As alluded to earlier, moderately increased albuminuria (previously microalbuminuria) is arbitrarily defined as excretion of 30 to 300 mg albumin/24 h in at least two of three consecutive urine samples (Table 30.1). There is substantial individual day-to-day variation in albumin excretion (coefficient of variation, 30% to 50%) and also between day and night collections (Fig. 30.18). Even in the upper quantiles of so-called normoalbuminuria, the risk for progression and cardiovascular events is elevated. At concentration of 30 to 300 mg/24 h, albumin is normally not detected by nonspecific tests for protein (e.g., Biuret reaction). Albumin can be detected, however, by use of specific techniques such as dipstick, enzyme-linked immunosorbent assay, nephelometry, and radioimmunoassay. Instead of difficult-to-obtain 24-hour urine collections, the albumin concentration can be determined in spot urine or, better, first-void morning urine samples. The normal range is less than 20 μg/ml.

The detection of urinary albumin is a specific indicator of DN only if confounding factors such as fever, physical exercise, urinary tract infection, nondiabetic renal disease, hematuria from other causes, heart failure, uncontrolled hypertension, and uncontrolled hyperglycemia have been excluded.[78]

TABLE 30.1 Urinary Albumin Excretion Rate Levels of 24-Hour and Overnight Urinary Albumin Excretion Rate (Uae) Are Diagnostic for Microalbuminuria and Overt Diabetic Nephropathy

	UAER	
Condition	**24 hr (mg/day)**	**Overnight (μg/min)**
Normoalbuminuria	<30	<20
Microalbuminuria	30-300	20-200
Overt nephropathy	>300	>200

As noted in the text, the terms for microalbuminuria and macroalbuminuria have been replaced by new terminology. These historical terms are still widely used and are presented here for clarity.

The main advantage of searching for microalbuminuria early in the course of diabetes is that it predicts a high renal and cardiovascular risk and thus allows targeted intervention. The American Diabetes Association (www.diabetes.org) and other societies recommend annual testing of all diabetic patients.

By definition, there is clinically overt DKD (severely increased albuminuria; formerly macroalbuminuria) if the rate of albumin excretion exceeds 300 mg/day. At this point, serum proteins other than albumin are usually excreted in the urine as well (nonselective proteinuria).

Although there are few guidelines regarding repeated measures of albuminuria or proteinuria after a diagnosis of diabetic kidney disease has been established, Kidney Disease: Improving Global Outcomes (KDIGO) recommends using the albumin-to-creatinine ratio or protein-to-creatinine ratio annually to determine if there is disease progression,[78] although assaying the urine ratio of albumin to creatinine can be much more expensive in certain countries.

Measurement of Blood Pressure

When measuring the BP in a diabetic patient, the following issues should be taken into account:

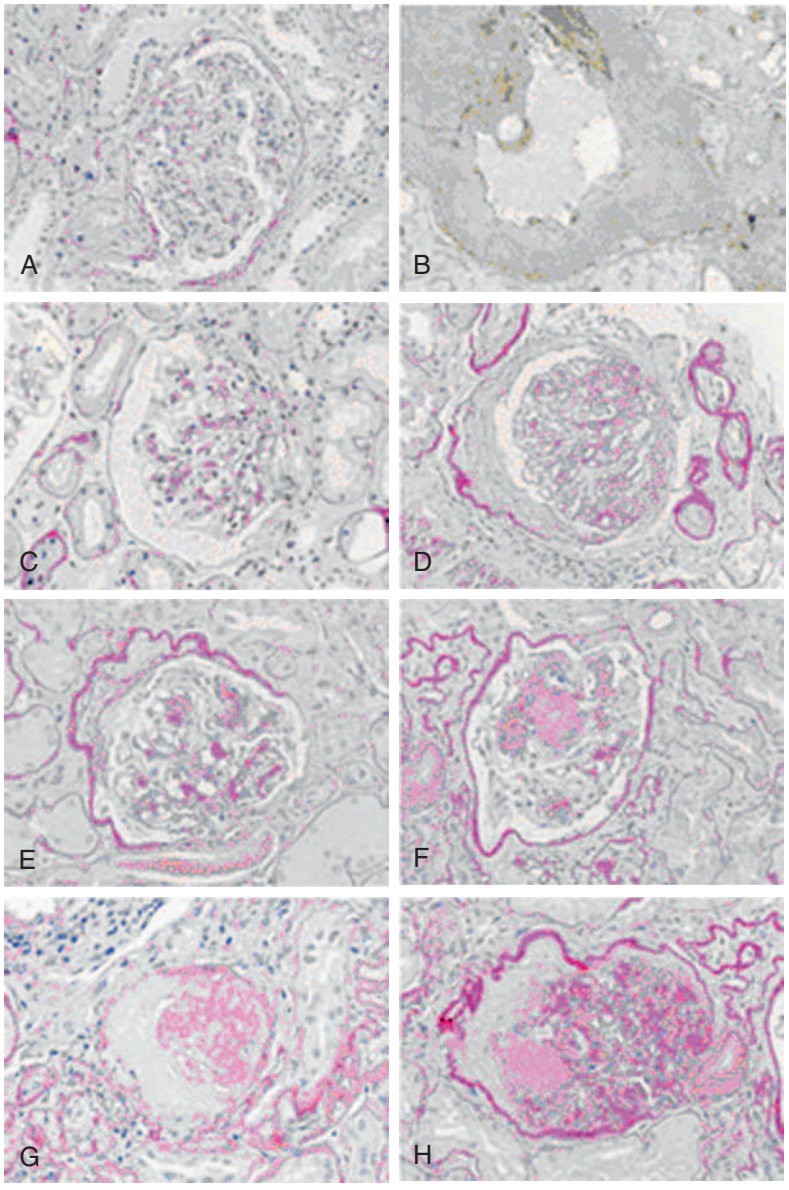

Fig. 30.16 Pathologic classification of diabetic kidney disease (DKD; according to Tervaert et al). Representative examples of the morphologic lesions in DKD. (A) Glomerulus showing only mild ischemic changes, with splitting of the Bowman capsule. No clear mesangial alteration. (B) Electron micrograph of this glomerulus. The mean width of the GBM was 671 nm (mean taken over 55 random measurements). Electron microscopy provides the evidence for classifying the biopsy with only mild light microscopy changes into class I. (C and D) Class II glomeruli with mild and moderate mesangial expansion, respectively. In C, the mesangial expansion does not exceed the mean area of a capillary lumen (IIa), whereas in D it does (IIb). (E and F) A class III Kimmelstiel-Wilson lesion is seen in F. The lesion in E is not a convincing Kimmelstiel-Wilson lesion; therefore, on the basis of the findings in this glomerulus, the finding is consistent with class IIb. For the purpose of the classification, at least one convincing Kimmelstiel-Wilson lesion (as in F) needs to be present. (H) Signs of class IV DKD consist of hyalinosis of the glomerular vascular pole and a remnant of a Kimmelstiel-Wilson lesion on the opposite site of the pole. (G) Example of glomerulosclerosis that does not reveal its cause (glomerulus from same biopsy as H). For the purpose of the classification, signs of DKD should be histopathologically or clinically present to classify a biopsy with global glomerulosclerosis in more than 50% of glomeruli as class IV. (From reference 77.)

- In overweight patients with type 2 diabetes, the size of the cuff has to be adapted to the upper arm circumference. When this exceeds 32 cm, cuffs of 18-cm width are indicated.
- Patients with severe autonomic neuropathy tend to develop orthostatic hypotension, defined as a decrease of systolic BP by more than 20 mm Hg in the upright position. It is therefore advisable to measure BP after being in the upright position for a defined period (e.g., 30 minutes). However, such an approach may not always be feasible in a primary care setting.
- The circadian BP profile tends to be abnormal in the early stages, and even a paradoxical increase in the nighttime BP is not rare. In the diabetic patient with nephropathy, it has been shown that a

nighttime increase in BP is independently associated with a 20-fold higher mortality and a higher risk for renal failure. Occasional measurements of ambulatory BP are particularly useful to assess the efficacy of antihypertensive treatment.

- In diabetic patients with sclerosis or calcification of the radial and brachial arteries, occasionally there may be pseudohypertension, or "white-coat hypertension," may occasionally occur, that is, spuriously elevated BP values despite normotension established by intraarterial BP measurements. This condition should be suspected if a discrepancy is found between modest target organ damage (e.g., left ventricular hypertrophy) and very high measured BP values. Such patients tend to develop marked hypotension even with relatively modest antihypertensive therapy.

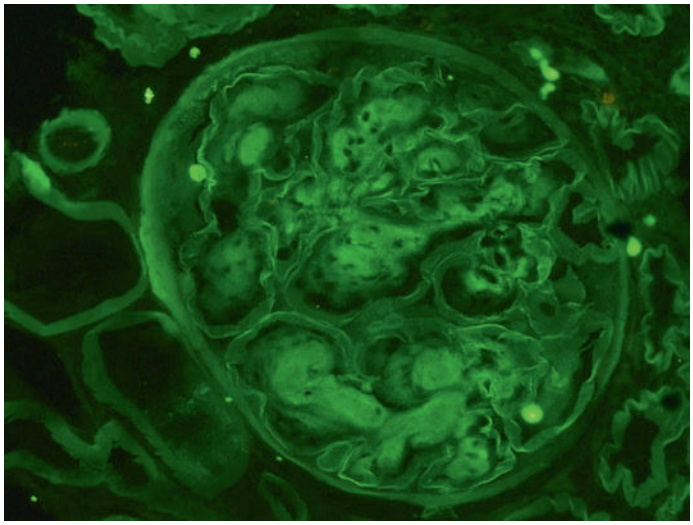

Fig. 30.17 Immunofluorescence for glomerular immunoglobulin G (IgG) in diabetic nephropathy. Faint staining of the glomerular basement membrane (GBM) for IgG results from passive trapping of IgG in the expanded GBM. (Courtesy Prof. Peter Furness, Leicester, UK.)

Measurement of Serum Creatinine and Estimation of Glomerular Filtration Rate

In clinical practice, the serum creatinine concentration is most frequently used to assess renal function, but it may be grossly misleading in wasted patients when muscle mass is low. This problem is particularly frequent in elderly female patients with type 2 diabetes. KDIGO recommends reporting estimated GFR in adults using the 2009 CKD-EPI (Chronic Kidney Disease Epidemiology Collaboration) creatinine equation.

Differential Diagnosis

Although hematuria has been considered one of the atypical features indicating the presence of nondiabetic renal disease in patients with diabetes, it may be present in DKD. Moreover, a study identified hematuric patients with pathologically defined DKD, who had significantly lower renal function than nonhematuric patients with DKD.[79] The prevalence of nephrotic syndrome and retinopathy was significantly higher in hematuric patients than in nonhematuric patients with diabetic glomerulosclerosis.

On the other hand, other forms of kidney disease may be found in patients with type 2 diabetes. Younger patients with diabetes, shorter duration of diabetes, and proteinuria in the absence of retinopathy strongly suggest nondiabetic renal disease.[80] Membranous nephropathy,

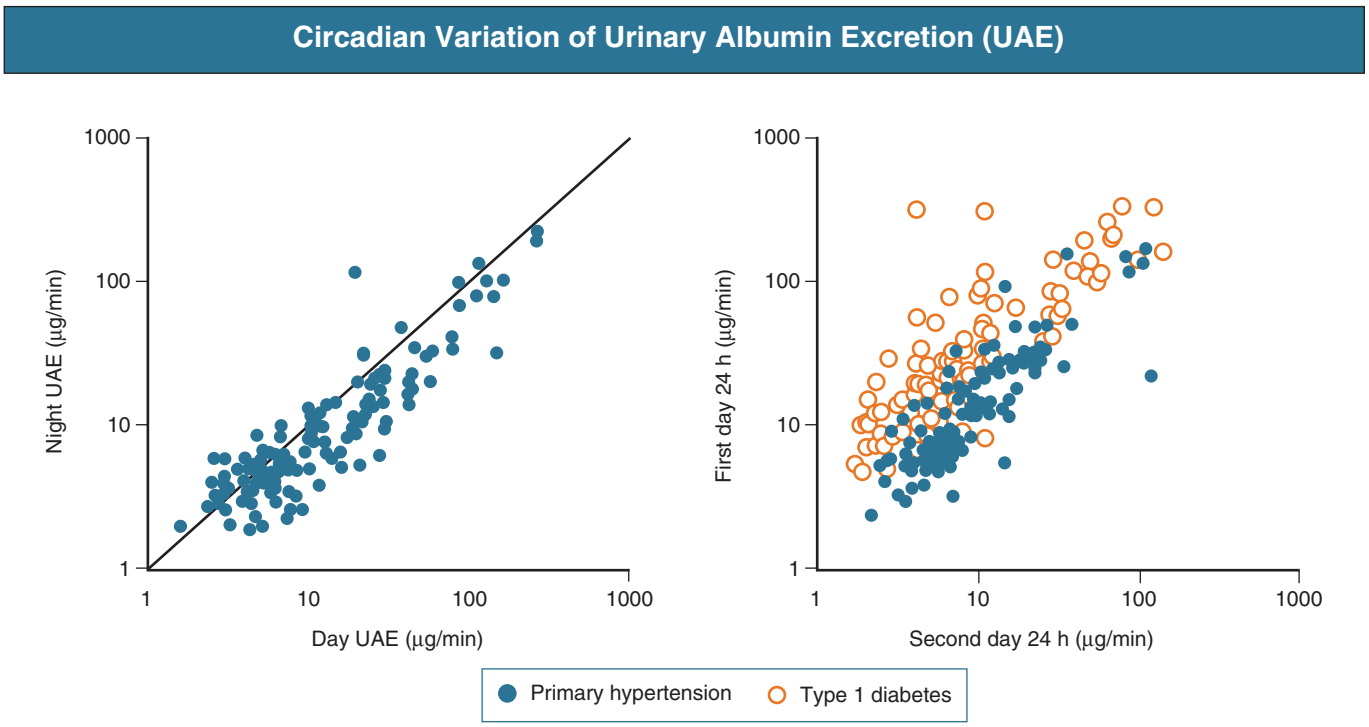

Fig. 30.18 Circadian variation of urinary albumin excretion *(UAE).* UAE is lower in resting conditions at night than during daytime activity. Relationship between UAE assessed on two different days 1 week apart in patients with type 1 diabetes *(open circles)* and primary hypertension *(closed circles)*. There is substantial individual day-to-day variation of albumin excretion and also between day and night collections. (From reference 78.)

FSGS, acute interstitial nephritis, postinfectious GN, and IgA nephropathy have all been described in patients with type 2 diabetes in whom DKD was clinically suspected (Fig. 30.19).

Indications for Renal Biopsy

Further investigation, including renal biopsy, should be considered in the following situations (Fig. 30.20):

- If retinopathy is not present in type 1 diabetes with proteinuria or moderately impaired renal function (absence of retinopathy does not exclude DKD in type 2 diabetes).
- If the onset of proteinuria has been sudden and rapid, particularly in type 1 diabetes, and if the duration of type 1 diabetes has been less than 5 years. Alternatively, if the evolution has been atypical, for example, without transition through the usual stages,

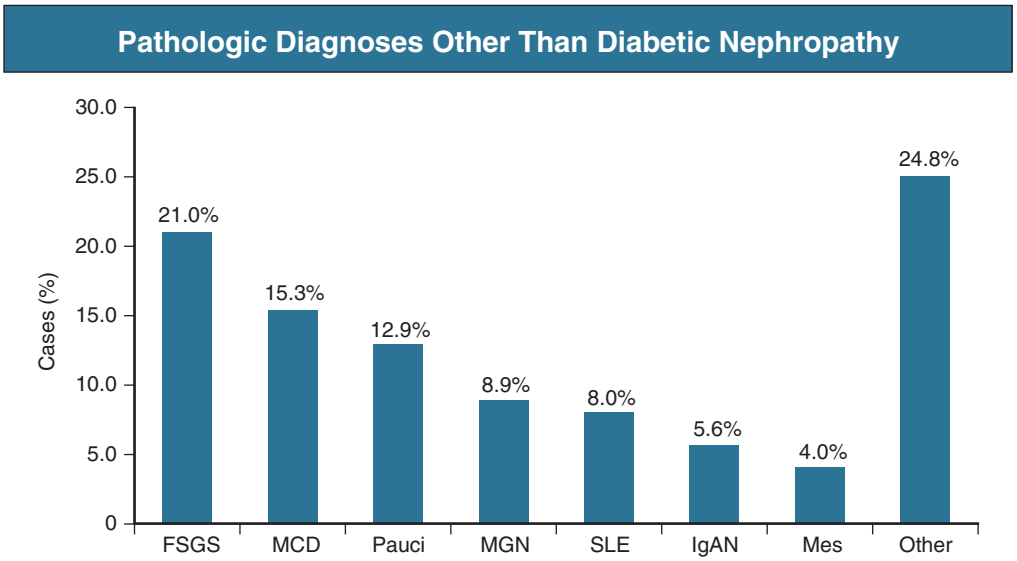

Fig. 30.19 Pathologic diagnoses other than diabetic nephropathy are found in more than half of patients with type 2 diabetes with proteinuria. A total of 233 patients were studied; 53.2% (124 patients) had a diagnosis of nondiabetic renal disease. *FSGS,* focal segmental glomerulosclerosis; *IgAN,* IgA nephropathy; *MCD,* minimal change disease; *Mes,* mesangial immune complex glomerulonephritis; *MGN,* membranous nephropathy; *Pauci,* ANCA-positive pauci-immune glomerulonephritis; *SLE,* systemic lupus erythematosus. (From reference 80.)

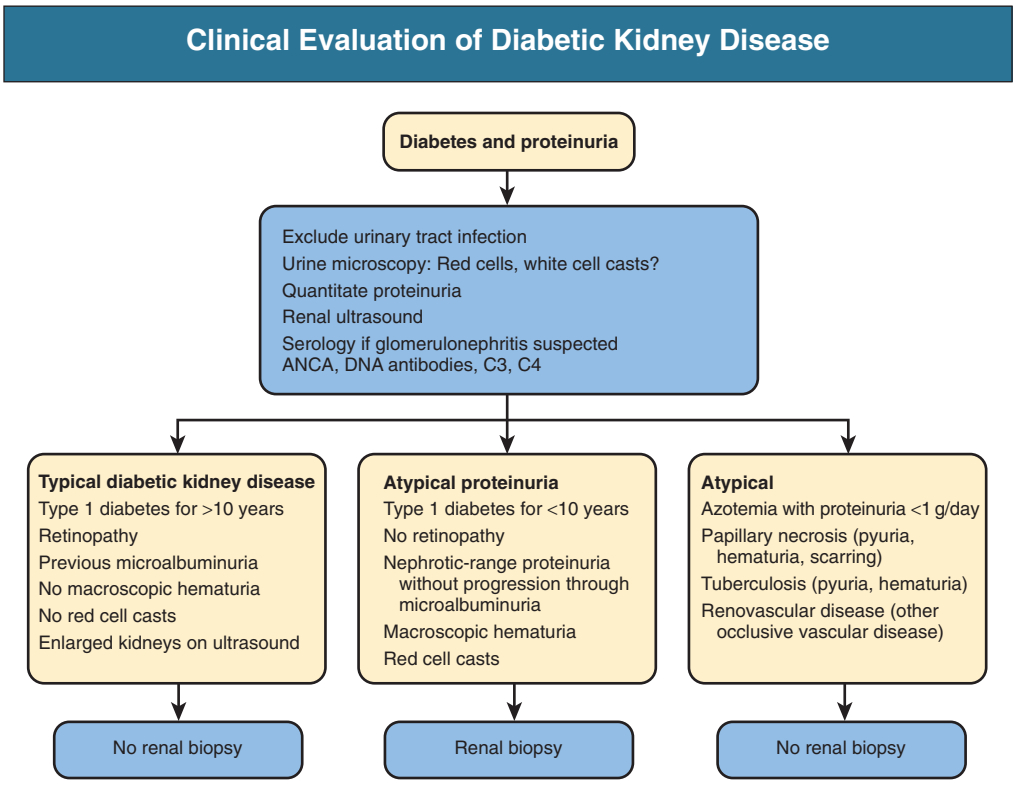

Fig. 30.20 Clinical evaluation of diabetic kidney disease. *ANCA,* Antineutrophil cytoplasmic autoantibody.

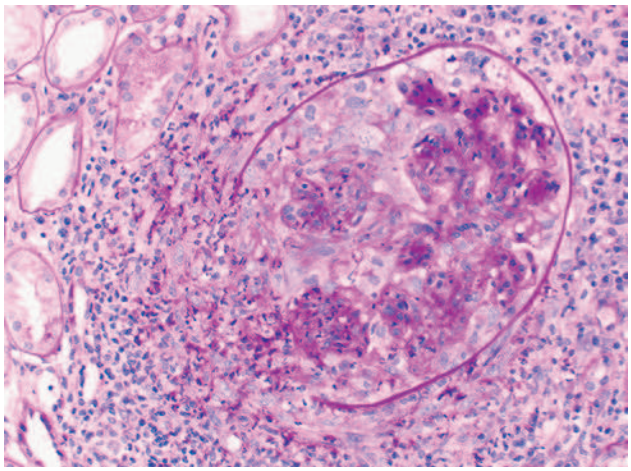

Fig. 30.21 Glomerulonephritis superimposed on diabetic kidney disease (DKD). A glomerulus showing a cellular crescent with rupture of the Bowman capsule superimposed on nodular DKD. The patient, known to have DN, presented with rapidly deteriorating renal function and red cell casts in the urine.

particularly the development of nephrotic syndrome without previous microalbuminuria.

- If there is macrohematuria or an active nephritic urinary sediment including acanthocytes or red blood cell casts suggesting GN; the sediment in DKD typically is unremarkable apart from some occasional erythrocytes.
- If the decline in renal function is exceptionally rapid, or if renal dysfunction is found without significant proteinuria (first, renovascular disease must be excluded) (Fig. 30.21).

If renal ultrasound reveals small kidneys or a significant size difference, it is prudent not to perform a renal biopsy. With the recognition of molecular tools to better classify kidney disease, there may be benefit for increased use of renal biopsies to better characterize the heterogeneity of disease in the future.

Approach to the Diabetic Patient With Impaired Renal Function

When seeing a diabetic patient with CKD, the nephrologist should do the following:

- Assess the cause of CKD (acute vs. chronic renal impairment; DKD vs. alternative causes of renal damage).
- Assess the magnitude of proteinuria and the rate of progression.
- Search for evidence of the typical extrarenal microvascular and macrovascular complications of diabetes.

The majority of diabetic patients with heavy proteinuria or renal failure have DKD. Renal ischemia (atherosclerotic renal artery stenosis or cholesterol embolism) is common in diabetic patients, and a substantial proportion of patients with type 2 diabetes have small kidneys and low GFR without albuminuria, possibly the result of macrovascular disease.

If urinary tract infection occurs, it is more severe in the diabetic than the nondiabetic patient. Purulent papillary necrosis and intrarenal abscess formation, however, have now become rare.

Diabetic patients with nephropathy are particularly prone to development of AKI after administration of NSAIDs or radiocontrast media or after cardiovascular events or septicemia. Preventive measures for AKI are discussed in Chapter 70. AKI superimposed on preexisting DKD carries a very poor renal prognosis.

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements about diabetic nephropathy is correct?
   - **A.** The pathophysiology for diabetic nephropathy is different in type 1 and type 2 diabetes.
   - **B.** Glomerulosclerosis, tubular atrophy, and tubulointerstitial lesions are typical pathologic findings in diabetic nephropathy.
   - **C.** Development of diabetic nephropathy is always associated with microalbuminuria.
   - **D.** Development of diabetic nephropathy is always associated with hypertension.
2. Which of the following is *not* a risk factor for the development of diabetic kidney disease?
   - **A.** Genetic background
   - **B.** Hyperglycemia
   - **C.** Smoking
   - **D.** Anemia
   - **E.** Type of diabetes
3. Which of the following findings may suggest a nondiabetic origin of the renal disease?
   - **A.** Proteinuria greater than 2 g/day
   - **B.** Large kidneys on ultrasound
   - **C.** Increased serum creatinine
   - **D.** Acanthocytes in urine sediment
4. Which of the following observations suggests inflammation is a feature in diabetic kidney disease?
   - **A.** Increased transforming growth factor-β levels
   - **B.** Inflammasome activation in the diabetic kidney
   - **C.** Markedly elevated C-reactive protein and ferritin levels
   - **D.** Peripheral leukocytosis
   - **E.** Presence of urinary red and white cell casts

31

Prevention and Treatment of Diabetic Kidney Disease

Li-Li Tong, Sharon Adler, Christoph Wanner

In diabetic patients, the development of diabetic kidney disease (DKD) signifies the presence of a generalized microvascular syndrome that is frequently accompanied by macrovascular disease. (see Chapter 30). The terms DKD and diabetic nephropathy (used in previous editions of this chapter) are synonymous, and encompasses the spectrum of vascular, glomerular, and tubulointerstitial components of chronic kidney disease (CKD) attributed to diabetes. Classically, DKD evolves through several clinical stages based on urine albumin excretion (UAE) values: normoalbuminuria, moderately increased albuminuria (previously called microalbuminuria), and severely increased albuminuria (previously called macroalbuminuria, or overt nephropathy).[1] Furthermore, a substantial proportion of diabetic patients have a nonproteinuric phenotype with progressive loss of glomerular filtration rate (GFR). There is consensus that both the level of UAE and GFR have predictive importance for both renal outcome and cardiovascular (CV) morbidity and mortality. Normoalbuminuria is arbitrarily defined by a UAE of less than 30 mg/24 h, a threshold far above the normal albumin excretion in most healthy individuals. Thus, even in patients with normoalbuminuria, an incremental elevation of UAE is associated with increased cardiorenal risk.

In patients with established DKD, regression of albuminuria and preservation of renal function, although difficult, is the ideal treatment goal. Strict blood pressure (BP) and glycemic control early in the disease course is vital. Aggressive lipid-lowering and lifestyle modifications, including adherence to low-protein and low-sodium diet, exercise, weight loss, and smoking cessation all are beneficial and likely to improve renal and CV outcomes. Such multifactorial therapy has been shown to result in impressive lowering of the risk for cardiovascular disease (CVD), nephropathy, retinopathy, and autonomic polyneuropathy in the Steno 2 trial in patients with type 2 diabetes, and even a delayed reduction of mortality was seen.[2] Most patients with advanced-stage diabetic kidney disease, however, are likely to die from CVD or progress to end-stage renal disease (ESRD), even though treatment may slow this progression.

This chapter reviews the current preventive and therapeutic strategies that promote renoprotection and cardioprotection in diabetic patients (Fig. 31.1). In general, the treatment principles for established DKD are similar to those adopted for the prevention of DKD, although multiple and more intensive strategies may be required for treatment and the magnitude of benefit tends to be greater at earlier stages of disease. Patients with DKD often require multiple antihypertensive agents (including renin-angiotensin system [RAS] blocking agents) to achieve BP goal, insulin therapy in type 1 diabetes, two or more drugs for glucose control in type 2 diabetes, at least one lipid-lowering agent, and aspirin or other antiplatelet agents for CV protection. One obstacle to achieving adherence is the complexity of these regimens. Therefore prevention and treatment of patients with DKD needs to be individualized and requires consideration of the cost, side effects, and convenience of the drug regimen measured against the anticipated benefits. Special considerations are indicated in the management of the diabetic patient with advanced CKD (see Chapter 32). Many therapeutic issues discussed here are not specific for DKD and thus are also relevant for CKD in general (see Chapter 79).

GLYCEMIC CONTROL

In patients with type 1 diabetes, strict glycemic control decreases the risk for albuminuria and impaired glomerular filtration rate (GFR). The Diabetes Control and Complications Trial (DCCT) compared the effects of intensive glucose control with conventional treatment on the long-term complications of type 1 diabetes (Fig. 31.2). During a 9-year period, patients with mean hemoglobin A_{1c} (HbA_{1c}) of 7% who received intensive therapy had a 35% to 45% lower risk for development of moderately increased albuminuria compared with the control group (mean HbA_{1c} 9%).[3] Furthermore, the DCCT and Epidemiology of Diabetes Interventions and Complications (EDIC) trial data indicated that the long-term risk for developing impaired GFR was lower by 50% in patients treated for an average of 6.5 years with intensive glucose control than among those treated with conventional therapy. This effect was not evident until more than 10 years after randomization, beyond the period of the DCCT treatment intervention.[4]

For patients with type 2 diabetes, several major studies have also demonstrated a lower risk for nephropathy with stricter glycemic control. In a study design similar to the DCCT, the Kumamoto study found a 60% reduction in moderately increased albuminuria in relatively young, nonobese patients with type 2 diabetes receiving intensive glycemic treatment (HbA_{1c} 7.1%) compared with conventional treatment (HbA_{1c} 9.4%).[5] In the United Kingdom Prospective Diabetes Study (UKPDS) trial, newly diagnosed patients with type 2 diabetes were assigned to intensive management (HbA_{1c} 7.0%) with a sulfonylurea or insulin or to conventional management (HbA_{1c} 7.9%) with diet alone. After 9 years of intensive therapy, relative risk reduction for the development of moderately increased albuminuria was 24%.[6] After termination of the study, patients were observed for a further 10 years. The differences in HbA_{1c} were lost within 1 year, but a 24% lower risk of microvascular disease and myocardial infarction (−15%) persisted. All-cause mortality was also reduced (−13%). This phenomenon of ongoing beneficial effects on diabetic complications after a period of improved glycemic control even if followed by a return to less intensive metabolic control has been termed "metabolic memory" or "legacy effect." It underlines the importance of early glycemic control in the primary prevention of microvascular and macrovascular complications in diabetic patients.

