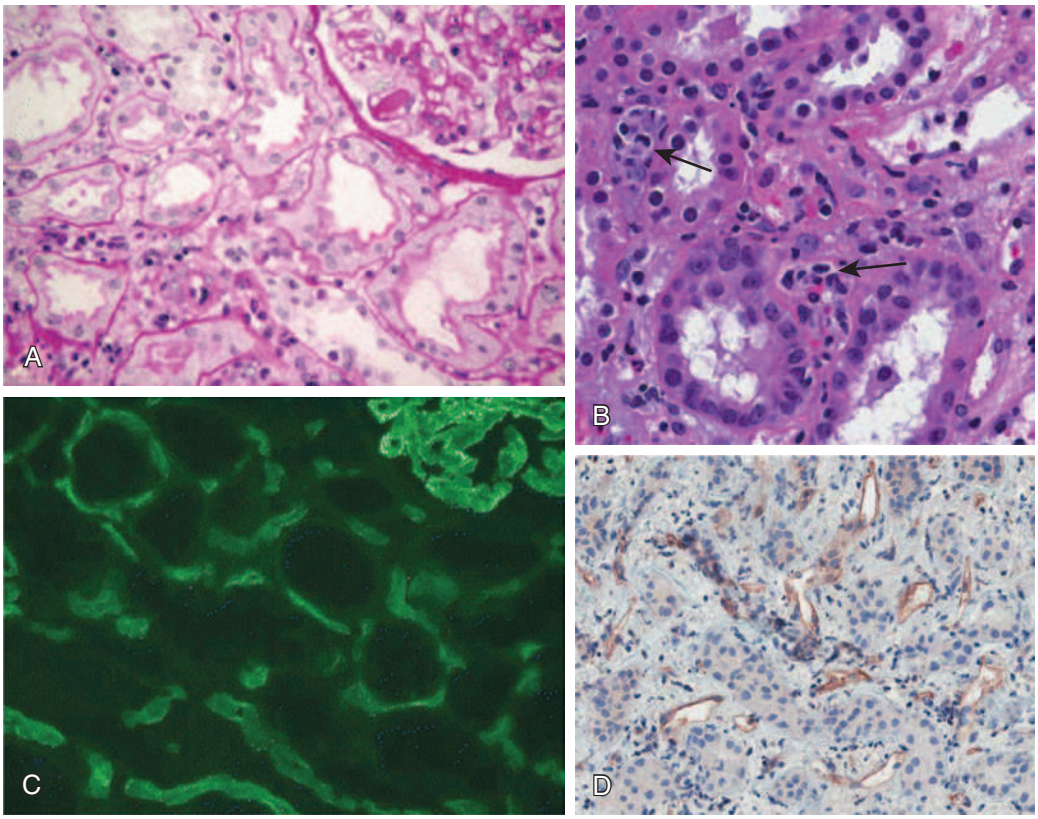

Fig. 104.3 Acute antibody-mediated rejection. (A) Peritubular and glomerular capillaries contain numerous polymorphonuclear leukocytes and mononuclear cells. (B) Numerous polymorphonuclear leukocytes are observed in a peritubular capillary *(arrows)*. Interstitial edema is noted. (Periodic acid–Schiff [PAS] stain, ×200.) of U.S. kidney transplant recipients received induction therapy in 2014. For higher risk patients such as those with prior sensitization (the presence of HLA antibodies quantified by percent reactivity against a panel of common HLA types, referred to as *percent panel reactive antibodies* or [PRA]), previous transplant, or African American ethnicity, induction therapy is usually combined with standard doses of immunosuppression to prevent rejection. For those with lower risk (living donor kidney recipients, first kidney transplants), induction therapy is often employed to minimize exposure to maintenance immunosuppression. The use of race as a risk factor for rejection has been questioned with a study demonstrating similar acute rejection rates in African Europeans compared with European Whites in France.[14] However, most studies still report a higher risk for rejection for African Americans than American Whites; thus induction therapy is commonly used in this population.[15]

Induction agents can be classified as T cell depleting or nondepleting. Nondepleting agents include the monoclonal humanized interleukin-2 (IL-2) receptor antibodies (IL-2ra) daclizumab (withdrawn from the market by the manufacturer because of lack of market demand) and basiliximab. The IL-2 receptor was identified as a potential immunosuppressive target because it is present on T cells and inhibition of IL-2/

BOX 104.2 Differential Diagnosis of Renal Allograft Dysfunction

Week 1 Post-Transplantation

- Acute tubular necrosis
- Hyperacute or accelerated rejection
- Urologic
  - Obstruction
  - Urine leak
- Vascular thrombosis
  - Renal artery
  - Renal vein
- Volume contraction

Less Than 12 Weeks After Transplantation

- Acute rejection
- Calcineurin inhibitor toxicity
- Volume contraction
- Urologic
  - Obstruction
- Infection
  - Bacterial pyelonephritis
  - Viral infections
- Interstitial nephritis
- Recurrent disease

Longer Than 12 Weeks After Transplantation

- Acute rejection
- Volume contraction
- Calcineurin inhibitor toxicity
- Urologic
  - Obstruction
- Infection
  - Bacterial pyelonephritis
  - Viral infections
- Chronic allograft nephropathy
- Recurrent disease
- Renal artery stenosis
- Post-transplantation lymphoproliferative disorder

BOX 104.3 Risk Factors for Acute Rejection

High Risk

- Sensitization (high panel reactive antibody percentage)
  - Previous transplantation
  - Pregnancy
  - Transfusion
- Delayed graft function
  - Deceased donor source
  - Increased donor age
  - Prolonged ischemic time
  - Donor brain death
  - Donor acute renal dysfunction
- HLA mismatching
- Positive pretransplantation B cell crossmatch
- ABO incompatibility
- Corticosteroid minimization
- Infection
  - Bacterial pyelonephritis
  - Cytomegalovirus
- Adolescent recipient
- African American recipient
- Previous rejection episode

Low Risk

- Zero HLA mismatch
- Elderly recipient of young donor kidney
- Preemptive transplantation
- Living donor source
- First transplant

HLA, Human leukocyte antigen.

IL-2r signaling inhibits T cell proliferation (see Chapter 101). Use of IL-2ra has resulted in a reduction in acute rejection rates with minimal side effects when combined with cyclosporine-based immunosuppression in the absence of mycophenolate.[16] Importantly, these agents have not been studied in a prospective randomized fashion in combination with a tacrolimus/mycophenolate-based maintenance regimen; thus questions remain regarding the relative benefits of the addition of IL-2ra with more potent, commonly used maintenance agents.[17]

Depleting agents include antithymocyte globulin and anti-CD52 monoclonal antibody (alemtuzumab). Unlike the IL-2ra agents, none of these agents have been compared with placebo for the prevention of rejection and thus their use as induction agents is considered off label in the United States. Antithymocyte globulin is a polyclonal preparation of antibodies directed at T cells prepared by immunizing animals with human lymphoid cells derived from the thymus. Currently, the most common antilymphocyte preparation in use is rabbit antithymocyte globulin (rATG,). Alemtuzumab binds to CD52, an antigen of unclear physiologic significance that is present on both B and T cells, and results in depletion of both lymphoid cell lines. Its ability to induce prolonged, significant lymphopenia for up to 6 to 12 months after dosing led to its use in refractory chronic lymphocytic leukemia. Unlike other depleting agents, it is a humanized antibody, and therefore has fewer infusion-related side effects than rATG. Initial trials suggest equivalence to other depleting agents in the prevention of rejection, but the long-term impact of prolonged lymphopenia on the risk for infection or post-transplant lymphoproliferative disorder has yet to be determined, and comparative trials of induction agents are lacking (see later discussion). Alemtuzumab has been rebranded for use in multiple sclerosis in the United States and thus will soon be cost-prohibitive as transplant induction therapy; however, it is still in use in some European centers.

Although depleting agents are effective in the inhibition of the T cell response, there is concern about long-term safety. Registry analyses suggest there is an increased risk for future development of lymphoma with depleting agents compared with nondepleting agents or no induction therapy,[18,19] an association that appears to be dose-dependent. Therefore the potential for recovery or improvement of graft function as a result of repeated or prolonged courses of depleting antibody therapy must be balanced against the potential long-term risk for malignancy.

Three multicenter randomized trials have compared the efficacy of induction agents in the prevention of acute rejection. A multicenter trial in patients at high risk for acute rejection (defined as recipients with an elevated risk for delayed graft function, elevated PRAs, repeat transplants, or HLA mismatches) compared the IL-2ra basiliximab to rATG with maintenance immunosuppression of cyclosporine, mycophenolate mofetil (MMF), and prednisone.[20] At 12 months, the rate of acute rejection in the basiliximab cohort was 26% versus 16% in the rATG arm. A second trial in patients at high risk for acute rejection (defined by elevated PRAs, repeat transplants, or loss of a previous kidney transplant to acute rejection) compared the IL-2ra daclizumab to rATG, with a remarkable increase in the risk for rejection for patients randomized to daclizumab (27%) compared with rATG (15%) at 1 year.[21] Thus for patients at increased risk for rejection, rATG provided greater prevention of acute rejection, supporting its use in higher risk populations. In contrast, the recently reported European multicenter randomized controlled HARMONY trial showed no difference in rejection rates among patients at low immunologic risk receiving either rATG followed by rapid steroid withdrawal or basiliximab with or without rapid steroid withdrawal.[22] Finally, a clinical trial compared anti-CD52 to either rATG in high-risk patients (repeat transplant, elevated PRAs, or Black race) or to an IL2-ra in low-risk patients, followed by early corticosteroid withdrawal and maintenance tacrolimus and mycophenolate immunosuppression.[23] Acute rejection rates over the first 12 months in the high-risk arms were 10% for anti-CD52 and 13% for rATG and in the low-risk arms were 20% for IL2-ra and 3% for anti-CD52, suggesting a benefit of anti-CD52 over IL2-ra in the population of low immunologic risk. Between 12 and 36 months, however, acute rejection rates in anti-CD52–treated patients were higher in both low- and high-risk arms, suggesting a delayed (>12 months) immunologic risk for immune reconstitution with anti-CD52 therapy. This may be problematic for transplant care providers who generally adhere to less rigorous late (>12 months) clinical monitoring protocols for otherwise stable transplant recipients. Therefore we recommend adhering to a more frequent late (>1 year) clinical monitoring protocol for patients receiving induction with alemtuzumab. In summary, it remains unclear whether induction therapy is required in low-risk patients pending further prospective head-to-head trials, whereas patients at higher immunologic risk appear to benefit from lymphocyte-depleting treatment. At our center, patients at high immunologic risk receive induction with rATG at 1.5 mg/kg for 3 doses and patients at low immunologic risk receive intravenous methylprednisolone without specific induction therapy. Common dosing regimens of induction agents are listed in Table 104.1.

Prevention of Acute Antibody-Mediated Rejection: Desensitization

The patient who has donor-specific antibodies or is blood type–incompatible to the donor before transplant has a near-universal risk for developing acute antibody-mediated rejection after transplant without pretransplant therapeutic intervention. Desensitization protocols may permit transplantation of these donor-recipient combinations.

TABLE 104.1 Agents Used for Induction and Treatment of T Cell–Mediated Rejection

Agent	Target	Dose (Induction)	Dose (Rejection)
Methylprednisolone	B cells, T cells, macrophages	250-500 mg IV with induction therapy, followed by taper over 1-5 days	3-5 mg/kg (250-500 mg) IV × 3-5 days
Basiliximab	IL-2 receptors on cells	20 mg IV × 2 on days 0 and 4	N/A
rATG	T cell surface antigens	1-1.5 mg/kg IV × 4-14 days	1-1.5 mg/kg IV × 7-14 days
Alemtuzumab	CD52 on T and B cells	30-60 mg × 1 or 2 on days 0 and 2	Same as induction

rATG, Rabbit antithymocyte globulin.

TABLE 104.2 Agents Used for Desensitization and Treatment of Antibody-Mediated Rejection

Treatment	Mechanism	Protocol (Desensitization)	Dose (Antibody-Mediated Rejection)
Plasma exchange*	Antibody removal	Two to four sessions or until XM acceptable, combined with IVIG	Two to five treatments, daily or every other day, combined with IVIG
IVIG*	Multiple, antibody inhibition?	100-200 mg/kg after plasma exchange until acceptable XM *or* 1-2 g/kg mo until transplant	100-200 mg/kg after plasma exchange
Rituximab*	Anti-CD20 B cell inhibition	375 mg/m^2 (day 15) combined with IVIG 1-2 g/kg (days 1 and 30)	375 mg/m^2 with plasma exchange and IVIG
Bortezomib	Plasma cell inhibition	Not established	1.3 mg/m^2 × four doses over 1-2 wk, usually combined with plasma exchange and IVIG
Eculizumab	Terminal complement C5 inhibition	Not established	For prevention in + XM transplant: 600-1200 mg/wk × 4 then biweekly until successful antibody reduction
Splenectomy	B cell removal	No longer used	N/A, for severe refractory cases only

*Commonly used.
IVIG, Intravenous immunoglobulin; *XM,* crossmatch.

Desensitization protocols typically involve removal of preformed antibody with plasma exchange and/or suppression of antibody production and action with intravenous immunoglobulin (IVIG) or B cell inhibition with rituximab. Several different desensitization strategies have been adopted by transplant centers over the previous decade and are generally influenced by factors such as type of transplant (living vs. deceased donor) and the degree of HLA-antibody reactivity one is attempting to overcome. In the case of living donation the crossmatch barriers are known in advance, allowing for plasma exchange followed by low-dose (100 to 200 mg/kg) IVIG to be employed and transplant to be pursued when the desired crossmatch results are obtained. Protocols consisting of monthly high-dose IVIG (1 to 2 g/kg) infusions with or without rituximab[24] have been used in situations in which pretransplant plasma exchange is not feasible, such as in sensitized patients without living donor options awaiting deceased donor kidneys; however, the effectiveness of this strategy has been questioned.[25]

Desensitization strategies have allowed transplantation in sensitized patients who otherwise may not be afforded the opportunity. However, these procedures are generally met with high rates of acute rejection, ranging from 20% to 70% (depending on a variety of factors, including specific protocol, induction immunosuppression, and immunologic risk), are often humoral and frequently progress to chronic antibody-mediated injury.[26,27] Despite these pitfalls, short-term graft survival after desensitization has been acceptable[26] and data suggest a survival benefit sustained for up to 8 years for desensitized patients undergoing transplant, compared with matched controls undergoing dialysis while on the waiting list.[28] Thus HLA desensitization for sensitized transplant candidates may be a reasonable option, especially for those with a living donor(s), and referral to a transplant center with experience in this field is warranted. Published desensitization agents and protocols are listed in Table 104.2.

Maintenance Therapy for Prevention of Acute Rejection

Current maintenance immunosuppression most commonly includes a CNI, an antiproliferative agent, and corticosteroids. This combination of agents forms the standard against which novel strategies are compared, such as corticosteroid withdrawal/avoidance and CNI withdrawal/avoidance. Cyclosporine has been replaced by tacrolimus as the preferred CNI in the United States, and together with the antiproliferative agent MMF, forms the most common immunosuppressive regimen in current practice in the United States and most Western countries (Table 104.3). More affordable regimens that include CsA and azathioprine (AZA) are commonly used in areas where access to health care resources is more limited; however, comparative clinical trials typically show more rejection in patients receiving this regimen.[29]

Calcineurin Inhibitors in the Prevention of Acute Rejection

Since the early 1980s when the introduction of CsA resulted in a reduction in the incidence of acute rejection and improvements in projected graft survival,[30] calcineurin inhibition has been a cornerstone of maintenance immunosuppression. Tacrolimus, first introduced in 1990s and compared head-to-head with CsA in multiple trials, appears to provide greater protection from acute rejection but with a different side effect profile. A recent meta-analysis of trials that compared tacrolimus and CsA-based immunosuppression demonstrated a reduction in risk for acute rejection by 31% but an increase in risk for development of diabetes by 86%. Tacrolimus was also associated with a better death-censored graft survival (hazard ratio, 0.56), particularly at target trough

TABLE 104.3 Immunosuppression Regimens in the United States, 2011

Regimen	Percent
Induction Regimens at Time of Transplant	
IL-2Ra	21
T cell depleting	59
Maintenance Regimens at Time of Hospital Discharge

doses less than 10 ng/ml, a finding that was not shown in individual studies.[31]

Antiproliferative Agents in the Prevention of Acute Rejection

AZA was the first antiproliferative agent used in kidney transplantation and was used initially in conjunction with corticosteroids and later with CsA. Although its development was critical in the advancement of allotransplantation, acute rejection was quite common, with acute rejection rates of 35% to 40% in a number of clinical trials using CsA/AZA/prednisone. Newer antiproliferative agents emerged in the 1990s with MMF and later with the mammalian target of rapamycin (mTOR) inhibitors sirolimus and everolimus that significantly reduced the incidence of acute rejection.

MMF, a purine antagonist that interferes with DNA synthesis in rapidly dividing cells such as activated lymphocytes, gained popularity after a number of multicenter prospective clinical trials demonstrated an approximately 50% reduction in the incidence of acute rejection compared with that for AZA.[32,33] A recent meta-analysis of 23 studies showed MMF to be associated with significantly fewer cases of acute rejection and graft loss compared with AZA.[29] Most studies in this analysis report outcomes of MMF and AZA in combination with CsA and thus may not translate to regimens using tacrolimus. One drawback of MMF has been its gastrointestinal (GI) tolerability, which often results in reduction of therapy with attendant risks for acute rejection[34] and graft loss.[35] An MMF analogue, enteric-coated mycophenolate sodium (MPA), has been developed and appears to be "noninferior" in efficacy to MMF,[36] with fewer GI side effects reported in one open-label study.[37]

Similar to MMF, the mTOR inhibitors sirolimus and everolimus were initially tested in clinical trials as a substitute for AZA and demonstrated reductions in acute rejection rates similar to those with MMF.[38] mTOR inhibitors inhibit the progression from G1 to S phase of the cell cycle and appear to have additional antiproliferative effects on nonimmune cells that may contribute to an increase in side effects (impaired wound healing, lymphocele formation, proteinuria, and slower recovery from delayed graft function) but also may reduce the incidence of viral infection and malignancy.[39,40]

Acute Rejection Rates in Calcineurin-Sparing and Corticosteroid-Sparing Immunosuppression Regimens

There has been increasing interest in how best to minimize side effects of immunosuppression. Avoidance of CNIs offers the hope of prolonged graft survival given the inherent nephrotoxicity of these medications, and avoidance of corticosteroids offers the hope of reducing a number of cosmetic, metabolic, and CV side effects attributable to prednisone.

Early corticosteroid cessation (within 7 days after transplant) has become increasingly popular in the United States. In 2014, over 32% of all patients were discharged after transplant without maintenance prednisone therapy. Generally, patients at lower immunologic risk (low PRAs, first transplants) are selected,[41,42] and immunosuppression includes induction therapy, a CNI, and an antiproliferative agent. Acute rejection rates in single-center studies range from 10% to 15%. In the largest prospective, double-blind multicenter study to date of corticosteroid cessation versus standard corticosteroid maintenance,[43] a standard steroid taper or a rapid elimination of steroids at 7 days post-transplant was compared on the background of induction therapy plus a tacrolimus/MMF-based immunosuppression. Patient survival, graft survival, and creatinine clearance were comparable at 5 years. CV risk factors and weight gain were not significantly different between groups, but corticosteroid withdrawal was associated with less bone disease, less insulin-requiring new-onset diabetes, and lower triglyceride levels. One cause for concern with corticosteroid withdrawal was that rejection rates were higher (18% vs. 11%, $P = .04$), and a post hoc analysis suggested a higher rate of chronic allograft nephropathy in the corticosteroid withdrawal arm. In contrast, the aforementioned HARMONY study reported similar rejection rates and significant reductions in post-transplant diabetes in two rapid (8 day) steroid withdrawal arms (one using basiliximab and the other using rATG induction) compared with the control arm of basiliximab induction and maintenance steroids, with all patients receiving tacrolimus and MMF.[22]

Clinicians must weigh the possibility of higher rejection risk versus the potential benefits noted previously when counseling patients regarding corticosteroid withdrawal. Both the Astellas Corticosteroid Withdrawal and the HARMONY trials were performed in patients at low immunologic risk without the presence of or at low risk for delayed graft function; thus consideration for corticosteroid withdrawal is best supported for the patient with a lower expected risk for rejection (low immunologic risk, expected immediate graft function) or high expected risk for corticosteroid-related complications such as bone disease and diabetes.

CNI avoidance has been studied with both dual therapy (MMF/prednisone) and triple therapy with two antiproliferative agents (sirolimus/MMF/prednisone) in combination with induction therapy. In general, MMF/prednisone maintenance immunosuppression does not appear to be effective in the prevention of rejection (70% incidence in one pilot study[44]), and although single-center studies report acute rejection rates of 6% to 13% with sirolimus/MMF/prednisone therapy,[45,46] a large multicenter trial using this combination and target trough concentrations of sirolimus 4 to 8 ng/ml also revealed an excessively high acute rejection rate (38%).[47] CNI avoidance was more successful in the BENEFIT trial, which compared the costimulation blocker belatacept at 2 doses to CsA with IL2ra induction and MPA/prednisone maintenance.[48] Despite higher 1-year acute rejection rates in the belatacept arms (22% and 17% for higher and lower intensity, respectively, vs. 7% for CsA) graft survival was comparable and measured glomerular filtration rate (GFR) significantly higher for those receiving belatacept (65 and 63 ml/min for high- and low-intensity belatacept vs. 50 ml/min for CsA). At 7 years of follow-up, the belatacept arms experienced a 43% reduced risk for a composite end-point of death or graft loss compared with CsA.[49] Importantly, because of higher rates of post-transplant lymphoproliferative disorder associated with belatacept use in Epstein-Barr virus (EBV)-seronegative patients, this option is available only to those with confirmed EBV seropositivity. The BENEFIT studies included patients at low to moderate immunologic risk (PRAs <50% first transplant, <30% repeat transplant), and we suggest that

TABLE 104.4 Maintenance Immunosuppression and Reported Rejection Rates in Randomized Multicenter Trials

Regimen	Induction	CNI Dose or Trough Level Goal	Antiproliferative Dosing	Acute Rejection at 6 Months (%)
Low Immunologic Risk				
CSA/AZA/Pred		4 mg/kg/day	1.5-2 mg/kg/day	36

*Acute rejection rate at 12 months.
Bold, Suggested regimens by the authors based on available data.

consideration of patients for belatacept therapy be limited to those who fall into this immunologic category. A post hoc analysis of patients included in both the BENEFIT and BENEFIT-EXT (the latter including patients receiving extended-criteria donor kidneys) showed significantly lower blood pressure, serum lipids, and incidence of new-onset diabetes (NODAT) in those randomized to belatacept regimens compared with CsA.[50] Thus patients with pretransplant metabolic profiles at risk for post-transplant metabolic complications in particular may benefit from belatacept-based CNI-free immunosuppression.

In contrast to their use in complete CNI avoidance strategies, mTOR inhibitors have achieved relative success when used in CNI withdrawal[51,52] and conversion protocols. In one study, patients receiving a CNI, MMF, and prednisone were randomized to continue this regimen or undergo CNI conversion to sirolimus at 1 to 6 months after transplant with statistically similar rates of acute rejection and comparable renal function at 2 years.[53] Another study, employing a similar approach of CNI conversion to everolimus at 4 to 5 months post-transplant, demonstrated equivalent rates of acute rejection (15% in both groups) and significantly improved estimated GFR (eGFR) at 12 months in the conversion group (72 ml/min vs. 62 ml/min in the CNI continuation arm).[54] A recent meta-analysis that included 23 studies comparing CNI conversion to mTOR inhibitors found a modest improvement in renal function with no difference in rates of rejection or graft loss.[55] Widespread acceptance of CNI to mTOR inhibitor conversion strategies has been hindered because of mTOR inhibitor–related side effects and reluctance to alter immunosuppression in stable transplant recipients.

Acute rejection rates by treatment regimen reported in recent multicenter clinical trials are shown in Table 104.4. These rates are often higher than rates reported to registries (see Fig. 104.1) because of the more rigorous follow-up and mandatory reporting within the context of clinical trials.

TREATMENT

Acute T Cell–Mediated Rejection

Treatment of T cell–mediated acute rejection is often directed by the findings on biopsy and the clinical response to pulse corticosteroids. For the patient with graft dysfunction and biopsy-proven rejection, treatment with intravenous methylprednisolone 3 to 5 mg/kg (250 to 500 mg/d) for 3 to 5 days is often effective if the histologic injury is tubulointerstitial (Banff class IA or IB). Remarkably few studies of the clinical response to corticosteroids in the treatment of acute rejection have been performed under modern immunosuppression, but prior data suggest that 60% to 70% of patients will respond with improved urine output and decreasing serum creatinine within 5 days. If there is inadequate response after corticosteroid pulse therapy or if there is vascular involvement (Banff class IIA, IIB), corticosteroids often must be supplemented with T cell–depleting antibody therapies in a similar dosing strategy but longer treatment course compared with their use for induction (see Table 104.1). Most studies have used these agents in 7- to 14-day treatment courses, with no clinical trials investigating the efficacy of shorter courses versus longer courses. For patients who

are on a maintenance regimen that is not tacrolimus based, tacrolimus conversion may be considered in the setting of rejection with an inadequate response to corticosteroids,[56] whereas for patients on a corticosteroid-free regimen, reinstitution of maintenance prednisone may be warranted.[57] For patients who do not respond adequately to corticosteroids, T cell–depleting agents are required. A typical course of rATG for T cell–mediated rejection is 1.5 mg/kg for 4 to 14 days dictated by clinical response and absolute lymphocyte counts, again with no controlled study comparing one treatment regimen versus another.

Acute Antibody-Mediated Rejection

Treatment of acute humoral rejection is indicated when the triad of graft injury, evidence of antibody/endothelium interaction, and circulating donor-specific antibody is present, but also should be considered in high-risk circumstances (prior desensitization or known donor-specific antibody) even if all three criteria are not met. High-quality randomized trials investigating treatment options for acute humoral rejection are lacking,[58] and strategies are generally dictated by center experience. Traditionally, treatment has entailed plasma exchange (to remove the pathogenic immunoglobulin[s]) and IVIG (to inhibit/suppress antibody production). In general, at least five plasma exchange treatments should be administered with 1 to 2 g/kg total dose IVIG. IVIG is removed by plasma exchange, so a common strategy is to administer IVIG 100 to 200 mg/kg after each exchange. For refractory acute humoral rejection, rituximab may be considered despite targeting B cells at an earlier phase of maturation than the antibody-producing plasma cell line.[59] The largest randomized clinical trial of rituximab treatment for antibody-mediated rejection to date found no difference between the treatment group and placebo when added to plasma exchange and IVIG for a composite end-point of early improvement in renal function at 12 days after treatment and graft loss at 1 year. However, the study was limited by a small sample size (n = 38) and significant crossover between groups with 42% of subjects in the placebo arm receiving rescue doses of rituximab.[60] In contrast, the proteosome inhibitor bortezomib directly inhibits antibody-producing plasma cells and has been reported in single-center case series as a potential treatment for refractory antibody-mediated rejection, usually in combination with other modalities such as plasma exchange and IVIG.[61] Eculizumab is a humanized monoclonal antibody that blocks terminal complement activation and has been shown to significantly reduce the risk for acute humoral rejection, as well as subsequent transplant glomerulopathy in patients who have undergone positive crossmatch kidney transplant[62]; however, feasibility of this approach is limited by high cost. Finally, there are case reports of splenectomy for refractory acute humoral rejection.[63] These therapies are typically coupled with targeted T cell therapy such as high-dose steroids and/or depleting antibody therapy, because histologic evidence of mixed T cell rejection is often present and helper T cell function may contribute to an enhanced B cell response. Agents used for treatment of acute humoral rejection are summarized in Table 104.2.

Chronic Rejection (T Cell–Mediated and/or Antibody-Mediated)

T cell–mediated or antibody-mediated injury in a graft without features of acute tissue injury remains a therapeutic dilemma in kidney transplantation. No specific intervention has been proven effective in reversing the chronic tissue injury; however, consideration should be given to optimizing or enhancing the maintenance immunosuppression by transitioning to tacrolimus/MMF therapy or increasing the dose of these agents if CNI nephrotoxicity is not identified.[64] Any intervention should be weighed against the potential for risk for enhanced immunosuppression and the lack of any long-term data describing the impact of enhancing immunosuppression. This topic is discussed in greater detail in Chapter 107.

PROGNOSIS

Episodes of acute rejection may predispose to chronic graft dysfunction, with increased histologic findings of chronic rejection and/or interstitial fibrosis and tubular atrophy and clinical findings of reduced graft survival. The clinical response to antirejection therapy appears to be critical in this regard, because the change in renal function from 6 and 12 months post-transplant is more predictive of long-term graft survival than the occurrence of prior episodes of acute rejection.[65] Two analyses (one examining the U.S. experience[66] and another examining the Australia/New Zealand experience[67]) have shed light on risk factors for graft loss after episodes of acute rejection. In general, acute T cell–mediated rejection that responds to therapy with return to near baseline renal function does not portend worse graft survival. However, vascular rejection, late rejection (after 3 months), and rejection that does not respond to within 75% of baseline serum creatinine is associated with worse graft outcomes. Although the risk for acute rejection has fallen significantly over the past decade, the likelihood of graft survival has not improved in parallel; one explanation for this finding is that the rejection now identified tends to be less responsive to therapy, with fewer cases achieving near-baseline serum creatinine levels. The long-term prognosis after episodes of acute antibody-mediated rejection has not been fully defined in prospective analyses. However, from single-center and retrospective studies, it appears that episodes of acute humoral rejection likely affect long-term graft survival. For example, a retrospective analysis of 302 patients with biopsy-proven acute rejection (192 with T cell–mediated rejection and 110 with antibody-mediated rejection) found a threefold to ninefold increased risk for graft loss at 5 years associated with antibody-mediated rejection compared with T cell–mediated rejection.[10] Similarly, the emergence of de novo HLA antibodies at any time after transplant has been shown to be associated with a 5% worse graft survival per year compared with those who do not form anti-HLA antibodies.[68] For this reason, patients who have had episodes of acute rejection must be rigorously monitored with optimization of baseline maintenance immunosuppression. Remaining questions include the value of escalated immunosuppression such as longer term scheduled antibody therapy and additional IVIG treatment for those without adequate clinical response or with persistently elevated titers of HLA antibodies.

SUMMARY AND RECOMMENDATIONS

The incidence of acute rejection has decreased over time, but it remains an important cause of graft dysfunction and progressive graft loss, particularly when antibody-mediated forms of injury are identified. Higher risk patients benefit from induction therapy with lymphocyte-depleting agents for the prevention of rejection. Although many maintenance immunosuppressive regimens have been used to minimize the incidence of rejection and side effects, the most effective maintenance immunosuppressive regimen for the prevention of rejection is a three-drug regimen consisting of tacrolimus, mycophenolate, and prednisone. Alternative immunosuppressive strategies may be considered for side effects or toxicities related to immunosuppressive agents, which in clinical practice has led to a myriad of treatment combinations (see Table 104.4). Steroid minimization and belatacept-based CNI-free immunosuppression have been associated with adequate short- and intermediate-term outcomes but should be limited to those patients at lower immunologic risk for acute rejection. Until there is an accurate means of determining an individual patient's degree of immune function,

suppression, or graft-specific immunity, the clinician must determine the best treatment regimen based on potency (potential to minimize rejection) and tolerability.

SELF-ASSESSMENT QUESTIONS

1. According to the Banff Working Classification of Renal Allograft Pathology, which of the following patterns would be recognized as acute antibody-mediated rejection?
   - **A.** Circulating donor-specific antibodies, severe tubulitis, interstitial inflammation
   - **B.** Peritubular capillary C4d deposition, peritubular capillaritis, interstitial inflammation
   - **C.** Circulating donor-specific antibodies, mild-moderate large vessel intimal arteritis, moderate interstitial fibrosis
   - **D.** Peritubular capillary C4d deposition, circulating donor-specific antibodies, peritubular capillaritis.
2. Which of the following statements is true regarding induction immunosuppression for the prevention of acute rejection?
   - **A.** Rabbit antithymocyte globulin is a monoclonal antibody directed against the CD3 subunit of the T cell receptor associated with a significant innate immune response resulting in a cytokine release syndrome.
   - **B.** Lymphocyte-depleting agents are more effective in preventing acute rejection compared with IL-2 receptor antibodies in patients at high immunologic risk.
   - **C.** The risk for post-transplant lymphoproliferative disorders is higher in patients treated with IL-2 receptor antibodies than in those treated with lymphocyte-depleting agents.
   - **D.** Patients at low immunologic risk experience higher early (<12 months) rates of acute rejection when treated with anti-CD52 therapy (Campath) compared with IL-2 receptor antibody therapy.
3. Which of the following is the most effective maintenance immunosuppressive regimen for the prevention of rejection:
   - **A.** Sirolimus, mycophenolate mofetil (MMF), prednisone
   - **B.** Tacrolimus, MMF, prednisone
   - **C.** Belatacept, MMF, prednisone
   - **D.** Tacrolimus, MMF, prednisone withdrawal at 7 days post-transplant
4. A 47-year-old man treated with tacrolimus, MMF, and 5 mg of prednisone after undergoing deceased-donor kidney transplant 5 months prior presents with an elevated serum creatinine of 5.2 mg/dl (recent baseline 1.3 mg/dl) and mild graft tenderness. Renal ultrasound is nondiagnostic, a workup for infectious causes is negative, and an assay for donor-specific antibody is negative. Allograft biopsy is performed and reveals severe tubulitis with vascular intimal arteritis without evidence of peritubular capillary C4d deposition. The most appropriate initial therapy consists of:
   - **A.** Increasing the dose of maintenance prednisone to 60 mg/day for 7 days followed by a dose taper back to 5 mg
   - **B.** 3-5 days of intravenous methylprednisolone at 500 mg/day
   - **C.** Rabbit antithymocyte globulin (rATG) 1.5 mg/kg intravenously for 7 to 14 days
   - **D.** Plasmapheresis followed by 100 to 200 mg/kg immune immunoglobulin for a total of five session

Medical Management of the Kidney Transplant Recipient
Infections and Malignancies

Phuong-Thu T. Pham, Joanna Schaenman, Phuong-Chi T. Pham

INFECTIOUS DISEASES

Infection follows cardiovascular (CV) disease as the second most common cause of death with a functioning graft in kidney transplant recipients. Most deaths attributable to CV disease are in patients with diabetes, whereas infection and malignancy are more commonly the cause of death among those without diabetes. Predisposing risk factors for infectious complications include immunosuppression, increased recipient age, indwelling Foley or vascular catheters, surgical drains, drug-induced leukopenia, and metabolic derangement. Epidemiologic exposures, shifts in nosocomial flora associated with repeated antimicrobial exposures (antimicrobial resistance), and improvement in molecular diagnostic assays also contribute to the emergence of novel infections and changes in the epidemiology of infections.[1]

Immunizations Before and After Transplantation

All kidney transplant candidates should receive immunization for hepatitis B, pneumococcus, and other standard immunizations appropriate for age and the presence of end-stage kidney disease. Vaccinations should be administered at least 4 to 6 weeks before transplantation to achieve optimal immune response and minimize the possibility of live vaccine–derived infection in the post-transplantation period. Household members, close contacts, and health care workers should also be fully immunized. A minimum of 4 weeks should elapse between live virus vaccine administration and transplantation. Live virus or live organism vaccines should be avoided after transplantation. In addition, exposure to persons who have chickenpox or herpes zoster should be avoided until the lesions have crusted over and no new lesions are appearing. Immunizations using inactivated or killed microorganisms, components, and recombinant moieties are safe for transplant recipients. Most centers restart vaccinations 3 to 6 months after transplantation. Vaccination during the first 3 months after transplantation may result in suboptimal response and protection because of heavy immunosuppression. Seasonal influenza vaccine is safe and effective, and no conclusive evidence exists for a link between vaccination and allograft dysfunction. For recommendations for prophylaxis or vaccination for transplant recipients who travel to countries where endemic infections such as malaria are present, refer to reference 2. Recommended immunizations before and after transplantation are listed in Table 105.1. Ensuring adequate response to hepatitis B vaccination is important to prevent transmission of donor-derived infection.

Infectious Causes

Both the type and occurrence of infections in the immunocompromised transplant recipient follow a "timetable pattern" (Box 105.1). However, the timing of infections may be altered by the intensity of immune suppression, use of target antibiotic prophylaxis, and patient exposures.

Risk Factors for Post-Transplant Infectious Complications

Risk factors for post-transplant infectious complications include active or latent infections in the donors, net state of immunosuppression, surgical instrumentation, wound, abdominal fluid collections, reactivation of latent infections, epidemiologic exposure, metabolic conditions (e.g., diabetes, uremia), infections with immunomodulating viruses, and hypogammaglobulinemia, among others. Severe hypogammaglobulinemia (immunoglobulin [Ig] G <400 mg/dl) during the first year post-transplantation is associated with a significant increase in the risk for cytomegalovirus (CMV) infection, fungal and respiratory infections, and 1-year all-cause mortality among recipients of solid organ transplantation.[3] Although prospective controlled trials are lacking, post-transplant monitoring of IgG levels and Ig replacement therapy to keep IgG level greater than 700 to 800 mg/dl may reduce infection rates in patients with hypogammaglobulinemia.

Donor-Derived Infections

Donor-derived infections include bacterial, fungal (*Candida* spp.), viral (HIV, hepatitis B and C [HBV and HCV], CMV), and parasitic infections (malaria, *Babesia* and *Balamuthia* infections, amebic meningitis). Allograft-transmitted infections with unusual viruses such as lymphocytic choriomeningitis virus, West Nile virus, and rabies also have been described. Despite routine surgical prophylaxis, transmission of resistant organisms, including methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE), and azole-resistant *Candida* spp. occurs with increased frequency. Donor-derived carbapenem-resistant *Klebsiella pneumoniae* (CRKP) infections are associated with high morbidity and mortality. Donation of organs that are directly involved in CRKP infection should be avoided (e.g., kidneys from donors with CRKP urinary tract infection [UTI], lungs from donors with CRKP airway infection or colonization).[4] All organ procurement organizations in the United States perform nucleic acid testing (NAT) to increase the likelihood of detecting HIV and hepatitis infections among donors at increased risk. If a donor is identified as being at increased risk for HIV, HBV, and HCV transmission according to the U.S. Public Health Service Guidelines, recipients of such kidneys should undergo protocol surveillance, including HIV RNA by NAT (or HIV Ab/Ag combination assays), HBsAg (or quantitative HBV DNA), and quantitative HCV RNA pre-transplant and at 6 weeks post-transplant. Repeat testing for HBsAg (or HBV by NAT), anti-HBsAb, and anti-HBcAb should be performed at 12 months after transplant.

TABLE 105.1 Recommended Immunizations Before and After Transplantation

Vaccine	Before TX	After TX (≥3 Months Post-Tx)	Comments (Vaccinations <3 Months Post-Transplant May Result in Suboptimal Response and Protection)
Measles-mumps-rubella	Y	Contraindicated	
Diphtheria-tetanus-pertussis	Y	See comments	Diphtheria and tetanus: Booster every 10 years.
Varicella-live	Y	Contraindicated	Should be administered ≥4 weeks before transplant.
Poliovirus	Y	Inactivated polio	For travelers to endemic areas (e.g., some parts of Asia, Africa).
Haemophilus influenzae type b	Y	Y	
Inactivated influenza vaccine Influenza A and B	Y	Y	Annually All patients who are >3 months post-transplant should receive seasonal influenza vaccine. May be administered in the immediate post-transplant period during an outbreak.
Live-attenuated influenza (nasal spray flu vaccine)	Contraindicated	Contraindicated	
Pneumococcal conjugate PCV13	Y	Y	For those who have not received either *Pneumococcus* vaccine, PCV13 should be administered first, followed 8 weeks later by PPSV23. Patients who have already received 1 dose of PPSV23 should receive PCV13 at least 1 year after PPSV23.
Pneumococcal polysaccharide PPSV23	Y	Y	Recommended post-transplant if not administered pretransplant. Patients who have already received 1 dose of PPSV23 should receive an additional dose 5 years after the first dose of PPSV23.
Hepatitis A	Y	Y	Recommended post-transplant if not administered pretransplant. For travelers to endemic areas.
Hepatitis B	Y	Y	Recommended post-transplant if not administered pretransplant. Monitor titers for response to vaccination and repeat vaccination series if needed.
Human papillomavirus (HPV)	Y	—	Nonpregnant female candidates ages 11-26, males ages 11-21.
Neisseria meningitides	Y	Y	Recommended for patients with properdin terminal component deficiencies or receiving eculizumab therapy, or those with functional or anatomic asplenia. *Others:* Military members, travelers to high-risk areas, college freshman living on campus.
Zoster-live (Zostavax)	Y	Contraindicated	Should be administered ≥4 weeks before transplant.*

*If inadvertently given within 4 weeks before transplant, consult infectious disease specialist and administer acyclovir to prevent reactivation of vaccine-strain virus.
TX, Transplant; *Y,* yes.

Month 1 After Transplantation

In the first month after transplantation, donor- and recipient-derived infections with common nosocomial bacterial microorganisms and *Candida* spp. predominate. Infections caused by multidrug-resistant bacteria are center specific. Despite the advent of potent broad-spectrum antimicrobial agents, infections caused by multidrug-resistant bacteria, including gram-positive bacteria (MRSA, VRE), extended-spectrum β-lactamases, and gram-negative bacilli and multidrug-resistant nonfermentative gram-negative bacilli, including CRKP, continue to be important causes of morbidity and mortality.

Most bacterial infections during this period involve wounds, catheters, and drainage sites. Aspiration pneumonia and UTIs are common. Most UTIs are caused by gram-negative bacteria (*Escherichia coli,* Enterobacteriaceae, *Pseudomonas*) and gram-positive bacteria *(Enterococcus).* Preventive measures for UTIs include early urethral catheter removal and antibiotic prophylaxis. Trimethoprim-sulfamethoxazole (TMP-SMX) prophylaxis (or ciprofloxacin for patients with sulfa allergies) during the first 3 to 6 months after transplantation may reduce the risk for UTIs and eliminate urosepsis unless anatomic or functional derangement of the urinary tract is present. In a series of 20 kidney transplant recipients with CRKP, antimicrobial prophylactic therapy with agents other than TMP-SMX was found to be a risk factor for the development of CRKP bacteriuria.[5] Strict aseptic surgical techniques and perioperative use of first-generation cephalosporins reduce the incidence of wound infections. Except for herpes simplex virus (HSV), viral infections are uncommon during this period.

Months 1 to 6

During months 1 to 6, unconventional or opportunistic infections secondary to immunosuppression are most common. Viral infections such as CMV, HSV, varicella-zoster virus (VZV), Epstein-Barr virus, HBV, and HCV may occur from exogenous infection or reactivation of latent disease. Reactivation or de novo HCV infection is an important cause of morbidity and mortality after transplantation because of the historical lack of effective treatments and the risk for precipitating acute allograft rejection with interferon therapy. The advent of the interferon-free, protease inhibitor–based regimen (e.g., sofosbuvir/ledipasvir) may improve outcomes in HCV-positive kidney transplant recipients. Repeated courses of antibiotics and corticosteroid therapy increase the risk for fungal infections, whereas viral infections not only may result from immunosuppression but may further impair immunity and increase the risk for additional opportunistic infections. TMP-SMX prophylaxis eliminates or reduces the incidence of *Pneumocystis* infection, *Listeria monocytogenes* meningitis, *Nocardia* spp. infection, and *Toxoplasma*

BOX 105.1 Timetable of Infections

FIRST MONTH AFTER TRANSPLANT

Common nosocomial bacterial pathogens and *Candida* spp. predominate.

Bacterial (Sites and Sources)

Urinary tract
Respiratory
Bacteremia
Surgical wound or intraabdominal sources (lymphoceles, hematomas, urine leak)
Vascular access or instrumentation (catheters, drains, urinary stents)
Anatomic or functional genitourinary tract abnormalities (ureteral stricture, vesicoureteric reflux, neurogenic bladder)
Clostridium difficile or center-specific multidrug-resistant species

Viral

Uncommon except for HSV

Fungal

Candida spp. predominate (recipient pretransplant colonization or donor-derived)

Organisms Transmitted with Donor Organs

MONTHS 1 to 6

Unconventional or opportunistic infections secondary to immunosuppression.

Viral

CMV, HSV, VZV, EBV, HBV, HCV, BK virus (exogenous infection or reactivation of latent disease as a result of immunosuppression)
Others: HHV-6, HHV-7, influenza, parainfluenza, RSV, adenovirus

Fungal

Aspergillus spp., *Cryptococcus,* agents of mucormycosis

Bacterial

Recurrent urinary tract infections or pyelonephritis
Nocardia, Listeria, Mycobacterium spp. (tuberculous and nontuberculous), *Legionella*

Parasitic

Pneumocystis jiroveci, Toxoplasma and *Strongyloides* spp., leishmaniasis, *Trypanosoma cruzi*

AFTER 6 MONTHS

Infection risks associated with duration and intensity of immunosuppression and epidemiologic exposures.

Stable Patients on Low-Dose Immunosuppressants

Community-acquired respiratory and GI viral pathogens

History of Multiple Rejection Episodes Requiring Intensification of Immunosuppression

Viral infections (invasive CMV such as CMV colitis or pneumonitis, VZV, parvovirus B19), late opportunistic infections *(Pneumocystis, Cryptococcus, Listeria, nocardiosis),* tuberculosis

Persistent Infections

HBV, HCV,* papillomavirus, BK virus

Geographically Restricted

For example, coccidioidomycosis, histoplasmosis, blastomycosis, paracoccidioidomycosis)

Deep-Seated Infections

For example, osteomyelitis, paravertebral abscess
Predisposing risk factors: Chronic skin infections, long-standing poorly controlled diabetes, peripheral vascular disease

Associated With Malignancies

EBV (PTLD), papillomavirus (squamous cell carcinoma), HSV (cervical cancer), HHV-8 (Kaposi sarcoma)

*Incidence may decrease with the use of the newer interferon- and ribavirin-free anti-HCV protease inhibitor combination therapy.
CMV, Cytomegalovirus; *EBV,* Epstein-Barr virus; *HSV,* herpes simplex virus; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *HHV-6,* human herpesvirus-6; *HHV-7,* human herpes virus-7; *PTLD,* post-transplant lymphoproliferative disease; *RSV,* respiratory syncytial virus; *VZV,* varicella zoster virus.

gondii. Reactivation of latent infection such as *Mycobacterium tuberculosis, Trypanosoma cruzi, Leishmania* spp., *Strongyloides stercoralis, Cryptococcus neoformans, Histoplasma capsulatum,* and *Coccidioides* and *Paracoccidioides* spp. may be observed. Community-acquired respiratory viruses are a common hazard in these vulnerable immunocompromised patients during this period, whereas BK virus infection remains an important cause of allograft loss (discussed later).

After 6 Months

After 6 months, the infection risk is largely a function of chronic maintenance immunosuppression, exposure to T cell–depleting agents, graft function, and epidemiologic exposures. Patients can be arbitrarily divided into three categories in terms of infection risks.

The first category consists of most transplant recipients (70% to 80%), who have satisfactory or good allograft function, relatively low doses of immunosuppressants, and no history of chronic viral infection. The risk for infection is similar to that of the general population, with community-acquired respiratory viruses constituting the major infective agents. Opportunistic infections are unusual unless environmental exposure has occurred.

The second group (~10% of patients) consists of those with chronic viral infection that may include HBV, HCV, CMV, Epstein-Barr virus (EBV), BK virus (BKV), or papillomavirus. In the setting of immunosuppression, such viral infections may lead to the development of progressive liver disease or cirrhosis (HBV, HCV), BK nephropathy (BKV), post-transplant lymphoproliferative disorder (EBV), or squamous cell carcinoma (papillomavirus). Alemtuzumab (a humanized monoclonal antibody directed against CD52 found on T and B cells) is associated with increased risk for late invasive viral and fungal infections because of its profound and prolonged effect on pan–T cell depletion. New infections occurring in this time period often reflect new exposures (e.g., *L. monocytogenes* [dietary ingestion], Lyme disease [tick exposure], and malaria [travelers to endemic areas]).[1]

The third group (~10% of patients) consists of those who experience multiple rejection episodes requiring repeated exposure to heavy immunosuppression. These patients are the most likely to develop chronic viral infections and superinfection with opportunistic infections. Causative opportunistic pathogens include *Pneumocystis, Listeria, Nocardia, Cryptococcus,* and geographically restricted mycoses (coccidioidomycosis, histoplasmosis, blastomycosis, paracoccidioidomycosis). We advocate lifelong antifungal prophylaxis in high-risk transplant recipients such as those with a history of infection or who live in endemic areas. Environmental exposure (primarily avoidance of pigeons and areas of active building construction) should be minimized.

MANAGEMENT AND PROPHYLACTIC THERAPY FOR SELECTED INFECTIONS

Suggested prophylactic therapy in kidney transplant recipients is shown in Table 105.2.

Cytomegalovirus Infection

CMV infection may cause primary infection in a seronegative recipient (donor seropositive, recipient seronegative), reactivation of endogenous latent virus (donor seropositive or seronegative, recipient seropositive) or superinfection with a new virus in a seropositive recipient (donor seropositive, recipient seropositive). Primary CMV infection is usually more severe than reactivated infection or superinfection.

Clinical Manifestations

CMV infection may be asymptomatic, manifesting as a mononucleosis-like syndrome, an influenza-like illness with fever and leukopenia or thrombocytopenia, or a severe systemic disease. Any organ system may be affected by CMV. Clinically, patients may present with hepatitis, esophagitis, gastroenteritis, pneumonia, carditis, chorioretinitis, and even otitis. Clinical manifestations usually occur 1 to 4 months after transplantation except for chorioretinitis, which occurs later in the transplant course. Results of quantitative CMV assays of serum in patients with invasive colitis and gastritis or neurologic disease, including chorioretinitis, are often negative. Diagnosis in such patients may require invasive testing and biopsies.

TABLE 105.2 Post-Transplant Antimicrobial Prophylaxis

Prophylaxis	Regimen	Comments
Pneumocystis jiroveci	*First line:* TMP-SMX × 6 months* *Second line (sulfa allergies):* Atovaquone, dapsone, or aerosolized pentamidine†	TMP-SMX also reduces the incidence of *Toxoplasma gondii, Listeria monocytogenes,* and *Nocardia asteroides* and reduces the incidence of UTI in kidney transplant recipients. Check glucose-6-phosphate dehydrogenase before initiation of dapsone.
Fungal	Nystatin S&S (×1 months) or fluconazole (×3-6 months)‡ (see comments)	Fluconazole recommended in high-risk recipients (e.g., combined liver-kidney or pancreas-kidney transplant recipients, history of coccidioidomycosis, patients who live in endemic areas).
CMV	Acyclovir, valganciclovir, ganciclovir (see Box 105.2)	Acyclovir for HSV and VZV prophylaxis for patients not on CMV prophylaxis.

*Restart TMP-SMX prophylaxis ×6-12 mo after any solumedrol pulse or antibody treatment.
†Listed in order of preference. Consider adding fluoroquinolones or other agents for antibacterial activity.
‡We advocate lifelong therapy in patients with history of coccidioidomycosis or in those who live in endemic areas.
CMV, Cytomegalovirus; *HSV,* herpes simplex virus; *TMZ-SMX,* trimethoprim-sulfamethoxazole *VZV,* varicella zoster virus.

Immunomodulating Effects of Cytomegalovirus Infection

CMV infection is associated with immune modulation and dysregulation of helper and suppressor T cells. It may be a risk factor for acute and chronic allograft rejection, secondary infection with opportunistic agents (e.g., *Pneumocystis, Candida, Aspergillus*), and reactivation of human herpesvirus 6 (HHV-6) and HHV-7 and may favor development of post-transplant lymphoproliferative disorder. CMV infection is also associated with acceleration of HCV infection and the development of post-transplantation diabetes mellitus (also known as *new-onset diabetes after transplantation*, see Chapter 106). Detection of CMV virus in blood may indicate that the patient's cellular immune response is impaired secondary to immunosuppression.

Risk Factors for Cytomegalovirus Infection

Donor and recipient serostatus (donor CMV seropositive, recipient CMV seronegative) and the use of blood products from CMV-seropositive donors are well-established risk factors for CMV infection. Other risk factors include the use of antilymphocyte antibodies, prolonged or repeated courses of antilymphocyte preparations, comorbid illnesses, concomitant HHV-6 and HHV-7 viral infections, neutropenia, lack of CMV-specific $CD4^+$ and $CD8^+$ T cells, and acute rejection episodes. Mycophenolate mofetil (MMF) may increase the risk for CMV viremia and disease, especially in patients receiving more than 3 g/day. Although the cause-and-effect relationship of CMV infection and allograft rejection remains hypothetical, several studies suggest that one may increase the risk for the other, possibly because of the release of inflammatory cytokines. Prevention of CMV infection, for example, results in a lower incidence of graft rejection. In addition, even with modern regimens for screening and prophylaxis, asymptomatic CMV viremia and even donor seropositivity and recipient seronegativity (D +/R–) in the absence of detectable CMV viremia or disease is associated with increased incidence of graft rejection.[6]

Prevention

Prophylactic therapy begins in the immediate postoperative period. Preemptive therapy involves treatment of those who are found to seroconvert by quantitative laboratory assays of the blood, such as CMV DNA polymerase chain reaction (PCR) or pp65 antigenemia during surveillance studies. The former assay is highly specific and sensitive for the detection of CMV viremia. Currently, with the widespread availability of NAT, antigen-based methods have largely been replaced by CMV DNA testing. Universal prophylaxis for CMV is recommended over initiation of preemptive treatment after detection of CMV viremia or antigenemia for patients in the highest risk group (D +/R–). Oral acyclovir is necessary for HSV and VZV prophylaxis in patients not receiving anti-CMV prophylaxis or treatment. Oral or intravenous ganciclovir or oral valganciclovir provides superior prophylactic or preemptive therapy against primary CMV infection or CMV reactivation. The Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines suggest oral ganciclovir or valganciclovir in CMV D +/R– or D +/R+ for at least 3 months after transplantation and for 6 weeks after treatment with T cell–depleting antibodies. Seronegative individuals who receive organs from latently infected seropositive donors are at greatest risk for primary infection and severe CMV disease. Delayed-onset CMV disease developing soon after completion of antiviral prophylaxis occurs in 15% to 38% of high-risk CMV D +/R– solid organ transplant recipients who received 3-month CMV prophylaxis and is associated with poor patient and graft survival. Other suggested risk factors for delayed-onset CMV disease include allograft rejection, overimmunosuppression, and lack of CMV-specific immunity. A suggested CMV prophylaxis protocol is shown in Box 105.2.

BOX 105.2 Suggested Cytomegalovirus Prophylaxis Protocol*

For CMV (–) recipient of a CMV (–) organ
Acyclovir 400 mg twice daily (for herpes prophylaxis) × 3 months**
CMV DNA q2wk × 3 months

For CMV (–) recipient of a CMV (+) organ:
During antibody induction treatment: Ganciclovir 5 mg/kg/day IV**
After antibody treatment: Valganciclovir 900 mg/day PO × 6 months**
If no antibody treatment: Valganciclovir 900 mg/day PO × 6 months**
CMV DNA q2wk × 3 months, then monthly up to 12 months

For CMV (+) recipient of a CMV (–) organ:
During antibody induction treatment: Ganciclovir 5 mg/kg/day IV**
After antibody treatment: Valganciclovir 900 mg/day PO × 6 months**
If no antibody treatment†: Valganciclovir 900 mg/day PO × 3 months**
CMV DNA q2wk × 3 months, then monthly up to 12 months

For CMV (+) recipient of a CMV (+) organ:
During antibody induction treatment: Ganciclovir 5 mg/kg/day IV**
After antibody treatment: Valganciclovir 900 mg/day PO × 6 months**
If no antibody treatment†: Valganciclovir 900 mg/day PO × 3 months**
CMV DNA q2wk × 3 months, then monthly up to 12 months

*Practice may vary among centers. Acyclovir, valganciclovir, ganciclovir: ****Dose adjustment for renal function necessary**
†May use acyclovir or valganciclovir (center-dependent).

Treatment

The 2013 AST Infectious Diseases Community of Practice guidelines recommend oral valganciclovir 900 mg orally every 12 hours, adjusted according to glomerular filtration rate [GFR]) for mild to moderate CMV disease, whereas intravenous ganciclovir 5 mg/kg every 12 hours, adjusted according to GFR) should be the initial therapy for patients with severe or life-threatening CMV disease, those with high viral load, those with questionable gastrointestinal (GI) tract absorption, or those who are intolerant of oral medication. Treatment should be continued until the following criteria are met: (1) resolution of clinical symptoms; (2) virologic clearance below a threshold negative value based on laboratory monitoring with CMV, quantitative CMV nucleic acid test (QNAT), or pp65 antigenemia; and (3) minimum 2 weeks of antiviral therapy. Reduction of immunosuppression should be considered in moderate to severe disease, in slow responders or nonresponders, and in those with high viral loads or leukopenia. Antiviral drug dose reduction because of side effects should be performed only for renal insufficiency, because dose reductions for leukopenia have been shown to be associated with development of antiviral resistance. Reduction or withholding of mycophenolic acid (MFA) products, azathioprine (AZA), or TMP-SMX should be considered before valganciclovir or ganciclovir dose reduction. Severe leukopenia (absolute neutrophil count <500 to 1000/mm^3) can be treated with granulocyte colony-stimulating factor. The beneficial effect of adding intravenous immunoglobulin (IVIG) or CMV Ig to existing antiviral treatment regimens remains unclear but may be considered adjunctive therapy in individuals with hypogammaglobulinemia, in life-threatening disease, in nonresponders to standard therapy, or in those with severe forms of CMV disease, such as pneumonitis.

Laboratory monitoring for CMV by PCR assays should be performed weekly during treatment, and CMV DNA should be negative before discontinuation of treatment. Secondary prophylaxis with valganciclovir 900 mg/day for 1 to 3 months should be considered. Alternatively, patients should have close clinical and/or virologic follow-up after discontinuation of treatment to assess the risk for relapse. Measuring anti-CMV cell–mediated immunity (using QuantiFERON-CMV assay to measure the level of T cell interferon-γ (IFN-γ) production after CMV exposure) to assess the risk for CMV infection or disease and to guide therapeutic response is a subject of ongoing clinical research.

Mutation in the viral kinase *UL97* gene that prevents phosphorylation of ganciclovir to its active form confers ganciclovir-resistance. Cidofovir and foscarnet should be reserved for those with clinically suspected ganciclovir-resistant strains because of their associated nephrotoxicity and potential synergistic nephrotoxicity with calcineurin inhibitors (CNIs). Mutation in the *UL54* gene, which encodes for CMV DNA polymerase (a target for all currently available systemic anti-CMV drugs) could lead to cidofovir or foscarnet resistance or cross-resistance among ganciclovir, foscarnet, and cidofovir. Concomitant *UL97* and *UL54* mutations often confers high-level ganciclovir-resistance and warrants infectious disease specialist referral.

Candida Infections

Candida infections are common in transplant recipients; *Candida albicans* and *Candida tropicalis* account for 90% of the infections. Risk factors include diabetes, high-dose corticosteroids, broad-spectrum antibacterial therapy, indwelling urinary tract device, and, rarely, donor-derived candidiasis. Fluconazole has historically been considered the drug of choice for the prevention or treatment of donor-derived candidiasis. Other azoles (such as voriconazole or itraconazole) and the echinocandins do not effectively get into the urine as active drugs and should not be used.

Superficial candidal infections involving the mouth or intertriginous areas can be treated with nystatin and topical clotrimazole, whereas candidal UTIs require systemic antifungal therapy (see Chapter 53). Whenever possible, bladder catheters, surgical drains, and urinary stents should be removed. Management of asymptomatic candiduria in immunocompromised patients is discussed in Chapter 53. Systemic antifungal therapy is indicated in the presence of any blood culture positive for *Candida* spp.

BK Virus Infection

The clinical spectrum of BKV infections include BK viruria, BK viremia, BKVN, and, less commonly, ureteral stenosis. The highest prevalence of BK viruria and viremia occurs at 2 to 3 months, and 3 to 6 months, respectively. Serum BK viral load of at least 10,000 copies/ml has been suggested to be predictive of BKVN. However, PCR assays are not standardized and the sensitivity and specificity of the assays may vary.

BKV is an important cause of allograft dysfunction and graft loss and commonly manifests with an asymptomatic rise in serum creatinine during the first post-transplantation year. However, BKVN may occur as early as the first week and as late as 6 years after transplantation. Diagnosis is made by allograft biopsy that demonstrates BK viral inclusions in renal tubular cell nuclei and occasionally in glomerular parietal epithelium (Fig. 105.1). Interstitial mononuclear inflammation, often with many plasma cells, degenerative changes in tubules, and focal tubulitis, may mimic acute rejection. BKV infection and acute rejection may occur simultaneously, and distinguishing between BKVN and acute rejection or the presence of both can be a diagnostic challenge.

Treatment strategies for BK viremia with or without BKVN vary, but immunologic containment of BKV replication is universally accepted as the mainstay of therapy.[7] Suggested strategies for reduction in immunosuppression include reduction or discontinuation of antimetabolites (MFA) derivatives or AZA, or reduction of CNIs or corticosteroid therapy. In one study, routine BKV surveillance and immunosuppression reduction alone on detection of significant viremia (defined as ≥10,000 copies/ml) effectively resolved viremia, preserved renal function, and prevented clinical BKVN and graft loss.[8] The effectiveness of immunosuppression reduction alone was also demonstrated by others.[9,10]

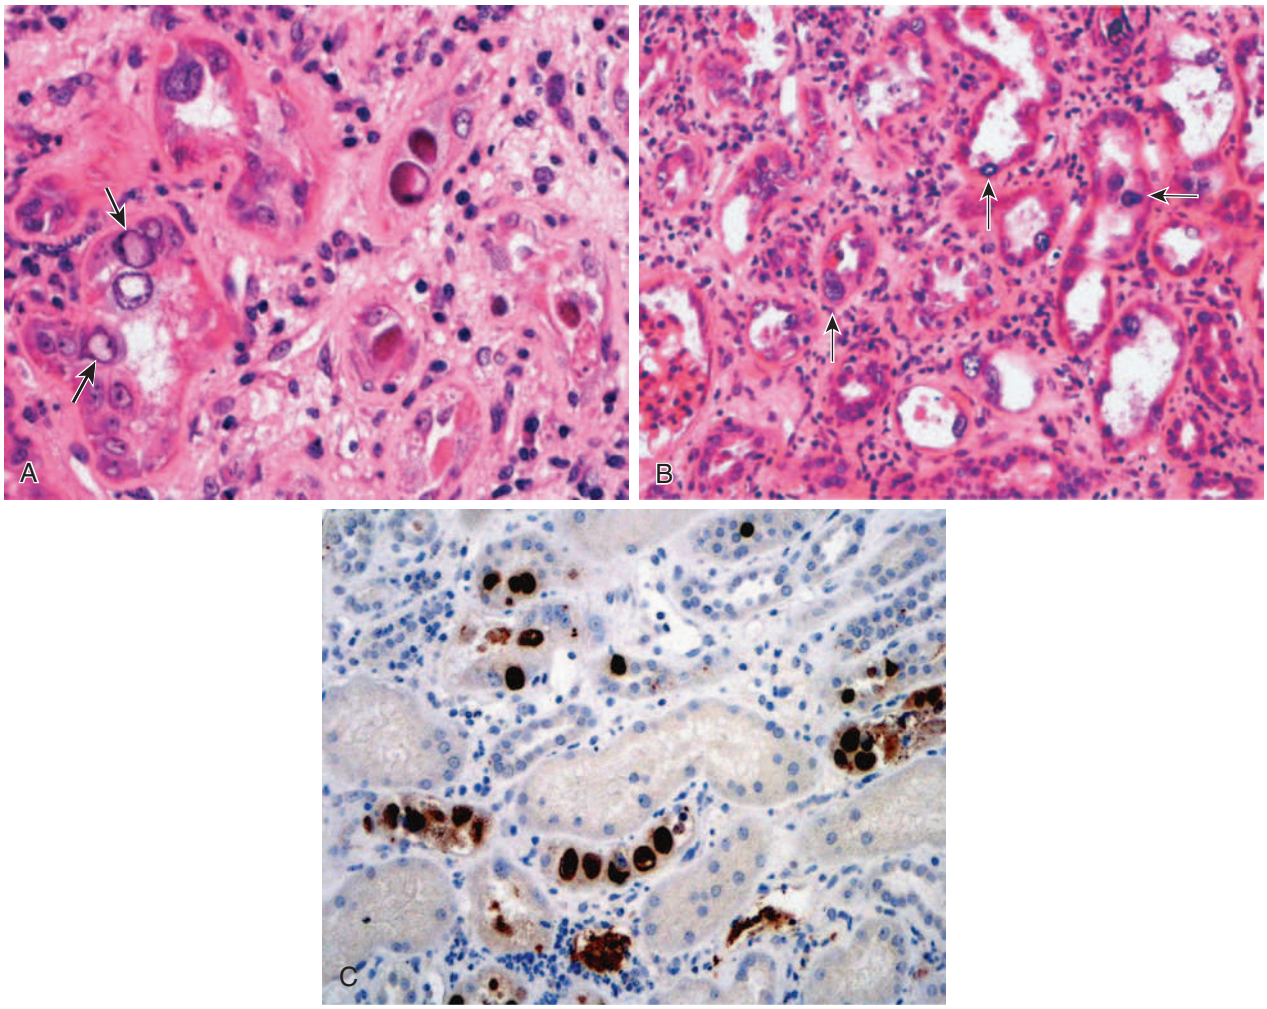

Fig. 105.1 BK virus nephropathy. (A) Prominent intranuclear viral inclusions are present within tubular epithelial cells *(arrows).* (Hematoxylin-eosin [HE] stain; original magnification ×400.) (B) Tubulointerstitial nephritis with diffuse intranuclear polyomavirus inclusions *(arrows).* (HE stain, original magnification ×200.) (C) Immunohistochemistry staining highlights intranuclear polyomavirus inclusions. (SV40 immunoperoxidase stain; original magnification ×200.) (Courtesy Charles Lassman and William Dean Wallace, David Geffen School of Medicine at UCLA, Los Angeles, California.)

Limited small case series demonstrated that tacrolimus to cyclosporine or sirolimus conversion therapy resulted in resolution of BKVN and viruria/viremia. Recent experimental studies demonstrated that sirolimus impairs BKV replication in renal tubular epithelial cells during viral early gene expression, but not during viral late gene expression by interfering with mammalian target of rapamycin (mTOR)-SP6-kinase activation. Cyclosporine was similarly shown to inhibit BKV replication, whereas tacrolimus activates BKV replication and reverses sirolimus inhibition, leading to increased BKV replication.[11] MMF to leflunomide or to sirolimus switch also has been suggested to be beneficial,[12] although this effect is probably linked more closely to discontinuation of MMF rather than direct antiviral effect of leflunomide therapy. In contrast to early studies, preliminary results of a single-center phase IV randomized trial evaluating the safety and efficacy of MMF to everolimus conversion versus 50% MMF dose reduction in the clearance rates of BK viruria and/or viremia at 3-months postrandomization showed no statistical significant differences in either primary or secondary end-point between the two treatment arms. The former was defined as a greater than 50% reduction of BK viruria and/or clearance of viremia at 3-months postrandomization and the latter as the percentage reduction in BK viremia at 3 months (www.clinicaltrials.gov, NCT01624948).

In BKV-associated disease refractory to immunosuppression reduction alone, the use of antiviral agents such as cidofovir, leflunomide, and fluoroquinolones has met with variable results and cannot be recommended (see Table 105.3).[7] There are only case series–level data regarding impact of IVIG. However, IVIG therapy may be considered for persistent BK viremia because it may have the added beneficial impact on limiting the negative effect of donor-specific antibodies, which may be seen arising in association with BK viremia.

In a small series of three pediatric kidney transplant recipients with biopsy-confirmed BKVN, ciprofloxacin to leflunomide conversion (if BK viremia did not decrease after 2 months of ciprofloxacin) and concomitant discontinuation of MMF resulted in complete resolution of BKVN.[13] In contrast, a meta-analysis of eight studies (two randomized controlled trials and six retrospective cohort studies) failed to show a beneficial effect of fluoroquinolone prophylaxis (for >1 month) in preventing BK viremia or BKVN at 1-year follow-up.[14]

Although small open-label case series demonstrated the possible beneficial effects of leflunomide, systematic review of 40 studies showed

TABLE 105.3 Therapeutic Interventions Targeting BK Virus Replication

Intervention	Proposed Mechanisms of Action	Adverse Effects	Eeefectiveness Comments
A. Manipulation of Immunosuppressive Therapy			
Reduction in immunosuppression	Reconstitution of BKV-specific immune response.	Acute/chronic rejection	Effective. Mainstay of therapy.
Tacrolimus to cyclosporine (CSA) switch	Experimental studies demonstrated that CSA may exert an antiviral effect on BKV via suppression of viral replication, whereas tacrolimus may activate BKV replication.		Cannot be recommended Further studies are needed.
Calcineurin inhibitor to mTOR inhibitor switch*	mTOR inhibitors inhibit phosphorylation of the 70-kDa ribosomal protein S6 kinase and reduce BK virus large T antigen expression. May promote differentiation of antiviral memory CD8 T-lymphocytes.		Effectiveness varies among studies. May have the added benefit of avoiding the long-term nephrotoxic effect of CNI therapy. [1] *"NCT01649609" clinical trial:* Substitution of tacrolimus for sirolimus vs. immunosuppression reduction for the treatment of BK viremia and prevention of BKVN (study completed. Results pending at the time of this writing).
Mycophenolate mofetil to mTOR inhibitor switch			[2] *Phase 4 clinical trial results:* MMF to everolimus switch *vs.* 50% MMF dose reduction in the clearance rates of viruria and/or viremia at 3 mo postrandomization shows no statistically significant differences in either first or second end-point between the two treatment arms (the former was defined as >50% reduction of BK viruria and/or clearance of viremia at 3-mo postrandomization and the latter as percent reduction in BK viremia at 3 mo). There was a nonstatistically significant trend toward improved clearance with everolimus conversion at 1 year
B. Antiviral Agents			May consider adjunctive antiviral agents in BKV-associated disease refractory to reduction or manipulation of immunosuppression although benefit is unclear.
Leflunomide	Tyrosine kinase inhibitor Inhibits BKV genome replication and early gene expression.	Anemia, hemolytic anemia, thrombocytopenia, thrombotic microangiopathy, transaminitis	Effectiveness varies among studies. [3] *Ongoing clinical trial (expected completion date March 2018):* Leflunomide in combination with orotic acid vs. standard of care in patients with high levels of BK viuria and absence of BK viremia.
Cidofovir	Inhibits BK viral replication by an unknown mechanism.	Potentially nephrotoxic Severe uveitis	Effectiveness varies among studies.
Fluoroquinolones	Inhibit BK DNA topoisomerase and SV40 large tumor antigen helicase.		No beneficial effect either as a prophylactic or therapeutic agent based on recent clinical data and two randomized trials. Authors' opinion: Not recommended
Intravenous immunoglobulins (IVIG)	BKV neutralizing antibodies. *Others:* Steric hindrance to receptor binding, complement-dependent cytotoxicity, viral agglutination, and antibody facilitated phagocytosis.		Effectiveness varies among studies. IVIG may be beneficial in patients with concomitant rejection and BKVN or in those with histopathologic changes that are indistinguishable from those of rejection.
C. Antiviremic and Antifibrotic Combination Therapy			
Leflunomide and sirolimus combination therapy			*Ongoing clinical trial (expected completion date 31/3/18):* The BK: KIDNI Trial (Standard immunosuppression reduction alone vs. replacement of antimetabolite with leflunomide and sirolimus in patients with BK viremia).

*Ongoing clinical trial www.clinicaltrials.gov NCT01289301. CNI to everolimus switch in kidney transplant recipients with biopsy-confirmed BKN (expected completion date: October 2018).
www.clinicaltrials.gov [1]NCT01649609, [2]NCT01624948, [3]NCT1620268.
BKVN, BK nephropathy; *CNI,* calcineurin inhibitor; *IVIG,* Intravenous immunoglobulins; *MMF,* mycophenolate mofetil.

no graft survival benefit of adding cidofovir or leflunomide to immunosuppressive reduction for the management of BKVN.[15] Whereas some studies demonstrated that therapeutic response to leflunomide generally correlates with blood levels between 40 and 100 mcg/mL,[16] other studies have not observed a similar association.[17] One single-center study demonstrated that simultaneous administration of three different anti-BKV agents (leflunomide, IVIG, ciprofloxacin) added no benefit to long-term outcome in patients with BKVN (follow-up 7.3 ± 4.99 years). In contrast, graft survival was significantly improved among those treated conventionally with immunosuppression reduction.[18]

Although reduction in immunosuppression is the mainstay of therapy in BK viremia/BKVN, it is not universally effective, suggesting that the balance between viral replication and virus-specific immune surveillance determines the clinical course of BKV-associated clinical syndromes. In recent years, BKV-specific T cell immunity has increasingly been recognized to play an important role in the containment of BKV infection.[19,20] In a series of 10 patients with BKVN, a strong cytotoxic T-lymphocyte response was associated with decreased BK viruria or viremia and low anti-BK antibody viral titers, whereas a low or undetectable cytotoxic T-lymphocyte response correlated with viral persistence and high anti-BK antibody titers.[19]

In the absence of conclusive evidence that any particular immunosuppressive agent has a specific advantage in terms of the risk for BKV replication, and the unclear benefit of antiviral agents, intensive monitoring of serum BKV using PCR in all kidney transplant recipients and immunologic containment of BKV replication should remain the mainstay of therapy in BKV-associated clinical syndromes.[7] Monitoring for plasma BKV alone appears to be cost-effective because BKVN is unusual in the absence of BK viremia. A proactive, preemptive approach often leads to resolution of viruria and/or viremia and halts the progression of BK viremia to BKVN. The 2009 Kidney Disease: Improving Global Outcomes (KDIGO) clinical practice guidelines recommend reduction in immunosuppression when BKV plasma NAT results are persistently greater than 10^4 copies/ml. However, in the authors' opinion, steadily rising plasma BKV DNA copies on serial measurements irrespective of BK copy levels warrants judicious immunosuppression reduction because early intervention prevents progression to BKVN. Patients with biopsy-proven BKVN and concurrent acute rejection should be treated with antirejection treatment, with subsequent reduction in immunosuppression. In patients with sustained high-level BK viremia despite reduction or manipulation of immunosuppressive therapy, antiviral agents may be considered, although the effectiveness of currently available antiviral agents is of uncertain benefit. In nearly all case series reported, adjuvant antiviral agents were initiated in conjunction with immunosuppression reduction. Furthermore, although antiviral therapy may reduce viral load, viral clearance may require continuous immune control. Optimal reduction of immunosuppressive therapy may allow sufficient reconstitution of BKV-specific T cells to control BKV replication while maintaining adequate immunosuppression to prevent allograft rejection. The routine recommendations of antiviral therapy or immunosuppression class switching in the prevention or treatment of BKV-related clinical syndromes await results of large prospective randomized trials. Therapeutic interventions targeting BK virus replication and suggested mechanisms of action of various antiviral agents are shown in Table 105.3.[7] Anecdotal reports suggested that IVIG may be effective in treating corticosteroid-resistant rejection. Its use may be beneficial in patients with concomitant BKVN and acute rejection (acute antibody-mediated or cellular rejection) or in those with histopathologic changes that are indistinguishable from those of rejection. Development of T cell or antibody-based vaccines against BKV is a subject of future research.[21] Suggested guidelines for post-transplant screening and monitoring for BKV replication are shown in Fig. 105.2.