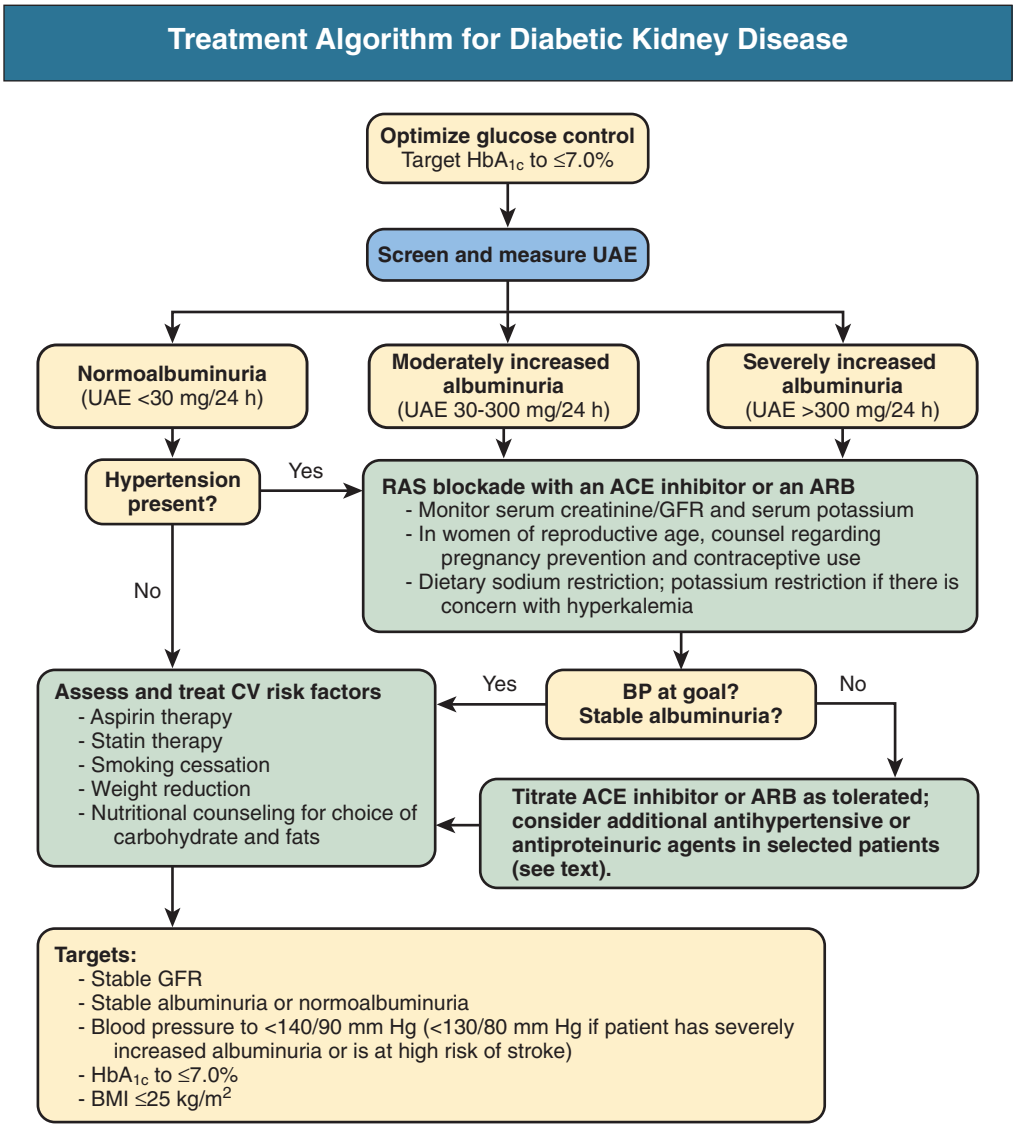

Fig. 31.1 Treatment algorithm for diabetic kidney disease. In considering the management of patients with diabetes and chronic kidney disease (CKD), a global perspective is required, which includes therapy that retards progression of kidney disease as well as therapy that minimizes cardiovascular risk and addresses other major diabetic complications, including coronary artery disease, peripheral artery disease, retinopathy, neuropathy, gastroparesis, and dyslipidemia. *ACE,* Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *BP,* blood pressure; *CV,* cardiovascular; *GFR,* glomerular filtration rate; *Hb,* Hemoglobin; *HTN,* hypertension; *RAS,* renin-angiotensin system; *UAE,* urine albumin excretion.

Most of the evidence favoring strict glycemic control comes from studies of patients with normoalbuminuria or early stages of DKD. Fewer studies addressed intensive glycemic control in patients with more advanced stages of DKD, in whom it may be difficult to show a benefit because the results are confounded by the effects of concomitant hypertension and CVD. Even so, there is evidence to support glycemic control in reducing the risk for worsening albuminuria and renal functional decline.[4,7] Furthermore, in patients with type 1 diabetes with DKD, glycemic control also may improve renal histology. Renal biopsy specimens from pancreatic transplant recipients in whom true euglycemia is restored showed stabilized glomerular structure at 5 year follow-up and improved glomerular and tubular structure at 10 years after transplantation.[8]

Glycemic Targets

Several major trials tested whether strict glycemic control reduced CVD risk in type 2 diabetics. The Action in Diabetes and Vascular Disease, Perindopril and Indapamide Controlled Evaluation (ADVANCE) study showed that intensive blood glucose control (HbA_{1c} 6.5% vs. 7.3%) yielded a 10% relative reduction in major macrovascular and microvascular events, in particular a 21% relative reduction in nephropathy.[9] However, in the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial, very tight glycemic control (lowering of HbA_{1c} to median of 6.4% vs. 7.5% with conventional control) was associated with 22% increase in mortality from any cause and did not significantly reduce major CV events.[10] A third major study of tight glucose control in

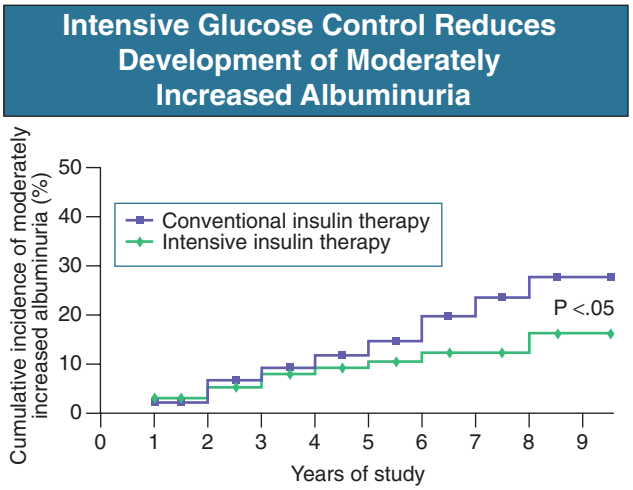

Fig. 31.2 Moderately increased albuminuria risk reduction with intensive versus conventional insulin therapy. Intensive glucose control was associated with a decreased risk for the subsequent development of moderately increased albuminuria in patients with type 1 diabetes. (Modified from reference 3.)

patients with type 2 diabetes, the Veterans Affairs Diabetes Trial (VADT), found no significant reduction in CV deaths or events over 7.5 years in high-risk patients treated aggressively for glycemic control (median HbA_{1c} 6.9%) compared with standard therapy (median HbA_{1c} 8.4%).[11]

It is apparent that glycemic control must be individualized and take into account the patient's age, duration of diabetes, presence of CVD, presence of CKD, and microvascular risks and complications, as well as previous glycemic control and susceptibility to and awareness of hypoglycemia. In younger patients with short duration of diabetes, high life expectancy, low risk for hypoglycemia, and no prior CV events, strict glycemic control can reduce the risk for nephropathy and other microvascular complications. Major guidelines, including the National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (KDOQI), recommend lowering HbA_{1c} levels to a goal of approximately 7.0% for most patients with type 1 and type 2 diabetes.[12] This roughly translates to maintaining a fasting glucose of 80 to 130 mg/dl (4.4 to 7.2 mmol/l) and a postprandial glucose of less than 180 mg/dl (10 mmol/l). However, a more cautious approach to glycemic control is sensible in the frail or elderly patient with long-standing diabetes or preexisting CV problems or who is susceptible to hypoglycemic episodes. In these patients, the HbA_{1c} goal may be set higher (e.g., <8.0%). Accordingly, the American Diabetes Association (ADA) and the European Association for the Study of Diabetes (EASD) endorse tight glycemic control at the onset of diabetes in patients with few comorbidities as a preventive strategy and less stringent control in patients with more advanced comorbidities.[13]

Antihyperglycemic Therapeutic Options in Type 2 Diabetic Kidney Disease

The choice of antihyperglycemic therapy in patients with type 2 diabetes is a highly individualized decision, with consideration of medication-associated adverse events, degree of renal impairment, patient preference, cost, and convenience of therapy (see Chapter 32). Recent trials of novel antihyperglycemic therapies such as sodium glucose cotransporter-2 (SGLT2) inhibitors, dipeptidyl peptidase-4 inhibitors (DPP4i), and glucagon-like peptide-1 (GLP-1) analogues have expanded the options to control glycemia and BP in patients with type 2 diabetes and improve CV and/or renal outcomes.

SGLT2 Inhibitors

Empagliflozin, dapagliflozin, and canagliflozin, are now widely approved antihyperglycemic therapies with a glycosuric mechanism. SGLT2 inhibitors induce osmotic diuresis and have natriuretic effects contributing to plasma volume contraction. They decrease systolic and diastolic BP by 4 to 6/1 to 2 mm Hg, respectively. They also decrease weight. SGLT2 inhibition is associated with an acute, dose-dependent reduction in eGFR by approximately 5 ml/min/1.73 m^2 and approximately 30% to 40% reduction in albuminuria. These effects mirror preclinical observations suggesting that proximal tubular natriuresis activates renal tubuloglomerular feedback through increased macula densa sodium and chloride delivery, leading to afferent vasomodulation.[14] Glycosuric effects are attenuated in patients with CKD (eGFR <60 ml/min/1.73 m^2) but BP, eGFR, and albuminuria lowering effects are preserved.

With regard to long-term clinical outcomes, the Empagliflozin Cardiovascular Outcome Event (EMPA-REG OUTCOME) trial, using empagliflozin 10 or 25 mg/day in patients with type 2 diabetes and established CVD reported a 14% reduction in the primary composite outcome of CV death, nonfatal myocardial infarction, nonfatal stroke, and more than 30% reductions in CV mortality, overall mortality, and heart failure hospitalizations.[15] The recently published Canagliflozin Cardiovascular Assessment Study (CANVAS) showed a similar magnitude of CV events reduction using canagliflozin in patients with type 2 diabetes and a high risk of CVD. Therefore some guidelines now recommend that SGLT2 inhibitors with proven CV benefit be prioritized in patients with type 2 diabetes with insufficient glycemic control and who have atherosclerotic CVD. Furthermore, the EMPA-REG OUTCOME study reported a 39% reduction in incident or worsening nephropathy that included doubling of serum creatinine (relative risk reduction, 44%) and renal-replacement therapy (relative risk reduction, 55%) in the empagliflozin group, while the CANVAS-Renal trial similarly reported an impressive 40% reduction in the composite renal outcome (defined as a sustained 40% reduction in the rate of eGFR decline, need for renal replacement therapy, or death from renal causes).[15a,16] However, one concern with the use of SGLT2 inhibitors is an increase incidence of acute kidney injury, which has been reported in up to 6% of cases, especially with canaglifozin.

Analogues of Human Glucagon-Like Peptide-1

Several GLP-1 analogues, including liraglutide and semaglutide, have been approved for the treatment of type 2 diabetes. They effectively lower glucose levels and slightly reduce weight and BP. The Liraglutide Effect and Action in Diabetes: Evaluation of Cardiovascular Outcome Results (LEADER) trial showed that fewer patients in the liraglutide group (relative risk reduction, 22%) died from CV causes, and the rate of death from any cause was lower (15%) as well. Fewer patients experienced a nephropathy end-point (−23%), which consisted mainly in a reduction of severely increased albuminuria.[17] Similar results were obtained in the Trial to Evaluate Cardiovascular and Other Long-term Outcomes With Semaglutide in Subjects With Type 2 Diabetes (SUSTAIN-6) study.[18]

Dipeptidyl Peptidase-4 Inhibitors

The dipeptidyl peptidase-4 (DPP-4) inhibitors (i.e., gliptins) represent another new class of antihyperglycemic therapy for patients with type 2 diabetes and can be used even in patients with advanced CKD. Treatment with DPP-4 inhibitors reduce albuminuria, although it is unclear whether this is a valid marker of renal protection. So far, clinical trials of DPP-4 inhibitors have demonstrated no additional CV outcome benefit compared with placebo.[19]

Blood Pressure Control

In patients with type 1 diabetes the appearance of moderately increased albuminuria typically precedes hypertension. In patients with type 2 diabetes, however, as many as 40% have known hypertension before the diagnosis of DKD. Once overt nephropathy develops, hypertension is an almost universal finding and is associated with volume expansion and salt sensitivity. The absence of hypertension in an untreated patient with overt nephropathy should raise suspicion for underlying cardiac problems. In both patients with type 1 and 2 diabetes, higher BP is associated with increasing albuminuria, with more rapid progression, and increased risk for kidney failure, as well as increased risk for fatal and nonfatal CV events.[20] Thus effective treatment of systemic hypertension is arguably the single most important strategy in the treatment of established DKD (Fig. 31.3). Antihypertensive therapies, regardless of agent used, reduce UAE, delay progression of nephropathy, postpone renal impairment, and improve survival in both patients with type 1 and type 2 diabetes with DKD.

The optimal BP target in DKD remains unclear. Guidelines published before the Action to Control Cardiovascular Risk in Diabetes Blood Pressure (ACCORD BP) trial suggested a BP target in diabetic patients of less than 130/80 mm Hg. However, this BP target was challenged by findings of the ACCORD BP trial. Among diabetic patients with high CV risk randomized to goal systolic BP of less than 120 mm Hg or standard therapy aiming for under 140 mm Hg, there was no difference in the risks for composite major CV events, but the risks for hyperkalemia and renal dysfunction were increased at lower BP goals.[21] A cross-sectional analysis of patients in the Swedish National Diabetes Registry also failed to show a reduction in mortality in patients with systolic BP below 130 versus 130 to 139 mm Hg.[22] In the Irbesartan Diabetic Nephropathy Trial (IDNT), progressive lowering of systolic BP to 120 mm Hg was associated with improved renal and patient survival, an effect independent of baseline renal function.[23] Mortality increased with systolic BP below 120 mm Hg, although a cause-and-effect relationship cannot be inferred from the data. From a safety perspective, low diastolic pressure is poorly tolerated, and the incidence of myocardial infarction and mortality increases at values below 70 mm Hg, at least in patients with coronary heart disease, presumably because coronary perfusion occurs only during diastole. Indeed, in the IDNT study, CV mortality increased not only with higher systolic pressure but also with low diastolic pressure.

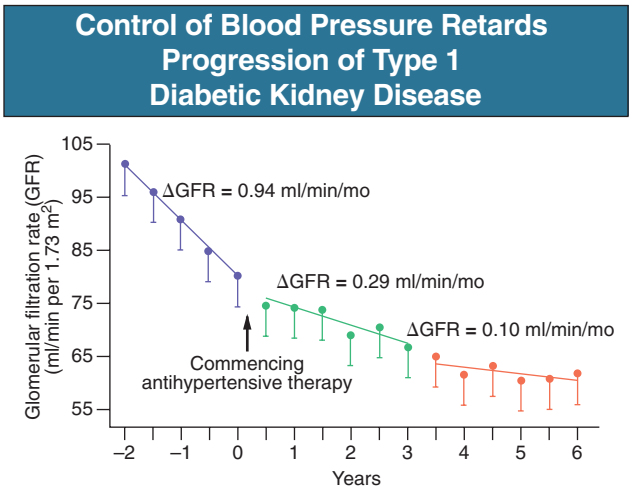

Fig. 31.3 Control of blood pressure reduces the risk for progression in type 1 diabetic kidney disease. (Modified from reference 20.)

Our recommendation for BP goals is consistent with the 2012 KDIGO guideline for BP control in diabetic patients, aiming for a target BP of less than 140/90 mm Hg for all diabetic patients and less than 130/80 mm Hg for patients with CKD and/or UAE of greater than 30 mg/24 h.[24] The 2016 American Diabetes Association (ADA), the 2014 Joint National Committee (JNC) 8, and the 2013 European Society of Hypertension/European Society of Cardiology (ESH/ESC) guidelines advocate similar targets. For diabetic patients at highest risk for cerebrovascular accident, the ACCORD BP trial showed that lower systolic BP goals (i.e., <120 mm Hg) may provide greater protection against stroke, but the potential risks for and burdens of serious adverse events attributable to antihypertensive therapy must be considered with such treatment goals.

Renin-Angiotensin System Blockade in the Prevention of Diabetic Kidney Disease

We do not recommend the use of RAS blockade in normotensive, normoalbuminuric diabetic patients for the primary prevention of DKD. Most patients with diabetes do not develop DKD, even after long periods of uncontrolled hyperglycemia, and there are hazards in the use of RAS blockers, including their potential teratogenicity. In a post hoc analysis of the multicenter Diabetic Retinopathy Candesartan Trials (DIRECT) program, which included patients with normotensive and normoalbuminuric type 1 diabetes and normoalbuminuric type 2 diabetes with or without hypertension, the ARB candesartan was found to have no effect on the development of moderately increased albuminuria.[25]

In hypertensive, normoalbuminuric diabetic patients, an ACE inhibitor or ARB are both effective as a first-line antihypertensive agent. The Bergamo Nephrologic Diabetes Complications Trial (BENEDICT), which randomized patients with hypertension, normoalbuminuria, and type 2 diabetes to placebo, verapamil, trandolapril, or a combination of verapamil plus trandolapril, showed less progression to moderately increased albuminuria in patients receiving trandolapril either alone or with verapamil.[26] Results with verapamil alone was no different from that with placebo. There were similar findings in smaller studies with other RAS blockers, implicating a class effect. Longer term studies would be required to demonstrate the effects of RAS blockade on the clinically important outcomes of death, dialysis, and doubling of serum creatinine level in normoalbuminuric patients.

Renin-Angiotensin System Blockade in the Treatment of Diabetic Kidney Disease

In diabetic patients with established DKD, RAS blockade with ACE inhibitors, or ARBs confers renoprotection that is independent of BP reduction. Intraglomerular hemodynamic and nonhemodynamic renal effects of angiotensin II best explain the observed renoprotection. Supporting this hypothesis, in vitro models of DKD show cellular effects of RAS inhibition that are consistent with benefits independent of BP effects (see Chapter 30).

Type 1 Diabetic Patients

In patients with type 1 diabetes with moderately increased albuminuria, ACE inhibitors reduce the risk for progression to overt nephropathy. In a meta-analysis in normotensive patients with type 1 diabetes and moderately increased albuminuria treated with ACE inhibitors, the majority for more than 2 years, treatment was associated with a 60% reduction in progression to severely increased albuminuria and a threefold increase in regression to normoalbuminuria.[27] Changes in BP cannot entirely explain the antiproteinuric effect of ACE inhibitors.

In patients with severely increased albuminuria or overt nephropathy, the Collaborative Study Group trial demonstrated that captopril reduced albuminuria, slowed loss of GFR, and delayed the onset of kidney failure

compared with placebo.[28] The beneficial effect of captopril was greater in patients with reduced GFR at baseline largely because one of the components of the composite end-point, a doubling of baseline serum creatinine level, was achieved more quickly in these patients.

Data are insufficient to demonstrate the efficacy of ARBs in type 1 DKD. Nevertheless, based on the shared properties of ACE inhibitors and ARBs in inhibiting the RAS, there is reason to believe that both are effective in the treatment of type 1 DKD.

Type 2 Diabetic Patients

In patients with type 2 diabetes, more data are available on the renoprotective effect of ARBs compared with ACE inhibitors. In the stage of moderately increased albuminuria, the IRMA 2 study showed that irbesartan reduced progression to overt nephropathy by 70% in patients with hypertension and type 2 diabetes during a 2-year follow-up period.[29] In the MARVAL trial, valsartan produced a greater reduction in UAE than did amlodipine (44% vs. 8%), with the same degree of BP reduction, suggesting that the antiproteinuric effect of ARBs is BP independent.[30]

In patients with type 2 diabetes with severely increased albuminuria and decreased GFR, large RCTs (IDNT and RENAAL) have demonstrated that ARBs are effective in lowering proteinuria and decreasing the relative risk for reaching the composite end-point of death, dialysis, and doubling of serum creatinine level.[31,32] However, the risk reduction for reaching the composite end-point was only 18% to 20% in these studies in patients with type 2 diabetes and nephropathy, compared with the more robust risk reduction of about 50% in patients with type 1 diabetes receiving captopril. ARBs did not decrease CV death in these trials but did decrease the incidence of heart failure.

Compared with ARBs, data on the efficacy of ACE inhibitors in type 2 DKD are less strong, largely because available studies had a small sample size or short follow-up. Nevertheless, some studies did show that ACE inhibitor use results in greater reduction in albuminuria and slower decrease in GFR compared with other antihypertensive agents. Whereas both ACE inhibitors and ARBs are probably effective for treatment of DKD in patients with type 2 diabetes, few studies have directly compared their efficacy. In a small RCT of patients with type 2 diabetes with early DKD and 5-year follow-up, telmisartan was not inferior to enalapril in providing long-term renoprotection.[33]

Aldosterone Blockade in Diabetic Kidney Disease

Although many studies have demonstrated a beneficial effect of ACE inhibitors and ARBs in retarding progressive renal disease, these studies did not differentiate between the relative contributions of the RAS blockade versus aldosterone system blockade (see Chapter 7). In fact, plasma aldosterone levels are elevated in a subset of patients despite ACE inhibitor and ARB therapy (also known as aldosterone breakthrough; see Chapter 79). In studies that defined aldosterone breakthrough as any increase from an individual's baseline serum aldosterone level (i.e., before RAS blockade), the incidence ranged from 40% over 10 months to 53% over 12 months.[34] In addition to its classic effects of promoting sodium retention and enhancing potassium and magnesium excretion, aldosterone promotes tissue inflammation and fibrosis.[35] Small studies have demonstrated considerably faster decline in GFR in patients who experienced aldosterone breakthrough (median, −5.0 ml/min/yr) than in those who did not (median, −2.4 ml/min/yr).

Aldosterone blockade using a mineralocorticoid receptor antagonist (MRA) such as spironolactone or eplerenone has been shown to reduce proteinuria when used alone and has an additive effect on proteinuria when combined with ACE inhibitor or ARB.[36] However, the risk for hyperkalemia frequently limits the use of combined MRA with ACE inhibitors or ARBs, especially in patients with reduced GFR. Current evidence is not strong enough to support widespread screening for aldosterone breakthrough. In select patients, the addition of a MRA with close monitoring of serum potassium levels may represent optimal therapy for patients with aldosterone breakthrough who no longer show maximal antiproteinuric effects with RAS blockers, although there is no definitive evidence that this will improve clinical outcomes. In addition to diuretic therapy, resins for chronic use that lower serum potassium can reduce the incidence of hyperkalemia in patients with CKD. Aggressive use of resins may offer the potential to enhance the therapeutic impact of renin-angiotensin-aldosterone inhibition while modulating hyperkalemia, but additional randomized trials are required.

Combination Therapy With Renin-Angiotensin System Antagonists

Combination therapy with RAS antagonists is not recommended in the treatment of DKD. Although earlier small trials suggested combined therapy with an ACE inhibitor and an ARB is more effective in reducing BP and proteinuria than is either drug alone,[37] results of several large trials failed to show improved clinical outcome. The Ongoing Telmisartan Alone and in Combination with Ramipril Global End-point Trial (ONTARGET), which included diabetic and nondiabetic patients with CV risk, failed to show improved CV outcomes from a combination of an ACE inhibitor and an ARB. Instead, it showed more rapid loss of kidney function in some patients, a trend toward an increase in the development of ESRD that fell just short of statistical significance, and a possible increase in mortality.[38] The more recent Veterans Affairs Nephropathy in Diabetes study (VA NEPHRON-D)[39] tested combination therapy with ACE inhibitor and ARBs in patients with type 2 diabetes with overt nephropathy and found no difference in the primary end-point of CKD progression or death. There was, however, an impressive increase in hyperkalemia (6.3 vs. 2.6 events/100 person-years; $P < .001$) and doubling of the risk for acute kidney injury (12.2 vs. 6.7 events/100 person-years; $P < .001$) with combination therapy compared with ARB alone.

ACE inhibitors or ARBs have been studied in combination with a direct renin inhibitor (aliskiren). Further reductions in proteinuria have been reported with these combinations compared with the ACE inhibitor or ARB alone. However, as was seen in ONTARGET and VA NEPHRON-D studies, an incremental antiproteinuric effect is not automatically translated into clinical outcome benefits. The large Aliskiren Trial in Type 2 Diabetics Using Cardio-Renal End-points (ALTITUDE) was terminated prematurely because of findings that a combination of aliskiren and ACE inhibitors or ARBs caused considerable increase in nonfatal stroke, hypotension, hyperkalemia, and renal complications after 1.5 to 2 years.[40] Thus aliskiren could be considered as an alternative RAS blocker for its antiproteinuric and BP effects, but more research is needed to demonstrate that it is as effective as ACE-inhibitors or ARBs.

Dosing and Adverse Effects Associated With Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

In individual patients, proteinuria may continue to respond to ACE inhibitor or ARB dose escalations beyond those recommended for BP control.[41] Unfortunately, maximal dosing of ACE inhibitors or ARBs may be limited by side effects, including hyperkalemia, hypotension, and reduced GFR. In women of reproductive age, counseling about pregnancy prevention and contraceptive use should begin before a RAS blocker is started.

Serum creatinine concentration may increase up to 30% in proteinuric patients with renal impairment after starting a RAS blocker. This rise in creatinine is associated with long-term renoprotection, and therapy should not necessarily be stopped in these patients. Increases in serum

creatinine concentration above 30% after initiation of a RAS blocker should raise the suspicion of renal artery stenosis. Aggressive dose increments of ACE inhibitors or ARBs, especially in conjunction with diuresis, can precipitate acute kidney injury. In advanced CKD and aggressive sodium restriction, although RAS blockers are not contraindicated, the de novo introduction of these agents or injudicious dose increments may precipitate the need for dialysis prematurely, so some caution is appropriate.

Other Antihypertensive and Antiproteinuric Agents

Diuretics and Low Sodium Intake

The antiproteinuric effects of RAS blockers are enhanced by a low-sodium diet (e.g., <2 g sodium/day) and diuretic use. In patients with DKD, a loop diuretic or a thiazide diuretic is frequently necessary as part of the antihypertensive regimen. Combination of a diuretic with a RAS blocker is more effective than either type of treatment alone for lowering BP and proteinuria.

Calcium Channel Blockers

Dihydropyridine calcium channel blockers (dCCBs; e.g., nisoldipine, nifedipine, amlodipine) may be used as additional antihypertensive agents, but they have not been shown to reduce albuminuria or slow the progression of renal disease.[42]

Nondihydropyridine calcium channel blockers (ndCCBs; e.g., diltiazem, verapamil) have been shown in some studies to have beneficial antiproteinuric effects. A meta-analysis of randomized trials of ndCCB and dCCB in hypertensive patients with proteinuric renal disease found that at comparable BP control, ndCCB reduced proteinuria by approximately 30% compared with baseline, whereas dCCB had no appreciable effects on proteinuria.[43] These findings suggest ndCCBs are reasonable agents for BP control and can be used in combination with a RAS blocker in patients with DKD.

β-Blockers

Classic β-adrenergic blockers have adverse metabolic effects and are therefore undesirable in diabetic patients, but this is no longer true for the novel β-blockers (e.g., carvedilol, nebivolol). Despite insufficient controlled evidence, β-blockade appears to be useful because of the extremely high CV risk in patients with DKD and can be used in combination with a RAS blocker to achieve optimal BP control.

Treatment of Dyslipidemia

Most patients with DKD have dyslipidemia characterized by low levels of high-density lipoprotein (HDL) cholesterol, high triglyceride (TG) levels, and a shift from larger toward smaller LDL cholesterol. Dyslipidemia in diabetic patients may contribute to the development of glomerulosclerosis and progressive renal disease.[44] In the Diabetes Atherosclerosis Intervention Study (DAIS), patients with type 2 diabetes taking fenofibrate had a significantly lower rate of progression from normoalbuminuria to moderately increased albuminuria at 3 years compared with the placebo group.[45]

The 2013 KDIGO guidelines for Lipid Management in CKD recommend treatment with a statin in adult diabetic patients with CKD who are not treated with chronic dialysis. Because treatment with statins provides substantial CV benefit, emphasis is now placed on assessing a patient's global risk for CVD and using maximum tolerated statin intensity for primary and secondary prevention of CVD. Furthermore, existing evidence does not support a specific on-treatment LDL cholesterol target.[46] Once a patient is placed on a maximum tolerated dosage of statin, follow-up measurement of lipid levels is usually unnecessary except in instances in which the results would modify management. In contrast, once a patient has ESRD and is placed on dialysis, statin therapy may come too late to translate into improved CV outcomes (see Chapter 32).[47]

In diabetic patients, LDL cholesterol is not the sole lipid that defines CV risk. As major statin trials have demonstrated, lowering of LDL cholesterol does not prevent the majority of adverse CV events and does not bring the CV risk in diabetics down to the level of nondiabetic patients (referred to as residual CV risk). Atherogenic dyslipidemia, specifically elevated TG, low HDL cholesterol, elevated apolipoprotein B, and elevated apolipoprotein C III, are thought to be key factors associated with residual CV risk in diabetic patients.[48] In the UKPDS, elevated TG was independently associated with albuminuria in patients with type 2 diabetes. Thus interventions aimed at improving all lipid targets are recommended. However, it is not clear whether this is best achieved by intensification of statin therapy or supplementation of statin therapy with a fibrate or omega-3 fatty acids. In the ACCORD Lipid trial, routine use of combination therapy with a statin plus a fibrate did not reduce CV risk in patients with type 2 diabetes.[49]

Nonpharmacologic Interventions

For all diabetic patients, emphasis should be placed on lifestyle modification to lower the risk for diabetic kidney disease and CV events, including dietary restriction of salt and saturated fat, weight reduction and exercise as appropriate, and smoking cessation.