Other Infections

Tuberculosis (TB) is an important cause of morbidity and mortality in solid organ transplantation with an estimated mortality rate of 20% to 30%. Over two thirds of reported cases of active TB in solid organ transplant recipients occur in the first post-transplant year (median 6 to 11 months). Although TB commonly results from inhalation of airborne bacilli, it more commonly emerges from the reactivation of dormant lesions in the setting of immunosuppressive therapy. Hence, all potential kidney transplant candidates should undergo a purified protein derivative (PPD) skin test or preferably the IFN-γ release assays before transplantation to diagnose latent TB. A positive skin test or IFN-γ release assay result or a history of TB mandates further evaluation to rule out active disease. Isoniazid (INH) prophylaxis for a total of 9 months is recommended for those who have a positive skin test or IFN-γ release assay result. Clinical, radiologic, or culture evidence of active TB infection is a contraindication to transplantation. INH prophylactic therapy should be considered in the following situations:

- Transplant candidates with a history of positive tuberculin skin test or IFN-γ release assay result
- Those with TB disease without adequate treatment
- Patients with evidence of old granulomatous disease on chest x-ray film and epidemiologic risk factors for TB
- Those with known prolonged exposure to a person with active TB
- Kidney transplant recipients in endemic areas
- Donor with positive tuberculin skin test or IFN-γ release assay result
- In highly endemic areas where TB transmission is common, universal INH prophylaxis for the first year post-transplant during the period of maximum immunosuppression is recommended by some transplant experts. However, in areas or countries where there is an increased prevalence of INH-resistance strain, such as in India, close monitoring and treatment of active infection is recommended over initiation of INH prophylaxis.
- In patients with a known history of adequately treated TB infection, we suggest secondary INH prophylaxis the first 9 months after transplantation in patients with a history of extensive disease such as positive blood cultures, visceral involvement, or recent treatment history (arbitrarily defined as <10 years before transplant). Others, however, have suggested that INH prophylaxis is not indicated for patients whose TB had been properly treated.

Strongyloides is a rare but important cause of infection in transplant patients, particularly those from endemic areas such as Southeast Asia. In the presence of immunosuppression, a "hyperinfection" syndrome may be observed with parasitic pneumonia and GI involvement.

GASTROINTESTINAL DISEASE

Post-transplantation GI complications are common. Selected complications are discussed.

Drug-Related Gastrointestinal Complications

MMF causes GI side effects, including nausea, vomiting, dyspepsia, anorexia, flatulence, and diarrhea. Dose reduction, temporary drug discontinuation, or administration of the drug in three or four divided doses often ameliorate the symptoms. A randomized, multicenter, open-label study demonstrated that switching from MMF to enteric-coated mycophenolate sodium (EC-MPS) may enable an increase in the maximum tolerated dose of MFA and reduce GI complications. Therefore conversion of MMF to EC-MPS should be considered in patients with GI intolerance associated with MMF use.

Proton pump inhibitor (PPI) use can reduce the dissolution of MMF by increasing gastric pH. In contrast to MMF, EC-MPS is not

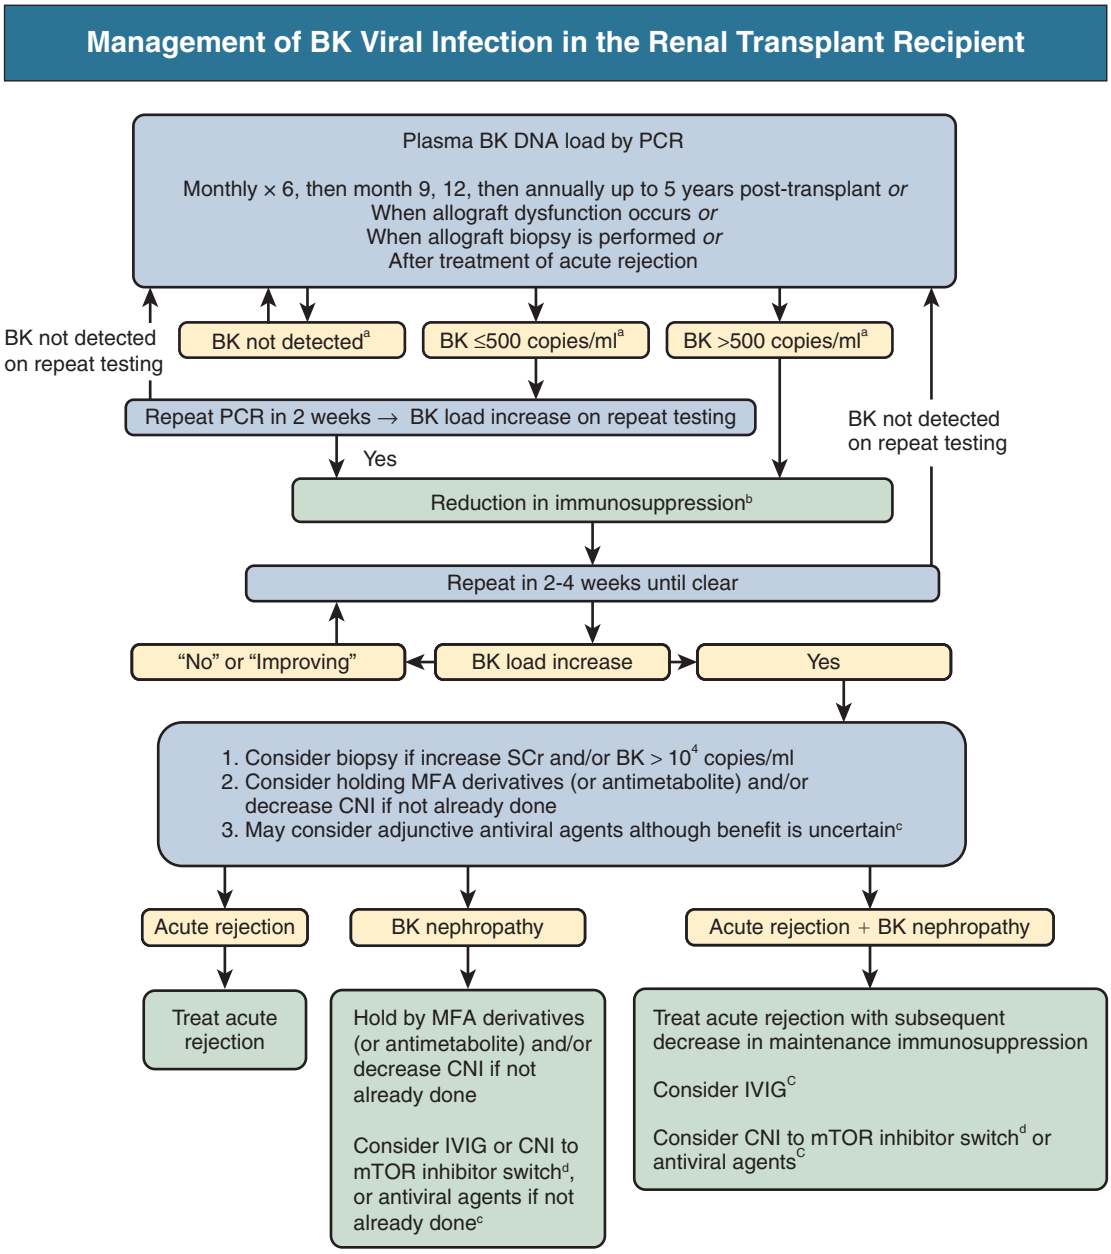

Fig. 105.2 Suggested approach for screening and management of *BK* virus (BKV)-associated clinical syndromes. [a]No standardized polymer chain reaction *(PCR)* assays for BKV are currently available. Cut-off levels for viral detection should be based on PCR assays used at individual institutions. Viral load of 500 copied/ml is the lowest detection level at the author's institution. [b]Common practice: (1) Decrease or hold mycophenolic acid *(MFA)* derivatives (or antimetabolite) (2) Decrease (MFA + calcineurin inhibitor *[CNI]*) by 25% to 50%. (3) Decrease CNI. Less common practice: (1) Decrease prednisone ± decrease CNI (2) CNI to mTOR inhibitor switch ± decrease MFA. (3) Tacrolimus to cyclosporine switch. [c]See text and Table 105.3 (ongoing clinical trials). [d]Evidence-based recommendations are lacking (ongoing clinical trials). May avoid long-term nephrotoxic effect of CNI therapy. Not recommended in patients with baseline significant proteinuria (arbitrarily defined as >500 mg/24 h or at the discretion of the clinician). *IVIG,* Intravenous immunoglobulin; *MFA,* mycophenolate acid; *mTOR,* mammalian target of rapamycin; *SCr,* serum creatinine.

absorbed in the stomach and its bioavailability is not affected by PPIs. The latter formulation delays the release of MFA. Sirolimus may cause oral mucocutaneous lesions that may resemble HSV or CMV infection but are culture negative. Drug-related oral ulcers usually resolve after discontinuation of the offending agent. Sirolimus, everolimus, tacrolimus, and cyclosporine may cause diarrhea in some patients.

Infections

Post-transplantation infections of the GI tract may have a viral, fungal, or bacterial cause. Viral infections are most commonly caused by CMV and HSV; *C. albicans* and *C. tropicalis* are common opportunistic fungal infections. Leukoplakia and post-transplant lymphoproliferative disorders (PTLDs) may develop in patients with EBV infection (PTLD is discussed

in a later section). Commonly encountered bacterial pathogens include *Clostridium difficile* and *Helicobacter pylori.*

Cytomegalovirus Infection

CMV can affect any segment of the GI tract. Patients may present with dysphagia, odynophagia, nausea, vomiting, gastroparesis, abdominal pain, diarrhea, or GI bleeding. Leukopenia and elevated transaminases are common. Persistent or unexplained symptoms of nausea, vomiting, or diarrhea, particularly in the early post-transplantation period or during intensification of immunosuppression, warrant further investigation with upper and lower endoscopies and biopsies. At the authors' institution, severe CMV and candidial gastritis/esophagitis were found in a patient who was heavily immunosuppressed with antithymocyte globulin and presented with intractable vomiting 4 months after transplantation. Histologic examination of the tissue obtained from the vomitus was compatible with foveolar gastric lining detachment (Fig. 105.3).

Herpes Simplex Virus Infection

HSV infection results primarily from reactivation of endogenous latent virus, causing clinical infection within the first 1 to 2 months after transplantation. Patients commonly present with oral mucocutaneous lesions or gingivostomatitis with or without odynophagia and dysphagia. HSV esophagitis has been noted to occur in patients receiving high-dose corticosteroids and antilymphocyte preparations for acute rejection. Limited oral mucocutaneous lesions are treated with oral acyclovir; extensive infections require intravenous acyclovir or ganciclovir. The routine use of acyclovir prophylaxis is recommended in the early post-transplantation period (see Box 105.2).

Fungal Infections

Candida stomatitis and esophagitis are common during the first 6 months after transplantation and are increased in patients with leukopenia, severe immunosuppression, diabetes, or concomitant infections. The use of prophylactic oral nystatin "swish and swallow" during the first month after transplantation is recommended. Fluconazole prophylaxis is warranted in high-risk candidates, including liver or pancreas transplant recipients and those receiving antilymphocyte antibody therapy.

Fig. 105.3 Tissue obtained from patient's vomitus. Histologic examination of the necrotic tissue showed numerous fungal organisms (consistent with *Candida* spp.), and degenerated squamous epithelium with detached columnar (gastric foveolar type) epithelium. Occasional cells demonstrated enlarged nuclei and intracytoplasmic granular eosinophilic inclusions, consistent with cytomegalovirus viral inclusions.

Helicobacter Infection

H. pylori infection is associated with a wide range of GI complications including chronic gastritis, duodenal and gastric ulcers, mucosa-associated lymphatic tissue (MALT) lymphoma, and gastric carcinoma, both in the general population and in solid organ transplant recipients. Unexplained dyspeptic or reflux symptoms should be investigated further with endoscopy and biopsy to exclude malignancy. *H. pylori*–associated MALT lymphoma in kidney transplant recipients may be less aggressive than other lymphomas, and the disorder may be cured by eradication of *H. pylori.*

Diarrhea and Colon Disorders

Diarrhea is common after solid organ transplantation because of adverse drug effects (discussed in earlier section) and infectious pathogens. *C. difficile* is the most commonly encountered bacterial pathogen, and CMV is the most commonly encountered viral pathogen. In recent years, norovirus is increasingly recognized as a cause of diarrhea after solid organ transplantation. Although norovirus often causes acute self-limited illness in immunocompetent individuals, it can cause both acute and chronic diarrhea in solid organ transplant recipients. Management is supportive and includes volume repletion, antimotility agents, and reduction in immunosuppression (inconclusive evidence). Anecdotal case reports suggest that nitazoxamide is effective in treatment of norovirus-associated diarrhea. In a series of three orthotopic heart transplant recipients treated with nitazoxanide, diarrhea resolved in two of three patients.[22] However, in both cases treatment was initiated in conjunction with reduction in immunosuppression.

Diverticulitis and colonic perforations may be life-threatening and difficult to diagnose after transplantation because symptoms may be masked by immunosuppressive therapy, particularly in the early post-operative period. Diverticulitis complicated by perforation, abscess formation, phlegmon, or fistula has been reported in 1% of kidney transplant recipients, and its incidence may be increased in patients with polycystic kidney disease. Early post-transplantation colonic perforations are largely caused by high-dose corticosteroids, diverticulitis, CMV colitis, and intestinal ischemia; perforations occurring late or years after transplantation are commonly caused by diverticulosis or malignant disease.

TRANSPLANT-ASSOCIATED MALIGNANCY

The overall incidence of de novo malignancies is twofold to fourfold greater in solid organ transplant recipients compared with the general population.[23] Among long-term survivors after kidney transplantation (>20 years), cancer was the most common cause of death with a functioning graft followed by CV disease.[24] The intensity and duration of immunosuppression as well as the ability of these agents to promote replication of various oncogenic viruses are important risk factors. Table 105.4 provides a summary of the incidence of cancers related to infections in solid organ transplant recipients.[25]

Skin cancers are the most common de novo post-transplant tumors in the adult transplant population and occur with increasing frequency with time. Among nonskin malignant neoplasms, PTLDs are the most common type of post-transplantation malignancy. The mean time to diagnosis of different neoplasms varies with the type of organ involved. Kaposi sarcoma, PTLD, testicular cancer, cancer of the small intestine, and thyroid cancer occur early after transplantation (<800 days after transplantation). By 20 years after kidney transplant, nearly 50% have one or more skin cancers and 10% to 27% have nonskin cancers.[23] Renal cell carcinoma (RCC) occurs mainly in native kidneys and is associated with acquired cystic kidney disease and dialysis duration. A bimodal distribution is observed with the highest incidence occurring

TABLE 105.4 Meta-Analysis Standardized Incidence Ratios for Cancers Related to Infections in Transplant Recipients

Cancers	Meta-analysis SIRs
EBV-Related Cancers	
Hodgkin lymphoma	3.89 (2.42-6.26)
Non-Hodgkin lymphoma	8.07 (6.40-10.2)
HHV-8–Related Cancer	
Kaposi sarcoma	208.0 (114-369)
HBV- and HCV-Related Cancer	
Liver	2.13 (1.16-3.91)
HPV-Related Cancers	
Cervix uteri	2.13 (1.37-3.30)
Vulva and vagina	22.8 (15.8-32.7)
Penis	5.8 (5.79-34.4)
Anus	4.85 (1.36-17.3)
Oral cavity and pharynx	3.23 (2.40-4.35)
Nonmelanocytic-related skin	28.6 (9.39-87.2)

in the first year and a second peak 4 to 15 years after transplant.[26] RCC occurring early after transplant is thought to reflect undetected or malignant transformation of preexisting cysts that developed during the course of end-stage renal disease. Common cancers in the general population, including cancers of the breast, colon, prostate, lung, bladder, stomach, and pancreas, were found to occur more frequently in kidney transplant recipients in some but not all studies. The KDOQI guidelines suggest an individualized screening plan for each kidney transplant recipient, considering the patient's medical and family history, tobacco use, and competing risk for death. In patients with compensated cirrhosis, annual hepatic ultrasound and measurement of α-fetoprotein level is recommended. Screening for cervical, breast, prostate, and colon cancer should follow local guidelines for the general population. In recipients with a history of preexisting malignant neoplasms, close monitoring for recurrences is mandatory. Suggested guidelines for tumor-free waiting periods for common pretransplant malignant neoplasms are shown in Box 105.3.

Post-Transplant Lymphoproliferative Disorder

PTLD encompasses a wide spectrum of lymphoid proliferations ranging from reactive polyclonal lesions to frank malignant monoclonal lymphomas. The World Health Organization (WHO) classification of PTLD is shown in Box 105.4. Most PTLDs are non-Hodgkin lymphoma of B cell origin, 80% to 90% of which are linked to EBV infection. However, the incidence of EBV-negative PTLD has increasingly been reported.

PTLD commonly occurs in the first year after transplant, although the cumulative incidence increases with time after transplantation. Registry studies and the United Network for Organ Sharing/Organ Procurement and Transplantation (UNOS/OPTN) database demonstrated that PTLD occurred at a median of 18 to 18.5 months after transplantation. Notably, EBV-negative PTLD generally manifests later after transplant (>5 years) and has been suggested to account for the bimodal distribution pattern of PTLD occurrence, with early cases being

BOX 105.3 Malignancy and Kidney Transplantation[1]

Most tumors: Wait time ≥2 years
No waiting time if cure at the time of transplantation
Incidental renal cell carcinoma
In situ carcinoma of bladder
In situ carcinoma of cervix
Basal cell carcinoma
Squamous cell carcinoma (skin) [2,3]
Waiting time ≥2-5 years[2]
Melanoma[2,4] 5 y
Wilms tumor 2 y
Renal cell carcinoma
  2 y if <5 cm
  5 y if >5 cm
Breast carcinoma[5] 2-5 y
Lymphoma 2-5 y
Colorectal carcinoma 2-5 y
Invasive bladder 2 y
Uterine body 2 y
Invasive cervical carcinoma 2-5 y

[1]Certain cancers may recur despite a tumor-free waiting period.
[2]Oncology evaluation or consultation with the Israel Penn International Transplant Tumor Registry at www.ipittr.org may be invaluable.
[3]Surveillance.
[4]In situ melanoma may require a shorter waiting period of 2 years (dermatology consultation is probably warranted).
[5]Early in situ (e.g., ductal carcinoma in situ) may require only 2-year wait. Individuals with advanced breast cancer (stage III or IV) should be advised against transplantation.

BOX 105.4 World Health Organization Classification of Post-Transplant Lymphoproliferative Disorder

1. **Early lesions**
   Plasmacytic hyperplasia
   Infectious mononucleosis
   Florid follicular hyperplasia
2. **Polymorphic PTLD**
3. **Monomorphic PTLD**
   B Cell Neoplasms
   Diffuse large B cell lymphoma

4. Classic Hodgkin lymphoma-type PTLD

NOS, Not otherwise specified; *PTLD,* post-transplant lymphoproliferative disorder.

predominantly EBV positive and late cases being EBV negative.[23,27] A French PTLD registry study suggests that late-occurring PTLD (8 to 10 years) is less likely to be due to EBV lymphoproliferation and more likely to be a consequence of aging and duration of immunosuppression exposure.[28]

Risk Factors

Risk factors for PTLD can be classified into those associated with the type of organ transplant, recipient age, type and intensity of immunosuppression, infectious agents, and human leukocyte antigen (HLA) mismatch.

Type of organ transplant. PTLD occurs in 1% to 2% of patients after kidney transplantation; 1% to 4% after liver transplantation; 2% to 3% after pancreas or simultaneous kidney-pancreas transplantation; 2% to 10% after heart, lung, and heart-lung transplantation; and up to 33% after small bowel and multivisceral transplantation. The high incidence of PTLD in bowel and multiorgan transplants has been attributed to the use of more intensive immunosuppression and the amount of donor-derived lymphoid tissue transferred at organ transplantation.

Age. PTLD is the most common malignancy in children, whereas in adults it is the second most common malignancy after skin cancer. The higher incidence of PTLD in children compared with adults has been attributed to the pretransplant EBV-naïve status of children.

Type of immunosuppression

Calcineurin inhibitors. Cyclosporine and tacrolimus may enhance the development of EBV-associated PTLD by directly promoting survival of EBV-infected B cells, presumably via the inhibition of EBV-transformed cells from apoptosis. Although single-center retrospective studies demonstrated that tacrolimus increased the risk for PTLD by twofold to fivefold compared with cyclosporine,[29] tacrolimus use has not been consistently shown to be associated with increased PTLD risk compared with cyclosporine.[30]

mTOR inhibitors. Sirolimus has a strong antiproliferative effect on PTLD-derived B cell lines. Experimental studies suggest that mTOR inhibitors may be beneficial in reducing the incidence of PTLD in high-risk patients or as an alternative method of immunosuppression in patients with established PTLD. However, a higher incidence of PTLD associated with the use of sirolimus-containing regimens compared with no sirolimus has been described. The UNOS/OPTN database demonstrated that in EBV-negative recipients, mTOR inhibitor–tacrolimus combination therapy was associated with a 1.4-fold increased PTLD risk, compared with MMF-tacrolimus combination therapy.[31] Analysis of 719 patients with PTLD similarly demonstrated that de novo sirolimus was associated with a 1.2-fold increased risk for PTLD in EBV-negative kidney transplant recipients.[32] In contrast, in a case series of 13 kidney transplant recipients with PTLD, immunosuppression reduction in conjunction with initiation of sirolimus alone was effective in induction of remission in 4 patients after a median time of 12 weeks (all 4 patients presented with extranodal disease and had histologic and immunophenotyping evidence of diffuse large B cell lymphomas).[33] Studies evaluating the association of sirolimus and PTLD risk may have yielded conflicting results because of differences in methodologies and overall intensity of induction and maintenance immunosuppression among studies. Limited studies suggest that high-dose mTOR inhibitor maintenance therapy may carry an increased PTLD risk.[34]

Antimetabolites. The use of antimetabolites such as AZA and MMF has not been consistently shown to be associated with an increased risk for PTLD.

Induction agents. Whereas induction therapy with muromonab CD3/OKT3 (removed from U.S. market in 2010) or antithymocyte globulin may increase PTLD risk, the use of interleukin-2 (IL-2) receptor inhibitors (daclizumab and basiliximab) or anti-CD52 antibody (alemtuzumab) induction has not been reported to increase PTLD risk. Analysis of the UNOS/OPTN database demonstrated that thymoglobulin was associated with significantly increased PTLD risk, whereas alemtuzumab, basiliximab, and daclizumab trended toward a protective effect ($P = .06$). In this study, maintenance therapy with an mTOR inhibitor was unexpectedly found to be strongly associated with PTLD, in contrast to earlier reports suggesting its beneficial effect on PTLD because of its antiproliferative and antiangiogenic effects. Although both alemtuzumab and thymoglobulin are T cell–depletional agents, the former has been shown to have a more pronounced B cell–depleting effect. It is speculated that depletional induction is not an independent risk factor for PTLD, but rather that maintenance drug selection and the balance between B cell and T cell depletion may be more relevant determinants of PTLD risk. Nonetheless, aggressive PTLD attributed to alemtuzumab induction has been reported.[35] It is conceivable that the overall intensity of immunosuppression increases PTLD risk by decreasing host cytotoxic T cells directed against grafted EBV-infected B lymphocytes.

Belatacept. Belatacept is a non–antigen-specific biologic agent that blocks T cell costimulatory signals, hence preventing T cell activation. Phase III clinical trials suggest that its use in transplant recipients with pretransplant EBV seronegativity is associated with an increased risk for PTLD.[36] However, the 2014 Cochrane Database systematic review suggested that belatacept use at different dosages and in patients who were EBV seronegative or seropositive before transplant confers no additional risk compared with CNI immunosuppression.[37] Nonetheless, the black box warning for belatacept use in EBV-seronegative transplant candidates remains, and its use should be avoided in transplant recipients with pretransplant EBV-seronegative or unknown EBV status. Further studies are needed.

Viral infection

Epstein-Barr virus. During primary infection, EBV is incorporated into B lymphocytes and establishes lifelong latency. Immunocompetent hosts mount an antibody response and, more importantly, an EBV-specific cytotoxic T cell immune response. EBV-naïve transplant recipients lack both virus-specific antibodies to neutralize the virions released by infected donor-derived B cells and EBV-specific T cells to control the outgrowth of subsequently infected recipient B cells. Hence, an EBV-negative recipient with an EBV-positive donor is at greatest risk for developing PTLD.

Hepatitis C virus. Whereas HCV infection has been linked to increased risk for lymphoma among immunocompetent individuals, the association between HCV and PTLD after solid organ transplantation has not consistently been shown. A large transplant registry study failed to demonstrate the link between HCV and PTLD. However, the risk for PTLD was increased among 2.8% of patients with HCV who were reported not to have received immunosuppressive therapy. It is speculated that chronic antigenic stimulation of the intact immune system is necessary for the development of HCV-related lymphoproliferation.[38]

Miscellaneous. Other suggested risk factors for PTLD include history of CMV infection, fewer HLA matches, pretransplant malignancy, and infections with HHV-8 and simian virus 40.

Clinical Manifestations

PTLD may manifest with constitutional symptoms such as fevers, night sweats, malaise, and weight loss or with localized symptoms of the respiratory tract (infection or mass, including tonsillar or even gingival involvement), GI tract (diarrhea, pain, perforation, bleeding, mass), or central nervous system (CNS; headache, seizure, confusion). Other clinical manifestations may include lymphadenopathy or symptoms

related to allograft dysfunction or compression of surrounding structures. Extranodal involvement occurs in more than two third of patients.[39] In contrast to lymphomas in the general population, the CNS is frequently involved in PTLD, occurring in up to 25% to 30% of patients, and can be the only site of disease. Early diagnosis requires a high index of suspicion in the appropriate clinical setting and radiologic findings. Although computed tomography and magnetic resonance imaging are the most commonly used imaging modalities in PTLD, 2-(fluorine-18) fluoro-2-deoxy-D-glucose positron emission tomography scan is superior to conventional imaging methods for detecting extranodal localization. Tissue sampling is necessary for a definitive diagnosis and subcategorization of PTLD.

Treatment

Reduction or discontinuation of immunosuppressive therapy, particularly cyclosporine, tacrolimus, or MMF, is the first-line treatment; prednisone can be continued to prevent allograft rejection. Although sirolimus has antiproliferative effects, there are insufficient data to recommend or refute its use in the treatment of PTLD. Suggested factors predictive of a poor response to reduction in immunosuppression alone include elevated lactate dehydrogenase (LDH), organ dysfunction at diagnosis, multiple organ involvement, bulky disease, advanced stage, and older age.

In patients who fail to respond to manipulation of immunosuppression alone, rituximab has been used with variable success. Suggested favorable predictive factors for response include EBV-positive PTLD, a shorter interval from transplantation to diagnosis of PTLD, a smaller number of involved sites, and a normal LDH level. Chemotherapy is often used in patients refractory to reduction in immunosuppression and rituximab, in those with aggressive disease at presentation, or in those with lesions not amenable to surgery. The treatment regimens are similar to those used to treat non-Hodgkin lymphoma. CHOP-based chemotherapy (cyclophosphamide, adriamycin, vincristine, and prednisone) with or without rituximab is the most widely used regimen. Adverse effects of chemotherapy include high mortality rates from sepsis and treatment-related toxicities. Surgical resection with or without adjunctive local radiation has been suggested for localized disease. Local radiation has been advocated as the treatment of choice for PTLD involving the CNS. Nonetheless, unless contraindicated, chemotherapy is still recommended by some experts in the field.[40] Acyclovir and ganciclovir are of unproven benefit because their activity is dependent on intracellular phosphorylation by virally encoded thymidine kinase. EBV-driven lymphomas do not express thymidine kinase. Adoptive immunotherapy using EBV-specific cytotoxic T lymphocytes or donor lymphocyte infusion (aiming to kill dividing B cells in EBV-associated PTLD) has emerged as a novel treatment strategies for PTLD.

Poor prognostic factors include multiple-site versus single-site involvement, tumor monoclonality, graft organ involvement, advanced age, CD20-negative large cell lymphomas, recipient EBV-negative serostatus, and the use of antilymphocyte globulin or antithymocyte globulin. Other poor prognostic factors include WHO performance status score of 3 or 4 (a score of 3 is defined as confined to bed or a chair for more than 50% of waking hours, and a score of 4 as completely disabled), late onset of disease (>1 year after transplant), elevated LDH, CNS disease, severe organ dysfunction, acute kidney injury at diagnosis, impaired kidney function, and T cell disease.[23,39,40]

Viral Load Monitoring and Preemptive Strategies

Limited studies in pediatric liver and kidney transplant recipients suggest that monitoring EBV load and preemptive immunosuppression reduction with or without ganciclovir in response to elevated EBV loads reduce the incidence of PTLD. Recent studies suggest that rituximab may prevent transmission of EBV to EBV-naïve transplant recipients. It is speculated that rituximab-mediated elimination of B cells may prevent transmission of EBV to the recipient, because EBV persistence requires the establishment of a latent infection in recipient B cells.[41]

The role of antiviral prophylaxis for the prevention of PTLD remains controversial. A systematic review of 31 studies showed no beneficial effect of antiviral prophylaxis on the incidence of PTLD in high-risk EBV-naïve transplant recipients. The findings were consistent across all types of solid organ transplants, age groups, prophylactic or preemptive therapy, duration of antiviral prophylaxis, or different antiviral agents (acyclovir, valacyclovir, ganciclovir, valganciclovir).[42]

Skin Cancer

Skin cancers are the most common de novo post-transplant tumors in the adult transplant population. Potential risk factors include light skin color, total sun burden and recreational sun exposure, genetic factors, history or present use of AZA, and duration of follow-up after transplantation. Whereas basal cell carcinoma is the most common type of skin cancer in the general population, squamous cell carcinoma has been reported to be two to five times more common than basal cell carcinoma in recipients of solid organ transplantation. In addition, immunosuppression in combination with enhanced sunlight exposure may induce malignant changes in papilloma-induced warts. Sirolimus may delay the onset or reduce the incidence of post-transplant skin and nonskin malignant neoplasms (discussed further later).

Management of Immunosuppressive Therapy in Post-Transplantation Malignancy

In principle, immunosuppression dose reduction improves immune surveillance against malignant cells. However, there are no systematic studies to demonstrate whether immunosuppression reduction or withdrawal might alter the natural history of established post-transplantation malignancy. In our opinion, a switch from CNI to sirolimus or CNI minimization in conjunction with sirolimus may be a viable therapeutic option in selected post-transplant malignancies (the antitumoral effect of sirolimus is discussed later). In patients with metastatic cancer, manipulation of immunosuppression is probably futile, and the risk for rejection and graft loss likely outweighs the benefit.

Studies suggest that immunosuppressive agents have different effects on cancer risk after transplantation. The carcinogenic effects of antithymocyte globulin, cyclosporine, tacrolimus, and AZA have been well documented. In contrast to AZA, MFA derivatives have been shown to have an antiproliferative effect and have been suggested to be protective of post-transplantation malignancy.[43] Analysis of more than 17,000 adult patients with preexisting diabetes indicated a significantly higher incidence of malignancy in AZA-treated than in MMF-treated patients (3.7% vs. 2.2%). In a nested case-control study to evaluate the association between immunosuppressive medications and squamous cell skin cancer risk among cardiac and kidney transplant recipients, an inverse association between MFA derivatives and squamous cell skin cancer was observed independent of tacrolimus use. MFA use was associated with a nearly 50% squamous cell skin cancer risk reduction compared with no MFA derivatives use. In contrast, AZA use was associated with a greater than twofold increase in squamous cell skin cancer risk compared with no AZA use.[44] The study findings suggest that the increased risk for squamous cell skin cancer historically associated with AZA is not seen in organ transplant recipients treated with newer immunosuppressants (e.g., MFA or tacrolimus). Whether MMF is protective of post-transplant malignancies warrants further exploration particularly because it is common practice among clinicians to reduce or discontinue MMF in the presence of malignancies because of the theoretical risk for net protumor effect of overimmunosuppression.

Both preclinical and clinical studies have demonstrated that sirolimus and everolimus have antiproliferative and antitumoral effects. There has been ample literature suggesting that mTOR inhibitor–containing regimen is associated with decreased nonmelanoma skin cancer risks, and its use is effective in both primary and secondary skin cancer prevention.[45-47] Furthermore, the earlier the conversion after an initial diagnosis of cutaneous squamous cell carcinoma, the greater is the efficacy.[46] It has been suggested that the protective effect of mTOR inhibitors against skin cancer is a result of its inhibition of several ultraviolet-induced mechanisms involved in skin carcinogenesis. The mTOR inhibitors also have been reported to be effective in inducing remission of Kaposi sarcoma in organ transplant recipients.[48,49]

Although sirolimus appears to provide satisfactory outcomes in primary and secondary skin cancer prevention, its use in the management of other malignancies after solid organ transplantation remains to be defined. A systematic review of 20 randomized controlled trials and two observational studies (n = 39,039 kidney transplant recipients) demonstrated that sirolimus use was associated with lower overall cancer incidence, driven by a reduction in nonmelanoma skin cancer incidence. The protective effect of sirolimus on nonmelanoma skin cancer (NMSC) risk was most notable in studies comparing sirolimus against cyclosporine (incidence rate ratio [IRR] = 0.19, 95% confidence interval [CI] = 0.04-0.84). After excluding NMSCs, there was no overall association between sirolimus and incidence of other cancers. Further analysis demonstrated that sirolimus use was associated with lower kidney cancer incidence (IRR = 0.40, 95% CI = 0.20-0.81), and higher prostate cancer incidence (IRR = 1.85, 95% CI = 1.17-2.91). The lower incidence of NMSC among sirolimus users was thought to be due in part to cyclosporine withdrawal. Overall, the study findings suggested that sirolimus may reduce kidney cancer risk but did not appear protective for other cancers (including non-Hodgkin lymphoma, Kaposi sarcoma, and lung cancers). In contrast, sirolimus use may increase prostate cancer risk.[50]

It is our current practice to start patients with newly diagnosed skin cancer or RCC (or those with a history of skin cancer or RCC) on sirolimus or everolimus in conjunction with discontinuation of antimetabolites (such as AZA or MFA derivatives) and reduction of CNI therapy tailored to each individual patient. Available data do not support the routine use of mTOR inhibitors in the management of other cancer types.

SELF-ASSESSMENT QUESTIONS

1. Which one of the following statements regarding immunization before and after transplantation is correct:
   - **A.** Seasonal influenza vaccine is contraindicated in the early post-transplant period because it is associated with allograft dysfunction and acute rejection.
   - **B.** Intranasal influenza vaccine is safe and effective before and after transplantation.
   - **C.** Live virus vaccination should be administered at least 4 weeks before transplantation to minimize the possibility of live vaccine–derived infection in the post-transplantation period.
   - **D.** Vaccinations should be administered at least 2 weeks before transplantation to achieve optimal immune response.
2. Clinical manifestations and management of cytomegalovirus (CMV) infection include all of the following *except:*
   - **A.** The absence of CMV viremia does not rule out invasive CMV disease.
   - **B.** In high-risk candidates, CMV prophylactic therapy is recommended over initiation of preemptive treatment after detection of CMV viremia.
   - **C.** Primary CMV infection is usually more severe than reactivated infection or superinfection.
   - **D.** The American Society of Transplantation Infectious Diseases Community of Practice guidelines recommend that antiviral therapy be continued until resolution of clinical symptoms or for a minimum of 2 weeks, whichever comes first.
3. The most widely accepted mainstay of therapy in BK virus–associated clinical syndromes includes:
   - **A.** Leflunomide
   - **B.** Immunosuppression reduction
   - **C.** Ciprofloxacin in conjunction with immunosuppression reduction
   - **D.** Substitution of calcineurin inhibitor (cyclosporine or tacrolimus) for mTOR inhibitor (sirolimus or everolimus)

Medical Management of the Kidney Transplant Recipient

Cardiovascular Disease and Metabolic Abnormalities

Phuong-Thu T. Pham, Son V. Pham, Phuong-Anh T. Pham, Gabriel M. Danovitch

CARDIOVASCULAR DISEASE

Cardiovascular disease (CVD) is the most frequent cause of death with a functioning graft. The U.S. Renal Data System (USRDS) 2014 annual data report revealed that mortality from CVD among kidney transplant recipients (kidney alone or combined organ transplant) is nearly twice that observed for infection or malignancy. An analysis based on the Assessment of Lescol in Renal Transplantation (ALERT) trial suggested that major CV events could be predicted with a seven-variable model including age, previous coronary heart disease (CHD), diabetes, low-density lipoprotein (LDL), creatinine, number of transplants, and smoking.[1] CV risk factors in kidney transplant recipients encompass both conventional and unconventional risk factors. Although kidney transplantation ameliorates some CV risks by restoring renal function, it introduces new CV risks, including impaired glucose tolerance or diabetes mellitus, hypertension, and dyslipidemia, which are derived in part from immunosuppressive medications. Box 106.1 summarizes suggested CV risk factors in transplant recipients.[2] Selected risk factors will be discussed.[2]

CONVENTIONAL CARDIOVASCULAR DISEASE RISK FACTORS

Post-Transplantation Hypertension

Hypertension is present in 50% to 90% of kidney transplant recipients. In one single-center study (n = 94), ambulatory blood pressure (BP) measurements demonstrated that only 5% of kidney transplant recipients were normotensive (defined as BP <130/80 mm Hg).[3] Hypertension is a risk factor for both CV disease and kidney graft failure. The Collaborative Transplant Study registry study revealed a graded risk for graft failure with increasing levels of systolic BP (SBP) and diastolic BP (DBP).[4] The Kidney Disease: Improving Global Outcome (KDIGO) guidelines suggest a BP goal of less than 130/80 mm Hg for kidney transplant recipients irrespective of the level of albuminuria. However, such recommendations are based solely on epidemiologic data because no randomized trials demonstrate the optimal BP target in kidney transplant recipients.

Risk factors for post-transplantation hypertension include preexisting hypertension, cyclosporine (and to a lesser degree tacrolimus), corticosteroids, various donor-related factors (e.g., donor age, donor hypertension, donor family history of hypertension), delayed graft function, chronic allograft injury, high body mass index (BMI) or excess weight gain, acute rejection episodes, recurrent or de novo glomerulonephritis, and transplant renal artery stenosis. Sodium intake after transplantation and excess renin output from the native kidneys also may contribute in some patients. In kidney transplant recipients with severe hypertension refractory to medical therapy, bilateral native nephrectomy has been reported to ameliorate BP control.[5] In a retrospective study of 118 kidney transplant recipients with the primary renal disease autosomal dominant polycystic kidney disease, ipsilateral native nephrectomy at the time of allograft transplant (n = 64) was associated with a significant decrease in the number and daily dose of antihypertensive drugs needed for hypertension control compared with kidney transplantation alone at 12-, 24-, and 36-month follow-up. Subsequent contralateral native nephrectomy (n = 32) further improved BP control.[6]

Management of post-transplantation hypertension should include identification and treatment of the underlying cause, lifestyle modifications (see Chapter 35), and treatment of associated CV risk factors. The initial target BP goal is below 130/80 mm Hg; a BP goal below 125/75 mm Hg for patients with proteinuria is of uncertain benefit. Although there is a lack of controlled clinical trials related to selection of antihypertensive agent, we recommend perioperative β-blockers in transplant candidates with a history of coronary artery disease because they reduce CHD events. In the early post-transplantation period, non-dihydropyridine calcium channel blockers (CCBs) and diuretics are frequently used, the former for their beneficial effect on intraglomerular hemodynamics and the latter to eliminate salt and water in patients who are volume expanded. The use of diltiazem and verapamil also permit calcineurin inhibitor (CNI) dose reductions of up to 40% and 30% to 50%, respectively. Although one retrospective cohort study[7] reported an unexpected association between the use of dihydropyridine CCBs and an increased risk for CHD, results of a large international cohort of kidney transplant recipients (n >14,000 from 10 centers worldwide) failed to show any significant association between any CV medication use (β-blockers, angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers [ARBs], diuretics, CCBs, antiplatelet agents, and/or statins) and the risk for major cardiac events at 12 months,[8] and there is no contraindication to CCB use in the transplant setting. In contrast, most transplant centers use dihydropyridine CCBs for initial therapy because of their added benefit of antagonizing CNI-induced afferent arteriolar vasoconstriction, and their demonstrated efficacy in the general population irrespective of age, gender, and salt intake.[9]

ACE inhibitors and ARBs can cause acute changes in renal function as well as hyperkalemia and hence are usually not started until allograft function is stable. Transplant renal artery stenosis should be considered when serum creatinine rises to more than 30% above baseline. The National Kidney Foundation and KDIGO expert panel endorses the use of CCBs and drugs that block the renin-angiotensin system because of their potential unique advantages compared with other agents. Limited

BOX 106.1 Cardiovascular Risk Factors in Kidney Transplant Recipients

Conventional Risk Factors

Modifiable

- Hypertension
- Dyslipidemia
- Obesity or metabolic syndrome
- Smoking

Nonmodifiable

- Age
- Family history
- Pretransplant diabetes
- Male gender
- History of pretransplant and post-transplant cardiovascular disease
- Race/ethnicity (White race)

Unconventional Risk Factors

Modifiable or Potentially Modifiable

- Proteinuria
- Post-transplantation diabetes mellitus
- Left ventricular hypertrophy
- Inflammatory markers (e.g., inflammatory cytokines, C-reactive protein)
- Anemia
- Hyperuricemia
- Cytomegalovirus infection
- Delayed graft function
- Hyperhomocysteinemia
- Dialysis vintage
- Chronic kidney disease (post-transplant)
- Low albumin
- Obstructive sleep apnea
- Prothrombotic state
- Low physical activity

Nonmodifiable

Recipient Factors

- Prior acute rejection episodes
- Chronic kidney injury from any cause
- Preexisting coronary artery calcification
- Cardiac troponin T

Donor Factors (Donor Quality)

- Donor age
- Donor hypertension
- Donor recipient size mismatch
- Donor *APOL1* gene polymorphism (may be associated with early graft dysfunction)

studies in kidney transplant recipients suggest that renin angiotensin aldosterone system (RAAS) blockade reduces CV events and ameliorates CNI-induced interstitial fibrosis and tubular atrophy.[10] However, the beneficial effect of ACE inhibitors or ARBs on patient or graft survival has not been consistently demonstrated.[9]

Because of the lack of conclusive evidence that one class of antihypertensive agent is superior to another in the transplant setting, treatment should be individualized based on efficacy, tolerability, concomitant comorbidity, and drug-drug interactions with immunosuppressive agents. Potential advantages and disadvantages of different classes of antihypertensive agents in kidney transplant recipients are shown in Table 106.1.

Post-Transplantation Dyslipidemia

Dyslipidemia is common after transplantation, in part because of the hyperlipemic effect of corticosteroids, cyclosporine, tacrolimus, sirolimus, and everolimus. Mammalian target of rapamycin (mTOR) inhibitors, sirolimus, and everolimus are associated with the worst lipid profiles, followed by cyclosporine, and to a lesser extent tacrolimus. One single-center study demonstrated that the mean values of total cholesterol, LDL cholesterol, and triglycerides (TGs) and the incidence of CHD were higher among patients receiving mTOR inhibitors compared with those receiving calcineurin inhibitor-based immunosuppression (controls). However, the risk for CV events was not significantly higher among patients receiving mTOR inhibitors compared with controls at 4-year follow-up.[11] Subsequent studies similarly demonstrated that CV risk is not higher in transplant recipients treated with mTOR inhibitors.[12] The antiproliferative and cardioprotective effects of mTOR inhibitors and the reduction in CNI-related risk factors may offset the adverse effects of hyperlipidemia. Other potential etiologic factors for post-transplant dyslipidemia include age, diet, rapid weight gain, hyperinsulinemia, preexisting hypercholesterolemia, allograft dysfunction, proteinuria, genetic predisposition, and the use of β-blockers and diuretics.

Management of hyperlipidemia includes lifestyle changes (diet and exercise) and statins. In addition to their lipid-lowering effect, statins may protect against CVD via their antiproliferative and antiinflammatory properties and ability to reduce circulating endothelin-1, C-reactive protein levels, SBP and DBP, and pulse pressure. The benefits of statins in the general population have been demonstrated in several large randomized controlled trials (RCTs). There has been only one single prospective randomized trial in transplant recipients comparing statins (fluvastatin) with placebo—the ALERT trial. Results of the ALERT study suggest a beneficial effect of early initiation of fluvastatin on post-transplant CV outcome. Patients who received statin therapy within the first 4 years after transplantation had a risk reduction of 64% compared with 19% for those who received therapy after 10 years.[13] The 2014 Cochrane meta-analysis of 17 studies comparing statin with placebo or no treatment, and 5 studies comparing two different statin regimens demonstrated a trend toward reduction in major CV events, CV mortality, and fatal or nonfatal myocardial infarction. No association between statin use and all-cause mortality or stroke was observed.

The KDIGO expert panel on Clinical Practice Guideline for Lipid Management in chronic kidney disease (CKD) advocate statin therapy in all adult kidney transplant recipients, although supporting evidence was considered weak. The 2013 American College of Cardiology/American Heart Association (ACC/AHA) guidelines indicate there is insufficient RCT evidence for guiding clinical recommendations for solid-organ transplant recipients and suggest clinical judgment weighing potential benefits, risks, and patient preferences. The KDIGO and ACC/AHA guidelines for the management of post-transplantation dyslipidemia are shown in Fig. 106.1. CVD risk reduction requires adherence to both medication and lifestyle regimens.

Statin Therapy

Kidney transplantation is regarded as risk factor for CHD similar to other conventional cardiac risk factors. Hence, despite the lack of evidence-based recommendations, most transplant centers assess and treat dyslipidemias aggressively with statin therapy in conjunction with lifestyle modification. The concomitant use of statins and CNIs, particularly cyclosporine, often results in a several-fold increase in statin blood level and an increased risk for myopathy and rhabdomyolysis. The risk is lowest with pravastatin and fluvastatin. In contrast, simvastatin appears to be particularly prone to drug-drug interactions compared with other statins because of its extensive metabolism by cytochrome

TABLE 106.1 Potential Advantages and Disadvantages of Different Classes of Antihypertensive Agents

Classes of Drugs	Advantages	Disadvantages
β-Blockers	Perioperative use: ↓ coronary heart disease events	↑ Risk for bradycardia when used with nondihydropyrine CCB Blunting of hypoglycemic awareness
CCBs	↓ CNI-induced vasoconstriction ↑ CNI level (diltiazem may permit CNI dose reduction by up to 40%, and verapamil by up to 30%-50%	
Diuretics	Beneficial in patients who are volume expanded	Hyperuricemia, gout
ACE inhibitors, ARBs	↓ Proteinuria Potential renoprotective and cardioprotective effects (the favorable impact on patient and graft survival has not been consistently demonstrated) Beneficial in post-transplantation erythrocytosis	Potential worsening anemia ↓ GFR, hyperkalemia
Aldosterone receptor blockers	May improve outcomes in heart failure	Severe hyperkalemia when used in combination with ACE inhibitor or ARB in patients with poor kidney function
α-Blockers	Benign prostatic hypertrophy Neurogenic bladder	
Direct vasodilators		Tachycardia
Central α-agonist		Depression

P450 (CYP3A4). Coadministration of simvastatin and cyclosporine should be avoided. Rhabdomyolysis associated with tacrolimus and statin use is generally seen in patients on concomitant diltiazem therapy.

Nonstatin Drug Therapy

Ezetimibe and statin combination therapy has been suggested to improve cholesterol control because of their complementary mechanisms of action. Ezetimibe blocks intestinal absorption of dietary cholesterol, whereas statin inhibits hepatic cholesterol synthesis. Results of The SHARP trial in which CKD patients were randomized to receive simvastatin 20 mg plus ezetimibe 10 mg (n = 4650) or placebo (n = 4620) demonstrated that simvastatin and ezetimibe combination therapy conferred a 17% CV risk reduction compared with placebo at a median follow-up of 4.9 years.[14] Limited studies suggest that statin and ezetimibe combination therapy is safe and effective in the treatment of dyslipidemia in kidney transplant patients who are refractory to statin therapy. In a single-center study consisting of 67 patients with post-transplantation hyperlipidemia resistant to statins, treatment with ezetimibe alone or with ezetimibe and statin significantly reduced total cholesterol and LDL cholesterol by 25% and 34%, respectively, during the first month of treatment.[15] To date, no data support the routine addition of nonstatin drug to statin therapy for CVD risk reduction in the general population or in the transplant setting. Nonetheless, based on the safety and efficacy data of ezetimibe use among CKD patients, ezetimibe is a second-line treatment option for high-risk kidney transplant recipients who are intolerant of statin or who are refractory to statin therapy. In the absence of evidence-based recommendations, adherence to lifestyle changes and to statin therapy should be reemphasized before adding a nonstatin lipid-lowering agent to statin therapy.

Management of Hypertriglyceridemia

Initial management should include lifestyle changes, increased physical activity, weight reduction, dietary counseling (carbohydrate restriction), smoking cessation, and correction of secondary causes. The latter may include untreated diabetes mellitus or excess alcohol intake or may be drug induced. Severe hypertriglyceridemia (TG level >500 mg/dl or 5.65 mmol/l) may occur with the use of sirolimus and everolimus. Management includes dose reduction, pharmacologic therapy, and, in refractory cases, switching of mTOR inhibitors to mycophenolic acid derivatives or tacrolimus.

Drug therapy for Hypertriglyceridemia

Fibrates. Fibrates have the most pronounced effect on lowering plasma TG levels of available lipid-lowering agents.[16] For patients with fasting TG levels above 1000 mg/dl (11.3 mmol/l), the Adult Treatment Panel (ATP) III recommends a diet very low in fat (<15% total calories), medium-chain TGs, and fish oils to replace some long-chain TGs. The National Kidney Foundation expert panel recommends gemfibrozil as the fibrate of choice. However, fibrates should be avoided in those with CKD stage 5. Of the major fibric acid medications (bezafibrate, ciprofibrate, fenofibrate, and gemfibrozil), the first three can increase serum creatinine in cyclosporine-treated patients. Although all fibrates in combinations with statins have been associated with creatinine kinase elevations with or without overt rhabdomyolysis and myopathy, gemfibrozil may have a greater risk for the development of myopathy compared with fenofibrate or bezafibrate. Fenofibrate is contraindicated in patients with an estimated glomerular filtration rate (eGFR) less than 30 ml/min/1.73 m^2. Data on the safety of gemfibrozil in patients with advanced CKD is lacking.

Ezetimibe. Limited studies demonstrated that ezetimibe has TG-lowering effects and is safe and effective in the transplant settings.[17]

Bile acid resins. Bile acid sequestrants must be used with caution because of their potential interference with the absorption of CNIs and mycophenolic acid derivatives. Coadministration of bile acid sequestrants and mycophenolic acid products is not recommended. Studies in the general population suggest that bile acid sequestrants may increase TG levels. Their use is contraindicated in individuals with TGs greater than 400 to 500 mg/dl.[16]

Niacin. Niacin lowers TG and LDL-C levels and has pronounced effects on increasing high-density lipoprotein (HDL) concentration. Niacin monotherapy has not been reported to cause myopathy, but its combined use with lovastatin, pravastatin, or simvastatin may be associated with rhabdomyolysis.

Summary

Statins should be the first-line therapy for the treatment of non–high-density lipoprotein (non-HDL) cholesterol because of their well-established safety and efficacy in preventing CVD in randomized trials in the general population. We recommend atorvastatin or rosuvastatin for patients with mixed dyslipidemia. Ezetimibe should be considered in those intolerant to statins despite dose reduction or despite switching to another statin. There are currently no data to suggest that adding fibrates to statin therapy is superior to adding ezetimibe to statin therapy in the treatment of post-transplantation hypertriglyceridemia. In the our opinion, adding ezetimibe to statin therapy seems reasonable in mild to moderate hypertriglyceridemia (TG <500 mg/dl or 5.65 mmol/l). However, fibrate is the preferred therapy in patients with TG levels above 500 to 1000 mg/dl (5.65 to 11.3 mmol/l) because it has a more pronounced TG-lowering effect than ezetimibe. Nonetheless, the choice of one agent over the other should be based on adverse effects and potential drug-drug interactions. Simvastatin and gemfibrozil combination therapy is associated with an increased risk for rhabdomyolysis and should be avoided.

Suggested guidelines for pharmacologic treatment of dyslipidemia are summarized in Fig. 106.1.

POST-TRANSPLANTATION DIABETES MELLITUS (NEW-ONSET DIABETES AFTER TRANSPLANTATION)

Post-transplantation diabetes mellitus (PTDM) occurs in 4% to 25% of kidney transplant recipients. Variations in incidence may result from differences in definition, duration of follow-up, and the presence of both modifiable and nonmodifiable risk factors. Over the years, PTDM has undergone changes in nomenclatures including steroid diabetes, PTDM, new-onset DM, transplant-associated hyperglycemia, and new-onset diabetes after transplantation (NODAT).[18] In 2014 the International Expert Panel recommended changing the terminology NODAT back to PTDM, excluding transient post-transplantation hyperglycemia.[19] Using the term NODAT is thought to be misleading because it seemingly excludes patients with pretransplant diabetes. Preexisting diabetes is often undiagnosed because of the effect of CKD on insulin metabolism and clearance and the lack of effective pretransplant screening.

Risk Factors

PTDM may arise from both transplant-related and traditional risk factors. The diabetogenic effect of corticosteroids, CNIs (tacrolimus > cyclosporine), and mTOR inhibitors have been well-described. Neither azathioprine nor mycophenolic acid derivatives are diabetogenic. Risk factors for PTDM are summarized in Fig. 106.2. They can be loosely categorized into those that are nonmodifiable, potentially modifiable, and modifiable.

Management of Post-Transplantation Diabetes Mellitus

Although there may be differences in the pathogenesis and manifestation of PTDM compared with type 2 diabetes, management of PTDM

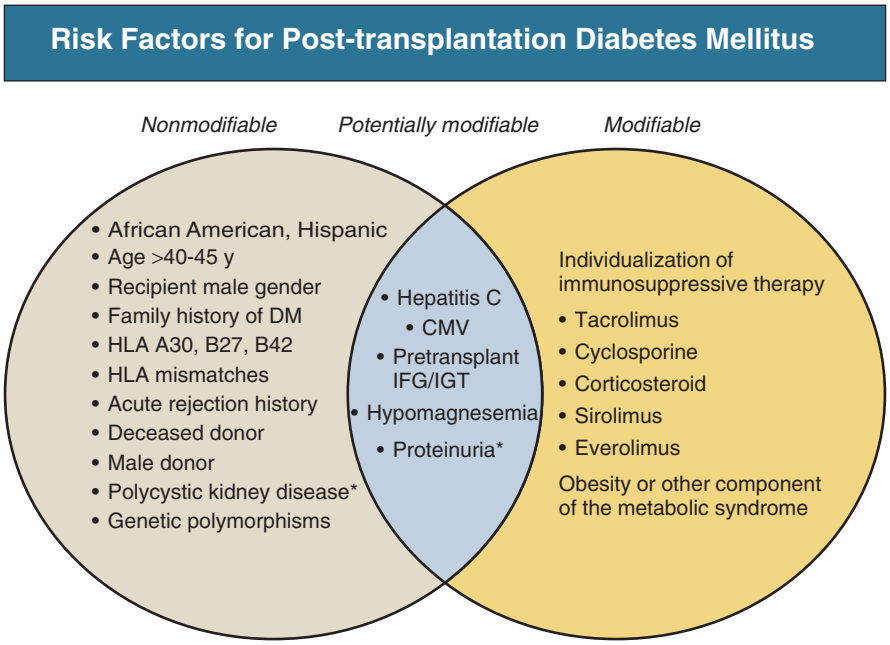

Fig. 106.2 Risk factors for post-transplantation diabetes mellitus (PTDM). *NOTE:* Restoration of insulin metabolism by a functioning graft may unmask pretransplant IFG or diabetes mellitus. *The association between polycystic kidney disease (or proteinuria) and PTDM has not been consistently observed. *CMV,* Cytomegalovirus; *IFG,* impaired fasting glucose; *IGT,* impaired glucose tolerance.

should follow the conventional approach and clinical guidelines as established by well-recognized organizations. Medical management usually involves a multidisciplinary team approach involving patients (and frequently family members), transplant coordinators, transplant physicians, and diabetic educators. A shared decision-making approach by which clinicians and patients exchange information and reach a consensus on treatment decisions can be helpful.

The American Diabetes Association and European Association for the Study of Diabetes recommend a hemoglobin A_{1c} (HbA_{1c}) target of less than 7% in most patients to reduce the incidence of microvascular disease. More stringent control (HbA_{1c} 6.0% to 6.5%) might be considered in a subset of patients with short disease duration, long life expectancy, and no significant CV disease, if this can be achieved without significant treatment-related adverse effects.[20] For PTDM, the 2009 KDIGO clinical practice guidelines suggest a target HbA_{1c} level from 7.0% to 7.5%, not to fall below 6.0%, particularly if hypoglycemic reactions are common.

Therapeutic Interventions

Nonpharmacologic Management

Obesity treatment seems to be a reasonable target for intervention because higher pretransplant BMI correlates with insulin resistance after transplantation. We recommend promoting lifestyle modification in kidney transplant recipients, including moderation of dietary sodium (<2400 mg sodium per day) and saturated fat intake (<7% calories from saturated fats, 2% to 3% calories from *trans*-fatty acids), regular aerobic exercise, and weight reduction. Carbohydrate intake should be limited to 50% to 60% of caloric intake. The AHA guidelines in nontransplant recipients also suggest intake of at least 25 g of dietary fiber per day and two servings of fish per week. Dietary guidelines for vegetarians are lacking. Flax seeds (or flaxseed oil) and chia seeds are alternative sources of omega-3 fatty acid. Dietitian referral is recommended. Defining realistic goals such as a target weight loss of 5% to 10% of total body weight and a patient-centered approach to education may be invaluable in achieving success.

Modification of Immunosuppression

Although clinical trials comparing the incidence of PTDM in cyclosporine- versus tacrolimus-treated patients have yielded variable results, tacrolimus has more consistently been shown to have a greater diabetogenic effect than cyclosporine. Modification of immunosuppression including cyclosporine to tacrolimus conversion therapy or steroid avoidance or withdrawal has variably been shown to improve glycemic control. However, manipulation of immunosuppression is not without immunologic risk. In a meta-analysis of controlled clinical trials to assess the safety and efficacy of early steroid withdrawal or avoidance, steroid avoidance or steroid withdrawal after a few days was found to be associated with a decrease in PTDM incidence among cyclosporine- but not tacrolimus-treated kidney transplant recipients.[21] However, among cyclosporine-treated patients, acute rejection episodes were more frequently observed in steroid avoidance compared with conventional steroid-treated groups. In another study, the same group of investigators demonstrated no significant benefit of late steroid withdrawal (3 to 6 months after transplantation) on the incidence of PTDM. In the current era of immunosuppression, the beneficial effect of steroid avoidance or withdrawal on the incidence of PTDM has been questioned by experts in the field because rapid steroid taper and the use of lower target cyclosporine and tacrolimus levels are now common practice.[19] It should be noted that mycophenolate exposure is lower with cyclosporine than with tacrolimus immunosuppression; hence mycophenolate dosage adjustment or drug level monitoring may be necessary. Because of the lack of well-defined guidelines, modification of immunosuppression to alleviate the incidence of PTDM should be tailored to each individual patient. Reduction in immunosuppression should be weighed against the risk for acute rejection.

Pharmacologic Treatment

When lifestyle modification fails to achieve glycemic control, medical intervention is often necessary. Metformin is not widely used in transplant recipients because of the concern for lactic acidosis in the presence

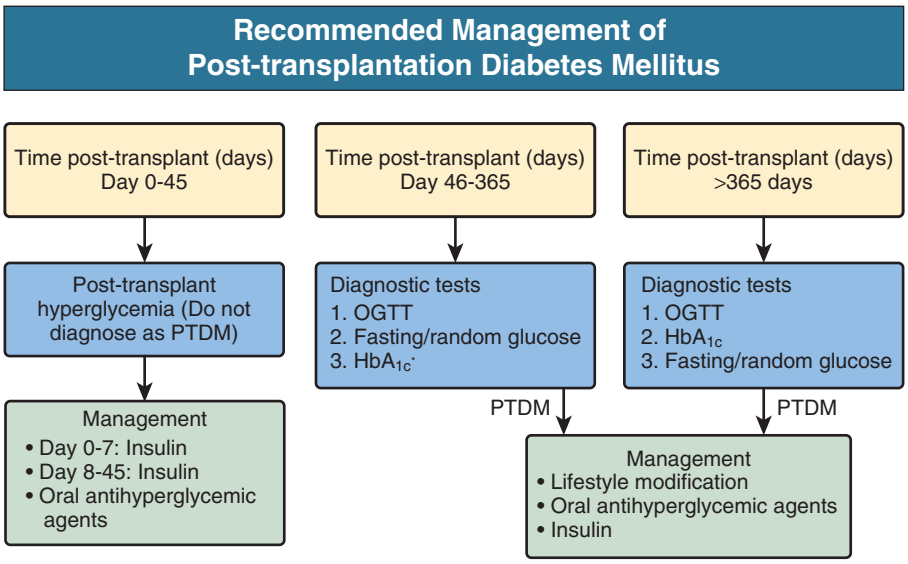

Fig. 106.3 The 2014 International Consensus Guidelines on Screening, Diagnosis, and Management of Post-Transplantation Diabetes Mellitus (PTDM). Hyperglycemia in the first 45 days post transplant should not be diagnosed as PTDM. Hemoglobin A_{1c} alone less than 365 days may underestimate PTDM and require confirmatory testing. *OGTT,* Oral glucose tolerance test.

of dynamic kidney allograft function particularly in the early post-transplant period. However, the potential beneficial effects of metformin including weight neutral or weight loss, cardioprotection, and lack of significant drug-drug interactions renders metformin an attractive treatment option for solid-organ transplant recipients. Further clinical trials to assess the risk and benefit ratio of metformin are needed before it can be endorsed as the antihyperglycemic agent of choice in PTDM.[19] Experimental studies suggest that sulfonylureas are associated with beta cell apoptosis and beta cell exhaustion, raising theoretical concern about their use in PTDM, particularly in the early post-transplant period.[22] In contrast, the newer antihyperglycemic dipeptidyl peptidase-4 (DPP-4) inhibitors have been shown to preserve pancreatic beta cell function in diabetic animal models.[23] Limited clinical studies suggest that DPP-4 inhibitors are safe and effective in the treatment of PTDM.[24] There currently are no data on the use of sodium-glucose cotransporter type 2 (SGLT2) inhibitor in the transplant setting. However, SGLT2 treatment is associated with increased risks for urinary tract infection and genital candidiasis, potentially limiting its use in kidney transplant recipients.

Evidence-based studies recommending one oral antidiabetic agent over the other in the context of transplantation are currently lacking. Hence, the choice should be based on the potential advantages and disadvantages of different classes of agents. Failure to achieve glycemic control despite oral antihyperglycemic agent combination therapy necessitates initiation of basal-prandial insulin therapy. The 2014 updated international consensus guidelines on the screening, diagnosis, and management of early post-transplant hyperglycemia and PTDM is shown in Fig. 106.3. It should be noted that HbA_{1c} cannot be accurately interpreted within the first 3 months after transplantation because anemia and impaired graft function can directly interfere with the HbA_{1c} assay. Recent blood transfusion or the use of dapsone may alter HbA_{1c} levels.

Cigarette Smoking

As in the general population, cigarette smoking is associated with increased CV disease morbidity and mortality in kidney transplant recipients. Smoking cessation 5 years before transplantation reduces the risk for death by 29%.[25] Every effort should be made to encourage patients to stop smoking. A multifaceted approach including behavioral and pharmacologic strategies appears to be most effective.

Obesity

The prevalence of obesity (BMI ≥30 kg/m^2) among transplant recipients in the United States doubled between 1987 and 2001, and over the past decade the number of obese transplant candidates and recipients continues to rise.[26]

A high BMI at transplant is a significant independent predictor of congestive heart failure and atrial fibrillation.[27] The association between BMI and cardiac-related death is U-shaped, with an increase in the adjusted risk for cardiac death at both low and high BMI compared with a referent BMI of 22 to 24 (hazard ratio [HR], 1.3 for BMI <20; HR 1.2 for BMI 30 to 32; HR 1.4 for BMI >36).[28] The Scientific Registry of Transplant Recipients database demonstrated that obesity is also an independent risk factor for delayed graft function, graft failure, proteinuria, and acute rejection. Furthermore, the risk for adverse outcomes progressively increased with higher BMI categories.[26]

Management of post-transplantation obesity includes lifestyle and dietary modification. Corticosteroid reduction or withdrawal must be balanced against the risk for graft rejection and graft loss. The use of pharmacologic agents for weight reduction in the post-transplantation period is currently not recommended because of unknown potential drug-drug interactions. Data are inadequate regarding the safety and efficacy of post-transplantation gastric bypass surgery or adjustable gastric banding in ameliorating comorbid conditions such as hypertension, DM, and dyslipidemia. All studies reported to date were limited by lack of suitable comparison group, short follow-up, and heterogeneity in type of bariatric procedure and approach.[29] However, with the refinement in surgical techniques and advancement in postoperative care, post-transplantation bariatric surgery for morbid obesity should be explored.

UNCONVENTIONAL CARDIOVASCULAR DISEASE RISK FACTORS

Proteinuria

Proteinuria occurs in 9% to 40% of kidney transplant recipients with a functioning graft. Proteinuria from native kidneys typically decreases rapidly after transplantation and resolves within the first month after transplantation. Persistent or worsening proteinuria is usually indicative

of allograft pathology. Hence, monitoring the urine protein-to-creatinine ratio at each clinic visit and allograft biopsy should be performed in kidney transplant recipients with persistent or worsening proteinuria and in those whose primary renal disease is focal segmental glomerulosclerosis, to monitor for disease recurrence. As in the nontransplant setting, post-transplantation proteinuria increases the risk for CV events, graft loss, and mortality. Controlled trials evaluating the beneficial effect of treating proteinuria in reducing CV risk in kidney transplant recipients remain limited. A Canadian double-blind RCT evaluating the effect of ramipril versus placebo in kidney transplant recipients with proteinuria greater than 0.2 g/day and eGFR greater than 20 ml/min/1.73 m^2 failed to show a beneficial effect of ramipril in ameliorating the composite primary end-point of reduction in doubling of serum creatinine, end-stage renal disease (ESRD), or death compared with placebo at a mean follow up of 48 months.[30] In contrast, in another RCT with 10-year follow-up, patients treated with an ACE inhibitor were found to have significantly better survival free of the composite end-point (death, major CV events, and renal graft loss or creatinine doubling) (P = .0102) and survival free of major CV events compared with those not receiving ACE inhibitors (controls), P = .0027. Furthermore, a significant increase in urinary protein excretion rate was observed only in controls. No significant differences in renal outcome were observed.[31] Although the routine recommendation of ACE inhibitor or ARB use in kidney transplant recipients with proteinuria awaits further studies, ACE inhibitors or ARBs should be considered in transplant recipients with proteinuria because of their well-established antiproteinuric and cardioprotective effects. The 2009 KDIGO clinical practice guidelines recommend an ACE inhibitor or ARB as first-line therapy for patients with hypertension and proteinuria of 1 g/day or greater.

Belatacept Use

Belatacept is a humanized fusion protein that inhibits the costimulatory pathway. Belatacept was developed to minimize CV risk and nephrotoxicity associated with CNI-based immunosuppression. Long-term follow-up of phase III RCTs comparing the safety and efficacy of belatacept-based versus cyclosporine-based immunosuppression in recipients of standard donor kidneys (BENEFIT study) and in those of extended-criteria donor kidneys (BENEFIT-EXT study) demonstrated that, compared with cyclosporine, belatacept-based regimens (1) resulted in lower BP, cholesterol levels, and incidence of PTDM, (2) significantly reduced death and graft loss, and (3) improved long-term renal function. Whether improvement in CV risk factor profile translates into reduction in CVD remains to be studied.

COMMON LABORATORY ABNORMALITIES

Anemia

In the immediate post-transplantation period, aggressive perioperative volume expansion may result in dilutional anemia. Refractory or severe anemia mandates aggressive evaluation to exclude the possibility of surgical postoperative bleeding, particularly in those with a rapid fall in Hb and hematocrit (Hct) levels.

Mild anemia is common in the early post-transplantation period when erythropoietin (EPO) therapy is typically discontinued, but usually improves within several weeks to months. Suggested etiologic factors for post-transplantation anemia include iron deficiency, impaired graft function, acute rejection episodes, recent infection, and medications (e.g., azathioprine, mycophenolic acid derivatives, sirolimus, everolimus, dapsone, ACE inhibitors, and ARBs).

Assessment of baseline iron stores at the time of transplantation may be invaluable because iron deficiency is common in the dialysis population. Profound iron deficiency should be treated with intravenous iron as tolerated. EPO therapy and darbepoetin alfa are effective in the treatment of anemic kidney transplant recipients. The 2012 KDIGO anemia guidelines recommend initiating an erythropoiesis-stimulating agent in CKD patients when Hb values are less than 9 to 10 g/dl, provided iron stores are adequate. A target Hb level of 10 to 11 g/dl is recommended. Large CKD anemia trials demonstrated a possible harmful effect of higher Hb levels and high epoetin doses. Observational studies in kidney transplant recipients similarly suggested that mortality may be increased with Hb levels above 12.5 g/dl. Although evidence-based recommendations in the transplant setting are lacking, management of post-transplantation anemia to keep Hb level in the range of 10 to 11 g/dl seems reasonable.

Refractory anemia or anemia that fails to rise gradually to a normal or near-normal level after the first few post-transplantation weeks can be a result of occult gastrointestinal bleeding, tertiary hyperparathyroidism, underlying inflammatory conditions, or parvovirus B19 infection. EPO-resistant anemia has been described in patients receiving sirolimus immunosuppression. In stable kidney transplant recipients, conversion from sirolimus to mycophenolic acid derivatives may help resolve anemia. Although uncommon, drug-induced hemolysis from agent such as dapsone should also be considered.

Leukopenia and Thrombocytopenia

Leukopenia and thrombocytopenia are most commonly related to adverse drug effects, including treatment with lymphocyte-depleting agents (e.g., thymoglobulin or alemtuzumab), azathioprine, mycophenolic acid derivatives, sirolimus, everolimus, and trimethoprim-sulfamethoxazole, among others. Withholding the offending agent or dose reduction generally corrects these hematologic abnormalities. Severe leukopenia may be safely treated with granulocyte-stimulating factor. Thrombotic microangiopathy (TMA) or cytomegalovirus (CMV) infection should be excluded. Parvovirus B19 infection may manifest with refractory anemia, pancytopenia, and TMA. Alemtuzumab can cause potentially fatal immune thrombocytopenia. Bortezomib, the first-in-class proteasome inhibitor introduced into clinical transplantation for the treatment of antibody-mediated rejection and desensitization protocols, has been reported to cause leukopenia and thrombocytopenia.

Erythrocytosis

Post-transplantation erythrocytosis (PTE) may develop within the first 2 years and generally affects those with good allograft function. Its incidence appears to have decreased to less than 10% concomitant with the more frequent use of ACE inhibitors and ARBs. Spontaneous remission is observed in one fourth of patients within 2 years from onset, whereas in the remaining three fourths erythrocytosis may persist for several years.[32] Risk factors for PTE include the presence of native kidneys, male gender, absence of rejection episodes, high baseline Hb before transplant, and hypertension. Smoking and diabetes have been shown to be risk factors for PTE in some but not all studies. Other suggested risk factors include polycystic kidney disease and glomerulonephritis as the cause of ESRD. Although transplant renal artery stenosis has not consistently been shown to be a risk factor for PTE, imaging studies to evaluate the iliac and renal arteries should be considered in patients with refractory PTE. In addition, the possibilities of renal cell carcinoma in the native or transplanted kidneys should be excluded.

Both hormonal systems and growth factors have been implicated in the pathogenesis of PTE. These may include defective feedback regulation of EPO metabolism, direct stimulation of erythroid precursors by angiotensin II, abnormalities in levels of circulating insulin-like growth factor 1 (IGF-1) and its binding proteins, and an increase in serum-soluble stem cell factors, which stimulates the growth of erythroid progenitor cells. Serum-soluble stem cell factors have been shown to

correlate with both Hct values and the observed and expected EPO values in kidney transplant recipients with PTE.[33]

Treatment is generally recommended for an Hb level exceeding 17 to 18 g/dl or an Hct level over 51% to 52% because of the associated risk for thromboembolic complications, hypertension, and headaches. Hb and Hct treatment range may vary depending on gender and institutional reference range. Treatment with ACE inhibitors or ARBs is often sufficient, although phlebotomy may occasionally be necessary. Relapse is common and often necessitates long-term ACE inhibitor or ARB treatment. A negative association between the use of sirolimus and PTE has been reported. Nonetheless, modification of immunosuppressive medications to treat PTE is uncommon in clinical practice.

Hyperkalemia

Mild hyperkalemia is commonly encountered in kidney transplant recipients, particularly in the early post-transplantation period when higher doses of CNI are used. It is often associated with mild hyperchloremic acidosis, a clinical presentation reminiscent of that of type 4 renal tubular acidosis. Suggested mechanism(s) of CNI-induced hyperkalemia include hyporeninism, hypoaldosteronism, aldosterone resistance, and inhibition of cortical collecting duct potassium secretory channels. In patients receiving cyclosporine or tacrolimus immunosuppression, a potassium level in the range of 5.2 to 5.5 mmol/l is typical. Higher potassium levels, especially in the presence of concomitant use of drugs that may exacerbate hyperkalemia such ACE inhibitors, ARBs, and β-blockers, may require their discontinuation. Caution is needed when potassium-containing phosphorus supplements are prescribed. Although both high-dose and standard-dose trimethoprim can cause hyperkalemia via an amiloride-like effect, the routine use of low-dose trimethoprim-sulfamethoxazole prophylactic therapy is rarely the cause of severe or refractory hyperkalemia in kidney allograft recipients. Nonetheless, withholding of trimethoprim should be considered in patients with severe or refractory hyperkalemia. Treatment of hyperkalemia is discussed in Chapter 9. Sodium polystyrene sulfonate (Kayexalate) or calcium resonium enemas should be avoided in the early post-transplantation period to avoid colonic dilation and perforation. Although the newer cation exchanger patiromer is effective in the treatment of hyperkalemia, its use in kidney transplant recipients may be hindered by potential drug-induced hypomagnesemia. This adverse drug effect may exacerbate the electrolyte abnormalities commonly seen in the post-transplantation period (discussed later).