Dietary protein restriction may alleviate uremic symptoms in patients at or approaching ESRD. However, it is of uncertain benefit in the treatment of DKD. Small trials have shown low-protein diets (0.8 g/kg/day) reduce proteinuria significantly with increased plasma albumin in patients with type 2 diabetes with severely increased albuminuria.[50] A meta-analysis concluded that although low-protein diet improved proteinuria; it was also associated with lower serum albumin concentrations and was not associated with a significant improvement of renal function in patients with either type 1 or type 2 DKD.[51] Nutritionist counseling is advised for all patients with advanced CKD to avoid protein-energy malnutrition and receive education on salt, potassium, and phosphate restriction, as well as choice of carbohydrates and fats (see Chapter 86).

Lifestyle modifications such as smoking cessation and weight reduction can provide additive renal benefits and lower the risk for CV events in patients with established DKD. Smoking in particular is an independent risk factor for the development of nephropathy in type 2 diabetes and is associated with an accelerated loss of renal function. Smoking cessation ameliorates progression of moderately increased albuminuria to severely increased albuminuria and improves renal prognosis.[52] Weight reduction also may improve renal outcome. In a small RCT of obese (body mass index, >27 kg/m^2) diabetic and nondiabetic patients with proteinuric renal disease, patients who lost weight through dieting had marked improvement in proteinuria compared with those who lost no weight.[53]

EMERGING TREATMENTS FOR DIABETIC KIDNEY DISEASE

A number of therapeutic agents, some experimental and others in clinical use for other indications, have been tried with the goal of preventing or treating DKD. Unfortunately, a high rate of attrition has been observed with many investigational drugs due to failure to meet primary clinical end-points or unacceptable side effect profiles. Bardoxolone methyl (an inducer of the Nrf2 pathway), ruboxistaurin (a protein kinase C inhibitor), pirfenidone (an antifibrotic agent), pimagedine/aminoguanidine/pyridoxamine (advanced glycation end-product formation inhibitors), palosuran (a vasopeptidase inhibitor), probucol (an antioxidant), and sulodexide (a glycosaminoglycan), have all failed in various phases of

TABLE 31.1 Selected Investigational Drugs for Diabetic Kidney Disease

Drug	Mechanism of Action	Clinical Trials and Comments
Finerenone,	MRAs	In phase 2 trials, the addition of finerenone to RAS blockers improved UAE, with a low incidence of hyperkalemia.[54] Phase 3 trials (FIDELIO-4800 pts., FIGARO-6400 pts.) are underway.
Atrasentan	Endothelin A receptor blocker	In phase 2 trials, atrasentan reduced albuminuria when used with RAS blocker in patients with type 2 diabetes; significant risk for peripheral edema noted in a subgroup of patients receiving a higher dose of atrasentan (1.75 mg).[56] A phase 3 trial (SONAR-4148 pts.) was stopped early due to lower than anticipated incidence of primary end-points.
Paricalcitol,	Vitamin D receptor activators	A RCT ($n = 281$) found that addition of paricalcitol to RAS blocker lowered albuminuria in type 2 patients with DKD.[57]
Allopurinol, febuxostat, topiroxostat	Purine analogue and inhibitor of xanthine oxidase that decreases uric acid formation	Limited short-term studies have shown improved blood pressure control and slowing of CKD progression after serum uric acid lowering with allopurinol.[59]
Pentoxifylline, CTP-499	Nonselective phosphodiesterase inhibitors	In a small trial ($n = 169$) of patients with type 2 diabetes, the addition of pentoxifylline to a RAS blocker had additive antiproteinuric effect and slowed renal disease progression after the first year of treatment and maintained statistical significance with placebo after 24 mo.[60]
CCX-140	C-C Chemokine receptor 2 antagonist	A phase 2 trial of patients with type 2 diabetes with DKD on a stable RAS blocker showed a statistically significant improvement in albuminuria compared with placebo.
Baricitinib	Selective JAK1/JAK2 inhibitor	A phase 2 trial to evaluate the safety and efficacy of baricitinib in reducing UAE in patients with type 2 diabetes with DKD was completed in 2014. Official results not published yet.
Selonsertib (GS-4997)	Selective apoptosis signal-regulating kinase 1 inhibitor	A phase 2 trial evaluating the efficacy and safety of GS-4997 on top of a RAS blocker in patients with type 2 diabetes with DKD was completed in August 2016. Outcome measurements include change in UAE and eGFR. Official results not published yet.
ASP-8232	Vascular adhesion protein 1 inhibitor	Ongoing phase 2 trial to evaluate the efficacy and safety of ASP-8232 in patients with type 2 diabetes with DKD.
Bardoxolone methyl (RTA-402)	Inducer of Nrf2 pathway	A phase 3 trial of bardoxolone methyl in DKD was halted because of excess serious adverse events in the treated group. There is an ongoing phase 2 trial to assess the safety and efficacy of RTA-402 in Japanese patients with type 2 diabetes with CKD.

CKD, Chronic kidney disease; *DKD,* diabetic kidney disease; *eGFR,* estimated glomerular filtration rate; *MRA,* mineralocorticoid receptor antagonist; *RAS,* renin-angiotensin system; *RCT,* randomized controlled trial; *UAE,* urine albumin excretion.

clinical development. Ongoing trials exploring new treatments in DKD include newer, selective MRAs, endothelin receptor antagonists, drugs that target oxidative stress, xanthine oxidase inhibitors, and other anti-inflammatory and antifibrotic agents (Table 31.1).

MINERALOCORTICOID RECEPTOR ANTAGONISTS

The use of available steroidal MRAs such as spironolactone and eplerenone is often limited because of adverse side effects arising from poor selectivity for mineralocorticoid receptors and hyperkalemia. Finerenone, a newer nonsteroidal MRA, improves markers of kidney function when added to a RAS blocker in patients with DKD. Unlike the steroidal MRAs, finerenone has greater receptor selectivity and affinity in vitro. In phase 2 trials, the addition of finerenone to a RAS inhibitor improved UAE with a very low incidence of hyperkalemia compared with placebo at 90 days.[54] Phase 3 trials of finerenone in patients with DKD are underway. Several additional novel MRAs (CS-3150, MT-3995, KBP-5074) with undisclosed molecular structures are in phase 2 trials.

ENDOTHELIN RECEPTOR ANTAGONISTS

The renal endothelin system is activated in experimental DKD and in patients with DKD. The antiproteinuric effect of an endothelin A receptor blocker was shown in the Avosentan on Doubling of Serum Creatinine, End stage Renal Disease and Death (ASCEND) phase 3 clinical trial. However, avosentan-related adverse events such as fluid retention led to early termination of the ASCEND trial.[55] Another endothelin A receptor blocker, atrasentan, is more selective than avosentan, and was shown in a phase 2 trial to reduce albuminuria when used in conjunction with a RAS inhibitor in patients with type 2 diabetes.[56] Significant weight gain was noted in patients receiving atrasentan, suggesting volume overload. A large phase 3 trial (SONAR) is underway assessing the effect of atrasentan versus placebo in type 2 diabetes mellitus with DKD. It has strict entry criteria that exclude patients at risk for fluid overload.

Vitamin D Receptor Activators

Vitamin D receptor activation has been shown to reduce proteinuria in small trials of DKD. A cross-sectional analysis of the 2001 to 2006 National Health and Nutrition Examination Survey (NHANES) data showed that there was an independent association between vitamin D deficiency and insufficiency with the presence of nephropathy. The largest phase 2 RCT investigating the effect of paricalcitol (a vitamin D analogue) 1 or 2 μg/day in patients with type 2 diabetes failed to meet its primary end-point (change in UAE), but post hoc analysis showed lowered albuminuria compared with placebo in patients with high sodium intake and on a higher dose of paricalcitol.[57] The study has many limitations, however. Only 58% of the patients assigned to 2 μg/day of paricalcitol received the

full dose during the study, and the follow-up period of 24 weeks was brief. A meta-analysis of pooled data from five small and heterogeneous clinical trials ($n = 219$) suggested no significant change in UAE after vitamin D supplementation.[58]

Xanthine Oxidase Inhibitors

Epidemiologic studies suggest an independent association between asymptomatic hyperuricemia and increased risk for arterial hypertension, CKD, albuminuria, CV events, and mortality. Several open-label clinical trials have shown improvements in BP control and slowing of CKD progression after serum uric acid lowering with allopurinol. In a meta-analysis of RCTs in patients with stage 3 to 5 CKD, allopurinol was found to have a small but statistically significant improvement in eGFR, as well as a tendency toward benefit for proteinuria.[59] Clinical trials of allopurinol and its novel analogues, febuxostat and topiroxostat, are underway to assess the impact of these drug in DKD.

Phosphodiesterase Inhibitors

Pentoxifylline (PTF) is a nonselective phosphodiesterase (PDE) inhibitor currently used for symptomatic relief of claudication. It has vasodilatory and antihypertensive effects and may have beneficial hemodynamic effects in the kidney. PTF also inhibits synthesis of inflammatory cytokines. In a small trial in patients with type 2 diabetes, the addition of PTF to RAS blockade had additive antiproteinuric effects and slowed kidney disease progression after the first year of treatment and maintained statistical significance compared with placebo after 24 months.[60] Based on this and several other positive outcomes of PTF trials, more selective PDE inhibitors (CTP-499, PF-489791) have been developed, though there are insufficient data on these agents at this time.

Novel Therapeutic Approaches

Several novel investigational agents, including CCX-140 (chemokine inhibitors), baricitinib (a selective JAK1/JAK2 inhibitor), selonsertib (a selective apoptosis signal-regulating kinase 1 inhibitor), ASP-8232 (a vascular adhesion protein 1 inhibitor), SER150 (a thromboxane A2 receptor antagonist), and several drugs currently in clinical use for other indications (e.g., N-acetylcysteine, colchicine), are being evaluated for treatment of proteinuric renal disease, including DKD. A new formulation of bardoxolone methyl, RTA 402 (an inducer of Nrf2 pathway), is being tested for safety and efficacy in Japanese patients with type 2 diabetes with CKD. The role of micro-RNAs in the pathogenesis of DKD is an emerging field and may also provide additional novel treatment approaches. New insights into the molecular mechanisms that underlie the origin and progression of DKD are emerging from large-scale genetic and molecular studies in experimental models and humans.

Management of the Diabetic Patient With Chronic Kidney Disease

Rosa M. Montero, David J. A. Goldsmith

Diabetes mellitus (DM) type 2 (T2DM), and to a lesser extent type 1 (T1DM), are rapidly increasing in incidence, with more than 642 million people predicted to be affected worldwide by 2040 (Fig. 32.1).[1] In this chapter we refer to the management of both types of DM and specify where differences in management arise between the two. DM is the leading cause of chronic kidney disease (CKD) and end-stage renal disease (ESRD) in the Western world, with current therapeutic strategies often slowing but rarely completely halting the disease in all cases.

DIAGNOSTIC CONSIDERATIONS

Few people with known DM and slowly evolving CKD undergo renal biopsy to diagnose diabetic nephropathy (DN).[2] Those who undergo renal biopsy are usually selected in the context of atypical presentations of DN, such as those with frank hematuria (requiring renal and bladder imaging, cystoscopy, and, if no cause found, a renal biopsy) or those with nephrotic range albuminuria in the presence of a normal glomerular filtration rate (GFR) or a rapid increase in the severity of albuminuria.

GENERAL MANAGEMENT CONSIDERATIONS

It is well established that not everyone with DN progresses (in terms of more severe albuminuria and/or declining estimated GFR [eGFR]); in some cases this is due to premature mortality from cardiovascular (CV) disease or other comorbidity.[3,4] CKD stages 1 to 3a DN are usually managed in the community or by diabetologists whose treatment strategies require little modification until renal function deteriorates further. Those referred to a nephrologist tend to be CKD stage 3b to 5, with some requiring dialysis and/or transplantation. Therefore the remainder of this chapter will focus on how to manage this group guided by current evidence and practice guidelines.[5] We also mention newer tools and treatments that may soon become available in clinical practice.

MONITORING DIABETIC RENAL DISEASE (STAGE CKD3B-5)

The mainstay of treating DM with CKD and monitoring its progression is based on successfully controlling the product of two assays; glycosylated hemoglobin A_{1c} (HbA_{1c}) and albuminuria (typically quantified by albumin-to-creatinine ratio [ACR]).

Hemoglobin A_{1c}

HbA_{1c} is a measure that arises from a nonenzymatic Maillard reaction, in which condensation of the aldehyde group of glucose and the N-terminal amino group of the β-chain of HbA0 [N-(1-deoxyfructosyl)Hb] occurs.[6] Approximately 6% of adult hemoglobin is glycated with HbA_{1c}, forming the majority of all glycohemoglobin in human blood. Fifty percent of HbA_{1c} value arises from the previous 30 days of glucose exposure, 40% from 31 to 90 days and 10% from 91 to 121 days; hence HbA_{1c} has evolved as a marker of medium-term glycemic control. An advantage of using HbA_{1c} is its low inter-subject biologic variability that is unaffected by diurnal variation or stress.[7] The disadvantages, however, include the discrepancy in its levels with short-term mean serum glucose levels because of the longer time span that forms the result. Age, ethnicity, pregnancy, and underlying disease also may affect HbA_{1c} values.[8] The life span of red blood cells directly affects the HbA_{1c}, which is also affected by erythropoietin, iron, folic acid, and/or vitamin B_{12} deficiency; hence the limitations in CKD are profound. Despite these limitations a raised HbA_{1c} (>8% [>64 mmol/mol]) has been shown to be associated with higher all-cause and CV mortality in advanced diabetic CKD, including in patients on dialysis and transplant recipients.[9-13] Lower HbA_{1c} levels (<5.4% [<36 mmol/mol]) have been associated with increased mortality in patients with poor nutritional status. DM patients with advanced CKD, including dialysis patients, have a U- or J-shaped curve of HbA_{1c} and mortality. Too high or too low HbA_{1c} levels are therefore detrimental and (<6.5% [<48 mmol/mol]) or (>8% [>64 mmol/mol]) should be avoided.[14]

In view of the risks for hypoglycemia in patients with advanced CKD, physicians should individualize glycemic targets based on the risks and benefits in such patients.[15] Table 32.1 shows a comparison of biomarkers available to determine glycemic control. Numerous clinical trials, however, have used HbA_{1c} as a reference, and thus until further studies are conducted specifically assessing any of the novel glycemic markers in the CKD population, HbA_{1c} will continue to be used.[14] Fig. 32.2 shows a flow chart for management targets of HbA_{1c} in DM CKD3b-5. Table 32.2 shows the current standard care and target values proposed for patients with DM CKD3b-5. In dialysis patients a target HbA_{1c} of less than 8.5% (<69 mmol/mol) is recommended[16]; however, continuous glucose measurements are likely to be increasingly used in the future.

Albuminuria

Detection of albuminuria in DM CKD has been the mainstay of monitoring progression through normoalbuminuria (<30 mg albumin/24 h), microalbuminuria (30 to 300 mg albumin/24 h; now often termed *moderately increased albuminuria*) and macroalbuminuria (>300 mg albumin/24 h; now often termed *severely increased albuminuria*). Previously it has been thought that most survivors with DM will eventually develop progressive DN, with increasing albuminuria, morbidity, and mortality.[17] However, this paradigm is being challenged as people with T2DM with nonproteinuric DM CKD have been described as

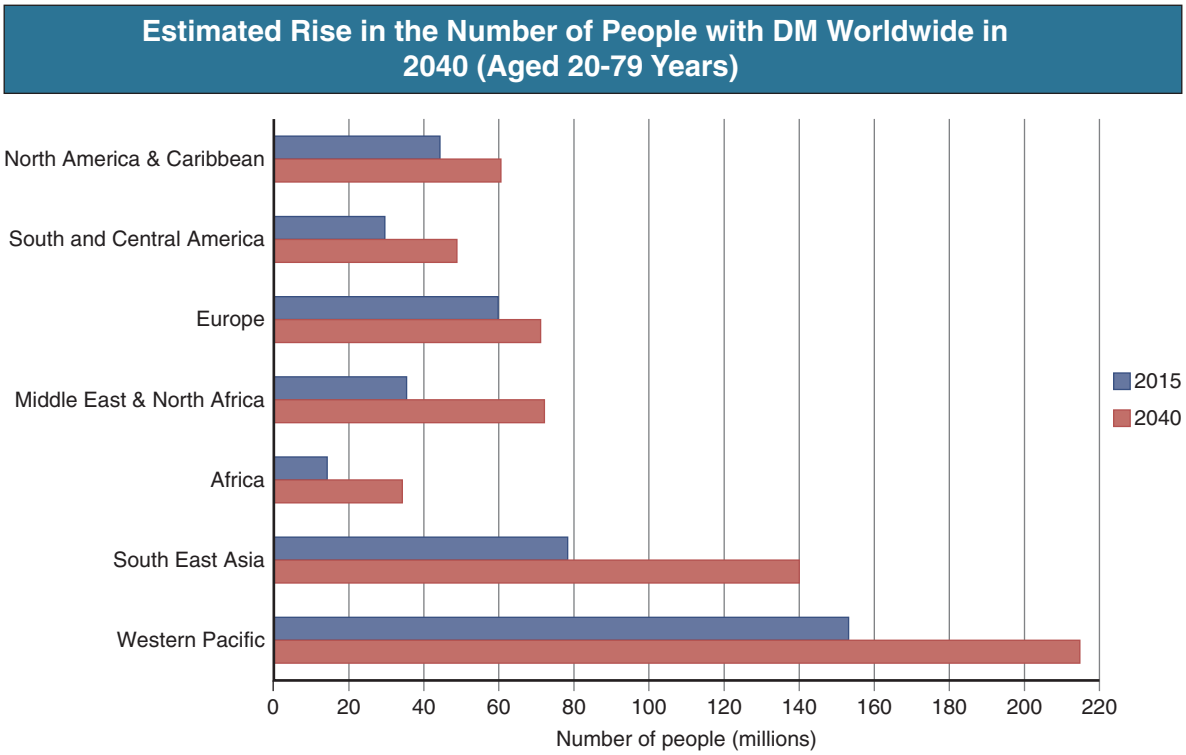

Fig. 32.1 Worldwide estimated rise in the prevalence of diabetes mellitus from 2015 to 2040. (Data from reference 1.)

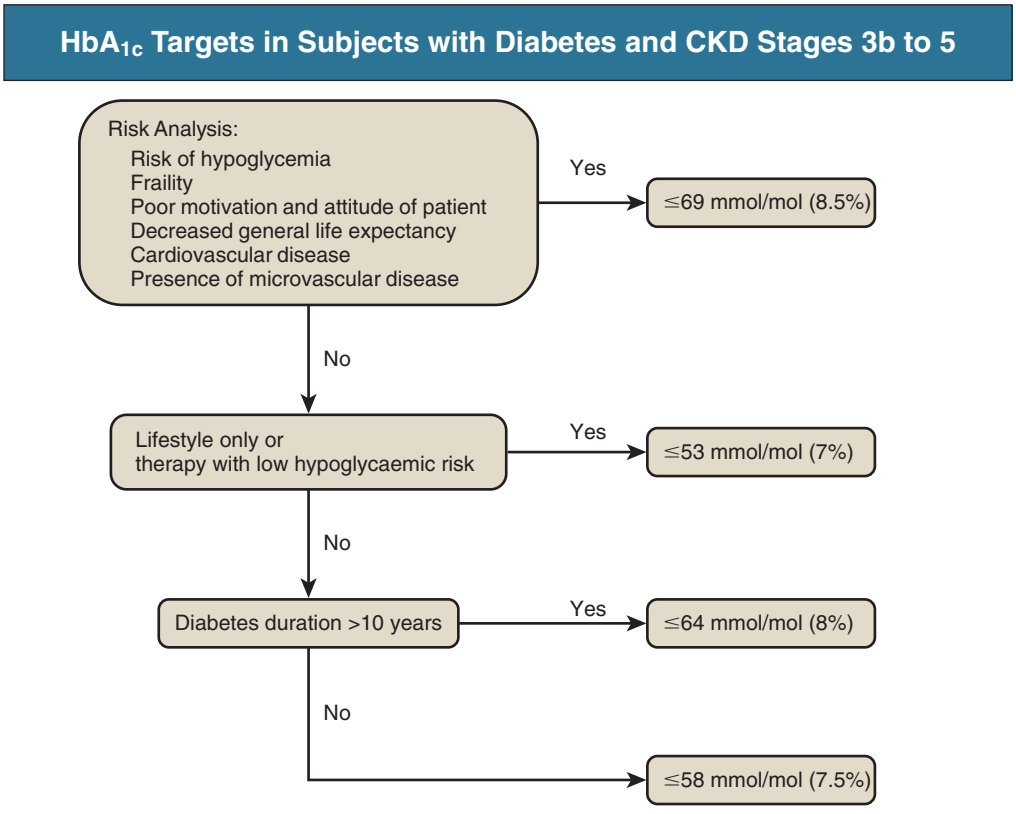

Fig. 32.2 Management targets for HbA_{1c} in patients in DM CKD3b-5. Modified from ERBP guidelines(5).

TABLE 32.1 Comparison of the Different Glycemic Markers in Diabetes Associated with Chronic Kidney Disease

Marker	Advantages	Disadvantages
HbA_{1c}	Long-term glycemic marker. Standardization of HbA_{1c} assays. In comparison with blood glucose, less sensitivity to preanalytical variables, lower within-subject biologic variability, little/no diurnal variations, little/no influence from acute stress, and little/no influence from common drugs known to influence glucose metabolism. Excellent separation of the HbA_{1c} fraction from other Hb adducts and with no interference from carbamylated Hb.	Falsely *increased* values with iron and/or vitamin B_{12} deficiency, decreased erythropoiesis, alcoholism, CKD, decreased erythrocyte pH, increased erythrocyte life span, splenectomy, hyperbilirubinemia, carbamylated Hb, intake of high-dose aspirin, chronic opiate use. Falsely *decreased* values after administration of; erythropoietin, iron, vitamin B_{12}; with reticulocytosis, chronic liver disease, ingestion of aspirin, vitamin C, vitamin E, hemoglobinopathies, increased erythrocyte pH, decreased erythrocyte life span, splenomegaly, rheumatoid arthritis, drugs; antiretrovirals, ribavirin and dapsone, hypertriglyceridemia. Variable changes with fetal Hb, hemoglobinopathies, methemoglobin, genetic determinants.
Glycated albumin	Short-term glycemic marker (2-3 wk). Independent of gender, erythrocyte life span, erythropoietin therapy, or serum albumin concentration. Associated with vascular injury markers.	Values can be influenced by lipemia, hyperbilirubinemia, hemolysis, increased uric acid, uremia, intake of high-dose aspirin, poor nutrition, age, albuminuria, cirrhosis, thyroid dysfunction, and smoking. Concentration inversely affected by body mass index, body fat mass, and visceral adipose tissue. Different reference ranges depending on applied methods. Limited data. Expensive, time-consuming, currently not widely available.
Fructosamine	Marker of average glucose levels in the previous 10-14 days. Simple, automated analysis.	Contradictory results concerning the correlation between fructosamine and glucose concentrations in CKD. Values can be influenced by nephrotic syndrome, thyroid dysfunction, glucocorticoid administration, liver cirrhosis. Concentration influenced by uremia, glycemia, hypoalbuminemia, hyperuricemia. Within-subject variation is higher than that for HbA_{1c}.
1,5 Anhydroglucitol	Marker of day-to-day changes in glucose levels. Retained metabolic inertness, steady-state levels in all tissues and negligible influence of sampling conditions such as collection time, body weight, age, sex, and food intake of subjects.	Poor diagnostic for diabetes in comparison to other glycemic markers. Contained in traditional Chinese herbal medicines. Limitations for use in subjects with renal tubular acidosis, advanced CKD or ESRD. Not widely available, limited data on its clinical everyday value.

Modified from European Best Practice guideline.
CKD, Chronic kidney disease; *ESRD,* end-stage renal disease; *Hb,* hemoglobin.

a subgroup developing ESRD.[18] Cross-sectional studies have reported T2DM without proteinuria and GFR less than 30 ml/min/1.73 m^2, illustrating that renal insufficiency may occur without albuminuria and thus reduce the benefit of using albuminuria as a marker for this subgroup. The metabolic syndrome has frequently been associated with nonproteinuric GFR decline with insulin resistance, obesity, and systolic hypertension. This phenotype of T2DM may progress with loss of GFR to ESRD without detection if albuminuria alone were to be used as the marker of progression. Not all people with moderately increased albuminuria progress to severely increased albuminuria[19]; and some patients with moderately increased albuminuria undergo spontaneous remission. The introduction of angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockers (ARBs) also may cause regression of albuminuria,[20] thus rendering albuminuria an unreliable marker of progression as people continue to develop ESRD.

Albuminuria arises from glomerular and/or tubular damage and typically occurs after 10 years of T1DM. T2DM is commonly diagnosed by the presence of albuminuria, and thus the time for its development is unclear. Thirty percent of people with retinopathy will develop albuminuria and therefore should be monitored for development of CKD to allow for early intervention.[21] Some patients with T2DM may present with retinopathy before being diagnosed with DM CKD, hence the importance of screening. Albuminuria also can be affected by exercise, fever, hypertension, heart failure, pregnancy and menstruation, urinary tract infection, marked hyperglycemia, and sepsis and in these instances should be interpreted with caution. Nevertheless, the presence and severity of albuminuria continue to be used as outcomes in clinical trials and have yet to be compared with new biomarkers entering the field.[22]

MANAGEMENT OF DIABETES IN SUBJECTS WITH STAGE 3B-5 CKD

A multidisciplinary approach is pivotal to successful management of DM CKD and its complications and should include nephrologists, diabetologists, cardiologists, renal/diabetes nurse specialists, podiatrists, ophthalmologists, and dieticians. The primary goal of current management is to slow the progression of kidney disease; however, the future

TABLE 32.2 Standard Care and Target Values Proposed for Patients With Diabetes Mellitus Who Have Chronic Kidney Disease

Parameter	Stage 3 and 4 CKD	Stage 5 CKD (Including Dialysis)
Metabolic Control		
HbA_{1c}	>6.5%-7.5%	>7.0%-8.0%
Preferred agents	Meglitinides, sulfonylureas, insulin	Insulin
Blood Pressure		
Systolic/diastolic BP	130/80 mm Hg	140/90 mm Hg
Preferred agents	ACEs/ARBs	β-blockers
Lipid Treatment		
LDL cholesterol	<100 mg/dl	?
Preferred agents	Statins	Statins in CKD stage 5, no agents to be commenced in dialysis as primary prevention
Anemia Treatment		
Hemoglobin level	11-12 g/dl (avoid >13)	11-12 g/dl (avoid >13)
Preferred agents	Iron/ESA	Iron/ESA
Vitamin D Supplements*		
	Vitamin D_3/1,25-OH D_3	1,25-OH D_3/vitamin D_3
Supportive Treatment		
Smoking cessation	++	++
Hypoglycemia awareness	++	+++
Low-dose aspirin	++	+
Exercise (daily/weekly)	++	++
Foot care	+++	+++
Prevention of falls	+	+++

*In case of vitamin D supplements, the therapeutic approach should be reversed from native vitamin D first in CKD3-4 to vitamin D analogues first in CKD5.

ACE, Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *ESA,* erythropoiesis-stimulating agent; *LDL,* low-density lipoprotein; *?,* benefit unknown; +/++/+++, moderately/very/highly indicated.

aim is to halt the disease process and reverse any damage. The remission clinics experience[23] illustrated the benefits of regular follow-up in CKD patients, with current recommendations for follow-up ranging from yearly to quarterly that is determined by the level of GFR and its rate of decline.

Hypoglycemia and Hyperglycemia

Hypoglycemia becomes increasingly frequent with advancing CKD because of changes in insulin, carbohydrate metabolism, and renal gluconeogenesis. As GFR declines to less than 60 ml/min/1.73 m^2, regular review of the oral antidiabetic regimen or insulin dosing is essential. These medications may need to be reduced or stopped to prevent the accumulation of the drugs and their metabolites that can cause various adverse effects, including hypoglycemia. Life-threatening episodes of hypoglycemia are more common in patients receiving dialysis. The onset of a hypoglycemic episode may result in 27% mortality 2 days after the hypoglycemic event, emphasizing the importance of monitoring and reviewing medications.[24] Elderly patients in particular who have a hypoglycemic episode have been shown to have increased mortality. The use of any hypoglycemic agents in dialysis patients should therefore be closely monitored and reviewed. The following agents may be used to effectively treat hyperglycemia to avoid the development of DM-related complications.

Oral Hypoglycemic Agents

Several currently available oral agents require dose adjustments in stage CKD3b-5 (Table 32.3). As renal function deteriorates there will be an increase in drug-drug interactions together with further complications of DM, for example, gastroparesis that can affect the pharmacokinetics of these oral medications.

Biguanides

Metformin is an insulin sensitizer that decreases hepatic glucose production, increases insulin sensitivity and insulin-mediated utilization of glucose in peripheral tissues while decreasing glucose intestinal absorption. Metformin is recommended as the first-line agent in T2DM when lifestyle measures alone are insufficient to reduce HbA_{1c} into range. It reduces all-cause and CV mortality in this population.[5] The dose of metformin should be reduced according to renal function and an information card or leaflet be given to those with CKD3b or higher (GFR <45 ml/min/1.73 m^2) that instructs patients to temporarily stop metformin in states of dehydration, before the administration of radiocontrast media and other situations in which there is an increased risk for acute kidney injury (AKI). The use of metformin historically has not been recommended with GFR less than 30 ml/min/1.73 m^2 because of the risk for lactic acidosis. However a recent Cochrane review[25] found no evidence that CKD3b or higher enhanced the risk for lactic acidosis in patients receiving appropriate doses of metformin.[5,26]

Sulfonylureas

Sulfonylureas are a class of insulin secretagogues that stimulate pancreatic insulin secretion and close K-ATP channels on β-cell plasma membranes. First-generation sulfonylureas are long-acting and almost exclusively excreted by the kidneys. These are best avoided in CKD or require dose adjustments (see Table 32.3). Second-generation agents are short-acting and primarily metabolized by the liver, with most metabolites undergoing renal clearance. Their use carries the risk for hypoglycemia as GFR declines and insulin clearance decreases. Sulfonylureas are highly protein-bound but can be displaced into circulation by other drugs used in patients with DM (e.g., salicylates, β-blockers), further contributing to hypoglycemia. Sulfonylureas may become ineffective over time as a result of islet cell exhaustion; thus glycemic control with these agents in advancing CKD should be monitored. The metabolites of gliclazide and glipizide are inert or weakly active and may be used in patients with ESRD on dialysis.

Thiazolidinediones

Thiazolidinediones are peroxisome proliferator-activated receptor (PPAR) modulators, which work to increase insulin sensitivity. Their use is limited by causing weight gain and fluid retention through transcriptional upregulation of tubular amiloride-sensitive sodium channels. This is problematic in subjects with CKD who are prone to cardiovascular disease (CVD) and congestive heart failure. Rosiglitazone was withdrawn from the market because of increased risk for myocardial infarction reported with its use, although pioglitazone remains in use. Higher rates of bone fractures also have been reported in patients treated with these agents.

TABLE 32.3 Daily Dosing for Oral Hypoglycemic Agents*

Class	Drug	CKD1 and 2	CKD3	CKD4	CKD5	Dialysis
Biguanide	Metformin	No adjustment	850-1500 mg	500 mg	Awaiting further data	Awaiting further data

Meglinitides

Meglinitides are primarily metabolized in the liver and act as insulin secretagogues similar to sulfonylureas. Repaglinide is converted to inactive metabolites that are mainly excreted in bile, with less than 10% renal excretion, and therefore is commonly used in patients with DM CKD. In contrast, more than 80% of nateglinide is excreted in the urine, and thus should be used cautiously with advancing CKD.

Incretin Mimetics: Glucagon-Like Peptide-1 Analogues

GLP-1 analogues promote glucose-mediated insulin secretion by pancreatic β-cells in response to food entering the gut and suppress glucagon secretion. The GLP-1 analogues help stimulate weight loss by appetite suppression, both centrally and by affecting gastric motility. European Renal Best Practice (ERBP) guidelines do not recommend these agents in advancing CKD; however, a recent systematic review and meta-analysis reports incretin-based therapies (e.g., GLP-1 agonists, DPP-4 inhibitors) effectively reduce HbA_{1c} levels in T2DM CKD3-5. No increased hypoglycemia, CV events, increased mortality, or progression to ESRD were reported.[27] However, there were wide confidence intervals, thus currently precluding any definitive conclusions.

Gliptins: Dipeptidyl Peptidase-4 Inhibitors

The gliptin class inhibits the effect of DPP-4, a cellular membrane protein expressed in a variety of tissues that function to rapidly degrade endogenous incretin hormones (e.g., GLP-1). Agents such as linagliptin are primarily metabolized by the liver and excreted in the bile, thus not requiring dose adjustments in CKD. Gliptins are advantageous because they do not cause weight gain.

α-Glucosidase Inhibitors

α-Glucosidase is an intestinal enzyme needed to digest carbohydrates. It hydrolyses complex starches to oligosaccharides in the lumen of the small intestine, releasing glucose. Inhibition of this enzyme maintains the integrity of complex carbohydrates, thereby allowing less glucose absorption, and thus should be taken at the start of meals. These agents may be maintained but require dose adjustment with advancing CKD.

Amylin Analogues

Amylin analogues regulate glucose levels according to food intake and control gastric emptying and postprandial glucagon secretion. They increase satiety and thus reduce food intake. It is unclear how effective these drugs are in subjects with stage CKD5 or those on dialysis and further studies are required.

SGLT-2 Inhibitors

Sodium glucose cotransporter protein subtype-2 (SGLT-2) in the renal proximal convoluted tubule is blocked by SGLT-2 inhibitors, thereby increasing renal excretion of glucose. There are increased risks for genital mycotic infections and, rarely, urinary tract infections; thus patients taking these should be cautioned. In the EMPA-REG OUTCOME trial,[28] patients with T2DM and GFR greater than 90 to 45 ml/min/1.73 m^2 were recruited. Empagliflozin was seen to reduce the risk for CV mortality, all-cause mortality, and hospitalization for congestive heart failure with favorable effects on weight, systolic blood pressure (BP), and serum uric acid.[29] This is consistent with previous reports of SGLT-2 inhibitors on reducing CV and all-cause mortality.[30] EMPA-REG OUTCOME also reported a reduction in doubling of serum creatinine and renal

replacement therapy (RRT) while reducing progression to macroalbuminuria[28]; however, the perceived renal benefits cannot be fully explained by the moderate reduction in HbA_{1c}, BP, or serum uric acid. It has been postulated that SGLT-2 inhibitors decrease proximal tubular reabsorption of sodium that increases distal sodium delivery to the macula densa that in turns activates tubuloglomerular feedback, resulting in afferent vasodilatation and a reduction of hyperfiltration. There is a reduction in intraglomerular pressure, BP, blood glucose, and blood volume. In addition, the increase in ketone body metabolism is thought to induce an energy-efficient oxygen consumption state at the mitochondrial level that reduces hypoxic stress in the kidney, reducing renal progression of DN.[29] A risk for euglycemic ketoacidosis and bone fractures in those with CKD3-5 taking SGLT-2 inhibitors has been raised that requires further investigation. Recently, more than 100 cases of AKI have been reported with this class of drug, with many cases occurring in the first few weeks of use, in addition to reports of irreversible renal failure and death. The mechanism of this is unknown, although it may relate to volume depletion and hypernatremia from the osmotic diuresis. Despite these concerns, SGLT-2 combined with metformin, sulfonylureas, or DPP-4 inhibitors, as a second agent for glycemic control, is gathering momentum in the general diabetic population, and this practice will likely become increasingly common in those with early DM CKD.[31] The effectiveness of SGLT-2 inhibitors in advancing CKD is currently unknown, and future studies need to address this.

Insulin

Endogenously secreted insulin undergoes first-pass metabolism in the liver, leaving approximately half available to enter the systemic circulation and be used by peripheral tissues. Thirty to eighty percent of insulin is removed by the kidney: 40% via proximal tubular reabsorption and intracellular degradation and 60% via glomerular filtration. Exogenous insulin is destroyed in the gastrointestinal tract and therefore is given parenterally, usually subcutaneously. After absorption, insulin is inactivated via enzymatic process in the liver and kidney and is excreted in the urine; thus with a falling GFR the risk for hypoglycemia is high and insulin dosing should be continuously reviewed with advancing CKD.[5]

Normally insulin sensitivity detects a raised blood glucose causing insulin secretion. This sensitivity is lost with the development of DM, and thus a loss of insulin secretion in response to glycemia is termed *insulin resistance*. In contrast, CKD progression in nondiabetic patients results in the loss of renal gluconeogenesis and a decline in insulin renal excretion that in itself may result in episodes of hypoglycemia because of the continued presence of insulin. Poor insulin degradation secondary to uremia, inflammation, and a raised catabolic rate seen in CKD also contribute to hypoglycemia and insulin resistance, and thus insulin must be dosed with caution.[32] The combination of progressive CKD and DM results in further insulin resistance and loss of sensitivity where regulatory mechanisms are unable to compensate, with studies therefore recommending a halving of insulin doses when GFR is less than 45 ml/min/1.73 m^2.[33]

Types of insulin. Limited data in patients with DN favor the use of analogues, in which the insulin molecule has been modified to rapid or long-acting forms so as to possess pharmacokinetics similar to physiologic insulin secretion, in contrast to traditional human insulins.

Insulin lispro maintains a similar metabolic profile, regardless of whether DN is present. Insulin aspart, a rapid-acting analogue, and long-acting analogues (e.g., glargine, detemir), also have been found to have a metabolic profile largely unaffected by CKD. Currently no specific insulin regimen is recommended in the setting of CKD. For T1DM, however, the basal bolus regimen of 3 daily injections of short-acting insulin with meals combined with 1 or 2 injections of long-acting insulin, as used in the Diabetes Control and Complications Trial (DCCT), is the standard treatment regimen. In T2DM, patients requiring insulin, the regimen usually starts on once-daily or twice-daily, long-acting, or intermediate-acting insulin. Mixed formulations (fixed percentages of short- to long-acting insulins) or the basal bolus regimen as in T1DM may be necessary if glycemic control is not achieved and requires regular review and adjustment as CKD progresses.

Future Therapeutics

New agents continue to be developed to prevent patients with diabetes developing CKD and progressing to ESRD. Alongside these treatment avenues is the development of more sensitive biomarkers that may aid the decision of when to commence new therapies. Table 32.4 shows potential new therapeutics for DN and their current stage of trial development that in the future may be introduced at variable stages of DM CKD.

MANAGEMENT OF HYPERTENSION IN THE DIABETIC SUBJECT WITH CHRONIC KIDNEY DISEASE

Blood Pressure Goals

The ERBP have recently recommended that BP targets in diabetic patients with stages CKD3b-5 should be the same as the general population, that is, a target of less than 140/90 mm Hg. In this way the risk for exacerbating autonomic dysfunction that is commonly seen in advanced DM CKD and may prejudice coronary perfusion, further exacerbating the risk for CV complications, is reduced. A Cochrane review[34] of five randomized control trials reported a reduced risk for stroke with a reduction in BP to less than 120/70 mm Hg, but this has not been reproduced in other studies, which found an increase in adverse events with no improvement in all-cause mortality or morbidity.[5] In contrast, the National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (KDOQI) and other major societies recommend a BP less than 130/80 mm Hg in DM CKD,[35] with the cut-off derived from observational studies (Multiple Risk Factor Intervention Trial [MRFIT], the Okinawa Screening Programme). Despite this, there is a lack of strong evidence from randomized controlled trials (RCTs) to support this target in secondary prevention of renal disease, with systematic review of relevant trials showing no benefit on renal outcomes (e.g., the rate of decline of GFR, progression to ESRD) but an increase in adverse events with tight BP control less than 120/70 mm Hg and are not recommended. The Action to Control Cardiovascular Risk in Diabetes (ACCORD), in Diabetes and Vascular Disease: Preterax and Diamicron MR Controlled Evaluation (ADVANCE), African American Study of Kidney Disease and Hypertension (AASK), and Modification of Diet in Renal Disease (MDRD) studies recommend a target systolic BP less than 130/80 mm Hg in patients with DM; however, there is no consistent recommendation in DM CKD that represents a benefit in CV or all-cause mortality with this target.

The Kidney Disease: Improving Global Outcomes (KDIGO) guidelines recommend targets of less than 140/90 mm Hg in CKD3 without albuminuria that are based on the conclusion that insufficient high-quality evidence from RCTs are available to recommend a lower target based on observational studies.[36] A target of less than 130/80 mm Hg in DM CKD with albuminuria is given with caution to adjust treatment to the individual due to the enhanced risk for CVD. The Australian Kidney Health Australia–Caring for Australasians with Renal Impairment (KHA-CARI) guidelines similarly recommend a less than 140/90 mm Hg target in those with CKD, unless CKD occurs with macroalbuminuria, and then a target of less than 130/80 mm Hg is adopted, but again with caution to tailor treatments to the individuals in view of adverse events.

TABLE 32.4 Potential New Therapeutics for Treatment of Diabetic Nephropathy

Agent	Target	Studies	Effect
Pyridoxamine dihydrochloride (vitamin B_6)	Advanced glycation end-product (AGE) inhibitor	Human: Phase 3	Decreases AGE levels and ACR, and improves creatinine
Nrf-2 activator (triterpenoid RTA dh404)	Nrf-2	Animal Human: Phase 2	Restores Nrf-2 activity and decreases oxidative stress. Japan phase 2 with careful selection of patients in view of adverse heart failure events leading to previous trial cessation
Endothelin 1A antagonist (atrasentan)	Endothelin 1A receptor	Animal and human: Phase 3	Reduction in ACR, BP, and lipids in DN and nondiabetic CKD. Dose-related adverse effects fluid overload
Thromboxane A2 receptor antagonist/ thromboxane synthase inhibitor (SER150)	Thromboxane receptor and thromboxane synthase	Human: Phase 2 trial	Reduction in ACR, improvement in GFR—results pending
Daglutril	Endothelin converting enzyme and neutral endopeptidase inhibitor	Animal Human: RCT	Antifibrotic in animals. Reduction in BP irrespective of A2RB in humans
Pentoxifylline	TNF-α blockade	PREDIAN: Human phase 3 trial	Reduction of albuminuria in addition to ACE inhibitor/ARB
LY3016859 monoclonal antibody	Epiregulin/ Anti-TNF-α	Human: Phase 2	Reduction in ACR
Baricitinib	JAK1/JAK2 selective inhibitor	Human: Phase 2	Reduction in ACR
GKT137831	NOX1/4inhibitor	Human: Phase 2	Reduction in ACR
Doxycycline	Metalloproteinase inhibitor, tetracycline	Human: Small RCT	Reduction in ACR while on treatment
Allopurinol	Xanthine oxidase inhibitor	Human: RCT	Reduction in ACR and serum creatinine, improves GFR
Silymarin (milk thistle)	Antioxidant, TGF-β	Human: Small RCT	Reduction in ACR, urinary TNF-α and malondialdehyde
Pirfenidone	TGF-β	Small RCT Animal studies	Improved GFR at 1 year, gastrointestinal side effects
Anti-CTGF monoclonal Antibody (FG-3019)	CTGF	Animal Human: Phase 1	Reduction in ACR in microalbuminurics
Paracalcitriol (vitamin D)	Vitamin D	Small RCT: VITAL study	Reduction in ACR in DN, no effect on overall mortality
RS102895	Chemokine receptor CCR2 antagonist	Animal Human: Phase 2 (CCX140-B)	Animal: Reduction in ACR, improved histologic features, decrease oxidative stress with improved glucose tolerance
Emapticap pegol (NOX-E36)	CCL2 antagonist	Human: Phase 2	Reduction in ACR
Vascular endothelial growth factor (VEGF) antibody antagonist	VEGF	Animal	Decrease glomerular hypertrophy, hyperfiltration, and albuminuria
VPI-2690B monoclonal antibody	Anti-$\alpha V\beta 3$ integrin	Human: Phase 2	Reduction in ACR
Octreotide	Somatostatin agonist	Animal Human	Improved GFR, reduction in ACR, normal renal volume
Sarpogrelate (Anplag)	$5HT_{2A}$ receptor antagonist	Human: Phase 4 (SONATA)	Reduction in ACR and urinary MCP-1 levels
Adrenocorticotropic hormone (ACTH) gel	ACTH	Human	Reduction in ACR, no effect on renal function
Finerenone	Mineralocorticoid receptor antagonist	Human: Phase 3	Reduction in ACR

Modified from reference 22.

5-HT2A, Serotonin 2A; *ACE,* angiotensin-converting enzyme; *ACR,* albumin-to-creatinine ratio; *BP,* blood pressure; *CKD,* chronic kidney disease; *DN,* diabetic nephrology; *GFR,* glomerular filtration rate; *MCP,* monocyte chemoattractant protein. *RCT*, randomized controlled trial.

The Systolic Blood Pressure Intervention Trial (SPRINT) trial reported a significantly lower risk for CVD outcomes and all-cause mortality in nondiabetic CKD populations with hypertension with systolic BP less than 120 mm Hg versus less than 140 mm Hg[37] (Chapter 79). In contrast, reports of increased all-cause mortality and CV morbidity have been reported in DM with systolic BP less than 130 mm Hg; thus these inconclusive studies require trials to be conducted in large DM cohorts to specifically address this. On the basis of current evidence we would therefore recommend a target BP of less than 130/80 mm Hg in CKD3b-4 and less than 140/90 mm Hg in CKD5 and dialysis.

What Agents Should Be Used?

Diabetic subjects with stages CKD3-5 without albuminuria have been shown to benefit from all BP-lowering medications. Patients with DM CKD usually will require more than one antihypertensive agent to achieve BP targets. Selective β-blockers are recommended as primary prevention in patients with DM stages CKD3b-5, and these should continue through advancing CKD if tolerated. Lipophilic (e.g., bisoprolol) rather than hydrophilic agents are advised because studies have shown these to decrease the risk for hospitalization, all-cause mortality, and sudden death.[5] Aldosterone antagonists can reduce target organ damage as well as albuminuria and left ventricular hypertrophy (LVH). The addition of spironolactone to an ACE inhibitor further reduces albuminuria; however, the risk for hyperkalemia limits their use and, if used, must be done so cautiously and considered in conjunction with a loop diuretic.[38] Other antihypertensive agents, such as calcium channel antagonists and thiazide-like diuretics, also have been shown to reduce the risk for CVD in DM, with some evidence of benefit in the DM CKD population.[39] In addition, salt restriction should be advocated to 5 to 6 g/day (<100 mmol/day Na^+) to improve BP control.[40]

Renin-Angiotensin-Aldosterone System Blockade

Numerous studies have illustrated the benefits of renin-angiotensin-aldosterone (RAAS) blockade specifically with ACE inhibitors/ARBs in DM[41,42]; however, the benefits of these agents alone or combined in advancing CKD have been debated in view of the risks for hyperkalemia and other adverse renal outcomes. ERBP recommends CKD3b-5 or those on dialysis with DM and CV indications (congestive cardiac failure, coronary heart disease [CHD]) should be treated with an ACE inhibitor. In instances in which patients are intolerant of ACE inhibitors the ARB should be substituted. Substantial evidence has shown that dual ACE inhibitor and ARB (or ACE inhibitor or ARB plus aliskirin) is potentially harmful and not recommended. The risk for hyperkalemia is reported to be 6.8 times higher with RAAS blockade in CKD with GFR less than 30 ml/min/1.73 m^2 compared with GFR greater than 50 ml/min/1.73 m^2.[5] Introduction of a loop diuretic or correction of metabolic acidosis may limit hyperkalemia; however, dual RAAS blockade is no longer recommended.

ERBP guidelines currently suggest discussion with patients with DM CKD5 regarding the advantages and disadvantages of stopping RAAS blockade to delay RRT. Discussion with patients is essential to their understanding the unpredictable rate of renal function decline with cessation of RAAS blockade. Some patients may accelerate toward RRT with cessation, whereas others may maintain the stability of their function and thus the importance of discussing options with the patient.

CARDIOVASCULAR COMPLICATIONS

The DCCT and Epidemiology of Diabetes Intervention (EDIC) trial in T1DM and the Steno-2 population reported an increase of CV death occurring before DM CKD patients reached ESRD.[43,44] ERBP guidelines recommend that formal workup of coronary heart disease in DM CKD to be the same as that in nondiabetic CKD patients (Chapter 81). Arguably, more patients with DM CKD should have more aggressive workup similar to those undergoing transplantation, because the latter have shown underlying silent CVD, yet further studies are required to determine which patients with DM CKD would benefit from aggressive workup and intervention.

Coronary Heart Disease

Patients with DM CKD3b-5 should have coronary angiograms and intervention if indicated irrespective of the radiocontrast agent risk in view of improved cardiac outcomes. In contrast, in patients with stable CAD, optimal medical management should be adhered to with β-blocker, statin, and aspirin or clopidogrel unless large areas of ischemia or significant left main/proximal left anterior descending coronary artery lesions are seen. Coronary artery bypass grafting (CABG) is preferred over percutaneous coronary intervention (PCI) in patients with multivessel or complex CAD (SYNTAX Score II; www.syntaxscore.com/). Studies show CABG reduces the risk from cardiac death more than PCI in DM CKD, including in patients on dialysis. In the event of an acute coronary event, those with DM CKD3b-5 should be treated the same as patients with CKD3b-5 without DM or patients with DM without CKD3b-5.

Peripheral Vascular Disease

Peripheral vascular disease occurs regularly in patients with DM CKD; thus regular clinical examination with investigations as directed by the diabetes vascular foot team should be undertaken. This will add to early revascularization to try and prevent amputation where possible.

Erectile Dysfunction

Erectile dysfunction frequently occurs in DM CKD as a combination of vasculopathy and medication side effects for treating CHD and hypertension. Phosphodiesterase inhibitors may be used unless the patients is taking nitrates or has uncontrolled CHD.

Antiplatelet Agents

Hyperglycemia has a procoagulant effect on platelet aggregation independent of insulin levels, and hyperinsulinemia itself carries an inhibitory effect on fibrinolysis and thus significantly increases the risk for thrombosis. Platelet reactivity is known to increase with advancing CKD (Chapter 83). Post hoc analyses of the Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance (CHARISMA) and Clopidogrel for the Reduction of Events During Observation (CREDO) trials found no benefit in adding clopidogrel to aspirin in patients with DN because this may lead to worse outcomes independent of bleeding risk. ERBP advises glycoprotein IIb/IIIa inhibitors should not be added to standard care in DM CKD3b-5. The addition of a thienopyridine or ticagrelor is not recommended in DM CKD3b-5, especially if there are additional risk factors for bleeding. Aspirin should be started as secondary prevention in DM CKD3b-5 unless contraindicated or intolerant, in which case clopidogrel may be considered as an alternative. Aspirin should be started only as primary prevention in DN patients without risk factors for major bleeding.

Dyslipidemia

Given the elevated risk for CVD in DM it is generally recommended that hyperlipidemia be treated (Chapter 81). KDOQI recommends that all patients with DM CKD1-4 should receive treatment if low-density lipoprotein cholesterol (LDL-C) is greater than 100 mg/dl, with a target of less than 70 mg/dl. The National Institute for Health and Care Excellence (NICE) UK guidelines stipulate a total cholesterol of less than 155 mg/dl and LDL-C less than 77 mg/dl for optimal prevention of

microvascular and macrovascular complications of diabetes.[35,45] Statins decrease the risk for cardiac mortality with no effect on kidney outcomes. In view of the increased risk for CV mortality, ERBP recommends a statin should be commenced in DM CKD3-4 and considered in stage 5 but not be commenced in patients with diabetes on dialysis.

In nondialysis CKD patients, a beneficial effect on lowering cholesterol was confirmed in the Study of Heart and Renal Protection (SHARP), which included more than 9000 patients with a wide range of CKD and no history of CVD, randomized to simvastatin and ezetimibe or placebo. A 17% reduction in adverse CV outcomes was seen for every 33 mg/dl reduction in LDL-C, whether the CKD subject was diabetic or nondiabetic, with no impact on mortality.[46] However, in DM dialysis patients the AURORA, SHARP, and 4D trials did not show significant reductions in CV events or mortality despite LDL-C falling by up to 42%. No consensus has been reached as to whether a statin commenced in early DM CKD should be stopped when reaching dialysis, and ERBP guidelines recommend continuation or cessation should be determined by the patients' condition and preference. Fibrates can reduce the risk for increased albuminuria and can replace statins in DM CKD3b patients who are intolerant of statins.[5] Dose reductions in statins are not normally required for advancing CKD because these drugs are safe to use in CKD, and, once commenced, subsequent lipid monitoring is not required.

MICROVASCULAR COMPLICATIONS OF DIABETES

Retinopathy

Annual screening is recommended to ensure prompt intervention.

Neuropathy

Gabapentin is commonly used to treat neuropathic pain associated with diabetes, but requires dose reduction with advancing CKD. Dosing may require alternate days or administration after hemodialysis sessions to avoid the known sedative and motor (myoclonus) effects of gabapentin accumulation that occur in individuals with reduced eGFR. Pregabalin is an alternative that is predominantly excreted by the kidneys and should be used cautiously with advancing CKD. Regular diabetic foot care is required because peripheral neuropathy masks the development of ulcers that may subsequently lead to amputation in view of the added burden of vascular disease seen with CKD.

Autonomic Neuropathy

Gastroparesis is common in diabetes and can affect the absorption of oral medication. It may be treated with endoscopically administrated Botox injections that can be used in DM CKD3b-5; however, hydration throughout the procedure should be maintained to avoid development of AKI. Optimizing the management of gastroparesis is extremely difficult but should be considered before transplantation in view of the potential effects on immunosuppressant absorption. Involving local gastroenterology and diabetologists allows new therapies to be trialed in this population.

Postural hypotension may pose difficulties with hemodialysis and thus agents such as midodrine have been used with variable success. Midodrine is contraindicated in patients with arrhythmias and previous cardiac events and, if used, should be done so with caution. Other measures such as adjustments to dialysis prescriptions together with consideration of peritoneal dialysis (PD) may improve patient symptoms; however, there is currently no evidence to advocate a specific treatment strategy in this area.

Diabetic Foot Disease

DM CKD3b-5 patients have a high risk for diabetic foot disease that is a major cause of hospitalization and nontraumatic amputation. Yearly inspection of the feet and examination of peripheral pulses and sensation is an essential part of the diabetic patient's consultation, along with general foot care (Chapter 86). Education on appropriate footwear and monitoring for signs of early infection are fundamental to prevention. DM CKD3b-5 patients and those on RRT should be seen regularly by their local podiatry services.

COMPLICATIONS FROM CHRONIC KIDNEY DISEASE

Anemia

Anemia occurs commonly in DN and acts as a risk multiplier for all-cause mortality in patients with DM CKD and an independent risk factor for LVH, CVD, and congestive cardiac failure (Chapter 82). Diabetic patients have lower hemoglobin (Hb) levels at every CKD stage than patients with CKD from other causes. One study found a prevalence of 41% in diabetic versus 17% in nondiabetic CKD patients, occurring before renal function begins to decline.[47] Therefore DM CKD3 should be screened for anemia. Patients with DN have increased levels of proinflammatory cytokines from low-grade systemic inflammation, causing resistance to the effects of erythropoietin in various tissues of the body that impairs the efficient use of iron in the generation of new erythrocytes. Other factors causing resistance include autonomic neuropathy, ACE inhibitors/ARBs, and microvascular damage in the bone marrow.

The Trial to Reduce Cardiovascular Events with Aransep Treatment (TREAT) was a landmark study in the use of erythropoiesis-stimulating agents ESAs for correcting anemia secondary to CKD in T2DM with a median follow-up of 29 months, GFR 20 to 60 ml/min/1.73 m^2, and Hb 11 g/dl or less. Patients were randomized either to darbepoetin-alfa (Hb 13g/dl) or control with rescue darbepoetin treatment if Hb was less than 9 g/dl. The treatment group had fewer CV revascularization procedures but significantly increased risk for fatal and nonfatal nonhemorrhagic strokes.[48] Of the TREAT cohort, 31% progressed to dialysis and death despite good BP, glycemic, and lipid control.

Mineral Bone Disease

Imbalance in mineral metabolism increases CV risk and is associated with renal bone disease in DM CKD. Targets for parathyroid hormone (PTH), calcium, and phosphate levels should be aligned to those with non-DM CKD (Chapter 84). Vitamin D insufficiency (<75 nmol/l concentration for plasma 25(OH)D_3) is common in CKD and DM. Routine repletion of native vitamin D, though likely not to be harmful, is not recommended unless levels are in the "depletion" range (<20 nmol/l for 25(OH)D concentrations). The use of pharmacologic therapies for the suppression of PTH is the same for non-DM CKD patients.

Diet and Malnutrition

DM CKD patients are often severely catabolic and tend to develop malnutrition (Chapter 86). This risk is particularly high during periods of intercurrent illness and fasting but also may arise from ill-advised recommendations to restrict protein intake. Anorectic obese patients with T2DM and advanced CKD often undergo massive weight loss, leading to normalization of fasting glucose concentration and even of hyperglycemia after a glucose load. Low muscle mass because of wasting is an important reason for misjudging the severity of CKD, resulting in a delayed start of RRT. Therefore weight loss recommendations in DM CKD patients who are overweight should be supervised by a dietician to avoid malnutrition. Physical exercise can be promoted, and DM CKD3b-5 patients should perform additional physical exercise at least three times per week for 30 to 60 minutes to decrease fat mass and improve quality of life according to ERBP.

Electrolytes and Fluid Retention

Salt restriction and diuretics are the mainstay treatment of fluid retention in DM CKD. Metabolic acidosis can be treated with bicarbonate supplementation; in patients with hyperkalemia, diet and RAAS blockade should be reviewed.