Hypophosphatemia

Hypophosphatemia is frequently encountered in the first months after transplantation. Concomitant hypercalcemia suggests post-transplantation hyperparathyroidism. In the absence of hypercalcemia, renal phosphate-wasting syndrome or malnutrition should be considered. Early after transplantation, hypophosphatemia has been attributed to a massive initial diuresis, particularly after a living-donor kidney transplant, defective renal phosphate reabsorption caused by ischemic injury, glucosuria (caused by hyperglycemia-induced osmotic diuresis), and corticosteroid use, the latter by inhibiting proximal tubular reabsorption of phosphate. Fibroblast growth factor-23 (FGF-23) has been suggested to play a major contributory role in the development of early post-transplantation hypophosphatemia independent of parathyroid hormone (PTH) level. FGF-23 is a phosphaturic hormone, and its levels are increased in the early stages of CKD and significantly elevated in dialysis patients. Pretransplant FGF-23 was found to be the main predictor of post-transplant phosphate levels.[34] In contrast to hypophosphatemia occurring in the early post-transplant period, persistent hypophosphatemia beyond 1 year after transplant is mainly due to persistent hyperparathyroidism rather than increased FGF-23 levels.

Hypercalcemia

Hypercalcemia is common after transplantation and is generally a result of persistent secondary hyperparathyroidism. The concomitant presence of severe hypophosphatemia, particularly in patients with excellent graft function, may exacerbate hypercalcemia through stimulation of renal proximal tubular 1α-hydroxylase. Resolution of soft tissue calcifications and immobilization are potential contributing factors. Hypercalcemia may be masked by high-dose corticosteroid therapy but may manifest during tapering. In about two thirds of patients, hypercalcemia resolves spontaneously within 6 to 12 months. However, spontaneous resolution occurs in less than half of those whose hypercalcemia existed before transplantation. Persistent hyperparathyroidism has generally been attributed to continued autonomous production of PTH from nodular hyperplastic glands, reduced density of calcitriol receptors, and decreased expression of the membrane calcium sensor receptors that render cells more resistant to physiologic concentrations of calcitriol and calcium. Persistently elevated FGF-23 levels after transplant may contribute to persistent hyperparathyroidism through inhibition of 1α-hydroxylase activity leading to low calcitriol levels. The risk for persistent hyperparathyroidism is increased with the duration of dialysis and the severity of pretransplant hyperparathyroidism. Severe and persistent hypercalcemia (≥11.5 to 12 mg/dl [2.87 to 3.0 mmol/l]) for longer than 6 months in the first post-transplant year requires further evaluation. Initial assessment should include an intact PTH level. Imaging studies, including neck ultrasound or parathyroid technetium-99m (^{99m}Tc)-sestamibi scan, are required to determine whether the clinically observed hyperparathyroidism arises from parathyroid adenoma, parathyroid gland hyperplasia, or hyperplastic nodular formation. Although therapeutic approaches differ across transplant centers, treatment with cinacalcet can be considered in kidney transplant recipients with hyperparathyroidism-associated hypercalcemia in the early post-transplant period. Serum calcium, phosphorus, and alkaline phosphatase should be monitored at each clinic visit. Because spontaneous resolution of hyperparathyroidism may not occur rapidly, it is generally advisable to delay any plan for parathyroidectomy to 1 year after transplant (see later for indication for parathyroidectomy). However, severe hypercalcemia associated with parathyroid adenoma often necessitates surgical parathyroidectomy.

Cinacalcet is commonly used off label by most U.S. centers to treat post-transplant hypercalcemic hyperparathyroidism. Subtotal parathyroidectomy is warranted in patients with tertiary hyperparathyroidism or persistent severe hypercalcemia (≥11.5 to 12 mg/dl [2.87 to 3.0 mmol/l]) for longer than 6 to 12 months, symptomatic or progressive hypercalcemia, nephrolithiasis, persistent osteitis fibrosa, calcium-related renal allograft dysfunction, or progressive vascular calcification and calciphylaxis.[35] In a retrospective cohort study of 83 kidney transplant recipients with tertiary hyperparathyroidism, parathyroidectomy resulted in a lower serum calcium level (9.28 mg/dl) compared with cinacalcet (10.20 mg/dl) (P <.01) at 6 weeks. One fourth of the observation group showed persistent hypercalcemic symptoms, compared with 7.7% in the cinacalcet and 0% in the parathyroidectomy group ($P < .01$).[36] In a more recent single-center study consisting of 59 stable kidney transplant recipients, the calcium-lowering effect of cinacalcet was found comparable to that of surgical parathyroidectomy at 8 weeks and at 1-year follow-up.[37] Subtotal parathyroidectomy was performed in patients with uncontrollable, long-standing, and marked osteitis fibrosa. Notably, 2 of 16 patients in the parathyroidectomy group were excluded from the study analysis because of surgical failures (defined as at least two of the three criteria including decrease in serum calcium, phosphorus, and PTH). Whether long-term calcimimetic use is safe and reduces the need for parathyroidectomy warrants further exploration. Although

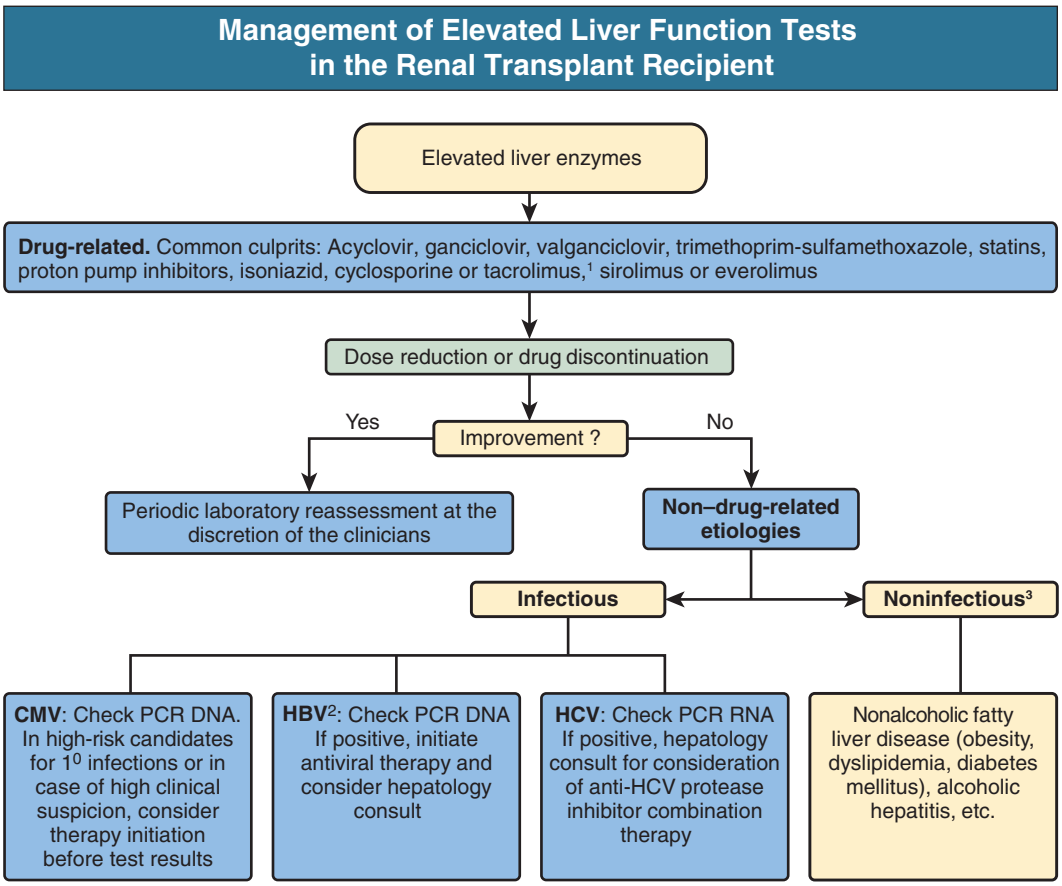

Fig. 106.4 Algorithm for the management of elevated liver enzymes in kidney transplant recipients. [1]Cyclosporine and, less commonly, tacrolimus may cause transient, self-limited dose-dependent elevations of aminotransferase levels and mild hyperbilirubinemia secondary to defective bile secretion. [2]We advocate antiviral prophylactic therapy in all HBsAg-positive candidates at the time of transplantation. [3]Appropriate evaluation and management similar to those in nontransplant settings.

seldom reported, clinicians should remain vigilant for the potential development of nephrocalcinosis associated with the use of cinacalcet.[38]

Hypomagnesemia

Cyclosporine, tacrolimus, and sirolimus can cause hypomagnesemia by inducing urinary magnesium wasting. Other factors that may contribute to post-transplantation hypomagnesemia include loop diuretic therapy, recovery from acute tubular necrosis, postobstructive polyuria, and renal tubular acidosis. Hypomagnesemia may be more common in diabetics. In the first 3 months after transplantation, a magnesium level below 1.5 mg/dl (0.62 mmol/l) is common. Dietary magnesium intake is usually insufficient, and high-dose oral magnesium supplementation (i.e., 400-800 mg magnesium oxide three times per day) may be required. Intravenous magnesium should be considered in patients with severe hypomagnesemia (<1.0 mg/dl or 0.41 mmol/l), particularly patients with a history of CHD or cardiac arrhythmias and those taking digoxin.

Abnormal Liver Function Tests

Elevation of liver enzymes is common in the early post-transplantation period and is generally caused by drug-related toxicity (Fig. 106.4). Cyclosporine and less commonly tacrolimus may cause transient, self-limited, dose-dependent elevations of transaminase levels and mild hyperbilirubinemia secondary to defective bile secretion. Elevated liver enzymes caused by drug-related adverse effects generally improve or resolve after drug discontinuation or dose reduction.

Persistent or profound elevation in liver enzymes should prompt further evaluation to exclude infectious causes, including CMV, hepatitis B, and hepatitis C infections. Evidence of post-transplant HBV reactivation should be treated with entecavir or another nucleotide analogue. We advocate antiviral prophylactic therapy in all hepatitis B surface antigen (HBsAg)-positive candidates at the time of transplantation. Historically there was no effective treatment for chronic hepatitis C in kidney transplant recipients because of the increased risk for allograft rejection and graft loss associated with interferon-α therapy. With the advent of the new direct-acting antiviral agents, patients with evidence of post-transplant reactivation of hepatitis C should be referred to a hepatologist for consideration for interferon-free anti-HCV protease inhibitor therapy. A suggested algorithm for the management of kidney transplant recipients with elevated liver enzymes is shown in Fig. 106.4.

BONE AND MINERAL METABOLISM AFTER KIDNEY TRANSPLANTATION

Post-transplantation bone disease is a common and complex complication after kidney transplantation because of the adverse effects of immunosuppression (particularly corticosteroids), hypophosphatemia, and disturbances in the FGF-23–PTH–vitamin D axis. Corticosteroids act on the skeletal system by directly inhibiting osteoblastogenesis and inducing apoptosis of osteoblasts and osteocytes and by increasing bone resorption through osteoclast activation. Other adverse effects of corticosteroids on bone mechanical integrity include inhibition of

intestinal calcium absorption, enhancement of renal calcium excretion, and direct suppression of gonadal hormone secretion. Low plasma calcidiol 25(OH) vitamin D level also may contribute to bone disease and is very common in kidney transplant recipients, with a reported prevalence of calcidiol deficiency of 30% and insufficiency of 81%. Suggested causative factors include nutritional deficiency, malabsorption, decreased sun exposure, and increased metabolism of calcidiol to calcitriol after a successful kidney transplant.

Other factors that have been suggested to contribute to post-transplantation bone loss include "normal" age-dependent osteoporosis, persistent metabolic acidosis, phosphate depletion, DM, hypogonadism, smoking, and CNI therapy. Experimental animal models suggest that CNIs may contribute to post-transplantation bone loss by stimulating bone resorption. Limited clinical studies demonstrated that CNI-based immunosuppression with low maintenance doses of corticosteroids induced slight bone formation but relatively potent, clinically relevant bone resorption. Nonetheless, the contributory role of CNIs in causing bone loss in kidney transplant recipients may be difficult to evaluate because of concomitant corticosteroid therapy. In a prospective study of 53 kidney transplant recipients randomly assigned to cyclosporine alone (n = 13), cyclosporine plus steroids (n = 20), or cyclosporine plus steroids plus azathioprine (n = 20), lumbar bone mineral density (BMD) increased significantly from transplant to 18 months after transplant among patients on steroid-free immunosuppression. In contrast, BMD significantly decreased among the two steroid-treated groups during the study period.[39]

Experimental studies suggest that mTOR inhibitors may have a bone-sparing effect. Sirolimus may interfere with the proliferation and differentiation of osteoblasts, and, more important, it may inhibit osteoclast formation. One small European study showed that sirolimus decreased serum level of bone resorption markers in patients treated with sirolimus compared with those receiving a CNI-based regimen.[40]

Osteoporosis

Post-transplantation decline in BMD is most pronounced in the first 6 months and correlates with higher corticosteroid exposure. This early rapid decrease in BMD is usually followed by a slower rate of bone loss, which reflects cumulative corticosteroid dose. BMD has been reported to decrease at a mean of 5.5% to 19.5% during the first 6 months after transplant, 2.6% to 8.2% from months 6 to 12, and 0.4% to 4.5% thereafter.[41] In recent years, the rates of post-transplantation bone loss and fractures appear to have decreased, in part, because of the use of lower corticosteroid doses or glucocorticoid-sparing regimen.[42]

Evaluation of patients for bone loss or osteoporosis relies on the measurement of BMD using dual-energy x-ray absorptiometry (DEXA) scan. The preliminary, revised 2016 KDIGO guidelines suggest BMD testing to assess fracture risk in kidney transplant recipients with CKD stage 1 to 5T (T indicating transplant patient) and risk factors for osteoporosis if the results alter therapy. Studies in the general population and limited studies in the transplant setting suggest that DEXA BMD predicts fractures across the spectrum of CKD severity. One retrospective cohort study of 238 kidney transplant recipients with CKD stage 1 to 5T demonstrated that osteopenia (HR 2.7, 95% confidence interval [CI] 1.6-4.6) and osteoporosis (HR 3.5, 95% CI 1.8-6.4) were associated with significantly increased hip fracture risk compared with normal BMD, independent of age, gender, and diabetes.[43] The mean eGFR at the time of DEXA testing was 48 ml/min (range 12 to 98 ml/min).

In patients with low BMD in the first 12 months after transplant, the KDIGO guidelines suggest that consideration should be given to treatment with vitamin D, calcitriol or alfacalcidol, or biphosphonates. The levels of calcium, phosphorus, PTH, alkaline phosphatase, and 25(OH) D may dictate the choice of therapy. Bone biopsy may be considered to guide treatment. Currently, data are insufficient to guide treatment after the first post-transplant year. Large prospective studies in kidney transplant recipients with CKD stages 1 to 5T to evaluate the utility of BMD testing and bone biomarkers as predictors of fractures are needed.

Avascular Necrosis

Post-transplantation avascular necrosis (AVN) occurs with an incidence of 3% to 16% and most commonly affects the femoral head and neck. Its prevalence appears to have decreased over the past two decades concomitant with the use of lower corticosteroid dose and rapid steroid tapering. AVN usually occurs within the first few years after transplantation and may affect other joints, including the knees, the shoulders, and less commonly the ankles, elbows, and wrists. Predisposing factors for AVN include greater exposure to intravenous corticosteroid pulse therapy, cumulative doses of more than 2 g for longer than 3 months,[42] low bone mass, hyperparathyroidism, increasing dialysis duration, excessive weight gain, hyperlipidemia, microvascular thrombosis, and a history of local trauma.

Early AVN of the femoral head commonly presents with hip or groin pain or referred knee pain. Magnetic resonance imaging is the most sensitive technique for early detection, and plain radiographs are of limited value. Corticosteroid dose reduction or discontinuation has little if any effect on altering the course of established AVN and may jeopardize graft function.

Prevention and Management of Post-Transplantation Bone Diseases

Management of post-transplantation bone disease has largely been based on studies involving postmenopausal osteoporosis and corticosteroid-induced osteopenia in nontransplant settings. Limited studies in solid organ transplantation have yielded variable and conflicting results, in part because of the complex pathophysiology of bone and mineral metabolism after transplantation, particularly in recipients of kidney transplants. Nonetheless, preventive measures to minimize post-transplantation bone loss should be initiated early after transplantation. Early ambulation and physical exercise should be encouraged. Adequate calcium supplementation (1000 mg/day) in nonhypercalcemic patients is recommended in the first post-transplantation year to prevent rapid bone loss resulting from corticosteroid-induced decreased intestinal calcium absorption. The KDIGO practice guidelines recommend measuring calcidiol levels and correcting vitamin D deficiency and insufficiency with use of treatment strategies recommended for the general population. In patients at increased risk for fracture, consideration should be given to rapid corticosteroid withdrawal or corticosteroid-free immunosuppressive protocols after weighing the risks and benefits of acute rejection. High pretransplantation PTH levels predict persistent hyperparathyroidism after transplantation, which may contribute to bone loss after transplantation. Hence, preexisting hyperparathyroidism associated with CKD should be treated according to the KDIGO guidelines.

In patients with preexisting secondary hyperparathyroidism, hypercalcemia and hypophosphatemia may develop after a successful kidney transplant because of the combined effect of persistent hyperparathyroidism and the newly elevated calcitriol level. The contributory role of FGF-23 in the development of post-transplant hypophosphatemia was previously discussed. Conservative management with phosphate replacement and suppression of hyperparathyroidism with cinacalcet has generally been recommended. Although no guidelines exist, phosphate supplementation should be considered in patients with a phosphate level of 1.5-1.7 mg/dl or less (0.5 mmol/l) to avoid complications associated with severe hypophosphatemia (e.g., rhabdomyolysis, left ventricular dysfunction, respiratory muscle weakness, and hemolysis). Treatment range may vary depending on institutional reference range. Patients

should be encouraged to increase phosphate-rich food intake, and phosphate replacement should be discontinued when serum phosphate stabilizes at around 2.0 mg/dl (0.64 mmol/l). Overaggressive phosphate replacement is not recommended because it can result in hypocalcemia or persistent hyperparathyroidism and may increase the risk for nephrocalcinosis.

Bisphosphonates increase BMD in postmenopausal women and patients with corticosteroid-induced osteoporosis, particularly at the lumbar spine and trochanter. Studies evaluating the safety and efficacy of bisphosphonates in the treatment and prevention of bone disease after kidney transplantation have yielded mixed and even contradictory results, in part because of differences in study design, concomitant use of calcium or vitamin D, timing of treatment, duration of follow-up, and preexisting renal osteodystrophy, among others. The beneficial effect of bisphosphonates on BMD may be site-specific (e.g., lumbar spine and femoral neck but not hip) and gender-specific. In a single-center study of 42 living donor kidney recipients randomized to receive either 35 mg of risedronate weekly or placebo for 12 months, treatment with risedronate did not affect bone BMD in the overall cohort. However, subgroup analyses demonstrated a trend toward preservation of BMD in female but not male subjects. Protocol bone biopsy at the time of transplant and after 12 months of treatment showed no evidence for the development of adynamic bone disease.[44] In contrast, other studies have shown that bisphosphonate therapy significantly increases the risk for developing low-turnover bone disease. In a study of 72 kidney transplant recipients randomized to receive either pamidronate with vitamin D and calcium or vitamin D and calcium only (control group), preservation of bone mass was observed in pamidronate-treated patients at 6 and 12 months, whereas decreased vertebral BMD was seen in the control group during the study period. Bone biopsy in patients undergoing scheduled living donor kidney transplant revealed that 50% of the patients had low turnover bone at baseline. At 6-months, bone biopsy demonstrated adynamic bone disease in all pamidronate-treated patients compared with 50% in the control group[45] Whether an improved BMD with adynamic bone histology is useful in maintaining long-term bone health or reducing fracture risk in kidney transplant recipients remains to be studied.

Calcitonin inhibits osteoclastic action by a direct receptor-mediated signal. Similar to bisphosphonates, calcitonin is effective in postmenopausal patients as well as patients with corticosteroid-induced osteoporosis. The beneficial effects of calcitonin on bone loss have not consistently been shown in the transplant setting. Furthermore, calcitonin has no effect on fracture risk in kidney transplant recipients. Data are currently insufficient to recommend or refute the use of calcitonin in kidney transplant recipients.

Estrogen or androgen deficiencies also have been suggested to contribute to post-transplantation bone loss. However, no data support or refute the use of hormonal therapy to prevent post-transplantation–related bone loss in postmenopausal women or in men with hypogonadism; hence, treatment should be individualized.

The 2007 Cochrane Database Systematic Review of RCTs showed that no individual therapy (bisphosphonates, vitamin D sterol, or calcitonin) reduced fracture risk compared with placebo in RCTs. However, meta-analysis of all such trials combined demonstrated that any treatment (i.e., bisphosphonates by any route, vitamin D sterol, or calcitonin) was associated with a reduction in the relative risk of fracture (RR 0.51, 95% CI 0.27-0.99). A beneficial effect on lumbar spine BMD was seen with all individual agents. Bisphosphonates and vitamin D sterol also had a beneficial effect on the BMD at the femoral neck. It is suggested that treatment with a bisphosphonate, vitamin D sterol, or calcitonin after kidney transplantation may protect against immunosuppression-induced reductions in BMD and prevent fracture.[46,47] Few or no data were available for combined hormone replacement, testosterone, selective estrogen receptor modulators, fluoride, or anabolic steroids.

Denosumab is a humanized monoclonal antibody that binds to and prevents RANKL (receptor activator of nuclear factor kappa-β ligand) from activating its receptor (RANK) on the surface of osteoclasts and their precursors. Denosumab has been shown to increase BMD and decrease fracture risk in postmenopausal women and is approved by the U.S. Food and Drug Administration (FDA) for the treatment of postmenopausal osteoporosis. Limited studies in kidney transplant recipients suggest that denosumab in combination with calcium and vitamin D may improve BMD compared with calcium and vitamin D alone.[48]

In summary, calcium supplementation, vitamin D, and bisphosphonates remain the backbone of treatment of abnormal bone and mineral metabolism after kidney transplantation. Persistent hyperparathyroidism or hypophosphatemia should be treated before considering additional therapies for osteoporosis. In the absence of evidenced-based recommendations, the use of bisphosphonates in the post-transplantation setting should be individualized. In our opinion, bisphosphonate therapy may be justifiable in high-risk individuals, including those with preexisting osteoporosis or documented overall low bone mass, those who are receiving high-dose corticosteroids or those with history of fractures, and those who are postmenopausal. Biphosphonates should be used with caution in patients with impaired kidney function and avoided in CKD stages 4 to 5. Biochemical markers of low bone turnover (serum PTH and bone-specific alkaline phosphatase levels below or at the lower limits of normal) may be used to guide therapy. In high-risk individuals who are intolerant of bisphosphonates, calcitonin, or denosumab can be used as an alternative treatment option. Profound hypocalcemia associated with the use of denosumab particularly in patients with low GFR has been reported and should not be overlooked.

GOUT

Potential risk factors for the development of post-transplantation hyperuricemia and gouty arthritis include pretransplantation hyperuricemia, graft impairment, obesity, diuretic use, and cyclosporine compared with tacrolimus. Cyclosporine has been suggested to impair renal excretion of uric acid secondary to decreased GFR, as well as increased net uric acid reabsorption by the proximal tubule.

Management of the acute gouty attack includes topical ice and rest of the inflamed joint. Pharmacologic treatments include colchicine, increased corticosteroid dose, or nonsteroidal antiinflammatory drugs (NSAIDS). The use of NSAIDS, however, should be avoided in the early post-transplant period and in patients with impaired allograft function. Temporary increase in corticosteroid dose is usually safe and effective (our experience). Progressive steroid tapering to low-dose maintenance antirejection therapy (usually over a 2- to 3-week period) is recommended to prevent rebound gout flare.

Management of chronic gout is directed at lowering uric acid levels. Allopurinol, a xanthine oxidase inhibitor, should be started at a low dose (100 to 200 mg/day), particularly in the presence of impaired allograft function, because renal impairment predisposes to severe allopurinol toxicity from retention of the metabolite oxypurinol. The dose can be increased by 50-mg increment (adjusted for renal function) every 4 weeks to maintain uric acid level below 6 mg/dl in symptomatic patients. We do not routinely recommend allopurinol therapy in asymptomatic patients based on uric acid level alone. In allopurinol-allergic patients, febuxostat (a nonpurine analogue xanthine oxidase inhibitor) can be used. It is administered as 40 or 80 mg/day, and the dosage is not modified in renal failure. Both allopurinol and febuxostat should be used cautiously in patients taking azathioprine because of the

inhibition of azathioprine metabolism by xanthine oxidase inhibitors (e.g., when used in combination therapy with allopurinol or febuxostat, consider azathioprine dose reduction by 25% and close monitoring of complete blood counts). Alternatively, azathioprine to mycophenolic acid derivative conversion therapy may be considered. The latter does not interact with allopurinol or febuxostat. Recombinant pegylated uricase (pegloticase), which converts uric acid to the more soluble and readily excreted purine end-product allantoin, rapidly reduces uric acid levels in patients refractory to conventional therapy. The drug was approved by the FDA in 2010 for treatment of refractory gout. However, the development of high titers of antibodies to pegloticase is associated with loss of efficacy and infusion reactions.[49] Whether immunosuppressive therapy in the transplant settings might prevent antipegloticase antibody development and retain the urate-lowering efficacy among organ transplant recipients warrants further exploration.

OUTPATIENT CARE

We recommend that patients be seen two times a week for the first 4 weeks after transplantation and weekly for the next month. After the first 2 months, the frequency of outpatient visits depends on the complexity of the patient's early postoperative course. Patients with stable graft function and an uneventful postoperative course can return to work or their regular daily activities 2 to 3 months after transplantation. Laboratory assessment during the first month after transplantation should include serum creatinine and electrolyte values, fasting glucose level, liver enzymes, immunosuppressive drug levels, and complete blood count with platelets. Urinalysis and, if clinically indicated, urine culture, and urine protein-to-creatinine ratio (see proteinuria section) also should be performed. At our institution, the patient's care will generally be returned to the referring nephrologist after 3 months. However, continued annual follow-up at the transplantation center is recommended.

SELF-ASSESSMENT QUESTIONS

1. Management of post-transplantation hypertension should include lifestyle modifications and which one of the following?
   - **A.** An angiotensin-converting enzyme (ACE) inhibitor is the antihypertensive agent of choice after kidney transplantation because it improves patient and graft survival.
   - **B.** The choice of antihypertensive agents should be individualized based on efficacy, tolerability, concomitant comorbidity, and drug-drug interactions.
   - **C.** The Kidney Disease: Improving Global Outcomes (KDIGO) guidelines suggest a blood pressure goal of less than 130/80 if albuminuria is present.
   - **D.** Calcium channel blockers should be considered as first-line treatment.
2. Which one of the following statements regarding post-transplantation dyslipidemia is correct?
   - **A.** The addition of ezetimibe to statin therapy reduces cardiovascular events compared with statin alone therapy.
   - **B.** Fibrate should be considered as a second-line treatment option for high-risk kidney transplant recipients who are intolerant of statin.
   - **C.** Ezetimibe should be considered as a second-line treatment option for high-risk kidney transplant recipients who are intolerant of statin.
   - **D.** Among currently available immunosuppressive agents, calcineurin inhibitors are associated with the worst lipid profiles followed by mTOR inhibitors.
3. Which one of the following immunosuppressive agents has not been shown to play a contributory role in the development of post-transplantation diabetes mellitus?
   - **A.** mTOR inhibitors (sirolimus and everolimus)
   - **B.** Mycophenolic acid derivatives (mycophenolate mofetil or mycophenolate sodium)
   - **C.** Calcineurin inhibitors (cyclosporine and tacrolimus)
   - **D.** Corticosteroids

Chronic Allograft Injury

Christian Morath, Martin Zeier

DEFINITIONS AND EPIDEMIOLOGY

The results after kidney transplantation have steadily improved over the last 30 years with a 1-year overall graft survival rate of about 94% and acute rejection rates within the first year after transplantation at 12%.[1] Loss of an allograft as a result of acute rejection has become a rare event and is predominantly found in patients who are presensitized against human leukocyte antigens (HLAs).[2] Today, most allografts are lost by chronic antibody-mediated rejection that is a consequence of (*de novo*) development of donor-specific HLA antibodies (DSAs). Every year, about 4% of kidney grafts are lost (Fig. 107.1). Only a decade ago, it was believed that nonimmunologic causes are the main factors leading to chronic allograft injury and graft loss.[3] However, our understanding has changed and HLA alloantibodies are today believed to be the main culprit, accounting for more than half of graft losses in the long term.[4] With the acknowledgment of alloantibodies as main factors that contribute to graft failure the term *chronic allograft nephropathy* had been replaced by more specific terminology in the Banff classification of renal allograft pathology (Table 107.1).[5,6]

Although immunologic causes are now believed to be mainly responsible for late allograft injury and graft failure, nonimmunologic causes still represent significant risk factors for (late) graft injury and graft loss. The donor graft may present with significant preexisting disease limiting long-term graft survival.[7] In addition, chronic interstitial fibrosis and tubular atrophy (IFTA) may result from early damage to the allograft such as ischemia/reperfusion injury or early acute rejection. Calcineurin-inhibitor (CNI) nephrotoxicity, recurrent or *de novo* glomerular disease, BK virus infection, and IFTA originating from other causes further contribute to graft damage and graft loss over the long term.

Whereas some allografts are lost because of one specific cause, others accumulate damage from several different causes with gradual loss of functioning nephrons. Main contributors to late graft injury and late graft loss are summarized in Box 107.1.

PATHOGENESIS: NONIMMUNOLOGIC FACTORS

Donor Age, Donor Gender, and Donor-Recipient Size Mismatching

Long-term graft survival is reduced in kidneys from older donors, an effect that is more pronounced in deceased compared with living kidney transplant recipients.[8] Impaired graft survival is attributed to a differential response of the older organ to injury, an impaired capacity to withstand stress, a limited ability to repair structural damage, or amplification of external injury as a result of preexisting structural abnormalities.[9]

Reduced nephron mass resulting in glomerular hyperfiltration and hypertension with accelerated senescence is also a postulated mechanism for a progressive decline in kidney graft function.[10] The effect of kidney size mismatching is thought to be related to insufficient numbers of nephrons within the donor kidney, which in turn leads to compensatory hyperfiltration.[11] Although there are experimental data to support this hypothesis, the extent to which an inadequate number of nephrons contributes to chronic injury in clinical transplantation is unknown.

Female donor gender has a negative impact on kidney graft survival, with reduced survival when female grafts are transplanted into male recipients (risk ratio, 1.22). This may be the result of reduced nephron mass of female donor kidneys (nephron underdosing). Other mechanisms may include possible differences in the immunogenicity of male and female grafts.[12,13]

Ischemia/Reperfusion Injury and Delayed Graft Function

Graft survival is lower in recipients with longer ischemia times, and longer cold ischemia time represents a risk factor for the development of IFTA at 6 months after transplantation.[14] Ischemia-reperfusion injury also may trigger immune-mediated injury because ischemia and oxidative injury resulting from reperfusion are associated with activation of the adaptive immune response, antigen-presenting cells and Toll-like receptors, and release of proinflammatory cytokines—all of which can lead to acute rejection and subsequent IFTA.[15] Pretreatment of the deceased organ donor with low-dose dopamine (aiming to reduce ischemia/reperfusion injury) reduced the need for dialysis early after kidney transplantation but failed to improve long-term kidney graft survival.[16,17] Similarly, therapeutic hypothermia compared with normothermia of the deceased organ donor was associated with reduced delayed graft function in the kidney transplant recipient (28% vs. 39%).[18] Another promising approach to reduce ischemia/reperfusion injury and improve early kidney graft function is the replacement of cold storage of kidneys by pulsatile machine perfusion during transportation that is currently being tested in clinical trials.

Delayed graft function, commonly defined by the need for dialysis in the first week after transplantation, is a risk factor for IFTA.[19] There are also independent associations between delayed graft function and late graft failure and between delayed graft function and graft failure that is mediated by acute rejection. Major risk factors for delayed graft function are prolonged cold ischemia time, donor age older than 50 years, and the presence of HLA alloantibodies.[2] Ischemia and oxidative injury resulting from reperfusion of an ischemic kidney may cause an upregulation of major histocompatibility complex (MHC) antigens or proinflammatory cytokines, predisposing to acute rejection.

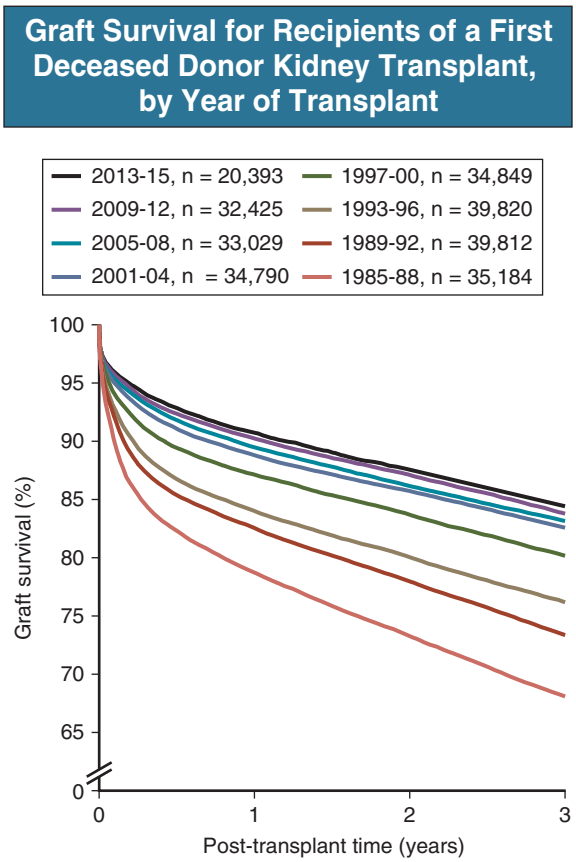

Fig. 107.1 Graft survival for recipients of a first deceased donor kidney transplant according to the year of transplantation. Graft survival has steadily improved over the past years but mainly as a result of reduction of early graft loss. (With permission from Prof. Gerhard Opelz, CTS Study).

BOX 107.1 Main Factors Contributing to Late Graft Injury and Late Graft Loss

Donor Factors
- Deceased donor kidney (DBD or DCD)
- Older donor age, female donor
- Donor vascular disease
- Ischemia/reperfusion injury and long ischemia time
- Delayed graft function

Recipient Risks (Nonimmune)
- Obesity
- Urinary tract infection
- Transplant ureteral obstruction
- BK virus nephropathy
- Calcineurin inhibitor toxicity
- Recurrent renal disease or *de novo* glomerulonephritis
- Hypertension, dyslipidemia, smoking
- Diabetes (preexisting or post-transplantation)

Recipient Risks (Alloimmune)
- Child or adolescent recipient
- Variable medication trough concentrations from malabsorption or nonadherence
- HLA mismatches, presensitization status (donor-specific HLA alloantibodies)
- Acute rejection that is severe, corticosteroid resistant, vascular, antibody mediated, or late occurring
- Late *de novo* donor-specific antibodies and chronic (antibody-mediated) rejection

DBD, Donation after brain death; *DCD,* donation after cardiac death; *HLA,* human leukocyte antigen.

BK Virus Nephropathy

BK virus is an endemic polyomavirus that is usually acquired during childhood and persists in the urinary tract. Although it is asymptomatic in the immunocompetent host, it becomes activated in the immunocompromised patient. Viremia may be found in 10% to 30% of patients within the first 6 months after transplantation with biopsy-proven BK virus–associated nephropathy in 1% to 10% of patients. BK virus–associated nephropathy mimics the pattern of interstitial cellular rejection but may be distinguished in immunohistochemistry by positive staining for the SV40 antigen. BK virus–associated nephropathy, if untreated, may lead to severe IFTA and graft loss in most patients. The mainstay of therapy is the reduction of immunosuppression.[20] The diagnosis and management of BK virus nephropathy are discussed further in Chapter 105.

Calcineurin Inhibitor Toxicity

CNI nephrotoxicity affects all histologic compartments of the transplanted kidney. Though not specific for CNI toxicity, CNI lesions include medial arteriolar hyalinosis, striped interstitial fibrosis, global glomerulosclerosis, and tubular microcalcification unrelated to other causes, such as tubular necrosis and hyperparathyroidism.[21,22] CNI-induced arteriolopathy is characterized by nodular hyaline deposits in the media of afferent arterioles sufficient to cause narrowing of the vascular lumen.[23,24] It is attributed to eosinophilic transformation and vacuolization of smooth muscle cells with subsequent necrosis. Arteriolar hyalinosis is the most reliable diagnostic marker of CNI nephrotoxicity. Confirmation of the diagnosis is made by exclusion of other causes, such as donor hyalinosis (which can be detected on the implantation biopsy specimen), diabetes, and hypertensive nephrosclerosis. Striped fibrosis is subjectively defined by a dense stripe of cortical fibrosis and atrophic tubules adjacent to normal cortex and is traditionally regarded as pathognomonic of CNI nephrotoxicity, but can be seen in any cause of fibrosis, especially those associated with microvascular injury. It is likely that the associated arteriolopathy and narrowing of the lumen contribute to development of fibrosis and atrophy after watershed infarcts within areas of ischemia. Local hypoxia leads to formation of free oxygen radicals, which promote cellular death by apoptosis. In addition, upregulation of transforming growth factor-β is considered an important etiologic factor in CNI toxicity.[22]

Today, CNI nephrotoxicity is believed to be responsible for only a small proportion of graft failures. The Study of Long-term Deterioration of Kidney Allograft Function (DeKAF) impressively demonstrated that 70% of patients with a primary or secondary histologic diagnosis of CNI nephrotoxicity had evidence of deposition of the complement split-product C4d and had DSA linking chronic graft failure to alloimmunity rather than CNI nephrotoxicity.[25,26]

Recurrent and *De Novo* Glomerular Diseases

Recurrent glomerulonephritis (GN) is diagnosed by exclusion of donor-transmitted disease and *de novo* GN. Its relative importance for graft loss increases as graft survival lengthens.[27] Given that it is a relatively common occurrence and has implications for treatment and retransplantation, recurrent GN should be looked for carefully in patients with a prior diagnosis of GN. Diagnosis and management of recurrent disease are discussed further in Chapter 108.

TABLE 107.1 Updated 2015 Banff Classification Categories

Category 1: Normal biopsy or nonspecific changes	
Category 2: Antibody-mediated changes	
Acute/active ABMR	All three features must be present for diagnosis. Biopsy samples showing histologic features plus evidence of current/recent antibody interaction with vascular endothelium or DSA, but not both, may be designated as suspicious for acute/active ABMR. Lesions may be clinically acute or smoldering or may be subclinical; it should be noted if the lesion is C4d positive or C4d negative, based on the following criteria: 1. Histologic evidence of acute tissue injury, including one or more of the following: • Microvascular inflammation (g >0 in the absence of recurrent or *de novo* glomerulonephritis and/or ptc >0) • Intimal or transmural arteritis (v >0)* • Acute TMA in the absence of any other cause • Acute tubular injury in the absence of any other apparent cause 2. Evidence of current/recent antibody interaction with vascular endothelium, including at least one of the following: • Linear C4d staining in peritubular capillaries (C4d2 or C4d3 by IF on frozen sections or C4d >0 by IHC on paraffin sections) • At least moderate microvascular inflammation ([g + ptc] ≥2), although in the presence of acute TCMR, borderline infiltrate, or infection; ptc ≥2 alone is not sufficient, and g must be ≥1 • Increased expression of gene transcripts in the biopsy tissue indicative of endothelial injury, if thoroughly validated 3. Serologic evidence of DSAs (HLA or other antigens) • Biopsies suspicious for ABMR on the basis of meeting criteria 1 and 2 should prompt expedited DSA testing
Chronic active ABMR†	All three features must be present for diagnosis. As with acute/active ABMR, biopsy samples showing histologic features plus evidence of current/recent antibody interaction with vascular endothelium or DSA, but not both, may be designated as suspicious, and it should be noted if the lesion is C4d positive or C4d negative, based on the criteria listed: 1. Histologic evidence of chronic tissue injury, including one or more of the following: • TG (cg >0), if no evidence of chronic TMA; includes changes evident by EM only (cg1a; Table 4) • Severe peritubular capillary basement membrane multilayering (requires EM)‡ • Arterial intimal fibrosis of new onset, excluding other causes; leukocytes within the sclerotic intima favor chronic ABMR if there is no history of biopsy-proven TCMR with arterial involvement but are not required 2. Evidence of current/recent antibody interaction with vascular endothelium, including at least one of the following: • Linear C4d staining in peritubular capillaries (C4d2 or C4d3 by IF on frozen sections, or C4d >0 by IHC on paraffin sections) • At least moderate microvascular inflammation ([g + ptc] ≥2), although in the presence of acute TCMR, borderline infiltrate, or infection, ptc ≥2 alone is not sufficient and g must be ≥1 • Increased expression of gene transcripts in the biopsy tissue indicative of endothelial injury, if thoroughly validated 3. Serologic evidence of DSAs (HLA or other antigens): • Biopsy results suspicious for ABMR on the basis of meeting criteria 1 and 2 should prompt expedited DSA testing
C4d staining without evidence of rejection	All three features must be present for diagnosis§: 1. Linear C4d staining in peritubular capillaries (C4d2 or C4d3 by IF on frozen sections, or C4d >0 by IHC on paraffin sections) 2. g = 0, ptc = 0, cg = 0 (by light microscopy and by EM if available), v = 0; no TMA, no peritubular capillary basement membrane multilayering, no acute tubular injury (in the absence of another apparent cause for this) 3. No acute cell-mediated rejection (Banff 1997 type 1A or greater) or borderline changes
Category 3: Borderline changes suspicious for acute TCMR	• Foci of tubulitis (t1, t2, or t3) with minor interstitial inflammation (i0 or i1) or interstitial inflammation (i2, i3) with mild (t1) tubulitis; retaining the i1 threshold for borderline from Banff 2005 is permitted, although this must be made transparent in reports and publications • No intimal arteritis (v = 0)

TABLE 107.1 Updated 2015 Banff Classification Categories—cont'd

Category 4: TCMR	
Acute TCMR	IA. Significant interstitial inflammation (>25% of nonsclerotic cortical parenchyma, i2 or i3) and foci of moderate tubulitis (t2) IB. Significant interstitial inflammation (>25% of nonsclerotic cortical parenchyma, i2 or i3) and foci of severe tubulitis (t3) IIA. Mild to moderate intimal arteritis (v1) with or without interstitial inflammation and tubulitis IIB. Severe intimal arteritis comprising >25% of the luminal area (v2) with or without interstitial inflammation and tubulitis III. Transmural arteritis and/or arterial fibrinoid change and necrosis of medial smooth muscle cells with accompanying lymphocytic inflammation (v3)
Chronic active TCMR	Chronic allograft arteriopathy (arterial intimal fibrosis with mononuclear cell infiltration in fibrosis, formation of neointima); note that such lesions may represent chronic active ABMR as well as TCMR; the latter also may be manifest in the tubulointerstitial compartment
Category 5: Interstitial fibrosis and tubular atrophy (IFTA)	Grade I. Mild interstitial fibrosis and tubular atrophy (≤25% of cortical area) II. Moderate interstitial fibrosis and tubular atrophy (26%-50% of cortical area) III. Severe interstitial fibrosis and tubular atrophy (>50% of cortical area)
Category 6: Other changes not considered to be caused by acute or chronic rejection	BK virus nephropathy Post-transplant lymphoproliferative disorders Calcineurin inhibitor nephrotoxicity Acute tubular injury Recurrent disease *De novo* glomerulopathy (other than transplant glomerulopathy) Pyelonephritis Drug-induced interstitial nephritis

From reference 5.

*These arterial lesions may be indicative of ABMR, TCMR, or mixed ABMR/TCMR. The v lesions are scored in arteries only having a continuous media with two or more smooth muscle layers.

†Lesions of chronic, active ABMR can range from primarily active lesions with early TG evident only by EM to those with advanced TG and other chronic changes in addition to active microvascular inflammation. In the absence of evidence of current/recent antibody interaction with the endothelium (those features in the second section of Table 3), the term "active" should be omitted; in such cases, DSAs may be present at the time of biopsy or at any previous time after transplantation.

‡Seven or more layers in one cortical peritubular capillary and five or more in two additional capillaries, avoiding portions cut tangentially.

§The clinical significance of these findings may be quite different in grafts exposed to anti–blood group antibodies (ABO-incompatible allografts), in which they do not appear to be injurious to the graft and may represent accommodation; however, with anti-HLA antibodies, such lesions may progress to chronic ABMR and more outcome data are needed.

ABMR, Antibody-mediated rejection; *cg,* glomerular double contours; *DSA,* donor-specific antibody; *EM,* electron microscopy; g, glomerulitis; i, inflammation; IF, immunofluorescence; IHC, immunohistochemistry; *ptc,* peritubular capillaritis; *t,* tubulitis; *TCMR,* T cell–mediated rejection; *TG,* transplant glomerulopathy; *TMA,* thrombotic microangiopathy; *v,* intimal arteritis.

Cardiovascular Risk Factors

The vasculopathy in chronic allograft injury resembles systemic vascular disease, raising the possibility that conventional cardiovascular disease risk factors may be implicated. Hypertension occurs in about 70% to 90% of transplant recipients and predisposes to graft failure.[28] Dyslipidemias, including raised total cholesterol, low-density lipoprotein cholesterol, and triglycerides, and cigarette smoking have also been associated with late graft failure. The management of CV risk factors in the transplant recipient is discussed in Chapter 106.

PATHOGENESIS: IMMUNOLOGICAL FACTORS

T Cell–Mediated Rejection

Acute T cell–mediated rejection, vascular or corticosteroid-resistant rejection, subclinical rejection, and late (chronic-active) T cell–mediated rejection all contribute to the burden of chronic allograft injury. Early acute T cell–mediated rejection (within 3 months of transplantation) that is adequately diagnosed and treated usually has no impact on long-term graft survival. But late chronic-active T cell–mediated rejection in which serum creatinine does not return to baseline usually translates into IFTA and/or vascular damage, contributing to graft injury. Multiple and severe late acute T cell–mediated rejection episodes are predictive of chronic graft dysfunction more than early cellular rejection and acute vascular rejection, which have stronger associations with acute graft loss.[29] There is some evidence from protocol biopsy studies that subclinical T cell–mediated rejection may be an important factor contributing to chronic graft injury.[30,31]

Besides the direct effects of T cell–mediated rejection on graft function, acute T cell–mediated rejection may be linked to the development of DSA and subsequent antibody-mediated rejection.[32]

Antibody-Mediated Rejection

Chronic antibody-mediated rejection is a leading cause of graft loss, together with death with a functioning graft, recurrent renal disease, and IFTA of unknown origin.[33]

For the diagnosis of antibody-mediated kidney graft rejection, histologic features of antibody-mediated rejection in the biopsy sample (Figs. 107.2 to 107.4), together with evidence of current or recent antibody

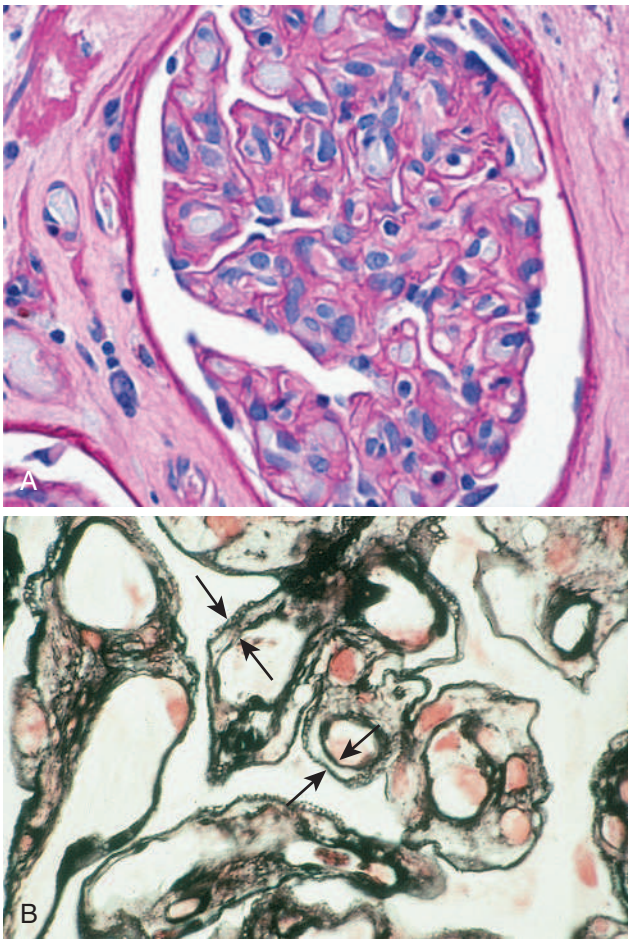

Fig. 107.2 Transplant glomerulopathy: light microscopy. (A) Note the mesangial expansion and thickening of the glomerular basement membrane (GBM). (B) Note the GBM reduplication in capillary loops *(between arrows).*

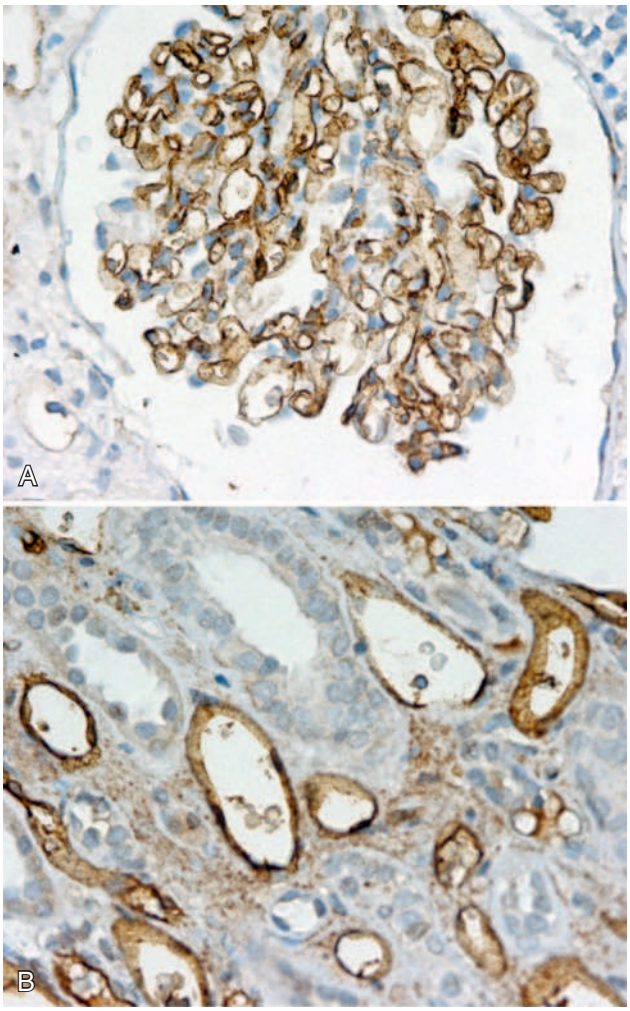

Fig. 107.3 C4d immunoperoxidase staining in association with chronic antibody-mediated rejection. Staining of glomerular capillaries (A) and circumferential staining of peritubular capillaries (B) are typical.

interaction with the vascular endothelium (see Fig. 107.3) and the detection of circulating DSA (either HLA or non-HLA) are required. Because C4d in peritubular capillaries is not detectable in more than 50% of patients with chronic antibody-mediated rejection, C4d-positivity is no longer a prerequisite for the diagnosis of antibody-mediated rejection.[6] This finding, together with the observation that chronic antibody-mediated rejection may occur in the absence of complement activation (e.g., the occurrence of transplant glomerulopathy in patients during effective therapeutic complement inhibition by eculizumab) led to the hypothesis that complement-independent mechanisms such as direct endothelial cell activation and infiltration of natural killer (NK) cells or monocytes may contribute to chronic antibody-mediated allograft injury. C4d-negative antibody-mediated rejection shares the same histologic and ultrastructural features as C4d-positive rejection. To improve the diagnosis of antibody-mediated rejection, a molecular microscope strategy was adopted in the 2013 update of the Banff classification.[34] This means that in the absence of C4d positivity or microvascular inflammation, antibody interaction with the vascular endothelium is also suggested by detection of an increased expression of specific gene transcripts in the biopsy tissue indicative of endothelial injury (the "molecular microscope"), though this approach still needs further validation.

Unrecognized DSAs, if strongly reactive and complement-activating, can cause hyperacute rejection or accelerated antibody-mediated rejections in the early phase after kidney transplantation. Acute antibody-mediated rejection in the early phase occurs in about 1% to 6% of patients overall, but in as much as 21% to 55% in patients who had detectable DSAs already before transplantation and who received desensitization therapy.[35-37] Weakly positive DSAs have been associated with rather subtle types of graft damage, often leading to delayed graft function.[2] Early damage can lead to chronic rejection, most probably because the structure of the endothelium is no longer intact and new antigenic epitopes are expressed on the surface of transplanted tissue. During later phases after transplantation, insufficient immunosuppression can facilitate the development of *de novo* DSAs against these new epitopes and result in chronic antibody-mediated rejection and failure of the transplanted organ. *De novo* DSAs, but to a lesser extent also persistence or reemergence of DSAs that were detectable before transplantation, are associated with poor allograft outcome.

Chronic antibody-mediated rejection is found more frequently in patients who are nonadherent to immunosuppressive medication or in whom immunosuppression was reduced for other reasons, such as conversion to CNI-free or steroid-free immunosuppressive protocols, recurrent infection, or malignancy.[38-40] In these patients, antibody-mediated lesions and T cell–mediated lesions are often found in kidney graft biopsy samples at the same time. Additional risk factors for the development of *de novo* DSAs and antibody-mediated rejection are HLA class II DR mismatches between donor and recipient, prior cellular

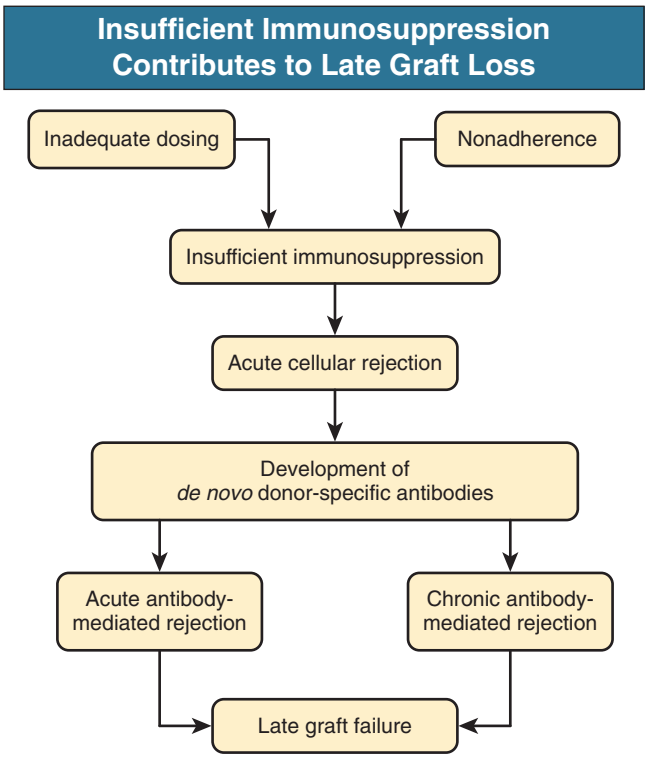

Fig. 107.5 Insufficient immunosuppression contributes to late graft loss.

rejection episodes and younger recipient age. In many patients with late antibody-mediated graft loss, even when HLA class I alloantibodies are detectable, HLA class II *de novo* DSAs are considered to be mainly responsible for rejection. In a recent study on the evolution of HLA alloantibodies after transplantation, *de novo* DSAs appeared at a mean of 4.6 years after transplantation, and the prevalence of *de novo* DSAs after 10 years was 20% in those adherent to the immunosuppressive regimen, compared with 60% in nonadherent graft recipients.[40] In another study, DSAs were found in 37% of patients who had an indication biopsy 7 days to 31 years after transplant.[4] *De novo* DSAs that were directed against HLA class II antigens had an especially strong association with strongly impaired graft survival. A recent development for the detection of harmful DSAs is the introduction of solid-phase assays into a clinical routine, which enables the distinction of complement-binding (C1q assay) HLA antibodies from antibodies that do not bind complement. It was recently demonstrated that the post-transplant occurrence of complement-binding DSA in a cohort of more than 1000 patients was associated with adverse events. The 5-year graft survival in patients with complement-binding antibodies was 54% compared with 93% in patients with DSAs that were not able to bind complement. The higher risk for graft loss in patients with complement-binding DSAs was attributable to a higher risk for chronic antibody-mediated rejection.[41] Recent preliminary data also suggest that DSAs of different immunoglobulin G subclasses may be associated with different distinct injury phenotypes in kidney allograft biopsies.

Other antibodies that may contribute to chronic antibody-mediated rejection are MHC class I–related chain A antibodies, angiotensin II type 1 receptor–activating antibodies, and other antiendothelial cell antibodies.[42,43]

Insufficient Immunosuppression and Nonadherence to Medication

The recognition that HLA alloantibodies are responsible for a great proportion of late graft losses[33,44] has focused attention on the role of insufficient immunosuppression and nonadherence to immunosuppressive medication as significant factors in chronic graft loss (Fig. 107.5).[38,45]

A retrospective analysis of more than 25,000 kidney transplant recipients showed that reduction or discontinuation of cyclosporine, tacrolimus, or mycophenolate mofetil after the first post-transplant year in patients with good graft function was associated with significantly reduced subsequent kidney graft survival.[38] In a recent study in which 64% of graft losses in a cohort with indication biopsies were attributable to (antibody-mediated) rejection, about half of the patients with rejection-associated allograft loss were identified as nonadherent.[45]

Young adults who are in transition from pediatric to adult nephrology care are at high risk for nonadherence. Other risk factors are previous nonadherence, psychiatric disorders, substance abuse, insufficient socioeconomic support, and adverse effects from immunosuppressive medication. Insufficient immunosuppression may also occur during immunosuppressive minimization (tapering) or CNI-avoidance trials. In a recent study, 14 of 61 patients (23%) who were converted from cyclosporine to everolimus at 3 to 4.5 months after transplantation developed DSA, compared with only 7 of 65 patients (11%) who continued on cyclosporine.[35] Eight patients on everolimus but only two patients on cyclosporine developed antibody-mediated rejection.

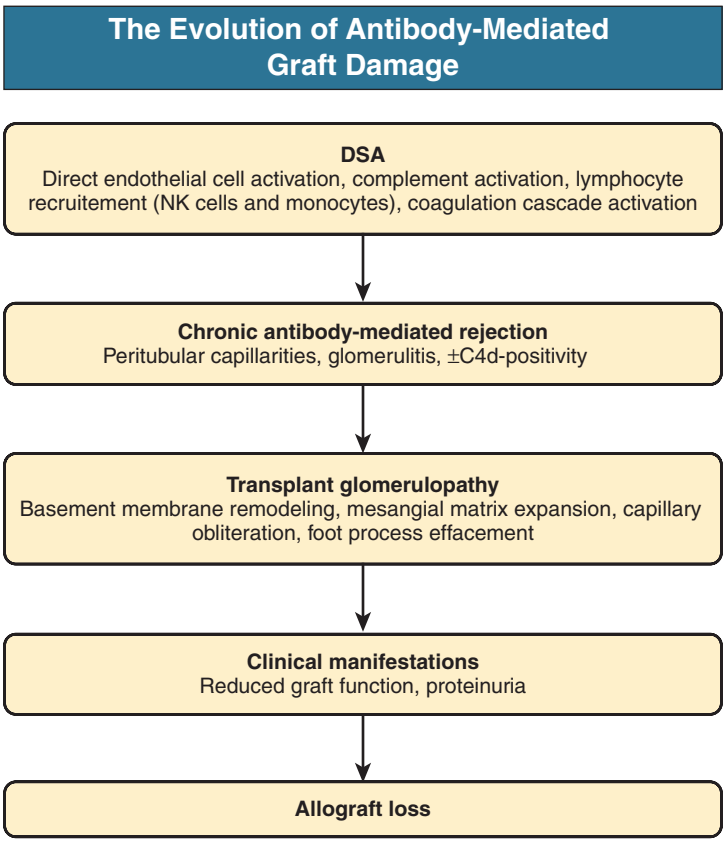

Fig. 107.6 The evolution of antibody-mediated graft damage from the binding of DSA to graft loss. *DSA,* Donor-specific antibodies; *NK,* Natural killer.

Therefore these patient cohorts should be rigorously evaluated for the development of alloantibodies and antibody-mediated allograft injury according to Transplantation Society Guidelines (see later).[46]

CLINICAL MANIFESTATIONS

Routine laboratory evaluation of graft function does not facilitate the early diagnosis of chronic allograft injury. A rise in serum creatinine is a late marker of allograft dysfunction. Reduction in the glomerular filtration rate is usually estimated by equations such as the Modification of Diet in Renal Disease (MDRD) formula or the chronic kidney disease epidemiology collaboration (CKD-EPI) formula. However, substantial nephron loss may occur before a rise in serum creatinine becomes evident.

Persistent or worsening proteinuria is also a late sign of chronic allograft injury. Proteinuria greater than 1 g/day typically occurs with recurrent or *de novo* GN or with severe chronic antibody-mediated changes such as transplant glomerulopathy (see Figs. 107.2 to 107.4). A definite diagnosis of antibody-mediated rejection requires transplant kidney biopsy together with serologic testing for alloantibodies and viral disease such as BK virus or cytomegalovirus infection. So far, no noninvasive tests can reliably diagnose antibody-mediated rejection. The evolution of antibody-mediated graft damage from the binding of DSAs to graft loss is given in Fig. 107.6.

PATHOLOGY

Chronic IFTA (Fig. 107.7) represents the final pathway of nephron injury and is not specific for any graft disease. IFTA is found in most late graft biopsies, whether a result of early graft damage (e.g., tubular injury from ischemia reperfusion injury, overt or subclinical rejection, or even preexisting disease of the donor) or later graft damage (secondary to CNI toxicity, hypertension and hyperlipidemia, recurrent glomerular disease, or immune-mediated injury) or of unknown origin (IFTA).

Chronic antibody-mediated rejection is characterized by structural remodeling of glomerular basement membranes (GBMs) (so-called transplant glomerulopathy) and similar changes in the peritubular capillaries together with IFTA and fibrous thickening of arteries (see Figs. 107.2 to 107.4). Transplant glomerulopathy is characterized by duplication of glomerular capillary basement membranes and mesangial matrix expansion, in the absence of immune deposits. In addition, deposition of C4d in peritubular and glomerular capillaries can sometimes occur (see Fig. 107.3). Clinicopathologic studies suggest that transplant glomerulopathy is a manifestation of capillary injury occurring in conjunction with interstitial, peritubular capillary, and glomerular inflammation, although it also may occur independently of IFTA or transplant arteriopathy.[47] On electron microscopy, there is expansion of the subendothelial space with deposition of flocculent or fibrillary material, interposition of mesangial cell cytoplasm in the lamina densa, and mesangial matrix expansion (see Fig. 107.4). Electron microscopy may be used to diagnose transplant glomerulopathy at its earliest stages. Ultrastructural abnormalities characteristic of endothelial activation occur long before GBM duplication and graft dysfunction are evident, implying that endothelial injury is the initial insult that resulted in GBM remodeling.[48] An association between transplant glomerulopathy and peritubular capillary basement membrane duplication has been well described, suggesting that the process resulting in transplant glomerulopathy involves the entire glomerular and peritubular capillary

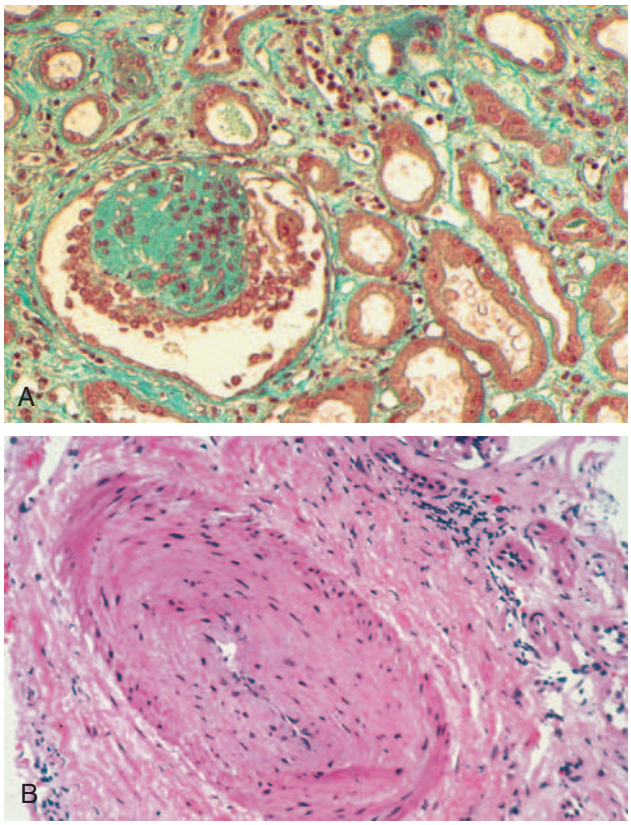

Fig. 107.7 Histologic features of chronic allograft injury and interstitial fibrosis–tubular atrophy with no evidence of specific cause. (A) Interstitial fibrosis and glomerulosclerosis. (Trichrome stain.) (B) Fibrointimal proliferation in an intrarenal artery. (Periodic acid–Schiff stain.)

beds.[49,50] It is currently debated whether transplant glomerulopathy represents scarring that is refractory to treatment.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

When chronic allograft injury has been identified by a gradual rise in serum creatinine and/or by new or worsening proteinuria, ultrasound should be performed to exclude ureteral or vascular problems and assess the Doppler resistive index. The Doppler resistive index gives an estimate of intrarenal (but also systemic) compliance and is most useful in longitudinal studies in the same patient to assess progressive graft vascular injury.

In addition, testing for BK virus in plasma is also advised during deteriorating graft function and for all kidney transplant recipients at 3-month intervals during the first 2 years after transplantation. Circulating HLA alloantibodies also should be documented during graft dysfunction and may further guide diagnostics and therapy. Many centers now perform routine HLA alloantibody screening in stable graft recipients at different time points after transplantation to facilitate early diagnosis of antibody-mediated rejection. According to the 2013 The Transplantation Society Consensus Guidelines, nonsensitized first kidney transplant recipients should be screened for DSAs at least once 3 to 12 months after transplantation.[46] In presensitized patients, more frequent screening is recommended. Although there is consensus that HLA alloantibodies are responsible for a significant proportion of late graft losses and that HLA antibodies in the context of deteriorating graft function are harmful, the significance of HLA alloantibodies that are detected solely during routine screening remains uncertain.[51,52]

Allograft biopsy is required to rule out a specific allograft pathology together with specific stainings, such as C4d, for detection of antibody-mediated allograft injury in all patients and SV40 if there is suspicion for BK virus nephropathy. Other specific examinations of the biopsy specimen for immunoglobulins, complement components, or electron microscopy may in addition be useful to rule out recurrence of primary renal disease or *de novo* GN. The role of protocol biopsies in the early detection of chronic allograft injury remains controversial.

Because the etiology of chronic allograft dysfunction is multifactorial, any specific diagnosis is made by combination of a biopsy with a review of the patient's history to identify important etiologic factors, such as preexisting donor disease, prior rejection, and high-titer anti-HLA antibodies, as well as issues not related to alloimmunity, such as CNI nephrotoxicity, *de novo* GN, or recurrent renal disease. Chronic allograft dysfunction is common and can have many causes. If it is left untreated, it can ultimately result in renal injury, which in turn will heal by scarring and interstitial fibrosis and progress to end-stage kidney disease.

Prevention of Antibody-Mediated Allograft Injury

In the absence of established treatments of circulating DSAs and chronic antibody-mediated rejection, only prevention of antibody-mediated allograft injury is effective in preventing future graft loss. Once harmful HLA antibodies such as C1q-binding DSA are detectable, it becomes very difficult to avoid allograft injury and decline of kidney function. Preventive measures include avoidance of sensitization by limitation of blood transfusions and poor HLA matching during first transplantations.[53,54] The introduction of erythropoietin about 20 years ago led to a dramatic decrease of recipient sensitization by a significant reduction in blood transfusions.[54] Sensitization should especially be avoided in young patients who may require retransplantation during their lifetime. New measures, such as matching for antibody epitopes in addition to whole HLA alleles may further help preventing sensitization.

When the patient is already sensitized, antibody-mediated allograft injury can best be prevented by transplantation of the patient with an organ against which the recipient has not developed HLA alloantibodies. This may be achieved by inclusion of patients in special programs such as Eurotransplant Acceptable Mismatch Program or by kidney-paired donation.[55,56] However, successful transplantation in patients with preexisting HLA alloantibodies usually requires desensitization in combination with other measures.[57]

After transplantation, chronic antibody-mediated allograft rejection is best prevented by conventional triple-drug therapy including a CNI (preferably tacrolimus), an antiproliferative agent (preferably mycophenolic acid–based therapy), and corticosteroids. Induction therapy, with an interleukin-2 receptor antagonist or antithymocyte globulin, should be used to prevent early acute cellular rejection.

Insufficient immunosuppression and nonadherence may lead, unless a patient is prone to tolerance, to cellular rejection and then, via development of *de novo* DSA, to antibody-mediated rejection and graft loss. Precise knowledge of the patient's alloantibody status before and after transplantation is a prerequisite for early diagnosis of allograft injury and early and targeted treatment to prevent antibody-mediated rejection and ensure long-term graft survival. HLA alloantibodies should be tested at least once after transplantation in all patients. In immunologically high-risk patients, desensitized patients, patients with suspected rejection, and during therapy of antibody-mediated rejection, antibodies need to be monitored more frequently with the goal of recognizing allograft injury in its early stages, and preventing its progression to chronic rejection.[46] Additional patient groups who may benefit from HLA alloantibody monitoring are patients who receive reduction, withdrawal, or change of immunosuppressive drugs, especially in the context of CNI- or steroid-free regimens. Protocol biopsies may

BOX 107.2 Strategies for the Prevention of Chronic Allograft Injury

- Avoid sensitization in future organ recipients (e.g., avoid blood transfusions, avoid poor HLA matching during first transplantation).
- Obtain complete donor and recipient typing and precise knowledge on HLA alloantibodies at time of transplantation.
- Minimize ischemia/reperfusion injury (e.g., short cold ischemia time).
- Avoid insufficient immunosuppression.
- Perform prophylaxis for CMV (first 3 to 6 months).
- Screen for BK virus after transplantation.
- Monitor donor-specific HLA alloantibodies after transplantation (at least in presensitized patients or during drug minimization).
- Perform protocol biopsies to detect subclinical rejection (at least in presensitized patients or during drug minimization).
- Review for nonadherence.

CMV, Cytomegalovirus; *HLA,* human leukocyte antigen.

BOX 107.3 Treatment of Chronic Allograft Injury

Treatment (Nonimmune)

- Treat hypertension (consider ACE inhibitors or AT_1 receptor antagonists)
- Lifestyle modification (stop smoking, control lipids)
- Control diabetes
- Prevention and treatment of urinary tract infection
- Target CNI toxicity by reduction or replacement of CNI (caveat: risk for insufficient immunosuppression)

Treatment (Alloimmune)

- Diagnose and treat early acute cellular rejection by steroids or antithymocyte globulin
- Diagnose and treat acute antibody-mediated rejection by means such as plasmapheresis or immunoadsorption ± anti-CD20 therapy
- Diagnose and treat chronic antibody-mediated rejection by means such as intravenous immunoglobulins ± anti-CD20 therapy
- Consider proteasome inhibitor or complement blockade (no clear evidence)

ACE, Angiotensin-converting enzyme; *AT_1,* angiotensin 1 receptor; *CNI,* calcineurin inhibitor.

further help in guiding post-transplant therapy at least in high-risk recipients, although definitive proof is lacking.

Strategies for the prevention of chronic allograft injury are summarized in Box 107.2.

Treatment of Chronic Allograft Injury

Although reduction of blood pressure to a target of less than 130/80 mm Hg is believed to be beneficial, the preferred agent for blood pressure reduction remains controversial; in particular the use of angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers has not uniformly shown benefit.[58,59] Nor have there been specific studies confirming the benefits of reducing proteinuria in chronic allograft injury, although by extrapolation for other progressive proteinuric diseases, there is strong a priori evidence for the benefits of renin-angiotensin system blockade with dietary salt restriction.

A beneficial effect of treating dyslipidemia with statins in the transplant recipient also remains controversial,[60-62] and the adverse effects of statins such as rhabdomyolysis when used with CNIs must be considered. After a specific diagnosis had been established, targeted treatments can be initiated. These are summarized in Box 107.3.

SELF-ASSESSMENT QUESTIONS

1. Which of the following is believed to be mainly responsible for late kidney graft loss?
   - **A.** Hypertension and hyperlipidemia
   - **B.** New-onset diabetes after transplantation
   - **C.** Recurrence of primary disease
   - **D.** Human leukocyte antigen (HLA) alloantibodies
   - **E.** Calcineurin inhibitors
2. Chronic antibody-mediated rejection:
   1. May be C4d negative in graft biopsy samples
   2. Has specific histopathologic features
   3. Is found more often in patients nonadherent to immunosuppressive medication
   4. Can be mediated only by HLA alloantibodies
   5. Is targeted by reduction of immunosuppression
      - **A.** Only 1 and 2 are correct.
      - **B.** Only 1, 2, 3, and 4 are correct.
      - **C.** Only 1, 2, and 3 are correct
      - **D.** All answers are correct.
      - **E.** No answer is correct.
3. Clinical manifestations of chronic antibody-mediated rejection are:
   1. A rise in serum creatinine
   2. A rise in protein excretion
   3. Specific for chronic antibody-mediated rejection
   4. Often late signs that occur after significant allograft damage has already occurred
      - **A.** Only 1 is correct.
      - **B.** 1 and 2 are correct.
      - **C.** All answers are correct.
      - **D.** 1, 2, and 3 are correct.
      - **E.** 1, 2, and 4 are correct.

Recurrent Disease in Kidney Transplantation

Steven J. Chadban, Melanie Wyld

Kidney transplantation is a treatment, not a cure. Although transplantation may restore kidney function, it does not necessarily remove the cause of the original kidney disease. Glomerulonephritis (GN) and diabetes are the two leading causes of end-stage renal disease (ESRD) worldwide, and they are also the most common primary diseases of patients who undergo kidney transplantation. That both diseases can recur after transplantation is a source of concern for recipients and clinicians.

The longer that a graft remains in situ, the more likely it is to be affected by recurrence. As graft survival rates have increased over the past 30 years, the apparent incidence of recurrence has grown.[1] An analysis of U.S. Renal Allograft Disease Registry data examining GN recurrence demonstrated a prevalence of 2.8% at 2 years, 9.8% at 5 years, and 18.5% at 8 years of follow-up after transplantation, and such patients were twice as likely to experience graft failure compared with those without recurrence.[2]

Recurrence has a powerful impact on transplant survival and one that is increasingly apparent with time after transplantation. In an analysis of data from the Australia and New Zealand Dialysis and Transplant Registry (ANZDATA) including more than 1500 patients with biopsy-proven GN who received a kidney transplant, biopsy-proven recurrence was found to cause graft loss in 0.5% within 1 year after transplantation, 3.7% within 5 years, and 8.4% within 10 years after transplantation[3] (Fig. 108.1). This study and several others have found recurrent disease to be the third most common cause of graft failure beyond the first year after transplantation, behind death with a functioning graft and chronic rejection (CR), but substantially ahead of acute rejection[3] (see Fig. 108.1).

De novo GN and new-onset diabetes after transplantation (NODAT) may affect the transplanted kidney, although both are relatively uncommon causes of graft failure and may be difficult to distinguish from recurrence or from CR. Like recurrent disease, the prevalence of both appears to increase with time after transplantation. Given the high incidence of NODAT and increasing graft survival,[4] de novo diabetic nephropathy may become a significant clinical problem in the future. However, at present the major impact of NODAT in the first 10 years after transplantation is an increase in cardiovascular mortality with little impact on death-censored graft failure.[5]

DEFINITIONS

Diagnosis of recurrence requires histologic demonstration of the same disease involving both the native and transplanted kidneys. Diagnosis of recurrence causing graft failure requires a clinical decision that recurrence was the dominant contributor to graft loss (other contributors, such as CR, may be present).

The incidence of recurrent disease is probably underestimated because a histologic diagnosis of the primary kidney disease is not always obtained, and many transplant biopsies are not done with recurrent disease in mind, so immunohistologic and electron microscopic examination (mandatory for optimal diagnosis of recurrent disease) may not be undertaken.[1] In addition, a clinical diagnosis of CR is often made in patients with declining graft function and proteinuria, so that recurrent disease is not properly excluded.

Additional factors confound the available evidence. Many reports of disease recurrence are retrospective, single-center studies. Recall bias and incomplete documentation, changes in practice over time, and peculiarities of local patient populations and local practices may limit relevance to other populations. The most definitive reports have come from analyses of the large registry databases of Europe, the United States, and Australasia. Registries capture data on large numbers of patients but are still subject to bias because of factors including unit participation rates, quantity and type of data collected, accuracy, consistency of reporting, and reliability of data entry. How recurrence is defined and diagnosed and which outcomes are measured is crucial. For example, immunoglobulin A (IgA) nephropathy (IgAN) recurred in 58% of patients in one series in which all recipients underwent biopsy,[6] but in approximately 25% of cases in which biopsy was performed only when clinically indicated.[7] When graft loss from IgAN recurrence is the outcome measure, the risk decreased to approximately 10% at 10 years of follow-up.[3] Thus definition of recurrence, outcome measures, study design, era, and source of data all need to be considered in assessing the published literature.

RECURRENT GLOMERULONEPHRITIS

Virtually all GN may recur after transplantation; however, the rate and consequences of recurrence vary enormously. For example, anti–glomerular basement membrane (GBM) disease (Goodpasture disease) recurs only rarely, but when it does, it is likely to cause rapid graft loss. In contrast, C3 glomerulopathy (formerly known as dense deposit disease and/or type II membranoproliferative glomerulonephritis [MPGN]) recurs in more than 80% of patients; however, the disease tends to be very slowly progressive, and graft survival beyond 10 years is typical. Recurrence of focal segmental glomerulosclerosis (FSGS), IgAN, and membranous nephropathy (MN) are the most frequently encountered clinical problems (Fig. 108.2).

Several factors may influence the risk for recurrence in addition to the type of GN. Time since transplantation is clearly important and may be related to the duration of graft exposure to the nephritogenic factors responsible for GN.[1] Those grafts that survive long term are exposed to nephritogenic factors for longer and are more likely to develop

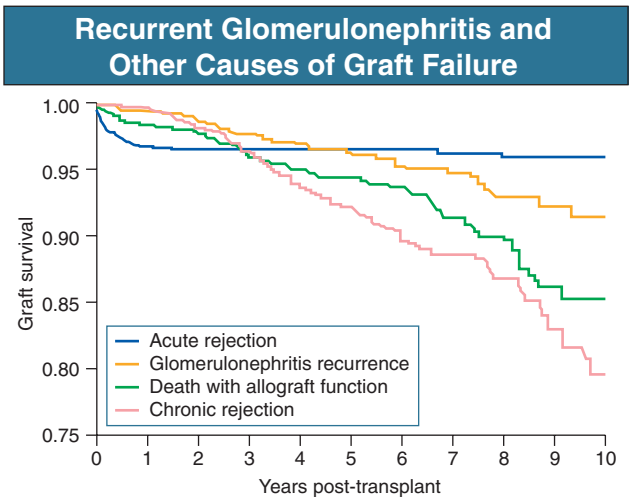

Fig. 108.1 Recurrent glomerulonephritis (GN) and other causes of graft failure. Kaplan-Meier analysis of the relative contributions of acute rejection, GN recurrence, death, and chronic rejection to graft loss during the first 10 years after transplantation among patients who underwent transplantation because of end-stage renal disease caused by GN. (Modified from reference 3.)

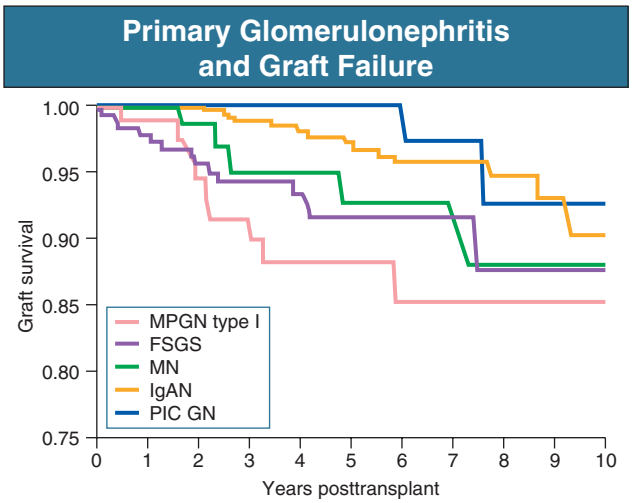

Fig. 108.2 Primary glomerulonephritis (GN) and graft failure. (Modified from reference 3.)

recurrent GN. Consistent with this, recipients of human leukocyte antigen (HLA)-identical transplants rarely experience rejection and enjoy prolonged graft survival but have a high rate of recurrent GN.[8] In one report of HLA-identical recipients, recurrent GN was present in 36% to 42% of those in whom biopsy was performed and resulted in 24% of graft losses, being the second most frequent cause of graft loss after death in this group.[8] Patients sustaining first graft loss from recurrent GN are also at higher risk for recurrence in a subsequent graft.

Improvements in immunosuppression over the past 40 years have led to reduced rates of acute rejection. Such improvements also may have had an impact on rates of graft loss from GN recurrence, which have declined by nearly 50% over the past 10 years according to one ANZDATA registry analysis.[9]

U.S. Renal Data System (USRDS) registry data failed to demonstrate superiority of any individual immunosuppressive agent on the incidence of recurrence.[10] Nevertheless, the immunosuppressive regimen may be important. For example, one small retrospective study found that induction therapy with rabbit antithymocyte globulin was associated with a lower risk for IgAN recurrence compared with either anti-CD25 antibodies or no induction.[11] Corticosteroid withdrawal may lead to increased rates of recurrence,[12] especially in recipients with IgAN, in whom a twofold increase in the risk for graft failure from recurrence of IgAN has been reported.[9] Similarly, inclusion or addition of cyclophosphamide to immunosuppressive regimens may treat recurrent vasculitis affecting the graft.[13] The use of sirolimus may result in proteinuria and renal dysfunction, especially in patients with underlying GN, suggesting that sirolimus may accelerate glomerular injury in the graft.[14] Effects of individual agents are likely to be disease-specific, but the necessary data remain sparse.

Strategies to reduce the risk for recurrence have been reported. Bilateral native nephrectomy to eliminate persistent antigenic stimulation appears unhelpful; indeed, nephrectomized patients experienced a higher incidence of recurrence compared with those with native kidneys left in situ in one large single-center, retrospective study.[15] Induction of disease remission before transplantation and prolonged time on dialysis pretransplantation (both aimed at permitting disease "burnout") do not appear to be effective except in the case of anti-GBM disease, in which a delay in transplantation until the patient has been serologically negative for at least 6 months virtually eliminates the risk for recurrence.[3] Avoiding living related donation to recipients with FSGS has been debated for years but overall appears not to have any impact on risk for recurrence.[16]

As with GN in native kidneys, proteinuria, hematuria, and deterioration in kidney function are the cardinal manifestations of recurrent GN. The pattern of renal and extrarenal manifestations is frequently similar to that of the native disease, except that, in our opinion, the overall rate of progression may be slower. Extrarenal features of the primary condition may recur, such as thrombocytopenia and hemolysis in hemolytic uremic syndrome (HUS) and extrarenal vasculitis in recurrent antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis. Serology may be helpful in some patients, such as anti-GBM antibody detection in those with Goodpasture disease, but not necessarily in others, such as those with recurrent lupus nephritis (LN).

The differential diagnosis of recurrent GN is clinically important because it may influence management (Table 108.1). CR and diabetic nephropathy, recurrent or de novo, may manifest with progressive graft dysfunction, proteinuria, and hypertension and may therefore be clinically indistinguishable from recurrence. De novo GN also should be considered. Viral diseases of the kidney should be considered (particularly BK nephropathy) because reducing immunosuppression and instituting antiviral therapy may provide benefit. Obstructive uropathy and tumors involving the graft should be excluded by an ultrasound scan. Finally, recurrence may coexist with CR or calcineurin inhibitor (CNI) toxicity. Indeed, every condition that can lead to chronic graft dysfunction should be considered in the differential diagnosis of recurrence (see Table 108.1 and Chapter 107).

Histologic evidence of recurrence is required in all patients. Biopsy can provide the diagnosis, exclude alternative diagnoses that may require different approaches to treatment, and provide important prognostic information pertinent to the affected graft and also relevant to any future consideration of retransplantation. Full evaluation of the biopsy specimen by light microscopy, immunohistology, and electron microscopy is desirable and in many patients essential

TABLE 108.1 Differential Diagnosis of Recurrent Glomerulonephritis

Diagnosis	Frequency and Timing	Clinical Features	Laboratory Features	Biopsy Features	Management
Recurrent glomerulonephritis	Common; variable timing, days to years	Proteinuria, hematuria, renal impairment, hypertension	Similar to primary glomerulonephritis; serology may be negative	Same as primary glomerulonephritis[4,5]	Disease specific
De novo glomerulonephritis	Uncommon; variable timing but typically later than recurrence	Proteinuria, hematuria, renal impairment	Type specific	Type specific[4,5,8]	Antiprogression strategies (see Chapter 79)
Chronic rejection	Very common; increasing incidence with time	Hypertension, proteinuria, renal impairment Calcineurin inhibitor exposure		Tubulointerstitial fibrosis, arteriolar hyalinosis, transplant glomerulopathy	Minimize calcineurin inhibitor and antiprogression strategies (see Chapter 79)
Graft pyelonephritis	Uncommon; typically early after transplantation	Fever, pyuria, renal impairment	Positive blood or urine cultures	Neutrophil infiltration	Antibiotics
BK nephropathy	Uncommon; typically 1-5 y after transplantation	Renal impairment, decoy cells in urine	Serum BK PCR positive	Tubulitis with tubular cell atypia and inclusions, normal glomeruli	Minimize immunosuppression and consider antiviral drugs
Acute rejection	Common; early	Renal impairment, oliguria	Nonspecific	Tubulitis with or without vasculitis[15]	Increase immunosuppression
Renal tumor/PTLD	Uncommon, rare; early or late	Renal impairment, renal mass	Anemia, EBV positive	Atypical cells, mitoses, monoclonality	Minimize immunosuppression, consider chemotherapy

EBV, Epstein-Barr virus; *PCR,* polymerase chain reaction; *PTLD,* post-transplantation lymphoproliferative disease.

to confirm recurrence.[17] Light microscopy and immunohistology are necessary to differentiate recurrent from de novo GN, rejection, and CNI toxicity. The presence of tubulitis should suggest acute rejection. CR may produce chronic interstitial inflammation and transplant glomerulopathy, which may be indistinguishable from MPGN on light microscopy (Fig. 108.3; see also Chapter 107). The use of immunohistology to define the immunoglobulin and complement component content of immune deposits and electron microscopy to establish the structure of basement membrane and location of deposits may clarify the diagnosis.[17] The risk for recurrence in common patterns of renal disease is summarized in Table 108.2.

RECURRENCE OF SPECIFIC GLOMERULAR DISEASES

Immunoglobulin A Nephropathy and IgA Vasculitis (Henoch-Schonlein Purpura)

IgA nephropathy is the most common form of GN leading to ESRD, and affected patients frequently become transplant recipients. Histologic recurrence is frequent and increases with time since transplantation. Published recurrence rates vary greatly (from 8% to 53%). Much of this variation appears to be due to study differences in biopsy indication (protocol or clinical) and length of post-transplant follow-up.[18] The highest published recurrence rates are from centers performing protocol biopsies in addition to those that are clinically indicated. This is likely because the early stages of IgAN recurrence are frequently not accompanied by clinical changes, such as proteinuria, hematuria, or graft dysfunction.[18]

Recurrence is difficult to predict. No large, prospective, multicenter cohort studies demonstrate risk factors for histologic and/or clinical recurrence. Single-center studies and registry analyses suggest that including younger age at transplantation, rapid progression of the native IgAN, degree of proteinuria, and donor factors (including HLA matching) may be associated with higher risk.[18] The suspicion that living donor grafts have higher rates of recurrence than deceased donors has not been confirmed.[18] Thus patients with IgAN should not be precluded from consideration for living donor transplantation. The number of HLA mismatches between donor and recipient also may have a role in recurrence rates. Two Australian registry studies have found that those with zero mismatch kidneys have higher rates of recurrence than those with one or more HLA mismatches.[9,19] Similarly, ABO-incompatible transplants have been found to have lower rates of recurrence, possibly because of differences in immunosuppression regimens.[20]

Choice of immunosuppression after transplantation is controversial. One large USRDS registry analysis suggested that individual drug choices did not affect the risk for graft loss attributed to recurrence.[10] In contrast, a retrospective analysis of ANZDATA found that continuation of corticosteroids was strongly associated with protection from graft loss caused by recurrence of IgAN, although not from other types of GN.[9] Observational data also suggest that induction with antithymocyte globulin may afford relative protection.[11]

The clinical expression of recurrent disease is variable and time dependent. Graft loss within the first 3 years after transplantation is uncommon (see Fig. 108.2), although it can occur, particularly when IgAN in the native kidney was rapidly progressive or after previous graft loss resulting from recurrence.[7] An Italian cohort study of 190 patients followed for 15 years recently reported that of their 22% of patients that developed recurrence, almost a third ultimately lost their graft because of IgAN recurrence during follow-up.[21] Death-censored

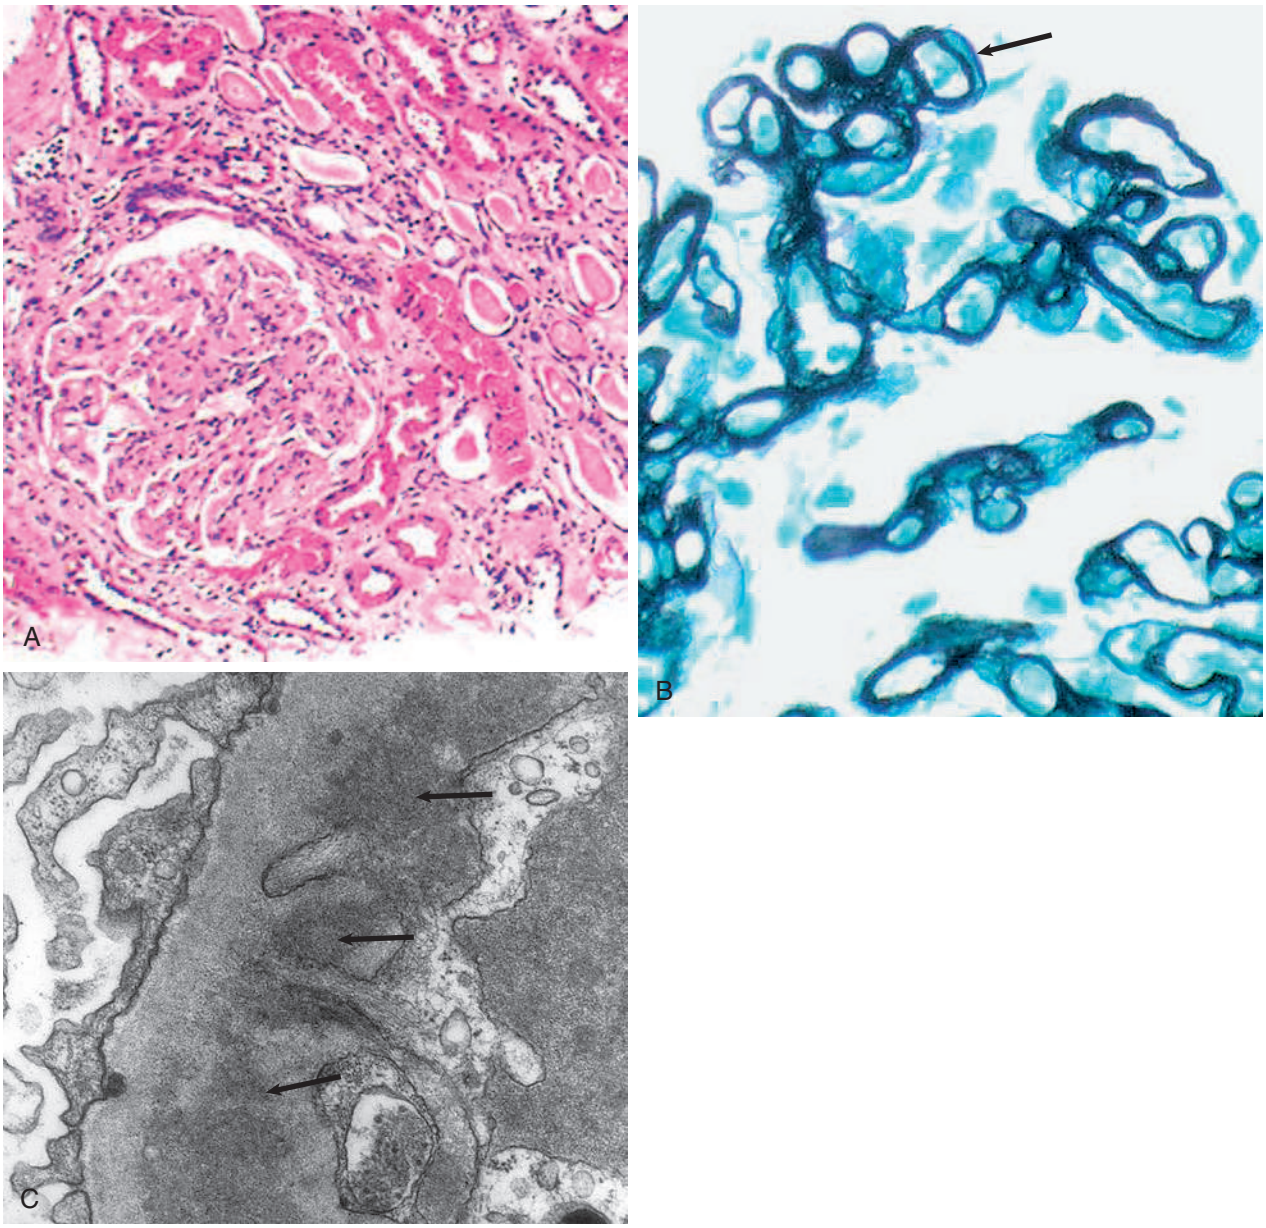

Fig. 108.3 Transplant glomerulopathy and membranoproliferative glomerulonephritis (MPGN). Transplant biopsy specimen from a patient with end-stage renal disease caused by biopsy-proven idiopathic MPGN type I, who received a kidney transplant and had a progressive reduction in glomerular filtration rate with proteinuria 1.5 g/day and hypertension. (A) Light microscopy. Glomerular hypercellularity and lobulation on a background of chronic interstitial inflammation and fibrosis, with protein casts within dilated tubules. (Hematoxylin-eosin stain; ×100.) (B) Subendothelial deposits and basement membrane reduplication *(arrow).* (Methenamine silver stain; ×400.) (C) Electron microscopy showing subendothelial electron-dense deposits *(arrows)* (×7500). There were also prominent C3 deposits on immunofluorescence (not shown). Light microscopy was therefore suggestive of recurrent MPGN but was also consistent with chronic rejection (CR) with transplant glomerulopathy associated with CR. Immunofluorescence and electron microscopy (subendothelial deposits) confirmed recurrence of MPGN. (Compare Figs. 107.3 through 107.5.) (*A* and *B* courtesy Dr. Paul McKenzie, Royal Prince Alfred Hospital, Sydney, Australia.)

graft survival at 15 years was approximately 10% lower in patients who had IgAN than in controls, largely attributable to IgAN recurrence.[21]

Recurrence of IgA vasculitis (IgAV) is less well characterized but appears to be similar to IgAN. An analysis of the United Network for Organ Sharing (UNOS) database including 339 patients with ESRD caused by HSP who received a first kidney allograft reported a frequency of graft loss caused by recurrence of 13.6% and no difference in 10-year graft survival between recipients with IgAN (58.4%) or IgAV (59.3%) as their primary renal disease.[22]

Treatment of recurrent IgAN and IgAV has not been systematically evaluated. The addition of corticosteroid maintenance in corticosteroid-free patients with recurrence is unproven but reasonable. A change to mycophenolate mofetil (MMF) or the use of fish oil, antiplatelet agents, and tonsillectomy cannot be recommended. The use of nonspecific

TABLE 108.2 Recurrent Diseases in Renal Transplants and Effects on Graft Survival

Disease	Clinical Recurrence Rate (%)	Graft Loss in Recurrent Disease (%)
Primary focal segmental glomerulosclerosis	20-50 (children), 10-15 (adults)	40-50
Membranoproliferative glomerulonephritis type 1	20-30	30-40
Dense deposit disease	80	20, often late
Hemolytic uremic syndrome (HUS)		
Classic D + HUS	0-13	Uncommon
Atypical D – HUS	30-50	55-100
Familial HUS	57	Approaching 100
IgA nephropathy	30-40, increases with longer duration of follow-up (30%-60% histologic recurrence rate)	16-33
IgAV (Henoch-Schonlein purpura)	Rare (despite 50% histologic recurrence rate)	Rare
Membranous nephropathy	10-29 (histologic recurrence may be more common)	Up to 50
Systemic vasculitis, including Wegener granulomatosis and microscopic polyangiitis	10-20	20-50
Anti-GBM disease (Goodpasture disease)	<5	50
Systemic lupus erythematosus	1-30	Rare
Amyloidosis	25	10-20

GBM, Glomerular basement membrane; *IgA,* immunoglobulin A; *IgAV,* IgA vasculitis.

measures to prolong kidney survival is appropriate, including tight blood pressure control, renin-angiotensin system (RAS) blockade, and avoidance of nephrotoxins.

Membranous Nephropathy

Histologic recurrence of MN can be found in up to 40% of grafts,[23] and for those with documented recurrence, graft loss rates of over 50% at 10 years of follow-up have been reported.[24] Patients who have previously lost a graft to recurrence are at higher risk on retransplantation, but disease course, duration of dialysis, HLA genotype, graft source, and immunosuppression have not been found to predict recurrence risk.[24]

In 2009 M-type phospholipase A_2 receptor (PLA_2R) was identified as the antigen targeted in 70% to 80% of idiopathic MN.[25] This has spurred interest in the use of anti-PLA_2R antibody titers in monitoring disease activity and predicting recurrence. Recently a number of small, single-center and multicenter observational studies suggested a role for the adoption of PLA_2R measurement as a clinical tool in transplantation, with higher levels at transplantation associated with higher rates of recurrence.[26-29] The largest of these studies reported a recurrence rate of 57% among patients with primary MN, with a median time to recurrence of 4.1 months.[26] The positive predictive value of pretransplant anti-PLA_2R antibodies was 83% (10 of 12), and the negative predictive value was 42% (5 of 12).[26] Current data show that the presence of anti-PLA2R at the time of transplant increases the risk for recurrence; however, both sensitivity and specificity are imperfect and larger studies are required. At present there is insufficient evidence to recommend delaying transplantation until anti-PLA_2R antibody status is negative.

Management of recurrent MN is based on anecdotal reports and extrapolation of data on the management of native kidney MN. There has been some success with rituximab reported in small case series, but the findings await confirmation in a randomized trial. Spontaneous remission appears to be less common than is seen in MN affecting native kidneys. The cumulative exposure to immunosuppressive therapy should be considered because these patients may be at increased risk for lymphoma. Living donor transplantation appears warranted for first grafts but in our opinion should probably be avoided for second grafts if the first was lost early because of recurrence.

To diagnose recurrence requires a native kidney biopsy showing MN as well as a graft biopsy showing MN. This is especially important in MN, in which de novo MN has been reported in 2% to 15% of transplant recipients and tends to manifest more insidiously and later than recurrent MN.[30]

Focal Segmental Glomerulosclerosis

FSGS recurs in 20% to 30% of first transplants.[31,32] FSGS is a heterogeneous group of conditions, and those with familial or sporadic forms associated with mutation of slit-diaphragm proteins such as podocin do not recur, although rare cases of post-transplant nephrotic syndrome caused by the development of antibodies directed against the "neoantigen" within the donor kidney have been reported. FSGS secondary to vascular disease or reflux nephropathy, and those with a very slow rate of progression are at very low risk for recurrence. In contrast, patients with primary FSGS and in particular those with an aggressive initial course (heavy proteinuria and renal failure within 3 years of onset), age younger than 15 years, mesangial hypercellularity on biopsy, or with recurrence in a previous graft are at greatest risk.[31,32] The rate of recurrence is higher than 75% in subsequent grafts when the first graft was lost because of recurrence.[33] Living related donor transplantation has previously been implicated as a risk factor for recurrence; however, a major analysis of U.S. registry data (USRDS) refutes this notion.[16]

Recurrence may occur early (typically within the first month post-transplantation) and manifests initially with heavy proteinuria, followed by hypertension and graft dysfunction. Patients with recurrent disease appear more susceptible to acute rejection and acute kidney injury,[34] as well as graft loss. Recurrence has been associated with early graft loss in up to 50% of patients[32]; however, treatment with plasma exchange appears to have delayed graft loss in many patients and decreased the incidence of overall graft failure[3] (see Fig. 108.2).

Primary FSGS appears to be caused by a circulating factor that targets podocytes, although the specific factor(s) involved remain unknown. Soluble urokinase plasminogen activator receptor (suPAR)

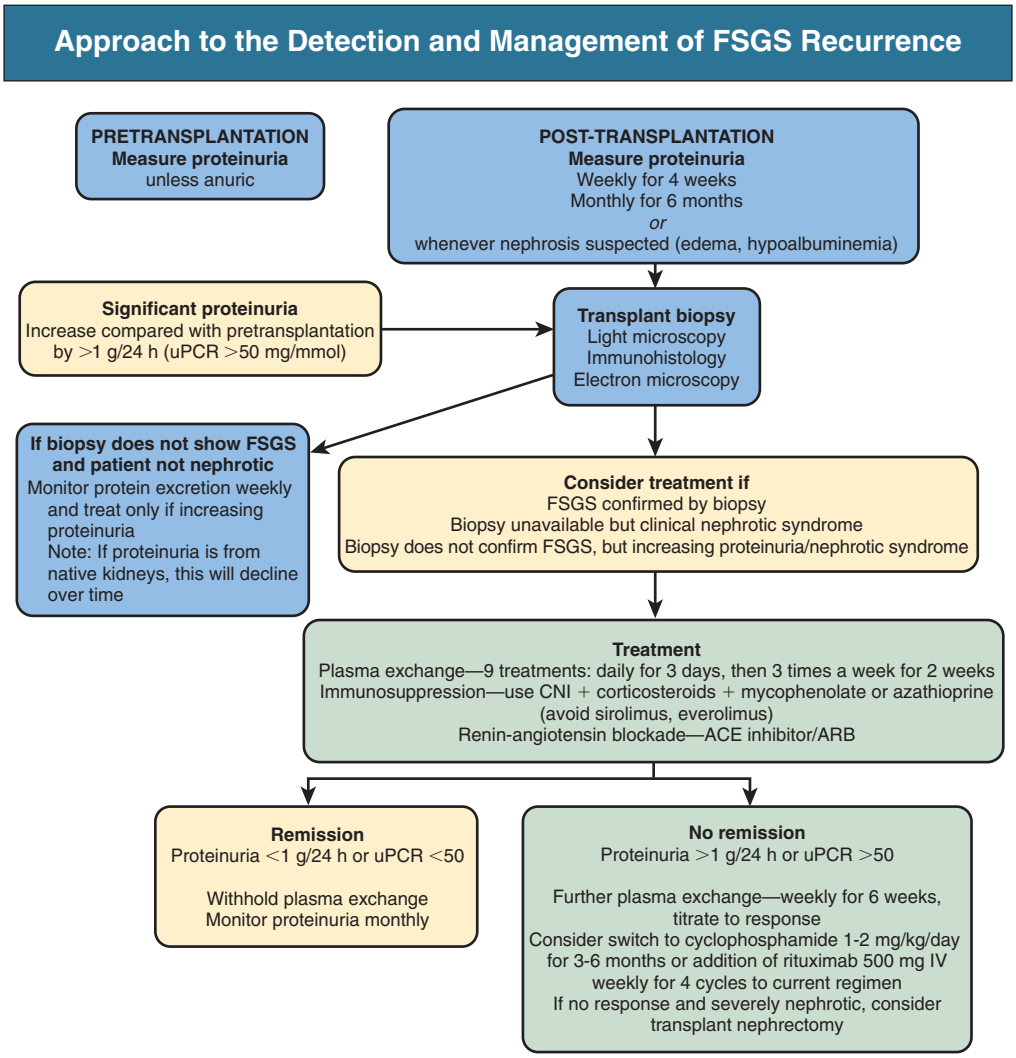

Fig. 108.4 Approach to the detection and management of focal segmental glomerulosclerosis (FSGS) recurrence. Authors' recommendation based on Davenport.[30] *ACE,* Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *CNI,* calcineurin inhibitor; *uPCR,* urine protein-to-creatinine ratio, mg/mmol.

and the costimulatory protein B7-1 (CD80) have been proposed to mediate recurrence; however, reports have been anecdotal and subsequent studies have failed to prove the role of either molecule or consistently demonstrate success with therapies targeting them.[35-39]

Plasma exchange or immunoadsorption with either a protein A or anti-IgG column is effective for some patients who develop recurrent FSGS, presumably because it removes the circulating permeability factor.[40,41] Although not studied in a randomized controlled trial (RCT), several series have reported disease remission in the majority of patients who receive treatment within 2 weeks of recurrence.[32,41] The potential for positive publication bias and the absence of RCT evidence make prognostic information speculative; however, response rates appear likely to exceed 50% when therapy is commenced within 2 weeks of clinical recurrence, with lower response rates anticipated when therapy is delayed. Given that graft survival appears to be significantly prolonged in patients who respond to therapy, a course of plasma exchange is warranted in all patients without contraindications (see Chapter 99). Immunosuppression should include a CNI, and addition of an angiotensin-converting enzyme (ACE) inhibitor should be considered. A minority of patients with an incomplete response or relapse after cessation of initial therapy will require repeated or long-term plasma exchange[42] or concurrent treatment with secondary agents such as rituximab or cyclophosphamide.[41-44] For such patients we recommend a course of rituximab 500 mg weekly for 4 weeks, in addition to existing immunosuppression and weekly plasma exchange. Pretransplantation plasma exchange has not been shown to be beneficial for preventing recurrence. See Fig. 108.4 for an approach to the management of recurrent FSGS.

Minimal change disease is a far less frequent cause of ESRD. Recurrence of disease after transplantation has been reported; however, it is difficult to be sure that the underlying disease was not FSGS.

Membranoproliferative Glomerulonephritis

Recurrent MPGN bears major clinical and histologic similarities with the subgroup of patients with CR who have transplant glomerulopathy, and comprehensive assessment of transplant biopsy specimens (see Fig. 108.3 and compare Figs. 107.4 and 107.5), as well as accurate diagnosis of the native kidney disease, is crucial in making this distinction (see Table 108.1). MPGN type I, rather than transplant glomerulopathy, is suggested by the presence of crescents on light microscopy, stronger

staining for C3 and weaker staining for IgM on immunohistologic examination, and subendothelial electron-dense deposits on electron microscopy.[17] This distinction has important clinical implications, particularly because a recurrence carries a higher risk for subsequent recurrence should retransplantation be considered. A retrospective analysis of renal biopsies that included 70 patients with MPGN suggests that the severity of histologic lesions is predictive of recurrence.[45]

Membranoproliferative Glomerulonephritis Type I

MPGN type I appears to be mediated by glomerular deposition of immune complexes, triggered by exposure to endogenous or exogenous (e.g., hepatitis C virus [HCV]) antigens). Because the antigens are not necessarily removed by transplantation, recurrence of disease is possible and is seen in 20% to 33% of graft recipients.[46] Graft loss has been reported in up to 40% of those with recurrence, and the risk for recurrence in subsequent grafts approaches 80%.[47] Significant geographical diversity in the risk for recurrence is evident, with much higher rates of graft loss resulting from recurrence in areas where the majority of patients with MPGN are HCV positive, such as Spain,[46] compared with low-HCV prevalence areas, such as Australia.[3]

No form of treatment for recurrent MPGN has been proven, and the underlying cause of MPGN should be considered in each patient. In HCV-associated MPGN, direct-acting antiviral therapy is effective for virus elimination and should provide substantial protection from HCV viremia and MPGN recurrence after transplantation. Other forms of MPGN type I have been successfully treated with immunosuppression or plasma exchange.

C3 Glomerulopathy

C3 glomerulopathy is a disease process secondary to abnormal complement activation (see Chapter 22). One form of C3 glomerulopathy is dense deposit disease, which also has clinical and histologic similarities to transplant glomerulopathy. Dense deposit disease is suggested by granular staining for C3 on capillary loops without immunoglobulin deposits, and the characteristic ribbon-like intramembranous dense deposits on electron microscopy (see Fig. 22.2).[17] Dense deposit disease has been found to recur in 50% to 80% of grafts, typically manifesting with proteinuria, hematuria, and slowly progressive loss of kidney function.[48] The disease course tends to be slow, and whereas graft loss caused by recurrence is ultimately seen in the majority of patients, this generally occurs beyond the first 10 years after transplantation.[3,48] Graft loss has been associated with male gender, crescents on biopsy, and heavy proteinuria.[48] No effective therapy is known, and although plasma exchange and immunosuppression have been described, these are not supported by good evidence, and control of blood pressure and proteinuria with renin-angiotensin blockade is the preferred therapy. Given the role of alternate complement pathway mutations in Dense deposit disease (see Chapter 22), plasma infusion or administration of complement antagonists may be beneficial but remain unproven.

Membranoproliferative Glomerulonephritis Type III

Recurrence of MPGN type III, a rare disease, has been reported and has resulted in graft loss in the longer term.[49]

Congenital Nephrotic Syndrome

Congenital nephritic syndrome of the Finnish type has been reported to recur after transplantation and cause graft loss; however, the mechanism of kidney damage is likely different between primary and recurrent disease. The primary disorder in some cases is caused by a mutation of the *NPHS1* gene that results in complete absence of nephrin, and therefore transplantation causes de novo exposure to nephrin in the transplanted kidney. Neoantigen exposure may cause antibody development and deposition that damages the slit diaphragm and produces a type of MN with podocyte fusion on electron microscopy and a clinical picture of heavy proteinuria and ultimately graft failure. Cyclophosphamide-based rescue therapy may be successful.[50]

Antineutrophil Cytoplasmic Antibody–Associated Pauci-immune Vasculitis

A pooled analysis of reported case series examining recurrence of ANCA-associated vasculitis, incorporating 127 patients,[51] showed that recurrence was detected in 17% of patients after 4 to 89 months of follow-up, with renal involvement demonstrated in approximately 60% and graft losses reported in 25% of these. Clinical parameters were not useful in predicting those patients likely to relapse. Pretransplantation disease course, duration of dialysis, ANCA titers at time of transplantation and during follow-up, cytoplasmic ANCA (c-ANCA) or perinuclear ANCA (p-ANCA) pattern, antibody specificity to PR3 or MPO, disease subtype (granulomatous polyangiitis [Wegener granulomatosis], microscopic polyangiitis, or renal-limited vasculitis), and donor source had no significant impact on recurrence rate.[51]

The prevention and management of relapse has not been prospectively examined. In most reports, patients did not receive a transplant until they were in clinical remission; however, successful transplantation in the face of persisting ANCA positivity is well recognized. In the absence of firm evidence, we recommend that clinical remission be maintained for at least 6 months before transplantation to reduce the risk for recurrence and also to avoid risks associated with performing transplantation in a debilitated patient, especially if ESRD has occurred soon after presentation with systemic vasculitis. Monitoring ANCA to indicate ANCA-associated vasculitis (AAV) recurrence is commonly performed; however, the test performance characteristics in this context have not been reported. Patients with renal relapses have generally been managed with cyclophosphamide-based regimens, as used for renal vasculitis in native kidneys, reported to be successful in inducing a remission in 11 of 16 (69%) cases.[51] Any negative impact of use of cyclophosphamide to treat relapse has not been reported, but cumulative dose, if it had also been used pretransplant, would significantly increase in the risk for bladder cancer.

Kidney transplantation for AAV is associated with a reduction in the frequency of disease relapse by approximately 50% compared with patients remaining on dialysis, and patient and graft survival post-transplantation is similar to that in other transplant recipients.[51]

Anti–Glomerular Basement Membrane Disease

Histologic recurrence of anti-GBM disease (Goodpasture disease) is seen in 50% of patients who receive a transplant while circulating anti-GBM antibodies persist, but rarely when patients undergo transplantation 6 months or more after the disappearance of anti-GBM antibodies. With delayed transplantation, the rate of clinical recurrence is very low, and since the implementation of this practice in Australia, no grafts were lost after transplantation in 47 patients followed for up to 10 years.[3] Rare episodes of recurrence should be treated as for native kidney disease with corticosteroids, cyclophosphamide, and aggressive plasma exchange (see Chapter 24).

Recurrent anti-GBM disease is distinct from de novo anti-GBM disease, which is seen in up to 15% of transplant recipients with Alport syndrome who develop anti-GBM antibodies in response to neoantigen exposure (α chain of type IV collagen) via the transplant.[52] This is discussed further in Chapter 24.

Lupus Nephritis

The reported recurrence rate of LN has varied from 2% to 54% depending on the diagnostic criteria used.[53,54] Recurrence has been reported

early (days) and late (years) after transplantation, with a median time to recurrence of approximately 4 years.[53,54] The clinical and histologic pattern of recurrence is variable but is typically more benign in histology and clinical expression than the patient's original disease. Whereas the majority of patients with ESRD caused by lupus have had diffuse proliferative (class III or IV) LN, mesangial proliferative (class II) LN is the most commonly described lesion after transplantation, followed by class III and membranous LN (class V).[54] Duration of dialysis and serologic activity before transplantation do not predict recurrence, and antinuclear antibody titer and complement levels are unreliable markers of disease recurrence. There is no consistent relationship between recurrence of nephritis and activity of extrarenal lupus after transplantation.

The long-term outcome for lupus patients after transplantation is controversial but appears similar to that of the general post-transplantation population.[53,55] Although recurrence is an uncommon cause of graft loss within the first 10 years after transplantation, with no cases of graft loss reported from 86 recipients in one registry analysis,[3] late graft losses do occur. It is clear that lupus patients, particularly those with a lupus anticoagulant, are at increased risk for thrombotic events after transplantation, including graft thrombosis.[56]

Management of recurrent LN has not been systematically studied; corticosteroids, cyclophosphamide, MMF, and plasma exchange have been used, with variable results reported. Anticoagulation during the perioperative and early post-transplantation phases should be considered for those with a history of thrombosis or lupus anticoagulant positivity. Successful retransplantation has been reported after graft loss caused by recurrence.[56]

Thrombotic Microangiopathy and Hemolytic Uremic Syndrome

Recurrence risk is clearly associated with the underlying cause of thrombotic microangiopathy (TMA). Typical childhood Shiga toxin–associated HUS seldom recurs, whereas recurrence of atypical HUS is frequent and, particularly in hereditary forms associated with mutation of complement components or complement regulatory factors, occurs in up to 80% of patients.[57] The diagnosis of recurrent TMA, including HUS, is complicated by the fact that de novo TMA is seen in 1% to 5% of kidney transplant recipients, most commonly associated with the use of CNIs (both tacrolimus and cyclosporine carry a similar risk), sirolimus, or OKT3 or with acute vascular rejection. Drug-induced de novo TMA is generally observed within 14 days of drug commencement.

A meta-analysis that examined 10 reports covering 159 grafts in 127 patients reported recurrence in 28% of grafts, and this was strongly associated with a poor outcome: 1-year graft survival was 33% for those with recurrence versus 77% in those free from recurrence ($P > .001$).[58]

The risk for atypical HUS recurrence and its impact on graft survival are dependent on the complement pathway mutation responsible. Mutations in factors H and I are associated with a recurrence risk of approximately 75%, and more than 90% of those with recurrence incur graft failure, typically within the first year.[59] In contrast, mutations of membrane cofactor protein are associated with a recurrence rate of only 20% and substantially better survival rates than in patients with factor H or I mutations.[60] Given these variations in risk for recurrence, genotypic evaluation of the recipient and any potential living donors before transplantation is advisable for all patients with ESRD caused by atypical HUS.[61] Combined liver-kidney transplantation may be considered in selected candidates with defined mutations.[62] Recurrence is also associated with an older age at onset, rapid progression of the original disease, earlier transplantation, living-related transplantation, and the use of CNIs.[57] Recurrence is generally within the first 6 months after transplantation; however, late recurrences have been reported.[57] The clinical presentation may be gradual or abrupt, with thrombocytopenia, hemolysis, and progressive renal dysfunction.

Whereas de novo disease may respond to withdrawal of the inciting agent, management of recurrent disease is uncertain. We recommend withdrawal of any potential causative agent such as CNIs, and if this is not effective after 48 hours, a trial of plasma exchange should be initiated with three half-plasma volume exchanges performed on 3 consecutive days with fresh-frozen plasma used for replacement. Because an increased incidence of acute rejection has been reported in patients with recurrence,[58] inadequate immunosuppression after CNI withdrawal should be prevented with a temporary increase in the dose of corticosteroids. In patients with life-threatening thrombocytopenia or hemolysis, hematologic stability may be restored by transplant nephrectomy. Eculizumab, a humanized monoclonal antibody targeting C5 of the complement membrane attack complex, is emerging as an effective therapy in the treatment of atypical HUS. In case reports, eculizumab has been reported to be successful in both the treatment of recurrence and prophylaxis pretransplantation. Multicenter phase II trials are currently under way to evaluate its efficacy. Plasma exchange may be effective in patients with mutations in factors H or I, as well as those who have autoantibodies directed against factor H. However, it may be less effective in patients with mutations of membrane cofactor protein or thrombomodulin, in which the protein is membrane bound. The prognosis with recurrent disease is poor. More than 50% of grafts are lost within the first year, and graft survival beyond 5 years is quite uncommon.[58] There is no evidence that CNI avoidance is useful in preventing recurrence.

Scleroderma

Few patients with scleroderma undergo renal transplantation. An analysis of 86 patients reported to the UNOS registry demonstrated graft survival of 62% at 1 year and 47% at 5 years after transplantation; 24% of recipients died during the 10-year observation period.[63] The recurrence rate could not be accurately determined; however, recurrence was responsible for graft loss in 21% of patients in whom the cause was identified, which is consistent with previously accepted recurrence rates. A recent review of the literature suggests that rapid loss of renal function after diagnosis may predict recurrence in the graft.[64] The effect of transplantation on the extrarenal manifestations of scleroderma has not been well documented. The management of scleroderma after transplantation is unstudied; however, the use of RAS blockade after transplantation to treat hypertension would seem appropriate. Overall, renal transplantation appears to be an appropriate treatment for those with scleroderma and ESRD.

AMYLOID, LIGHT-CHAIN DISEASE, AND FIBRILLARY AND IMMUNOTACTOID GLOMERULOPATHIES

Amyloidosis

The risk and impact of recurrence for patients who undergo transplantation because of systemic amyloidosis are dependent on its cause. Management of AL amyloid is primarily directed at treating the underlying plasma cell dyscrasia, most commonly by high-dose chemotherapy and autologous stem cell or allogeneic bone marrow transplantation. Recurrence after transplantation is likely if the malignancy is not fully controlled but may be susceptible to further chemotherapy. The largest reported series includes 25 patients who received a kidney transplant for AL amyloid–induced renal failure, of whom 22 had received chemotherapy, which placed 3 patients in complete remission and 13 patients in partial remission at the time of the kidney transplant.[65] Graft survival rates at 5 and 10 years were 74% and 25%, respectively. Recurrence in the graft was documented by iodine-123 (^{123}I)-labeled serum amyloid

P component scintigraphy in 28% at a median of 5 years after transplant, although no grafts were lost through recurrence. Myeloma recurred in 5 patients (28%), of whom 3 achieved complete remission with further chemotherapy. The major cause of graft failure was death, in 13 patients (52%), most commonly caused by sepsis. Cardiac involvement on echocardiogram was noted in 5 patients before transplantation, and 1 died of cardiac failure after transplant. Thus transplantation appears to be a viable option for patients with ESRD caused by AL amyloidosis, provided they have achieved at least a partial remission after chemotherapy and have little or no cardiac involvement.

Secondary (AA) amyloidosis is typically a more insidious disease; renal failure is a relatively frequent complication, and renal transplantation is frequently effective.[65] The risk for recurrence of AA amyloid depends on the ability to eradicate the underlying cause of chronic inflammation. In AA amyloid, recurrence as a result of chronic infection is unlikely if the infection can be eradicated pretransplantation, whereas conditions such as rheumatoid arthritis may persist after transplantation and lead to recurrent amyloid in the graft. Less than 5% of patients with AA amyloid associated with familial Mediterranean fever (which can be managed with colchicine after transplantation) have recurrence at 10 years after transplantation.[66] A Norwegian series of 62 transplants in patients with AA amyloid, mostly secondary to rheumatic diseases, demonstrated a recurrence rate of 10% at an average of 5 years of follow-up, with recurrence causing graft loss in two patients only. Overall, patient and graft survival rates were 65% and 62%, respectively, at 5 years, with most losses resulting from infection.[67]

Light-Chain Nephropathy

Patients with light-chain nephropathy have occasionally received transplants, and recurrence is common; one case series reported recurrence in five of seven patients at a range of 2 to 45 months after transplantation. Those with recurrence developed proteinuria, hypertension, and progressive graft dysfunction. One of seven has had long-term graft function, and one died soon after transplantation because of myeloma.[68] Kidney transplantation is therefore generally inadvisable for patients with this disease, unless performed in conjunction with bone marrow transplantation as a means of curing the underlying disease. Rituximab and bortezomib have been used with success in patients with light-chain nephropathy recurrence in the graft, but insufficient evidence exists to recommend either agent as a standard of care.

Fibrillary and Immunotactoid Glomerulopathies

Fibrillary and immunotactoid glomerulopathies are known to recur in approximately 50% of those undergoing transplantation for these diseases, and although early graft loss as a result of recurrence has been reported, decline in graft function is most commonly slow and does not appear to have an impact on 5-year graft survival rates.[69]

RECURRENCE OF METABOLIC DISEASES AFFECTING THE KIDNEY TRANSPLANT

Diabetes Mellitus

Diabetes mellitus is the most common cause of ESRD in most parts of the world. However, these patients undergo transplantation less commonly than those with GN because of a higher prevalence and severity of cardiovascular comorbidity.[70] Recurrence of diabetic nephropathy affects at least 25% of recipients at an average follow-up of 6 years and with some patients diagnosed within 3 years of transplantation.[71] Histologic and clinical features are similar to those of native kidney diabetic nephropathy. The risk for graft loss from recurrence has not been well documented but appears to be significantly less than with GN, probably because of the competing risk for death from cardiovascular disease. NODAT is also common and has been reported to cause nephropathy in the graft, also manifesting within 5 years of transplantation in a small proportion of cases. The extent to which this contributes to graft loss also awaits clarification, although a registry analysis suggests that the impact on graft failure is insignificant in comparison with the impact on premature death with a functioning graft.[5]

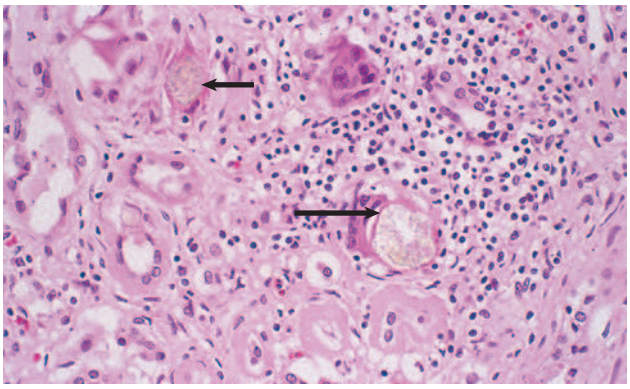

Fig. 108.5 Recurrent primary hyperoxaluria. Light microscopy demonstrates oxalate crystals within the tubular lumen *(arrows)* with a secondary interstitial inflammatory infiltrate.

Primary Hyperoxaluria

Primary hyperoxaluria (see Chapter 57) is a rare autosomal recessive disease caused by defective or absent hepatic production of alanine glyoxylate aminotransferase, resulting in systemic accumulation of calcium oxalate (oxalosis). Kidneys and blood vessels in particular are affected. Kidney transplantation alone is frequently complicated by hyperoxaluria and consequent recurrence in the graft and ultimately graft loss (Fig. 108.5). By contrast, combined liver-kidney transplantation corrects the underlying metabolic deficit and permits long-term kidney graft survival, provided the total body burden of oxalate present at the time of transplantation can be managed. In an analysis of the USRDS that included 190 adults with oxalosis who went on to undergo renal transplantation, 134 patients who received a kidney transplant alone experienced 48% 8-year death-censored graft survival. This was inferior to 56 patients who also received a liver (76%) and inferior to a control group with a primary diagnosis of GN (61%).[72] Aggressive removal of residual oxalate before transplantation by dialysis and after transplantation by maintenance of high urine volumes, urinary alkalinization, and pyridoxine supplementation for pyridoxine-sensitive patients also may decrease the risk for graft damage.

Fabry Disease

Fabry disease results from a defect in the lysosomal α-galactosidase A enzyme, which results in tissue accumulation of trihexosylceramide, eventually causing ESRD (see Chapter 46). Recurrent Fabry disease has been documented within the graft; however, graft survival does not appear to be affected. Treatment with recombinant α-galactosidase A, should this become widely available, is likely to reduce the risk for ESRD and also for recurrence.

RECURRENCE OF VIRUS-ASSOCIATED NEPHROPATHIES AND TUMORS IN THE TRANSPLANTED KIDNEY

Virus-associated kidney diseases may recur after transplantation. Hepatitis B and C virus–associated MPGN and MN are known to recur;

however, the risk for this can be substantially decreased by successful antiviral therapy before transplantation (see Chapter 55).

Retransplantation has been reported in patients experiencing graft loss because of BK virus nephropathy. In the largest series, recurrence was documented in 1 of 10 transplant recipients at an average follow-up of 3 years.[73] Measures to decrease the risk for recurrence included delay in retransplantation by an average of 13 months and transplant nephrectomy in 7 patients. CNI-based triple immunosuppressive therapy was used in all patients, and the 1 patient with recurrence experienced stabilization of graft function after a reduction in immunosuppression.[73] Thus retransplantation, ideally delayed until BK virus is not detectable in serum by polymerase chain reaction, appears to be safe and effective.

Patients with post-transplantation lymphoproliferative disease who incur graft loss secondary to direct infiltration or rejection after the withdrawal of immunosuppression may safely and successfully undergo retransplantation after they recover. There was no evidence of recurrence reported in one series of five cases.[74]

SELF-ASSESSMENT QUESTIONS

1. Risk for graft loss because of recurrent disease is highest for kidney transplant recipients whose kidney failure was caused by:
   - **A.** Immunoglobulin A nephropathy (IgAN)
   - **B.** Familial focal segmental glomerulosclerosis (FSGS)
   - **C.** Type 1 diabetes
   - **D.** Lupus nephritis
   - **E** Reflux nephropathy
2. A diagnosis of recurrent disease affecting the allograft requires which of the following pieces of information?
   - **A.** Allograft biopsy confirming the disease
   - **B.** Biopsy diagnosis of the native kidney disease
   - **C.** Clinical features of the original kidney disease recurring after transplant
   - **D.** Allograft failure caused by the disease
   - **E.** Both A and B
3. Regarding management of recurrent FSGS:
   - **A.** First-line therapy includes a 3-day course of daily intravenous pulses of methylprednisolone.
   - **B.** Cyclophosphamide should be commenced once recurrence is confirmed.
   - **C.** In a patient who develops nephrotic-range proteinuria 2 weeks after transplant, a biopsy specimen that is normal on light microscopy excludes the diagnosis of recurrent FSGS.
   - **D.** Plasma exchange should be commenced once a diagnosis of recurrent FSGS is made, with a plan to complete approximately nine cycles of therapy.

Outcomes of Renal Transplantation

Jeremy R. Chapman

Improving the outcome for patients with end-stage renal disease (ESRD) is the only justification for renal transplantation. If there were not objective and relevant data on outcomes that are meaningful to the patient, few would trust the benefits of the procedure, which has the risk for multiple adverse events. The first patients in the 1950s were comparing the potential benefits of transplantation with certain death as a result of ESRD in the absence of dialysis therapy,[1] and this is still the stark choice offered in far too many countries today[2]; some chance of life is better than no chance. In the developed world, patients face a more complex decision, with excellent and available dialysis treatment, that must be compared with their risks and benefits of renal transplantation.

The field of renal transplantation is rich with data, and increasingly sophisticated outcome measures and analyses are available to inform patient decisions. Nevertheless, when a patient is faced with a clinical problem, the evidence base is often insufficient to inform a specific decision. Transplantation guidelines that have been created by several societies[3] and by Kidney Disease: Improving Global Outcomes (KDIGO)[4] demonstrate through the grading of evidence, that many decisions can be informed only by consensus opinion. At the very least, this emphasizes that there is often no right answer but also provides a challenge to prove more about the assumptions that are made in clinical practice every day.

This chapter reviews the techniques and factors that deliver the outcome measures available today to inform patients' decision making about renal transplantation.

METHODS OF MEASUREMENT AND ANALYSIS

Types of Outcome Analyses

Survival Analyses

If the outcomes of people transplanted at different times and in different places are measured, some will inevitably die over the following years. They may die because of the transplant, or they may have an accident or some other intervention that leads to death. How can this be related to the success or failure of the transplant? Table 109.1 provides a comparison of the commonly used analytic methods in transplantation. The most conventional method is to use a Kaplan-Meier plot that yields an actuarial estimate of outcome, as opposed to an actual measure.[5,6] Events—deaths in this case—are recorded, and the time to that event from the transplant then measured. The Kaplan-Meier method uses the time of follow-up for each individual to contribute to the analysis, providing a better estimate of what will happen to the entire group of patients and not just the small group who have reached a particular time point. An example of such an analysis is shown in Fig. 109.1 from the Collaborative Transplant Study.[7] When one is comparing two groups of individuals there may be issues that should be considered, such as age. For example, if one group had an average age of 30 years and the other 60 years, differing death rates would be predicted. Thus it may be important to show results adjusted for example for age and gender, to get appropriate comparisons between the results in different transplant programs. A multivariate analysis will provide the opportunity to adjust the results for all of the factors that, on their own, appear to have an impact on the outcome. It may be that there are statistically significant differences in death rates if the group is divided, based on age, the presence or absence of diabetes, gender, or the center where they were transplanted.[8,9] Using a multivariate analysis it is then possible to see which of these outcomes is influenced by the particular distribution of the others. It may be that one transplant center that appears to have worse results transplants mostly older patients and those with diabetes, whereas another with excellent results selects only young nondiabetic recipients for transplantation. The multivariate analysis may indicate that both centers would likely achieve the same results if they transplanted similar patients.

Half-Life Analysis

Half-life analysis is the second type of analysis used to extrapolate results beyond where the data stop. It may be that no one has passed the 10-year mark in a particular center, yet patients seek an estimate of how long their kidney may last. Actuarial analysis may indicate an 80% chance of a transplant lasting 10 years, but does not provide information about what happens after 10 years. A half-life analysis allows extrapolation from the known data. There are two different half-life calculations in the literature: the median survival, which is the time that the middle patient in the series survives, and the conditioned half-life, which is the median survival of only the patients who have survived 1 year or more. Fig. 109.2 provides an example of the use of half-life calculations to demonstrate the difference in outcomes related to human leukocyte antigen (HLA) matching between donor and recipient.[10]

Graft Survival

Graft survival is subject to two different presentations, each valid in its own right, but yielding quite different answers. One of the problems in the field is that many graft survival analyses do not make clear which is being used. It is possible to understand the problem with an example. Assume that 1000 patients were transplanted and 100 died with their transplant still functioning at the time of death, whereas 80 lost their grafts from rejection and other causes and returned to dialysis. If one counts death as a cause of graft loss, 180 of the 1000 patients lost their grafts; if one ignores death as a cause, only 80 of the surviving patients lost their grafts. The latter calculation is best described as "death-censored

TABLE 109.1 Analytic Methodologies in Transplantation

Outcome Analyses	Pros	Cons
Actuarial	Captures all data	Provides estimates
Actual	Considers only part of the data	Limits information potentially available
Univariate	Considers one factor	May miss relevant factors
	Multivariate Hard to power with sufficient numbers	Considers all factors
Half-life	Provides understandable outcome analyses	Artificially hides early loses
Study Types		
Randomized controlled trials	Hypothesis driven	Not easy to power
Cohort studies	Subject to bias	May be only approach
Meta-analyses	Collects all data	Bad data cannot be made good by aggregation
Case reports	Unique examples	May never happen again
Guidelines	Careful consideration of all data	Often unable to answer critical questions
Qualitative studies	Describe ranges of answers	Provide more questions than answers
Economic analyses	Provides economic answers	Useless if hard to cost/value

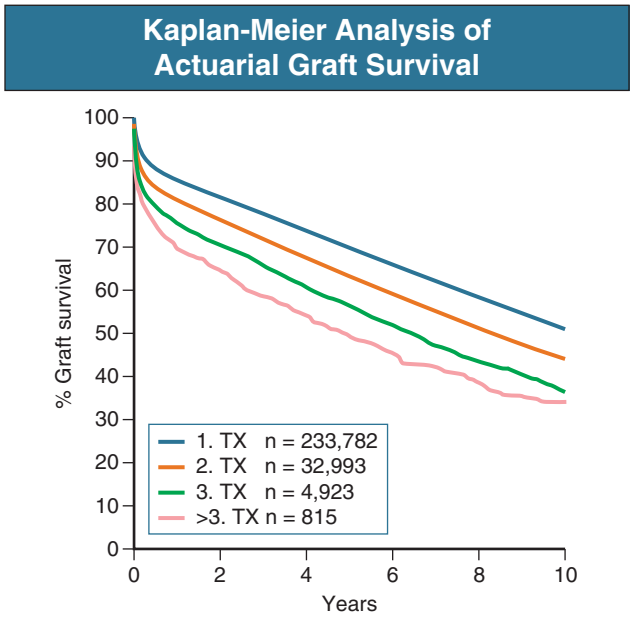

Fig. 109.1 Kaplan-Meier analysis of actuarial graft survival. Collaborative Transplant Study analysis of actuarial survival of deceased donor renal transplants by recipient graft number (1st, 2nd, 3rd, and >3rd). (Data available at www.ctstransplant.org/public/graphics.shtml. Accessed January 12, 2016.)

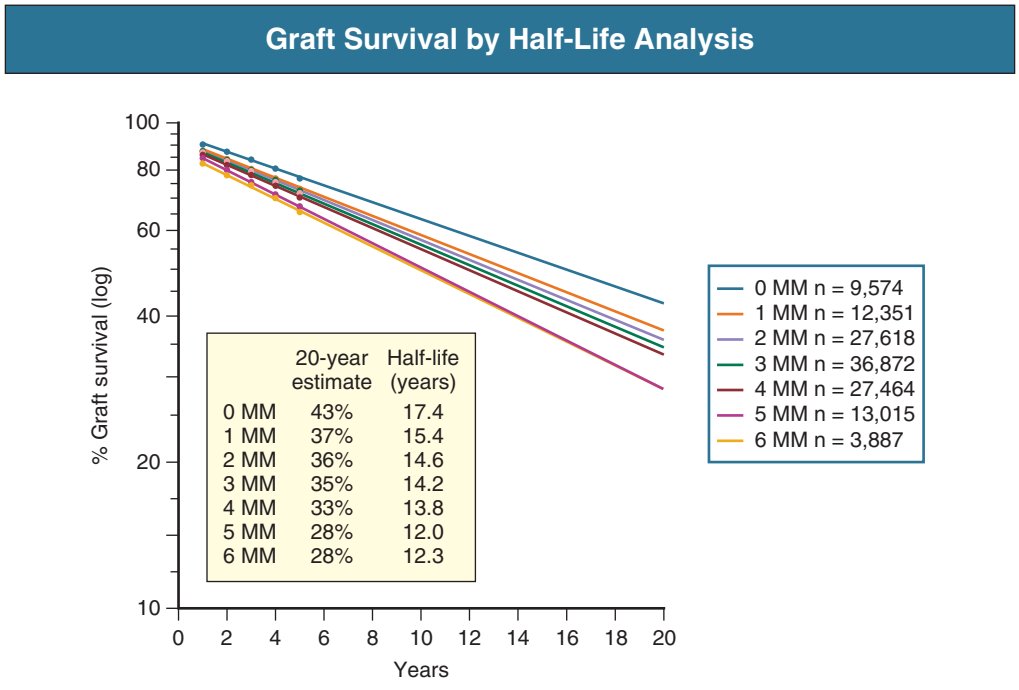

Fig. 109.2 Graft survival by half-life analysis. Collaborative Transplant Study analysis of survival of first deceased donor renal transplants performed between 1985 and 2011 by human leukocyte antigen (HLA) mismatch *(MM)* showing the half-life calculation and 20 year estimates of survival. (Data available at www.ctstransplant.org/public/graphics.shtml Accessed January 12, 2016.)

graft survival," whereas the inclusive analysis is described as "patient and graft survival." When the analysis is not specified, the findings can be misleading and may make no sense. Both approaches are of course relevant to different situations: on the one hand to understand what causes kidneys to fail and separately to understand what causes patients to die.

Randomized Controlled Trials

Randomized controlled trials (RCTs) are a conventional way of determining difference between two or more therapies and have been used extensively in transplantation to evaluate new pharmaceutical products. Most RCTs compare two drug regimens—one with and one without the new agent. Two critical problems account for the value of RCTs in renal transplantation; first, the relatively small number of transplants performed in any one center means that it is hard to mount studies with sufficient power to detect significant differences, and, second, the lack of good early surrogate markers for long-term outcomes. In cardiovascular studies, in contrast, it is often possible to randomize many thousands of patients and detect differences in meaningful outcomes other than death. However, in cancer studies it is possible to use short-term evidence of tumor response as a surrogate for longer term outcomes. In an earlier era of renal transplantation, relatively small studies could be highly informative. An example of an RCT from the 1980s is the Oxford Cyclosporine trial,[11] in which azathioprine and prednisolone were compared with cyclosporine with sufficient power to detect a difference with fewer than 100 patients randomized to each group. This was because the survival rates in the control arm were susceptible to large improvements, and 5-year graft and patient survival improved by 20% from a baseline around 47% to 67% with the addition of cyclosporine. Today the results of standard of care therapy are so high that recruitment of sufficient patients to detect either graft or patient survival differences at 1 or 2 years is not only extremely expensive but, unless the trials are very large, likely to founder on small random variations.

In the 1990s the introduction of a composite end-point controlled the required size of RCTs. The composite end-point became an acceptable indicator of benefit for the U.S. Food and Drug Administration (FDA) and other regulatory authorities to register a drug for therapeutic use. The composite end-point includes patient death, graft loss, acute rejection episodes, and lost to follow-up. (Inclusion of the latter measure thus conservatively defaults the patients who are lost to follow-up as failing the therapy.) Analysis is by "intention to treat"; in other words for outcome analysis the patient is assigned as randomized, regardless of whether the patient ever received the assigned treatment. Three key studies confirming the benefit of mycophenolate mofetil (MMF) were conducted using this approach, and each recruited around 500 patients allocated randomly into three study arms.[12,13]

Moving forward another 10 years, the largest transplant RCT undertaken to date (the Symphony Trial)[14] required randomization of more than 1500 patients and even then was only powered for a surrogate marker of long-term outcome—notably differences in renal function. It is now accepted wisdom that transplant RCTs cannot be sufficiently powered to detect differences in the hard end-points of patient and graft survival and must all be powered for a composite end-point and surrogates of long-term outcomes. Which short-term surrogates provide good predictors of long-term outcomes has yet to be determined. Acute cellular rejection was, in the 1990s, a short-term measure of importance for long-term results, but perhaps that is no longer true when using current immunosuppressive regimens.[15]

There has been a dramatic influx into the literature of new potential biomarkers of immune responses and allograft damage.[16] The gold standards in use today include serum creatinine and renal histology, which were both introduced without the rigor required in today's regulated environment. Novel biomarkers range from gene sets to predict graft fibrosis[17,18] to marketed functional assays such as ImmunKnow (Cylex, Columbia, Md).[16] The next few years will test the ability of validation and clinical utility of these biomarkers to improve the outcomes of transplantation.

Cohort Studies

Some clinical issues are not susceptible to testing by RCT. For example, an RCT design will never be able to test whether a particular cancer is more prevalent in patients on dialysis compared with patients after transplantation, first because randomization to dialysis or transplantation is ethically unachievable, and second because the numbers required to power such a study would exceed global transplant capacity. However, it is still important to understand if the risks change between dialysis and transplantation and thus to understand if there is any action that can increase or decrease death from cancer after transplantation. An example of an analysis addressing these questions is the Australian cancer study in which data from the Australia and New Zealand Dialysis and Transplant (ANZDATA) Registry on a cohort of patients who were first treated for ESRD between 1982 and 2003 was linked to data from the national cancer registries.[19] It is critical to ensure the selection of the cohort is appropriate to the question being asked. All too often a cohort study is selected from a convenience sample and thus has critical systemic flaws. A typical convenience sample is all patients being followed by a particular transplant unit. The analysis becomes an assessment only of patients still alive and still coming to the transplant unit for follow-up. The cohort has been distorted by lack of the patients crucial to the analysis.

Meta-Analyses

Some areas of transplantation are rich in both RCTs and nonrandomized studies of a particular intervention, for example, interleukin-2 receptor blockade for induction in renal transplantation. Because the studies have produced variable results, which one should be believed? This issue is approached by meta-analyses and exemplified by the International Cochrane Study.[20] An example of a Cochrane review is demonstrated in Fig. 109.3.[21] These types of analyses combine the results from patients who have undergone the same interventions from all similar studies, which thus gives much greater statistical power than each study alone can provide. The methodology requires searching for all studies of the question and especially capturing unpublished studies. The problem of publication bias plagues the field, with studies with a positive finding for the intervention more likely to be published than negative studies. The compulsory preregistration of all trials of a drug by commercial entities in a public database such as www.clintrials.gov is designed to avoid this publication bias, and it is now widely accepted that nondisclosure of data by commercial sponsors of clinical trials is neither scientifically acceptable nor tolerated by the regulators.

Case Reports

Can a case report provide valuable information about outcomes after transplantation? There are some instances of rare events in which the knowledge from a case report has proved important. One example is the early anecdotal reports of hepatitis B (HBV) transmission from HBV surface antigen (HBsAg)-negative donors to recipients of their livers.[22] A few case reports led to a cohort analysis, which in turn led to an understanding that HBV can be transmitted from a donor who tests negative for HbSAg but positive for HBV core antibody. The surveillance and vigilance strategy for the safety of cells, tissues, and organs of human origin is based on this concept—identifying and publicizing

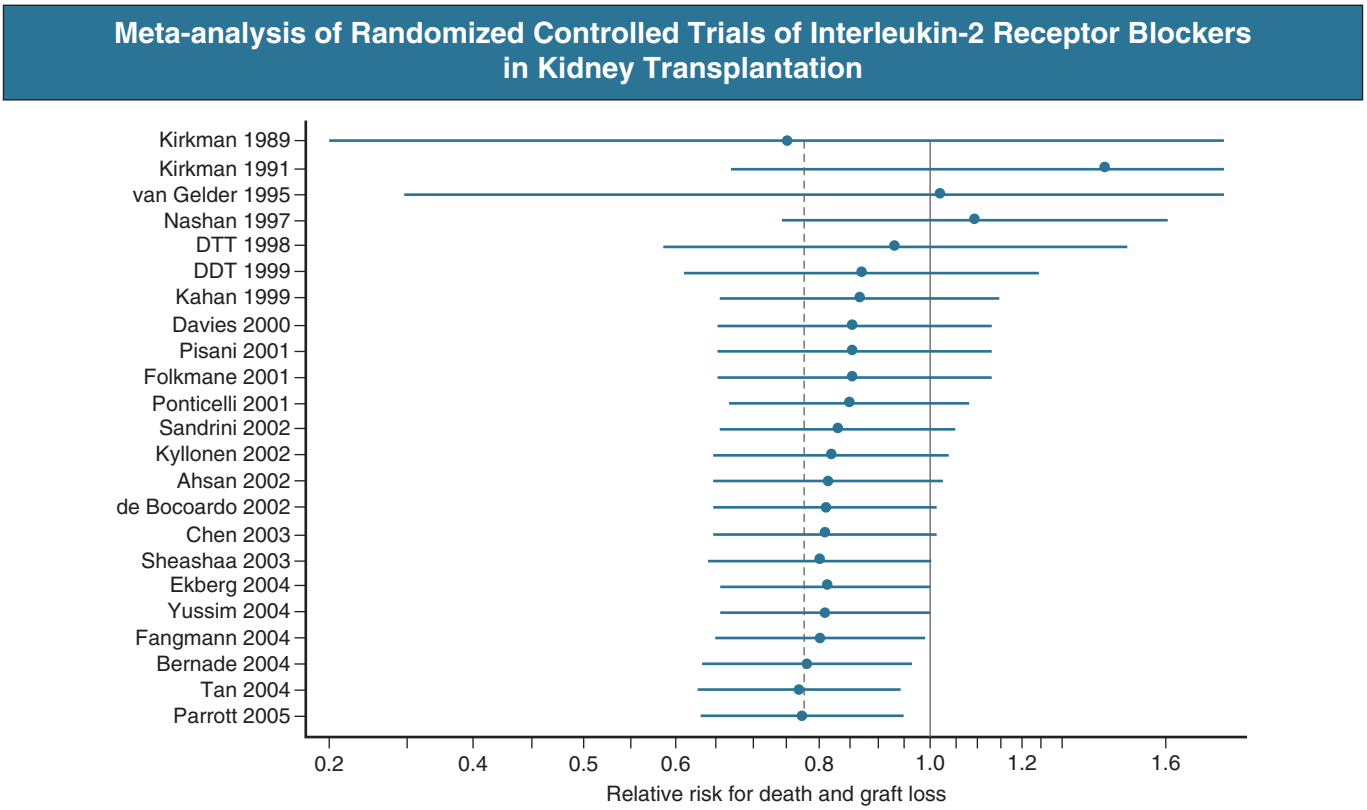

Fig. 109.3 Meta-analysis. A cumulative meta-analysis showing the effect of increasing numbers of trial on the confidence intervals of the outcome of death and graft loss in patients receiving interleukin-2 receptor blockers compared with placebo in all randomized controlled trials published between 1985 and 2005. *DDT,* Deceased donor transplants. the rare cases so the problems can be recognized (see www.notifylibrary.org). Unfortunately, publication bias ensures that once a case is reported it becomes unique because the journal editor asked to publish the second and subsequent cases will usually decline to.

Expert Opinion Guidelines

Pervasive in the transplantation literature is citing of "expert opinion" leading to clinical practice guidelines. Only the major questions have answers in RCTs, meta-analyses, or cohort studies. The clinician is repeatedly faced with unanswered questions in day-to-day clinical decision making. Guidelines rate the available evidence on particular questions from good to nonexistent. An example of a widely disseminated set of guidelines is the KDIGO guidelines on the care of a transplant recipient,[4] which clearly set out the limits of knowledge in the area. Much of the guidance provided on how to maximize outcomes for particular patients is based on the combined wisdom and experience of clinical practitioners and not on RCT or other data analyses. However, we should beware of expert opinion because it can provide a rich tapestry of self-sustaining false wisdom.

Qualitative Studies

Some questions are not amenable to quantitative data collection yet are of great importance to the field. What causes potential living donors to decide to donate? What do physicians consider most important in assessment of living donors? Why does a particular community not donate organs after death? These questions are amenable to qualitative research and can be assessed and measured, not to produce proof related to a particular question, but to generate testable hypotheses. Qualitative studies create insights into behaviors and attitudes and do not assume that there is a single reality to be discovered. People have different views on organ donation, and using any system of measurement that expects everyone to be driven by the same perspectives is going to be a disappointment. A guide to the approach of qualitative studies in transplantation has been published to assist scientists familiar mostly with quantitative studies.[23]

Economic Analysis

Health funders and government policy makers rely on multiple inputs to make investment decisions; principal among these inputs is health economic analysis, which can be the dominant policy driver in high-cost areas of medicine. Transplantation has perhaps been slow to embrace these techniques that sometimes yield counterintuitive results when comparing the high cost of keeping a patient alive and well with a transplant to an inexpensive death.[24]

Types of Data Collection

All analyses of data depend on the methodology of data collection and completeness of the data. Clearly if the data entered into an analysis are flawed in some way, the analysis will simply embed those flaws and provide spurious confidence in the outcomes of the analysis. Once the flaws of data collection are hidden by an analysis, they usually are never again identified and clinical practice is influenced based on a false assumption. It is thus essential that the reader of any analysis verifies that the data are collected in a manner that is trustworthy and relevant to the question. There are many ways to collect data, all of which have their utility when used in the right way.