END-STAGE RENAL DISEASE

According to ERBP, patients with DM CKD5 should be given the choice of RRT because no evidence exists to suggest one modality is better than another. The increase in mortality seen in DM continues and is at its highest on RRT.[22] Decisions regarding the preferred modality of RRT should begin at DM CKD4-5. Education should be given on the different treatment options, and transplant workup investigations should be started in potentially suitable candidates. Hepatitis B vaccinations should be given early in patients with DM CKD3b to increase immunity.

Dialysis

Hemodialysis

Mortality is unchanged whether hemodialysis (HD) or hemodiafiltration is used; however, it is recommended that high flux rather than low flux dialysis be performed. The IDEAL study comparing early to late initiation of HD (with 34% of both groups having diabetes as the primary cause of ESRD), found no significant survival benefit[49] (Chapter 80). Considerations for the timing of RRT initiation in DN are similar to those in patients without DM and include the speed of renal function decline, the probability of functioning vascular access, and the projected life expectancy of patients.

Vascular Access

Evidence recommends avoiding tunneled central venous catheters as a primary access in patients with DM starting HD because of the higher risk for associated infection[5] (Chapter 91). The advantages and disadvantages of each access should be discussed with patients. Vascular mapping may increase the likelihood of successful arteriovenous fistula (AVF) creation in those with DM (especially in females and the elderly). Proximal AVFs have been reported to be more successful than distal AVF as the high calcific atherosclerosis commonly found in DM CKD causes difficulty in creation and maturation of AVF.

Peritoneal Dialysis

PD may be used in DM CKD requiring RRT and as a result of the slower ultrafiltration rate compared with HD may lower risks for precipitating CV events or hypotension (Chapter 97). Glucose intake from PD contributes 400 to 800 kcal/day (100 to 200 g/day of glucose). Intraperitoneal insulin (soluble human insulin) can be injected through the connecting tubing before starting dialysis or added to dialysate. Intraperitoneal insulin is adsorbed onto plastic surfaces of the delivery systems and bioavailability depends on the solution, therefore insulin requirements are often higher using this administrative method than subcutaneous injections. Intraperitoneal insulin is absorbed through the portal circulation, with decreased amplitude of glucose excursions and improved mean plasma glucose, resulting from inhibition of hepatic gluconeogenesis. However, soluble human insulin increases the risk for subcapsular hepatic steatosis that is linked to the dosage of intraperitoneal insulin used and there is a lack of high-quality evidence demonstrating its effects on risk for infection and quality of glucose control, as compared with subcutaneous insulin.

Non–glucose-containing solutions (e.g., icodextrin) avoid the risk for hyperglycemia and the potentially harmful effects of glucose degradation products, while resulting in better ultrafiltration volume, BP control, and preservation of residual function (Chapter 97). Some metabolites of icodextrin also can act as a substrate for the glucose dehydrogenase present in blood glucose meters, resulting in potential overestimation of blood glucose levels.

Transplantation

The U.S. Renal Data System data showed 5-year survival rates of 29% in diabetic patients starting dialysis compared with those undergoing kidney transplants (75% deceased-donor, 85% living-donor).[50] Ideally, the transplant should be preemptive to avoid an interim period of dialysis in which uremic symptoms are minimal. For patients with T1DM, the ideal form of transplantation is simultaneous pancreas and kidney transplantation or living-donor kidney transplant[5] (Chapter 110). Other options are sequential living-donor kidney transplantation, followed by deceased-donor pancreas transplant or islet transplantation prior to living donor kidney transplant. Initially there were concerns with this approach because of possible worse outcomes in terms of survival and the pancreas graft itself; however, outcomes have improved in recent years.[5]

Islet after kidney transplantation does not improve survival and is not recommended. In contrast, kidney transplantation alone is recommended by the ERBP for T2DM CKD requiring RRT. Providing patients meet the inclusion criteria for transplantation, DM CKD patients should not be denied kidney transplantation on the basis of their DM. Pancreas alone or simultaneous pancreas and kidney transplantation is not recommended in T2DM in view of insulin resistance.

SELF-ASSESSMENT QUESTIONS

1. Which of the following falsely increases hemoglobin A_{1c} readings?
   A. Antiretrovirals
   B. β-Thalassemia
   C. Rheumatoid arthritis
   D. Alcoholism
   E. Erythropoietin
2. Which of these antidiabetic medications are safe to use in end-stage kidney disease (ESRD)?
   A. Empagliflozin
   B. Exenatide
   C. Gliclazide
   D. Metformin
   E. Tolbutamide
3. Which of the following statements are *true* in diabetic chronic kidney disease (CKD)?
   A. T2DM should be given pancreas alone transplants.
   B. Hemodialysis should be introduced in preference to peritoneal dialysis in diabetic patients with ESRD.
   C. There is clear evidence that statin therapy improves cardiovascular mortality in the dialysis population.
   D. Anemia in diabetic patients can occur even with normal renal function.
   E. Coronary artery bypass grafting is contraindicated in patients with diabetic CKD.
4. Which of the following is *not* an underlying mechanism or pathology of hypoglycemia in diabetic CKD?
   A. Loss of renal gluconeogenesis
   B. Increasing plasma concentrations of oral antidiabetic agents
   C. Reduced renal clearance of insulin
   D. Loss of insulin sensitivity
   E. Formation of renal calculi

33

Normal Blood Pressure Control and the Evaluation of Hypertension

*William J. Elliott, William J. Lawton**

NORMAL BLOOD PRESSURE CONTROL

Systemic arterial blood pressure (BP), or the pressure of the blood within the arteries exerted against the arterial wall, is produced by the contraction of the left ventricle (producing blood flow) and the resistance of the arteries and arterioles. *Systolic* blood pressure (SBP), or *maximum* BP, occurs during left ventricular systole. *Diastolic* blood pressure (DBP), or *minimum* BP, occurs during ventricular diastole. The difference between SBP and DBP is the pulse pressure.[1] The mean arterial pressure (MAP) is calculated clinically as the DBP plus one third of the pulse pressure.

Blood flow, *Q,* as defined by the hydraulic analogy of Ohm's law, varies directly with the change in pressure, *P,* across a blood vessel, and varies inversely with the resistance, *R,* defined as $Q = P/R$. Rearrangement shows that pressure varies directly with blood flow and resistance, $P = QR$. Ohm's law suffices for an overall view of the circulation. However, the flow within a vessel is governed by the Hagen-Poiseuille equation:

$$Q = \Delta P \times (\pi r^4/8L) \times (1/\eta)$$

where r is the radius of the pipe, L is its length, and η is the coefficient of viscosity. Thus, as the lumen of a vessel decreases, the pressure increases by the fourth power of the radius, to maintain the same blood flow.

Normal BP is controlled by cardiac output and the total peripheral resistance and is dependent on the heart, the blood vessels, the extracellular volume, the kidneys, the nervous system, humoral factors, and cellular events at the membrane and within the cell (Fig. 33.1). Cardiac output is determined by the stroke volume in liters per minute (l/min) and the heart rate. In turn, stroke volume is dependent on intravascular volume (regulated by the kidneys) and myocardial contractility. Myocardial contractility involves sympathetic and parasympathetic control of heart rate, intrinsic activity of the cardiac conduction system, complex membrane transport and cellular events requiring influx of calcium that lead to myocardial fiber shortening and relaxation, and effects of humoral substances (e.g., catecholamines) on increasing heart rate and myocardial fiber tension.

Total peripheral resistance is regulated by baroreflexes and sympathetic nervous system (SNS) activity, response to neurohumoral substances and endothelial factors, myogenic responses, and intercellular events mediated by receptors and mechanisms for signal transduction.[2] Baroreflexes are derived from (1) high-pressure baroreceptors in the aortic arch and carotid sinus and (2) low-pressure cardiopulmonary baroreceptors in ventricles and atria. Aortic baroreceptor nerve fibers travel via the vagus nerve (cranial nerve X); carotid sinus fibers travel via the glossopharyngeal nerve (cranial nerve IX). These receptors respond to stretch (high pressure) or filling pressures (low pressure) and send tonic inhibitory signals to the brainstem. If BP and tonic inhibition increase, inhibition of sympathetic efferent outflow occurs, decreasing vascular resistance and heart rate. However, if BP decreases, less tonic inhibition occurs, and heart rate and peripheral vascular resistance (PVR) increase, thereby increasing BP.

The brainstem cardiovascular (CV) centers are localized in the dorsomedial medulla. Neural afferents from cranial nerves IX and X are integrated in the nucleus tractus solitarius (NTS). From here, vasoconstriction and increased heart rate are mediated through the caudal and rostral ventrolateral medulla by the SNS. Efferents from the NTS communicate with the nucleus ambiguus (vagal nucleus) to decrease heart rate via the vagus nerve. Also, the central neural control of renal function modulates renal blood flow, glomerular filtration rate (GFR), excretion of sodium and water, and renin release. These factors in turn regulate intravascular volume, vascular resistance, and BP.[3] This complex physiology has taken on greater clinical relevance recently, given the mixed results of pivotal trials of percutaneous, catheter-based renal denervation.[4,5]

Inhibitory reflexes also originate in the kidney. Increases in urine flow rate increase renal pelvic pressure, which stretches the renal pelvic wall, leading to activation of mechanosensory nerves in the renal pelvic wall. Activation of these sensory nerves decreases renal sympathetic nerve activity and induces diuresis and natriuresis, an inhibitory renorenal reflex response. The responsiveness of the renal sensory nerves is modulated by dietary sodium. A high sodium intake enhances the responsiveness of the afferent renal mechanosensory nerves; conversely, renal denervation increases urinary flux and fractional excretion of sodium.[6]

Numerous vasoactive substances have effects on blood vessels, the heart, the kidneys, and the central nervous system (CNS) to regulate BP (Table 33.1). The renin-angiotensin-aldosterone system (RAAS) regulates volume and PVR (Fig. 33.2), particularly in the long term (hours to weeks, Fig. 33.3). Angiotensin II (Ang II) constricts vascular smooth muscle; stimulates aldosterone secretion; potentiates SNS activity; stimulates salt and water reabsorption in the proximal tubule;

*The authors thank Drs. DiBona, Kopp and Luft for their contributions to previous editions of this chapter.

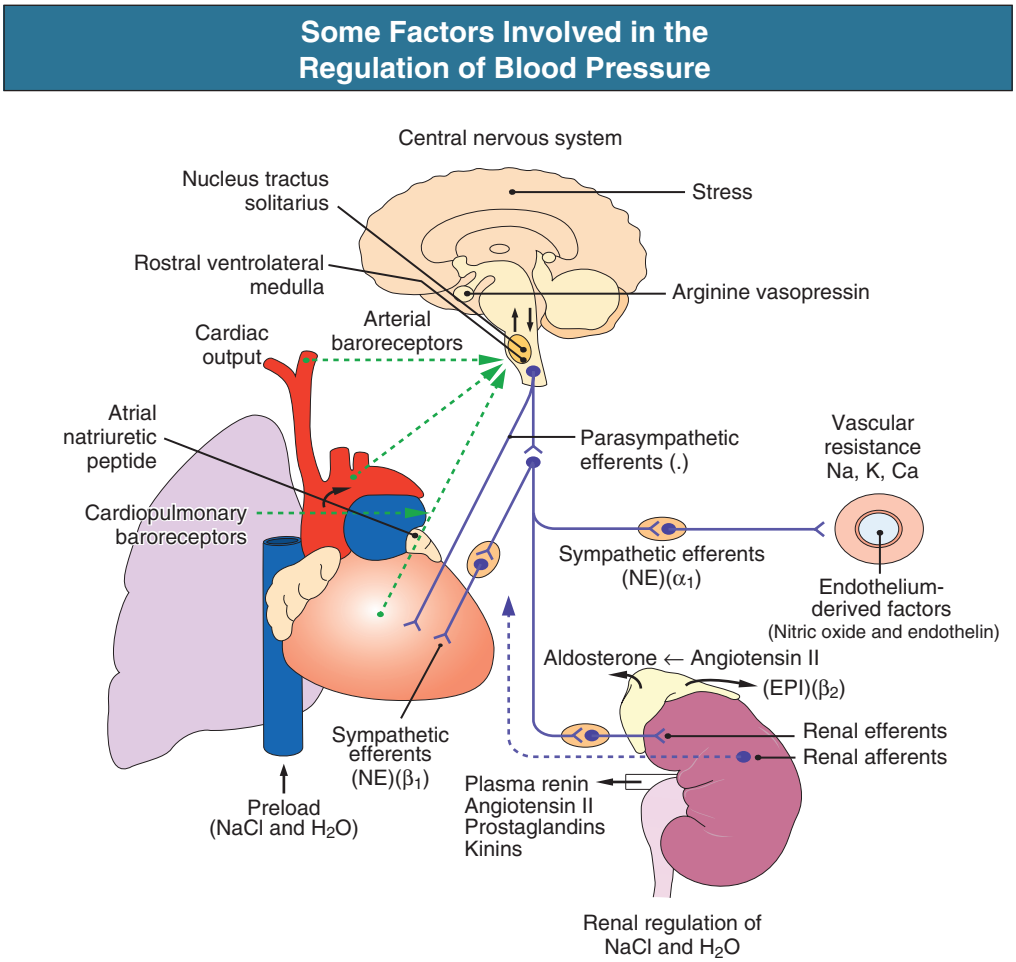

Fig. 33.1 Some factors involved in regulation of blood pressure. *Dashed lines* refer to feedback to the central nervous system from cardiovascular *(green dash)* or renal *(purple dash)* sites. *ACh,* Acetylcholine; *EPI,* epinephrine; *NE,* norepinephrine; α_1, β_1, β_2, adrenergic receptors.

stimulates prostaglandin, nitric oxide (NO), and endothelin release; increases thirst; and stimulates vascular remodeling and inflammation. Aldosterone stimulates sodium channels in distal renal tubular epithelium, leading to sodium retention and potassium excretion. It also exerts inflammatory and fibrotic effects through the mineralocorticoid receptor in vascular cells and in the heart.[7] Plasma concentrations of renin and aldosterone are both inversely related to salt intake and are influenced by many antihypertensive medications.

The second major effector system, working primarily over seconds to minutes (see Fig. 33.3), is the SNS. Sympathetic nerve endings release the vasoconstrictor (norepinephrine) that binds the α-adrenergic receptor (adrenoceptor) on vascular cells, renal cells, and other cells (e.g., adipocytes). Epinephrine increases heart rate, stroke volume, and SBP through α- and β-adrenoceptors. The hormone is released from the adrenal medulla. Increased sympathetic tone has long-term influences on CV regulation and may cause hypertension and contribute to chronic kidney disease (CKD).[8] In the kidneys, sympathetic nerves mediate renin release. Furthermore, innervation of each individual nephron affects sodium reabsorption. In doing so, the SNS regulates both effective circulating fluid volume and PVR.

The kallikrein-kinin system counters the RAAS and produces vasodilator kinins, which stimulate prostaglandin and NO production (see Fig. 33.2). Prostaglandin E and prostacyclin block the vasoconstriction by Ang II and norepinephrine. Two endothelium-derived factors have opposite effects on the blood vessels: NO is a vasodilator, whereas the endothelins are vasoconstrictors. Natriuretic peptides, of the atrial, brain, or C-types, induce vasodilation and natriuresis and inhibit other vasoconstrictors (RAAS, SNS, endothelin). See Chapter 36 for a detailed discussion of all the drugs that affect the previously discussed physiologic systems that regulate BP.

Other physiologic systems that control BP can be used as investigative tools, but not yet therapeutically in humans. Renalase is a flavin adenine dinucleotide–dependent amine oxidase that is secreted by the kidney, circulates in the blood, and modulates cardiac function and systemic BP by metabolizing catecholamines; there is currently debate about whether mutations in the gene coding for renalase are associated with hypertension.[9] Heme oxygenase-1 is an intrarenal and systemic BP modulator that inhibits oxidants, resulting in decreased BP; in one study, individuals with an unfavorable gene promoter for this enzyme had a higher prevalence of hypertension and increased mortality.[10] Endogenous digitalis-like factors, which inhibit cell surface Na^+,K^+-ATPase and include an ouabain-like factor and marinobufagenin, also appear to regulate BP, CV, and renal function.[11] Urotensin II is a locally expressed vasoconstrictive cyclic vasoactive peptide that stimulates proliferation of vascular smooth muscle cells and fibroblasts, inhibits insulin release, and modulates GFR. Nonetheless, high plasma urotensin II levels were associated with reduced CV complications and death in 122 patients with CKD, stages 2 to 5, and in an earlier cohort of 191 hemodialysis patients from the same center.[12,13] In obese persons, leptin may increase

TABLE 33.1 Some Vasoactive Substances That Modulate Blood Pressure

Group	Compound	Cellular Effects
Catecholamines	Norepinephrine, epinephrine, dopamine	Adrenergic receptors (α_1, α_2, β_1, β_2) causing protein phosphorylation and increased intracellular calcium through G proteins linked to ion channels or second messengers (cyclic nucleotides, phosphoinositide hydrolysis)
Renin-angiotensin system (RAS)	Angiotensin II (Ang II)	Angiotensin receptors (AT_1, AT_2, AT_4) causing increased intracellular calcium and protein phosphorylation through second messenger, phosphoinositide hydrolysis, and activated protein kinases Aldosterone stimulation
Mineralocorticoids	Aldosterone	*Genomic:* Binds to cytoplasmic mineralocorticoid receptor, translocates to nucleus, modulates gene expression, and signal transduction and effectors (S_gK, CHIF, K_i-Ras), which increases transport proteins (increasing ENaC number and open probability) *Nongenomic:* Effects through separate membrane or cytosolic proteins
Kallikrein-kinin system	Bradykinin	Bradykinin receptors (B_1, B_2), B_2-G protein coupling causes activation of phospholipase C, increased inositol phosphates, and intracellular calcium
Arachidonic acid oxidation products	Prostaglandins: Prostaglandin E (PGE), prostacyclin, thromboxanes Lipoxygenase enzyme products: Leukotrienes, hydroxyeicosatetraenoates	Nine prostaglandin receptors coupled to G proteins: (e.g., PGI_2 [receptor IP], PGE_2 [receptors EP_1, EP_2]); $PGF_{2\alpha}$ (receptor FP)
Endothelium-derived factors	Endothelium-derived relaxing factor (nitric oxide) Endothelins (ET-1, ET-2, ET-3)	Increased levels of cyclic guanosine monophosphate cause activation of protein kinases G proteins activate phospholipase C and I-type calcium channels Class 2 G protein–coupled receptor
Natriuretic peptides	Atrial, brain, and C-type	Activation of three receptor types; further effects mediated by cGMP
Posterior pituitary hormones	Arginine vasopressin	Vasopressin receptors (AVPR 1A; AVPR 1B) mediated by second messenger system, phosphatidyl inositol/calcium; AVPR2 effects via adenylate cyclase (cAMP)
Cyclic vasoactive peptides	Urotensin II (UT II)	UT II binds to G protein receptor GPR 14
Other substances	Acetylcholine, adenosine, insulin, neuropeptide Y, serotonin, sex hormones (estrogens, progesterone, androgens), glucocorticoids, other mineralocorticoids, substance P, vasopressin, renalase, heme oxygenase 1, uric acid	

ENaC, Amiloride-sensitive epithelial sodium channel.

BP by activating the CNS through a melanocortin pathway.[14] Although its clinical importance is hotly debated, higher serum uric acid levels have been associated with BP and CV outcomes in some (but not all) cohort studies, and at least two hypouricemic drugs have lowered BP in pilot studies. Intracellular urate also may activate the renin-angiotensin system (RAS), induce intrarenal oxidative stress, block endothelial NO, and directly affect the vasculature.[15] T cells also may be involved in primary hypertension, possibly via heat shock protein 70 and/or interleukin-17, because they invade target organs and lead to release of Ang II and oxidants.[16] Chemoreceptors in the brain medulla and the carotid and aortic bodies respond to changes in carbon dioxide and oxygen tension, resulting in renal vasoconstriction and dilation of the CNS and coronary vasculature.[17] The small guanosine triphosphatase, Rho, and its kinase, stimulate vasoconstriction and may have a role in cerebral artery spasm, hypertension, heart failure, and other CV conditions.[18]

The kidney has long been recognized as a source of hypertension, based on renal cross-transplantation experiments,[19] and the hypotensive effects of bilateral nephrectomy in patients with end-stage renal disease (ESRD) and severe hypertension. However, activation of CNS and renal SNS pathways are now recognized as important in long-term BP control, in part by delayed effects on the kidneys.[20] Renal sympathetic denervation by radiofrequency ablation through the renal arteries has led to substantial reduction in BP in patients with resistant hypertension, but the large U.S. trial did not achieve significantly better BP control at 6 months, compared with sham-operated controls.[21,22] This negative result more likely stemmed from technical issues in the conduct of the trial than a nonsignificant contribution to the pathophysiology of hypertension.

DEFINITION AND CLASSIFICATION OF HYPERTENSION

In the general population, BP is nearly normally distributed, with a shift to the left in the young and the opposite in older people and those with CKD. Thus any definition of hypertension is arbitrary. Hypertension is often asymptomatic, with symptoms more commonly attributed to sequelae of hypertension or its treatment. Hypertension may be classified by its associated morbidity and mortality, as increases over arbitrary cut points, or by thresholds defining therapeutic benefit.

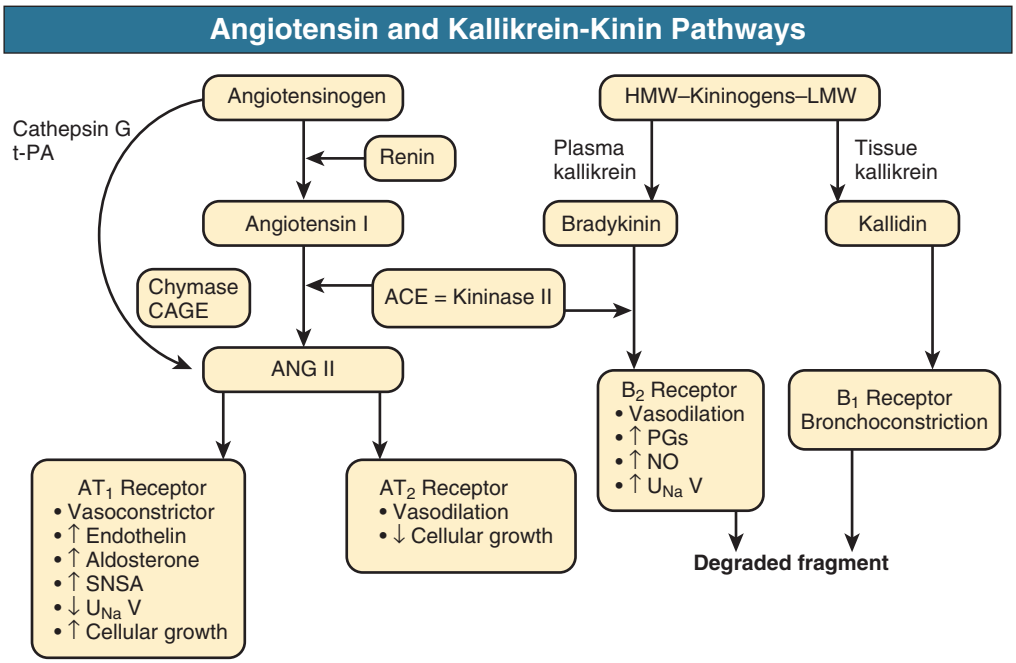

Fig. 33.2 Interactions and functions of renin-angiotensin and kallikrein-kinin systems. *ACE,* Angiotensin-converting enzyme; *ANG II,* angiotensin II; AT_1, AT_2, angiotensin receptors; B_1, B_2, bradykinin receptors; *CAGE,* chymostatin-sensitive angiotensin II–generating enzyme; *HMW,* high molecular weight; *LMW,* low molecular weight; *NO,* nitric oxide; *PGs,* prostaglandins; *SNSA,* sympathetic nervous system activity; *t-PA,* tissue plasminogen activator; U_{Na} *V,* urinary sodium excretion.

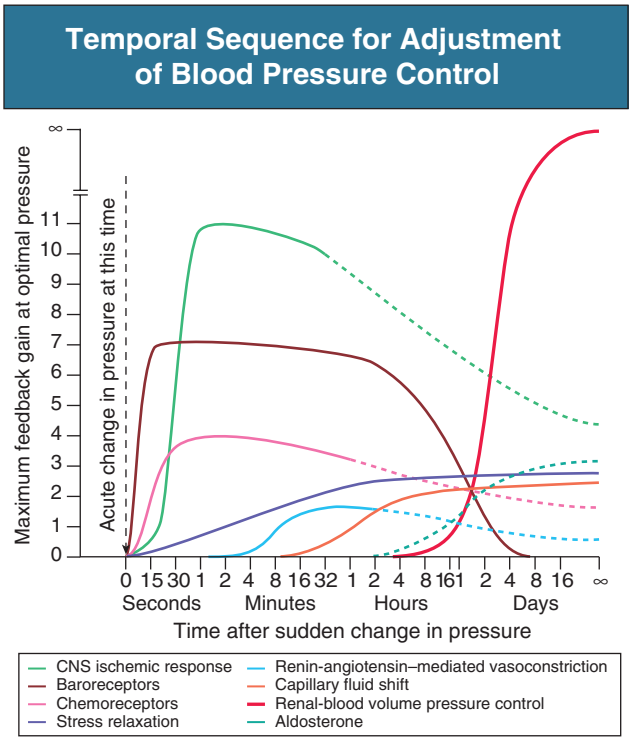

Fig. 33.3 Temporal sequence for adjustment of blood pressure control. Degree of activity, expressed as feedback gain, of several arterial blood pressure (BP) control systems at various times after a sudden change in arterial BP. Note the infinite gain of the renal-volume mechanism for BP control. *CNS,* Central nervous system. (From reference 1.)

Blood Pressure in Relation to Morbidity and Mortality

The first approach defines hypertension by relating BP levels to the risk for morbidity and mortality. The association of SBP and DBP with CV and renal complications is continuous over the entire BP range.[23] Death from both heart disease and stroke increases progressively and linearly from BP as low as 115/75 mm Hg upward in all age groups from 40 to 89 years (Figs. 33.4 and 33.5). In observational studies an increase in SBP of 20 mm Hg or DBP of 10 mm Hg was associated with a doubling of mortality from heart disease or stroke. Several interventional trials have observed a J-shaped curve (suggesting that mortality increases below a threshold SBP), yet this phenomenon is also seen in the bottom decile in both individual and pooled observational studies of untreated subjects (see Figs. 33.4 and 33.5), indicating that those in the lowest decile have a higher risk, irrespective of treatment. Elevated SBP has been identified by the Global Burden of Disease study to be the leading contributor to disability-adjusted life-years worldwide in 2013 and again in 2015. In both reports, these investigators characterized a SBP between 110 and 115 mm Hg as the "theoretical minimum risk level" for BP. Although all national and international hypertension guidelines agree about the continuous relationship between risk and BP, as well as a recommendation for lifestyle modifications in people with BP 120/80 mm Hg or greater, many differ regarding how BP should be classified, especially if the BP is between 120 and 139/80 and 89 mm Hg. The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) introduced the term *prehypertension* for individuals with SBPs from 120 to 139 mm Hg, or DBPs between 80 to 89 mm Hg[24]; this term was also recommended for these BP values by the American Society of Hypertension/International Society of Hypertension 2013 guidelines. The 2013 European Society of Hypertension/European Society of Cardiology guidelines distinguished BPs between 120 and 129/80 and 84 mm Hg

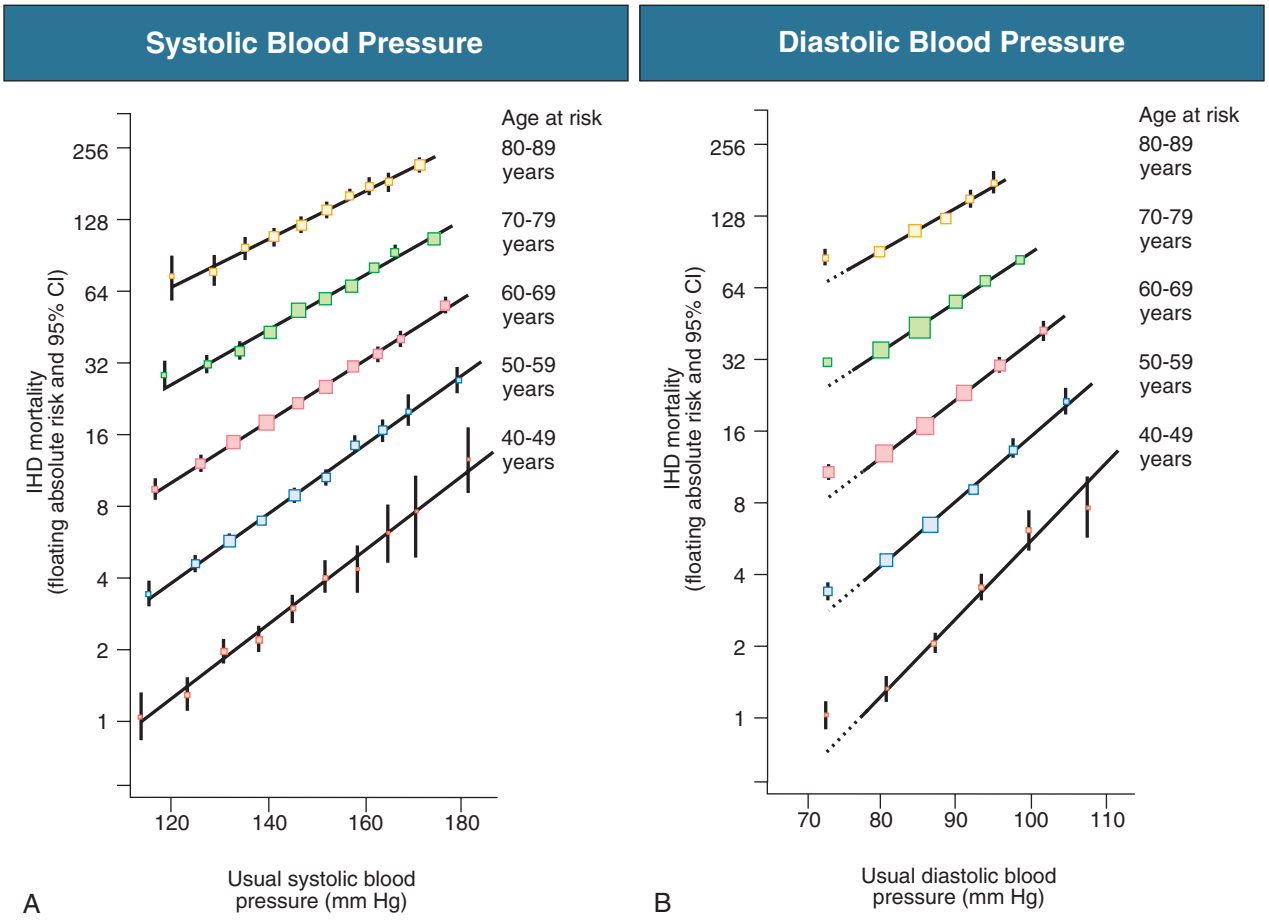

Fig. 33.4 Ischemic heart disease (IHD) mortality rate in each decade of age versus usual blood pressure at start of that decade. (A) Systolic blood pressure. (B) Diastolic blood pressure. Floating absolute risk is a relative risk score that adjusts for the absolute death rate within a particular age group. The size of the squares correlates inversely with the variance of the data collected for that data point. *CI,* Confidence interval. (From reference 23.)

TABLE 33.2 Working Group–American Society of Hypertension Definition and Classification of Hypertension

Class	BP Elevation		CV Disease*	CV Risk Factors	Early Disease Markers	Target Organ Disease
Normal	Normal or rare	or	None	None or few	None	None
Hypertension						
Stage 1	Occasional intermittent	or	Early	Several	Usually present	None
Stage 2	Sustained	or	Progressive	Many	Overtly present	Early signs present
Stage 3	Marked and sustained	or	Advanced	Many	Overtly present with progression	Overtly present with or without CV disease events

Modified from reference 26.
*Cardiovascular *(CV)* disease determined by constellation of risk factors, early disease markers, and target organ disease.

(termed *normal*) and 130 and 139/85 and 89 mm Hg (termed *high-normal*) and recommended an initial assessment of CV risk, based on these (and higher) BP thresholds and the number of CV risk factors present in the individual (see later discussion).[25] A different approach was taken by a Writing Group of the American Society of Hypertension (WG-ASH), which proposed that hypertension is a complex CV disorder that includes target organ damage, early disease biomarkers (including BP), and CV risk factors[26] (Table 33.2). This risk-based approach seeks to identify individuals with an increased likelihood of future adverse CV and/or renal events at any BP level, and includes the prehypertension category of JNC 7. In contrast, the recent report of the panel members appointed to JNC 8 focused on BP management and not on classification or risk assessment.[27]

Elevation of Blood Pressure by Arbitrary Cut-Off Points

A second approach defines hypertension by the frequency distribution within a population. This statistical approach arbitrarily designates values

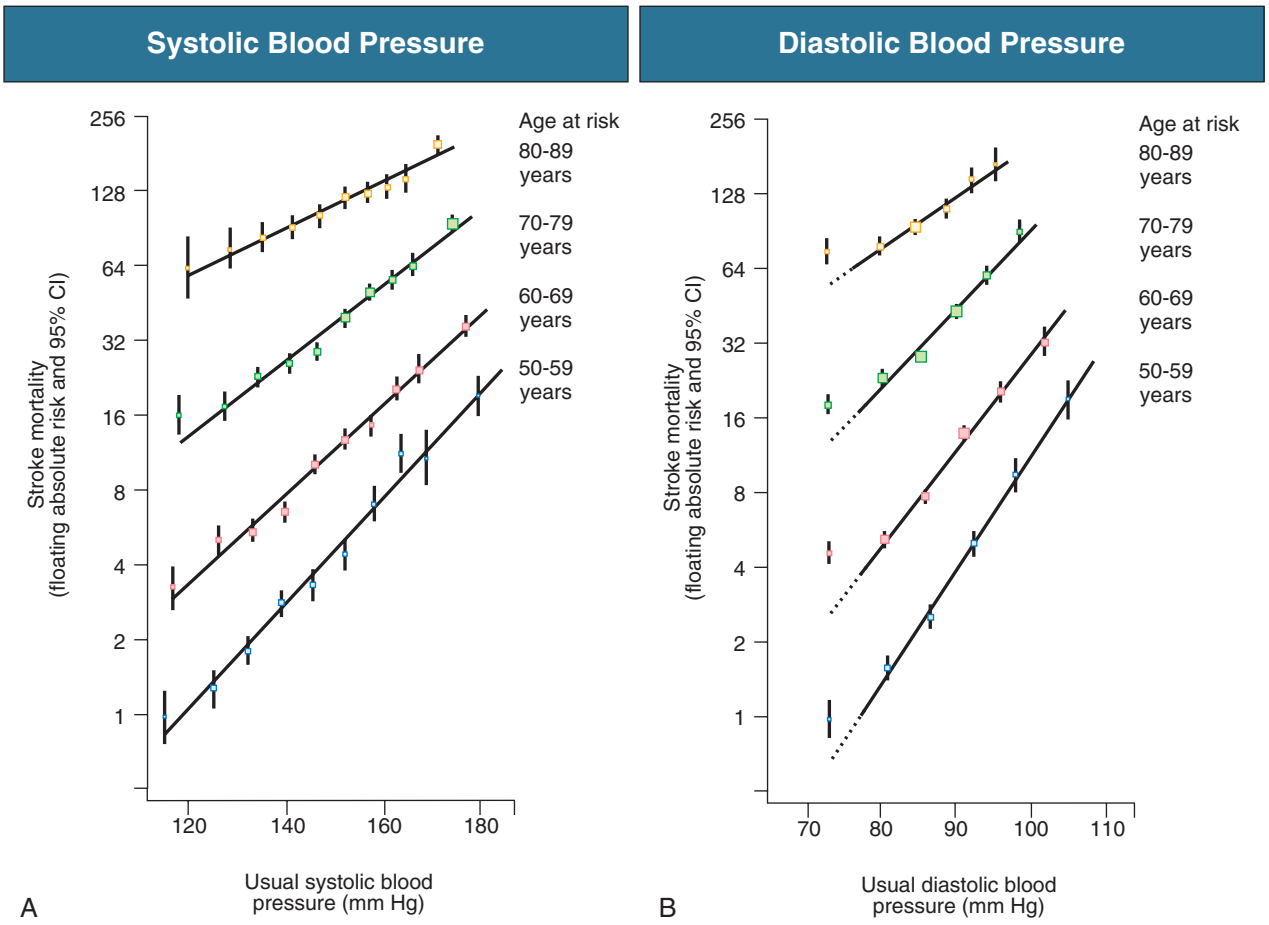

Fig. 33.5 Stroke mortality rate in each decade of age versus usual blood pressure (BP) at start of that decade. (A) Systolic BP. (B) Diastolic BP. Floating absolute risk is a relative risk score that adjusts for the absolute death rate within a particular age group. The size of the squares correlates inversely with the variance of the data collected for that data point. *CI,* Confidence interval. (From reference 23.)

above a certain percentile as "hypertensive" and was formerly used in defining hypertension in American children. Age, gender, body size, and race/ethnicity are all significant and strong predictors of BP. Using a frequency distribution method is less helpful for identifying a threshold for initiation of antihypertensive treatment, but is common in epidemiologic studies. The crude prevalence of hypertension in adults (older than 20 years of age) in the United States, traditionally defined as BP of 140/90 mm Hg or greater or taking antihypertensive medication, has increased progressively from 11% in 1939 to 33.5% in 2013 to 2014, but has been relatively stable, after age-adjustment, at 31% ± 2% since the mid-1990s.[28] These prevalence figures are slightly higher than those reported from other high-income countries (28.5%, on average, in 2010), and about the same as those reported from low- and middle-income countries (31.5% in 2010), based on 135 population-based surveys involving 968,419 adults in 90 countries.[28]

Threshold of Therapeutic Benefit

The third concept for defining hypertension is derived from randomized controlled trials (RCTs) that compared two or more BP targets and showed significant reductions in morbidity and mortality. The Hypertension Optimal Treatment (HOT) study showed no significant outcome differences among 18,790 hypertensive subjects randomized to DBP targets of 80, 85, or 90 mm Hg or less, although a significant benefit was seen in diabetic patients with a diastolic target of less than 80 mm Hg.[29] A post hoc analysis of the in-trial BPs determined that maximal prevention of major CV events was seen at a BP of 138.5/82.6 mm Hg. Of the relatively few outcome-based RCTs comparing traditional and lower BP targets, only the recent Systolic blood PRessure INTervention (SPRINT) trial showed significant reductions in both CV events and mortality when treating to a SBP target of less than 120 compared with the traditional less than 140 mm Hg.[30] Some have argued that this benefit came at a huge cost of more medications, more office visits, more adverse effects (including emergency department visits), and greater than 30% worsening of renal function in those without CKD at baseline. Others have cast doubt about SPRINT's generalizability, because less than 17% of adult American hypertensives would have been eligible to participate, because of the large number of exclusion criteria (which, because of prior negative National Institutes of Health [NIH]-sponsored trials, included diabetes mellitus, prior stroke, polycystic kidney disease, or estimated GFR less than 20 ml/min/1.73 m^2, among many others).

Operational Definitions

On 13 November 2017, the American College of Cardiology and American Heart Association, in conjunction with nine other learned societies and volunteer health organizations, issued their "2017 United States hypertension guideline."[32] This guideline "redefined" hypertension as a usual office blood pressure ≥ 130/80 mm Hg, added the new diagnostic category of "elevated blood pressure," re-emphasized the value of out-of-office blood pressure measurements, reinforced lifestyle modifications as appropriate for most people with higher-than-normal blood pressures, and revised some treatment targets for specific patient groups

(see Table 33.3 below, and Chapter 36 for more details). About three months earlier, the American Academy of Pediatrics released their "Clinical practice guideline for screening and management of high blood pressure in children and adolescents,"[33] the authors of which were privy to an advance copy of the 2017 adult guidelines, and arranged their recommendations to be consistent with them. These new definitions have increased the overall prevalence of hypertension in US adults to 46%, but decreased the prevalence in children and adolescents to 3.5%. The 2017 ACC/AHA hypertension guideline also recommended an office blood pressure target of < 130/80 mm Hg for individuals with a 10-year cardiovascular risk > 10%, but retained the traditional < 140/90 mm Hg for most lower-risk individuals. These new guidelines are controversial; some learned societies have declined to endorse or adopt them.

The European Society of Hypertension (ESH), recently in conjunction with the European Society of Cardiology (ESC) has traditionally divided "normotension" into three categories (optimum, normal, high-normal) and classified hypertension as mild, moderate, or severe[25] (Table 33.4). The European guidelines also provided threshold values for automated 24-hour BP measurements, divided into daytime and nighttime.

In the United States, JNC 7 defined hypertension for individuals 18 years and older.[24] The Committee classified BPs as normal, prehypertension, and stage 1 and stage 2 hypertension (Table 33.5). For children, JNC 7 agreed with the Fourth Report of the National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents, so that BP at or above the95th percentile, based on age, gender, and height, is defined as hypertension.

The concept of evaluating a person's "total CV risk" had been prominent in several prior U.S. guidelines on BP, dyslipidemia, and acute coronary syndrome. It was largely abandoned by JNC 7, but still plays a major role in other countries,[25,33] and is now used for determining the BP treatment goal in the 2017 ACC/AHA U.S. hypertension guidelines,[31] because clinicians routinely evaluate hypertensive patients and their progress toward treatment goals on the basis of overall CV risk factors, not by BP alone. Age, gender, and ethnicity are important nonmodifiable risk factors, whereas low-density lipoprotein (LDL) cholesterol, smoking, control of diabetes, obesity, and left ventricular hypertrophy are potentially modifiable[33] (Fig. 33.6). The cluster of risk factors that increase CV risk and are often associated with hypertension is termed the *metabolic syndrome*[34] (Table 33.6). CKD, now diagnosed on the basis of decreased estimated GFR or by increased urinary albumin excretion, is also recognized as an independent risk factor for ESRD, CV events, and death.[35] JNC 7 included recommendations for serial follow-up evaluation of BP and CV risk factors based on initial BP measurement (Table 33.7).

Special Definitions

Prehypertension. Prehypertension was defined in JNC 7 as SBP of 120 to 139 and DBP of 80 to 89 mm Hg[24] and was found in 36.3% of American adults without CV disease or cancer in U.S. national representative surveys from 1999 to 2006.[36] Prehypertension is associated with age, obesity, dyslipidemia, impaired fasting glucose levels, a higher risk for both CV and renal events, and progression to hypertension (which was significantly delayed by drug therapy in two RCTs). Yet all current guidelines

TABLE 33.3 2017 ACC/AHA Hypertension Guideline: Categories of Blood Pressure in Adults

Blood Pressure Category	Systolic Blood Pressure		Diastolic Blood Pressure
Normal	< 120 mm Hg	and	< 80 mm Hg
Elevated	120-129 mm Hg	and	< 80 mm Hg
Hypertension			
Stage 1	130-139 mm Hg	or	80-89 mm Hg
Stage 2	≥ 140 mm Hg	or	≥ 90 mm Hg

Individuals with systolic and diastolic blood pressures in two different categories should be assigned into the higher category. Blood pressures are based on an average of ≥ 2 careful readings obtained on ≥ 2 occasions, usually separated by a week or more.
(From reference 31.)

TABLE 33.5 JNC 7 Classification of Blood Pressure for Adults (2003)

BP Classification	SBP (mm Hg)		DBP (mm Hg)
Normal	<120	and	<80
Prehypertension	120-139	or	80-89
Stage 1 hypertension	140-159	or	90-99
Stage 2 hypertension	≥160	or	≥100

DBP, Diastolic blood pressure; *SBP,* systolic blood pressure.

TABLE 33.4 European Society of Hypertension and European Society of Cardiology Classification Scheme and Diagnostic Thresholds for Hypertension

CLASSIFICATION OF OFFICE BP				THRESHOLD BPS FOR DIAGNOSIS OF HYPERTENSION			
Category	Systolic (mm Hg)		Diastolic (mm Hg)	Category	Systolic (mm Hg)		Diastolic (mm Hg)
Optimal	<120	and	<80	Office BP	≥140	and/or	≥90
Normal	120-129	and/or	80-84	Ambulatory BP			
High normal	130-139	and/or	85-89	Daytime (or awake)	≥135	and/or	≥85
Grade 1 hypertension	140-159	and/or	90-99	Nighttime (or asleep)	≥120	and/or	≥70
Grade 2 hypertension	160-179	and/or	100-109	24-hour	≥130	and/or	≥80
Grade 3 hypertension	≥180	and/or	≥110	Home BP	≥135	and/or	≥85
Isolated systolic hypertension	≥140	and/or	<90				

Classification scheme proposed by the European Society of Hypertension and European Society of Cardiology 2013 guidelines (see reference 25).

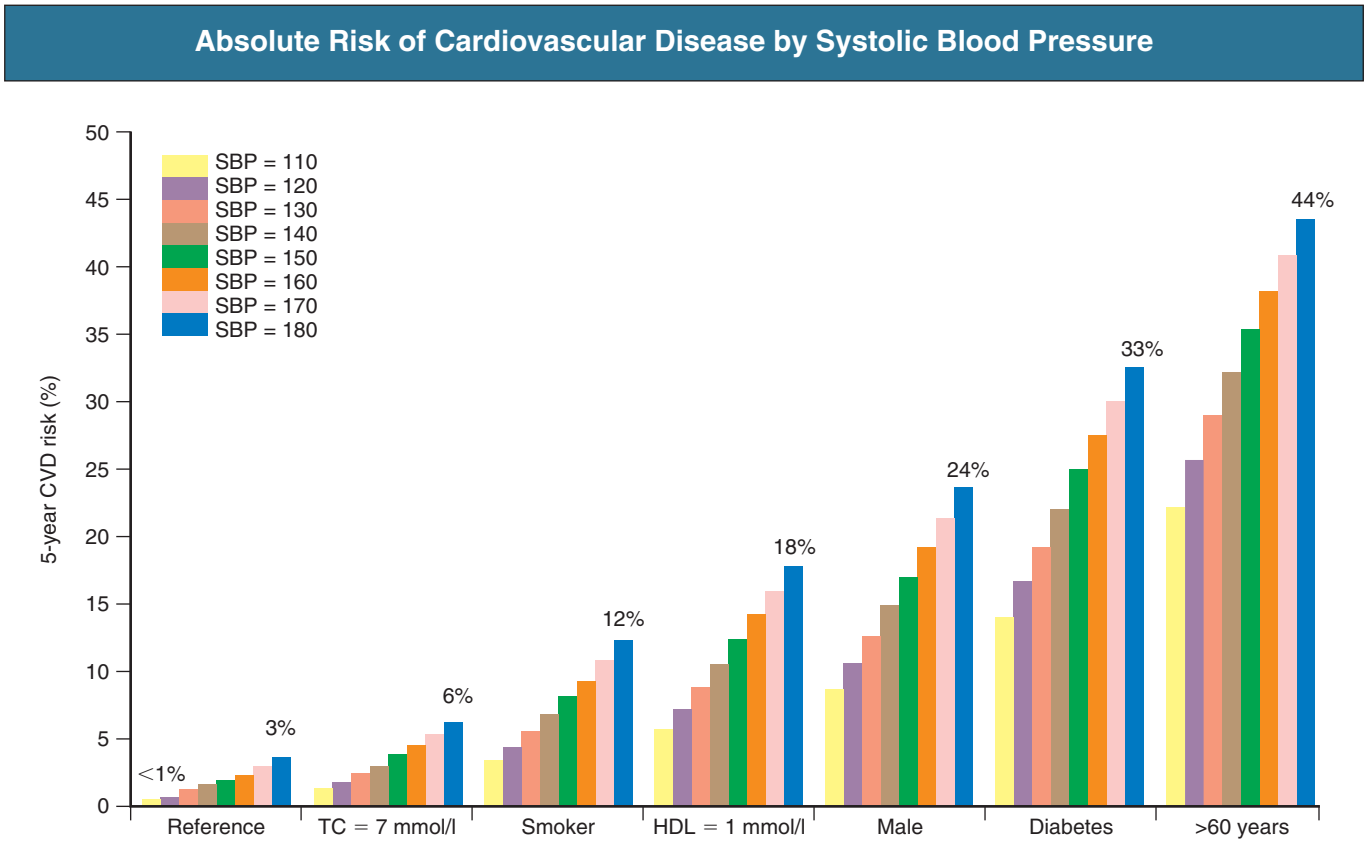

Fig. 33.6 Absolute risk for cardiovascular disease during 5 years in patients by systolic blood pressure at specified levels of other risk factors. Reference category is a nondiabetic, nonsmoking woman age 50 with total cholesterol *(TC)* level of 4 mmol/l (155 mg/dl) and high-density lipoprotein *(HDL)* level of 1.6 mmol/l (62 mg/dl). Risks are given for systolic blood pressure *(SBP)* levels of 110, 120, 130, 140, 150, 160, 170, and 180 mm Hg. In the other categories, additional risk factors are added consecutively; for example, the diabetes category is a diabetic 50-year-old male cigarette smoker with TC level of 7 mmol/l (270 mg/dl) and HDL level of 1 mmol/l (39 mg/dl). *CVD,* Cardiovascular disease. (From reference 33.)

recommend that affected persons receive only lifestyle modifications (see Chapter 35) until their BP exceeds thresholds for hypertension.

White coat hypertension. "White coat" hypertension, defined as normal BP during usual daily activities, yet elevated only in a clinical setting, has a prevalence of 20% to 25% in hypertensive persons and is most accurately diagnosed by ambulatory BP monitoring (with home BP measurements a distant second choice). Unfortunately, ambulatory BP monitoring is not widely available for routine clinical use in many countries (including the United States), despite having become the gold standard for diagnosis in research settings. The "white coat" (or "alerting") phenomenon is less common when a nurse or technician measures the BP (compared with when taken by a physician), and is rare when automated office BPs are taken with the patient alone in the examination room (as was routine in the SPRINT trial[32]). Although the most recent meta-analysis of 14 studies suggests that people with white coat hypertension have an increased long-term risk for CV events,[37] several prior studies (using carefully standardized diagnostic criteria) have concluded that CV risk in untreated persons was not significantly elevated compared with normotensive individuals[38] (Fig. 33.7). Nevertheless, many white coat hypertensive persons have subtle target organ damage and presence of biomarkers that are intermediate between normotensive and sustained hypertensive persons. As many as 50% to 75% of white coat hypertensive persons progress to sustained hypertension over time, which may be less than the more than 90% lifetime prevalence of hypertension for 50-year-old individuals. Most authorities therefore agree on the need for ongoing risk assessment and continued follow-up for persons with white coat hypertension, because many eventually receive antihypertensive medications.

Masked hypertension. Masked hypertension is defined as normal BP in the medical setting but elevated during ambulatory (or, perhaps less strictly, home) BP measurements and has a prevalence of 10% to 15% in the general population. Not surprisingly, such people often have target organ damage (which is often the only clue on initial evaluation) and a CV prognosis that is not much different than individuals with sustained hypertension[38] (see Fig. 33.7).

Sustained hypertension. Sustained (sometimes *persistent*) hypertension is diagnosed when the BP is elevated both inside and outside the medical setting, including at home and during usual daily activities. Patients with sustained hypertension should receive antihypertensive drug therapy, which reduces their risk for CV and renal events, albeit not to the level of normotensives (see Fig. 33.7).

Pseudohypertension. Pseudohypertension is defined as a significantly higher BP measured by cuff compared with that measured by an intra-arterial catheter. Typically this condition occurs in older patients and is attributed to calcium deposition, atheromatosis, and/or medial hypertrophy of the brachial (and likely other) arteries. It is suggested by the presence of a "positive Osler maneuver" in which the nonperfused radial or brachial artery is palpable despite inflating the cuff to greater than 20 mm Hg higher than the palpated SBP. Confirmation requires arterial catheterization documenting a BP 10 to 15 mm Hg lower compared with a cuff-measured BP.

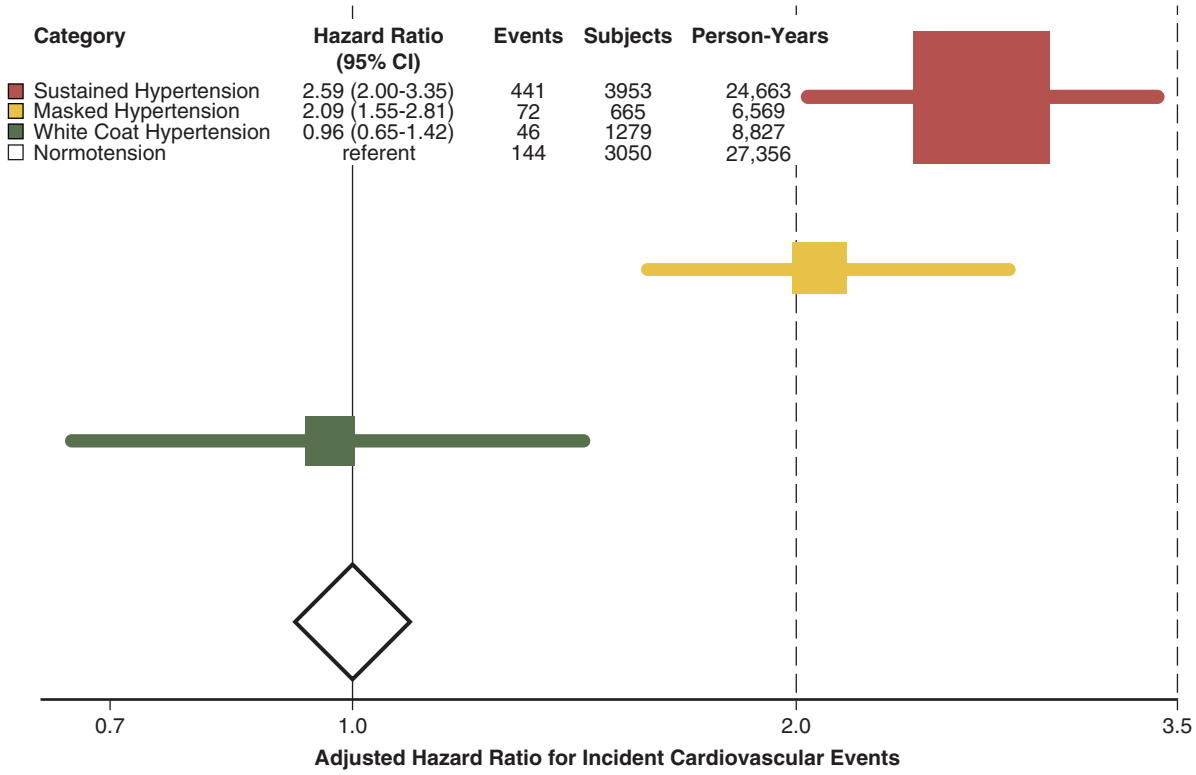

Fig. 33.7 Meta-analysis of prognosis of four types of untreated blood pressure patterns, as classified by ambulatory blood pressure monitoring: Normotension, white coat hypertension, masked hypertension, and sustained hypertension. *Horizontal lines* represent the bounds of the 95% confidence intervals (CI), *squares* are drawn in proportion to the number of events. (Modified from reference 38.)

TABLE 33.6 Common Definitions for the Metabolic Syndrome

Criterion	NCEP ATP III, 2005 Update	International Diabetes Federation, 2005
Criterion	**(≥3 Criteria)**	**(Obesity + 2 Other Criteria)**
Abdominal obesity	Waist circumference	Required for diagnosis
Men	>40 inches (>102 cm)	>94 cm
Women	>35 inches (>88 cm)	>80 cm
Hypertriglyceridemia	>150 mg/dl (≥1.7 mmol/l)	>150 mg/dl (≥1.7 mmol/l), or treatment
Low HDL		
Men	<40 mg/dl (<1.03 mmol/l)	<40 mg/dl (<1.03 mmol/l), or treatment
Women	<50 mg/dl (<1.30 mmol/l)	<50 mg/dl (<1.30 mmol/l), or treatment
Hypertension	≥130/85 mm Hg or taking antihypertensive medication	≥130/85 mm Hg or taking antihypertensive medication
Impaired fasting glucose or diabetes	Glucose ≥100 mg/dl (5.6 mmol/l) or taking insulin or hypoglycemic medication	Glucose ≥100 mg/dl (5.6 mmol/l) or taking insulin or hypoglycemic medication

Modified from reference 34.
HDL, High-density lipoprotein; *LDL,* low-density lipoprotein; *NCEP ATP III,* National Cholesterol Education Program–Adult Treatment Panel III.

TABLE 33.7 Recommendations for Follow-up Based on Initial Blood Pressure Measurements for Adults

INITIAL BLOOD PRESSURE (mm Hg)*		
Systolic	**Diastolic**	**Follow-up Recommendation**
<130	<85	Recheck in 1 year.
130-139	85-89	Recheck in 1 year; provide information about lifestyle modification.
140-159	90-99	Confirm within 2 months.
160-179	100-109	Evaluate or refer to source of care within 1 month.
≥180	≥110	Evaluate or refer to source of care immediately or within 1 week, depending on clinical situation.

*If systolic and diastolic categories are different, follow recommendations for the shorter time for follow-up. The schedule for follow-up should be modified according to reliable information about past BP measurements, other cardiovascular risk factors, or target organ disease.

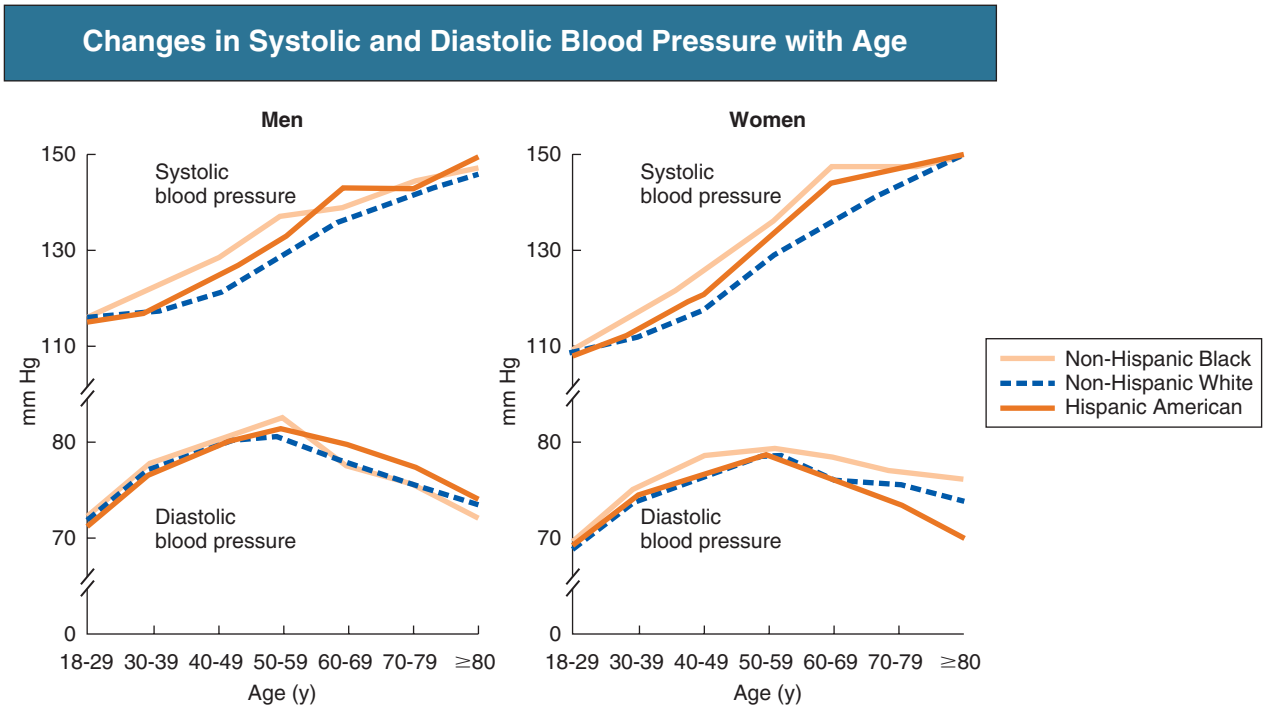

Fig. 33.8 Changes in systolic and diastolic blood pressures with age. Systolic blood pressure and diastolic blood pressure by age and race or ethnicity for men and women older than 18 years in the U.S. population (NHANES III, 1988-1991). (From reference 39.)