Registries

The methodology of registry data collection varies from voluntary to compulsory and from automated to manual. The completeness of data is related to the amount collected, the frequency with which it is updated, and the methods used. National transplantation registries are often voluntary, such as the ANZDATA Registry in Australia and New Zealand[25] or the similar Malaysian Dialysis and Transplant Registry. Some, such as the North American United Network for Organ Sharing (UNOS) database are mandatory in that financial penalties are threatened for failure to fill in critical data elements.[26] The largest international registry is the Collaborative Transplant Study run from Heidelberg, Germany, which uses voluntary data collection on the repeatedly stressed basis that all sequential transplants from contributing units are entered and followed.[7] Donor registries tend to be complete because they capture all data at the time of organ donation as a part of the process of donation.[27] Registries that collect data in a manner that is integrated into the process they are measuring, such as taking data directly from the patients' medical records (e.g., Hong Kong), tend to have the most reliable data. In the United States the Scientific Registry of Transplant Recipients (SRTR) could use data linkage between databases to increase its accuracy.[28] Data available to SRTR include deaths in the United States and Medicare billing data to cross-check whether a transplant recipient is being billed for dialysis, both useful pieces of information to construct an accurate view of survival of either the patient or the graft.

Incompleteness of follow-up data is a weakness of many transplant registries and depends on the ability of transplant programs to follow their patients and report outcomes. Regrettably, outcomes can be artificially inflated by assuming patients are alive and well. Bad data thus produce apparently good results.

Registries usually seek at least one data point annually that confirms the patient has been seen alive and the graft is still functioning and, otherwise, define the patient as lost to follow-up at the point of last contact. This technique yields the most benefit from the data that is known about any one individual and does not allow uncertain data to contribute to analyses.

International Statistical Collections

The most useful international statistics collections are perhaps those conducted by the World Health Organization and published on the Global Observatory for Donation and Transplantation (GODT) website (www.transplant-observatory.org). These data are contributed by all national governments and probably represent the best estimates of global transplantation activity, but little or nothing is available from that source on outcomes. The GODT does allow relationships to be analyzed between donation and transplantation indices on the one hand and national health and financial statistics on the other, as in Fig. 109.4.

Randomized Controlled Trials: Data Collection

The techniques of data management of commercially sponsored clinical research probably make these the most robust data available, because the primary data source is the patients' medical records, which are used to collect specific items of carefully predefined data and, most crucially, are audited for accuracy. These three elements—primary data source, predefined information, and auditing—deliver the most trustworthy data. There is, however, one major drawback: the predefined duration of the studies ensures that long-term outcomes are almost always missing. The longest clinical trial data collections are usually for only 5 years unless data are accrued from a different source, such as through a registry.[29,30]

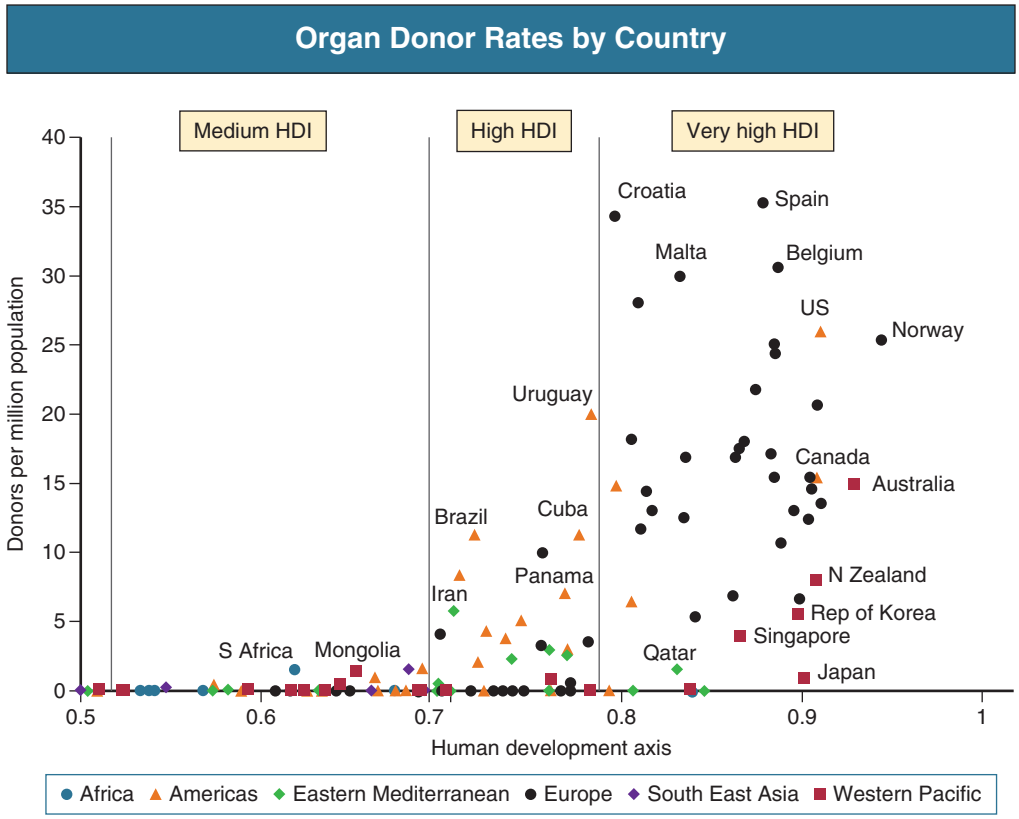

Fig. 109.4 Organ donor rates by country. World Health Organization data analysis of the number of organ donors plotted against the Human Development Index *(HDI)* by member state. (Data reproduced with permission. Global Observatory on Donation and Transplantation.)

Structured Reviews

Structured literature reviews are derived from medical reference literature search engines such as PubMed and EMbase. There are also two transplantation-specific databases of published clinical trials in the Cochrane Collaboration[20] and the Transplantation Library.[31] These databases contribute most information for the structured literature reviews needed for meta-analyses and guideline development, but searching of conference proceedings and abstracts are also needed to ensure complete data identification. The final source of data that must be included on registered therapeutic products is the manufacturing pharmaceutical company, which may hold critical unpublished data.

VARIABLES AFFECTING THE OUTCOMES OF TRANSPLANTATION

Deceased Donor Variables

The best transplant outcomes have been assumed to come from transplantation of kidneys from young adult male donors with simple head trauma as the cause of brain death and with no other medical conditions. These were the donors with which most transplant programs commenced and have become increasingly rare as road safety, accident retrieval, and neurosurgical interventions have all improved. The older recipient with previous medical conditions who finally dies from a cerebrovascular accident after many years of uncontrolled hypertension has been transplanted warily and somewhat reluctantly, usually into an older recipient. An analysis in the United States demonstrated that these extremes yield a twofold difference in graft survival.[32] Four donor factors provide the clearest distinction of outcome: donor age, cerebrovascular cause of death, history of hypertension, and renal function at the time of donation. These criteria provided a matrix of relative risk for graft failure that ranges from 1.00 for a 10- to 35-year-old donor with no adverse features to nearly a threefold increased risk for failure (2.69) for a donor over 60 years with a cerebrovascular accident, history of hypertension, and terminal serum creatinine over 1.5 mg/dl. These criteria were grouped to simplify the definition of a donor kidney likely to be associated with worse graft outcomes as the expanded criteria donor (ECD) using a cut-off of 1.7-fold worse outcome, with all other donors being classified as standard criteria donors (SCDs) (Table 109.2).

TABLE 109.2 Expanded Criteria Donor Relative Risk for Graft Failure in the United States: 1999 to 2000

				Donor Age 50-59 yr	Donor Age >60 yr
No comorbidity	—	—	—	1.41	1.90
1 Comorbidity	CVA	—	—	1.61	2.17
	—	HTN	—	1.60	2.16
	—	—	Creat	1.53	2.04
2 Comorbidities	CVA	HTN	—	1.83	2.47
	CVA	—	Creat	1.75	2.37
	—	HTN	Creat	1.75	2.37
3 Comorbidities	CVA	HTN	Creat	1.99	2.69

Compared with donor 10 to 39 yr with no adverse factors: Relative risk = 1.00.
Relative risk increases with increasing donor age, and presence of one or more of the following three comorbidities:
CVA = Death resulting from a cerebrovascular accident.
HTN = Donor history of hypertension.
Creat = Terminal predonation serum creatinine >1.5 mg/dl.
Definition of expanded donor criteria based on relative risk >1.70

The survival of recipients who received ECD grafts was 91% at 1 year compared with 95% for SCD, but because these kidneys had been allocated to older recipients the results were not directly comparable. However, by comparing within age cohorts it can be seen that there was a reduced patient survival after transplantation of a kidney from an ECD (Table 109.3). In a separate analysis it has been shown that the mean creatinine clearance 6 months after transplantation declines from around 65 ml/min if the donor was 20 to 25 years to only 35 ml/min with donors over 70 years.[33] The approach to allocation of such ECD kidneys varies around the world, for example, with the Eurotransplant policy to allocate older donors to older recipients.[34]

Further development of donor/recipient risk evaluation was undertaken using the U.S. donation and transplantation data. A more comprehensive Kidney Donor Risk Index (KDRI) was developed, tested, and implemented as an allocation tool.[35] The power of this index for estimating post-transplant survival has been tested on data from other countries and found to be robust, with a 40% to 50% difference in 10-year survival between the best and worst quintiles of KDRI.[36] This has allowed the KDRI to be used more widely to assist individuals' clinical decision making around every deceased donor offer.

The 10 factors of the KDRI are those that are most influential on long-term graft and patient survival and are worthy of analysis in all outcomes studies because of the impact they can have on the recipient results.[37] Donor age is perhaps the most obvious factor that, along with donor comorbidities identified by hypertension or death from cerebrovascular disease, predicts lower baseline donor renal function or nephron mass. In development of the KDRI, Rao and colleagues[38] added donor height, weight, ethnicity, history of diabetes, serum creatinine, and hepatitis C (HCV) infection status, as well as the mode of death after circulatory arrest rather than brain death. The numerical profile of donor quality thus can be used to provide rapid estimates of recipient outcome from transplantation with each kidney, the lowest numbers denoting the highest quality organs and best outcomes, with nearly a doubling of 5-year graft survival from 40% for the worst to 80% for the best KDRI in the United States.[38] Other countries and regions have adapted the KDRI for local use by testing the highest indicators of graft loss locally and transposing ethnicity based on North American Black populations with the equivalent high-risk local ethnic groups.

Donation after circulatory arrest (donation after cardiac death [DCD]) rather than after a diagnosis of brain death (donation after brain death [DBD]) now accounts for up to 20% of kidney donations in some countries. It has thus become important to determine the impact of DCD on short-term and long-term outcomes. The data are reassuring, in that although DCD kidneys more often have delayed graft function, graft survival, patient survival, and long-term renal function are not different from those in transplantation of DCD kidneys under the age of 45 years compared with DBD kidneys.[39] Markov modeling has

TABLE 109.3 Patient Survival (Percent) After Receiving an Expanded Criteria Donor Kidney Versus a Standard Criteria Donor Kidney in the United States: 1999 to 2000

Recipient Age	ECD		SCD	
	1 yr	5 yr	1 yr	5 yr
35-49	96	78	97	85
50-64	89	63	92	75
65+	86	55	89	59

Data from reference 32.

TABLE 109.4 Graft Survival After Transplantation Between 1985 and 1989 Percentage of Actuarial Nondeath Censored Graft Survival

Years	1	5	10	15	20
Living donor	91	75	61	45	35
Deceased donor	81	66	47	33	21

Reproduced with permission. From reference 25.

demonstrated that the combination of DBD and DCD donation is economically superior to a simpler strategy that focuses only on the use of DBD kidneys.[40]

Living Donor Variables

The assessment of the living donor is primarily directed at donor safety to ensure risk to the donor is minimized as far as possible. The secondary assessment is of factors that may affect the recipients' chances of a successful outcome. Impaired renal function or significant donor hypertension or diabetes are, for example, usually exclusion criteria based on donor safety rather than recipient outcomes.[41] Assessment of the living donor is further discussed in Chapter 102. The cumulative data from almost all studies show that transplantation of a living donor kidney offers superior outcomes to deceased donation, though the precise reason for this is probably a mixture of recipient and donor factors, including the ability to perform preemptive transplants with living donors. A long-term analysis performed by ANZDATA (shown in Table 109.4 and Fig. 109.5[25]) shows there was a 10% advantage to living donation at 1 year stretching to a 14% advantage by 20 years after transplantation.

A North American study of living kidney donors and recipients used a half-life calculation based on survivors at 1 year after transplant.[42] They demonstrated that the half-life—that is, the time at which 50% of grafts were still functioning and the patients were alive—was between 10 and 16 years when the donors were under 60 year of age and the recipients were under 60 years, but the results fell to between 7 and 10 years if either the donor or the recipient were over 60.

Other Donor Variables

Additional donor-related factors are known to affect both long-term and short-term graft and patient outcomes, such as those leading to initial nonfunction, and determine whether the recipient will need dialysis postoperatively (Box 109.1). These factors can be used in modeling outcomes, as recently undertaken to provide a decision aid for recipients offered one or more organs.[43] The models need to be adjusted for transplant year, cause of ESRD, panel-reactive antibody to HLA at transplant, previous transplant, years on dialysis, HCV serologic status, insurance status, recipient and donor race and ethnicity, and donor history of cigarette use. In addition to simple donor factors, such models need also to consider combined donor-recipient factors including age, sex, body mass index (BMI) of 30 or less, weight ratio, height ratio, HLA mismatch, and ABO compatibility, because it is the interaction of the donor and recipient characteristics that creates the risk.

Recipient Variables

Many factors affect both patient and graft outcomes that relate directly to the recipient, some of which may be modifiable and some of which are intrinsic. Perhaps the most modifiable factor in theory would be when to perform a transplant: before the need for dialysis (preemptive transplantation) or after dialysis has commenced. The analysis of the benefit of preemptive transplantation is complex because the comparison cannot be between people receiving preemptive transplants and those who are transplanted after dialysis, as the delayed patients must survive long enough to be offered a transplant. Despite these complexities of lag time in analysis, there is both an economic argument (it is cheaper to avoid dialysis) and a survival advantage (patients with preemptive transplants have 5% to 10% better 5-year post-transplant survival). Fig. 109.6 shows the Australian experience with access to a living donor transplant showing that people in the top two socioeconomic demographics have greater chance of a preemptive transplant and greater total access to living donor transplants.

The various modifiable and unmodifiable factors influencing graft outcomes are shown in Table 109.5, and BMI is illustrated in Fig. 109.7.[44] In assessment of individual outcomes there are unfortunately no simple tables of risk analogous to cardiovascular risk profiles for the general population, but the dominant features affecting outcomes remain recipient age and cardiovascular comorbidities.

Comparison of the Long-Term Outcomes of Transplantation by Era in Australia and New Zealand After Living and Deceased Donation

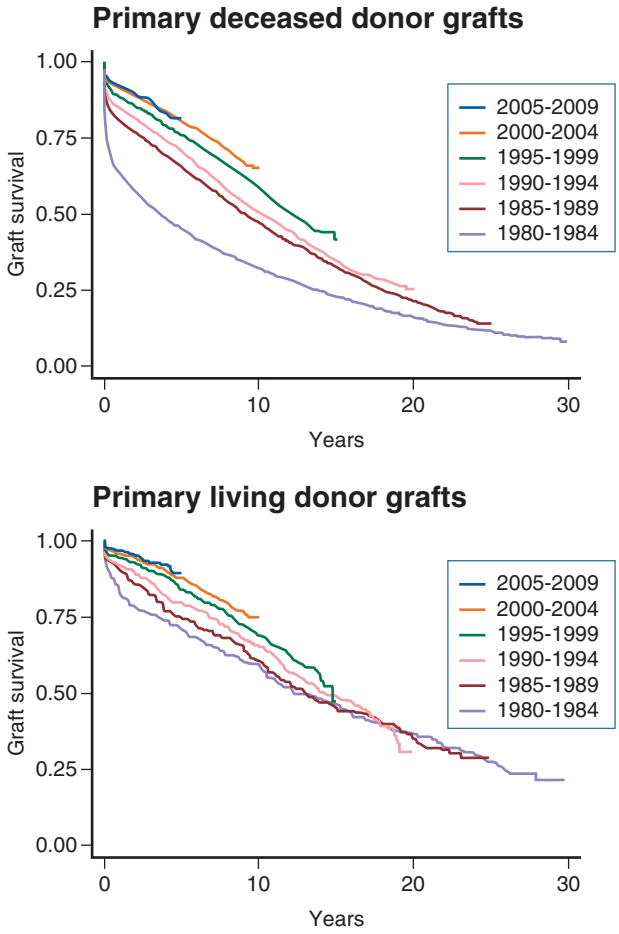

Fig. 109.5 Comparison of the long-term outcomes of transplantation by era in Australia and New Zealand after living and deceased donation. (Reproduced with permission. From reference 25.)

The two recipient diseases that have undergone the most significant transformations in the past few years are HIV and HCV infections. HIV-infected recipients are not only stabilized and living much more normal life expectancies today with antiretroviral therapy, but it is possible to transplant them successfully with minimal immunosuppression dose adjusted for drug interactions.[45] HCV infection is now a fully treatable disease with high rates of sustained virologic responses using current direct-acting antiviral agents such as a combination of sofosbuvir and ledipasvir.[46] The option to treat patients either before or after transplantation and to accept treated HCV-positive donors routinely for all recipients are now being tested. Again, the interaction of the new agents with renal function and immunosuppressant drugs needs to be considered.

BOX 109.1 Donor Factors Known to Worsen Graft and or Patient Outcomes After Transplantation of the Kidney

- Deceased versus living donor
- Donation after circulatory arrest compared with donation after brain death
- Increasing donor age
- Donor history of hypertension or diabetes
- Cause of donor death: Cerebrovascular disease or prolonged anoxia/drowning
- Worse terminal renal function
- Use of inotropes before donation
- Duration of final intensive care admission
- Female gender compared with male
- Nephron mass (donor/recipient weight ratio)
- Histology (percent of sclerosed glomeruli)
- Ex-vivo perfusion not used
- Transmissible disease (infection/malignancy)

Effects of Immunosuppression on Transplant Outcome

There are many examples of the use of outcome analysis to determine alternatives for immunosuppressive therapy after renal transplantation.[11-14] The proliferation of alternative immunosuppressive therapeutic regimens has yet to be resolved in the way that cancer chemotherapeutic regimens have specific strategies for specific indications. The standard therapy against which comparisons now must be made includes a calcineurin inhibitor, generally assumed to be tacrolimus despite some reluctance by the FDA to accept it over cyclosporine, MMF or mycophenolate sodium, and corticosteroids. The choice of immunosuppressive regimens is discussed further in Chapter 104.

The adverse outcomes of immunosuppression such as excess cancer risk[19] and observations of reduced cancer risk with inhibitors of the target of rapamycin (mTOR)[47] have, for example, led to the individualization of therapy for those with a high risk for skin cancer.[48] This is discussed further in Chapter 105.

Transplant Center Variables

The outcome of transplantation in different transplant centers is largely, but not entirely, driven by case selection. In the United States a center-based report card has been used to identify low-performing centers (which have statistically significant worse outcomes than predicted from their case mix) that remain low performing and do fewer transplants after a low performance report, suggesting that the information about poor outcomes assists both patients and administrations identify

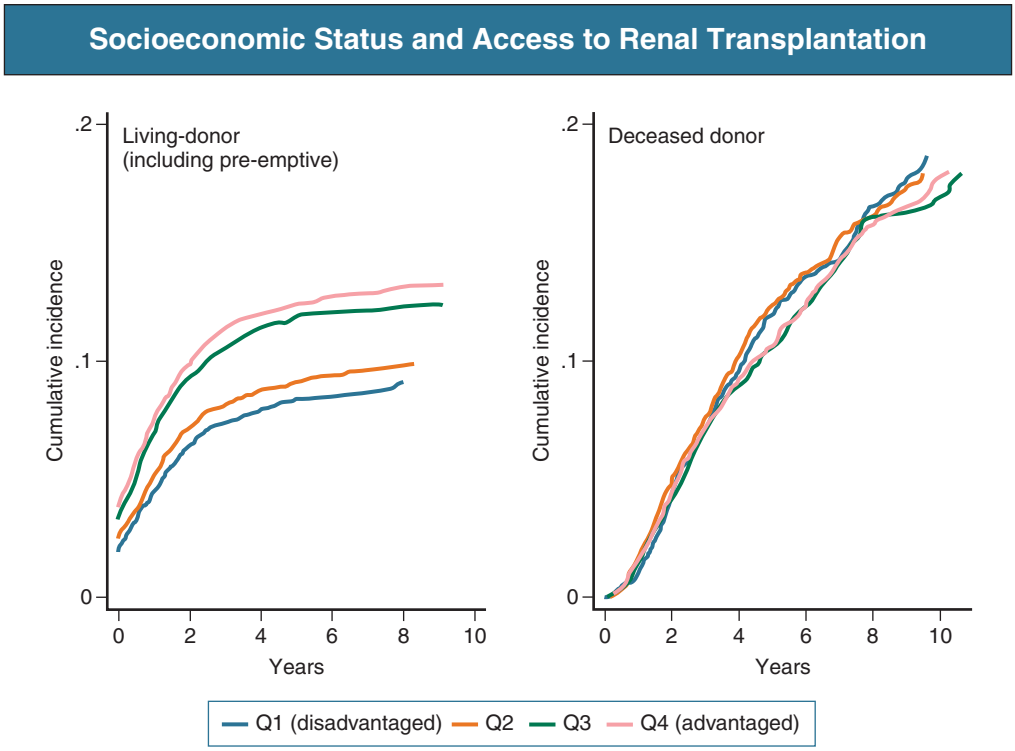

Fig. 109.6 Socioeconomic status and access to renal transplantation. Access to transplantation in Australia and New Zealand 2000 to 2010 by socioeconomic status of postcode of residence, demonstrating the cumulative incidence of transplantation by time from commencement of dialysis. There were no preemptive deceased donor transplants and no effect of socioeconomic status, but living donor transplants were accessed more frequently and sooner by the top two socioeconomic groups with an approximately 25% of living donor grafts being preemptive. (Data courtesy ANZDATA. From reference 25.)

TABLE 109.5 Recipient Factors Affecting Graft and Patient Survival After Renal Transplantation*

Patient-Related Factors	
Age	*Adults:* Outcome worse with increasing age. *Children:* Outcome worse <7 kg.
Gender	Better outcomes from male donor to female recipient presumed to be based on nephron mass.
Race	Worse outcomes compared with White in United States for African Americans, but better for Asians. Variable effects in other countries but generally worse for indigenous races.
Anti-human leukocyte antigen (HLA) antibodies	Worse with increasing sensitization as a result of previous blood transfusions, pregnancies, grafts.
Previous transplants	Worse outcomes with second and subsequent grafts.
Primary renal disease	Specific risks for recurrent disease by type of primary disease.
Comorbidities	Worse outcome with cardiovascular disease, chronic respiratory disease, diabetes mellitus, hepatitis B or C infection.
Body mass index (BMI)	Worse outcomes at extremes of BMI: <20 and >35 (see Fig. 109.7).
Medication and clinical follow-up adherence	Worse outcome with poor adherence to follow-up and medication protocol.
Transplantation-Related Factors	
Surgical experience	Worse outcomes with inexperienced surgeon.
Graft and patient vascular anatomy	Worse outcomes with multiple arteries and veins.
Warm ischemia time	Worse outcome with prolonged time.
Cold ischemia time	Worse outcome with prolonged time.
Transplant center experience and results	Center effects are usually not significant and are related more to patient and donor selection criteria than center expertise. However, some centers in some countries have been shown to produce worse outcomes based on multivariate analysis of all relevant factors, leaving center expertise the most likely remaining outcome variable.
HLA matching	Worse outcome with poor matching (see Fig. 109.2).
Donor-specific antibodies	Easily detected high titer anti-HLA class I and II antibodies detected by cytotoxicity crossmatch tests are associated with hyperacute, accelerated, and acute rejection. Anti-HLA antibodies detected only by solid-phase assay depending on their titer are associated with worse long-term outcomes (see reference 42).

*There is significant variation in some of these factors in different countries.

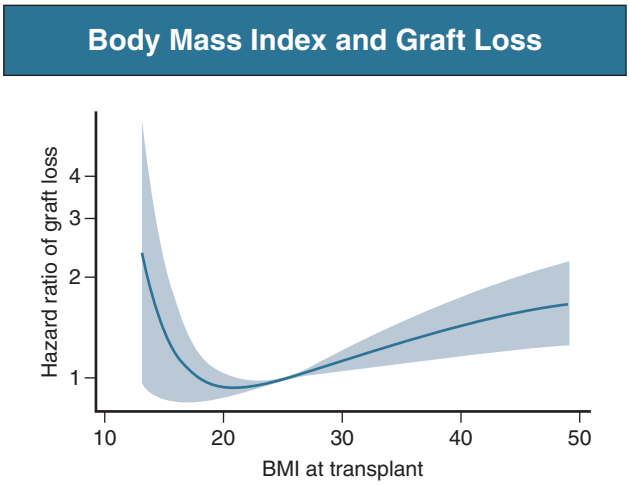

Fig. 109.7 Body mass index *(BMI)* and graft loss. Univariate analysis of graft loss by BMI in 5684 patients in ANZDATA from 1991 to 2004. Obesity was not associated with cardiovascular disease (CVD)-related mortality and was associated with age, males, smoking, diabetes, CVD, long-term dialysis $P < .001$. (From reference 44.)

problems and avoid transplantation at those centers, but sadly not that the report leads to changes in low-performing centers and turns them into high-performing centers.[9,49]

Transplantation Matching Variables

HLA matching is perhaps the most dominant feature of individual patient outcome, with 15% 5-year differences in graft survival quite common across different analyses (see Fig. 109.2).[10,50] The advent of specific definition of anti-HLA antibodies through solid-phase assays, especially those using beads read by dual-laser flow cytometry,[51] has increased the precision of HLA typing and matching. However, a critical question remains that has not yet been amenable to long-term outcome analysis: at what sensitivity level and against which HLA antigens should an anti-HLA antibody be avoided? A recent consensus meeting has helped define the knowns and unknowns, but has not yet led to a conformity of HLA matching and crossmatching criteria.[52] Desensitization of patients with anti-HLA antibodies has been shown to be a successful way of transplanting patients who would otherwise not be transplantable.[53]

The blood group barrier, once thought immutable, is like the HLA antibody barrier, amenable to intervention providing the titer of anti-ABO antibody is known and reduced by physical removal to a low level at the time of transplantation.[54] The data support the view that antibodies to both HLA and blood group substances may be tolerated once the graft is in situ and it is only the critical early post-transplant days and weeks that cannot be accommodated. Understanding of the

mechanism of accommodation has yet to be achieved, because continued activation of complement is seen in ABO-incompatible grafts but without obvious pathologic graft damage.[55]

OUTCOMES INFORM THE RECIPIENT DECISION

Patients with progressive end-stage chronic kidney disease must decide whether they wish to commence dialysis, receive a transplant, or elect not to be treated. The outcomes of the alternatives are obviously critical to that decision, and thus it is the responsibility of the treating physician and team to ensure each patient is properly informed to make that choice. The components of that decision extend beyond the medical facts and in many countries involve financial and other social factors, such as availability of therapy. The medical decision for each individual revolves around prognosis related to comorbidities, organ availability (of both living and deceased donor kidneys), and alternative dialysis therapies. The advantages are not all exactly as might be predicted. For example, a 25- to 35-year-old adult with no comorbidities can be predicted to do well after transplantation with either a living or deceased donor, but such an individual will also do well on dialysis, so the life year gain from transplantation may not be as much as expected.[56] On the other hand, a 55-year-old diabetic patient may have a poor prognosis with a transplant but will do even worse on dialysis and thus may wish to seek the added life years from transplantation.

SELF-ASSESSMENT QUESTIONS

1. Actuarial survival is a:
   - **A.** Method of calculating how long a patient will live after kidney transplant failure
   - **B.** Statistical method of maximizing the information available for analysis of outcome from a group of patients and events
   - **C.** Way of making "actual results" seem more plausible
   - **D.** Statistical method to estimate the outcomes of patients who are lost to follow-up
2. The composite end-point accepted by the U.S. Food and Drug Administration for immunosuppressive drug trials in transplantation includes:
   - **A.** Graft failure and patient death
   - **B.** Graft failure, chronic rejection, and lost to follow-up
   - **C.** Acute rejection, graft failure, lost to follow-up, and patient death
   - **D.** Biopsy-proven acute cellular and acute antibody-mediated rejection
3. Meta-analysis is a:
   - **A.** Way of deciding which of several randomized trials is correct
   - **B.** Statistical software package
   - **C.** Method of combining the results from all similar trials to gain statistical power
   - **D.** Trial design used in large studies to decide which factor is most important in determining an outcome.

Pancreas and Islet Transplantation

Jonathan S. Fisher, Christopher L. Marsh

Pancreas transplants are performed to treat insulin-requiring diabetes. Initially, pancreas transplants were performed only in those diabetic patients with chronic kidney disease who needed kidney transplants; these patients underwent simultaneous pancreas-kidney transplantation (SPK). Today, pancreas transplantation alone (PTA) or pancreas transplantation after living or cadaveric renal transplantation (PAK) is increasingly common. SPK accounted for 72% of all pancreas transplants in 2010 (Fig. 110.1). There were approximately 2800 people in the United States waiting for pancreas transplants in 2016.[1] The 2014 Annual Report of the Organ Procurement and Transplantation Network (OPTN) and the Scientific Registry of Transplant Recipients (SRTR) reveals that the number of new registrations as well as of pancreata recovered and transplanted in the United States steadily increased from 1997 to 2004, but there has been some decline since then.[2] Although data are less complete for pancreas transplants outside the United States, the trends are similar with a decline in non-U.S. transplants performed since 2007. Several factors are thought to play a role. New insulin formulations and delivery systems in the form of insulin pumps have reduced the need for transplant in some patients. Selection criteria for potential recipients have become increasingly stringent as the average age of recipients has increased as well as the number of transplants being done in patients with type 2 diabetes. Simultaneously, there has been a trend over time toward tighter donor criteria as transplant centers strive to ensure excellent outcomes. Last, there have been recent downward trends in numbers of patients registered for pancreas transplants. New SPK registrations in the United States rose from 1412 in 1997 to a high of 2007 in 2000 and declined to 1264 in 2015. Some of this reduction may be due to an increase in the number of patients receiving islet cell transplants.

PATIENT SELECTION CRITERIA FOR PANCREAS OR ISLET TRANSPLANTATION

Indications for Transplantation

Indications for pancreas or islet transplantation include insulin-dependent diabetes with associated diabetic complications (nephropathy, neuropathy, and retinopathy) and diabetes with episodes of hypoglycemic unawareness.

The relative roles of pancreas and islet cell transplantation remain controversial, but several factors influence the choice between these two approaches in clinical practice. Because the quantity of islets that are available for transplantation remains a limiting factor, islet transplants are more appropriate for patients with smaller insulin requirements, typically slender women. Larger patients (usually with higher insulin requirements) are more reliably served with whole-organ pancreas transplants. Islet transplantation is performed by a radiographic procedure and therefore is better suited for patients who cannot tolerate the surgical stress of whole-organ transplantation, such as older patients with severe coronary heart disease.

Pancreas or islet transplantations have not routinely been performed for type 2 diabetes mellitus because the primary defect in type 2 diabetes is insulin resistance, not insulin deficiency. There may be a role for pancreas transplantation in patients with type 2 diabetes who develop islet failure after years of insulin resistance or those who have deficiencies in beta cell function such as maturity onset diabetes of the young types 1-6. A review of the United Network for Organ Sharing (UNOS) registry from 2000 to 2007 revealed that after adjusting for a variety of factors (e.g., age, race, weight, time on dialysis, cardiovascular disease) there were no differences in risk for death or kidney or pancreas failure according to diabetes classification.[3] The analysis suggested that insulin-requiring patients who have type 2 diabetes, are younger than 50 years, and have body mass index (BMI) less than 30 kg/m^2 will become insulin independent with a pancreas transplant.[4] The proportion of pancreas transplants performed in people with type 2 diabetes has increased from 2% in 1995% to 9% in 2014.[5]

Should living kidney donor recipients be offered a PAK transplant? An analysis of UNOS data revealed no difference in survival of SPK recipients and living kidney donor recipients at up to 8 years of follow-up.[6] However, a European study showed an improved 10-year patient survival (83% in SPK vs. 70% in kidney transplants alone) and noted a significantly lower progression of macrovascular disease (cerebrovascular, coronary, and peripheral vascular) with SPK transplants.[7] Kidney graft ultrastructure and function are better preserved comparing SPK with LKD transplantation alone.[8] A review of the UNOS registry 1997 to 2007 divided those recipients with type 1 diabetes who received a living donor kidney transplant into two groups: those who subsequently received a PAK within a year of the kidney transplant (n = 1026) and those who did not (n = 3528). At the end of the eighth year, the patients who subsequently received a PAK had superior patient (85% vs. 75%) and kidney graft survival (75% vs. 62%).[9] Therefore the two-stage approach of PAK after a living donor kidney transplant should be considered for patients who have a living kidney donor and in whom the cardiovascular risk for the extended procedure required for SPK is considered too great.

The role of PTA transplants in those with preserved renal function remains unclear. A single-center study of 131 PTA recipients revealed that PTA is an independent risk factor for the development of kidney failure, presumably because of the nephrotoxicity of long-term immunosuppression.[10] Analyses of the UNOS database have shown conflicting results with respect to survival for those with diabetes and preserved kidney function receiving a PTA than for those who remained on the waiting list and received conventional therapy.[11,12] Further study is warranted, keeping in mind that a prospective, randomized trial of pancreas transplantation versus conservative therapy is not practical.

MEDICAL EVALUATION

The medical evaluation for the prospective pancreas transplant candidate is similar to that of the kidney-only recipient (see Chapter 102), although the cardiac workup is more extensive. The best candidates for transplantation are younger than 50 years and have a limited number of major complications of diabetes, such as hypoglycemic unawareness or diabetic neuropathy. Additional complications, such as vascular disease, orthostatic hypotension, and severe gastroparesis, put patients at higher risk for post-transplantation complications, but none of these factors by themselves exclude a patient from transplantation. It has been argued that chronologic age alone should not exclude a patient from pancreas transplant candidacy. Patient and graft survival has been shown to be comparable between younger patients and carefully selected older patients; however, there is a higher incidence of cardiac events in the older population.[13] Thus cardiovascular status is the primary deciding factor for transplantation eligibility because the surgery, infections, risk for thrombotic complications, and, until recently, rejection are more severe in the pancreas transplant recipient, demanding that the cardiovascular system be able to withstand multiple prolonged, hemodynamically stressful events. Cardiovascular or cerebrovascular problems (31%) and infections (21%) remain the leading causes of recipient death.[14] All patients require noninvasive cardiac stress evaluation because of the limited exercise capabilities of many patients. Cardiac catheterization is performed based on the results of noninvasive testing or is performed first for high-risk status (age older than 45 years, those with diabetes duration of more than 25 years, smokers of more than 5 pack-years, and those with an abnormal electrocardiogram). Peripheral vascular disease is evaluated by clinical examination and by arterial duplex ultrasound. Patients with limb-threatening ischemia are typically poor pancreas transplant candidates. The medical evaluation for islet transplantation is similar to that for pancreas transplantation, but exclusion criteria are fewer because of lower surgical and inflammatory risks.

The last criteria for transplantation are that the donor and recipient match for ABO blood group and that the recipient sera are crossmatch

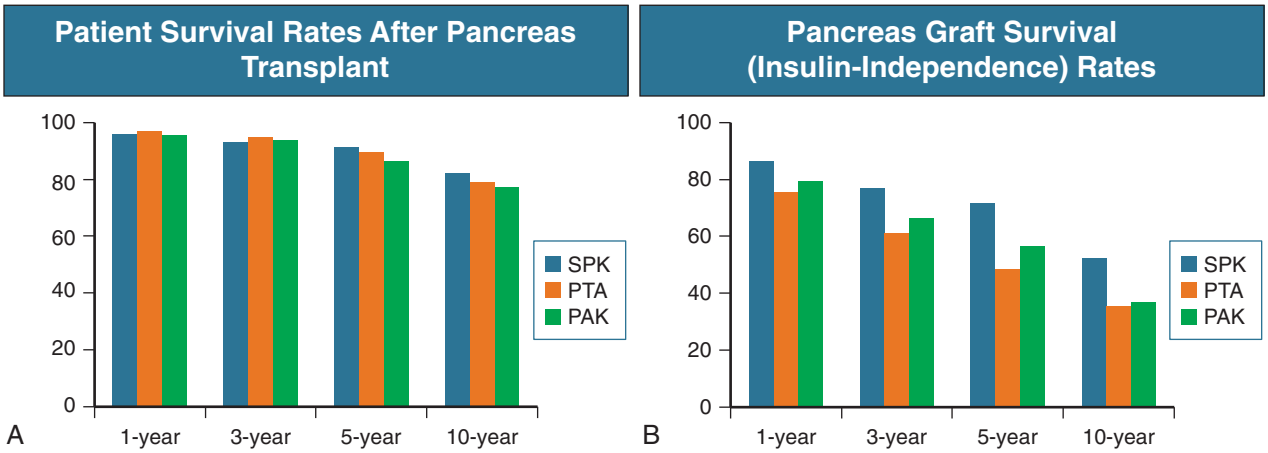

Fig. 110.2 Patient and graft survival after pancreas transplantation. Unadjusted pancreas patient and graft survival by type. (A) Patient survival rates. negative against donor T cells by either the standard antiglobulin or flow cytometry crossmatch.

PANCREAS TRANSPLANTATION

Patient and Graft Survival

The reported 1-, 5-, and 10-year patient survival rates show a marked improvement from 1991 to 1995 to 2012 to 2013.[2] Pancreas graft survival rates have shown similar improvements (Fig. 110.2). Better outcomes are due to changes in surgical techniques, donor selection criteria, and improvement in the composition of the preservation fluid, as well as more effective immunosuppressive regimens, despite an increasing proportion of high-risk patients.

There has been a trend toward tighter donor selection criteria. The ideal donor is between 10 and 40 years of age, with a BMI less than 27.5 kg/m^2 and a cause of brain death other than cerebrovascular disease.[15] The UNOS database demonstrates that over the past 5 years more than 60% of such donors have had a cold ischemic time of less than 12 hours.[2]

Most organs are stored in the University of Wisconsin (UW) solution, which has increased early pancreas graft function and reduced the occurrence of preservation pancreatitis. A second cold storage solution, histidine-tryptophan-ketoglutarate (HTK), offers better tissue perfusion because of lower viscosity, less reperfusion hyperkalemia, and significantly lower cost. However, studies have suggested a higher incidence of graft pancreatitis and an increased rate of graft loss with HTK, particularly with longer cold ischemia times.[16,17] Approaches using either a two-layer storage method with UW or an HTK solution and a second layer of highly oxygenated perfluorocarbon or the attachment of the pancreas to a low-pressure pulsatile perfusion system are being investigated.

The current gold standard immunosuppression for pancreas transplants is antibody induction therapy, tacrolimus, mycophenolate mofetil (MMF), and corticosteroids; this has led to a 40% decrease in incidence of rejection and an increase in 1-year graft survival to more than 90%. Graft survival is not directly impacted by human leukocyte antigen (HLA) matching, though rejection, particularly for solitary pancreas transplants, has been correlated with the number of mismatches with a roughly twofold increase in the risk for rejection with four or more mismatches or with mismatching at the HLA-B or HLA-DR loci.[18] Moreover, rejection during the first year after transplant is the most critical factor in predicting whether the patient would reach 5 years with a functioning pancreas.[19] The same analysis suggested that either positive donor or positive recipient cytomegalovirus (CMV) status significantly decreases the likelihood of long-term graft function.

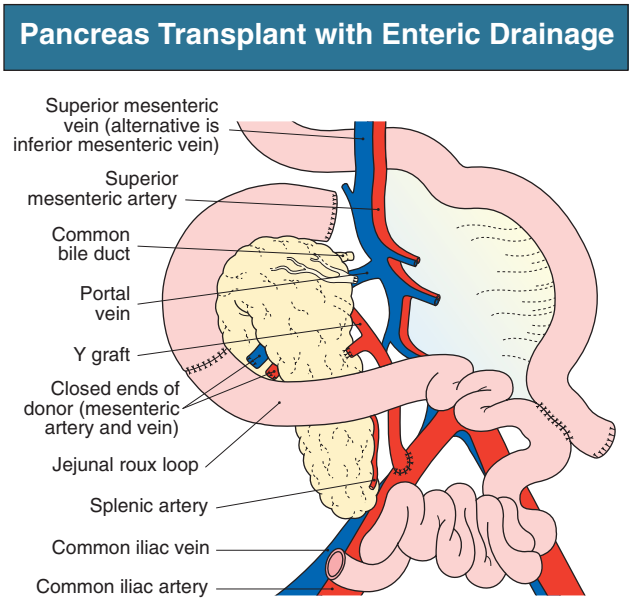

Fig. 110.3 Pancreas transplant with enteric (portal) drainage.

Surgical Procedure

Current practice is to transplant the whole pancreas with a cuff of duodenum, which preserves the blood supply of the head of the pancreas and provides a means to drain exocrine secretions into either the small bowel (enteric drainage) or the bladder (Figs. 110.3 and 110.4).[1] A growing majority of the pancreas transplants in the United States are now enterically drained (Fig. 110.5).[1] The graft may be placed in the right iliac fossa like a kidney, intraperitoneally, and vascularized from the common iliac vessels so that the secreted insulin enters the systemic circulation. However, an alternative is to construct the venous anastomosis to the superior mesenteric vein, allowing more physiologic insulin output through the portal circulation. Currently, 15% to 20% of

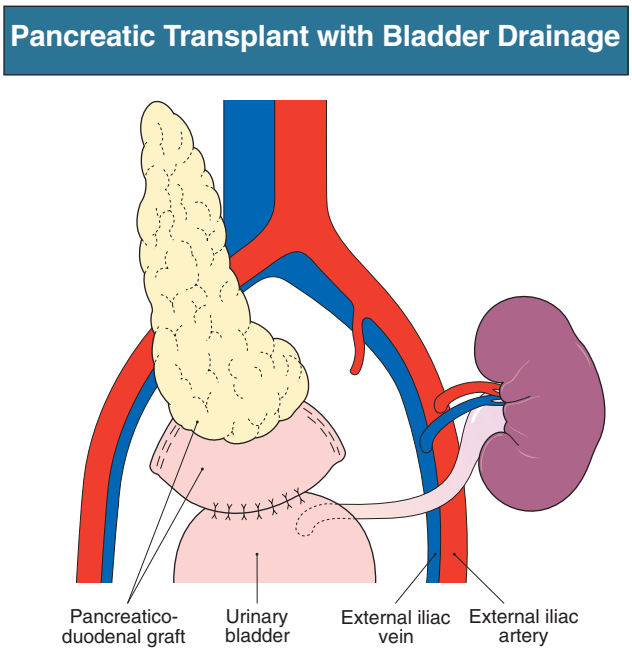

Fig. 110.4 Pancreas transplant with bladder drainage. The pancreas may be placed in either the intraperitoneal or extraperitoneal position.

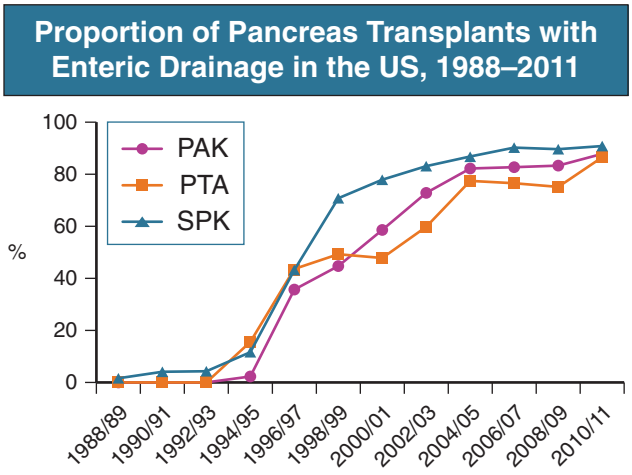

Fig. 110.5 Pancreas transplant technique. Proportion of U.S. primary pancreas transplantations using enteric drainage, by recipient category and era, 1988 to 2008. There has been a shift toward enterically drained compared with bladder-drained pancreas transplantation. *PAK,* Pancreas transplantation after living related or unrelated kidney transplantation; *PTA,* pancreas transplantation alone; *SPK,* simultaneous pancreas-kidney transplantation. (Modified from reference 4.)

enterically drained transplants use portal drainage. In either approach, an interposition graft from the donor (typically a Y graft containing common iliac artery with external and internal branches) is used to provide inflow from the recipient common iliac artery to the graft superior mesenteric and splenic arteries. Some surgeons have advocated reconnection of the graft gastroduodenal artery if the pancreaticoduodenal arcades are not intact.

Bladder drainage allows monitoring for rejection by measurement of urinary amylase and avoids enterotomy-associated risks for infection and leak. The disadvantages of bladder drainage include susceptibility to dehydration, metabolic acidosis, and frequent urologic complications. Primary enteric drainage avoids these complications and is more physiologic but does not allow urinary amylase monitoring. With improved surgical techniques, increased use of real-time ultrasound, and percutaneous needle biopsy, the outcomes of enteric drainage now match those of bladder drainage. Bladder drainage is still appropriate when there is a history of major abdominal surgery, in the presence of Crohn's disease or other small bowel disease, and for older patients with less cardiovascular reserve, in whom a laparotomy may be avoided through a smaller lower quadrant retroperitoneal incision similar to that for a kidney transplant. Pancreas transplants with venous outflow to the superior mesenteric vein can be placed either anterior to the small bowel mesentery or in a retroperitoneal position behind the ascending colon, where the superior mesenteric vein is reached from the side. Surgical outcomes do not differ whether the venous drainage is systemic or portal. Although portal drainage is considered more physiologic and avoids hyperinsulinemia, these benefits are not well characterized.

BOX 110.1 Causes of Pancreas Graft Dysfunction

- Ductal obstruction
- Vascular: arterial or venous thrombosis (partial or complete), arteriovenous fistula
- Volume depletion
- High calcineurin inhibitor levels
- Graft pancreatitis (preservation, viral, bacterial, or fungal)
- Exocrine secretion anastomotic leak
- In cases of bladder drainage
  - Reflux pancreatitis
  - Urinary tract infection
  - Bladder outflow obstruction
- In cases of enteric drainage
  - Bowel obstruction

Immunosuppression

Most centers use antibody induction therapy during the first 1 to 2 weeks after transplantation, mostly antithymocyte globulin (ATG).[20] Other centers use an interleukin-2 (IL-2) receptor antagonist (basiliximab) or, most recently, an anti-CD25 antibody (alemtuzumab).[21,22] Antibody-mediated rejection may be more common than acute cellular rejection in patients receiving alemtuzumab.[23] Most centers employ triple-drug maintenance immunosuppression with tacrolimus (or less commonly cyclosporine), MMF (or rarely azathioprine), and corticosteroids. There is increasing evidence of equivalent success with rapid corticosteroid elimination or corticosteroid avoidance protocols. Some centers replace the calcineurin inhibitor (CNI) or MMF with sirolimus typically after at least 1 month after surgery (after primary wound healing). With the more profound immunosuppressive induction produced by the newer antibodies (particularly alemtuzumab), there have been reports of immunosuppression protocols limited to a depleting antibody and a single additional agent.[22,24] Fortunately, CMV infection rates appear to be lower in corticosteroid-free regimens,[22] although there has been some increase in CMV infection in those receiving depleting antibody therapies.[21]

Graft Monitoring

The causes of pancreas graft dysfunction and the evaluation process are shown in Fig. 110.6, Box 110.1, and Table 110.1.

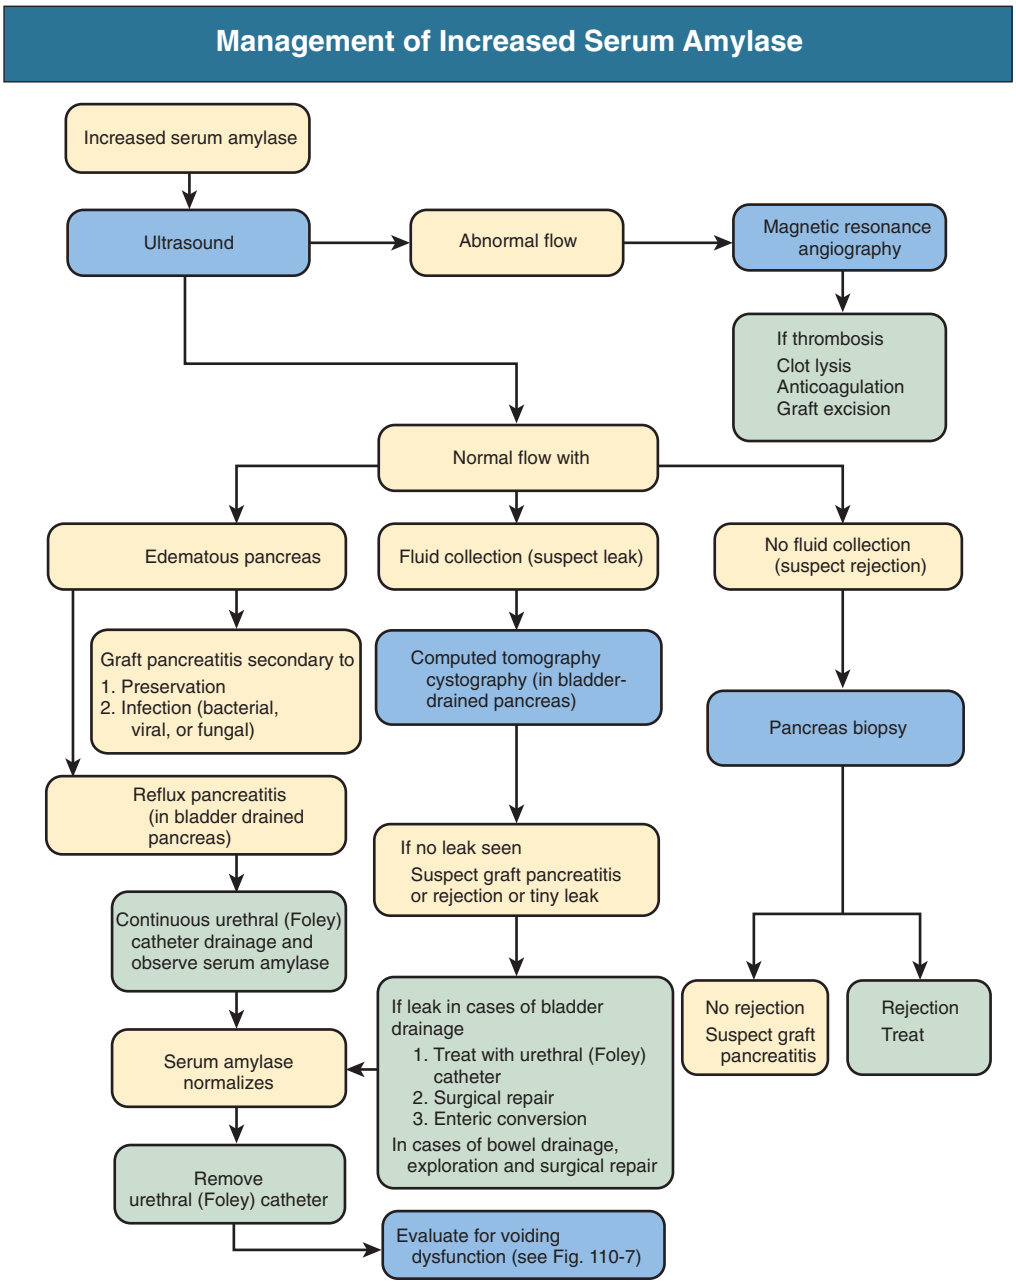

Fig. 110.6 Management of increased serum amylase after pancreas transplantation.

During the immediate perioperative phase, intravenous insulin is used to maintain serum glucose concentration around 100 to 120 mg/dl (5.5 to 6.6 mmol/l). Serum glucose values are not an early marker of pancreas dysfunction; elevations are observed only after significant parenchymal pancreatic damage has occurred. During the first 1 to 2 weeks after transplantation, serum amylase may be elevated as a result of pancreatic preservation injury. Trends are followed rather than absolute values, taking into consideration factors such as length of cold ischemic time and degree of gland edema. Stable serum levels are usually attained within 2 weeks after transplantation. Rising serum amylase or lipase concentration (typically by more than 20% of baseline) indicate possible graft injury requiring evaluation. Elevated serum amylase and serum lipase concentrations are moderately sensitive markers of pancreas rejection. However, other conventional causes of pancreatitis can still occur. Elevated fasting glucose and 2-hour postprandial glucose levels are relatively late indicators and only indicate dysfunction, without revealing cause.

With bladder drainage, urinary amylase excretion serves as an additional indicator and can be measured in 12-hour collections and reported as units per hour. In contrast to serum amylase, urinary amylase decreases with organ dysfunction. Like serum amylase, trends are followed rather than absolute levels, stable levels are usually achieved with 2 weeks of transplant, and other causes of pancreatitis may alter levels.

Ultrasound examination of the pancreas transplant is performed frequently in the early post-transplantation period to rule out vascular thrombosis. If the pancreas cannot be well visualized by ultrasound scan, magnetic resonance imaging and angiography may be informative. Any inflammatory state also can yield images of an edematous gland; however, other than for vascular thrombosis, imaging generally cannot reveal the cause of the dysfunction.

TABLE 110.1 Evaluation of Pancreas Graft Dysfunction

Assessment	Tests
Laboratory tests	Serum amylase, blood glucose, human anodal trypsinogen, cyclosporine or tacrolimus levels, C peptide In bladder-drained cases, urinary amylase and urine culture
Doppler ultrasound	Pancreatic blood flow, peripancreatic fluid collection, pancreatic ductal dilation In bladder-drained cases, evidence of bladder outlet obstruction
Computed tomography with or without cystography	Looking for leak and collections; this is performed by cystography in bladder-drained cases

Biopsy of the pancreas transplant remains the gold standard for diagnosis of acute or chronic rejection. A biopsy may be performed in apparently well-functioning grafts by protocol or at times of clinically suspected graft dysfunction to identify rejection or other causes of pancreatic injury before irreversible tissue damage has occurred. The easiest approach is a percutaneous biopsy with ultrasound or computed tomography guidance. Cystoscopic biopsy through the duodenal cuff is used in bladder-drained transplants if the percutaneous technique is not possible because of difficult visualization or overlying bowel. The most frequent complication of percutaneous biopsy is a perigraft hematoma or transient hematuria, but rarely seen are pancreatitis, arteriovenous fistula, abdominal hemorrhage, bowel perforation requiring exploration, and even graft loss. Because of the risks associated with biopsy, if the clinical picture is consistent with a mild case of rejection, patients may be treated without biopsy confirmation.

Treatment of pancreas rejection is similar to that of kidney rejection and generally involves pulse intravenous corticosteroids or antilymphocyte antibodies (see Chapter 104).

Treatment response is monitored by following the return of serum amylase and lipase or urinary amylase to baseline values. Imaging can be used to show resolution of edema and inflammation. Repeated biopsy, usually at a 2-week interval, is required to show resolution of more moderate or severe rejections and to look for histologic signs of the development of chronic rejection.

Patients with isolated pancreas rejection have an increased risk for kidney graft loss, supporting the concordance of acute rejection in the majority of patients.[25] In SPK or PAK patients, when biopsy of the pancreas cannot be performed safely, a kidney transplant biopsy may be used as a surrogate indicator. This must be done, however, in conjunction with serum and urine tests because synchronous rejection occurs only 70% to 80% of the time.[26]

Antimicrobial Prophylaxis

Antimicrobial prophylaxis is much like that for a kidney transplant alone. Trimethoprim-sulfamethoxazole is prescribed for the prevention of urinary tract infections (UTIs) and *Pneumocystis* infection. Oral clotrimazole or nystatin is used for the prevention of oral candidiasis; some centers use fluconazole for prophylaxis of *Candida* UTIs and intraabdominal fungal or yeast infections. Oral acyclovir is given to patients with a history of herpes simplex infection and to patients who are CMV negative and receive CMV-negative donor organs. Otherwise, valganciclovir or ganciclovir is given for 3 months after transplantation to all patients who are CMV positive. Patients who are CMV negative who receive CMV-positive organs are often treated for 6 months. Patients treated for rejection are typically returned to any discontinued antiinfectious prophylaxis for 1 to 3 months after rejection therapy.

Metabolic Monitoring

In addition to monitoring of the serum and urinary concentrations of amylase and the serum concentration of lipase, serum creatinine, potassium, magnesium, and bicarbonate levels must be monitored. Magnesium wasting is common with CNIs and frequently requires oral supplementation. With bladder drainage, there is high urinary loss of bicarbonate in pancreatic exocrine secretions, which may require as much as 130 mmol/day of replacement. Without replacement, patients develop metabolic acidosis with nausea and vomiting, which may lead to volume depletion, hypotension (exacerbated by underlying autonomic neuropathy), and graft thrombosis. Oral sodium bicarbonate, typically 2 g four times daily, is needed. Fluid intake should be 2.5 to 3 l/day to accommodate pancreatic and renal fluid outputs. This intake may be difficult to achieve because abdominal bloating from diabetic gastroparesis is exacerbated by the large fluid intake and the gas released from sodium bicarbonate tablets. Patients who are unable to maintain adequate oral intake may require intravenous fluids, including sodium bicarbonate. In patients who require intravenous repletion for longer than 1 month, consideration should be given to placement of a tunneled venous catheter or a buried central venous port for fluid administration.

Surgical Complications

Surgical complications of pancreas transplantation are shown in Table 110.2. Superficial infections and deep-seated abscesses are commonly fungal. The source of fungal contamination is thought to be the duodenal segment. Therefore topical antibiotic and antifungal solutions are used to irrigate the donor duodenum during procurement and implantation. Patients commonly receive 24 to 48 hours of postoperative antibiotics and fluconazole.

The causes of wound drainage are seroma, lymphocele, pancreatic fistula from either the tail or the anastomosis to the bladder or bowel, wound dehiscence, and preservation pancreatitis. Preservation pancreatitis is a complication of cold storage and may lead to wound drainage of whitish yellow, thick, noninfectious material formed from the enzymatic digestion of tissue, leading to fat necrosis and saponification. Wound drainage is seen more often with the extraperitoneal placement of the pancreas and also occurs when a pancreas from an obese donor is used. It is also associated with a mild increase in serum amylase concentration, low urinary amylase excretion, and variable changes in the serum glucose concentration.

Vascular complications occur in about 5% of patients and include arteriovenous fistulas secondary to surgery or biopsy, venous and arterial thrombosis, and, rarely, mycotic aneurysms. Vascular thrombosis rates were previously as high as 10%, but current rates are below 5%. Means of reducing the rate of thrombosis include minimization of warm and cold ischemia, no-touch procurement procedures using the duodenum and spleen as handles, and postoperative treatment with aspirin. In cases with longer cold ischemia times, a more edematous graft, or concern about low inflow or outflow, intravenous heparin is sometimes used for the first few postoperative days. Partial thrombosis may resolve with thrombolytic therapy or anticoagulation. More extensive thrombosis requires urgent surgical intervention. Complete graft thrombosis, especially in the immediate postoperative period, mandates urgent graft removal to prevent sepsis or a diffuse hypercoagulable state that might precipitate complications such as myocardial infarction.

Nonsurgical Complications

Nausea and vomiting are common, and causes include gastroparesis, constipation, cholelithiasis or esophageal reflux developing from motility

TABLE 110.2 Surgical Complications After Pancreas Transplantation

Type of Complication	Presentation	Diagnostic Findings and Testing	Treatment Options
Abscess	Fever, erythema of wound, wound drainage	Elevated WBC count, fluid collection on CT scan, pus on aspiration	Open or percutaneous drainage
Graft pancreatitis	Pain over allograft, lower abdominal pain	Elevated serum amylase, enlarged pancreas allograft	Octreotide or somatostatin Urethral (Foley) catheter if bladder drained
Lymphocele	Mass on palpation, urgency if bladder compression	Fluid collection on CT scan, clear fluid on aspiration	Open or percutaneous drainage
Wound drainage	Pancreatic debris, no erythema	Culture, CT scan to rule out deep abscess	Local wound care
Dehiscence	Wound open		Wound care, surgical closure
Arteriovenous fistula	Hematuria, abdominal bleeding	Doppler ultrasound, angiography	Embolization, surgical repair
Graft thrombosis	Elevated blood glucose Bloody urine if bladder drained	Low serum and urine amylase, sepsis-like syndrome; ultrasound or magnetic resonance imaging	If partial, thrombolytic therapy or anticoagulation (high risk for bleeding), graft pancreatectomy
Pancreatic fistula or leak (bowel drained)	Pain over allograft, sepsis, peritonitis, fever	Elevated WBCs, fluid collection on CT scan	Surgical drainage and repair

CT, Computed tomography; WBC, white blood cell.

TABLE 110.3 Urologic Complications of Bladder-Drained Pancreas Transplants

Complication	Cause	Presentation	Evaluation	Treatment Options
UTI	Diabetic bladder dysfunction (DBD)	Asymptomatic, or dysuria, fever, sepsis	Urine culture; check postvoid residual, if elevated urodynamics	Culture-specified antibiotics, prophylactic antibiotics *Female:* Double and timed voiding, CIC *Male:* α-Adrenoceptor blockers to aid bladder emptying, CIC, bladder neck–prostate incision If treatment failure, enteric conversion: Foley catheter drainage
Reflux pancreatitis	DBD	Asymptomatic or pain over pancreas allograft, elevated serum amylase	Check serum amylase, CT cystogram to exclude leak or duct obstruction	*If DBD:* Double and timed voiding, CIC, α-blockers to aid bladder emptying *If multiple and symptomatic episodes:* Bladder neck–prostate incision or enteric diversion
Duodenal cystotomy leak	Ischemic injury to duodenal cuff, cytomegalovirus or other infection, rejection, DBD	Pain over allograft, or peritonitis, elevated serum amylase	Check serum amylase, elevated creatinine, leak on CT cystogram	Foley catheter drainage, if small If early, open surgical repair with resection and closure of layers, evaluate for DBD after recovery If late, consider enteric conversion
Urethritis or dysuria syndrome, occasional urethral disruption	UTI or DBD causing activation of pancreatic enzymes with digestion of urethral mucosa	Dysuria, urinary retention, hematuria	Check postvoid residual, low-grade UTI; after recovery, evaluate for DBD	Foley catheter, analgesics, empiric treatment of UTI *If multiple and symptomatic:* Enteric conversion

UIT, urinary tract infection; CIC, clean intermittent catheterization; CT, computed tomography.

problems, and esophagitis with or without CMV disease. Antiemetics plus histamine-2 (H_2) blockers or proton pump inhibitors are usually effective therapy and are given for 2 to 3 months after transplantation. Persistent symptoms may require prokinetic agents (metoclopramide or erythromycin). Diarrhea can be caused by immunosuppressive medications, intrinsic gut motility problems, food intolerance, or CMV or other infection. Constipation is treated with increased fluid intake, dietary modification, increased activity, and regular low-dose schedule of stool softeners or laxatives.

Orthostatic hypotension may worsen after transplantation because of prolonged bed rest in the presence of diabetic autonomic neuropathy. Treatment may include a high-sodium diet with a mineralocorticoid (fludrocortisone) or an α-adrenergic agonist (midodrine).

Urologic Complication

Urologic complications are common after bladder drainage (Table 110.3).[27] Pretransplantation bladder dysfunction secondary to diabetic autonomic neuropathy causes a large-capacity bladder, decreased bladder sensation, increased residual urine volume, and decreased urinary flow rates. Bladder function is worsened by the autoaugmentation of the bladder by the added duodenal segment. Preoperative urodynamics are abnormal in up to 43% of patients but do not predict

post-transplantation urologic complications such as reflux pancreatitis or infections.[28]

Urinalysis is difficult to interpret with the bladder-drained pancreas. The urine contains white cells from duodenal mucosal sloughing and may be leukocyte esterase positive without bacteriuria. Urine protein excretion is elevated to 1 to 3 g/day in most patients, composed of pancreatic enzymes, immunoglobulins, other globulins, albumin, and digested fragments of these proteins. Urinary albumin, if it is measurable in the presence of enzymatic degradation, may come from the transplanted or native kidneys.

Macrohematuria occurs in up to 28% of bladder-drained pancreas recipients. Early hematuria is related to surgical trauma to the bladder or duodenal mucosa near the cystoduodenostomy site and usually clears with diuresis or bladder irrigation.[27] Continuous bladder irrigation requires caution because the cystoduodenostomy is vulnerable to rupture if the drainage catheter becomes obstructed. Late hematuria, beyond 2 to 4 weeks after transplantation, can arise from anastomotic bleeding, duodenal mucosal sloughing or ulceration, reflux pancreatitis, cystitis, graft thrombosis, rarely arteriovenous fistulas, and pseudoaneurysms. Evaluation should include ultrasound, urine culture, and cystoscopy. If the pancreas appears to be the source on cystoscopy, biopsy of the pancreas may be required to determine the exact cause.

Microhematuria should be evaluated. Evidence is sought for recurrent disease, new renal disease, or genitourinary malignant neoplasms.

Urinary Tract Infections

Risk factors for UTI after bladder-drained pancreas transplantation include large bladder capacity, incomplete bladder emptying, high bladder urine pH (as a result of pancreatic bicarbonate), bladder and urethral mucosal irritation from activated pancreatic enzymes with the loss of mucosal barrier, prolonged bladder catheterization, and immunosuppression.[28] Most centers administer oral antibacterial and antifungal prophylaxis for up to 6 to 12 months or indefinitely after transplantation.

Urinary reflux pancreatitis, which causes pancreas graft dysfunction, may be associated with perigraft abdominal pain and fever. It is often a result of poor bladder function and requires drainage with a bladder catheter for 5 to 7 days and assessment of bladder dysfunction (Fig. 110.7).

A urethritis dysuria syndrome occurs in 2% to 8% of pancreas recipients with bladder drainage and is caused by uroepithelial exposure to the activated pancreatic proenzymes trypsinogen, chymotrypsinogen, and procarboxypeptidase. Pancreatic exocrine secretions consist of bicarbonate, amylase, lipase, and proenzymes, which are activated by the enterokinase in the graft duodenal brush border. Increased intravesical enzyme activation occurs with low-grade UTIs and urinary stasis, and patients will develop voiding pain or penile, glandular, meatal, or vulvar ulceration. Enzyme activation may be minimized by treatment of low-count bacteriuria, increase in fluid intake, and frequent voiding. If emptying does not improve with α-blockers, continuous Foley catheter drainage for 7 to 10 days is effective.[29]

Enteric Conversion

Enteric conversion is an option for most of the chronic urologic complications associated with bladder-drained pancreas transplantation. The indications are urethral disruption, recurrent urine leak, persistent bleeding, chronic UTI, dysuria, recurrent hypovolemia, and metabolic acidosis. The conversion rate varies from 8% to 14%. It is ideal to wait until 6 to 12 months after transplantation, when possible, to allow monitoring of urine amylase for early rejection episodes.

Late Complications

Late complications after pancreas transplantation typically fit into one of two patterns. There can be an acute presentation of graft rejection,

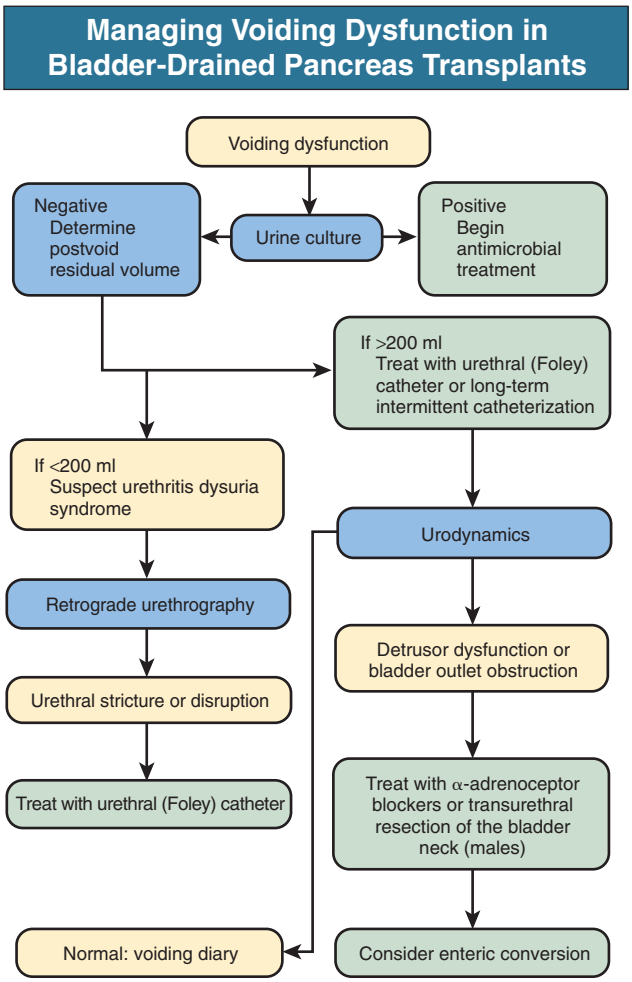

Fig. 110.7 Management of post-transplantation voiding abnormalities. (From reference 27.)

not different from that seen in early graft dysfunction. The second pattern is more insidious; chronic inflammatory states from chronic rejection, ischemia, or infection may lead to gradual graft loss. Unfortunately, there is no practical test to measure small decrements in graft function in the way serum creatinine allows detection of kidney transplant dysfunction. Although its sensitivity is not optimal, patients are typically asked to measure 2-hour postprandial glucose levels (which are more sensitive than fasting blood glucose levels) weekly and to report trends or sudden increases to the physician.

IMPACT OF PANCREAS TRANSPLANTATION ON DIABETIC COMPLICATIONS

Pancreas transplantation is performed to eliminate the need for exogenous insulin and the risk for severe hypoglycemic episodes and to stop or to reverse the consequences of hyperglycemia. Well-functioning pancreas transplants result in normal fasting blood glucose concentrations, normal glycated hemoglobin levels, and only slightly abnormal oral glucose tolerance testing.[30]

Hypoglycemia

Although severe hypoglycemia is rare, mild hypoglycemia may develop in patients with a well-functioning pancreas graft once low baseline immunosuppression has been reached, especially in patients who have

regained little weight after transplantation and who are physically active. Postprandial hypoglycemic episodes are not always symptomatic. They are associated with high-carbohydrate meals, excessive intake of caffeine or alcohol, excessive exercise, and, in some patients with hypoglycemia, circulating antiinsulin antibodies. This is not often a significant clinical problem and is usually resolved by avoidance of carbohydrate-rich meals.

A major benefit of pancreas transplantation is restoration of glucagon secretory responses to hypoglycemia. In patients with type 1 diabetes, the absence of functional beta cells within the islet eliminates the normal physiologic response by which intraislet insulin tonically dampens secretion of glucagon from alpha cells. Consequently, diabetic subjects are usually at risk for prolonged hypoglycemia secondary to injected insulin because there is failure of the normal counterregulatory action of glucagon on the liver to increase glycogenolysis. Despite the fact that the transplanted pancreas is placed ectopically and does not develop vagal control, the transplanted organ has normal glucagon responses to insulin-induced hypoglycemia and resultant counterregulation of hypoglycemia through increased hepatic glucose production. After pancreas transplantation, hypoglycemic awareness returns, as well as partial return of defective epinephrine secretion during insulin-induced hypoglycemia.

Hyperglycemia

Post-transplantation hyperglycemia may be caused by pancreas graft dysfunction, inadequate insulin release secondary to high tacrolimus or occasionally cyclosporine levels, resistance to insulin secondary to corticosteroids, weight gain, and inadequate physical activity. Although the use of tacrolimus has reduced pancreas graft rejection, it also decreases insulin gene transcription. If laboratory and imaging evaluations (see Table 110.1) are normal, hyperglycemia is the result of decreased insulin production or peripheral insulin resistance, which can be identified by measurement of glucose utilization rates and glucose/arginine-potentiated insulin secretion. In the absence of graft rejection, post-transplantation hyperglycemia should first be managed by dietary intervention and exercise. Insulin may be needed initially but often can be discontinued as oral hypoglycemic agents begin to take effect. Sulfonylureas are effective therapy. Hyperglycemia secondary to rejection is a late event and indicates irreversible graft damage. Because of the increased risk for rejection with manipulation of immunosuppression, minimizing the tacrolimus dose or changing to cyclosporine or sirolimus should not usually be considered until these measures have failed.

Microvascular Complications

Retinopathy

In a prospective fundoscopic study of patients with SPK over 45 months, there was a decreased need for post-transplantation laser therapy and the diabetic retinopathy showed stabilization in 62%, improvement in 21%, and progression in 17%.[31] In the postoperative period, patients may develop neoproliferation and retinal hemorrhages if preoperative blood glucose control is very poor and blood glucose normalizes rapidly after transplantation. Patients remain at risk for retinal detachment because of scarring secondary to previous retinal damage. Cataracts are more common after transplantation.

Neuropathy

Sensory and motor nerve conduction velocities improve rapidly after pancreas transplantation and then stabilize.[32] Greater recovery is seen in nonobese, younger, shorter patients; in those with better initial action potential amplitudes; in those not receiving renal replacement therapy; and possibly in those receiving angiotensin-converting enzyme inhibitors or angiotensin receptor blockers.[33] The recovery of action potential amplitudes is gradual, continuing to improve up to 5 years beyond transplantation. Recovery is more complete in sensory than in motor nerves.

There is greater improvement in autonomic reactivity and gastric emptying in SPK recipients compared with diabetic kidney-only transplant recipients.[34] But if autonomic symptoms are severe at the time of pancreas transplantation, improvement is unlikely.

Nephropathy

Early diabetic nephropathy is characterized by increased glomerular basement membrane thickness and an increase in mesangial volume. Renal transplant biopsy specimens from diabetics with SPK and kidney-only transplants within 2.5 years of transplantation show glomerular basement membrane thickness within the normal range. After 2.5 years from transplantation, 92% of renal biopsy specimens from the kidney-pancreas recipients have a normal glomerular basement membrane thickness compared with only 35% of the biopsy samples from the kidney-only recipients; relative mesangial volume was normal in 82% of the biopsy specimens from kidney-pancreas recipients compared with only 12% in the kidney-only recipients.[35] Thus concurrent pancreas transplantation decreases the occurrence of the changes of diabetic nephropathy that may result in allograft loss.