Isolated systolic hypertension. Isolated systolic hypertension (SBP ≥140 mm Hg, but DBP <90 mm Hg) is recognized by current hypertension guidelines in Europe[25] but not in the United States. Its prevalence increases markedly with age, becoming by far the most common form of hypertension after the age of 60 years. It arises from vascular aging and large artery stiffening, both of which reduce their capacitance, accelerate pulse wave velocity, and widen the pulse pressure. Perhaps as a consequence of these processes, SBP continuously increases throughout life, whereas DBP usually decreases after the age of 50 years (Fig. 33.8).[39] Although there was once great concern that lowering BP in patients with isolated systolic hypertension would push the DBP below the "J-curve inflection point" (and increase the risk for cardiac ischemia), all three RCTs (Systolic Hypertension in the Elderly Program in the United States, Systolic Hypertension in Europe trial, and Systolic Hypertension in China trial) showed a similar, significant decrease in stroke, and *no* increase in cardiac events, with active drug treatment compared with placebo. The significant benefits on stroke and mortality of antihypertensive drug therapy (beginning with a thiazide-like diuretic) have now been extended to relatively healthy octogenarians (most of whom had isolated systolic hypertension) in the Hypertension in the Very Elderly Trial.[40] This RCT established a SBP target of less than 150 mm Hg for octogenarians, which was also recommended by JNC 8 for patients over the age of 60 years,[27] but the dissenting minority of panel members later suggested that the more traditional SBP target of less than 140 mm Hg is reasonable, even if not directly supported by RCT evidence.[41] This position was strengthened by the subgroup analysis of SPRINT subjects over age 75 years of age, who enjoyed a 34% reduction in the primary composite end-point and a 33% reduction in mortality, if randomized to the SBP of less than 120 mm Hg.[42]

Resistant hypertension. Resistant hypertension is defined as BP above treatment goal, despite optimal doses of three antihypertensive drugs, including a diuretic.[43] Some clinical trials suggested that resistant hypertension may occur in 30% of hypertensive patients, but more population-based surveys put the U.S. prevalence at 9% to 12%. Older age and obesity are strong risk factors; in several datasets from Southern European countries, white coat hypertension is found in up to 38% of individuals with resistant hypertension. Although nonadherence to prescribed antihypertensive drug therapy is the most common cause overall, suboptimal medication regimens and secondary hypertension (especially sleep apnea) are more frequently seen in referral centers.

Hypertensive emergencies and urgencies. A hypertensive emergency exists when elevated BP (usually BP >180/120 mm Hg) is associated with severe, ongoing target-organ damage (e.g., aortic dissection, hypertensive encephalopathy, cardiac ischemia, hematuria, etc.), which benefits from BP reduction within minutes to hours, typically using intravenous, short-acting antihypertensive agents in an intensive care unit (see Chapter 37). Examples include acute aortic dissection, acute decompensated heart failure, intracranial hemorrhage, eclampsia, and pheochromocytoma crisis.[44] Hypertensive urgencies, if they really exist, often have similar elevations in BP, but no ongoing severe target organ damage, and can be handled in the outpatient department with oral antihypertensive agents and quick follow-up efforts. Recent data have confirmed observations from nearly 30 years ago that aggressive drug therapy and intensive monitoring in this situation has little benefit.[45]

Hypertension in children and adolescents. As discussed earlier, hypertension in youth was defined in the U.S. (until 2017) on a purely statistical basis: SBP or DBP at or above the 95th percentile for age, gender, and height, measured on at least three occasions.[28] Although this made quality assurance for hypertension simple in large pediatric practices, the 2017 hypertension guidelines for children and adolescents have made this rubric more complex.[31] Children have a higher risk for secondary hypertension than adults; most secondary hypertension in young children has a renal origin. Most adolescents with hypertension have primary hypertension; risk factors include a family history of hypertension and obesity, but renal causes of hypertension are more common in stage 2 hypertension (see Table 33.5).

Hypertension in pregnancy. Hypertension occurs in more than 5% of all pregnancies and in approximately 5% of women taking oral contraceptives.[46] Definitions and implications of hypertension in pregnancy are discussed in Chapters 42 and 43.

Classification by Cause of Hypertension

In 90% to 95% of adults with hypertension, the cause is unknown and therefore the diagnosis is "primary" (or essential) hypertension (see Chapter 34). Table 33.8 lists the more common causes of secondary hypertension, in descending order of prevalence in large series. Renal parenchymal disease is most common (especially in nephrology clinics, particularly in diabetics; see Chapters 31 and 32), followed by endocrine causes (Chapters 38 and 39), renovascular hypertension (Chapter 41), sleep apnea, coarctation of the aorta, drug-induced hypertension, and rare monogenetic causes (see Chapter 47).

EVALUATION OF HYPERTENSION

Blood Pressure Measurement

Arterial BP is traditionally measured in the brachial artery with the cuff-based sphygmomanometer by detecting sounds that are generated (auscultatory method) or by recording vascular pulsations (oscillometric method) after decompression of a compressed artery. Box 33.1 lists guidelines for traditional BP measurement. The most common error is using an inappropriately sized cuff, because cuffs that are too small routinely underestimate the BP. Table 33.9 provides acceptable bladder dimensions for varying arm sizes. Because of the low frequency of Korotkoff sounds, the bell of the stethoscope provides better detection than the diaphragm. Accurately taking BP is a teachable and testable skill, but many routine measurements are made with little effort to ensure their quality. As a result, many health care systems have transitioned to using automated oscillometric office BP measurements, which minimize the white coat effect, and after 5 minutes of quiet rest, provide standardized triplicate measurements in a 5-minute period. Because elemental mercury (used in classic manometers and sphygmomanometers) has been eliminated from workplaces in most countries, because of potential toxicity, and aneroid ("dial") manometers are fragile, oscillometric techniques have become increasing popular. This method directly measures MAP and then uses a proprietary algorithm to estimate SBP and DBPs. Many such semiautomatic (typically for home BP readings) and fully automatic oscillometric devices (more often used for office and ambulatory BP monitoring) have been validated against the traditional mercury column.[47] Unfortunately, semiautomatic and automatic devices may pass certifying protocols with as few as 60% of automated readings within 5 mm Hg of the observed BP. Automated BP devices require regular calibration, validation, and maintenance.

Variability of Blood Pressure

Office Versus Home Blood Pressure and Circadian Variation

BP varies considerably throughout the day, and over time, even in the same individual. This intrinsic variation causes difficulty in identifying hypertensive individuals, because there are many false negatives and even more false positives. Aside from measurement errors (which can be overcome by proper technique), intrinsic biologic variation can be addressed by taking at least three BP readings at a given visit. Recent U.S. guidelines consider the lowest SBP and DBP at any given visit (even if not measured simultaneously) to be *the* BP for that visit.[48] Confirming elevated readings at a second visit takes advantage of "regression to the mean" to better identify the true BP for a given individual. Another widely recommended option is to measure home BPs (see later discussion).

In addition to physical/mental activity, and emotional/environmental stress, BP is affected by circadian variation. About 80% of the population display a "dipping" pattern, with average nocturnal BP that is 10% to 20% lower than the daytime average; this difference diminishes with increasing age. The normal "morning surge" in BP and heart rate that begins about 30 minutes before awakening correlates with an increased risk for death, myocardial infarction, and stroke in the early morning hours. Individuals with a "nondipping" nocturnal BP pattern more commonly have CKD, target-organ damage, secondary hypertension, autonomic dysfunction, and/or an increased risk for CV events.

TABLE 33.8 Secondary Hypertension: Acquired Causes

Condition/ Disorder	Diseases: Comments
Renal disorders	Renal parenchymal disease, including acute and chronic glomerular diseases, chronic tubulointerstitial disease, PKD, diabetic nephropathy, and obstructive uropathy Renovascular disease: Renal artery stenosis caused by atherosclerosis or fibromuscular dysplasia; arteritis; extrinsic compression of renal artery Other renal causes: Renin-producing tumors, renal sodium retention (Liddle syndrome)
Endocrine disorders	Adrenocortical disorders: Primary aldosteronism, congenital adrenal hyperplasia, Cushing syndrome Adrenomedullary tumors: Pheochromocytoma (also extra-adrenal chromaffin tumor) Thyroid disease: Hyperthyroidism, hypothyroidism Hyperparathyroidism with hypercalcemia Acromegaly Carcinoid tumors
Exogenous substances and/or drugs	Oral contraceptives, sympathomimetics, glucocorticoids, mineralocorticoids, NSAIDs, calcineurin inhibitors, tyramine-containing foods and monoamine oxidase inhibitors, EPO, ergot alkaloids, amphetamines, herbal remedies, licorice (mimics primary aldosteronism), ethanol, cocaine and other illicit drugs, abrupt withdrawal of clonidine
Pregnancy	Preeclampsia and eclampsia
Coarctation of the aorta	Usually congenital, diminished pulses below the coarct, positive Hill's sign
Neurologic disorders	Sleep apnea Increased intracranial pressure: Brain tumors Affective disorders Spinal cord injury: Quadriplegia, paraplegia, Guillain-Barré syndrome Baroreflex dysregulation
Psychosocial factors	Hostility, time-urgency/impatience, depression, anxiety, occupational stress
Intravascular volume overload	Pedal or presacral edema, jugular venous distention, pulmonary râles
Systolic hypertension	Loss of elasticity of aorta and great vessels Hyperdynamic cardiac output: Hyperthyroidism, aortic insufficiency, anemia, arteriovenous fistula, beriberi, Paget disease of bone
Obesity	White adipose tissue that has endocrine function: Leptins, adiponectin, cytokines, chemokines, Ang II, other adipokines

Ang II, Angiotensin II; *EPO,* erythropoietin; *NSAIDs,* nonsteroidal antiinflammatory drugs; *PKD,* polycystic kidney disease.

BOX 33.1 Guidelines for Measurement of Blood Pressure: Patient Factors, Equipment, and Technique

Patient Factors

- Caffeine should not be consumed for 1 hour before the BP measurement.
- Cigarettes should not be smoked for at least 15 minutes before the BP reading.
- The standard BP measurement should be made with the patient not talking and seated comfortably, back and arm supported, and legs uncrossed. The cuff must be at the level of the heart, and the arm should be bare.
- The urinary bladder should be empty.
- Initially, BP should also be checked in both arms in the supine position after 5 minutes of rest; thereafter the arm with the higher reading is used for both supine and standing readings (after 2 minutes), especially in patients who are diabetic, older than 65 years, or receiving antihypertensive therapy. If sequential BP readings are taken in the same position, at least 30 seconds should elapse between BP readings. In patients younger than 30 years, check BP in one leg initially.
- To establish a diagnosis of hypertension, obtain BP readings on two different occasions, at least 1 week apart.

Equipment

- The bell of the stethoscope is preferred. The length of the bladder with the cuff should encircle at least 80% of the arm.
- The width of the cuff should be equal to two thirds of the distance from the antecubital space to the axilla and should be 40% of the arm circumference. The best cuff for most adults is the 15-cm-wide cuff with a bladder of 33 to 35 cm in length. The distal edge of the cuff should be 2.5 cm (1 inch) above the antecubital fossa. For leg BP, thigh cuff length should encircle 80% of the thigh, and width should be 40% of the thigh circumference. For leg BP, the patient should be prone and popliteal artery sounds detected by auscultation.
- For infants, ultrasound equipment may need to be used.

Technique

- The initial systolic BP should be checked by palpating the disappearance of the radial or brachial pulse before auscultation and the cuff then deflated.
- The second BP check requires cuff inflation 20 mm Hg above the palpable systolic level.
- Deflate the cuff at a rate of 2 to 4 mm Hg per second, for heart rates of 60 to 120, respectively.
- Record the Korotkoff sound I (appearance of sound) as the systolic BP and record the Korotkoff sound V (silence, 2 mm Hg below the last sound) as the more reproducible diastolic BP. If the sounds do not disappear, record the muffled sound (phase IV) as the diastolic BP.
- The sounds may be augmented by having the patient raise the arm and open and close the hand 10 times before inflating the BP cuff.
- Do not stop between systolic and diastolic BP readings; deflate the cuff, wait at least 30 seconds, and then reinflate. On each occasion, record at least two (and preferably three) BP readings. If the BP readings vary by more than 5 mm Hg, take additional BP readings until two are within 5 mm Hg.
- In children, the same standards apply for cuff size; Korotkoff sound V should be used. If the child is uncooperative, the systolic BP may be determined by palpation.

TABLE 33.9 Acceptable Bladder Dimensions for Various Arm Sizes

Usual Patient	Arm Circumference Range at Midpoint (cm)	Bladder Width (cm)	Bladder Length (cm)
Newborn	6	3	6
Infant*	6-15	5	15
Child*	16-21	8	21
Small adult	22-26	10	24
Adult	27-34	13	30
Large adult	35-44	16	38
Adult thigh	45-52	20	42

From reference 52.

*To approximate a bladder width to arm circumference ratio of 0.4 more closely in children, additional cuffs are available. There is some overlap in the recommended ranges for arm circumference to limit the number of cuffs. It is suggested that the larger cuff be used if it is available.

Home and Ambulatory Blood Pressure Monitoring

Most ambulatory BP monitors use oscillometry and record BPs for 24 hours, making measurements frequently during the daytime (e.g., every 15 minutes) and less so at night (e.g., every 30 minutes). Inaccurate readings can occur with inappropriately sized cuffs, cardiac dysrhythmias, vigorous activity, inability to sleep because of pain resulting from cuff insufflation, and many other conditions. Because ambulatory BP monitoring (1) can diagnose white coat, masked, and nocturnal hypertension; (2) correlates better with both target-organ damage and future CV events than either office or home BPs; and (3) has been found to be cost-saving in many countries, it has been recommended (as at least one of several options) by many policymaking authorities, including the 2011 and 2013 British hypertension guidelines, 2013 European hypertension guidelines,[25] 2016 Canadian Hypertension Education Program, and the U.S. Task Force on Preventive Services,[49] before starting antihypertensive drug therapy. Multiple national and international expert panels have issued guidelines regarding indications, technique, reporting, and implications of the procedure.[50]

Because of the limited availability of, and scarce reimbursement for, ambulatory BP monitoring, home BP monitoring with semiautomated devices (typically duplicate measurements morning and evening for a week) has been recommended.[25] Home BP readings, on average, are slightly higher than ambulatory BP readings (because the latter includes nocturnal BPs) and slightly lower than office BPs. Home BP readings should be obtained with a device that has been calibrated (usually in the practitioner's office), are subject to reporting bias (which can be minimized by telemonitoring systems), and their interpretation is not often reimbursed. In general, home BP readings correlate better with target-organ damage and CV outcomes than office BP measurements, but less well than ambulatory BP results. The results of an early study with 11 years of follow-up[51] comparing methods of BP measurement (Fig. 33.9) are consistent with this view. For many reasons, therefore, ambulatory BP monitoring is preferred over home BP recording in several settings[48] (Fig. 33.10 and Box 33.2).

Risk Assessment in Hypertension

The medical history, physical examination, and a limited laboratory evaluation (biochemistry panel, including estimated GFR, and fasting

BOX 33.2 Indications for Ambulatory Blood Pressure Measurement

- White coat hypertension
- Evaluation of apparent drug resistance
- Hypotensive symptoms
- Autonomic dysfunction
- Episodic hypertension
- Evaluation of nocturnal decreases in BP as a prognostic factor for target organ damage (e.g., left ventricular hypertrophy, ischemic optic neuropathy)
- Evaluation of BP changes in patients with paroxysmal nocturnal dyspnea and/or nocturnal angina
- Carotid sinus syncope
- Pacemaker syndromes
- Safety of withdrawing antihypertensive medication
- Assessment of 24-hour BP control in patient receiving once-daily medication
- Borderline hypertension with target organ damage (evaluation for masked hypertension)
- Evaluation of antihypertensive drug therapy in clinical trials

glucose and lipid panel, urinalysis and urinary albumin-to-creatinine ratio, complete blood count, electrocardiogram) provide useful information to assess the presence and extent of target-organ damage, and estimate future CV and renal risk (see Chapter 34).[24-26,33] The 2017 ACC/AHA U.S. hypertension guideline added serum thyroid-stimulating hormone to the list of recommended initial tests.[31]

Consideration of Primary Versus Secondary Hypertension

If the history, physical examination, or screening laboratory studies suggest secondary hypertension, additional studies may be warranted (Tables 33.10 and 33.11). If renal parenchymal disease is suspected, ultrasound may be useful to evaluate renal size and echogenicity (to help assess chronicity) and rule out obstructive uropathy; Doppler flow studies also can help stratify risk for renovascular hypertension, although none of four RCTs has shown significant outcome benefits after angioplasty/stenting (see Chapter 38). Because primary aldosteronism can now be controlled either with chronic aldosterone antagonists or (occasionally) after laparoscopic surgery, a ratio of plasma aldosterone to plasma renin activity ratio may be useful (see Chapter 39). Suggested evaluations for other forms of secondary hypertension are listed in Table 33.11.

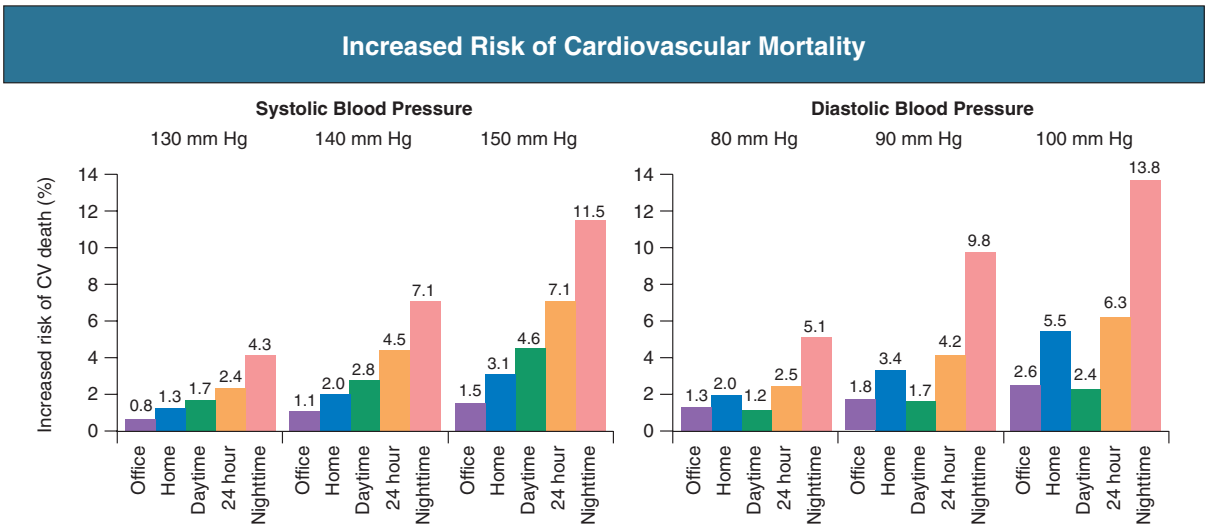

Fig. 33.9 Risk for cardiovascular mortality in an early population-based Italian study. Risk for cardiovascular death (%) over 11 years, for a 10 mm Hg increase in office, home, and ambulatory blood pressure (BP) readings at various initial BP values. (From reference 51.)

TABLE 33.10 Evaluation for Primary Versus Secondary Hypertension

Classification	Medical History	Physical Examination	Laboratory Studies
General information and evaluation of target organs	Duration and course of hypertension Prior workup and treatment Diet/lifestyle: Salt intake, tobacco, caffeine	Evaluation of volume status, optic fundi, heart, lungs, peripheral vessels, and nervous system	Complete blood count, fasting glucose, lipid profile (includes HDL, LDL, cholesterol, triglyceride), uric acid Consider echocardiogram
Primary (essential or idiopathic) or secondary?	Family history: Hypertension, cardiovascular and renal diseases Symptoms of target organ disease (related to eyes, central nervous system, cardiorespiratory, and peripheral vasculature)	See Table 33.11 for signs suggestive of secondary hypertension	See Table 33.11 for additional laboratory studies to rule out secondary hypertension

HDL, High-density lipoprotein; *LDL,* low-density lipoprotein.

TABLE 33.11 History, Physical Examination, and Initial Laboratory Evaluation for Secondary Hypertension

Target Organ/ System	Medical History	Physical Examination	Laboratory Studies
Kidney			
Renal parenchymal	History of renal disease (including glomerulonephritis, nephrotic syndrome, calculi, urinary tract infection) Symptoms include nocturia, frequency, dysuria, hesitancy, urgency, incomplete emptying, dribbling, hematuria, pyuria, flank pain	Tenderness in costovertebral angles; palpable kidneys, edema	BUN, serum creatinine; urinalysis, urine culture if indicated; first morning urine albumin-to-creatinine ratio
Renovascular hypertension		Epigastric bruit; other vascular bruits	Renal ultrasound with duplex Doppler flow study; consider angiography or magnetic resonance angiography
Endocrine			
Primary aldosteronism	Muscle weakness, cramps		Serum aldosterone/plasma renin activity ratio
Cushing syndrome	Weight gain, muscle weakness, changes in body habitus	Body habitus: Central obesity, dorsocervical fat pad, abdominal striae	Midnight salivary cortisol; consider morning serum cortisol after dexamethasone suppression
Pheochromocytoma	Headaches, vasomotor symptoms, (inappropriate sweating, pallor), cardiac symptoms (awareness, tachycardia, palpitations)	Paroxysmal or intermittent hypertension (50% of patients)	24-hr urine for VMA, metanephrines, and catecholamines or plasma fractionated metanephrines
Carcinoid	Flushing		24-hr urine for 5-hydroxyindoleacetic acid
Hyperthyroidism	Weight loss, tachycardia, palpitations, sweating, heat intolerance	Palpable thyroid	Ultrasensitive serum thyroid-stimulating hormone level
Hypothyroidism	Weight gain, dry skin, cold intolerance, hair loss	Palpable thyroid	Serum ultrasensitive thyroid-stimulating hormone level
Hyperparathyroidism	Nausea, vomiting, bone pain, nephrolithiasis		Serum calcium, intact parathyroid hormone levels
Acromegaly	Change in size of head, hands, or feet (adult)	Appearance	Serum insulin-like growth factor 1level (see Box 40.1)
Medication	Review of prescribed and over-the-counter medications (especially oral contraceptives, NSAIDs, sympathomimetic agents [cold and allergy remedies], illicit or recreational drugs, including alcohol, herbal remedies)		
Coarctation of the Aorta	Onset or detection of hypertension in childhood or adolescence	Simultaneous palpation of radial and femoral arteries to detect pulse lag in femoral arteries; leg blood pressure	Chest radiograph for heart size, configuration of aorta, rib notching; consider echocardiogram
Neurologic Disorders			
Sleep apnea	Obesity; weight gain; daytime somnolence; snoring, poor sleep habits (frequent awakening, not rested on arising); early-morning headache	Obesity, narrowed airway in hypopharynx, redundant pharyngeal tissue	Berlin questionnaire; consider formal sleep study (polysomnography)
Increased intracranial pressure	Headache, neurologic symptoms	Papilledema	Increased cerebrospinal fluid pressure
Affective disorders*			
Spinal cord injury*			
Psychosocial Factors	Family and support structure, occupation, education, stressors		

Continued

TABLE 33.11 History, Physical Examination, and Initial Laboratory Evaluation for Secondary Hypertension—cont'd

Target Organ/ System	Medical History	Physical Examination	Laboratory Studies
Volume Overload	Excess salt and water intake (may be iatrogenic with excess parenteral fluid)	Increased jugular venous distention, pulmonary crackles, presacral and peripheral edema, hepatomegaly	Chest radiograph
Isolated Systolic Hypertension		Pseudohypertension (positive Osler maneuver), cardiac and vascular examination (aortic insufficiency, arteriovenous fistula)	

A more detailed discussion is provided in other relevant chapters. Pregnancy-associated hypertension is discussed in Chapters 42 and 43.
*Medical history, physical examination, and laboratory tests are beyond the scope of this discussion.
BUN, Blood urea nitrogen; *NSAIDs,* nonsteroidal antiinflammatory drugs; *VMA,* vanillylmandelic acid.

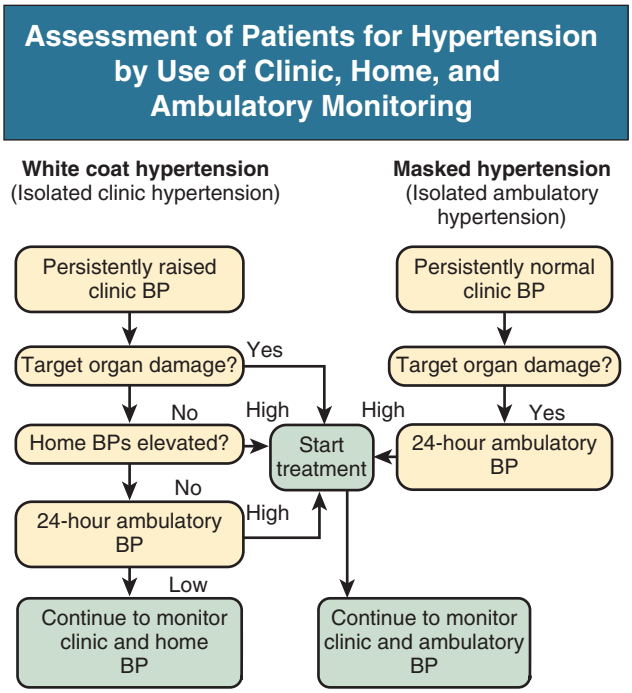

Fig. 33.10 Algorithm for diagnosis of hypertension using clinic, home, and/or ambulatory monitoring of blood pressure.

SELF-ASSESSMENT QUESTIONS

1. Short-term (within seconds to minutes) regulation of blood pressure in normal humans is most often attributed to which of the following physiologic systems?
   A. Atrial natriuretic peptides
   B. Endothelin
   C. Kallikrein-kinin system
   D. Renin-angiotensin-aldosterone system
   E. Sympathetic nervous system
2. An asymptomatic, presumably healthy, 67-year-old man visits the physician's office, and has seated blood pressures of 140/96, 138/94, and 142/88 mm Hg, as measured personally and appropriately by the physician. According to guidelines, promulgated by HEDIS 2016 and JNC 7, his blood pressure at this visit was most appropriately classified using which of the following terms?
   A. Normal
   B. Prehypertension
   C. Stage 1 hypertension
   D. Stage 2 hypertension
   E. Isolated systolic hypertension
3. A 62-year old nonblack man visits the nephrologist because his routine tests last week showed that his estimated GFR was 59 ml/min/1.73 m^2 and his first morning voided urine contained 28 mg of albumin per gram of creatinine (normal: <30 mg albumin per gram creatinine or <2.0 (men) and <2.8 (women) mg albumin per millimole creatinine). His past medical history includes prehypertension since 2015, but he takes not medications. Blood pressure is 136/84, 134/86, and 132/82 mm Hg, when measured personally and appropriately by the nephrologist. His 10-year risk of a CV event is estimated at 9.2%. According to the 2017 ACC/AHA U.S. hypertension guidelines, the most appropriate recommendation for this patient is which of the following?
   A. Recheck blood pressure in this office in 1 year.
   B. Recheck blood pressure in this office in 3-6 months and provide guidance about lifestyle modifications.
   C. Repeat blood and urine tests in 3 months, and recheck blood pressure in this office soon thereafter.
   D. Recheck blood pressure within 2 months.
   E. Institute antihypertensive drug therapy with an angiotensin converting-enzyme inhibitor or angiotensin II receptor blocker today.
4. A 32-year-old woman is referred to the nephrologist because her ophthalmologist noted grade II hypertensive retinopathy last month, and her obstetrician/gynecologist noted 2+ proteinuria on dipstick (without blood or nitrite), despite normal office blood pressures last week. Past medical history is remarkable for preeclampsia 4 and 6 years ago, but both of her children were delivered without complications, and her blood pressure has since been normal. Office blood pressures are 128/84, 126/82, and 124/80, measured by a calibrated automated oscillometric device. In addition to the retinopathy, an electrocardiogram shows voltage criteria for left ventricular hypertrophy, and a random urinalysis shows 3+ protein. According to recent surveys, her condition is most commonly seen in what proportion of which population?
   A. Less than 1% of people older than 65 years
   B. 5% to 10% of the hypertensive population
   C. 10% to 15% of the general population
   D. 20% to 25% of the hypertensive population
   E. 29% to 32% of the general population
5. A 56-year-old nonblack man is referred to the nephrologist because his blood pressures in his primary care medical home have never been below 190/120 mm Hg, yet all the rest of his evaluation is normal. A request for prior authorization for ambulatory blood pressure monitoring was denied by his insurance plan. His home blood pressures, measured with a validated semiautomatic oscillometric device, have a mean and standard deviation of 128 ± 4/78 ± 3 (122 measurements over 3 months). He has no family history of hypertension. Office blood pressures, taken with the same machine, were 194/122, 196/120, and 192/118 mm Hg. Physical examination and laboratory studies were unremarkable. The most appropriate recommendation for him is which of the following?
   A. A renal biopsy is indicated to identify the cause of his hypertension.
   B. He should have an iothalamate clearance measured, to ensure that the estimated glomerular filtration rate (GFR) is accurate.
   C. He should undergo renal ultrasound with Doppler flow studies, a 24-hour urine collection for vanillylmandelic acid and metanephrines, and a ratio of plasma aldosterone to renin activity to rule out common causes of secondary hypertension.
   D. He should start an angiotensin-converting enzyme inhibitor or an angiotensin II receptor blocker today and return to this office in 1 month for repeat blood pressure measurement by his home device.
   E. He should continue to monitor his home blood pressures and call for another appointment when/if they exceed 130/80 mm Hg.