Vascular Disease

Successful kidney-pancreas transplantation results in a significant improvement in the control of hypertension compared with kidney transplant alone in patients with type 1 diabetes.[36] Increase in peripheral vascular disease has been reported in kidney-pancreas transplant recipients compared with kidney-alone transplant recipients[37]; however, another study found the same prevalence of peripheral vascular disease after pancreas transplantation as occurred in diabetic kidney-only recipients who refused pancreas transplantation for nonmedical reasons and in nondiabetic kidney transplant recipients.[38] Encouragingly, one study showed that after a 10-year mean observation period, the progression of macrovascular diseases (cerebrovascular, coronary, and peripheral vascular) was significantly lower in recipients with a functioning SPK compared with a kidney transplant alone.[7]

A study using intravital microscopic evaluation of nail bed and conjunctival vasculature found improved vascularization (as assessed by a reduction in venular diameter, increased number of arterioles per unit area, and elevation of the perfusion capacity) only in kidney-pancreas recipients.[39]

Quality of Life and Social Issues

Pancreas transplantation is a very stressful event and can tax even the strongest of family relationships. Pretransplantation debilities (decreased vision, neuropathy, muscle weakness, orthostatic symptoms) can be exacerbated by the surgery and immunosuppressive medications. Patients who smoke or drink significant amounts of alcohol and are without family support have worse survival after transplantation than those who do not. However, kidney-pancreas transplant recipients with social support and well-functioning grafts report an increased global quality of life and frequently return to work, although the number returning to work is not much different from those receiving a kidney transplant alone.[40] In living donor simultaneous kidney-pancreas transplantation, preliminary results suggest that quality of life is stable for donors whereas recipients experience improvement.[41]

Pregnancy After Pancreas Transplantation

Within 1 year of transplantation, menstruation and ovulation return in most women of childbearing age. The U.S. National Transplantation Pregnancy Registry has reported 62 pregnancies in 40 SPK patients.[42] The outcomes were 50 live births, 3 therapeutic and 10 spontaneous

abortions (1 twin reduction), and 1 ectopic twin pregnancy. The newborn outcomes were prematurity (39 of 50), low birth weight (32 of 50), other neonatal complications (28 of 50), and neonatal death (1 of 50). Ten patients had rejections that resulted in graft loss, and 58% of the patients required cesarean section. Hypertension, prematurity, preeclampsia, and growth restriction frequently complicated the pregnancies, even with good renal function. Gestational diabetes appeared in 3%.

All transplant recipient pregnancies require high-risk obstetric care. Consensus opinion is that pregnancy is safe by 1 year after transplantation under the following conditions: no rejection has occurred in the past year, graft function is stable, no active infections that could have a negative impact on the fetus (e.g., CMV infection) are present, and the patient is not taking any teratogenic medications.[43] MMF has been linked to structural malformations, and patients planning on conception should transition to another agent 6 weeks before trying to conceive.[44] Cyclosporine and tacrolimus levels often decline during pregnancy and require close monitoring to prevent rejection. Cesarean section is not mandatory, but vaginal deliveries must be observed for signs of allograft duodenal rupture. The average gestational period is 35 ± 2 weeks; the average birth weight is 2150 ± 680 g. There is no evidence that the children of transplant recipients are more likely to have abnormal development.

The management of other medical issues does not differ from that in kidney-only transplant recipients (see Chapters 105 and 106).

ISLET TRANSPLANTATION

Islet transplantation, with its reduced antigen load, technical simplicity, and low morbidity, has the potential to dramatically improve the quality of life of individuals with type 1 diabetes. The first series of islet allotransplantations in patients with type 1 diabetes were reported in 1977.[45] There were then sporadic reports in the 1990s of insulin independence for extended periods after islet allotransplantation.[46,47] Autotransplantation studies (free of any donor-recipient immunologic issues) then demonstrated that a critical mass of 300,000 islet equivalents (IE) could reestablish and maintain insulin independence beyond 2 years.[48] To date, the longest period of insulin independence after autotransplantation is more than 16 years.[49] The primary goal of islet transplantation remains optimal glycemic control without severe hypoglycemia rather than insulin independence.[50]

Preliminary work suggests that an artificial pancreas can improve average glycemic control and simultaneously reduce moderate hypoglycemia. Though untested, it should be able to prevent severe hypoglycemia. Technical problems remain, such as glucose sensor accuracy, network connectivity, and insulin pump reliability. Combining an artificial pancreas and an islet transplant may eventually allow the former to deliver a large fraction of the required insulin and the latter to provide fine tuning.[50]

Islet allotransplantation will never supply sufficient islets for the treatment of the millions with diabetes. Additional potential future sources of islets include xenogeneic islets (mostly from pigs), stem cells, or beta cell regeneration, though these remain in the preclinical realm.

Islet After Kidney Transplantation

The initial allogeneic islet transplants in patients with type 1 diabetes beginning in the late 1970s were in patients with end-stage renal disease as sequential islet after kidney (IAK) or simultaneous islet-kidney transplantation. Because the kidney transplant patients were already immunosuppressed, the IAK transplant procedure carried a minimal risk. However, there could be destabilization of the transplanted kidney and also islet dysfunction because most kidney transplant immunosuppression protocols included corticosteroids. Nevertheless, there were beneficial effects from improved glycemic control on both survival and function of transplanted kidneys.[51] Metabolic control (hemoglobin A_{1c} [HbA_{1c}] level and fasting glycemia) improved after IAK even in patients receiving low-dose corticosteroids. Adverse events included procedure-related pleural effusion and cholecystitis.[52]

Of the 237 well-documented allotransplants recorded in the Islet Transplant Registry from 1990 to 2000, less than 12% of recipients were insulin free at 1 year after transplantation. The reasons for this failure rate may include subtherapeutic islet implant mass, high rate of engraftment failure, islet damage in the liver (the site of implantation) by direct local toxic effects of the immunosuppressants, ineffective immunosuppression that fails to prevent rejection, recurrent autoimmune diabetes, and islet functional exhaustion. Four criteria were associated with insulin independence: (1) an islet implant mass of more than 6000 IE/kg, (2) a cold ischemia (preservation) time of less than 8 hours, (3) induction therapy with polyclonal antibodies such as antilymphocyte globulin or ATG, and (4) the liver as the favored implantation site. Early immunosuppressive regimens were relatively ineffective in preventing allograft rejection compared with their effect on vascularized pancreas grafts. Most if not all immunosuppressive agents were associated with impaired beta cell function and reduced graft revascularization.

As of the end of 2013, there were 1011 allogeneic islet transplant recipients, both islet transplant alone and islet after or simultaneous with kidney. Overall achievement of insulin independence was 65% in the first year after islet infusion (with or without reinfusion), and by year 2 this rate increased to 75%.

More success with insulin independence was reported in nonuremic patients with type 1 diabetes transplanted with an average of 800,000 islets by use of the Edmonton protocol, a corticosteroid-free immunosuppression regimen of daclizumab, sirolimus, and low-dose tacrolimus. Although follow-up of this cohort has since confirmed long-term C-peptide production with therapy that is safe and well tolerated, insulin independence is maintained in only a minority.[53] There has since been an exponential increase in clinical islet transplant activity; more patients with type 1 diabetes have now received islet transplants in the past 5 years than in the entire preceding 30-year history of islet transplantation.

Partial graft function, such as improvement of fasting C-peptide alone (to 0.3 to 0.5 ng/ml) combined with exogenous insulin, is sufficient to be associated with improved HbA_{1c}, glycemic control, and lower levels of severe hypoglycemia. The results are improved with higher fasting C-peptide level.

Technique of Islet Transplantation

The current technique of islet transplantation involves deceased donor pancreas procurement, organ preservation, enzymatic isolation of the islets, purification, and percutaneous injection of sterile islets into the liver through the portal vein by a catheter placed under radiographic guidance (Fig. 110.8).[54] Although accessing the portal vein percutaneously is relatively invasive, the entire procedure can be performed on outpatients. Effective mechanical and physical methods to seal the catheter track reduce the risk for postprocedural bleeding. Bleeding related to the procedure (23%), thrombus in segmental branches of the portal vein (8%), and punctured gallbladder (3%) are the most observed acute complications after islet transplantation.[54]

Medical Complications

There are also complications of islet transplantation that are not directly related to the procedure itself.[49] Changes consistent with fatty liver are reported in 22% of subjects who had magnetic resonance imaging after transplantation. Mouth ulcers occur in 90% of patients, usually

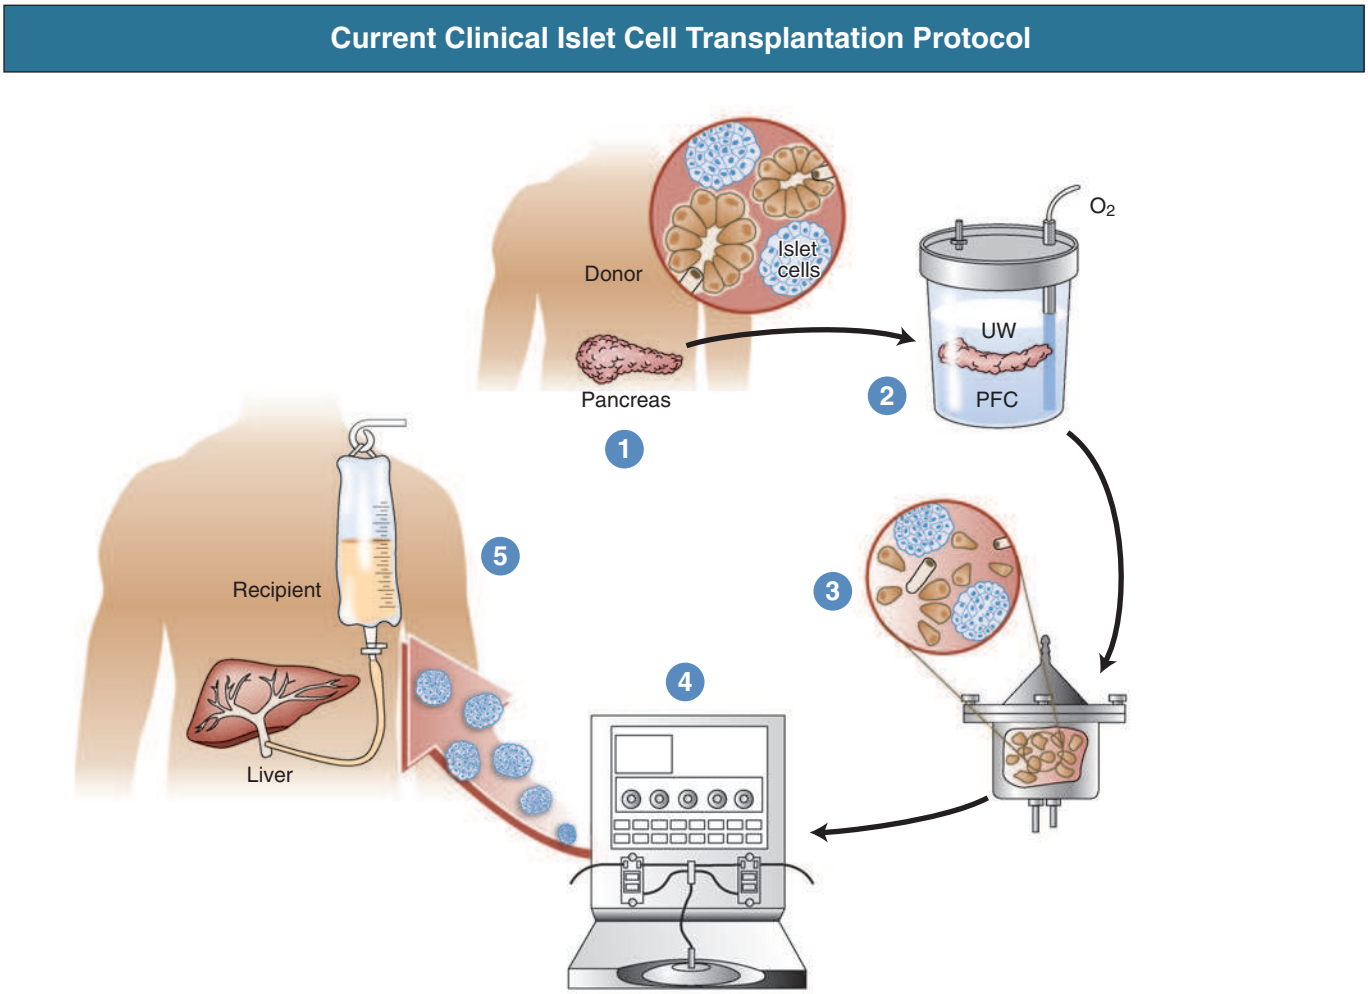

Fig. 110.8 Clinical islet cell transplantation protocol. The retrieved donor pancreas *(1)* is preserved *(2)* with a two-layer storage method using University of Wisconsin solution *(UW)* over a layer of highly oxygenated perfluorocarbon *(PFC)*. The pancreas is distended with collagenase and placed in a digestion chamber *(3)*. The disrupted exocrine and endocrine elements are purified by centrifugation *(4)*, and the islet preparation free from exocrine elements is transplanted by intrahepatic portal vein infusion *(5)*. (Modified from reference 53.)

responding to simple antiseptic measures or topical triamcinolone ointment together with a reduction in the dose of sirolimus. Diarrhea (60%) and acne (52%) are frequent. Forty-three percent of recipients reported edema, severe enough in 12% to necessitate a change in the immunosuppressive regimen. Weight loss is common.

In 27 of the 571 islet recipients in the Collaborative Islet Transplant Registry, 29 incidents of neoplasm were diagnosed. Of these incidents, 21 (72%) were benign and 6 were malignant.

Glycemic Control and Insulin Independence

Successful islet transplantation establishes normal HbA_{1c} levels, although the fasting glucose concentration tends to be slightly elevated and there is often impaired glucose tolerance. Another difference between successful pancreas and islet transplants is that placement of islets within the liver results in failure of the beta cell response to hypoglycemia, even though there is responsiveness to intravenous arginine. In a recent analysis, 82% of 118 islet recipients in three North American centers were insulin free at 1 year.[55] However, in a 5-year follow-up in Edmonton,[55] only 7.5% maintained insulin independence, although 82% had detectable C-peptide (Fig. 110.9). The median duration of insulin independence was 15 months.

Between 1997 to 2002, the prevalence of insulin independence at 1 year after islet transplant was 51%, decreasing to 18% by post-transplant 5 year. Improvements in islet isolation and transplant procedures has improved the prevalence of insulin independence to 66% by 1 year and 44% by 3 years after transplant for procedures performed in 2007 to 2010 (Fig. 110.10). Durability of islet graft function improved significantly when comparing islet transplants between 1999 to 2003 and 2004 to 2007, with 1- and 5-year fasting C-peptide of 0.3 ng/ml or greater of 74% and 35%, compared with 78% and 43%, respectively (see Fig. 110.10).[56]

Immunosuppressive Regimens

Tacrolimus, cyclosporine, and corticosteroids are diabetogenic through increased peripheral insulin resistance or direct islet cell toxicity. Oral administration increases portal venous drug concentrations and the

possibility of significant injury to intrahepatic islet grafts. Most programs use corticosteroid-free and CNI-sparing protocols for islet or kidney recipients with different combinations of MMF and sirolimus. MMF reduces early pancreas rejection rates. Insulin independence has now been achieved with islet grafts derived from non–heart-beating donors and after sequential kidney-islet transplantations using sirolimus-based therapy. Islet engraftment also can be improved with use of a CNI-free regimen with profound T-cell depletion. Anti–T cell therapy using ATG may be associated with a cytokine storm, which is toxic to islets, and newer induction agents (anti–IL-2 receptor blockers) may be particularly useful to minimize cytokine release.

Several new immunosuppressive agents that offer the potential for more islet-friendly approaches are now entering clinical trials. These include combinations of biologic agents, such as ATG, rituximab, and alemtuzumab; novel anti–T cell biologic agents, some of which offer the prospect of inducing tolerance based on animal studies; and agents that produce costimulatory blockade.[57]

Based on Collaborative Islet Transplant Registry (CITR) data, the highest prevalence of insulin independence at 5 years after transplant (60% to 70%) was seen with a combination of T-cell depletion and tumor necrosis factor antagonists and a maintenance combination that included (calcineurin) CNI and MMF. This regimen was first used in

the 2004 to 2006 era of islet transplantation, leading to improved likelihood of insulin independence at 1 and 3 years (see Fig. 110.10).[58] However, one recent study used CNI-free protocol arms based on belatacept (a costimulation blocker) or efalizumab (an antileukocyte functional antigen-1 antibody) and produced 3-year insulin independence as high as 70%.[59]

Preliminary data suggest there may be a role for the pancreas after failed islet and islet after failed pancreas transplants to help preserve renal function, be it from native kidneys or renal transplant if performed in a timely manner. The former has been more difficult due to increased antigen sensitization and thus longer waiting times. However, this may change as current islet induction and maintenance protocols are much less susceptible to recipient sensitization.[60]

SELF-ASSESSMENT QUESTIONS

1. Transplant options for insulin-dependent diabetics with renal failure include which of the following:
   - **A.** Cadaveric renal transplant alone
   - **B.** Living donor kidney transplant alone
   - **C.** Simultaneous kidney-pancreas transplant
   - **D.** Kidney transplant followed by pancreas after kidney transplant
   - **E.** Kidney transplant followed by islet after kidney transplantation
   - **F.** All of the above.
2. Which of the following statements about pancreas transplantation is false?
   - **A.** It is a viable treatment option for both select type 1 and type 2 insulin-dependent diabetics.
   - **B.** Pancreas transplant recipients require the same amount of immunosuppression as kidney transplant recipients.
   - **C.** The beneficial effect of pancreas transplantation on long-term diabetic complications takes 8 to 10 years to be seen.
   - **D.** Hypoglycemic unawareness may be a sufficient indication for an insulin-dependent diabetic to receive a pancreas transplant.
   - **E.** Most pancreas transplants performed in 2013 had their exocrine secretions enterically drained.
3. Which of the following statements about islet transplantation is true?
   - **A.** Islets are infused in the portal vein and seed the liver.
   - **B.** Islet transplants are more successful in patients with lower body mass index (BMI).
   - **C.** The primary goal of islet transplantation remains optimal glycemic control without severe hypoglycemia rather than insulin independence.
   - **D.** An appropriate islet cell mass has been shown to be critical to produce insulin independence.
   - **E.** All of the above.

Kidney Disease in Liver, Cardiac, Lung, and Hematopoietic Stem Cell Transplantation

Claire Kennedy, Colm C. Magee

It is now well recognized that kidney disease can complicate all forms of nonrenal solid organ transplantation (SOT) and is associated with longer hospitalization, higher morbidity, higher mortality, and greater expense.[1,2] Although there are organ-specific factors that can have an impact on the incidence and severity of kidney disease, some useful generalizations can be made.

GENERIC ISSUES OF KIDNEY DISEASE IN NONRENAL SOLID ORGAN TRANSPLANTATION

Use of Serum Creatinine and Derived Equations to Estimate Glomerular Filtration Rate

Transplant candidates and recipients often have low muscle mass and low creatinine generation. Hence, a mildly elevated serum creatinine concentration may represent severe kidney disease.[2,3] Such patients should have their glomerular filtration rate (GFR) estimated by 24-hour urinary creatinine clearance (which will tend to overestimate because of tubular secretion) or preferably by direct measurement of iothalamate clearance. Of the various serum creatinine–based equations to estimate GFR, the Chronic Kidney Disease–Epidemiology Collaboration (CKD-EPI) and Modification of Diet in Renal Disease (MDRD) equations appear to correlate best with true post-transplantation GFR.[3]

Nephrotoxicity of Calcineurin Inhibitors

Calcineurin inhibitors (CNIs) are the cornerstone of immunosuppression in SOT recipients, but there is little doubt that they contribute significantly to acute kidney injury (AKI) and chronic kidney disease (CKD) in this setting.[1] It is probable that CNI nephrotoxicity is more severe in nonrenal (than renal) transplantation because higher blood concentrations of CNIs may be recommended in nonrenal SOT recipients and the transplanted kidney is denervated, which may protect it from early sympathetic-mediated CNI injury. CNIs also exacerbate post-transplantation hypertension and diabetes mellitus, which cause renal damage in the long term.

Acute CNI nephrotoxicity is mainly a prerenal syndrome caused by vasoconstriction of the afferent glomerular arteriole (see Chapter 101); tubular damage and microvascular disease may occur in more severe cases. It may be difficult to quantify the contribution of CNI toxicity to post-transplant AKI, and thus in practice the CNI is often temporarily reduced. Acute CNI-induced thrombotic microangiopathy (TMA) is rare after SOT but is associated with a poor prognosis. In many cases there is a precipitant such as infection, rejection, or addition of a mammalian target of rapamycin (mTOR) inhibitor to CNI-based immunosuppression. Treatment usually involves discontinuation of the CNI (or mTOR inhibitor if triggered by its initiation).

Chronic CNI nephrotoxicity is probably a result of prolonged renal ischemia and other effects, such as direct stimulation of renal fibrogenesis. Typically the patient is hypertensive and there is a steady fall in GFR, most marked in the first 6 to 12 months after transplantation (Fig. 111.1).[4,5] Dipstick urinalysis usually shows minimal/no hematuria and minimal/mild proteinuria. Renal histologic examination shows striped interstitial fibrosis, arteriolar hyalinosis, arteriosclerosis, and secondary focal glomerulosclerosis.[4] There also may be features of chronic TMA.[4]

However, not all CKD in this setting is CNI related. Indeed, the typical histologic findings listed previously are nonspecific, making it difficult to estimate the actual true contribution of CNI toxicity to CKD. Biopsy series have reported a variety of histologic diagnoses in this context; in practice, renal biopsies are rarely performed unless there are clinical features suggestive of a renal disorder other than CNI toxicity.[6]

The presumed high prevalence of chronic CNI nephrotoxicity has generated interest in low-dose or even zero-dose CNI protocols.[1,2,4] Another strategy is to use tacrolimus as the de novo CNI or to switch from cyclosporine to tacrolimus if there is evidence of nephrotoxicity. The rationale here is that tacrolimus provides equivalent or even better immunosuppression at concentrations that are less nephrotoxic than cyclosporine. Furthermore, tacrolimus is associated with less hypertension and hyperlipidemia (which might exacerbate CKD) than cyclosporine. Conversely, tacrolimus is associated with more post-transplant diabetes mellitus. CNI-sparing strategies are discussed in more detail later.

The usefulness of dihydropyridine calcium channel blockers in ameliorating CNI nephrotoxicity in SOT remains controversial. Experimental studies suggest that agents that block the renin-angiotensin system (RAS) may provide protection against the arteriolar hyalinosis and tubulointerstitial injury associated with chronic CNI use. Control of hypertension per se is probably more important than use of any particular antihypertensive agent.

Acute Kidney Injury in the Immediate Pretransplant Period

AKI is common in the days to weeks immediately before liver, heart, or (less commonly) lung transplantation and is typically prerenal (e.g., renal hypoperfusion or hepatorenal syndrome), intrarenal (ischemic or toxic tubular injury), or a combination. A mildly elevated serum creatinine may mask a significant fall in GFR in malnourished patients with severe organ failure.[2]

Management of AKI focuses on treatment of the underlying cause and provision of dialytic support according to standard criteria. Because the patients are critically ill, continuous renal replacement therapy (CRRT) may be preferred to intermittent hemodialysis (HD), but there

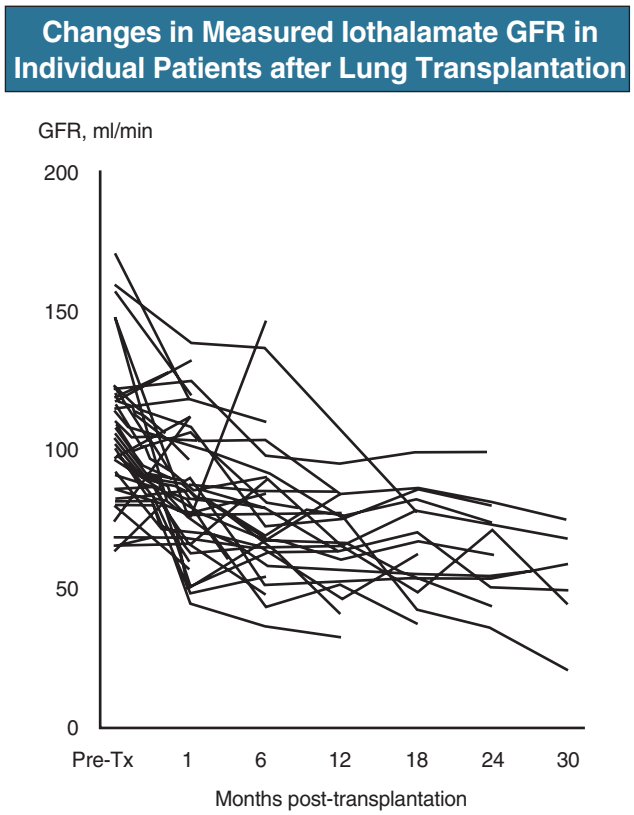

Fig. 111.1 Changes in measured iothalamate glomerular filtration rate *(GFR)* in individual patients after lung transplantation. Note the variation in GFR before transplant and the large fall in GFR in many patients within the first 6 months. *Tx,* Transplantation. (Modified from reference 5.)

TABLE 111.1 Advantages and Disadvantages of Simultaneous Renal and Nonrenal Transplantation

Advantages	Disadvantages
Potentially provides much better renal function over the short and long term	Surgery more technically complex and prolonged
Single donor—potential for lower cumulative dose of immunosuppression (as opposed to kidney transplantation later)	Deprives patients with "definite" end-stage renal disease of a kidney transplant
	Not needed when the acute kidney injury is reversible

BOX 111.1 Causes of Acute Kidney Injury After Solid Organ Transplantation

Prerenal
- Hypovolemic shock (e.g., aggressive diuresis)
- Cardiogenic shock (e.g., severe cardiac allograft dysfunction)
- Distributive shock (e.g., sepsis)
- Cyclosporine or tacrolimus

Intrarenal (Acute Tubular Injury)
- Prolonged shock
- Cyclosporine or tacrolimus
- Aminoglycosides, amphotericin
- Intravenous contrast
- Hydroxyethyl starch, intravenous immunoglobulin
- Massive hemolysis

Postrenal
- Rare

are no randomized controlled trials (RCTs) showing improved outcomes with CRRT. There is a small evidence base advocating intraoperative CRRT in selected patients undergoing liver transplantation; typically those who have severe AKI preoperatively and are likely to tolerate the surgery poorly from a fluid/transfusion perspective.

When severe or prolonged AKI occurs before planned/anticipated transplantation, estimation of reversibility becomes very important, because presumed irreversible severe AKI is generally a contraindication to transplantation or shifts the management toward simultaneous dual-organ (e.g., liver plus kidney) transplantation. Kidney biopsy might be useful in determining the degree of reversibility, but in practice it is not commonly performed because of technical difficulties in critically ill—often coagulopathic—patients.

The advantages and disadvantages of simultaneous dual-organ transplantation are shown in Table 111.1. Concerns exist in the transplant community regarding current practice. Liver, lung, and heart allocation is based on medical urgency, whereas kidney allocation is generally based on waiting time and immunologic factors. As a result, multiorgan transplants assume the priority of the nonkidney organ and may therefore divert kidneys from those with "definite" end-stage renal disease (ESRD), who may wait a long time for a kidney-only transplant. Often standard criteria donor kidneys (rather than expanded criteria donor kidneys) are prioritized for this multiorgan transplant group, again diverting these kidneys from the kidney-only wait-list. Recent guidelines address some of these controversies.[7,8] Other specific issues are discussed in detail later.

Acute Kidney Injury in the Early Post-Transplant Period

AKI is common in the days to weeks after transplant and is often multifactorial (Box 111.1). AKI is associated with higher mortality in the early postoperative period and, in those who survive, an increased risk for developing CKD.[9,10] Delayed introduction or reduced doses of CNIs are sometimes used, usually under the cover of induction antibody immunosuppression.[9]

Passenger lymphocyte syndrome can occur in the early weeks after transplant (usually liver, but also other SOT) in the setting of a minor ABO or other blood group system mismatch (e.g., blood group O donor for blood group A or B recipient). Donor lymphocytes—"passengers" with the transplant—produce anti–blood group antibodies, which causes hemolysis that, if severe, can lead to renal failure and other complications.

Acute Kidney Injury in the Late Post-Transplantation Period

Severe AKI occasionally occurs several months after transplantation. The major causes are shown in Box 111.1. Severe rhabdomyolysis has been reported; usually when statins are prescribed with cyclosporine and an inhibitor of the cytochrome P-450 system, such as diltiazem or azole-based antifungal agents.

Chronic Kidney Disease

With the growing number and longer survival of transplant recipients worldwide, the absolute number of recipients with CKD has increased.

In the most comprehensive study to date, the cumulative incidence of post-transplant CKD (defined as estimated GFR <30 ml/min/1.73 m^2) at 5 years varied according to organ transplanted, from 7% to 21% (Fig. 111.2).[10]

By multivariate analysis, the following pretransplant variables increased the risk for CKD: older age, female, white or black (as opposed to Asian) ethnicity, lower GFR, diabetes mellitus, hypertension, hepatitis C virus infection, and need for dialysis. Several post-transplant variables were also implicated: postoperative AKI and initial use of cyclosporine (as opposed to tacrolimus).[10] Minimizing post-transplantation AKI (see earlier) and controlling hypertension and diabetes are therefore likely to prevent or slow CKD. Safe and effective low-dose CNI protocols would be an important advance in preventing severe CKD, as discussed elsewhere.

Many studies have confirmed that CKD (particularly ESRD) after nonrenal transplantation portends a poor prognosis (Fig. 111.3), as well as increased hospitalization and infection rates.[10,11]

Although not well studied, the complications of CKD in this setting are likely exacerbated by other post-transplant factors. For example, antiproliferative immunosuppressant medications exacerbate anemia and corticosteroids exacerbate metabolic bone disease.

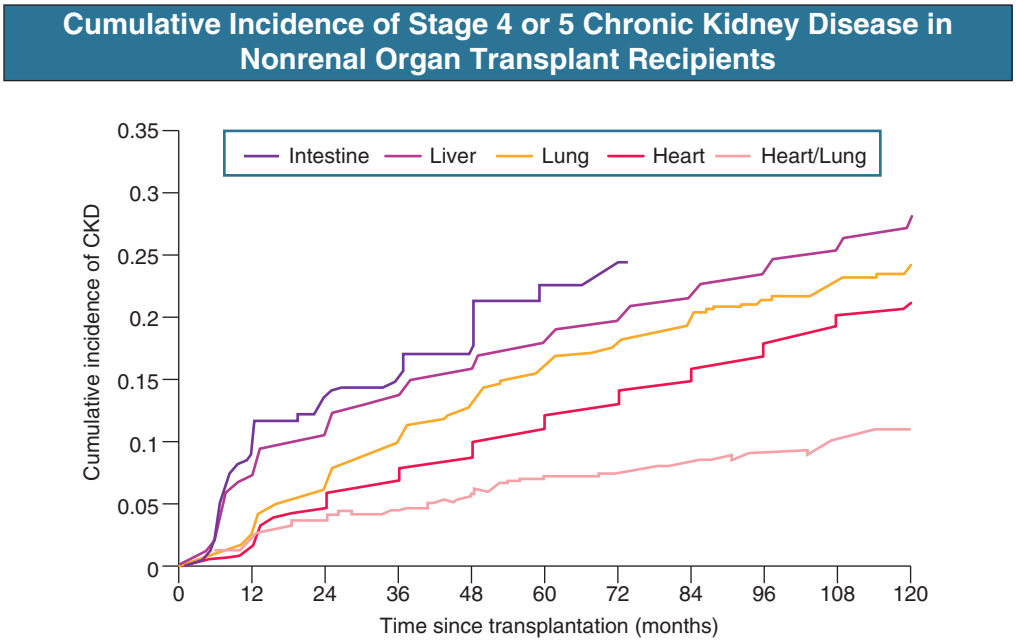

Fig. 111.2 Cumulative incidence of chronic kidney disease *(CKD)* (estimated GFR *[eGFR]* <30 ml/min/1.73 m^2) after transplantation of various solid organs. (Modified from reference 10.)

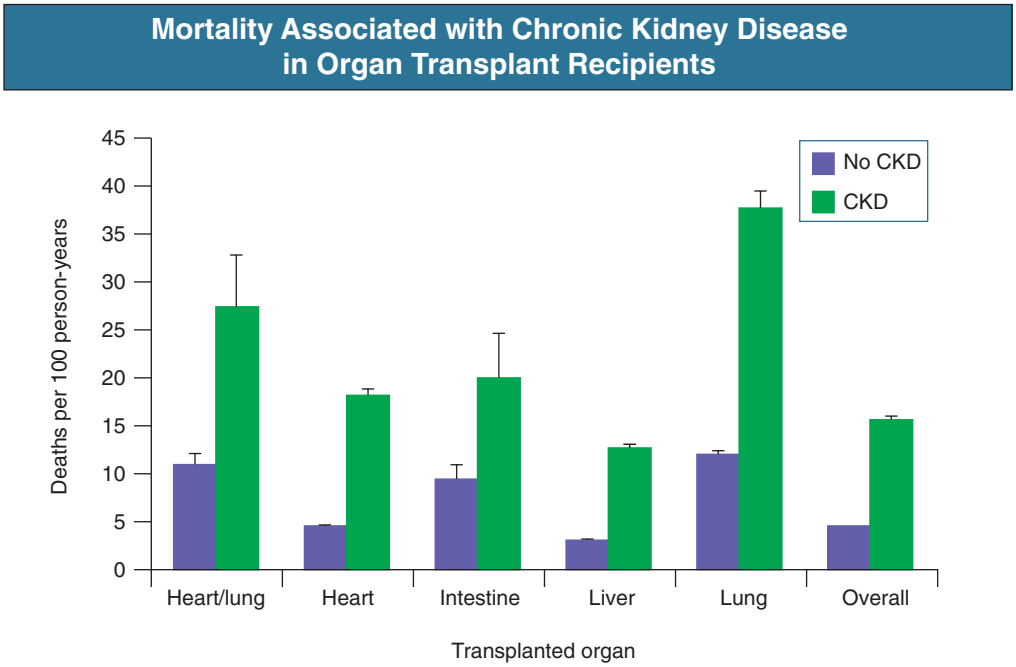

Fig. 111.3 Mortality associated with stage 4 and 5 chronic kidney disease *(CKD)* in organ transplant recipients. (Data from Scientific Registry of Transplant Recipients.)

Management of Chronic Kidney Disease

The CKD-EPI equation (despite its limitations) is useful in identifying CKD in this setting. Referral to a nephrologist should be considered in those with a falling eGFR. The initial evaluation should include thorough review of renal function in the peritransplantation period and exposure to nephrotoxins. If urinalysis shows moderate/severe proteinuria or hematuria or both, renal biopsy should be considered; it may identify pathologies other than CNI nephrotoxicity.[6]

Close consultation with the primary transplant team is important. When CNI toxicity is deemed the main cause of CKD (as it is in most patients), reduction in CNI dosage for patients at low immunologic risk should be considered. If the patient is receiving azathioprine, a change to mycophenolate mofetil (MMF) should be considered to maintain adequate immunosuppression; if the patient is already receiving MMF, the dose probably should be increased. An alternative strategy (one that we favor less) is to substitute an mTOR inhibitor for the CNI; this should not be done in the early post-transplant period because of the adverse effects of mTOR inhibitors on wound healing. Experimental models also demonstrate delayed recovery of renal function as a result of effects on tubular cell proliferation in sirolimus-treated animals with renal injury; mTOR inhibitors also potentiate the nephrotoxicity of cyclosporine and sometimes induce proteinuria. Finally, some have advocated switching cyclosporine to low-dose tacrolimus, although the supporting data are less compelling. It should be noted that most studies of CNI reduction or cessation in these settings are small and with limited follow-up. There is still understandable reluctance to pursue such protocols because CNIs are effective immunosuppressants and organ replacement therapy analogous to dialysis is not available for other SOT recipients if severe rejection occurs.

In the absence of specific studies, it seems reasonable to apply standard CKD guidelines for the management of hypertension, anemia, hyperparathyroidism, etc. Although there is experimental evidence that angiotensin-converting enzyme (ACE) inhibitors may have antifibrotic effects in nonrenal transplant CKD, there are no trials showing improved renal outcomes with ACE inhibitors or angiotensin receptor blockers compared with other antihypertensive agents.

In those with advanced CKD, there is little doubt that sequential renal transplantation is the best form of RRT in those fit enough for the procedure. The addition of the renal allograft does not require a huge increase in immunosuppression (typically this is increased in the perioperative period only). Where feasible, a preemptive living donor transplant is the best option. In the immediate post-transplant period, mortality is higher than remaining on the waiting list (reflecting the complications of surgery and more immunosuppression), but mortality in the medium to long term is much lower.[10] The number of patients with a nonrenal transplant subsequently wait-listed for a renal transplant in the United States has increased dramatically over the last 15 years.[12]

Patients who do not receive a preemptive kidney transplant are typically managed with HD rather than with peritoneal dialysis (PD), although the choice of modality should be dictated by patient-specific factors. With either modality, mortality is much higher compared with that in matched nontransplant controls.[12] Nevertheless, some have reported reasonable outcomes with home therapies (both HD and PD).[13]

BK Virus Nephropathy

BK viruria is occasionally noted after nonrenal transplantation, but the absolute risks for BK viremia and nephropathy remain low and routine screening is not recommended. This probably reflects the lack of a "second hit" to the native kidneys, such as human leukocyte antigen mismatching or inflammation. BK virus nephropathy should be considered in the differential diagnosis of unexplained renal dysfunction after SOT, especially because more intensive maintenance immunosuppressive protocols are being increasingly used.

KIDNEY DISEASE IN LIVER TRANSPLANTATION

AKI is common before liver transplantation. Indeed, use of the Model for End-Stage Liver Disease (MELD) scoring system (which measures severity of liver dysfunction based on international normalized ratio, serum creatinine and bilirubin, and predicts 90-day risk for death) to guide allocation of deceased donor liver allografts means that a raised serum creatinine concentration increases the chances of the patient being offered a liver transplant.[14] In the United States, the United Network for Organ Sharing (UNOS) updated policy on liver allocation (termed "Share 35") was implemented in 2013. This policy facilitates regional organ sharing to prioritize those with a MELD score of 35 or greater to reduce wait-list mortality.[15]

The most common causes of AKI before transplantation are hepatorenal syndrome (see Chapter 73), acute tubular necrosis (ATN), or both. Prolonged hepatorenal syndrome may cause ATN. Glomerulonephritis (GN) is relatively common (cirrhosis is associated with immunoglobulin A nephropathy and hepatitis C with membranoproliferative glomerulonephritis) but is rarely the cause of severe pretransplantation kidney disease. If RRT is required, CRRT is often preferred, in part because it is thought to have less effect than intermittent dialysis on intracranial pressure.

Post-transplantation AKI is also common and is usually multifactorial.[16] In one series, 37% of liver transplants were complicated by some degree of AKI, 19% requiring RRT.[16] Requirement for RRT was associated with higher 30-day and 1-year mortality rates. Pretransplant AKI associated with hepatorenal syndrome often (but not always) improves if the transplant is successful.

Although relatively low doses of CNIs are traditionally used in liver transplantation (because rejection is less of a concern than in other SOT), CKD remains common and is associated with higher mortality.[10] Thus, although CNIs are an important cause of CKD, other factors must play a role. These include the high prevalence of hepatitis B and C viral infections (which predispose to GN) and the high prevalence of diabetes mellitus.

Protocols involving reduction or cessation of CNIs have been studied with mixed results.[17,18] Delayed introduction of tacrolimus, with the cover of interleukin-2 (IL-2) receptor blockade, has been shown to better preserve renal function while maintaining excellent allograft and patient outcomes.[19] A phase II study evaluating belatacept (in CNI-free regimens) in de novo liver transplant recipients was terminated early because of safety concerns with belatacept despite a higher GFR.[11] De novo use of sirolimus is not recommended because there is concern that it may be associated with hepatic artery thrombosis.

The number and percentage of simultaneous liver-kidney transplants (SLK) have increased greatly in the United States since the 2002 allocation policy based on the MELD score was adopted. In 1998, for example, there were 98, and in 2015, there were 626 (~8.8% of total liver transplants).[20] This is likely to increase in the years following Share-35 implementation.

Although selected patients with severe pretransplant kidney disease benefit from SLK transplant, a critical issue is predicting which patients are likely to have meaningful renal recovery without kidney transplant. Duration of time on dialysis before the liver transplant is often used as a surrogate marker of renal recoverability, although the duration beyond which a recovery to independent renal function is unlikely is controversial.[21] In those not on dialysis, or on dialysis for a short period, prognostication is further complicated by the known poor accuracy of GFR estimations and concerns about the high risk for renal biopsy.

BOX 111.2 United Network for Organ Sharing and Organ Procurement and Transplantation Network Policy Regarding Candidacy for Simultaneous Liver-Kidney Transplant in Patients Listed for Liver Transplant

- CKD defined as GFR <60 ml/min/1.73 m^2 for >90 days and one of:
  - Dialysis dependence
  - GFR <35 ml/min/1.73 m^2 at transplant wait-listing
- AKI defined as ≥6 weeks of one or a combination of the following:
  - GFR <25 ml/min/1.73 m^2 at least once every 7 days
  - Dialysis at least once every 7 days
- Specific metabolic diseases
  - Hyperoxaluria
  - Atypical hemolytic uremic syndrome (from factor H or I deficiency)
  - Methylmalonic aciduria
  - Familial non-neuropathic systemic amyloidosis

Modified from reference 8.
AKI, Acute kidney injury; *CKD,* chronic kidney disease; *GFR,* glomerular filtration rate.

Single-center studies suggest that using a combination of clinical and histologic criteria allows effective prediction of which patients will benefit most from SLK transplantation.[22,23] Renal biopsy was performed by the percutaneous or transjugular method and had a moderate rate of complications.

In the United States the Organ Procurement and Transplantation Network (OPTN) policy has provided updated recommendations as to who should receive SLK transplants (Box 111.2).[8] Some think SLK does not represent good use of available kidneys because of a high rate of renal allograft failure in this population and argue that organ allocation should instead assign priority for delayed kidney transplant after recovery from liver transplant.[24] The Canadian forum guidelines suggest that patients are eligible for SLK if they are dialysis dependent for more than 3 months. They are "possibly eligible," to be determined on a case-by-case basis, if they are on dialysis for a shorter time or if they have an estimated GFR (eGFR) less than 30 ml/min/1.73 m^2 for more than 1 month.[7]

There is single center experience of delayed (up to 3 days) deceased donor kidney transplant after liver transplant from the same donor. This ensures stabilization of the liver transplant recipient and potentially more effective kidney utilization. Good short to medium term results were reported.[25]

KIDNEY DISEASE BEFORE CARDIAC TRANSPLANTATION

Preoperative AKI is common. In the largest reported study, 1% of heart transplant recipients required RRT before transplantation.[10] The main cause of AKI is renal hypoperfusion from severe congestive heart failure. Ventricular assist devices are increasingly used as a bridge to cardiac transplantation and can improve renal function in this setting. Interestingly, emerging evidence suggests that venous congestion is independently associated with the presence of AKI; whether therapies directed at reduction of central venous pressure improve renal outcomes remains to be proven. In some patients there may also be a component of CKD caused by chronic hypoxia, renovascular disease, hypertension or atheroembolism.

Postoperative AKI is also common, with a strong association between the stage of AKI (as defined by Kidney Disease: Improving Global Outcomes [KDIGO] criteria) and both mortality and renal dysfunction at 1 year.[26] In addition to the causes shown in Box 111.1, risk factors after cardiac transplant surgery are prolonged aortic cross-clamping, large fluid volume shifts, prolonged cardiac allograft ventricular dysfunction, postoperative bleeding, and reexploration.

CKD is now well recognized as an important complication in the medium to long term (see Fig. 111.2). The cumulative incidence of stage 4 or stage 5 CKD in cardiac transplant recipients has been reported as 11% at 5 years, which is lower than in bowel, liver, or lung transplant recipients.[10] The principal cause of CKD after cardiac transplantation is CNI toxicity. Several studies have shown that early or late renal dysfunction is a risk factor for death after cardiac transplantation; furthermore, cardiac transplant recipients on dialysis have poorer survival than other ESRD patients.[27]

A number of studies have assessed the renal effects of CNI reduction after cardiac transplantation. The majority are small, single-center studies and have shown improvement in GFR with no adverse effects on the allograft.[28,29] However, these studies involve patients at low immunologic risk with short-term follow-up. CNI withdrawal, on the other hand, showed less favorable outcomes. One study showed high rates of rejection after patients were switched to a corticosteroid plus MMF protocol.[30] Another pilot study showed concerning outcomes with a de novo CNI-free protocol,[31] which cannot be recommended at present.

Low-dose everolimus (an mTOR inhibitor), in combination with low-dose cyclosporine, MMF, and steroids (compared with standard-dose cyclosporine, MMF, and steroids) was associated with improved renal function at 1 year, with less cardiac allograft vasculopathy and similar cardiac function (despite more episodes of asymptomatic biopsy proven acute rejection).[11] These results need validation in larger trials with longer follow-up.

The question of whether the patient is best served by heart-alone or simultaneous heart-kidney transplant sometimes arises. The absolute number of such dual transplants remains low but is steadily increasing in the United States (141 in 2015, equivalent to about 5% of total heart transplants).[20] Some single-center and registry reports document good results.[32,33] One recent UNOS registry analysis found that simultaneous heart plus kidney (as opposed to heart-alone) transplantation was associated with a long-term survival benefit in those patients requiring dialysis before cardiac transplant and in those with reduced eGFR (<60 ml/min/1.73 m^2) plus a high risk for post-transplant renal failure (based on several clinical factors).[34] Canadian guidelines are as outlined above in the SLK discussion.[7] At this time, it seems reasonable to limit the combined transplants to patients with at least a severity of kidney disease similar to that shown in Box 111.2

KIDNEY DISEASE IN LUNG TRANSPLANTATION

Preoperative AKI is less common in this group, with 0.1% of lung transplant recipients requiring dialysis before transplantation.[10] Postoperative AKI is common; in one series, 56% of patients had at least a doubling of serum creatinine in the first 2 weeks after transplantation.[35] CKD, although often underappreciated, is common in the first year after lung transplantation, and the incidence increases thereafter. UNOS data showed that 5.5% of patients required RRT after lung transplantation, with dramatically lower survival.[36]

AKI can occur for the usual reasons (see Box 111.1), but several factors specific to lung transplantation may be important. First, aggressive diuresis is often prescribed to minimize any pulmonary edema.[35] Second, nephrotoxic antimicrobial agents, such as aminoglycosides and amphotericin, are sometimes required to treat resistant or severe infections.[35,37] Acute oxalate nephropathy leading to irreversible renal failure has been described in lung transplant recipients. It is thought that

enteric hyperoxaluria is caused by either prolonged antibiotic administration (which interferes with colonic flora, specifically *Oxalobacter formigenes*) and/or cystic fibrosis–related pancreatic exocrine insufficiency which leads to fatty acid malabsorption and increased oxalate bioavailability in the colon.[37] Although it is probably rare, this "new disease" emphasizes the importance of maintaining a broad differential diagnosis for any kidney disease occurring after SOT and the utility of renal biopsy when the clinical manifestation is unusual.

As with other forms of post-transplantation CKD, the most common cause is probably CNI toxicity.[37] CNI dosages tend to be higher because of the increased risk for rejection in lung transplantation. Although CNI withdrawal is poorly tolerated in this setting, a small number of studies have reported improvements in GFR when doses of CNIs were reduced. CNI reduction should be accompanied by addition/optimization of MMF. De novo use of mTOR inhibitors is not recommended because they may cause breakdown of the bronchial anastomosis; later use is associated with a risk for pneumonitis.

Patients with pulmonary hypertension appear to have a lower GFR immediately before transplant than those with other diagnoses but have a less severe fall in GFR after transplantation.[5] This probably reflects the adverse effects of pulmonary hypertension on renal perfusion and reversal of these effects after successful lung transplantation. Simultaneous lung-kidney transplantation is rarely performed.[20]

KIDNEY DISEASE IN HEMATOPOIETIC STEM CELL TRANSPLANTATION

The goal of hematopoietic stem cell transplantation (HSCT) is to allow administration of otherwise lethal (and ideally curative) doses of chemo-radiotherapy, followed by engraftment of stem or progenitor cells for marrow recovery.[38,39] HSCT is most commonly used to treat hematologic cancers, but other indications include certain nonhematologic cancers, severe genetic disorders (such as immunodeficiencies), and severe autoimmune diseases.[40] Stem and progenitor cells may be harvested from peripheral blood, bone marrow, or umbilical cord blood. Myeloablative HSCT uses intensive conditioning regimens involving high-dose chemo-radiotherapy; the hematopoietic system is then reconstituted by infusion and engraftment of stem cells. In *allogeneic* myeloablative HSCT, nonself stem cells are used; in *autologous* myeloablative HSCT, the patient's own cells are used. The toxicities of myeloablative regimens generally preclude older and sicker patients; nonmyeloablative or "reduced-conditioning" regimens have been developed to allow allogeneic HSCT in such patients. In both forms of allogeneic HSCT, acute and chronic graft-versus-host disease (GVHD) can be problematic; CNIs are prescribed to prevent and treat this complication. The main target organs of GVHD are the liver, gastrointestinal tract, and skin. AKI and CKD are common complications of HSCT and are associated with higher early and late mortality (Table 111.2).

Acute Kidney Injury After Hematopoietic Stem Cell Transplantation

AKI is common after HSCT, but its incidence and severity depend on the type of HSCT (and on the definition of AKI used). It is most common (over 70% of patients in some series) after myeloablative allogeneic HSCT, reflecting the propensity of this regimen to cause profound immunosuppression (with associated risk for sepsis) and liver damage (with associated risk for hepatorenal syndrome). Furthermore, CNIs are routinely prescribed for the first 100 days after transplantation.[39] Severe AKI is less common after nonmyeloablative HSCT (although patients are older and sometimes sicker), reflecting the shorter period of pancytopenia and rarity of hepatic sinusoidal obstructive syndrome (SOS). The principal cause of AKI in this setting is probably CNI toxicity; severe AKI necessitating dialysis is relatively rare.[39] Whatever the form of HSCT, if dialysis is required, the overall prognosis is usually very poor (early mortality >70%).[39] Fortunately, rates of AKI are decreasing; this is probably related to multiple improvements in peritransplant care.

It is helpful to consider the causes of AKI according to the period after HSCT (Box 111.3).[38] Nephrotoxic effects of the transplant itself include tumor lysis syndrome and marrow infusion toxicity. Marrow infusion toxicity occurs when autologous bone marrow transplant patients are exposed to cell lysis products (including hemoglobin and

TABLE 111.2 The Three Types of Hematopoietic Stem Cell Transplantation and Their Associated Renal Complications

	Myeloablative Allogeneic	Myeloablative Autologous	Nonmyeloablative Allogeneic
Diseases treated	Many leukemias, NHL, myelodysplastic syndromes	Lymphomas, multiple myeloma	As for myeloablative allogeneic type
Used in patients older than 60 years	Rarely	Sometimes	Common
Comorbidities permissible before HSCT	Minimal	Minimal	Some
Intensity of conditioning regimen	High	High	Low
GVHD after HSCT	Common	None	Common
CNIs used routinely	Yes	No	Yes
Incidence of AKI	Very common; sometimes severe	Common	Common; rarely severe
Causes of AKI	Hepatic sinusoidal obstruction syndrome, shock syndromes, nephrotoxic drugs, CNIs	Shock syndromes, nephrotoxic drugs; occasionally hepatic sinusoidal obstruction syndrome	CNIs
Incidence of CKD	Common	Common (but less severe than myeloablative allogeneic type)	Mild forms probably common
Causes of CKD	Irreversible AKI, renal TMA, CNIs, ? GVHD	Irreversible AKI	Pretransplant mild CKD, irreversible AKI, CNIs, ? GVHD

AKI, Acute kidney injury; *CKD,* chronic kidney disease; *CNIs,* calcineurin inhibitors; *GVHD,* graft-versus-host disease; *HSCT,* Hematopoietic Stem Cell Transplantation; *NHL,* non-Hodgkin lymphoma; *TMA,* thrombotic microangiopathy.

BOX 111.3 Causes of Kidney Disease According to Time After Hematopoietic Stem Cell Transplantation

Immediate (Very Rare)
- Tumor lysis syndrome
- Marrow or stem cell infusion toxicity

Early (Acute Kidney Injury in First 3 Months)
- Prerenal
  - Hypovolemia
  - Hepatorenal syndrome
  - CNI toxicity
- Intrarenal
  - Ischemic and/or toxic acute tubular necrosis (shock syndromes, aminoglycosides, amphotericin, etc.)
- Postrenal
  - Hemorrhagic cystitis

Later
- Thrombotic microangiopathy*
- Calcineurin inhibitor toxicity
- Irreversible acute kidney injury
- Membranous nephropathy or other glomerular diseases
- Recurrence of original disease, which then affects kidneys (e.g., myeloma)*
- ? Graft-versus-host disease

Modified from reference 41.
*Can cause late acute kidney injury.

myoglobin) released during cryopreservation. This can lead to pigment cast formation and/or toxic ATN. Within the first few weeks of myeloablative HSCT, when the conditioning regimen has caused pancytopenia, mucositis of the gastrointestinal tract, and liver damage, recipients are at high risk for many forms of AKI. These include prerenal syndromes caused by hepatorenal syndrome (see later) and hypovolemia (induced by vomiting and diarrhea or bleeding). Neutropenia predisposes to septic shock. Exposure to nephrotoxic agents, such as amphotericin, aminoglycosides, intravenous contrast agents, and CNIs, is relatively common and may also precipitate acute tubular injury. GVHD is associated (directly or indirectly) with various forms of intrarenal AKI (see later). Obstructive uropathy is much less common but can be caused by severe hemorrhagic cystitis or fungal infection of the collecting system. Causes of hemorrhagic cystitis include high-dose cyclophosphamide and viral infection (by adenovirus or BK virus). BK virus nephropathy and adenovirus nephropathy have been described but appear to be rare.

Hepatic Sinusoidal Obstructive Syndrome

Hepatic SOS, previously called venoocclusive disease of the liver, is one of the most common causes of severe AKI after myeloablative HSCT, particularly allogeneic myeloablative HSCT (see Table 111.2 and Box 111.3). The pathophysiology is thought to involve radiotherapy- and chemotherapy-induced damage to the endothelium of hepatic venules with subsequent venular thrombosis and sinusoidal and portal hypertension that in turn decreases renal perfusion. Risk factors include allogeneic HSCT, older age, female, hepatic irradiation, preexisting liver disease, use of cyclophosphamide or busulfan in the conditioning regimen, and exposure to methotrexate, progesterone, or antimicrobial drugs (i.e., infection).[41]

Clinically, SOS manifests as a form of hepatorenal syndrome during the first 30 days after HSCT. There is frequently a precipitating factor such as sepsis. The initial symptoms and signs are weight gain, edema, and ascites, followed by right upper quadrant abdominal pain and tenderness, jaundice, and abnormal liver function tests. Falling urine output, low urine sodium, and rising serum creatinine then follow.[41] In mild to moderate cases, sodium and fluid restriction, diuresis, and analgesia may suffice until liver function recovers. Severe SOS complicated by liver and renal failure (and frequently respiratory failure) carries a mortality approaching 100%. The differential diagnosis includes acute GVHD of the liver, sepsis, drug-induced cholestasis, gallstone disease, and hepatotoxic effects of parenteral nutrition. The diagnosis of SOS is usually based on the typical clinical and laboratory features. Liver biopsy is occasionally performed to confirm the diagnosis.

Current preventive strategies for SOS, although based on nonconclusive evidence, include avoidance of precipitating factors where possible and use of ursodeoxycholic acid (UDCA) or low-dose heparin.[42] UDCA alters the bile acid milieu, rendering bile less hydrophobic and toxic to parenchymal cells if cholestasis is present; it also exerts local cytokine-mediated immunomodulatory effects. Defibrotide, an oligonucleotide with antithrombotic and fibrinolytic effects on microvascular endothelium, but with apparently few systemic adverse effects, has demonstrated encouraging results both in preventing and treating SOS.[43]

Management of Acute Kidney Injury After Hematopoietic Stem Cell Transplantation

Evaluation of the patient should be as for any patient with hospital-acquired AKI but with particular focus on the possible contribution of hepatorenal syndrome to the clinical picture. The patient's cancer diagnosis, conditioning regimen, and type of HSCT are important factors. Where possible, further exposure to nephrotoxic drugs should be minimized (e.g., effective alternatives to amphotericin are now often available). If CNI trough concentrations are high, dose reduction should be considered.

No RCTs have compared intermittent HD with CRRT in this setting, and thus the decision is usually based on the hemodynamic stability and volume status of the patient. Whatever the modality used, the prognosis in those who develop severe AKI after HSCT is poor. In the setting of hepatorenal syndrome, there is some evidence that continuous therapies are associated with less increase in intracranial pressure than intermittent hemodialysis (see Chapter 73). In addition, the daily obligate fluid intake in these patients is frequently massive, and fluid balance is most easily controlled by a continuous technique. Vascular access can be problematic because of thrombocytopenia and neutropenia predisposing to bleeding and infection, respectively.

Chronic Kidney Disease After Hematopoietic Stem Cell Transplantation

CKD is an important long-term complication of HSCT, particularly allogeneic HSCT.[39] The reported cumulative incidence of CKD varies between 10% to 50%.[39] As recipients of HSCT are living longer, CKD may become more prevalent.

The role of GVHD in the development of AKI and CKD remains controversial. There is evidence from animal and human studies that GVHD or its accompanying inflammatory state can cause glomerular disease (see later); some think it also may play a role in the pathogenesis of CKD.[39] The causes of CKD are shown in Table 111.2.

Thrombotic Microangiopathy

Subacute or chronic renal TMA is probably the most common cause of CKD (particularly severe CKD) after HSCT.[44] It typically manifests 4 to 12 months after HSCT with slowly rising serum creatinine, hypertension, and disproportionate anemia (see Chapter 29), although some patients have a more fulminant presentation (e.g., severe nephritic syndrome). Dipstick urinalysis shows variable proteinuria and hematuria.

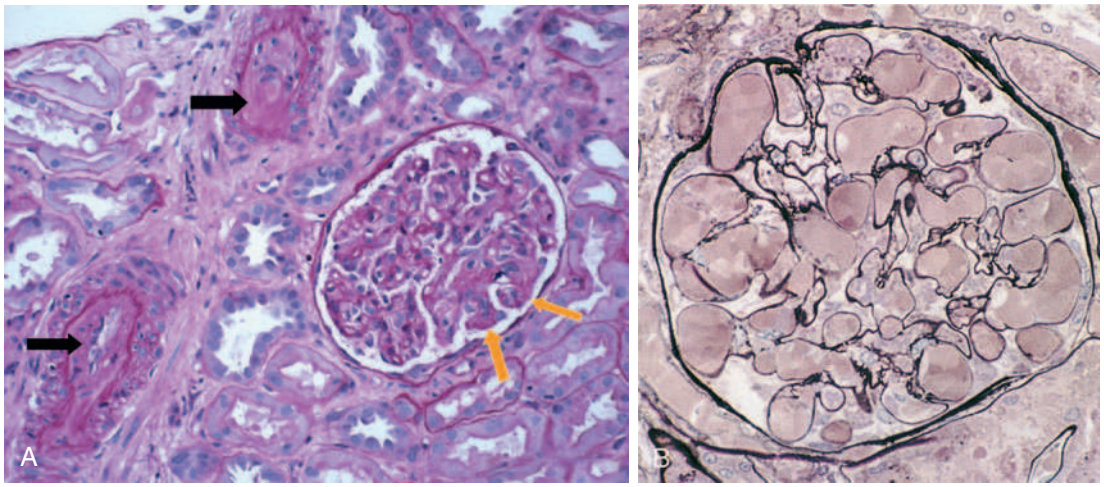

Fig. 111.4 Thrombotic microangiopathy after allogeneic hematopoietic stem cell transplantation (HSCT). (A) Renal biopsy specimen from a patient who had undergone allogeneic HSCT and developed subacute renal failure 12 months later. Periodic acid–Schiff (PAS) staining shows near occlusion of two small arteries by subintimal connective tissue and swollen endothelium *(black arrows).* The glomerulus shows thickened capillary walls with "double contours" and segmental occlusion and collapse of capillaries *(orange arrows).* (B) Severe mesangiolysis in a patient with thrombotic microangiopathy after HSCT. Note the aneurysmal capillary loops and the lack of mesangial cells or matrix. (*A* courtesy Dr. H. Rennke, Harvard Medical School, Boston, Massachusetts.)

Careful review of previous laboratory test results often will show evidence of an intermittent or persistent low-grade TMA, although the classic laboratory findings of TMA may not all be present. Diagnostic criteria (and their limitations) are summarized elsewhere.[44] Renal imaging is usually unremarkable. Kidney biopsy carries increased risks in patients with thrombocytopenia and is rarely required unless the presentation is atypical. Histopathology typically shows microthrombi in arterioles and glomerular capillaries, mesangiolysis, glomerular basement membrane duplication, and tubular injury with interstitial fibrosis (Fig. 111.4).[44] The main cause of TMA after HSCT is thought to be direct damage to the renal endothelium, and possibly the tubulointerstitium, by the chemoradiotherapy conditioning regimen (particularly the radiotherapy component).[44] Renal cells have a much slower mitotic rate than mucosal cells, and thus manifest chemoradiotherapy damage much later. Other factors such as infection, GVHD, CNIs, and activation of the RAS may play a facilitating role (Fig. 111.5).[38,44] Although deficiency of ADAMTS13 is thought not to be the primary cause in most patients, recent studies have suggested a role for complement factor H abnormalities and factor H autoantibodies.[44]

Treatment of renal TMA after HSCT is mainly supportive (see later). Prevention involves renal shielding (from irradiation damage) and avoidance of other nephrotoxic agents at the time of conditioning. Plasma exchange does not appear to be beneficial.[44] Given the complement pathway abnormalities described previously, there is recent interest in eculizumab. A series of 30 patients treated with eculizumab showed improved survival compared with standard therapy.[44]

Calcineurin Inhibitor and Sirolimus Nephrotoxicity

CNIs are routinely prescribed after allogeneic HSCT to prevent and to treat GVHD. Because CNIs are often stopped after 3 to 6 months (unless there is ongoing GVHD), their contribution to CKD is thought to be limited. The contribution of CNIs to chronic renal TMA is unclear. TMA can certainly occur in patients on non-CNI protocols.[45] There is a high incidence of TMA when sirolimus is added to CNI therapy (particularly if drug levels are high), but fortunately this is often reversible.[46]

Glomerular Disease

Nephrotic syndrome has been described after both allogeneic (particularly nonmyeloablative) and autologous HSCT. In allogeneic HSCT, it appears to be strongly associated with the presence of GVHD. Clinical response is usually seen with increased immunosuppression (typically corticosteroids and/or CNI; some reports of rituximab). De novo membranous nephropathy is the most common biopsy finding, and minimal change disease also has been reported.[47] The original hematologic disease (such as myeloma) may recur with renal involvement.

Management of Hematopoietic Stem Cell Transplantation–Related Chronic Kidney Disease

General treatment should be as recommended for any patient with CKD. Aggressive control of hypertension is warranted. There is limited evidence regarding the superiority of RAS blockade, but their use seems reasonable.[48] CNI doses should be minimized, if this is thought appropriate for the management of the HSCT. Alternatively, substitution of CNIs with IL-2 receptor blockers in the setting of GVHD and renal dysfunction might improve renal function but remains experimental at this time.[49]

Approximately 4% of patients will progress to ESRD, and overall these patients have worse survival on dialysis than non-HSCT controls.[44,45] Suitability for renal transplantation should be judged on a case-by-case basis. On occasion, the allogeneic stem cell donor can donate a kidney; the great benefit of this approach is that tolerance to the kidney allograft should exist, and hence minimal or no immunosuppression is required.[50] If this option is not available and the patient receives a conventional kidney transplant, low-dose immunosuppression should generally be prescribed because HSCT recipients may not have normal immunity and remain at higher risk for infection. Good outcomes after renal transplantation have been reported in carefully selected patients.[50,51]

SELF-ASSESSMENT QUESTIONS

1. A 28-year-old woman is referred to the renal clinic with serum creatinine 2.3 mg/dl (200 µmol/l). Six years ago she underwent lung transplantation because of respiratory failure associated with cystic fibrosis. The lung transplant is working well. However, her serum creatinine has increased slowly over the last 5 years from 1.1 mg/dl (97 µmol/l). Her medications are cyclosporine, azathioprine, prednisolone, simvastatin, and pancreas enzyme supplements. The main findings on examination are finger clubbing and blood pressure (BP) 148/84 mm Hg. The urine dipstick shows trace protein only. Which of the following is true?
   - **A.** The underlying cause of her chronic kidney disease (CKD) is most likely cyclosporine toxicity.
   - **B.** An urgent renal biopsy is indicated.
   - **C.** Switching azathioprine to sirolimus is indicated.
   - **D.** If her CKD progresses, kidney transplant is contraindicated because of underlying cystic fibrosis.
   - **E.** Diltiazem should be added to control the hypertension.
2. A 30-year-old man is referred to the renal clinic because of rising serum creatinine and worsening hypertension. Eight months ago he underwent an allogeneic stem cell transplant for acute myeloid leukemia (AML). His conditioning regimen included total body irradiation and cyclophosphamide. His early post-transplant course was relatively uncomplicated. However, he remained on cyclosporine because of graft-versus-host disease (GVHD) of the skin. Recent cyclosporine trough concentrations have been 60 to 90 ng/ml. His medications are low doses of cyclosporine, prednisolone, valacyclovir, and sulfamethoxazole-trimethoprim. The main findings on examination are BP 166/98 mm Hg (148/86 mm Hg, 3 weeks ago), mild GVHD of the skin, and mild leg edema. The urine dipstick shows 3+ blood and 3+ protein. Other test results are as follows: white blood cells (WBCs) 4.2×10^9/l, hematocrit (Hct) 26.0 (32, 3 weeks ago), platelets 82×10^9/l (130, 3 weeks ago), creatinine 2.3 mg/dl (200 µmol/l) (1.2 mg/dl [105 µmol/l], 3 weeks ago), albumin 3.2 g/dl, and 24-hour urine protein 3.2 g. The prothrombin time and activated partial thromboplastin time are normal. Which of the following is true?
   - **A.** The main cause of the renal disease is probably cyclosporine toxicity.
   - **B.** The patient has nephritic syndrome, most likely caused by membranous nephropathy.
   - **C.** The plasma lactate dehydrogenase (LDH), serum haptoglobin, and blood film should be checked urgently.
   - **D.** The main cause of the renal disease is recurrence of AML, with infiltration of the kidneys.
   - **E.** Computed tomography with intravenous contrast should be performed urgently to exclude obstruction of the urinary tract.
3. A 30-year-old man is referred urgently to the renal clinic because of an increase in creatinine from baseline 2.0 mg/dl (176 µmol/l) to 2.9 mg/dl (255 µmol/l). One week ago he was diagnosed with community-acquired pneumonia and treated with antibiotics. His breathlessness and cough have improved, but he reports mild headache and pain in the right big toe. Ten years ago he underwent a heart transplant for severe heart failure caused by idiopathic dilated cardiomyopathy. The heart transplant is apparently working well. His medications are cyclosporine, azathioprine, prednisolone, ramipril, atorvastatin, and (in the last week) cefuroxime plus clarithromycin. Examination shows fine hand tremor, pulse 90/min and regular, BP 142/84 mm Hg, oxygen saturation 98% on room air, normal breath sounds with no added sounds, and no leg edema. The right big toe is inflamed, consistent with acute gout. The urine dipstick shows trace protein only. Tests show serum creatinine 2.9 mg/dl (255 µmol/l), potassium 5.9 mmol/L, WBCs 4.9×10^9/l (with normal differential), Hct 30, platelets 189×10^9/l. Which of the following is true?
   - **A.** The most likely cause of the acute renal dysfunction is allergic interstitial nephritis resulting from cefuroxime.
   - **B.** The main underlying cause of the CKD is cardiac failure (of the transplanted organ).
   - **C.** If the patient's CKD progresses to GFR below 15 ml/min, the treatment of choice would be peritoneal dialysis.
   - **D.** Allopurinol should be added to treat the gout.
   - **E.** The most likely cause of the acute renal dysfunction is acute cyclosporine nephrotoxicity caused by impairment of cyclosporine metabolism by clarithromycin.
4. A 44-year-old woman is admitted to the intensive care unit with severe, decompensated liver disease. The underlying cause is cirrhosis from hepatitis C (HCV) infection. Over 1 week she becomes oliguric; serum creatinine increases from 1.0 (88 µmol/l) to 2.5 mg/dl (221 µmol/l). The urine dipstick shows trace blood and trace protein only. The fractional urine excretion of sodium is 0.2%. Low-dose noradrenaline is started, causing the mean arterial pressure to increase to 65 mm Hg and the urine output to increase to 800 ml/24 h. A decision is made to list her for an emergency liver transplant. Which of the following is true?
   - **A.** The baseline serum creatinine of 1.0 mg/dl likely reflects normal renal function.
   - **B.** The clinical picture is consistent with hepatorenal syndrome.
   - **C.** The acute renal dysfunction is a result of HCV-related glomerulonephritis.
   - **D.** At this time, a simultaneous liver-kidney rather than a liver-alone transplant should be performed.
   - **E.** After successful liver transplantation, her risk for developing stage 4 or 5 CKD over the long term is negligible.
5. A 39-year-old woman is referred for opinion regarding kidney transplantation. She has a background of complex congenital cyanotic heart disease and has undergone several procedures for this. However, her cardiac function is worsening and she is therefore being considered for cardiac transplantation. Her serum creatinine has steadily increased over the last 3 years. Medications are furosemide, digoxin, bisoprolol, omeprazole. She reports poor appetite and breathlessness on minimal exertion. On examination she is thin, pulse is 114 beats/min and regular, BP 152/92 mm Hg, and respiratory rate 22/min at rest. The fingertips are cyanosed. The jugular venous pressure is increased. There are reduced breath sounds in the left lung base. The liver edge is palpable; the femoral pulses are strong with no bruits. There is trace leg edema. Tests show urine dipstick 3+ protein and trace blood, plasma creatinine 4.0 mg/dl, potassium 5.1 mmol/l, albumin 3.1 g/dl, and 24-hour urine protein 4.2 g. Which of the following is true?
   - **A.** The renal dysfunction is mainly a result of the severe heart failure and thus should improve significantly after successful cardiac transplantation.
   - **B.** Because of the risk that cyclosporine or tacrolimus will worsen renal function after cardiac transplantation, you should advise the cardiologists to avoid using these drugs after transplantation.
   - **C.** Simultaneous heart-kidney transplant is a relatively common procedure and should be considered here.
   - **D.** Simultaneous heart-kidney transplant is an uncommon procedure but should be considered here.
   - **E.** You should recommend that a kidney transplant be performed first and only later consider cardiac transplantation.

Palliative Nephrology

Edwina A. Brown, Fliss E. Murtagh

Palliative care is defined by the World Health Organization as "An approach that improves the health-related quality of life of patients and their families facing the problem associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial, and spiritual."[1] The term *supportive care* is usually preferred by patients and families and is the term used by the Kidney Disease: Improving Global Outcomes (KDIGO) summary document on supportive care in kidney disease[2] and likewise in this chapter. As shown in Fig. 112.1, supportive care should begin at the time of diagnosis of advanced kidney disease. Fig. 112.2 shows how the different components can be used at different times.

PROGNOSIS

Informing patients accurately about prognosis is key to individualizing dialysis and associated supportive care. Patients with advanced kidney disease often have other comorbidities and complications of treatment; these and increasing age are causes of a high burden of morbidity affecting quality of life and shortening length of life. Physicians, however, often are not good at estimating prognosis with quotes in recent literature such as *"if you're on dialysis you could last 10, 15, 20 years (male 76 years old)"* or *"you will probably have 6 years on dialysis (male 82 years old)"*.[3] Patients often want to have conversations about life expectancy,[4] and failure to do so can result in high expectations and increased desire for aggressive treatment.[5] Being aware of prognosis is a key part of shared decision making.[6] At the individual level, the surprise question "Would you be surprised if the patient died in the next 6 or 12 months?" has been shown to enhance prognostic prediction,[7] although it has the limitation of being subjective and depending on clinician perception.

Prognostic tools have therefore been developed to enable clinicians to estimate the prognosis of patients. Factors that can be used to develop tools are summarized in Box 112.1; more detailed information can be found in an overview by Couchoud et al.[6]

Prognostic tools, however, have limitations because they provide an estimate of average survival for a population of similar risk but not for the individual. Before using a particular tool, it is important to know whether the patient concerned is similar to those used for the development of the tool in terms of age, ethnicity, renal replacement therapy (RRT), clinical data available, etc. The tool that is most readily accessible is the ARO score, which is based on simple clinical and laboratory data for prevalent European patients on hemodialysis[7]; it can be easily calculated on the ARO Risk Score website.[8] For patients not yet on dialysis, a risk score for mortality in the first 90 days of dialysis has been developed for older patients from the French Renal Epidemiology and Information Network (REIN) registry.[9] In routine clinical practice these tools can inform discussions with patients and families.

The prognostic tools discussed herein are all specific for kidney disease and mostly for patients on dialysis. Clinical tools useful as prognostic indicators in the general population are also applicable in the presence of kidney disease. The concept of frailty is rapidly becoming one of the useful prognostic indicators for hospitalization, complications of procedures, and mortality in the general population.[10] Clinically, frailty manifests as a composite of poor physical function, exhaustion, low physical activity, and weight loss and is associated with an increased risk for falls, cognitive impairment, hospitalization, and death. It is more common in the CKD population and not surprisingly is a strong predictor of mortality.[11] There are various methods of assessing frailty, but the easiest to use clinically is the Canadian Frailty Scale (Table 112.1), which has been shown to correlate with more complex assessment methods and predicts hospitalization and mortality.[12] Using this scale, the Frail Elderly Patient Outcomes on Dialysis (FEPOD) study has shown that it is frailty, not dialysis modality (assisted peritoneal dialysis [PD] and hemodialysis [HD]), that is associated with symptom score, physical functioning, and measures of quality of life.[13] Determining a frailty score routinely in older patients approaching or on dialysis enhances prognostication both of survival and quality of life. Frailty therefore is another factor that should inform discussions with patients and families.

COMMUNICATION AND SHARED DECISION MAKING

Good communication is key to enabling people to optimize quality of life and achieve their goals at all stages of a long-term condition. Conversations must include awareness of prognosis and wishes for end of life planning. These latter conversations are commonly referred to as advance care planning, but ideally they are easier for all concerned if conversations about prognosis and realistic outcomes of potential treatments and their limitations are conducted as part of routine care at all stages of advanced kidney disease. Treatment decisions should be made

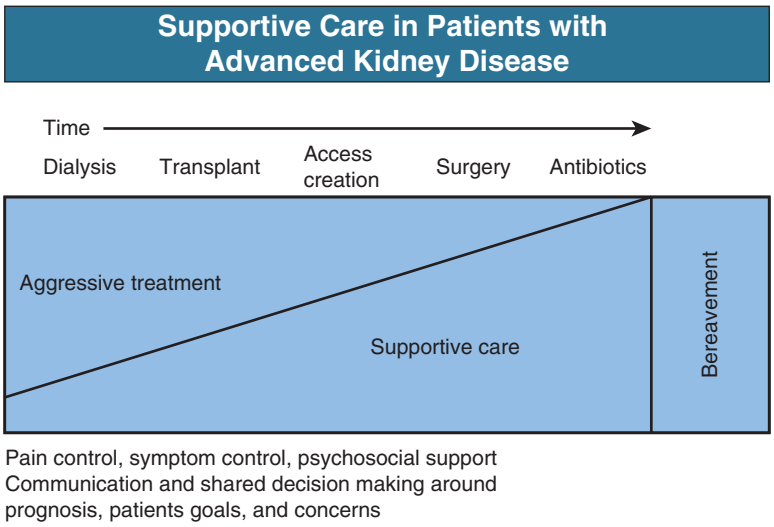

Fig. 112.1 Schematic diagram of how supportive care fits into patient pathway with advanced kidney disease.

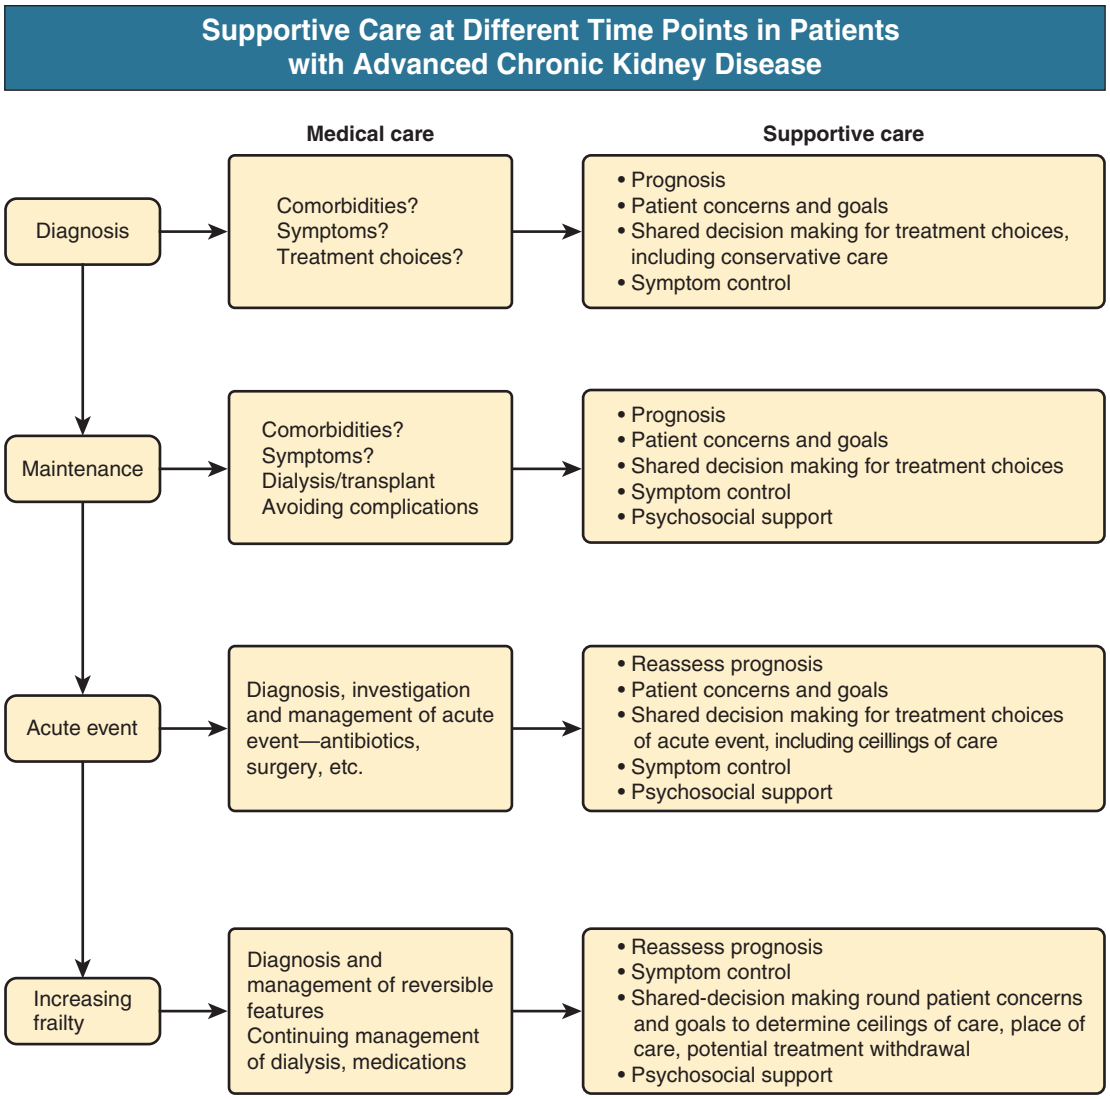

Fig. 112.2 Use of supportive care at different time points in life with advanced kidney disease.

BOX 112.1 Factors Used to Develop Prognostic Tools

Clinical Data
- Age
- Assistance with activities of daily living
- Gender
- Congestive heart failure
- Peripheral vascular disease
- Dysrhythmia
- Active malignancy
- Mobility
- Diabetes
- Body mass index
- Behavioural disorders
- Frequency of hospitalization

Dialysis-Related
- Use of central vein dialysis catheter
- Early nephrology referral

Laboratory Values
- Plasma albumin
- Plasma creatinine
- C-reactive protein

TABLE 112.1 Clinical Frailty Scale

Score	Definition
1	*Very fit:* Robust, active, energetic, well-motivated and fit
2	*Well:* No active disease, but less fit than people in category 1
3	*Well, with treated comorbid disease:* Disease symptoms are well controlled compared with category 4
4	*Apparently vulnerable:* Although not frankly dependent, commonly complain of being "slowed up"
5	*Mildly frail:* With limited dependence on others for instrumental activities of daily living
6	*Moderately frail:* Help is needed with both instrumental and noninstrumental activities of daily living
7	*Severely frail:* Completely dependent on others for the activities of daily living or terminally ill

From reference 10.

with and not *for* the patient, in other words using shared decision making. This is a process in which patients, when faced with an important choice about their health care, can review all the treatment options available to them and participate actively with their health care professional in making that decision,[14] thereby enabling patient autonomy to be respected.[15] Shared decision making is embedded in the U.S. Renal Physicians Association guidelines on dialysis initiation and withdrawal,[16] which state that "they reflect the ethical principle of respect for autonomy because clinicians, family members, and others have an ethical duty to accept the decisions regarding medically indicated treatment made by competent patients and, in the absence of competence, to formulate decisions that would respect patients' wishes, or if wishes are unknown, advance the best interest of their patients." To enable patients and families to make these decisions, they need to be given evidence-based information about what is happening regarding disease process, what is likely to happen regarding prognosis, what the treatment options are available, and what are the realistic outcomes from these treatments. Health care professionals, on their part, should seek to understand the patient's concerns and lifestyle priorities and then use these to guide the patient through decision making about wishes regarding specific treatments, ceilings/limits of care if they are no longer able to make decisions, place of care at end of life, etc. A summary of when such conversations could and should take place are shown in Box 112.2.

There are challenges to having advance care planning discussions—time needed, cultural and linguistic challenges,[17] and overcoming inhibitions of health care professionals to have difficult conversations, particularly when the prognostic future is uncertain.[18] Some useful questions to overcome these challenges are shown in Box 112.3.

BOX 112.2 Time Points for Advance Care Planning Discussions

- As part of renal replacement therapy planning, particularly if transplant ineligibility or conservative care is discussed.
- Starting or within first few months of starting dialysis.
- Failing transplant and patient does not want dialysis or is anticipated to have poor outcomes on dialysis.
- Failing peritoneal dialysis (PD) and patient does not want hemodialysis (HD) or is anticipated to have poor outcomes on HD and transplantation not feasible.
- Recurrent vascular access problems in HD patient who does not want or cannot transfer to PD, and transplantation not feasible.
- Patient wants to withdraw from dialysis.
- After intercurrent event that results in worsening of prognosis, such as stroke, fall and bone fracture, worsening cognitive function, new malignancy.
- Development of intercurrent event needing major surgical intervention, such as coronary artery bypass surgery or major abdominal surgery.
- Increasing frailty and/or cognitive decline.
- Answer of "no" to surprise question: "Would you be surprised if patient died in the next 12 months?"

BOX 112.3 Questions and Statements to Use in Advance Care Planning

- How is your health now compared with a few months ago?
- Would you be surprised if I told you that things are not going well?
- It is always hard to predict the future, but it would not be a surprise if some major acute event occurred or your health deteriorated significantly in the next few months (or other applicable time scale). We should therefore discuss what your wishes would be should this occur ….
- It is a good idea to talk about what we can do and how to get help if you get more unwell ….
- Different people make decisions in different ways. Do you make decisions on your own, do you involve your family, or does someone from your family make important decisions for you?
- Do you have a faith or spiritual beliefs that help you in difficult times?
- Have you ever thought how much treatment you would want if you are very ill, unable to communicate to make your own decisions, and unlikely to leave hospital and be independent?
- You know you have a choice about where you would like your end of life care to take place. Would you like to talk through the options?
- Some people decide to stop dialysis when their health has deteriorated and they feel that dialysis has become a burden and is no longer of benefit. We do not need to mention that any further now, but it is something you may want to discuss later.

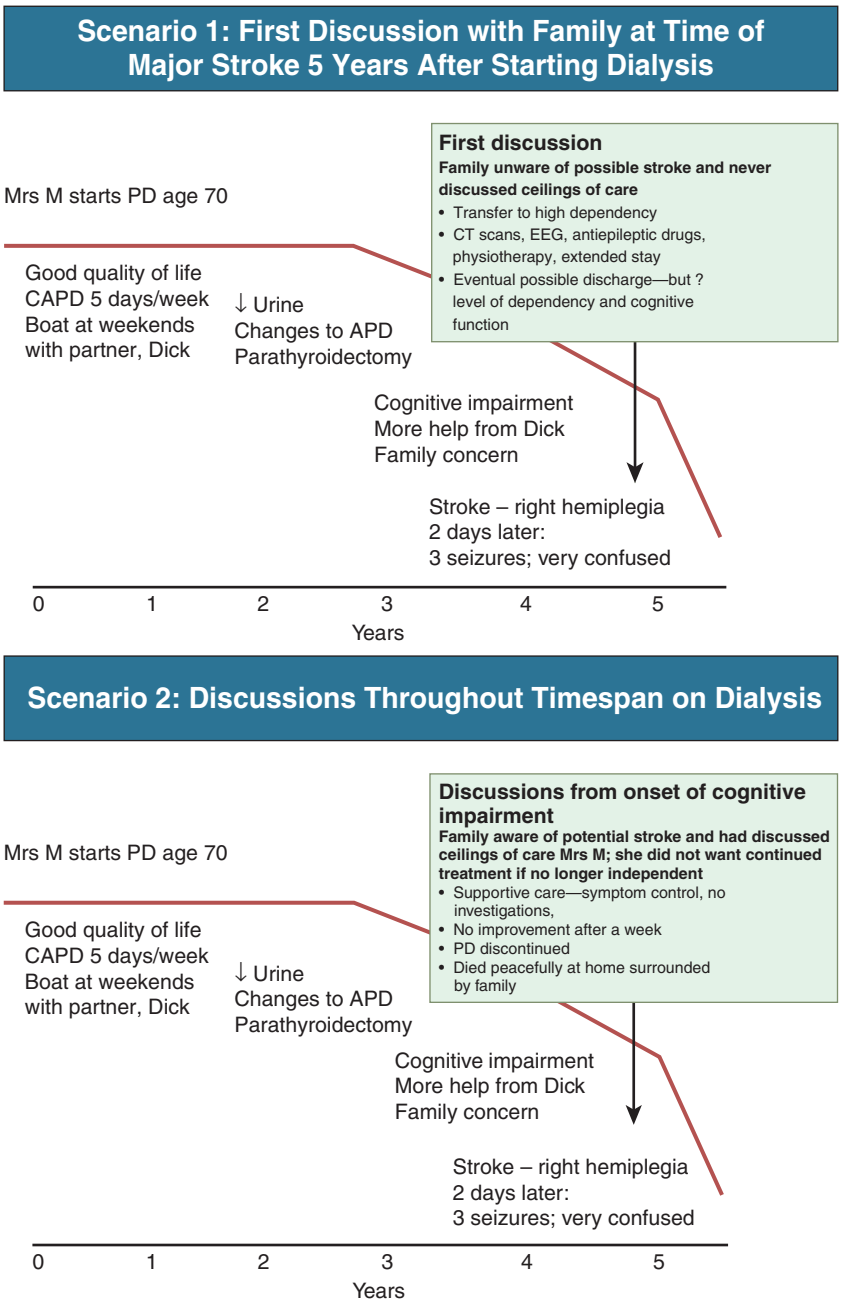

Fig. 112.3 How communication and advance care planning can influence patient outcomes. **Scenario 1:** First discussion with family at time of major stroke 5 years after starting dialysis. **Scenario 2:** Discussions throughout time span on dialysis. *APD,* Ambulatory peritoneal dialysis; *CAPD,* continuous ambulatory peritoneal dialysis; *CT,* computed tomography; *EEG,* electroencephalogram; *PD,* peritoneal dialysis.

Conversations about prognosis and advance care planning should be embedded in nephrologic practice. The timing and frequency of discussions can have a huge influence on patient outcomes. Fig. 112.3 gives the example of a woman who has had a major stroke 5 years after starting dialysis at the age of 70 and who has had progressive cognitive impairment in the last 2 years. In the absence of any previous discussions, the family would be unaware of the high probability of stroke and in all likelihood, would not have had discussions about extent of treatment in such an event; there would then be a high probability of them expecting intensive investigations and management. In reality, for this particular patient, there had been a number of discussions after the onset of cognitive impairment and the patient had made it clear that she did not want continuing active management if she was not going to be independent; this made the final decision making by the family very much easier. This has been confirmed by randomized controlled studies in elderly and dialysis populations showing better quality of life at end of life and improved certainty about decision making by close family members.[19,20]

CONSERVATIVE CARE

Conservative (nondialytic) kidney care has been defined (Box 112.4), using the term *comprehensive conservative care* and encompassing all the components required for effective comprehensive care.

BOX 112.4 Definition of Comprehensive Conservative Care

Comprehensive conservative care is planned holistic patient-centered care for patients with stage 5 (glomerular filtration rate category 5) chronic kidney disease that includes:

- Interventions to delay progression of kidney disease and minimize risk for adverse events or complications
- Shared decision making
- Active symptom management
- Detailed communication, including advance care planning
- Psychological support
- Social and family support
- Cultural and spiritual domains of care

Comprehensive conservative care does not include dialysis.

From reference 2.

BOX 112.5 Distinct Conservative Care Populations

Comprehensive conservative care: Conservative care that is chosen or medically advised.

Choice-restricted conservative care: Conservative care for patients in whom resource constraints prevent or limit access to renal replacement therapy; therefore a choice for conservative care cannot be recognized.

Unrecognized stage 5 chronic kidney disease: Chronic kidney disease is present but has not been recognized or diagnosed; therefore a choice for conservative care cannot be recognized.

From reference 2.

It has also been proposed that globally there are three distinct groups within the conservative care population (Box 112.5); this reflects limited availability of RRT, the consequent (lack of) options for choice in low-income and middle-income countries, and constraints on diagnosis of stage 5 chronic kidney disease in resource-poor settings.

Rates of conservative management vary considerably among and within countries, and it is likely that individual nephrology practice is at least a factor in this variation.[21] It is important therefore to consider all available evidence on survival of those managed conservatively and to contrast this to evidence on survival with dialysis. However, this is challenging, because those who are more fit usually opt for dialysis, and others are advised to follow conservative nondialytic management because of comorbidity or other factors that adversely influence survival. This selection bias makes it hard to meaningfully compare survival between those with dialysis and those managed conservatively. The summary of the evidence by O'Connor and Kumar[22] provides a good overview of current evidence, although further comparative studies[23-27] have since been published. This collected evidence shows that there is a substantial survival advantage with dialysis; however, for older people with end-stage renal disease (ESRD) (older than 75 to 80 years) with comorbidity, much of this survival advantage is lost. When time in hospital and receiving dialysis is also taken into account, there is little or no survival advantage to be gained from dialysis for these older patients with comorbidities. However, there are two notes of caution in interpreting and applying this evidence; first it must be recognized that the evidence from those receiving conservative care remains very limited, and second the conservative care population is heterogeneous. This makes it much harder to relate to individual circumstances, yet decisions for conservative care always need to be individually tailored.

BOX 112.6 Situations Where Dialysis Withdrawal is Appropriate

- Patients with decision-making capacity, who being fully informed and making voluntary choices, refuse dialysis or request that dialysis be discontinued
- Patients who no longer possess decision-making capacity
  - who have previously indicated refusal of dialysis
  - whose legal agents/surrogates request that it be discontinued
- Patients with irreversible, profound neurological impairment such that they lack signs of thought, sensation, purposeful behaviour and awareness of self and environment

From the Kidney Disease I Improving Global Outcomes (KDIGO) Controversies Conference on Supportive Care in Chronic Kidney Disease (2)

It is important to also consider symptoms, quality of life, illness experience, and survival. There is robust evidence that patients rarely prioritize survival above all else; quality of life is equally important and often takes precedence.[28] The systematic review cited previously[29] shows that patients managed conservatively (as do those receiving dialysis) report significant symptom burden, with an average of 9 to 17 symptoms. Quality of life is generally similar between patients on dialysis and patients receiving conservative, although there may be some decrease in life satisfaction in relation to dialysis adjustment.[30] Of note, with good renal supportive care many of the conservatively managed patients have stable or improved symptoms and quality of life.[31]

DIALYSIS WITHDRAWAL

As already demonstrated in the case discussed in Fig. 112.3, patients may decide to stop dialysis. The median time to death after stopping dialysis is 8 to 9 days[32] but can be considerably longer if there is significant residual renal function. There is information for patients and carers about stopping dialysis on both U.K. and U.S. patient support websites.[33,34] The situations in which dialysis withdrawal is appropriate are shown in Box 112.6.

Studies suggest that the rate of dialysis withdrawal has increased over the years, but this needs to be interpreted with caution because there is no well-accepted definition of dialysis withdrawal.[35] A recent report published from the Scottish Renal Registry[36] has defined death resulting from withdrawal as patients refusing further treatment, therapy ceased for other reasons, and dialysis withdrawn for medical reasons. In this study, dialysis withdrawal was the primary cause of death in 19% of all deaths (a rate of 41 in 1000 patient-years) over a 7-year period; in a further 17% of patients, withdrawal from dialysis was considered to have contributed to death, but not to be the main cause. Using this definition, deaths attributed to dialysis withdrawal accounted for around a third of deaths; this did not change over the 7 years of the study, but did vary significantly across the different renal centers with dialysis withdrawal accounting for 3.3% to 55.8% of all deaths per center.[36] This variation also has been found on a larger scale between different European countries, with higher reports of dialysis withdrawal if respondents in the survey worked in a public center, if stopping life-supporting treatments was perceived as allowed, if withdrawal decisions were considered shared between patients and doctors, and if palliative care was reimbursed by payers.[37] The patient factors associated with dialysis withdrawal vary in individual studies, but many of the following have been consistently identified: older age, female sex, White race, higher comorbidity burden (particularly cerebrovascular disease), being on HD, early initiation of dialysis, and late referral to nephrologist.[36,38,39]

Withdrawal from dialysis is ethically and clinically acceptable only after a process of shared decision making with the patient (and close

persons if the patient is no longer able to make decisions). These discussions need to be attuned to the culture (ethnic and religious) of the individual.[17] It is also incumbent on all providers caring for a patient who is contemplating stopping dialysis to address potentially remedial factors contributing to the decision, such as depression or other symptoms, such as pain, as well as potentially reversible social factors.[2] **It is essential to ensure access to appropriate supportive and/or hospice care as an integral part of care after any decision to withdraw dialysis.**[2] Details of this are discussed in the following section.

SYMPTOM CONTROL AND MANAGEMENT OF LAST DAYS

Symptoms are as common in those managed conservatively as among those on dialysis, with 3 in 4 reporting weakness and pruritus; 1 in 3 reporting drowsiness, breathlessness, and edema; and more than 1 in 2 patients with ESRD reporting pain.[40] These symptoms are not mild; a high proportion (over two thirds) of those with pain, for instance, have moderate or severe pain, often related to comorbid conditions rather than to renal disease. In addition, symptoms often accumulate, with an average of 12 symptoms experienced by each patient that impair quality of life and need optimal management.

Evidence on management of symptoms is often extrapolated from other populations or based on best understanding of the pharmacodynamics and pharmacokinetics in severe renal impairment. This evidence is limited but is well summarized in a recent series of articles.[41]

In the last days of life, additional symptoms may arise from uremia (nausea, vomiting, drowsiness, myoclonus, pruritus), fluid overload (breathlessness and edema), and immobility and poor tissue perfusion (pain, muscle soreness, pressure sores). It is best practice to prescribe "as required" doses of an analgesic, an antiemetic, a sedative, and an antisecretory agent for all patients with ESRD as they enter the last few days of life, to anticipate any distressing symptoms and ensure they can be rapidly addressed.

As end of life approaches, both patient and family often need much more information and explanation than is provided by health professionals. Encouragement to ask questions, straightforward but sensitively judged responses, and frequent opportunities for professionals to check on concerns and anxieties, can go a long way to provide support to the patient and family at a difficult and challenging time.

SELF-ASSESSMENT QUESTIONS

1. Which of the following factors have been shown to be associated with a poor survival prognosis in an 80-year-old man who has been on dialysis for 2 years?
   - **A.** Being on peritoneal dialysis
   - **B.** Peripheral vascular disease
   - **C.** Use of central venous catheter
   - **D.** Requiring assistance to get dressed
   - **E.** Low plasma albumin
2. Advance care planning should include which of the following?
   - **A.** Legal process resulting in advance decision
   - **B.** Informing patient that he or she will not be resuscitated
   - **C.** Discussion about prognosis
   - **D.** Identification of patient concerns
   - **E.** Opportunity for patient to record future wishes
3. Which of the following statements can be made about dialysis withdrawal?
   - **A.** Approximately 20% of deaths of dialysis patients are stated to be due to dialysis withdrawal.
   - **B.** Death invariably occurs within 3 days of stopping dialysis.
   - **C.** Dialysis withdrawal can be viewed as euthanasia.
   - **D.** Shortness of breath is the main symptom after withdrawing dialysis.
   - **E.** Dialysis can be stopped in patients lacking decision-making capacity who have made a previous decision to this effect.
4. The following statements can be made about conservative care:
   - **A.** Survival rates of multimorbid patients older than 80 years are similar on dialysis and conservative care.
   - **B.** Survival of functionally independent patients 70 to 75 years old are the same on dialysis and conservative care.
   - **C.** Patients choosing conservative care should be persuaded to start dialysis if they deteriorate acutely.
   - **D.** Anemia management with erythropoietin is appropriate for patients choosing conservative care.
   - **E.** Conservative care is not "rationing" because patients choose not to have dialysis themselves.

ANSWERS

CHAPTER 1

1. A. Are unable to replicate
2. E. Serves as the effector structure of mesangial cell contraction
3. A. 30 nm
4. D. Contain nitric oxide synthase

CHAPTER 2

1.
   A. Albumin has an effective radius of 3.6 nm and is small enough to be filtered.
   B. The filtration barrier is negatively charged, which restricts filtration of negatively charge proteins.
   C. Net ultrafiltration pressure is determined by the balance of hydrostatic and oncotic pressure across the capillary.
   D. Correct. Dilation of the afferent arteriole alone will increase hydrostatic pressure within the glomerular capillary network and therefore increase filtration.
   E. Mesangial cells are contractile and can influence the net filtration area.

2.
   A. Correct. The proximal tubule normally reclaims almost all of the filtered glucose via SGLT2. Impairment of this pathway can explain glycosuria in Fanconi syndrome.
   B. Impaired fluid reabsorption in the proximal tubule can explain polyuria. However, the proximal tubule is "leaky" and cannot sustain a large osmotic gradient, so this statement is incorrect. It reabsorbs large amounts of water because of a high hydraulic permeability.
   C. Approximately 65% of the filtered calcium is reabsorbed in the proximal tubule and injury to this segment can cause hypercalciuria. This answer is incorrect because calcium reabsorption mostly occurs through the paracellular pathway and not via a calcium pump in the apical membrane.
   D. The proximal tubule reabsorbs phosphate via a dedicated cotransport protein that uses the electrochemical gradient for sodium. Impairment of this process, as can occur in the Fanconi syndrome, causes hyperphosphaturia.
   E. This is incorrect. The proximal tubule is a leaky epithelium.

3.
   A. Vasopressin-stimulated sodium and urea transport in the thick limb of Henle and will increase the gradient.
   B. Correct. Increased blood flow through the medullary vasa recta causes "washout" of osmolytes from the interstitial fluid, diminishing the gradient.
   C. Activation of this system increases the medullary gradient.
   D. Activation of this system increases the medullary gradient.
   E. Urea contributes significantly to the gradient.

CHAPTER 3

1. D.
   Larger than average body size based on height and weight.
2. F
   Chronic kidney disease is defined as markers of kidney damage or decreased GFR for ≥3 months, so ascertainment of kidney damage and confirmation of decreased GFR could be used to confirm the diagnosis.
3. B.
   ACE inhibitors cause a reversible decline in GFR in patients with chronic kidney disease.

CHAPTER 4

1. B. Is not adequate for the evaluation of the renal patient
   This is because reagent strip detects only albumin, has a low sensitivity (does not detect urine albumin ≤0.25-0.30 g/l), supplies only semiquantitative results, and there is no standardization between manufacturers.
2. A. Is the correct approach for urine sediment examination
   This is correct because phase contrast plus polarized light allows the best identification of morphologic details, especially of cells and casts, and allows the best identification of lipids and crystals when they come with unusual morphology.
3. D. Are not adequate for the evaluation of the renal patient
   This is correct because automated urine sediment analyzers do not identify clinically relevant epithelial cells (renal tubular cells, transitional cells either deep or superficial, decoy cells); underestimate casts, of which they can recognize only hyaline and "nonhyaline" or "pathologic" subtypes; identify only a few types of crystals; do not identify lipids.

CHAPTER 5

1. C. Hypoechoic
2. A. CO2 angiography
3. D. Diffusion-weighted MRI
4. D. History of cerebral aneurysm clip
5. A. Noncontrast CT scan

CHAPTER 6

1.
   A. Correct. Half-life of naproxen is up to 16 hours; therefore after 24 hours platelet function would still be deranged.
   B. This level of BP is not a contraindication.
   C. This may indicate the presence of urinary infection, but in the absence urinary symptoms it is not a contraindication to biopsy.
   D. With appropriate ultrasound imaging it should be possible to perform a biopsy of the kidney away from the cysts.
   E. Although this may make visualization of the kidneys difficult, high BMI is not a contraindication to renal biopsy.

2.
   A. This is likely related to pre-eclampsia, and a biopsy should not be required for diagnosis.
   B. Investigation for this can be delayed until after the pregnancy is complete, assuming renal function is stable.
   C. This will require imaging of the renal tract, but a renal biopsy is unlikely to be useful during pregnancy.
   D. This is likely related to pre-eclampsia, and a biopsy should not be required to diagnose this.
   E. Correct. This may indicate the presence of a renal disease that may require specific treatment during pregnancy, and therefore knowledge of the underlying pathologic process is important.

3.
   A. This is possible, but B is a better answer because the bleeding diathesis is correctable.
   B. Correct. This will provide functioning platelets to circumvent the clopidogrel-mediated platelet dysfunction.
   C. This will not reverse clopidogrel-induced platelet dysfunction.
   D. A delay of at least 7 days is required for the correction of the effects of aspirin and clopidogrel on platelets.
   E. This will not reverse clopidogrel-induced platelet dysfunction.

4.
   A. This supports a diagnosis of diabetic nephropathy, and the diagnosis usually can be comfortably made with clinical criteria alone.
   B. This supports a diagnosis of diabetic nephropathy, and the diagnosis can usually be comfortably made with clinical criteria alone.
   C. This would be expected with diabetic nephropathy.
   D. Correct. The proteinuria of diabetic nephropathy is progressive over months to years. A negative urinalysis 4 months earlier suggests the presence of an alternative diagnosis to diabetic nephropathy.
   E. This provides no additional information in terms of clarifying the cause of proteinuria.

CHAPTER 7

1. B. Underfilling of the arterial circulation resulting from splanchnic venous dilation causing neurally and hormonally mediated renal sodium retention

   This patient presents with extracellular fluid expansion secondary to chronic liver disease/cirrhosis, as suggested by consistent history of alcohol dependence and physical examination findings. In cirrhosis, nitric oxide and carbon monoxide overproduction leads to splanchnic and peripheral arteriolar vasodilation. In advanced stages of cirrhosis, this causes underfilling of the systemic arterial vascular space. Baroreceptor-mediated activation of the renin-angiotensin-aldosterone system (RAAS), sympathetic nervous system stimulation, and nonosmotic release of antidiuretic hormone (ADH) occur to restore the normal blood volume homeostasis. This results in renal sodium and water retention and constitutes the major mechanism for sustained ascites formation.

2. D. Administer intravenous mannitol to increase osmotic pressure within the tubule and thus sodium and water reabsorption

   Therapy for extracellular fluid volume excess in patients with cirrhosis attempts to achieve negative sodium balance by dietary sodium restriction and diuretics. Other measures can be used when the patient has inadequate or no response to diuretics or when rapid decompression of the abdomen is desired. Large-volume paracentesis with albumin infusion can thus be used. Intravenous mannitol has augmented natriuresis in diuretic-resistant patients with cirrhosis but is not typically recommended.

3. C. Treat for presumptive bacterial peritonitis

   The clinical scenario is consistent with presumptive spontaneous bacteria peritonitis (SBP). Although the patient remains hypotensive, there is clear evidence that her venous volume is now replete; in this case a pressor might be a reasonable choice. Randomized trials have reported adverse outcomes of patients in the intensive care unit treated with HES compared with lactated Ringer solution. The creatinine rise indicates acute kidney injury, and the urine sodium concentration suggests that she may have developed acute tubular necrosis. There is no clear indication for dialysis, despite the rise in creatinine.

CHAPTER 8

1. D. Increased solute load and measurement of electrolyte-free water clearance

   A calculation would reveal that this patient is excreting electrolyte-free water despite the urine osmolality being much greater than serum osmolality. In such a patient setting, the failure to replace electrolyte-free water losses results in increased serum sodium concentration. The hyperosmolality of the urine is primarily caused by the extremely high excretion of urea in this patient receiving high-protein enteral feedings.
2. B. Patient probably has idiopathic SIADH

   The data described fulfil the criteria for the syndrome of inappropriate antidiuretic hormone secretion (SIADH). This patient not taking a thiazide diuretic does not protect her from developing SIADH, which can occur in elderly individuals occasionally without an obvious underlying cause. The high urinary osmolality speaks against poor solute intake. There is no known change in vasopressin metabolism in elderly patients.
3. B. 0.5 ml of 5% dextrose in water per milliliter of urine

   This patient also is excreting electrolyte-free water, most likely because of the loop diuretic. The regimen would match water losses, and the serum sodium would remain unchanged. Because the patient is also hypervolemic, a negative sodium balance is desirable and would be undermined by the other three regimens, all of which contain sodium.

CHAPTER 9

1. **D. Hypomagnesemia often leads to renal K^+ wasting and hypokalemia. Correction of the hypomagnesemia, whether by discontinuation of causative medications or by magnesium supplementation, corrects the renal K^+ wasting and allows successful correction of the hypokalemia.**
2. A. Terazosin
   Blockade of α_1-adrenoreceptor can stimulate cellular K^+ uptake. This class of medication does not lead to hyperkalemia.
3. Hypokalemia is associated with which of the following conditions?
   E. All are correct.

CHAPTER 10

1. C. Correct. Malignant neoplasias
   A. Secondary hyperparathyroidism is associated with normal or low plasma calcium level.
   B. Cholecalciferol or ergocalciferol therapy rarely induce hypercalcemia, except when very high doses are administered.
   D. Familial hypocalciuric hypercalcemia is a rare disease.
   E. Hypomagnesemia induces hypoparathyroidism and/or peripheral resistance to PTH and thus hypocalcemia.
2. D. Vitamin D overload; E. Treatment by calcium-based phosphate binders
   A. Primary hypoparathyroidism is a common cause of hypocalcemia.
   B. Secondary hyperparathyroidism occurs when plasma calcium and/or $1,25(OH)_2$-vitamin D levels decrease.
   C. Hyperphosphatemia
   D. Correct. This treatment may be a cause of hypercalcemia, not hypocalcemia.
   E. Correct. This treatment may be a cause of hypercalcemia, not hypocalcemia.
3. B. Adrenocorticotropin hormone
   A. Parathyroid hormone decreases phosphate reabsorption by the proximal tubule.
   B. ACTH
   C. FGF-23 decreases phosphate reabsorption by the proximal tubule.
   D. Klotho is a factor required for the proper response of the proximal tubule to FGF-23.
   E. Growth hormone increases phosphate reabsorption by the proximal tubule.
4. E. Worsening of secondary hyperparathyroidism
   A. It may be associated with, but not clearly causally linked to, untreated hyperparathyroidism in patients with CKD.
   B. It may be associated with, but not clearly causally linked to, untreated hyperparathyroidism in patients with CKD.
   C. It may be associated with, but not clearly causally linked to, untreated hyperparathyroidism in patients with CKD.
   D. It may be associated with, but not clearly causally linked to, untreated hyperparathyroidism in patients with CKD.
   E. Correct. Worsening of secondary hyperparathyroidism is causally linked to untreated hyperparathyroidism in patients with CKD.
5. A. Anemia

CHAPTER 11

1. B. Increases proximal tubular ammonia production
   In normal individuals, the net effect of K^+ deficiency is typically a minor change in acid-base balance. Chronic K^+ deficiency increases the proximal tubule apical membrane Na^+-H^+ antiporter and basolateral membrane Na^+-HCO_3^--CO_3^{2-} cotransporter activities. Chronic K^+ deficiency also increases proximal tubular ammonia production and increases collecting duct H^+ secretion. As counterbalance to these effects, K^+ deficiency decreases aldosterone secretion, which can inhibit distal acidification. Thus, in normal individuals, the net effect of K^+ deficiency is typically a minor change in acid-base balance.
2. D. Nonthyroid glycoproteins Rhbg and Rhcg are involved in collecting duct ammonia secretion.
   The nonerythroid glycoproteins Rhbg and Rhcg are likely involved in collecting duct ammonia secretion. Most of the ammonia (NH_3) that leaves the proximal tubule is transported out of the loop of Henle, predominantly in the thick ascending limb (TAL). Lumen-positive voltage provides a driving force for passive paracellular ammonium (NH_4^+) transport out of the TAL. NH_4^+ can be transported out of the lumen by the furosemide-sensitive Na^+-K^+-2Cl transporter. NH_4^+ also can leave the lumen across the apical membrane K^+ channel of the TAL cell. Ammonia is secreted by the collecting duct.
3. D. Daily volatile acid production is approximately 1 mmol H^+.
   In general, animal foods are high in proteins and organophosphates, thereby providing a net acid diet. Lysine and arginine yield acid on metabolism. Sulfur-containing amino acids are metabolized to H_2SO_4. Under normal circumstances, daily net nonvolatile acid production is approximately 1 mmol H^+/kg.

CHAPTER 12

1. B. Correct. Serum HCO3$^-$ concentration will increase after oral bicarbonate administration but then decrease to 18 mmol/l after therapy is discontinued.
   A. Choice A is incorrect because distal, not proximal, RTA is associated with nephrocalcinosis.
   B. The patient presents with hypokalemia and normal gap acidosis in association with glycosuria and normal plasma glucose concentration. These findings suggest Fanconi syndrome and type 2 or proximal renal tubular acidosis (RTA). The large amount of proteinuria but only a trace positive dipstick suggests excretion of a cationic protein caused by multiple myeloma. With proximal RTA, administration of bicarbonate will only transiently increase serum [HCO_3^-], and once discontinued, plasma [HCO_3^-] will fall to a lower T_{max}, usually 16 to 18 mmol/l.
   C. A side effect of bicarbonate therapy is a worsening of hypokalemia due to increased renal K^+ wasting as distal Na^+ delivery is increased.
   D. The urine will acidify in proximal RTA once the serum bicarbonate falls to the lower T_{max} after discontinuation of oral bicarbonate therapy.
   E. The urine anion gap is not negative in proximal RTA because proximal tubular dysfunction also impairs renal ammonia genesis.
2. C. Correct. Serum uric acid levels are likely to be low in this patient.
   A. The child may present with an anion gap metabolic acidosis alone, particularly soon after ingestion.
   B. Hypokalemia is the result of increased renal potassium excretion. Renal K^+ wasting is the result of increased distal delivery of Na^+ in combination with increased circulating aldosterone (secondary to volume depletion).
   C. With high-dose aspirin therapy or in the patient with aspirin overdose, the renal excretion of uric acid is increased and hypouricemia may be present. In this setting, the hepatic glucuronidation of salicylic acid is saturated, and large quantities of free salicylate are filtered into the tubule. Free salicylate interferes in the reabsorption of uric acid by the proximal tubule, accounting for the uricosuric effect. Aspirin overdose is associated with a variety of acid-base and electrolyte disturbances. Salicylates have a direct stimulatory effect on the respiratory center, such that respiratory alkalosis is a prominent feature in the overdose setting. An anion gap metabolic acidosis is also present primarily as a result of increased production and accumulation of ketoacids and lactic acid. Salicylic acid accumulation accounts for only a minor component of the increase in anion gap.
   D. Urinary Na^+ excretion is increased because of urinary excretion of Na^+-salicylate
   E. Lactic acid production is increased because of the uncoupling effect of aspirin on oxidative phosphorylation in the mitochondria. Adult patients with aspirin overdose usually present with a mixture of respiratory alkalosis and anion gap metabolic acidosis.
3. A. Correct. Propylene glycol toxicity
   A. The development of the anion gap metabolic acidosis in association with an increased osmolar gap is best explained by propylene glycol toxicity. Propylene glycol is used as a diluent to enhance the solubility of various drugs, including lorazepam. With high doses infused for prolonged periods, propylene glycol can accumulate in the plasma and lead to an osmolar gap. Lactic acid is a by-product of metabolism, thus explaining the development of lactic acidosis. Case reports suggest prolonged propylene glycol exposure can also cause acute renal failure.
   B. The serum glucose concentration of 120 mg/dl excludes the diagnosis of diabetic ketoacidosis.
   C. Lactic acidosis is likely present but only as part of the toxicity of propylene glycol toxicity. Lactic acidosis is not characteristically accompanied by an osmolar gap.
   D. The mild worsening of renal failure is not of sufficient magnitude to explain the development of an anion gap acidosis.
   E. Isopropyl alcohol leads to an increased osmolar gap as a result of the accumulation of acetone. The metabolism of this alcohol does not consume HCO_3^- and is not associated with the development of metabolic acidosis.

CHAPTER 13

1. A.
   While metabolic alkalosis is caused by a variety of factors, including chloride depletion, potassium depletion or increased secretion of mineralocorticoids, the end result is *always* impaired renal excretion of excess bicarbonate.
2. D.
   The most important next step is the history and physical examination. Any laboratory data obtained should be interpreted in relation to history and physical. If the patient has a clear history of nausea and vomiting, for example, no further laboratory tests are needed for management. Although blood gases may be helpful in some instances, history and physical examination will provide the indication for such measurements. Urine chloride and aldosterone levels are not helpful in the most common causes of metabolic alkalosis.
3. B.
   A central abnormality in the pathophysiology of metabolic alkalosis is continued stimulation of ENaC. For excess bicarbonate to be excreted, this transporter must be downregulated. The other transporters are often activated or suppressed in various causes of metabolic alkalosis, but not uniformly in all causes.
4. D.
   The history and physical examination findings in this woman are suggestive of pseudohyperaldosteronism, so one should go right to measurements of serum aldosterone and renin. Serum aldosterone and renin levels should both be vanishingly low in Liddle syndrome or in the syndrome of apparent mineralocorticoid excess. Serum aldosterone will be elevated, with a very low renin level in primary hyperaldosteronism or in glucocorticoid remedial aldosteronism. Urine chloride is only helpful if one is suspecting surreptitious vomiting, and such a patient would not have hypertension or a body mass index of 26. There is no indication for computed tomography or measurement of blood gases in this patient.

CHAPTER 14

1. E.
   Acute adaptation to respiratory acid-base disorders (respiratory acidosis and respiratory alkalosis) originates exclusively from titration of the body's nonbicarbonate buffers. It remains unaltered in patients with end-stage renal disease. By contrast, chronic adaptation to respiratory acid-base disorders entails changes in renal acidification mechanisms. Therefore chronic adaptation is essentially absent in patients with end-stage renal disease. Consequently, these patients experience greater deviations in blood pH than normal subjects in response to chronic respiratory acidosis and chronic respiratory alkalosis.
2. B.
   There is acidemia and hypercapnia, signifying the presence of respiratory acidosis (i.e., a primary increase in $Paco_2$, the respiratory component of the Henderson equation). The $Paco_2$ is elevated by 22 mm Hg above the average normal value of 40 mm Hg. In response to sustained hypercapnia, upregulation of renal acidification mechanisms generates new HCO_3^- for the body fluids, resulting in an average increase in serum $[HCO_3^-]$ of about 0.35 mEq/l for each millimeter of mercury chronic increment in $Paco_2$. This process requires 3 to 5 days to reach completion. Therefore serum $[HCO_3^-]$ would be expected to increase by 7.7 mmol/l ($22 \times 0.35 = 7.7$) above the average normal value of 24 mmol/l, that is, to the level of 31.7 mmol/l, a value that is in close agreement with the observed value of 31 mEq/l. There is appropriate hypochloremia and the serum anion gap is normal at 9 mmol/l. The data are consistent with chronic respiratory acidosis. Acute respiratory acidosis is excluded, because the serum $[HCO_3^-]$ is higher than that obtained in response to acute adaptation (on average, serum $[HCO_3^-]$ increases by about 0.1 mEq/l for each millimeter of mercury acute increment in $Paco_2$). There is no support for metabolic acidosis, as a single or mixed disorder, because serum $[HCO_3^-]$ is increased and appropriate for the level of chronic hypercapnia.
3. E.
   A clue to the coexistence of a mixed acid-base disorder is the normal blood pH despite substantial deviation in both $Paco_2$ and serum $[HCO_3^-]$ from normal values. The treatment with diuretics and a low-sodium diet resulted in the superimposition of metabolic alkalosis on the background of a continuing chronic respiratory acidosis. For a sustained level of $Paco_2$ that is higher than the average normal level of 40 mm Hg by 24 mm Hg, serum $[HCO_3^-]$ would be expected to increase by 8.4 mmol/l ($24 \times 0.35 = 8.4$) above the average normal value of 24 mmol/l, that is, to the level of 32.4 mEq/l. Note that serum $[HCO_3^-]$ is substantially higher than the level signifying the coexistence of an element of metabolic alkalosis. This is not an uncommon occurrence in patients with CO_2 retention treated for circulatory congestion with diuretics and a low-sodium diet. The resulting rise in blood pH can further damp the ventilatory drive and worsen CO_2 retention and hypoxemia. The acid-base data are not consistent with the simple disorders listed, metabolic alkalosis, acute respiratory acidosis, or chronic respiratory acidosis. In addition, they are not consistent with chronic respiratory acidosis and metabolic acidosis, because the serum $[HCO_3^-]$ is higher, not lower, than anticipated for the prevailing level of sustained hypercapnia.

CHAPTER 15

1.
   A. Tubular proteinuria is low-molecular-weight proteinuria (including smaller proteins such as α_1-microglobulin), whereas immunoglobulins are not usually present in significant amounts.
   B. The metabolic response to heavy proteinuria is variable, and sometimes a normal serum albumin is maintained, probably as a result of both increased albumin synthesis and reduced catabolism.
   C. In orthostatic proteinuria, there is *less* proteinuria when lying down; the early morning urine has no increase in protein.
   D. Correct. Light chain excretion should be suspected when the urine dipstick is negative for albumin when other tests show heavy proteinuria.
   E. Functional proteinuria occurs with fever, exercise, heart failure, and hyperadrenergic states.

2.
   A. True (Reference: Kidney International 2013; 3[Suppl 1]:1-150).
   B. The major mechanism by which ACE inhibitors and ARBs reduce proteinuria is hemodynamic, reducing glomerular efferent arteriolar tone. However, they also may directly reduce glomerular capillary wall permeability.
   C. Risk for hyperkalemia when using the combination of ACE inhibitor and ARB increases with falling glomerular filtration rate (GFR). Addition of a loop diuretic will usually reduce serum potassium.
   D. Correct. Statin or a statin-ezetimibe combination is recommended in adults younger than 50 years with CKD only if there is established cardiovascular disease or diabetes.
   E. Dietary protein recommendations must account for urine protein loss to minimize the risk for malnutrition.

3.
   A. Diuretic resistance is common in nephrotic syndrome with normal GFR; reduced protein binding limits drug access to the site of action in the tubule, increased protein binding once the drug has reached the urine reduces efficacy; and intestinal edema may reduce drug absorption.
   B. Dietary protein recommendations should take account of urinary losses, but very high protein intakes (e.g., 2 to 3 g/kg/d), even if achievable, may worsen proteinuria.
   C. Correct. It also should be considered when the serum albumin is 2 to 2.5 g/dl if there are additional risk factors for thromboembolism, such as immobilization in hospital or a prior history of thromboembolism.
   D. Microscopy and culture of ascetic fluid is required only when there is any evidence of systemic infection; but routine screening for infection is not useful.
   E. Nephrotic children are more prone than adults to hypovolemia. Care is needed to avoid too rapid diuresis, which may provoke shock.

CHAPTER 16

1.
   A. 70% of White and 50% of Asian patients with MN exhibit these autoantibodies.
   B. 10% or less of patients with MN exhibit these autoantibodies.
   C. Occur in neonatal MN.
   D. Correct. Has been related to atypical hemolytic uremic syndrome.
   E. May induce MN.
2.
   A. Classic pathway complement activation is typical of this condition.
   B. Classic pathway complement activation is typical of this condition.
   C. Classic pathway complement activation is typical of this condition.
   D. Correct. Despite autoantibody deposition in glomeruli and lung alveoli there is usually no systemic complement consumption.
   E. Classic pathway complement activation is typical of this condition.
3.
   C. Correct. Podocyte, in particular slit diaphragm, injury typically leads to severe, often nephrotic proteinuria.
4.
   A. FSGS mostly results from focal podocyte damage.
   B. FSGS is a nonspecific term to describe a glomerular scar and should not be confused with the clinical entity FSGS.
   C. Correct. Some clinical FSGS cases seem to originate from as-yet unknown circulating factors, which can give rise to rapid post-transplant recurrence of the disease.
   D. So far there is little evidence to implicate autoimmunity in the majority of FSGS cases.
   E. Although some FSGS may relate to mutations of podocyte proteins, most cases originate from other types of podocyte injury.

CHAPTER 17

1. D.
   MCD may be precipitated by upper respiratory tract infections, allergens, certain drugs (nonsteroidal antiinflammatory drugs [NSAIDS] and interferon-α alfa), and certain tumors, classically Hodgkin lymphoma.
2. D.
   A number of factors have been associated with MCD, including angiopoietin-like-4, CD80/B7.1, IL-13, and hemopexin. None of the other factors have been linked with MCD. (See text.)
3. C.
   Treatment of MCD requires 4 to 6 weeks of high-dose steroids given daily followed by a taper. Alternate-day steroids are commonly used during the taper to minimize side effects. Most patients will undergo a remission with treatment. Spontaneous remissions are rare. Frequent relapsers can be treated with an 8- to 12-week course of cyclophosphamide.

CHAPTER 18

1. D. Amlodipine
2. B. Glomerulomegaly and perihilar segmental sclerosis and hyalinosis
3. C. Remission of proteinuria is a strong predictor of a favorable outcome.

CHAPTER 19

1. C. Autosomal dominant
2. C. *CTN4*
3. A. Glomerular epithelial
4. B. 30%
5. B. Coenzyme Q_{10}

CHAPTER 21

1. A.
   The IF finding of strongly positive IgG and C3 with a kappa light chain restriction is compatible with the diagnosis of an MPGN secondary to a monoclonal gammopathy. The results of serum or urine protein electrophoresis are not provided. However, these studies are negative in a large number of patients. A MPGN due to infection (option B) is usually associated with strong IgM on IF. MPGN secondary to alternative pathway of complement (option C) is characterized by predominant C3 staining with little or no immunoglobulin deposition. The biopsy shows a MPGN type I based on the old EM classification, but the case cannot be considered idiopathic given the IF findings.
2. D.
   Focal segmental glomerulosclerosis (option A), minimal change disease (option B), and membranous nephropathy (option C) are all causes of nephrotic syndrome, defined as proteinuria greater than 3.5 g/24 h and serum albumin less than 3.5 g/dl, which is not present in this patient. The nephritic sediment and low C4 in a patient with HCV infection indicates cryoglobulinemic glomerulonephritis. The presence of circulating cryoglobulins is further supported by a positive rheumatoid factor.
3. A.
   Henoch-Schönlein purpura nephritis (option B) and anti-GBM disease (option C) are not associated with hypocomplementemia. Poststreptococcal glomerulonephritis (option D) is typically associated with low serum complement C3. Mixed cryoglobulinemia is typically associated with activation of the classic complement pathway, manifested by low levels of complement C4.
4. D.
   Although the skin rash on the lower extremities and nephritic syndrome suggest a diagnosis of Henoch-Schönlein purpura and IgA nephropathy (option A), the low C4 complement level is not compatible with this diagnosis. Linear staining for IgG (option B) is seen in anti-GBM disease, but anti-GBM serologic result is negative. An association between C3 glomerulonephritis and autoimmune diseases has been described, but patients usually exhibit positive ANA and/or anti-DS-DNA antibodies. Although acute or chronic tubulointerstitial nephritis is the most common lesion in patients with Sjögren syndrome, MPGN and mesangioproliferative glomerulonephritis can be seen later in the disease course. IF usually shows dominance of IgM.

CHAPTER 23

1.
   A. Fish oil is recommended, although the evidence is rather weak.
   B. There is inconsistent evidence from observational studies of a benefit for tonsillectomy.
   C. This treatment approach exceeds the dosage used in previous trials, and prednisolone is recommended only after 6 months of optimal supportive therapy, including blood pressure control with renin-angiotensin system blockade.
   D. Correct. Small randomized trials have not shown consistent evidence of benefit for this agent.
   E. A randomized trial showed no additional benefit when azathioprine was used in addition to corticosteroids.

2.
   D. Correct. Cellular crescents were not associated with clinical outcome in the original Oxford Classification, although only a small number of cases had crescents in the original analysis

3.
   A. IgAN is more common in Asia than Europe.
   B. The diagnosis of IgAN requires a renal biopsy. Glycosylation of serum IgA is abnormal in the majority but not all cases of IgAN.
   D. More commonly, AKI with macrohematuria is due to acute tubular injury secondary to blockage by erythrocytes.
   E. There is no evidence that different maintenance immunosuppressive regimens influence the recurrence rate of IgAN.

4.
   A. Although most common in childhood, IgAV can occur at any age.
   B. Correct. The same alteration in IgA glycosylation is described in IgAV and IgAN.
   C. There is no evidence that delay reduces recurrence risk.
   D. A French controlled trial of cyclophosphamide in adults with IgAV failed to detect benefit compared with steroids alone (reference 50).
   E. Randomized trials showed no benefit of corticosteroids in reducing nephritis risk.

CHAPTER 24

1. B.

   It is not uncommon for low levels of autoantibodies to persist some months after successful treatment of the acute illness, so we would not consider reinstituting plasma exchange or prolonging exposure to cyclophosphamide. In our experience, any persisting low-level autoantibodies disappear over subsequent months even when immunosuppression is withdrawn, so this is our preferred approach. However, one could justify continuing immunosuppression until autoantibodies become undetectable (or 1 year at most) to potentially bring forward the time when transplantation could be considered, in which case MMF would probably be preferred over continuing cyclophosphamide.

2. C.

   Recovery of renal function is very unlikely if all glomeruli are severely affected with crescents. In such cases there is no renal benefit from immunosuppression, so potentially toxic treatment is only justified if there is lung hemorrhage. In this case we would recommend supportive treatment and close monitoring anticipating spontaneous reestablishment of self-tolerance and disappearance of autoantibodies, followed by preparation for renal transplantation.

3. B.

   Goodpasture generally has such an acute and dramatic manifestation, with renal failure, haematuria, and oliguria with normal sized kidneys, that it does not generally get labeled "unknown cause." And recurrence of Goodpasture's after transplantation is now practically unheard of. Therefore this would be unlikely here. Alport syndrome, however, may progress without any particular symptoms and be labeled as unknown cause. New anti-GBM disease post-transplant is therefore more likely to be the very rare condition of Alport anti-GBM disease.

   In this case, subsequent analysis at a reference laboratory demonstrated there were abundant serum antibodies to alpha-5 collagen IV at the time the standard anti-GBM assay was negative.

CHAPTER 25

1.
   A. GN occurs only in small-vessel vasculitis.
   B. Correct. GN occurs only in small-vessel vasculitis.
   C. GN occurs only in small-vessel vasculitis because it is a manifestation of capillary inflammation.
   D. GN occurs only in small-vessel vasculitis.
2.
   A. One third to one fourth of patients with anti-GBM also have ANCA.
   B. ANCA disease may recur even if the anti-GBM disease enters remission.
   C. Correct. ANCA occurs with anti-GBM, and the ANCA disease may recur even if the anti-GBM disease enters remission.
   D. The disease is more like anti-GBM disease.
3.
   A. GN does not occur in PAN. GN is a marker of small-vessel vasculitis, and PAN is a medium-vessel vasculitis.
   B. Pulmonary hemorrhage does not occur in PAN. Pulmonary capillaritis is a marker of small-vessel vasculitis, and PAN is a medium-vessel vasculitis
   C. Polymyalgia rheumatic is associated with giant cell arteritis and not PAN.
   D. Correct. There is an association between hepatitis B infection and PAN.
4.
   A. The gradual narrowing of arteries by chronic inflammation does not cause acute ischemia with infarction, unlike PAN, which can cause infarction because of acute inflammatory narrowing and thrombosis.
   B. The gradual narrowing of arteries by chronic inflammation does not cause acute renal failure.
   C. GN is not a feature of Takayasu arteritis.
   D. Correct. Narrowing of main renal arteries by the arteritis causes renovascular hypertension.
5.
   A. Clinical trials have shown no difference in adverse events.
   B. Correct. Clinical trials have shown noninferiority between induction therapy with rituximab compared with cyclophosphamide.
   C. Clinical trials have shown noninferiority between induction therapy with rituximab compared with cyclophosphamide.
   D. Rituximab has been approved by the FDA for induction therapy.

CHAPTER 26

1. C. Mycophenolate mofetil (MMF) or cyclophosphamide is an appropriate choice. Ovarian protection or cryopreservation of eggs should be considered if cyclophosphamide is to be used.
2. C. Reduce the MMF to 1000 mg bid and plan to continue for 3 years unless otherwise indicated.
3. A. Corticosteroids
4. B. Intravenous rituximab

CHAPTER 27

1. E. Best evaluated by assessment of brain natriuretic peptide (BNP) in patients with glomerular filtration rate (GFR) <30 ml/min/1.73 m^2
2. C. Frequently responsible for nondiabetic glomerulosclerosis
3. E. Electron microscopy
4. A. Renal failure

CHAPTER 28

1. C. Lecithin–cholesterol acyltransferase deficiency
2. B. Bezafibrate
3. C. Idiopathic (primary) membranous nephropathy
4. D. Antiphospholipid antibody test

CHAPTER 29

1. A. Thrombocytopenia, nonimmune hemolytic anemia, with or without neurologic and/or renal dysfunction
2. B. Shiga toxin *E. coli*–associated hemolytic uremic syndrome
3. C. *CFH* mutations
4. B. Eculizumab
5. C. TTP with anti-ADAMTS13 antibodies

CHAPTER 30

1. B.
   Glomerulosclerosis, tubular atrophy, and tubulointerstitial lesions are typical pathologic findings in diabetic nephropathy.
2. E.
   Type of diabetes.
3. D.
   Acanthocytes in urine sediment.
4. B.
   Inflammasome activation in the diabetic kidney.

CHAPTER 32

1. C. Rheumatoid arthritis
2. C. Gliclazide
3. D. Anemia in diabetic patients can occur even with normal renal function.
4. E. Formation of renal calculi

CHAPTER 33

1.

A. Atrial natriuretic peptides can work quickly, but generally have only small effects on blood pressure in normal humans.

B. Endothelin has variable effects on blood pressure in normal humans, but most effects occur over hours to days.

C. Although the kallikrein-kinin system can act relatively quickly, it is thought to contribute only in minor ways to regulation of blood pressure in normal humans.

D. Modulation of the renin-angiotensin-aldosterone system generally takes hours to days to affect blood pressure in normal humans.

E. Correct. Catecholamines are heavily involved in modulation of blood pressure during hypovolemia and/or hemorrhage, especially in normal human subjects. (See Fig. 33.3.)

2.

A. None of his three blood pressures fall into the <120/<80 mm Hg range.

B. Correct. HEDIS 2016 and its several predecessors have used the lowest systolic and lowest diastolic blood pressures, even if measured separately, as the blood pressure for this visit. As a result, his blood pressure for this visit would be 138/88 mm Hg, which is in the prehypertensive range, according to JNC 7. (See references 24 and 47.)

C. In many clinical trials, the average of the last two of three readings is used as the blood pressure for a visit, which would be 140/91 mm Hg in this case. This would be in the stage 1 hypertensive range, according to JNC 7. But HEDIS 2016 changed its methodology recently, so that the lowest systolic blood pressure need not be recorded simultaneously with the lowest diastolic blood pressure. (See references 24 and 47.) Note also that JNC 8 suggested a systolic treatment target of less than 150 mm Hg for individuals older than 60 years, although this is quite controversial.

D. None of his three blood pressures fall into the >160/>100 mm Hg range.

E. This diagnosis is appropriate for systolic blood pressure ≥140 mm Hg and diastolic blood pressure <90 mm Hg. In the calculation using either option B or C, both of these conditions are not met (either 138/88 or 140/91 mm Hg).

3.

A. This is most appropriate for a healthy person with blood pressures in the <130/<85 mm Hg range, according to JNC 7. But there is the unresolved issue of CKD, which needs to be confirmed or rejected, and which might (according to the "suggestion" of KDIGO) prompt drug therapy if the albumin excretion rate was much higher.

B. This is most appropriate for a healthy person with prehypertension, according to JNC 7. But there is the unresolved issue of CKD, which needs to be confirmed or rejected, and which might prompt more intensive treatment than just lifestyle modifications.

C. Correct. The diagnosis of CKD hinges on a 3-month history of abnormal renal function, which has not yet been established. Repeat testing to confirm the diminished GFR is necessary; a repeat blood pressure measurement is unlikely to cause drug therapy to be initiated, given that KDIGO and JNC 8 now recommend a blood pressure of <140/90 for patients with CKD, although KDIGO "suggests" <130/80 mm Hg for those with abnormal albumin excretion rates.

D. This is the JNC 7 recommendation for healthy people with initial blood pressures in the stage 1 hypertension range. It might be appropriate here, but there is the unresolved issue of CKD that also needs to be addressed. Rechecking renal function in 2 more months might be appropriate, but it would not fulfill the diagnostic criteria for CKD.

E. The U.S. Food and Drug Administration does not recognize albuminuria as an indication for antihypertensive drug therapy, and his blood pressures do not meet current diagnostic criteria for hypertension. Angiotensin-receptor blockers have prevented the progression of prehypertension to hypertension, but are not currently indicated or recommended for this use. Many nephrologists would argue that even a little albuminuria is prognostically bad, but there are few, if any, outcomes data to demonstrate that giving an antiproteinuric drug improves the time to death, dialysis, or renal transplantation.

4.

A. This is probably higher than the prevalence of pseudohypertension, which is said to be associated with a positive Osler maneuver. No such finding is described in the vignette; she is likely too young to have developed this condition.

B. This is the expected prevalence of secondary hypertension in the hypertensive population. Although it is possible that she has secondary hypertension, there are no clinical clues, and the description is more likely that of masked hypertension.

C. Correct. This is the expected prevalence of masked hypertension, which fits the description in her case. It is likely that an ambulatory blood pressure monitor or home blood pressure monitoring will demonstrate elevated blood pressures, which might prompt treatment. Some have speculated that masked hypertension can occur in people with child care responsibilities, if they arrange for a babysitter during office visits.

D. This is the expected prevalence of white coat hypertension, which does not fit her case history, in that she has target organ damage and normal office blood pressures, the opposite of what would be expected with white coat hypertension.

E. This is the expected, age-adjusted, prevalence of hypertension in the United States over the last 15+ years. Yet her in-office blood pressures do not meet diagnostic criteria for this diagnosis; it is likely that because NHANES also uses an automated sphygmomanometer, she would not be identified as hypertensive in national surveys.

5.

A. Renal biopsy is more often used to determine the cause of glomerulonephritis or nephrotic syndrome and is seldom useful in the diagnosis of hypertension.

B. Although iothalamate clearance is more accurate than calculations of estimated GFR, it is expensive; exposes staff, patient, and the environment to radioactivity; and was abandoned by the National Institutes of Health after the vanguard phase of the African American Study of Kidney diseases and hypertension (AASK). The CKD-Epi equation is more accurate (especially for those with an estimated GFR >60 ml/min/1.73 m^2) than the updated MDRD equation, which is widely used by most U.S. laboratories.

C. A search for a secondary cause of hypertension is typically undertaken only when there is strong suspicion on clinical grounds or when the blood pressure is resistant to treatment. Screening all hypertensives for secondary hypertension is unlikely to be cost-effective.

D. The most likely diagnosis for him is white coat hypertension, which typically does not respond with a lowered office blood pressure after institution of antihypertensive drug therapy. It might be worth a try, but it is unlikely to improve his office blood pressures much and puts him at risk for hypotension outside the office.

E. **Correct. The most likely diagnosis for him is white coat hypertension, but some people with this diagnosis progress to sustained hypertension, which can be detected by home blood pressure monitoring. He should be counseled about therapeutic lifestyle changes as appropriate (e.g., DASH diet, dietary salt restriction, weight reduction, tobacco avoidance, reduction of alcohol). If and when sustained hypertension is diagnosed, he would be a good candidate for drug therapy.**

CHAPTER 34

1. B.
   Salt sensitivity increases with age.
2. E.
   The presence of transmural necrosis should prompt consideration of vasculitis, not primary hypertension
3. E.
   Although coffee is not a risk factor, caffeine tablets, or high caffeine content such as in "power drinks" may be potential risk factors for hypertension.

CHAPTER 35

1. C.
   Although stress reduction techniques may be beneficial for other reasons, they are not recommended by ASH/ISH for the management of hypertension.
2. B. 1 mm Hg.
3. D. People younger than 40 years
4. A. Has little or no effect on BP.

CHAPTER 36

1. C.
   A common side effect of dihydropyridine (DHP) CCBs is dose-dependent peripheral edema, which is not caused by fluid retention but by transudation of fluid from the vascular compartments into the dependent tissues as a result of precapillary arteriolar dilation. There is evidence that this edema also may be reduced by coadministration of an angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) because of their effects on venous capacitance. (de la Sierra A. Mitigation of calcium channel-related oedema in hypertension by antagonists of the renin–angiotensin system. *J Hum Hyptens.* 2009;23[8]:503-511.)
2. C.
   Early studies focused primarily on diastolic BP as the treatment target, but systolic BP is more difficult to control and more closely linked to cardiovascular (CV) outcomes and should now be the primary but not the sole focus of treatment. (See references 4 to 6.)
3. B.
   Data from the ONTARGET and ALTITUDE trials demonstrated that dual RAS blockade in high-risk patients with an ACE inhibitor plus ARB combination in ONTARGET,[28] or an ACE inhibitor or ARB plus a direct renin inhibitor (DRI) in ALTITUDE,[29] was no more effective than renin-angiotensin-aldosterone (RAAS blocker monotherapy at preventing major CV events in a high-risk population, including those with diabetes. The risk for adverse events, especially renal impairment, was greater with dual RAAS blockade in both studies.
4. E.
   Most patients with drug-resistant hypertension are likely to be retaining sodium and will respond to further diuretic therapy. The PATHWAY-2 study demonstrated that low-dose spironolactone 25 to 50 mg/day, when added to A+C+D, was more effective at lowering BP than placebo, a β-blocker (bisoprolol), or α-blocker (modified-release doxazosin). (See reference 19.)
5. C.
   ARBs likely have a renoprotective effect similar to those of ACE inhibitors in nondiabetic CKD, but supportive data are limited. (Asselbergs FW, Diercks GFH, Hillege HL, et al. Effects of fosinopril and pravastatin on cardiovascular events in subjects with microalbuminuria. *Circulation.* 2004;110(18):2809-2816; Esnault VLM, Brown EA, Apetrei E, et al. The effects of amlodipine and enalapril on renal function in adults with hypertension and non-diabetic nephropathies: a 3-year, randomized, multicenter, double-blind, placebo-controlled study. *Clin Ther.* 2008;30:482-498; Marin R, Ruilope LM, Aljama P, et al. A random comparison of fosinopril and nifedipine GITS in patients with primary renal disease. *J Hypertens.* 2001;19:1871-1876.

CHAPTER 37

1. D.
   The patient has hypertensive urgency, not a hypertensive emergency. In the absence of target organ damage, the patient can be treated less aggressively. The key is rapid follow-up (within a week).
2. C.
   While the INTERACT2 trial does suggest that reduction of BP to levels of 140/90 in subjects with hemorrhagic stroke, nitroprusside is not a desired antihypertensive agent as it obliterates cerebral autoregulation, and nicardipine is a superior agent. Reducing BP to 160/90 remains the standard target for these patients.
3. B.
   For subjects with aortic dissection, reducing the BP to 100 mm Hg systolic is the goal. Labetalol is an effective antihypertensive agent for this purpose.

CHAPTER 38

1.
   A. Mutations affecting the aldosterone synthase gene *(CYP11B2)* are present in FH-I. They are not a common cause, however, of APA.
   B. Mutations in the mineralocorticoid gene are not a common cause of APA.
   C. Mutations in the AT1 receptor are not a common cause of APA. Some evidence suggests, however, that activating autoantibodies directed against the AT1 receptor may be pathogenic in primary aldosteronism from bilateral adrenal hyperplasia.
   D. Correct. Mutations in the *KCNJ5* gene are present in approximately 40% of APA.
   E. Mutations in ENaC occur in Liddle syndrome, but not in APA.

2.
   A. Eplerenone appears to have less effect to decrease blood pressure (BP) in patients with primary aldosteronism.
   B. The rate of side effects and drug discontinuation appears to be similar between spironolactone and eplerenone.
   C. Correct. Spironolactone appears to decrease BP significantly more, by about twofold, than does eplerenone in patients with primary aldosteronism.
   D. The rate of side effects and drug discontinuation appears to be similar between spironolactone and eplerenone.

3.
   A. Most patients with primary aldosteronism do not have hypokalemia.
   B. Cannot differentiate between primary aldosteronism and secondary hyperaldosteronism and has significantly less sensitivity to identify primary aldosteronism.
   C. Although a suppressed plasma renin activity is a hallmark of primary aldosteronism, by itself it cannot identify primary aldosteronism.
   D. Correct. This is the preferred first-line test for primary aldosteronism.
   E. Cannot identify primary aldosteronism from other causes of hypertension.

CHAPTER 39

1. D.
   Typical signs and symptoms are frequently absent or subtle in any form of endocrine hypertension. Hypertension frequently remains present and requires ongoing pharmacotherapy even when the underlying condition has been appropriately managed. Overall, most cases of endocrine hypertension have no clear familial origin. Resistance to multiple combinations of multiple antihypertensive drugs is indeed a frequent alert to the possible presence of endocrine hypertension.
2. B.
   Organ imaging is not indicated until urinary free cortisol, overnight low-dose dexamethasone suppression test results, and/or late night salivary cortisol levels are found to be abnormal, consistent with Cushing syndrome. High-dose dexamethasone suppression testing is used later in the workup when plasma ACTH is elevated, if it is necessary to distinguish between pituitary and ectopic sources of ACTH. Bilateral inferior petrosal sinus sampling is used when preliminary biochemical tests and imaging yield equivocal results and it is necessary to prove the pituitary or nonpituitary location of excess ACTH release.
3. B.
   The majority (over two thirds) of incidentalomas are not hormonally active. In large carefully characterized series, up to 4% of incidentalomas are adrenal carcinomas. Incidentalomas are associated with a somewhat higher prevalence of hypertension than the matched population without incidentaloma.

CHAPTER 40

1.

A. In this patient the presenting BP is higher than the limit for tPA administration; thus administration of intravenous tPA after acute BP lowering to <185/110 mm Hg is appropriate.

B. Correct. After intravenous tPA administration, the American Heart Association/American Stroke Association guidelines recommend maintenance of BP <180/105 mm Hg. Therefore a diastolic BP of 110 mm Hg should be lowered to a target value of <105 mm Hg. In this case the patient presented with signs consistent with an acute ischemic stroke, and given that the CT scan shows no hemorrhage, acute cerebral ischemia is the most likely diagnosis. In that setting the correct first-line therapy in the absence of contraindications is intravenous tPA.

C. In this patient intravenous labetalol or nicardipine would be the drug of choice. Sublingual nifedipine is proscribed because nifedipine can lead to a substantial reduction in BP.

D. In the setting of acute ischemic stroke there are no evidence-based data to support use of vasopressors to augment BP, especially in this case in which BP is elevated and above the recommended threshold for post tPA BP management.

2.

A. Because the patient reportedly had the first presentation 2 days previously, it is unlikely that any further clinically significant expansion will occur.

B. Lowering BP has not been conclusively proven to decrease the incidence of hematoma expansion.

C. Because the patient is fully conscious with a relatively small hematoma, lack of decline after 2 days from the onset of symptoms and no associated hydrocephalus, there is no clinical evidence for increased intracranial pressure (ICP) and no indication for ICP monitoring.

D. Some studies had suggested that there may be perihematomal ischemia around an ICH, but this theory has been largely discredited by more recent studies.

E. Correct. This patient presents with an ICH without intraventricular extension or hydrocephalus and no impairment of consciousness. In this case, clinically significant hematoma expansion is expected in about 40% of the patients. Additionally, hematoma expansion in hypertensive ICH is rare after the first 36 hours.

3. E.

All of the mentioned are features of carotid hyperperfusion syndrome.

CHAPTER 41

1. C.
   This patient has coarctation. She has key clinical signs, including hypertension, heart murmur best heard over the posterior thorax and radio-femoral pulse delay. One must also consider Takayasu arteritis, but the symmetry in pulses and bruits make this diagnosis less likely. Similarly, the other choices would also be on the differential, but the key finding of radio-femoral delay makes coarctation the correct answer.
2. B.
   This patient has atherosclerotic RA stenosis on the right side. The present evidence-based consensus recommendations are to optimize medical therapy first, including the use of renin-angiotensin-aldosterone system (RAAS) blockade. Given the risk for renal disease progression and electrolyte abnormalities, once a RAAS blocker is started a patient should be monitored closely. Revascularization is not indicated until medical therapy is optimized.
3. D.
   This patient has acute kidney injury (AKI) with a marked increase in proteinuria. Her ($\dot{V}/\dot{Q}$) scan suggests pulmonary embolism; thus she likely has renal vein thrombosis. A renal ultrasound and renal vein Doppler study will assist with the diagnosis. Given her lupus history the antiphospholipid antibody is necessary to probe the cause of the thrombotic events. Given her presentation and the high probability ($\dot{V}/\dot{Q}$) scan, CTA of the pulmonary arteries is not needed to confirm the diagnosis of pulmonary embolism and would also unnecessarily expose this patient with AKI to intravenous contrast.
4. D.
   This patient has diminished renal function at baseline with a current AKI. The renal dysfunction would make a captopril renogram difficult to interpret. There is also risk to the patient with intravenous contrast exposure (CTA) and gadolinium exposure (MRA). Hence, the best choice is to perform direct angiography and employ carbon dioxide in lieu of radiocontrast.
5. C.
   Given the new-onset atrial fibrillation associated with flank pain, renal infarction via arterial embolism is high on the differential diagnosis. The lack of dysuria and pyuria make a pyelonephritis less likely. The CT with and without contrast along with an LDH evaluation will allow for the effective diagnosis of nephrolithiasis and/or a renal infarction.
6. B.
   This patient has a post–coronary angiography rise in serum creatinine making either contrast or cholesterol emboli the likely diagnoses. The increase in eosinophils and the nature of the rash suggest cholesterol emboli because contrast-mediated renal injury would not manifest with a rash. Although the AKI, rash, and eosinophils could be indicative of acute interstitial nephritis, the proximity to the coronary artery instrumentation and stent placement make cholesterol emboli more likely.

CHAPTER 42

1. B. Hypernatremia
2. D. Trimethoprim
3. E. All of the above
4. A. Proteinuria 2 g/day
5. C. Thrombotic thrombocytopenic purpura/hemolytic uremic syndrome

CHAPTER 43

1.

A. Women with ADPKD with hypertension have a higher risk for preeclampsia and preterm delivery than those without hypertension, and therefore answer A is incorrect.

B. Preimplantation genetic testing can be offered, but many women with ADPKD prefer to conceive spontaneously.

C. Correct. Aspirin should be offered to all women with chronic hypertension to reduce the risk for preeclampsia.

D. Amlodipine has not been demonstrated to be teratogenic, but more experience of safety is with nifedipine, which could be offered as an alternative agent but requires twice or three times daily dosing. BP control before pregnancy should be optimized.

2.

A. Conception after transplantation is recommended to be delayed until at least 12 months post-transplantation to ensure graft stability. The optimal time to conceive remains unclear; however, in view of increased maternal age and graft stability in this case, it would not be unreasonable to switch MMF to azathioprine at 12 months, ensure graft stability, and then for the woman to attempt to conceive.

B. Breastfeeding should be encouraged in women with renal transplants, particularly those with preterm deliveries with greatest infant benefit. Standard immunosuppression during pregnancy, that is, prednisolone, azathioprine, and tacrolimus, can be continued safely with lactation, and only minimal quantities of each drug have been identified in breast milk.

C. There are no data regarding breastfeeding with MMF, and therefore it is not currently recommended. Azathioprine should be substituted for MMF. High-dose prednisolone may be associated with gestational diabetes, maternal infection, osteoporosis, and preterm delivery and therefore should be avoided.

D. Correct. Women with lupus nephritis may continue to have anti-Ro or La antibody that is transferred by the placenta and may lead to neonatal lupus syndromes, including fetal heart block. Fetal cardiac monitoring from 16 to 18 weeks of gestation is recommended in those with positive antibody.

3.

A. Correct. At this early gestation, attempts should be made to prolong pregnancy to optimize neonatal outcomes.

B. Fetal assessment will determine timing of delivery. If maternal compromise persists despite BP control, delivery may be needed, but a balance between maternal and fetal benefit needs to be considered by obstetricians, nephrologists, and neonatologists. This presentation also could be consistent with progression of underlying renal disease, and placental and fetal ultrasound will help determine whether preeclampsia is evolving.

C. Intravenous magnesium should be used only if there is evidence of neurologic involvement such as brisk reflexes, scotoma, or HELLP syndrome (hemolysis, elevated liver enzymes, low platelet count) but not routinely in a woman with suspected preeclampsia.

D. Labetalol may be used to treat hypertension, but there is no evidence of benefit of aspirin to treat gestational hypertension and its associated complications.

CHAPTER 44

1. E.
   These have all been shown to contribute to the rate of progression of the renal cystic disease in ADPKD.
2. C.
   The risk for rupture of an intracranial aneurysm depends on their size and location. Aneurysms in the posterior circulation of the circle of Willis have an increased risk for rupture compared with those in the anterior circulation. Although some authors argue that all patients with ADPKD should undergo presymptomatic screening for intracranial aneurysms, there is no evidence to support the efficacy or cost-effectiveness of this strategy. Most intracranial aneurysms do not rupture. Screening for intracranial aneurysms by magnetic resonance angiography does not require administration of gadolinium.
3. A.
   Hypocitraturia is a common metabolic abnormality in patients with ADPKD even before there is a decline in renal function. Hypercalciuria, hyperuricosuria, and hyperoxaluria do not occur more frequently in these patients. Renal tubular acidosis is rarely associated to ADPKD.
4. D.
   The HALT PKD study showed that ACE inhibitor monotherapy is very effective to control BP in the majority of patients with ADPKD; however, superiority to β-blockers has not been proven in head-to-head studies. Rigorous BP control was found to be superior to standard control in young patients with ADPKD with a GFR >60 ml/min/1.73 m^2 in the HALT PKD Study A clinical trial, but rigorous BP control was not used in Study B with more advanced ADPKD.

CHAPTER 45

1. E.
   ARPKD has a diverse set of extrarenal complications that primarily involve the liver, less commonly impact growth, and very rarely involve intracranial aneurysms.
2. B.
   The term *nephronophthisis* derives from Greek, meaning "progressive loss of nephrons." Nephron loss combined with fibrosis (another hallmark of NPHP) leads to small kidneys.
3. C.
   Angiomyolipomas are a major clinical feature of TSC and the most common renal lesion in patients with TSC patients.
4. D.
   VHL-associated disease clusters into two complexes based on the nature of the germ-line mutation.
5. A.
   MSK is generally considered to be a sporadic disorder, but familial clustering with autosomal dominant inheritance and evidence for genetic alteration in the RET-GDNF axis suggest a genetic basis for MSK in at least a subset of patients.

CHAPTER 46

1.
B. His mother has Alport syndrome.

2.
E. All of the above.

3.
C. Hearing loss in Alport syndrome initially targets high frequencies above the range of conversational speech.

CHAPTER 47

1. C. Gitelman syndrome
2. E. All are correct
3. B. Enhanced Na^+ transport through the epithelial Na^+ channel ENaC in the collecting duct
4. C. 5% Dextrose in water

CHAPTER 48

1. B. Cystinosis
2. A. Arginine, lysine, ornithine
3. B. Medications
4. E. SLGT2
5. D. ClC-5

CHAPTER 49

1. A.
   Although hyperfiltration was thought to develop in older children and teenagers, recent studies such as the Baby HUG study (see references 24 to 26) have shown that it occurs from infancy, as young as 9 months old. The glomerular filtration rate (GFR) will typically peak in early adulthood and then starts to decline from the third to fourth decade of life. (See Fig. 49.7.)
2.
   A. The prevalence is the same in both patient groups as the majority of hemoglobin in both groups is HbS, leading to an increased risk for SCN.
   B. α-Thalassemia protects against albuminuria as it reduces the hemolysis rate. Increased hemolysis has been shown to be associated with increased risk for developing albuminuria. (See references 17 and 28.)
   C. Patients with HbSS disease are more at risk for developing albuminuria and SCN than patients with HbSC disease.
   D. High levels of hemolysis are associated with increased risk for albuminuria. (See reference 28.)
3.
   A. These agents should be used in patients with SCD and proteinuria, but serum potassium should be monitored. Studies in patients with nondiabetic proteinuric renal disease have demonstrated that inhibition of the renin-angiotensin system slow progression of CKD. Although patients with SCD are at increased risk for developing hyperkalemia, these drugs can be used safely if the potassium is monitored.
   B. Only one small trial in SCN has been carried out and was negative.
   C. Inhibitors of the renin-angiotensin-aldosterone system (RAAS) can cause acute kidney injury during periods of dehydration and illness, so they should always be stopped in patients who are acutely unwell.
   D. Nocturnal administration can avoid postural hypotension and improve the symptoms of nocturia in some patients. There are no specific advantages to taking the medication in the morning.

CHAPTER 50

1. A.
   Unilateral renal agenesis occurs in approximately 1 in 500 to 1 in 1000 births. Bilateral renal agenesis occurs in approximately 1 in 10,000 births. Unilateral renal agenesis is often inherited in an autosomal dominant manner, and therefore ultrasound screening of first-degree relatives is recommended. It can occur as part of numerous syndromes, including Kallman syndrome, branchio-oto-renal syndrome, and Fraser syndrome.
2. C.
   Patients with prune-belly syndrome present with a characteristic clinical triad:
   1. An abnormal urinary tract, including a grossly dilated bladder with bilateral hydroureteronephrosis and often evidence of vesicoureteral reflux
   2. Abdominal muscle aplasia or hypoplasia
   3. Bilateral cryptorchidism in males

   The disorder can be seen rarely in females. Although males exhibit azoospermia, successful paternity has been reported using intracytoplasmic sperm injection.
3. B.
   Ureterosigmoidostomy can cause a hyperchloremic, hypokalemic acidosis. Large quantities of ammonium ions are produced by the action of the fecal bacteria on urinary ammonia. Ureterosigmoidostomies are associated with an increased risk for developing colon cancer usually after a period of 20 to 30 years.
4. E.
   Posterior urethral valves are obstructing membranous folds found in the male posterior urethra and do not occur in females. Most cases are now detected on antenatal ultrasound, but many patients present as infants with failure to thrive, urinary tract infection (UTI), or difficulties voiding. Urinary drainage is achieved through primary valve ablation during cystoscopy or vesicostomy. Urofacial syndrome is a rare autosomal recessive disorder that can manifest with UTI and features of a neuropathic bladder with a dilated upper urinary tract; however, patients display a characteristic facial grimace when smiling.
5. B.
   Asymptomatic UTIs often do not require treatment (except during pregnancy). For patients with urinary diversions, it is important to obtain a catheter specimen of urine because urine taken from a bag is invariably infected. Struvite or calcium phosphate stones are most common in the context of infected urine.

CHAPTER 51

1. B. Ciprofloxacin
2. D. Periodic screening and treatment of asymptomatic bacteriuria
3. B. Nitrofurantoin
4. C. Pregnant women and patients undergoing urologic instrumentation

CHAPTER 52

1. C.
   Immune reconstitution inflammatory syndrome (IRIS) is a pathogen-specific inflammatory response in HIV-infected patients that may be triggered after initiation, re-initiation, or change to more active antiretroviral therapy. It is a paradoxical phenomenon of apparent clinical and radiologic worsening occurring in HIV-infected patients who had TB, inactive cytomegalovirus retinitis, or quiescent cryptococcal infection. It is usually accompanied by an increase in CD4 cell count and/or a rapid decrease in viral load. It may occur in patients with HIV when treatment with antivirals is started together with specific chemotherapy. Higher incidence of IRIS has been observed if the load of organisms is higher.
2. D.
   In the usual doses, ethambutol is a bacteriostatic drug. It is bactericidal only if very high doses are used.
3.
   A. Painless macroscopic hematuria occurs in immunoglobulin A nephropathy, other glomerular diseases, and urinary TB. In other conditions, such as stone, tumor, trauma, and acute urinary tract infection, it is painful.
   B. Acid sterile pyuria is unique to tuberculosis. The combination of persistent increase in urinary white cells, negative conventional cultures, and acidic pH of urine.
   C. Sterility (in women) and epididymorchitis is a common genital involvement in females and males, respectively.
   D. Characteristic lack of constitutional symptoms in urinary TB. Most symptoms are related to drug treatment.
   E. Icterus is not a manifestation of TB. If it occurs, it is due to drug therapy.
4.
   A. No dose change. The main route of excretion is by the biliary route.
   B. Dose to be modified. For streptomycin, increase dosing interval (over 45 years, 50% dose) and monitor for ototoxicity. For ethambutol, increase dosing interval and monitor visual acuity, field, and color vision.
   C. Pyrazinamide should be avoided in liver disease. Use carefully for short term in renal failure.
   D. No dose change. The main route of excretion by the biliary route.
5. B.

CHAPTER 53

1. C.
   C. *albicans* is the species isolated most commonly in both urinary tract infections (UTIs) and candidemia.
2. E.
   Pyuria is not a helpful sign for the diagnosis of a *Candida* UTI when a catheter is present or when there is a concomitant bacterial infection. If there is no catheter and no bacteriuria, pyuria is sometimes useful as a marker for UTI with *Candida* species.
3. B.
   Flucytosine is excreted in the urine, and serum levels rise when creatinine clearance is diminished. Toxic effects on bone marrow and liver and are directly related to serum levels greater than 100 μg/ml. The other drugs are metabolized in the liver or elsewhere in the body and do not accumulate with kidney failure.
4. B.
   Shown by placebo-controlled clinical trial (see reference 14).

CHAPTER 54

1. B. Schistosoma-associated *Salmonella* bacteremia
2. D. Infiltrative bladder cancer
3. D. Concomitant virus-induced cryoglobulinemia

CHAPTER 55

1. A.
   Infection-related GN in developed countries is more often seen in adults with comorbidities, often infected with *Staphylococcus*. It often is IgA-dominant, and this is now more common than post-streptococcal GN in these areas. (See reference 2.)
2. A.
   Complement levels related to the alternative complement pathway are decreased, whereas those such as C4 and C1q associated with other complement pathways typically are not reduced. (See reference 6.)
3. A.
   Infective endocarditis–related GN often may manifest as crescentic GN, but not always, with immune complex deposition. (See reference 28.)
4. B.
   A meta-analysis of 12 clinical trials with 317 patients found that combined antiviral and immunosuppressive therapy can improve proteinuria in HBV-associated GN without altering HBV replication or damaging liver or renal function. (See reference 43.)

CHAPTER 56

1. A.
   APOL1 renal risk variants are associated with FSGS variants but not with immune complex kidney disease.
2. C.
   Tenofovir disoproxil fumarate causes proximal tubular dysfunction (Fanconi syndrome); tenofovir alafenamide is much less likely to do so because of reduced uptake from plasma into tubular cells via the organic ion transporters. The other medications do not cause this syndrome.
3. D.
   Chronic tubular injury resulting from tenofovir or other tubular toxins manifests as tubular atrophy and interstitial nephritis, but the characteristic finding of tenofovir is enlarged and abnormal mitochondria in proximal tubular epithelial cells. Tenofovir is a nucleoside analogue that inhibits DNA synthesis. The mitochondrial toxicity is unique to the kidney perhaps because of accumulation and phosphorylation.

CHAPTER 57

1.

A. Antibiotic therapy is important to reduce struvite stone growth and for stone prevention. Bacteria will remain in the stone interstices and stones will continue to grow unless chronic antibiotic suppression is maintained or the calculi are completely eradicated. Thus a short course of antibiotics is not sufficient.

B. Struvite stones are composed of magnesium ammonium phosphate and calcium carbonate apatite. They form when urease production by certain bacteria that breaks down urea to ammonium and a carboxyl group.

C. Insoluble urinary phosphate forms a solid phase with magnesium, calcium, and ammonium.

D. With alkaline urine, urinary phosphate becomes insoluble and forms a solid phase with magnesium, calcium, and ammonium.

E. Bacteria will remain in the stone interstices after a short course of antibiotics until calculi are completely eradicated by surgical interventions.

2.

A. Dietary salt restriction is associated with decreased urine calcium excretion.

B. Animal protein ingestion increases the frequency of renal stone formation by a number of mechanisms, including generation of sulfate ions, which render urinary calcium ion less soluble, and metabolic acidosis, which can cause calcium release from bone and a consequent increase in the filtered load of calcium.

C. Several studies have demonstrated that there is a decrease in stone incidence when people consume adequate dietary calcium. This beneficial effect has been attributed to intestinal binding of ingested oxalate by dietary calcium.

D. Most calcium stones are composed of calcium oxalate, either alone or in combination with calcium phosphate or uric acid. Thus dietary oxalate should be restricted.

3.

A. Uric acid stones are radiolucent and therefore poorly visible on plain radiographs.

B. Uric acid stones often occur in patients with insulin resistance. The rising incidence of obesity and insulin resistance in the United States has led to a parallel increase in uric acid stones.

C. Allopurinol should be prescribed if uric acid excretion remains high despite dietary intervention, to keep urinary uric acid excretion below 750 mg/day. This patient already had uric acid excretion below 750 mg/day.

D. Low urine pH is the principal metabolic disorder found in patients with uric acid stones. Potassium citrate can raise urine pH and prevent stone formation.

E. An increase in urine volume for more than 2 to 2.5 liters daily has been proven to reduce the incidence of stones. This patient's urine volume was only 1.5 liter per day and thus inadequate.

CHAPTER 58

1.

A. Hydronephrosis describes dilation of the upper urinary tract and can occur in the absence of functional obstruction.

B. Urinary tract obstruction may affect neonates, children, and adults of both genders, and the underlying causes and outcomes are therefore highly diverse, with most patients not developing ESRD.

C. Urinary tract obstruction may be associated with oliguria or even anuria if the obstruction is bilateral and complete. However, it is important to note that patients with a partial obstruction may report polyuria and nocturia as a result of an impaired ability of the kidney to concentrate the urine.

D. Urine dipstick analysis is highly variable in patients with urinary tract obstruction, and there are no "typical" findings. Microscopic hematuria may be evident in patients with renal calculi or tumors, but urinalysis is often negative for blood and protein.

E. Urinary tract obstruction results in urinary stasis and is a risk factor for infection, with infections often being more difficult to eradicate if obstruction is ongoing.

2.

A. Recent work suggests the opposite, with the development of marked diuresis (>7 liters per 24 hours) being associated with a very good outcome with preservation of renal function.

B. Examples include adynamic segments of the ureter that result in pelviureteral junction obstruction, and diseases such as multiple sclerosis or diabetes may be complicated by a hypertonic or atonic bladder, respectively.

C. Many inflammatory, degenerative, or neoplastic conditions may affect the retroperitoneum and involve the ureters, thereby causing urinary tract obstruction.

D. The obstructed kidney develops chronic inflammation that is associated with progressive scarring. Long-term obstruction leads to profound parenchymal damage and cortical thinning.

E. Patients with IgA nephropathy may develop severe macroscopic hematuria. The red cells are of glomerular origin and may thus obstruct the nephron lumen and cause significant intrarenal urinary tract obstruction that is associated with acute renal dysfunction.

3.

A. Various aspects of tubular function may be abnormal, including urinary acidification, potassium handling, and urinary concentration.

B. The blood flow of the obstructed kidney is also reduced, with renal vasoconstriction associated with increased intrarenal levels of angiotensin II and thromboxane A_2.

C. Renal tract ultrasound remains the first-line investigation for the majority of patients with suspected urinary tract obstruction because it does provide very useful information despite being operator dependent. Non–contrast-enhanced spiral CT scanning is useful for the primary assessment of patients with acute flank pain but, unlike ultrasound, does expose the patient to radiation.

D. A diuresis renogram is used to assess whether a dilated system is actually obstructed. The absence of functional obstruction is indicated by the rapid washout of the isotope after diuretic administration.

E. Although unusual, urinary tract obstruction may occur in the absence of hydronephrosis, as in transplanted kidneys that are encased in dense fibrous tissue. In addition, retroperitoneal fibrosis or infiltrating tumors may surround the ureters and prevent dilation but still obstruct native kidneys.

CHAPTER 59

1. C.
   Standard practice is to manage distal nonobstructing calculi conservatively for a period of 2 to 4 weeks, with a trial of medical expulsive therapy, given the high spontaneous passage rate.
2. D.
   Any patient with unexplained visible hematuria should undergo full urologic workup with flexible cystoscopy, renal function tests, and CT urogram, although local resources often dictate other imaging strategies such as intravenous urography (IVU) and ultrasound as first-line interventions. Anticoagulation should not be considered an explanation for hematuria because underlying malignancy is common.
3. C.
   Partial nephrectomy has emerged as a favorable procedure when compared with radical nephrectomy because concerns over reduced oncologic clearance have been unfounded. If technically possible, this should be performed laparoscopically. Although cryosurgery and radiofrequency ablation are promising alternatives to partial nephrectomy, they should be considered experimental at present.

CHAPTER 60

1. A.
   Both NSAIDs and PPIs are among the classes of drugs most commonly responsible for AIN.
2.
   A. This diagnostic procedure does not have a poor negative predictive value.
   B. This diagnostic procedure does not have a poor negative predictive value.
   C. Some drugs other than NSAIDs can induce AIN associated with heavy proteinuria, including ampicillin, rifampin, lithium, interferon, phenytoin, pamidronate, and D-penicillamine.
   D. Correct. The course of drug-induced AIN is not always benign, and it leads to chronic kidney disease in at least 40% of the cases.
3. D.
   The course of drug-induced AIN is not always benign, and it leads to chronic kidney disease in at least 40% of the cases.

CHAPTER 61

1. E.
   All of the above.
2. B.
   Voiding cystourethrogram.
3. E.
   All of the above.

CHAPTER 62

1.
   A. Calcific deposits in the interstitium are characteristic of hypercalcemic nephropathy.
   B. This patient has anorexia nervosa and associated hypokalemic nephropathy.
   C. Noncaseating granuloma is the classic finding of sarcoidosis but is relatively nonspecific.
   D. Infiltration of IgG4-positive mononuclear cells is the central feature of IgG4-related tubulointerstitial nephritis.
   E. Acellular interstitial nephritis with intranuclear inclusion bodies in the proximal tubules is observed in chronic lead nephropathy.
2.
   A. Uroepithelial carcinoma often develops in patients with analgesic nephropathy.
   B. Inflammatory bowel disease can be associated with chronic tubulointerstitial nephritis, but that is a distinct clinicopathologic entity.
   C. Cerebral aneurysm is observed in patients with autosomal dominant polycystic kidney disease.
   E. Angiokeratoma is characteristic in patients with Fabry disease.
3. A.
   This is a case of chronic lithium nephropathy with nephrogenic diabetes insipidus. MRI without the use of gadolinium or ultrasound is useful in the detection of the microcysts in the kidney. Blood oxygen level–dependent MRI (BOLD-MRI) is used to evaluate oxygenation of various organs, including the kidney, but its clinical use is still preliminary.

CHAPTER 63

1. B.
   All of the above.
2. A.
   All of the above.
3. B.
   All of the above.
4. E.
   All of the above.

CHAPTER 64

1.
   A. Calcium is associated with prerenal kidney impairment.
   B. Uric acid is not a common cause of renal injury in myeloma.
   C. Correct. Myeloma cast nephropathy is due to an excess of filtered light chains exceeding the capacity of the proximal tubule and causing distal cast formation.
   D. Immunoglobulins are not filtered and may cause other forms of mesangial or glomerular injury.
   E. β_2-Microglobulin is a marker of cell turnover and injury but is not nephrotoxic.

2.
   A. Amyloidosis usually manifests with nephrotic syndrome.
   B. LCDD usually manifests with nephritic syndrome, and less than 20% have myeloma.
   C. Correct. Cast nephropathy secondary to proximal tubular injury and distal tubular cast obstruction is the most common histologic pattern of injury in 30% to 50% of all biopsy samples.
   D. Urate nephropathy is a very rare complication of myeloma.
   E. Tubular crystals are a very rare form of light chain disease often manifesting with Fanconi syndrome.

3. E.
   The proteasome inhibitor bortezomib is the most effective chemotherapy for the rapid targeting of plasma cells to reduce the light chain load.

4. D.
   The serum free light chain ratio by nephelometric assay is the most sensitive and specific test for the rapid diagnosis of myeloma in patients with acute kidney injury. The others provide additional information but are less sensitive, slower to perform, and not diagnostic. A renal biopsy is diagnostic but may not be needed in the presence of a highly abnormal free light chain ratio.

CHAPTER 65

1. D.
   In a Danish population-based study of 1.2 million cancer patients, the incidence of AKI defined by the RIFLE criteria was highest in patients with renal cell cancer (44%), multiple myeloma (33%), liver cancer (32%), and leukemia (28%). Compared with patients without cancer, critically ill patients with cancer have a higher incidence of AKI requiring RRT. In a prospective survey of 3558 patients admitted to a comprehensive cancer center, AKI occurred in 45% of patients during the first 2 days and in 55% thereafter. The study also found significant correlation with diabetes mellitus, hyponatremia, and exposure to intravenous contrast, chemotherapy, and antibiotics and was associated with poorer clinical outcomes. The presence of cancer alone should not preclude patients from being considered for dialysis. Critically ill cancer patients with advanced renal failure would benefit of dialysis for at least 48 hours so a proper evaluation can be made for the role of continuing dialysis.
2. A.
   Many malignancies enhance tumor survival by overexpressing ligands that bind these inhibitory T cell receptors, such as programmed death-1 protein (PD-1) and cytotoxic T lymphocyte–associated antigen-4 (CTLA-4). This leads to a decrease of infiltrating activated T cells within the tumor microenvironment and inhibits antitumor T cell responses. Ipilimumab is a fully human, immunoglobulin G1 (IgG1) monoclonal antibody that blocks CTLA-4, and pembrolizumab is a monoclonal antibody that antagonizes the PD-1 receptor. Biopsy-proven acute interstitial nephritis (sometimes with granulomas) has been shown to be the most common pathologic finding in AKI caused by ipilimumab and pembrolizumab. Glucocorticoids have been shown to be an effective treatment with reversal of kidney injury in most cases.
3. C.
   This case fits the proposed laboratory and clinical criteria for tumor lysis syndrome. With the hyperkalemia, hyperphosphatemia, hyperuricemia, AKI, oliguria, and large tumor burden, RRT would be the most effective modality for treatment. Rapid release and accumulation of potassium and phosphate will develop in the setting of chemotherapy initiation, which can be life threatening. Use of urinary alkalinization and IVFs in a patient with oliguria may lead to more volume overload. Also, urinary alkalinization may cause calcium-phosphate deposition within the tubules (acute nephrocalcinosis). Treatment of the acute hyperkalemia with insulin and glucose will transiently shift the potassium into cells, but will be insufficient. The patient has mild hydronephrosis that may be contributing to AKI; however, initiation of chemotherapy will shrink the tumor mass and resolve the hydronephrosis.
4. B.
   The patient presents with euvolemic hyponatremia, which is likely the syndrome of inappropriate antidiuretic hormone secondary to his malignancy. A retrospective analysis of 3357 patients with cancers noted that hyponatremia (serum sodium <135 mEq/l) developed in 47% of admissions. Hyponatremia in these cancer patients increased hospital length of stay and 90-day mortality, in a graded, inverse fashion compared with their degree of hyponatremia. In another publication, 46% of 3446 cancer patients with at least one serum sodium manifested hyponatremia.

CHAPTER 66

1. A.
   Acute tubular injury occurs in tubular regions secondary to an imbalance between blood supply and metabolic work. The proximal tubule (especially the S3 segment) and loop of Henle both lie within the outer medulla where blood supply is limited and both have high metabolic requirements secondary to sodium reabsorption at these sites (Na-K-ATPase).
2. D.
   Reduction in left ventricular function triggers the release of potent vasoconstrictors (sympathetic nervous system, angiotensin II, antidiuretic hormone, endothelin) that can cause AKI by impairing renal perfusion. NSAIDs inhibit the production of protective prostaglandins impairing compensatory afferent arteriole vasodilation in this setting. Note that NSAIDs may cause acute interstitial nephritis (sometimes associated with heavy proteinuria), acute papillary necrosis, and, rarely, AKI associated with minimal change disease.
3.
   A. Cisplatin inhibits mitochondrial adenosine triphosphate generation.
   B. Methotrexate may form intratubular crystals that block tubular flow and cause an interstitial nephritis.
   C. Gentamicin accumulates in proximal tubular cells and interferes with cellular energetics and induces oxidative stress.
   D. Amphotericin punches holes in cell membranes.
   E. Tacrolimus causes renal vasoconstriction leading to renal ischemia in addition to direct tubular toxicity.
4. Contributing factors include renal vasoconstriction, obstruction from tubular cell casts, and enhanced tubuloglomerular feedback as a result of increased delivery of chloride to the macula densa.

CHAPTER 68

1.
   A. Presence of anion gap acidosis with high serum phosphate level, hyperkalemia, and urinalysis positive for blood yet no red blood cells on urine microscopy is consistent with rhabdomyolysis.[46] Note that his serum creatinine level is higher than expected for his degree of acute kidney injury (AKI) given increased release of creatinine from injured muscle.
   B. Although it is conceivable that his aortic dissection could have expanded to involve both kidney arteries. In the setting of a normal blood lactate level, bilateral renal artery occlusion would not explain his anion gap acidosis, urinalysis findings, or rapid rise in serum phosphate level.
   C. Kidney biopsy is reserved for cases in which the diagnosis remains uncertain. The cause of AKI is consistent with rhabdomyolysis in this case.
   D. The clinical picture does not fit for a small-vessel vasculitis, which characteristically has both blood and protein on urinalysis and red blood cells with red blood cell casts on urine microscopy.
   E. Urine indices may be helpful in distinguishing between prerenal AKI and acute tubular necrosis (ATN); however, neither of these causes would explain the acid-base values, electrolyte disorder, or urinalysis.
2.
   A. In the setting of antidiuresis and the presence of antidiuretic hormone, urine osmolality can approach 1200 mOsm/kg.
   B. Fractional excretion of urea less than 35% is associated with renal sodium conservation in prerenal settings.
   C. With healthy kidneys, serum creatinine levels are less than 1.7 mg/dl. Therefore the levels of BUN to serum creatinine exceed 20:1, which is consistent with prerenal conditions.
   D. In a state of volume contraction, spot urine sodium levels would be expected to be less than 20 mEq/l.
   E. E is incorrect.
3.
   A. Although a kidney ultrasound can be diagnostic of urinary obstruction, it is not the best option in this case because it cannot provide therapeutic relief of the obstruction.
   D. A postvoid bladder catheterization can both diagnose and treat opioid-induced urinary retention or prostate-related obstruction.

CHAPTER 69

1. D.
   Thyroid disorders are not associated with the risk of AKI.
2. C.
   The incidence of AKI in hospitalized patients has increased by approximately 13% per year over the last three decades.
3. D.
   All of the above appear to be consequences of AKI.
4. B.
   The incidence of stage 4 CKD or greater in AKI survivors is approximately 120 per 100,000 person-years.

CHAPTER 70

1. C.
   Randomized controlled trials have shown that starches increase the risk for dialysis.
2. E.
   Metformin should be stopped to prevent lactic acidosis associated with metformin accumulation and the other drugs to prevent acute kidney injury (AKI).
3. A.
   Urine output should be maintained around 300 ml/h until CK levels are lower than 5000 U/L.
4. B
   Correct.

CHAPTER 71

1.

A. The use of intermittent acute renal replacement therapy (ARRT) as initial modality results in the same outcomes as the use of continuous renal replacement therapy (CRRT) as initial modality, as long as one switches in a timely manner as best practice and clinical indications dictate. Patients who are hemodynamically unstable, including those with cardiogenic shock, appear to have better organ recovery if they are treated with CRRT or prolonged intermittent renal replacement therapy (PIRRT).

B. This is still an experimental approach, and to date definitive evidence is missing or negative. Importantly, high-volume CVVH removes beneficial substances (e.g., antibiotics, amino acids, etc.) and is therefore not harmless; however, the risks versus benefits of this promising therapy are still unknown

C. High-quality evidence shows that thrice-weekly treatment is adequate as a default prescription for those receiving intermittent RRT modalities. Of course, an individual's clinical situation might mandate more intensive treatment for any given case, but this does not mean that more intensive treatment is better for all cases.

D. Correct. Delivering adequate dialysis is a core quality indicator for RRT programs and mandates routine and regular measurement of delivered dose; underdelivery is the rule, rather than the exception.

2.

A. Catheter choice should be based on their operating characteristics, to suit the requirements of the patient, the therapy, and the moment. None are inherently "better" than the others.

B. Evidence-based guidelines and cumulative clinical experience both favor the use of arteriovenous access for intermittent HD.

C. Correct. Recent advances in catheter design include the use of symmetric (nonstepped) bias-cut spiraled ports on their tips. Unlike catheters with stepped tips, this design results in minimal or acceptable access recirculation in both normal and reversed configuration.

D. Left-sided internal jugular and subclavian catheters provide flows that are more erratic and up to 100 ml/min lower than elsewhere. Femoral and right-sided internal jugular or subclavian catheters provide the best *Qb*. Overall, data support a recommendation for right-sided internal jugular catheters with bias-cut spiraled ports as the first choice for intermittent HD and PIRRT, with femoral and left-sided internal jugular catheters as the second and third choices, respectively.

3.

A. Low rates of infection require both adherence to specific clinical guidelines and grounding of activities within a formal quality improvement framework. There is strong evidence that standardizing catheter insertion techniques to best practice results in a near-zero catheter-related infection rate. The relevant interventional bundles are contained in position statements of the Institute for Healthcare Improvement (IHI) and the Centers for Disease Control and Prevention (CDC) Healthcare Infection Control Practices Advisory Committee (HICPAC). The core elements appropriate for dialysis catheters are listed in Box 71.3.

B. Topical antibiotic ointments are not recommended because of their potential to promote fungal infections and antimicrobial resistance.

C. Antibiotic- or antiseptic-impregnated lines are recommended by the CDC for patients whose catheters are expected to remain in place for longer than 5 days, and those at high risk for infection (e.g., extensive burn injury, neutropenia, etc.).

D. There is ongoing controversy around the risk for infection with different insertion sites, but on balance the internal jugular site is preferred, especially in those with a larger body mass index. However, it is likely that the way the catheter is handled is more important at preventing

CHAPTER 72

1. C.
   A and B.
2. D.
   No established therapy for these patients has been shown to improve outcome.
3. D.
   Hemoconcentration is an indicator of plasma refill during ultrafiltration.
4. C.
   Replace ACE-inhibitor with sacubitril/valsartan.

CHAPTER 73

1.

A. Correct. Patients with HRS have vasodilation of the splanchnic circulation as a result of the activation of the vasodilator systems at this level

B. Correct. In patients with HRS the heart cannot increase its output to compensate for a decrease in cardiac preload (secondary to the accentuation of splanchnic arterial vasodilation)

C. Correct. Systemic inflammation represents an important pathogenic factor for HRS

D. HRS is a functional renal disorder. The presence of significant glomerular and/or tubular disease excludes the diagnosis

2.

B. HRS is a functional renal disorder with a diagnosis that is based on clinical criteria. Moreover, renal biopsy is risky in patients with liver disease with severe coagulopathy.

C. Activation of the vasoconstrictor systems (the renin-angiotensin-aldosterone system, the sympathetic nervous system, and vasopressin) is a key factor in the pathogenesis of HRS. Plasma renin activity/concentration is markedly increased in the majority of patients. However, its measurement is complicated and not useful in the clinical setting.

D. Correct. The diagnosis of HRS is mainly one of exclusion and should be suspected in any patient with subacute or chronic liver disease with advanced liver failure and portal hypertension who develops progressive renal impairment.

3.

A. HRS should be suspected in any patient with subacute or chronic liver disease with advanced liver failure and portal hypertension.

B. Correct. In the splanchnic circulation, there is marked arteriolar vasodilation resulting in reduction of systemic vascular resistance and arterial hypotension.

C. Activation of the vasoconstrictor systems (the renin-angiotensin-aldosterone system, the sympathetic nervous system, and vasopressin) is a key factor in the pathogenesis of HRS.

D. Correct. HRS occurs in patients with advanced liver failure. The presence of ascites is mandatory.

E. Infection is the most frequent trigger event of HRS.

4.

A. Among the vasoconstrictor therapies, intravenous terlipressin, combined with daily albumin infusion, is the preferred therapy.

B. TIPS could be an alternative treatment of type 1 HRS in patients without response to terlipressin/norepinephrine plus albumin.

C. Dialysis is not tolerated in patients with HRS (already hypotensive) and does not improve survival. It should be reserved for critically ill cirrhotic patients with severe uremia and volume overload.

D. Some studies suggest that albumin dialysis may have beneficial effects in patients with type 1 HRS.

E. In patients with HRS, the administration of midodrine, octreotide and albumin is much less effective in improving renal function than the combination of terlipressin plus albumin.

5.

A. Primary prophylaxis of SBP with norfloxacin prevents SBP delays the development of HRS, and improves short-term survival in cirrhotic patients with advanced cirrhosis.

B. Albumin infusion prevents HRS in patients with SBP.

C. Two randomized controlled trials have failed to show that albumin administration improves survival in infections other than spontaneous bacterial peritonitis (SBP).

D. No study supports this contention.

CHAPTER 74

1. C.
   See the equation on page 872: Fraction of normal dose = 1 − 0.8(1-0.25) = 0.4
   Therefore the dose should be reduced to 40% of the original dose.
2.
   A. High-flux membranes have larger pore sizes and therefore increase removal.
   B. Low protein binding allows a greater portion of unbound drug to be available for clearance.
   C. A low volume of distribution indicates a larger portion of the drug dose that is in the plasma available for removal by dialysis.
   D. Correct. Large molecular sizes prevent drug removal because the drug cannot pass through the membrane pores
3.
   A. Correct. Renally cleared, although it has a wide therapeutic index and limited toxicity, so dose reduction usually is not clinically required for standard courses of oral doses.
   B. Extensively renally cleared with significant toxicity requiring significant dose reduction.
   C. Extensively renally cleared with significant toxicity and narrow therapeutic index requiring significant dose reduction.
   D. Extensively renally cleared with significant potential toxicity requiring dose reduction.
   E. Extensively renally cleared with significant potential toxicity requiring significant dose reduction.
4.
   A. Clarithromycin is a potent CYP3A4 and P-glycoprotein (P-gp) inhibitor significantly increasing sirolimus exposure.
   B. Phenytoin is a potent enzyme-inducing agent that significantly increases the metabolism of coadministered hepatically cleared drugs such as prednisolone.
   C. Fluconazole is a weak inhibitor of CYP3A4 and P-gp and may increase tacrolimus exposure, especially during prolonged combination use.
   D. Correct. Roxithromycin is a weak inhibitor of CYP3A4 and P-gp and rarely causes clinically significant increases in drug exposure, especially during typical 5-day courses of therapy.
   E. Verapamil is a strong inhibitor of CYP3A4 and P-gp and significantly increases everolimus exposure.

CHAPTER 75

1.
   A. Correct. Extensively renally cleared. Accumulation in renal impairment increases the risk for bleeding.
   B. Correct. Extensively renally cleared. Accumulation in renal impairment increases the risk for central nervous system (CNS) adverse effects.
   C. Significantly renally cleared, although accumulation is not clinically significant and dose reduction is usually not required.
   D. Extensively hepatically cleared. Dosing is based on clinical response.
   E. Correct. Extensively renally cleared. Accumulation in renal impairment increases the risk of CNS adverse effects.
2.
   A. Weak CYP3A4 inhibitor. CNI concentration may increase. Base subsequent dose modification on measured CNI concentration changes.
   B. Correct. Strong CYP3A4 inhibitor. CNI concentration expected to increase. Avoid combination or significantly reduce CNI dose if combination is essential.
   C. Renally cleared and does not affect CYP3A4. No interaction expected.
   D. Renally cleared and does not affect CYP3A4. No interaction expected.
3.
   A. Hepatically cleared without active or toxic metabolites
   B. Correct. Metabolized to oxypurinol, which can accumulate in renal impairment
   C. Renally cleared without active or toxic metabolites
   D. Hepatically cleared without active or toxic metabolites
   E. Correct. Metabolized to toxic metabolite meperidine, which is renally cleared
4.
   A. **Correct. Small molecule that is renally cleared and significantly removed by dialysis**
   B. Large volume of distribution so minimal amounts removed by dialysis
   C. Correct. Small molecule renally cleared and significantly removed by dialysis
   D. Significantly protein bound so minimal removal by dialysis
   E. Correct. Small molecule renally cleared and significantly removed by dialysis.

CHAPTER 76

1. B.
   Aristolochic acid nephropathy.
2. C.
   Chronic tubulointerstitial nephritis (Balkan endemic nephropathy).
3. A.
   Cystine crystal.
4. A.
   Acute rejection.

CHAPTER 77

1. A.
   The KDIGO guideline on the classification of CKD recommends using a CGA staging system, including cause of disease, GFR, and level of albuminuria.
2. C.
   The presence of albuminuria has been linked to the development of albuminuria in many studies (see references 1 to 3). Work by the CKD Prognosis Consortium found that low GFR remains a significant risk factor for morbidity (including end-stage renal disease [ESRD]) and mortality in older adults[4] and that there was little difference in the risk associated with albuminuria between men and women.[5] Assays for proteinuria are less accurate than those for albuminuria.
3. B.
   APOL1 risk alleles are almost solely present in persons of African descent. However, lower socioeconomic status and poor access to medical care is a big determinant of racial disparities in ESRD as well as other health outcomes.
4. C.
   Rates of new dialysis patients rise progressively with age, at least until approximately 75 to 80 years of age. They are highest in some Southeast Asian countries and the United States, among males, and among people with lower socioeconomic status.
5. D.
   Among patients with CKD, vascular mortality rates are higher than in the general population; if rates of these were lower, a greater number of people would survive to reach ESRD. Issues of competing in other senses of the word are not relevant. Propensity score matching is a technique for dealing with potential confounders, not competing risks.

CHAPTER 78

1. B.
   Podocytes are damaged by excessive protein load after size selectivity is lost. Protein uptake by podocytes may occur through binding to megalin, a receptor for albumin and immunoglobulin light chains that is endocytosed after ligand binding, as shown in cultured murine podocytes. Excessive protein uptake by podocytes also induces transforming growth factor-β (TGF-β) production, which contributes to cell apoptosis, an additional cause of podocyte loss in proteinuric glomerulopathies.
2. A.
   Loss of podocytes secondary to protein-induced cell injury may lead to reduced production of vascular endothelial growth factor (VEGF), a molecule constitutively expressed and secreted by podocytes, influencing the formation of glomerular endothelial fenestrae and eventually promoting endothelial cell apoptosis.
3. B.
   Exposure of rat proximal tubular cells to excess autologous albumin, as in the case of proteinuric nephropathies, results in the formation of the N-terminal 24-residue fragment of albumin ($ALB_{1\text{-}24}$). This peptide is taken up by dendritic cells, where it is further processed by proteasomes into antigen peptides. These peptides were shown to have the binding motif for MHC class I and to be capable of activating $CD8^+$ T cells.
4. C.
   The progressive enlargement of cysts in the renal tubules in autosomal dominant polycystic kidney disease is largely attributable to the proliferation of mural epithelial cells and transport of fluid into cavities generated by accelerated epithelial cell growth.

CHAPTER 79

1. E.
   SPRINT found no benefit of the Intensive intervention with regard to protecting kidney function in the CKD cohort.
2. E.
   ACE inhibitor and ARB therapy are generally comparable. However, the evidence strongly favors ACE inhibitor with regard to reducing mortality. For this reason, ACE inhibitor should be the initial choice for renin-angiotensin system (RAS) blocker therapy.
3. E.
   In comparing proteinuria magnitude between large populations (e.g., epidemiology studies), spot uPCR is acceptable because the marked variability of spot uPCR likely is random. So this variability is offset when the spot uPCR values are averaged and then compared between the study populations. However, in individual patient management, reliance on spot uPCR results can lead to errors in management because its large inherent variability.

CHAPTER 80

1. D.
   Cardiovascular disease.
2. C.
   The Chronic Kidney Disease–Epidemiology Collaboration (CKD-EPI) formula.
3. B.
   Weight.
4. B.
   Nocturia.
5. D.
   Creatinine 13.5 mg/dl.

CHAPTER 81

1. D.
   Hyperhomocysteinemia.
2. E.
   The calcific aortic stenosis progression rate is only slightly higher in dialysis patients compared to the general population.
3. C.
   Stroke.
4. C.
   Carvedilol.

CHAPTER 82

1. E.
   The RBC life span is usually normal.
2. D.
   The defined upper dose limit of epoetin is 60,000 IU/wk because it is known that cardiovascular toxicity occurs above this dose level.
3. A.
   Patients receiving darbepoetin alfa were randomized to either a target hemoglobin (Hb) of 13 or a target Hb of 9 g/dl.
4. D.
   Intravenous iron may improve the anemia of chronic kidney disease in up to 30% of patients not receiving ESA therapy who have a low ferritin level.

CHAPTER 83

1.

A. Up to 40% of patients with bacteremia do not develop fever in CKD. This is a direct consequence of the CKD-related immune deficit and makes fever a very unreliable sign for any kind of infection.

B. Patients with CKD often have volume overload that impairs the reliability of radiologic chest findings.

C. The Mendel-Mantoux skin test for tuberculosis is negative in the majority of CKD patients who had contact with *Mycoplasma tuberculosis*. This test should be replaced by interferon-γ release assays that have a much better sensitivity in this patient group.

D. Correct. Blood culture can and should be used frequently in CKD patients with suspected bacteremia; CKD does not influence the sensitivity

E. C-reactive protein is elevated permanently or intermittently in the majority of CKD patients in the absence of infection.

2.

A. Correct. Nearly 80% of dialysis patients who have acute HBV infection develop chronic infection. This is a much higher percentage than that found in the general population infected with the virus (~10%).

B. Acute infections with HBV often go unnoticed in patients with CKD because the typical symptoms are missing as a result of immune deficit. In particular, jaundice is very infrequent.

C. Vaccination efficacy is impaired by immune deficiency of CKD. Therefore patients should always receive double-dose injections and many need extended vaccination schedules.

D. HCV infection is a more chronic disease with few clinical symptoms in all patients. The immune deficit of CKD does not relevantly alter the clinical course of the infection.

E. Standard hygienic precautions are of utmost importance for the prevention of nosocomial hepatitis virus infection. The strong decrease in new infections of HBV may be facilitated by vaccination; however, the successful containment of HCV risk in dialysis depends solely on hygiene, indicating the importance of these measures.

3.

A. The plasma levels of several coagulation factors may be affected by uremia. However, those changes do not generally induce prolonged prothrombin time.

B. In the same vein, changes in plasma levels of several coagulation factors by uremia do generally not prolong partial thromboplastin time.

C Some minor changes in platelet counts may occur in CKD because consumption of platelets may override their bone marrow production. However, severe thrombocytopenia does not generally occur. Very low platelet counts should raise the awareness for other, specific underlying hematologic diseases

D. Anemia may contribute to hemorrhagic diathesis. However, anemia in CKD will usually manifest as hypochromic or normochromic anemia, because of iron deficiency and/or low erythropoietin levels.

E. Correct. None of These

4.

A. Desmopressin acts by releasing large factor VIII:von Willebrand factor multimers from endothelial cells into the plasma, and potentially by increasing the membrane glycoprotein expression of platelets.

B. Estrogens may act on coagulation by limiting the production of L-arginine, which is a precursor of nitric oxide. Thus estrogens may lower elevated nitric oxide (NO) production in CKD patients and subsequently reduce NO-induced guanylyl cyclase stimulation and cyclic guanosine monophosphate (cGMP) synthesis, which will finally increase TXA and adenosine diphosphate availability. Estrogens may additionally lower hemorrhagic diathesis by affecting production of coagulation factors and of their inhibitors.

C. TXA is an antifibrinolytic agent, which may be considered for life-threatening bleeding events in CKD patients.

D. The effects of cryoprecipitates are supposed to be mediated by factor VIII:von Willebrand factor multimers, fibrinogen, and other factors that enhance platelet aggregation.

E. Correct. Clopidogrel is an antiplatelet agent, which may be considered in primary and secondary prevention of cardiovascular disease. As a side effect, it may induce more bleeding events

CHAPTER 84

1. C.
   Although the PTH value of this woman is in the desired range, her phosphate levels are too high. In particular in this situation, additional calcium loading should be avoided.
2. E.
   The very low PTH of this dialysis patient is almost diagnostic of low turnover bone disease. The key measure to improve bone turnover is avoidance of calcium loading.
3. E.
   Calcimimetics are not licensed for use in patients with stage 4 CKD stage. There is concern that in this situation calcimimetics lead to increases in serum phosphate.

CHAPTER 85

1. A.
   Use of gabapentin for neuropathic pain.
2. F.
   A, B, and C are correct.
3. C.
   Iron overload and deposition in the basal ganglia.

CHAPTER 86

1. B.
   Low predialysis urea and electrolytes along with low cholesterol may indicate a reduced protein and calorie intake and warrant further dietary investigation. The breathlessness also may indicate that although the target weight has been stable for months, dry weight has been lost over previous weeks (or months) and has been replaced by fluid, so reassessment of target weight is needed. It is a common mistake to see low blood urea nitrogen and electrolytes in a dialysis patient and reduce the amount of dialysis given. This can cause appetite to reduce further, exacerbating the problem. Serum albumin, with its relatively long half-life, does not always drop with a poor dietary intake and therefore is not a good marker of nutritional status on its own. Although one might consider starting a diuretic in a patient with some urine output, there is no indication to restrict fluids in this patient.
2. C.
   The patient is very enthusiastic about exercise and was found to be taking protein supplements. Protein intake works out to be 1.5 g/kg of body weight. If protein intake is high, a reduction toward 1 g/kg may reduce symptoms and also lesson the phosphate and potassium intake and the acid load. Although the BMI is 27, if the patient is exercising extensively, this higher BMI may reflect a higher muscle mass; a lower calorie intake is not necessarily indicated. In fact, if protein intake is being reduced, it will be important to ensure that advice is given to maintain calorie intake for weight maintenance. Sodium intake is high, and because the blood pressure is elevated, it would be very beneficial to advise on ways to reduce sodium in the diet. Potassium is at the top of the reference range, but reducing protein intake often leads to a reduction in the potassium intake, and the correction of acidosis with bicarbonate is likely to also have a beneficial effect on potassium.
3. D.
   The symptoms suggest reduced gastric emptying, possibly because of a combination of diabetic autonomic neuropathy and renal failure. Reducing dialysis volumes would be wrong because having clearances above the minimum target does not exclude inadequate dialysis as a cause of his symptoms (and 2-liter exchanges are not particularly large for this patient). It may even be appropriate, if other measures do not help, to increase the dialysis prescription in case there is a contribution of uremia to his symptoms. Attempting a weight-reduction diet would be inappropriate in this patient, who is already losing weight and raising concerns about his nutrition. Initial forms of nutritional supplementation would be by oral means (dietary advice and supplements if needed) rather than amino acid dialysate as first-line treatment.

CHAPTER 87

1. E.
   All of the above.
2. E.
   In all patients.
3. E.
   Is not limited to any subgroup of patients with uremic pruritus
4. D.
   Warfarin and coumarins.
5. E.
   Is related to exposure to iodine radiocontrast agents.

CHAPTER 88

1.

A. Kidneys of patients with ADPKD have typically many more than four or five cysts and are most often drastically enlarged compared with normal kidneys with simple cysts.

B. Correct. ACKD is a common finding in patients with ESRD ranging from about 20% at the begin of RRT to nearly 100% after more than 10 years. Hematuria may be one of the typical complications of renal cysts.

C. We recommend that asymptomatic dialysis patients younger than 60 years with a high life expectancy should be screened for ACKD and RRC. However, the cumulative incidence of RCC in ACKD is probably less than 1%.

D. Cystic disease of organs other than the kidneys is not a typical feature of ACKD.

E. Exposure to benzidine and 2-naphthylamine is a risk factor for the development of transitional cell cancer (TCC) of the bladder. A connection to ACKD has not been established.

2.

A. Some of the increased risk for malignancy is directly related to the underlying renal disease. For example, patients with analgesic nephropathy or Chinese herbs/aristolochic acid nephropathy are at high risk for development of TCC of the upper urinary tract. In addition, the immunosuppression that may have been administered to patients with immune-mediated renal disease, such as cyclophosphamide therapy, may predispose to bladder and ureteral cancer.

B. Registries from the United States, Europe, and Australia have shown an increased risk for cancer of the kidneys and bladder, cervix, and thyroid and other endocrine organs, as well as multiple myeloma in patients with ESRD, compared with the general population.

C. Cyclophosphamide is carcinogenic and may increase the risk for developing lymphomas, leukemia, skin cancer, TCC of the bladder, or other malignancies.

D. Plants containing aristolochic acids have a long history for medicinal purposes and are commonly used in Chinese herbs. Compounds of this family have been shown to be carcinogenic, mutagenic, and nephrotoxic. They are associated with kidney disease and urothelial cancers.

E. **Correct. Large registries have not shown an increased risk for cancer of the intestinal tract in dialysis patients compared with that in the general population.**

3.

A. ACKD is a common finding in patients with ESRD ranging from about 20% of patients being affected at the beginning of RRT to nearly 100% after more than 10 years of RRT.

B. Up to 25% of kidneys with ACKD harbor tumors, most of which are papillary adenomas and only about one third are carcinomas.

C. ACKD does usually not cause any symptoms. If symptomatic, it can manifest with hematuria or symptoms of cyst infection.

D. Correct. ACKD is a risk factor of RRC, but only less than 1% of affected patients develop RCCs so that nephrectomy is not indicated. We suggest, however, that asymptomatic patients with high life expectancy should be screened by ultrasound on a yearly basis to detect suspicious masses.

E. Contrast-enhanced CT and MRI are the most sensitive diagnostic procedures to detect renal masses. Especially for small kidney tumors they are superior to ultrasound.

CHAPTER 89

1. A.

   This patient has the typical findings of a hypersensitivity reaction to a nonsteroidal antiinflammatory drug (NSAID).[1] Clinically, this syndrome manifests with the abrupt onset of nephrotic syndrome and an acute deterioration of renal function. The pathologic findings are usually a combination of MCD and interstitial nephritis (with a T cell infiltrate and minimal eosinophil accumulation).[1] Spontaneous recovery on discontinuance of the drug is the rule, but corticosteroid therapy may hasten recovery in severe renal failure and perhaps prevent long-term sequelae.[2]

   1. Whelton A. Nephrotoxicity of nonsteroidal anti-inflammatory drugs: Physiologic foundations and clinical implications. *Am J Med.* 1999;105:13S-24S.
   2. Inoue M, Akimoto T, Saito O, et al. Successful relatively low-dose corticosteroid therapy for diclofenac-induced acute interstitial nephritis with severe renal failure. *Clin Exp Nephrol.* 2008;12:296-299.

2. B.

   Recent data have demonstrated that elderly nursing home patients who start HD seldom achieve significant functional benefit and many continue to deteriorate or even deteriorate at a faster rate than before starting dialysis.[1] Home HD and assisted PD are options but likely will not result in any significant benefit for this patient other than allowing her to remain in her care setting. The first 3 months after dialysis is begun is a very vulnerable period, and if there is no benefit seen within this time frame, it is unlikely that the patient will see any significant functional improvement from dialysis moving forward.[2]

   1. Kurella M, Covinsky K, Collins A, Chertow G. Octogenarians and nonagenarians starting dialysis in the United States. *Ann Intern Med.* 2007;146:177-183.
   2. Jassal S, Watson D. Dialysis in late life: Benefit or burden. *Clin J Am Soc Nephrol.* 2009;4:2008-2012.

3. B.

   Although older than 75 years, this man does not have any additional risk factors precluding transplantation. His outcome with a kidney transplant would likely be superior to that on dialysis even at this age. After transplantation, his highest risk for death would be within the first 3 to 4 months. He would benefit the most if he received a kidney transplant preemptively or within 6 months of starting dialysis. Even if he is not able to undergo surgery within this time, the longer he waits while undergoing dialysis, the poorer his overall and graft survival. Although true regardless of age, living donation is particularly attractive for this patient because of the likelihood that the time on dialysis will be shorter and the improved outcomes associated with shorter organ cold ischemia time. The results of the old-for-old program in Europe suggest that the use of donors with less-than-perfect organs is acceptable; therefore there is no contraindication to older patients going on the extended-criteria donor wait list.[1]

   1. Frei U, Noeldeke J, Machold-Fabrizii V, et al. Prospective age-matching in elderly kidney transplant recipients: A 5-year analysis of the Eurotransplant Senior Program. *Am J Transplant.* 2008;8:50-57.

CHAPTER 90

1. B.
   In patients who are suitable for kidney transplantation, outcomes with a kidney transplant are superior to any dialysis modality. Preemptive transplantation gives superior outcomes to transplantation after dialysis has been started. A living donor kidney gives superior outcomes to a deceased donor kidney.
2. D.
   The IDEAL study[16] showed no improvement in outcomes with early initiation of dialysis, but health care costs were increased.[17]
3. C.
   There is no single threshold of eGFR when dialysis should be started. Answers B and D can be managed without dialysis.
4. D.
   Physical and psychological preparation for dialysis or transplantation takes many months. The appropriate trigger for transferring a patient to multidisciplinary renal care is therefore the time before RRT is expected to be needed, rather than an arbitrary level of kidney function.
5. A.
   If a patient expresses a clear wish not to have dialysis, the physician is obliged to respect this because to treat patients against their will constitutes an assault.
6. C.
   In the presence of a good performance status and little or no comorbidity, age alone does not indicate a poor prognosis on dialysis.

CHAPTER 91

1. C.
   The primary patency of AVF is 60% to 70% at 1-year follow-up. AVGs have a primary patency of 25% because of a higher number of thromboses resulting from stenoses in the AVG conduit. To get higher patencies, AVGs need multiple interventions. This is not the case in AVFs.
2. B.
   A flow of 800 ml/min is just enough to keep an access open. Further flow reduction by banding or RUDI has the risk for fistula thrombosis. Therefore the first treatment option is to enhance flow to the forearm and hand by bypass surgery (DRIL procedure).
3. D.
   Multiple studies clearly indicate tunneled central venous catheter over nontunneled central venous catheter because of the higher risk for infection. Other items outlined in the answers are similar between tunneled and nontunneled catheters.
4. A.
   The thrombosis rate of autogenous AVF is lower compared with AVG because of a lower incidence of stenosis formation resulting in flow decline. In addition, AVFs can experience lower flows because of the presence of endothelium in the access conduit. These cells prevent thrombosis. Only with very low flows (<400 ml/min) the risk for thrombosis increases, while, for instance, in AVGs this risk is already present with higher flow rates (usually ~600 ml/min).
5. B.
   Recent studies show high recurrence rates for primary percutaneous transluminal angioplasty without stenting of central vein occlusions. Primary stent placement results in better primary patencies.

CHAPTER 92

1. B.
   False
2. C.
   Less than 30% residual stenosis and resolution of physical indicators of stenosis.
3. D.
   A and B.
4.
   A. An ultrasound of the kidneys should be performed in all patients with chronic renal failure to rule out obstructive uropathy and polycystic kidney disease and to exclude advanced, irreversible disease (small kidneys with thin cortex) for which a biopsy will not be useful.
   B. In many patients with acute renal failure, the cause is apparent from the clinical picture (i.e., sepsis) and imaging is useful only when the cause is not apparent, the clinical picture suggests urinary obstruction, and it is not clear how much of the renal failure is acute or chronic.
   C. Correct. Ultrasound is the modality of choice for diagnosing bladder outlet obstruction, with a negative study essentially ruling this out.
   D. Normal ureters are too small to be detected by sonography. Even when dilated, they are often not apparent because of overlying bowel gas.
5. E.

CHAPTER 93

1. A.
   Endotoxin molecular weight is too high (~100,000) and thus cannot pass through dialysis membranes.
2. C.
   The bacterial microflora in the gut metabolizes some amino acids and other precursors into uremic toxins, for example, tryptophan into indoles, L-tyrosine into *p*-cresol, and choline into trimethylamine.
3. D.
   A large body of high-quality evidence indicates that a hemodialysate at a temperature below the patient's core temperature results in improved intradialytic hemodynamic stability.
4. A.
   A recent study showed an increased morbidity and mortality in HD patients with prolonged intradialytic hypoxemia.
5. B.
   Water preparation according to national and international guidelines is the foundation of dialysate preparation.Chapter 94

1. C.
   Probably 3 hours of dialysis time because there would not be enough time to remove interdialytic volume without a dangerously high ultrafiltration rate. The other factors may not be optimal but are far less dangerous.
2. A.
   Use of antihypertensive drugs in large trials rarely reduce systolic BPs by more than 10 mm Hg. The other actions are more effective, particularly C and D together.
3. B.
   Application of abdominal pressure would not be useful in these circumstances. Decreasing dialysate temperature will cause arteriolar vasoconstriction, and reducing ultrafiltration will maintain circulating volume. Having a easier (higher) weight target to reach will indirectly result in lower ultrafiltration rates and maintenance of BP.
4. D.
   An increase in dialysate flow rate does not affect the convective volume in online HDF. All the other actions listed here, either individually or in combination with one or more of the other actions, are useful to increase convection volume.
5. C.
   This indicates the importance of apparently even small degrees of residual function. (2.00 is the minimal standard KtV prescribed dose.)

CHAPTER 95

1. C.
   Intravascular volume depletion.
2. D.
   Avoidance of excessive interdialytic weight gains.
3. E.
   Heparin exposure.
4. B.
   Potting compound.
5. E.
   All of the above.

CHAPTER 96

1. B.
   The glucose molecules are smaller than the ICO molecules and therefore are relatively "inefficient" as osmotic agents in small pores, but relatively more efficient across AQP.
2. E.
   None of the catheters above shows significant clinical superiority
3. C.
   Increases in small-solute transport (PET_{creat}) combined with no or only moderate increases in the UF coefficient (L_pS)
4. D.
   They produce higher concentrations of the dialysate effluent marker CA-125.
5. E.
   Icodextrin is polydispersed, but with 30% of the molecules being larger than 3 kDa.
6. A.
   Small pores

CHAPTER 97

1. A and C.
   A is false because although there is some emerging evidence of the superiority of the laparoscopic technique, this is not a substitute for a well-audited and experienced surgical team. C is false because normal pH solutions should be considered if available. Note that E is true but occasionally is due to fluid tracking down the abdominal wall from a deep cuff leakage.
2. B and C.
   B is false because antifungals should be commenced intraperitoneally, but the catheter should be removed and treatment continued systemically. C is false because treatment should await cultures; the indications for immediate treatment are purulent discharge of clinical evidence of infection of the tunnel. Note that D is true for both exit site infections and peritonitis. E is true and remains the most common reason for PD-associated peritonitis death.
3. B and D.
   B is false because the target should take residual renal function into account; an anuric patient obtaining less than 1 liter should have his or her membrane and prescription examined. D is false; CT can be used to confirm that obstructive symptoms are a result of encapsulation but should not be used to screen for EPS in the absence of symptoms. Note that A is true because of both increasing solute transport and loss of osmotic conductance. For E, progressive loss of osmotic conductance is not treatable, and PD should be continued only in patients with otherwise low life expectancy.

CHAPTER 98

1. A.
   Ethylene glycol is metabolized to glycolic acid and oxalate by alcohol dehydrogenase. Its presentation is associated with oxalate crystals in the urine and a raised anion gap acidosis.
2. E.
   Acute kidney injury is not associated with a raised osmolar gap, whereas all of the other conditions are.
3. C.
   All of the other drugs/poisons are effectively removed by intermittent HD.
4. A.
   Hemoperfusion remains the 1st choice treatment for removal of theophyllines.

CHAPTER 99

1.
   A. Not linked to plasma exchange.
   B. Plasma exchange can be a treatment for hyperviscosity syndromes: replacement with albumin or fresh-frozen plasma (FFP) does not alter normal plasma viscosity.
   C. Correct. This is a very common complication, especially when using FFP replacement that contains citrate.
   D. Can be associated with the need for central venous access to undertake plasma exchange but uncommon
   E. Thrombocytopenia can occur

2.
   A. Correct. Should be started immediately while awaiting complement studies and possible use of eculizumab
   B. Probably no role for plasma exchange
   C. Evidence for any benefit of plasma exchange increasingly absent: critical therapy is early start of chemotherapy probably including bortezomib to rapidly deplete light chains
   D. No role for plasma exchange
   E. No good evidence for benefit of plasma exchange in lupus nephritis, and patients should start urgent therapy with cyclophosphamide, mycophenolate, or rituximab

3.
   A. Correct. Good evidence for benefit of plasma exchange
   B. CD4 staining alone is not sufficient to diagnose antibody-mediated rejection
   C. No good evidence for benefit; initially drug should be stopped
   D. No role for plasma exchange
   E. No role for plasma exchange

CHAPTER 100

1. B.
   HLA genes are inherited in a mendelian codominant fashion, meaning that a copy of each HLA gene (i.e., one haplotype) is inherited from each parent and expressed as antigens. It can thus be predicted that siblings from the same set of parents will have a 25% chance of having zero mismatches, 50% chance of one haplotype mismatch, and 25% chance of two haplotype mismatches. In kidney transplantation, efforts are made to match HLA-A, -B, and -DR genes and proteins.
2. D.
   Both cellular and antibody types of rejection can be early or late, fulminant or indolent, and isolated or concomitant and can share pathologic features on biopsy. Tubulitis is a characteristic feature of acute cellular-mediated rejection.
3. E.
   Patients normally have no preexisting immunoreactivity to alloantigen, unless they have been exposed to alloantigen through pregnancy, blood transfusion, or prior transplantation. However, microbial antigens that cross-react with alloantigens (molecular or antigenic mimicry) can lead to the generation of alloantigen-specific memory cells through a process termed *heterologous immunity.*
4. C.
   T cells recognize alloantigen as peptides presented by intact MHC molecules on donor (direct pathway) or recipient (indirect pathway) antigen-presenting cells. MHC class II molecules process extracellular proteins for presentation to CD4 T cells. The MHC class I system is designed to sample intracellular, not extracellular, proteins and present them to CD8 T cells.

CHAPTER 101

1. A.
   Calcineurin inhibitors (CNIs) are still considered the cornerstone of modern immunosuppression, but CNI nephrotoxicity has limited progress in graft survival for the past two decades. Chronic renal injury is presumably the result of prolonged renal vasoconstriction with ischemia and over time is characterized by afferent arterial hyalinosis and tubulointerstitial fibrosis. Hypertension is common after transplantation but usually can be managed with a combination of antihypertensive agents. TMA is rare but potentially serious adverse advent that may require the reduction or removal of the offending CNI. Alopecia is a common side effect seen with tacrolimus, but hirsutism is associated with cyclosporine.
2. C.
   Belatacept is a selective T cell costimulation blocker that binds to CD80 and CD86 on antigen-presenting cells, thereby blocking CD28-mediated costimulation. So far, belatacept appears to be a promising renal-sparing agent. Eculizumab blocks complement C5 cleavage, thus preventing the formation of the C5b-9 membrane attack complex, and it has been used as rescue therapy for refractory acute rejection. Basiliximab is a monoclonal antibody that targets CD25 on the IL-2 receptor, and it is used as induction immunosuppression. Rituximab in a monoclonal antibody that is directed against the CD20 antigen, which blocks B cell proliferation and differentiation, and it has been used in the treatment of antibody-mediated rejection and desensitization protocols.
3. D.
   Mycophenolate has a black box warning for its use during pregnancy because an increased risk for first-trimester miscarriages and congenital birth defects. Patients are strongly advised to stop mycophenolate if pregnant or attempting to get pregnant. Both tacrolimus and prednisone are U.S. Food and Drug Administration (FDA) pregnancy class C but have been successfully used throughout pregnancy. Despite being an FDA pregnancy class D agent, azathioprine has been around for 50 years and has been considered acceptable by the transplant community.
4. B.
   Basiliximab induces a relatively mild immunosuppression and is used as an induction agent, but not to treat established acute rejection.[9,10] Antithymocyte globulin is a potent polyclonal agent that depletes T and B lymphocytes and has been used as therapy for steroid-resistant acute rejection. Rituximab is a monoclonal antibody that targets B cells and is used as a treatment for acute antibody-mediated rejection. Intravenous immunoglobulins appear to reduce alloantibodies through inhibition of antibody production—though the mode of action is not well understood—and it used as therapy for acute antibody-mediated rejection.

CHAPTER 102

1. A.
   Active sepsis will likely worsen with immunosuppression, and so it is important to have this resolved before transplantation. Responses B to E are no longer seen as contraindications, although special care must be taken to address the specific issue and potentially modify the immunologic, medical, and surgical approach to transplantation.
2. D.
   A normal stress echocardiography result does not necessarily exclude coronary heart disease, however the negative predictive value for myocardial infarction or cardiac death is in excess of 90% in patients with renal failure.
3. D.
   Deceased donors over the age of 60 years without any other medical history of significance meet the definition for expanded-criteria donors. If there is a history of hypertension or death from a cerebrovascular accident, the age for classifying a donor as meeting expanded-criteria can be lower between 50 and 59 years old. Diabetes, smoking, vascular disease, and hepatitis C virus (HCV) are not factors used to classify donors as expanded-criteria. The new KDRI/KDPI system is more detailed and does use donor age, diabetes, hypertension, HCV, and mode of death in the formula when deriving the donor score.
4. B.
   A colonoscopy would usually be considered only in donors with bowel symptoms, iron deficiency, or a family history of colonic cancer. Urine microscopy and imaging are important tests in assessing underlying renal conditions in the donor and defining anatomy before donation. Hepatitis serology is important in assessing the risk for disease transmission. An electrocardiogram will help define the donor's cardiac status and possible risks associated with the surgical procedure and anesthetic.
5. C.
   A positive T cell cytotoxicity–dependent crossmatch is likely to be indicative of a very high level of donor-specific antibodies against class I human leukocyte antigen, making the risk for hyperacute rejection extremely high. Additionally, this test is functional in that it uses T cells from the donor (therefore expressing antigens that also may be present on the allograft) to assess the recipient's immunologic reactivity to the allograft.

CHAPTER 103

1. A and D.
2. A and D.
3. C.
4. C and E.
5. A.

CHAPTER 104

1. D.
   The most recent Banff criteria for the diagnosis of antibody-mediated rejection requires 1) evidence of circulating donor-specific antibodies 2) histologic evidence of tissue injury in the form of microvascular inflammation, arteritis, thrombotic microangiopathy, and/or acute tubular injury, and 3) evidence of antibody/endothelial interaction in the form of either peritubular capillary C4d deposition, at least moderate microvascular inflammation, or molecular markers. Option D is the only answer here that includes these criteria.
2. B.
   While the utility of induction immunosuppression in patients at low immunologic risk is debatable, acute rejection rates are significantly lower in higher immunologic risk patients treated with lymphocyte depleting agents vs. IL-2 receptor antibodies. Answer A refers to OKT3 which is no longer in production. Answer C is incorrect in that patients treated with IL-2 receptor antibodies are likely at LOWER risk of lymphoproliferative disorders vs. those treated with lymphocyte depleting agents. Finally, anti-CD52 therapy reduces early acute rejection rates, with higher rebound rejection rates after 12 months.
3. B.
   The ELITE-SYMPHONY study showed tacrolimus/MMF/prednisone containing regimens to be associated with lower acute rejection rates compared to a sirolimus-containing CNI-free regimen (answer A). Belatacept may prove to improve long term graft outcomes compared to CNI-containing regimens, however is associated with increased rates of acute rejection early after transplant. Early prednisone withdrawal strategies (answer D) are used by approximately 30% of US transplant programs and are associated with an approximately 2-fold increased risk of acute rejection, especially in patients at higher immunologic risk NOT receiving lymphocyte-depleting induction.
4. C.
   This patient has banff class II cellular rejection, the appropriate treatment for which includes rATG. Options A and B may be adequate for more mild forms of acute cellular rejection (banff class 1a). Option D describes treatment for antibody-mediated rejection.

CHAPTER 105

1. C.
   There has been no conclusive evidence to suggest that vaccination increases the risk for allograft dysfunction or acute rejection. Intranasal influenza vaccine is a live attenuated influenza vaccine and is contraindicated before and after transplantation. Vaccinations should be administered at least 4 to 6 weeks before transplantation to achieve optimal immune response.
2. D.
   The AST Infectious Diseases Community of Practice guidelines recommend that antiviral therapy be continued until the following criteria are met: (1) Resolution of clinical symptoms, (2) Virologic clearance below a threshold negative value based on laboratory monitoring with CMV QNAT or pp65 antigenemia, and (3) Minimum 2 weeks of antiviral therapy.
3. B.
   The effectiveness of currently available antiviral agents is of uncertain benefit. In nearly all case series reported, adjuvant antiviral agents were initiated in conjunction with immunosuppression reduction. Furthermore, although antiviral therapy may reduce viral load, viral clearance may require continuous immune control. Judicious immunosuppression reduction may allow sufficient reconstitution of BKV-specific T cells to control BKV replication while maintaining adequate immunosuppression to prevent allograft rejection. The routine recommendations of antiviral therapy or immunosuppression class switching in the prevention or treatment of BK virus–related clinical syndromes await results of large prospective randomized trials.

CHAPTER 106

1. B.
   The beneficial effect of ACE inhibitors or antiotensin receptor blockers (ARBs) on patient or graft survival has not been consistently demonstrated. The KDIGO guidelines suggest a blood pressure goal of less than 130/80 mm Hg for kidney transplant recipients irrespective of the level of albuminuria. There has been no conclusive evidence that one class of antihypertensive agent is superior to another in the transplant setting. Hence, treatment should be individualized based on efficacy, tolerability, concomitant comorbidity, and drug-drug interactions with immunosuppressive agents.
2. C.
   To date, there have been no data to support the routine addition of nonstatin drug to statin therapy to further reduce cardiovascular disease events in the general population or in the transplant setting. However, based on the safety and efficacy data of ezetimibe use among chronic kidney disease patients, ezetimibe can be considered as a second-line treatment option for high-risk kidney transplant recipients who are intolerant of statin or are refractory to statin therapy. Mammalian target of rapamycin (mTOR) inhibitor–based immunosuppression is associated with the worst lipid profiles, followed by cyclosporine, and to a lesser extent tacrolimus.
3. B.
   The diabetogenic effect of corticosteroids, calcineurin inhibitors (tacrolimus > cyclosporine), and mTOR inhibitors have been well-described. However, neither azathioprine nor mycophenolic acid derivatives are diabetogenic.

CHAPTER 107

1. D.
   Human leukocyte antigen (HLA) alloantibodies.
2. C.
   Only 1, 2, and 3 are correct.
3. E.
   1, 2, and 4 are correct.

CHAPTER 108

1. A.
   Risk is approximately 5% to 10% within 10 years after transplantation for IgAN, less than 1% for B, C, and D and E does not recur
2. E.
   A histologic diagnosis pre- and post-transplantation is required for the diagnosis of recurrent disease.
3. D.
   Plasma exchange should be commenced once a diagnosis of recurrent FSGS is made, with a plan to complete approximately nine cycles of therapy.

CHAPTER 109

1. B.
   Statistical method of maximizing the information available for analysis of outcome from a group of patients and events.
2. C.
   Acute rejection, graft failure, lost to follow-up, and patient death.
3. C.
   Method of combining the results from all similar trials to gain statistical power.

CHAPTER 110

1. F.
   There are several options for insulin-dependent diabetics, depending on cardiac status, surgical candidacy in general, and availability of a living donor kidney transplant.
2. B.
   Pancreas transplants require additional amounts of immunosuppression because of an increased risk for rejection. The other statements are all true.
3. E.
   Transplantation of an adequate islet cell mass through the portal vein to the liver can establish a normal hemoglobin A_{1c} in patients with lower BMI.

CHAPTER 111

1.
   A. The slowly falling glomerular filtration rate (GFR), the hypertension and the bland urinalysis are all suggestive of chronic cyclosporine nephrotoxicity.
   B. A renal biopsy is not considered urgent in the setting of bland urinalysis and a high pretest probability of cyclosporine toxicity, although it may be performed at some point for confirmation and prognostication purposes.
   C. The combination of sirolimus + cyclosporine *increases* the risk for further renal damage.
   D. Cystic fibrosis of itself is not a contraindication to renal transplantation.
   E. Diltiazem will impair the metabolism of both cyclosporine and simvastatin, increasing their blood and tissue concentrations, which will increase the risks for acute kidney injury (AKI) and rhabdomyolysis.

2. C.
   The most likely process here given the risk factors (time frame, total body irradiation) and clinical and laboratory features (hypertension, low platelets, rising creatinine with proteinuria and hematuria) is thrombotic microangiopathy. Plasma LDH, serum haptoglobin, and blood film will confirm this suspicion. Membranous nephropathy tends to cause nephrotic (not nephritic) syndrome. Hematologic malignancies can infiltrate the kidneys, leading to AKI, but would not manifest with nephritic syndrome. Ultrasound is the preferred method for identifying obstructive uropathy (especially in the setting of renal dysfunction, in which intravenous contrast could cause further renal injury).

3. E.
   Clarithromycin increases cyclosporine levels (by reducing cytochrome P450 [CYP]3A activity, which is involved in cyclosporine metabolism), giving rise to the typical manifestations of acute calcineurin inhibitor toxicity: tremor, AKI, hyperkalemia. Allopurinol and azathioprine should not be coadministered because of the risk for severe pancytopenia. Preemptive kidney transplant would be the best treatment for this patient because he is young, relatively healthy, and likely to withstand the stress of kidney transplant surgery.

4. B.
   Here, the baseline serum creatinine of 1.0 mg/dl likely reflects some degree of CKD, given the young age, female gender, and likely low muscle mass in the face of end-stage liver disease. Glomerulonephritis, although not uncommon in hepatitis C infection, tends to have a more subacute presentation and—at least when acute—is characterized by hematuria and proteinuria. Simultaneous liver-kidney transplant is not currently indicated because her acute kidney dysfunction has been ongoing for 1 week only. Given her baseline CKD and current AKI, she has a significant risk for developing severe CKD over the long term.

5. D.
   Although severe heart failure is likely contributing to the renal dysfunction, the hemodynamic insults at cardiac transplantation and the post-transplant nephrotoxic medications (without which outcomes are poor) make it more likely that the renal function will further deteriorate. Furthermore, the proteinuria suggests there is also intrinsic kidney disease such as secondary focal segmental glomerulosclerosis (which can occur in cyanotic heart disease). Therefore, although not commonly performed, simultaneous heart-kidney transplant should be considered here. A kidney transplant in isolation (i.e., without an improvement in cardiac status) is not recommended because of her high risk for morbidity and mortality perioperatively.

CHAPTER 112

1. B, D, E.
   Survival on dialysis for elderly patients does not depend on dialysis modality, but is related to frailty and comorbidities
2. C, D, E.
   Advance care planning is an outcome of shared decision making and is not a legal process. It therefore involves sharing information between patient and health care team to arrive at an informed decision made by the patient
3. A and E.
   Dialysis withdrawal is withdrawal of life-sustaining treatment that is no longer effective in sustaining quality of life for the patient. In the absence of renal function, patient survival is around 7 days, depending on comorbidities; survival can be considerably longer if the patient still has some residual renal function.
4. A, D, E.
   The decision for a patient to have conservative care is made after shared decision making. A number of retrospective studies have shown no survival advantage of dialysis compared with conservative care for patients older than 80 years and multimorbid patients older than 75 years. Conservative care is no dialysis but includes optimal management of kidney disease complications, comorbidities, and symptoms.