34

Primary Hypertension

Richard J. Johnson, George L. Bakris, Bernardo Rodríguez-Iturbe

DEFINITION

Primary (essential) hypertension is defined as blood pressure (BP) 140/90 mm Hg or greater without an identifiable cause. Several readings at different times, following the American Heart Association and other guidelines, are necessary to document the diagnosis of primary hypertension. Variability in BP results from several factors, but under normal circumstances, a natural circadian rhythm generates the most significant increase in BP in the morning (6 to 10 AM). BP falls during sleep, secondary to a decrease in sympathetic nervous system (SNS) tone and reduced activity of other neuroendocrine systems. There are also minute-to-minute variations in BP (Fig. 34.1). Transient elevations in BP, reaching 150 mm Hg systolic, occur in the majority of normotensive individuals in any given day, especially during exercise.[1] However, BP that is 140/90 mm Hg or greater for an average of two or more seated BP measurements, properly measured with well-maintained equipment, at each of two or more visits to the office or clinic is considered *hypertensive.* Chapter 33 describes the method and interpretation of BP measurements, including the use of ambulatory BP monitoring.

Primary hypertension has recently undergone changes in definition, based on new guidelines from the American College of Cardiology and the American Heart Association Task Force[2]. The definition of stage I hypertension has changed from 140/90 mm Hg to either a systolic BP of >130 and/or a diastolic BP of > 80 mm Hg, and elevated blood pressure has replaced "prehypertension" and is now considered a systolic BP of 120 to 129 mm Hg and diastolic BP < 80 mm Hg (Table 34.1). These changes were made to reduce complacency since increased cardiovascular risk occurs even in the "prehypertensive" group compared to normotensive people.

When only the systolic BP (SBP) is elevated (SBP >140 and diastolic BP [DBP] <90 mm Hg), the term used is *isolated systolic hypertension. White coat hypertension* is an increase of more than 20 mm Hg in SBP noted only in the physician's office above that seen at home or in another setting. In contrast, *masked hypertension* is BP that is normal in the office but elevated by more than 20 mm Hg when measured by ambulatory BP measurement.

Other terms used to describe specific clinical presentations include *hypertensive emergencies,* associated with acute end-organ damage requiring immediate treatment, usually in a critical care setting, and *hypertensive urgencies,* in which BP needs correction in hours or a few days (see Chapter 37). In hypertensive emergencies, the reduction of BP will halt, prevent, or reverse decreasing glomerular filtration rate (GFR). These terms have replaced "malignant hypertension" and "accelerated hypertension." *Resistant hypertension* is defined as hypertension that remains above 140/90 mm Hg despite use of three maximally dosed antihypertensive medications of different classes, including a diuretic.

ETIOLOGY AND PATHOGENESIS

Many studies suggest that the physiologic basis for hypertension is a defect in renal sodium excretion. Whereas in most individuals an increase in sodium intake results in an increase in pressure associated with prompt excretion of the salt load, this "pressure-natriuresis" relationship is abnormal in the hypertensive patient (Fig. 34.2).[3] In some hypertensive patients, especially those under 40 years of age, the response to a salt load is similar to that in normal individuals but is shifted rightward, such that higher pressures are required for a specific salt load, called *salt-resistant hypertension.* In contrast, most hypertensive patients, especially older and African American individuals, have both a rightward shift and a change in the slope, such that BP increases more for the same sodium load, called *salt-sensitive hypertension.* Dietary sodium content also correlates with the prevalence of hypertension in various populations, and intervention studies with salt restriction or loading have shown that the BP response in many hypertensive patients is salt sensitive. The basis for this renal defect in hypertension remains controversial, but three major hypotheses have been proposed.

Genetic (Polygene) Hypothesis

Studies led by Lifton and colleagues[4] have made the compelling case that genetic polymorphisms that favor sodium retention by the kidney, coupled with excessive salt intake (>10 g/day) may have a major role in driving primary hypertension. The observation that numerous monogenic forms of both hypertension and hypotension are mediated by specific mutations involving renal sodium transport, especially involving the epithelial sodium channel (see Chapter 47), supports this hypothesis (Table 34.2). Currently, more than 20 genes have been identified in which mutations or polymorphisms influence BP.[4] Many of these involve sodium transport in the distal tubule or the collecting duct. Some heterozygous mutations, such as the Na-K-2Cl cotransporter *SLC12A1,* the inward rectifier K^+ channel *KCNJ1* (carrier state for Bartter syndrome), and the heterozygous mutation of the Na-Cl cotransporter *SLC12A3* (carrier state for Gitelman syndrome), confer protection from hypertension. Although genetic mechanisms are likely of major importance in the pathogenesis of hypertension, most studies suggest they contribute to only a minority of cases and that other mechanisms are also involved in driving the hypertensive response.

Congenital (Low Nephron Number) Hypothesis

A second major hypothesis is that environmental stress during pregnancy may lead to epigenetic or other changes that affect the fetus and translate into hypertension later in life (fetal programming). In 1989 Barker and associates[5] reported that infants with low birth weight

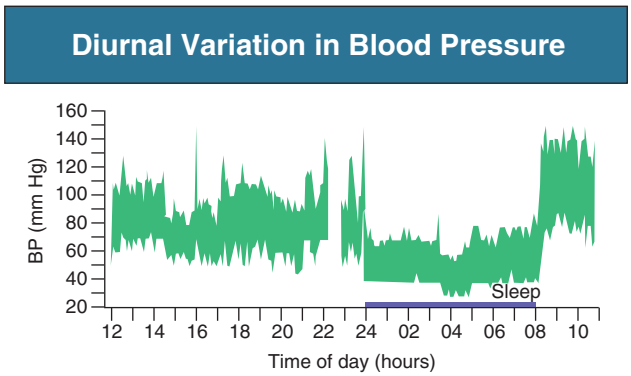

Fig. 34.1 Blood pressure variability in normotensive individual. In most normal individuals, systolic blood pressure (BP) reaches 150 mm Hg at least once daily. (From reference 1.)

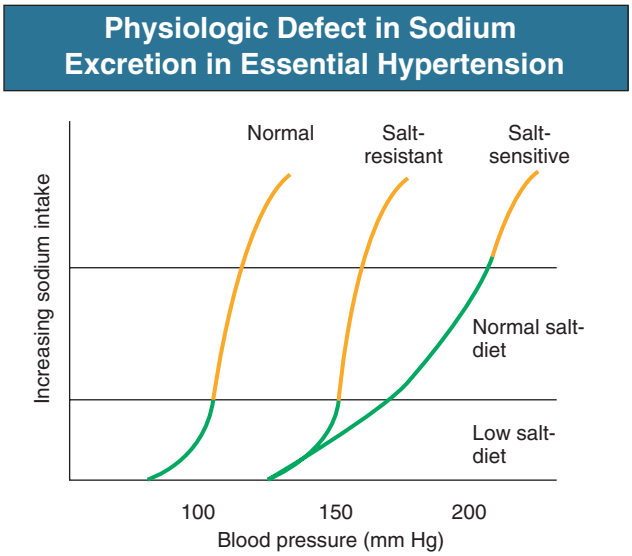

Fig. 34.2 Physiologic defect in sodium excretion in primary hypertension. Evidence suggests that in patients with primary hypertension, a higher blood pressure is required to excrete an individual sodium load. In salt-resistant hypertension, the pressure-natriuresis curve has a rightward but parallel shift; with salt-sensitive hypertension, it is both a shift to the right and a change in slope. (Modified from reference 3.)

TABLE 34.1 Categories of BP in Adults*

BP Category	SBP		DBP
Normal	<120 mm Hg	and	<80 mm Hg
Elevated	120–129 mm Hg	and	<80 mm Hg
Hypertension			
Stage 1	130–139 mm Hg	or	80–89 mm Hg
Stage 2	≥140 mm Hg	or	≥90 mm Hg

*Individuals with SBP and DBP in 2 categories should be designated to higher BP category. BP indicates blood pressure (based on an average of ≥2 careful readings obtained on ≥2 occasions, as detailed in DBP, diastolic blood pressure; and SBP systolic blood pressure.

(LBW) are at increased risk for hypertension, and these infants were also shown later to be at risk for diabetes and obesity. Mothers of LBW infants frequently have hypertension, obesity, preeclampsia, or malnutrition, and these maternal factors also carry an increased risk for hypertension in the infant. Brenner and colleagues[6] postulated that LBW might lead to hypertension because of impaired renal development, leading to lower nephron number. Maternal malnutrition in laboratory rats predisposes to small babies, low nephron number, and the future predisposition for hypertension. A study of Whites with primary hypertension found almost 50% fewer nephrons than in age- and gender-matched controls.[7] Other studies, however, could not confirm a relationship between birth weight or low nephron number and hypertension.[8] Another study also reported that LBW infants have a 25% risk for developing hypertension as an adult, but infants with high birth weight also carried a 20% risk.[9] Thus LBW and low nephron number likely reflect risk factors for development of hypertension rather than the underlying mechanism.

The Role of the Immune System and Acquired Renal Injury

The most actively studied mechanism currently involves the role of the immune system, and especially T cells, in mediating hypertension. Low-grade inflammation, consisting of T cells and macrophages, have been demonstrated in the interstitium of 90% or more of renal biopsy samples from patients with primary hypertension.[10] Historically the inflammatory changes, as well as the microvascular injury involving the afferent and interlobular artery, were considered the consequence of hypertensive renal damage.

However, experimental studies have made the compelling case that the immune system may be mediating the hypertensive response by inducing persistent renal vasoconstriction and an impairment in pressure natriuresis. Indeed, in numerous models of hypertension, the administration of mycophenolate mofetil (MMF) could be shown to block the interstitial inflammation and hypertensive response (see Table 34.1).[11] Both T[12] and B[13] lymphocytes are necessary for the development of experimental hypertension. Studies have shown that the effect appears to be mediated by both macrophages and T cells (especially the CD8 cell) and to be counter-regulated by CD4 T regulatory cell populations. More recent studies suggest that the development of hypertension may involve an initial activation of the innate immune system (involving dendritic cells and macrophages via inflammasome-dependent pathways) followed by activation of adaptive immunity in which the T cells become sensitized to neoantigens, leading to an autoimmune mediated hypertension.

Two autoantigens have been identified, including heat shock protein 70 (HSP70) and oxidized (isoketal-containing) proteins.[14,15] The role of HSP70 as a neoantigen that drives an autoimmune response is supported by experimental studies showing that blocking T-cell sensitization to HSP70 can block hypertension and sensitization of T cells to HSP70 in the kidney can induce a rise in BP. Clinical studies also have found evidence for both autoantibodies and T-cell sensitization to HSP70 in humans with primary hypertension. Isoketal accumulation in dendritic cells is associated with production of interleukin-6 (IL-6), IL-1B, and IL-23 and increase in costimulatory CD80 and CD86 proteins. Isoketal-modified proteins have been demonstrated in circulating dendritic cells and monocytes of hypertensive patients, and scavengers of isoketals prevent or ameliorate hypertension in several models of hypertension.[13] Pilot studies also suggest that blocking the immune system, such as by MMF, can lower BP in subjects with primary hypertension.[11]

The mechanism by which T cells reduce sodium excretion is thought to be by mediating intrarenal oxidative stress, inducing a decrease in nitric oxide, and increasing intrarenal angiotensin II (Ang II) levels.[11] Activation of renal afferent sympathetic nerves, likely secondary to the local inflammation, also impairs sodium excretion. The consequence is persistent afferent arteriolar vasoconstriction and a right shift of the pressure-natriuresis curve with a change of the slope, characteristic of salt-sensitive hypertension.

TABLE 34.2 Monogenic Diseases Associated With Alterations in Blood Pressure

Condition	Gene	Inheritance	Site	Manifestations
Glucocorticoid-remediable aldosteronism (GRA)	Chimeric ACTH-responsive promoter with aldosterone synthase	AD	Collecting duct	Hypertension, metabolic alkalosis
Mendelian hypertension exacerbated by pregnancy	MR gain of function	AD	Collecting duct	Hypertension, worsened by pregnancy (progesterone)
Liddle syndrome	Gain-of-function of β or γ subunit of ENaC	AD	Collecting duct	Hypertension, metabolic alkalosis
Pseudohypoaldosteronism type 1 (PHA1)	ENaC loss of function MR loss of function	AR AD	Collecting duct	Neonatal hypotension, acidosis, salt wasting
Gitelman syndrome	Na-Cl cotransporter loss of function	AR	DCT	Low BP, salt wasting, metabolic alkalosis
Bartter syndrome	Four gene mutations: Na-K-2Cl, K channel, C1 channel, Barttin	AD or AR	Thick ascending limb	Low BP, salt wasting, metabolic alkalosis
Metabolic syndrome	Mitochondrial transfer RNA	Maternal	?	Hypertension, hypercholesterolemia, hypomagnesemia
Pseudohypoaldosteronism type 2 (PHA2) or Gordon syndrome	WNK1 and WNK4 serine-threonine kinases	AD	DCT and collecting duct	Hypertension, increased K, metabolic acidosis

ACTH, Adrenocorticotropic hormone; *AD,* autosomal dominant; *AR,* autosomal recessive; *BP,* blood pressure; *DCT,* distal convoluted tubule; *ENaC,* epithelial sodium channel; *MR,* mineralocorticoid receptor; *WNK,* "with no lysine" kinase.

WHAT INITIATES THE RENAL INFLAMMATORY RESPONSE?

Several potential mechanisms have been proposed to initiate the renal immune response. Experimentally, one can induce persistent hypertension by inducing vasoconstriction and ischemia to the kidneys that results in local inflammation, such as by transient exposure to Ang II. This could potentially explain why risk factors for hypertension include substances that can induce renal vasoconstriction, such as oxidative stress, endothelial dysfunction, and overactivation of the SNS. Hyperuricemia is also a strong epidemiologic risk factor for hypertension and experimentally induces renal vasoconstriction and ischemia. Similarly, diets high in fructose-containing sugars are also associated with hypertension in humans and can induce hypertension and renal inflammation in vivo. More recently, high-salt diets themselves have been shown to directly induce activation of the immune system through a hyperosmolarity-dependent mechanism.

How Does Sodium Retention Lead to Hypertension?

The two primary hypotheses are that sodium retention may lead to hypertension either as a consequence of volume expansion or as a response to hypertonicity. Most of the recent literature suggests that hypertonicity may play a major role.[16,17]

Salt-induced hypertonicity also can activate the central nervous system (CNS) SNS, induce vasopressin release, and increase BP in mice. A possible explanation is that, in the setting of tubulointerstitial injury and intrarenal ischemia, the salt load triggers an intense renal afferent SNS activity that stimulates CNS sympathetic output. Alternatively there is some evidence that elevated CNS Na concentrations may mediate the effect.[16] Important work by Titze's group[17] suggests that sodium-induced hypertonicity may induce sodium compartmentalization to the interstitium. In particular, the skin can act as a subcutaneous reservoir for sodium in the form of sodium proteoglycans that is mediated by salt-induced hypertonicity with activation of local macrophages to release vascular endothelial growth factor C which stimulates lymphangiogenesis. The increase of lymph capillaries attenuates the hemodynamic effects of sodium retention. In these tissues the macrophages have an antihypertensive effect because depletion of the mononuclear phagocyte system blocks lymphangiogenesis and induces salt-sensitive hypertension (Box 34.1).

The role of volume expansion in the increment in BP appears to involve the release of circulating endogenous cardiotonic steroids, which function as Na^+,K^+-ATPase inhibitors. For example, ouabain is a digitalis-like factor that is released from the hypothalamus, hippocampus, and pituitary and stimulates the SNS, and marinobufagenin is a digitalis-like factor released from the adrenal cortex. These factors block Na^+,K^+-ATPase in the kidney, thereby facilitating the excretion of sodium, but at the expense of also blocking Na^+,K^+-ATPase in the vascular smooth muscle, resulting in increased intracellular calcium with vascular smooth muscle contraction and systemic vasoconstriction.[16] Circulating nitric oxide synthase (NOS) inhibitors are also present in some patients with primary hypertension. The increase in systemic vascular resistance also may be amplified by the loss of systemic capillaries (microvascular rarefaction) that occurs in this condition.

BOX 34.1 Mechanisms That Can Trigger Salt-Sensitive Hypertension in Experimental Animals Through Induction of Microvascular Injury and Interstitial Inflammation

- Angiotensin II infusion
- Inhibition of nitric oxide synthesis (treatment with L-NAME)
- Catecholamine infusion
- Diet-induced hypokalemia
- Hyperuricemia induced by uricase inhibition
- Reduced nephron number through maternal malnutrition
- Induction of nephrotic syndrome with use of bovine serum albumin
- Page kidney
- Lead-induced hypertension
- Cyclosporine nephropathy
- Genetic models of hypertension (Dahl salt-sensitive rat, spontaneously hypertensive rat)

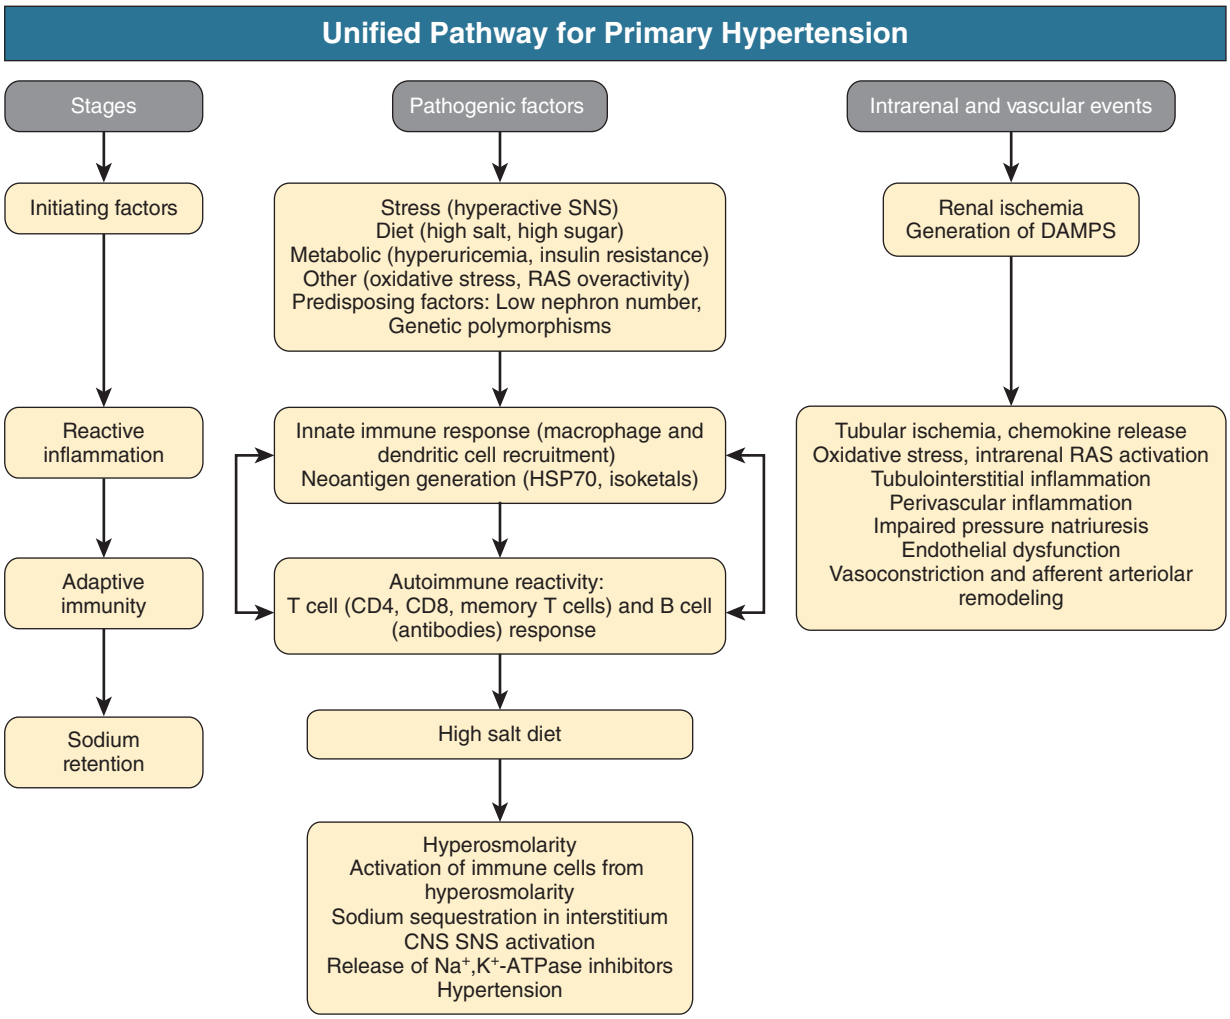

Fig. 34.3 Unified pathway for primary hypertension. *CNS,* Central nervous system; *DAMPS,* damage-associated molecular patterns; *HSP70,* heat shock protein 70; *RAS,* renin-angiotensin system; *SNS,* sympathetic nervous system.

Pathogenic Mechanisms Driving the Current Epidemic of Hypertension

As discussed under Epidemiology, there has been a marked rise in the prevalence of hypertension in the last century. The rise in hypertension corresponds with the introduction of Western diet and lifestyle and with the dramatic increase in obesity. Obesity may cause hypertension through multiple mechanisms, including subtle renal injury, effects of hyperleptinemia or hyperinsulinemia, hyperuricemia, coexistence of endothelial dysfunction, and activation of the SNS.[18] Chronically elevated leptin levels, which are common in obese persons, can activate the SNS in the CNS through pro-opiomelanocortin neurons that activate melanocortin-4 receptors.[19]

Another proposed mechanism is an elevated uric acid level, possibly driven by intake of fructose-containing sugars. Experimental studies have reported that elevated uric acid can mediate hypertension in association with the development of subtle renal injury, and small clinical trials have reported a benefit on BP of reducing uric acid in adolescents with either prehypertension or primary hypertension.[20] Some studies also have implicated a hyperactive SNS in early hypertension, particularly in young or borderline hypertensive patients.[21] Postulated mechanisms include a defect in baroreceptor sensitivity and an increase in SNS response to emotional or work-related stress. Activation of either the systemic or the local renin-angiotensin system (RAS) is also common in hypertension. Whereas plasma renin activity is elevated in 20% of patients, renin activity is either normal (50%) or low (30%) in the majority. However, normal renin activity may be inappropriately high in relation to the total body sodium.

In addition, some hypertensive patients have elevated plasma aldosterone, especially if the RAS is inhibited with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs), known as *aldosterone breakthrough.*[22] Typically, such patients are obese and have hyperinsulinemia or some degree of endothelial dysfunction. Their aldosteronism is driven by a mechanism other than Ang II or hyperkalemia.

A proposed schema for the pathogenesis of hypertension is shown in Fig. 34.3.

EPIDEMIOLOGY

Primary hypertension is epidemic. In the United States, the prevalence has increased steadily since the early 1900s and has leveled in the last few years[23] (Fig. 34.4). Although some of the increase in hypertension reflects an increasingly aging population, there is also an increase in primary hypertension in the pediatric population. The increase in

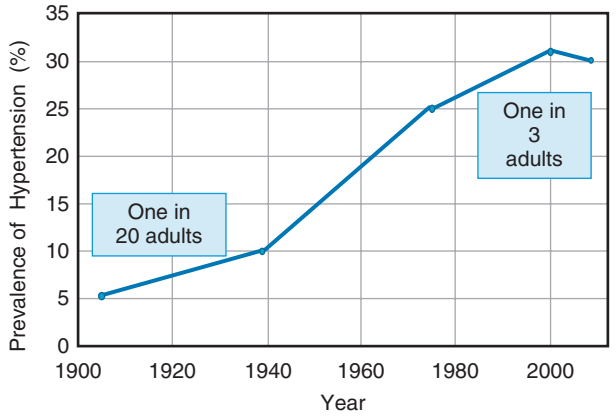

Fig. 34.4 Epidemic of hypertension. The prevalence of primary hypertension (defined as BP >140/90 mm Hg) in the United States increased from 11% in 1939 to 31% in 2008, leveling to 29% of the population in 2012.

TABLE 34.3 Major Risk Factors for Primary Hypertension

Genetic	Family history Polymorphisms (adducin, endothelial nitric oxide synthase, angiotensinogen, β_2-adrenoceptor, human G protein β3 subunit)
Congenital	Low birth weight, low nephron number, maternal hypertension, maternal preeclampsia, maternal malnutrition
Physical	Obesity, older age, African American, African Caribbean, some Bantu-speaking peoples in Africa, increased heart rate (>83 beats/min), increased emotional stress
Diet/toxin	Increased sodium intake, low potassium intake, low dairy products intake, heavy alcohol intake, high intake of added sugars, low level lead or cadmium intoxication
Metabolic*	Elevated serum uric acid, insulin resistance, elevated hematocrit
Other	Low socioeconomic status, urban versus rural

*Laboratory-based parameters.

hypertension correlates with increasing frequency of obesity, type 2 diabetes, and chronic kidney disease (CKD), suggesting a strong interrelationship.

Of risk factors for hypertension, family history is very important (Table 34.3). One major risk factor is age, and by 80 years of age, 90% of individuals are likely to be hypertensive.[24] This age-related increase in prevalence of hypertension has been observed in most Western countries but has not been uniformly observed in all populations. Second, hypertension is more common in men, although the prevalence in women is similar to and slightly exceeds that of men after age 55. Certain racial groups are at increased risk for developing hypertension much earlier in life, particularly African Americans and Filipino Americans in the United States and various minority populations throughout the world (e.g., Australian aborigines and Maoris). Risk factors for hypertension include strong family history, obesity, insulin resistance, hyperuricemia and/or gout, sleep disorders including sleep apnea, and persistent high-stress living environments either at work or home. Certain physical features, such as elevated heart rate or an increased BP response to exercise, are also predictive, as is elevated hematocrit.

Genetic factors also contribute, as discussed earlier. Although the inheritance patterns do not follow Mendelian genetics for a single gene locus, evidence suggests that 20% to 30% of hypertension may have a genetic basis, because of the cumulative effect of multiple susceptibility genes (the polygene hypothesis). A recent genome-wide association screen found 29 polymorphisms that could account for approximately 13% of primary hypertension, with several of the polymorphisms linked with natriuretic peptide and NO signaling.[25] Others have noted polymorphisms involving immune system and oxidative stress mechanisms (HSP-70 variants, xanthine oxidase, and extracellular superoxide dismutase), vasoactive mediators (angiotensinogen, endothelial NOS, prostacyclin synthase, β_2-adrenoceptor, 20-HETE synthase [*CYP4F2* gene], G protein β3), mediators of vascular smooth muscle tone (calcium-dependent potassium channel, *KCNMA*), or mediators controlling renal sodium transport (α-adducin and 11β-hydroxysteroid dehydrogenase type 2, aldosterone synthase, "with no lysine" kinase [WNK] kinases).

Hypertension is more likely to occur if the mother has a history of hypertension, obesity, preeclampsia, or malnutrition. These risk factors are all associated with intrauterine growth restriction and LBW, both of which predispose to future hypertension, as well as diabetes and obesity.

Dietary and other environmental factors may contribute to the risk for hypertension. Obesity, with or without features of insulin resistance and metabolic syndrome, is a major risk factor for hypertension and parallels the rise in hypertension in these countries. Epidemiologic and interventional studies have linked salt intake and low potassium intake with persistent BP elevation, leading to earlier development of hypertension, and although the relationship is best demonstrated in older patients and in African Americans, it is true across the world. Increasing potassium intake lowers BP in both experimental and human studies. More recently, intake of added sugars (e.g., sucrose, high-fructose corn syrup) has been found to predict higher BP. Certain toxins, most notably low-level lead and cadmium intoxication, are also associated with increased frequency of hypertension.

CLINICAL MANIFESTATIONS

Evaluation of a patient with hypertension requires a careful history and physical examination, an evaluation of risk factors for hypertension, a search for potential secondary causes, and an evaluation for end-organ damage.

BP should be measured on at least three occasions to confirm persistent hypertension using the techniques described in Chapter 33. Home BP monitoring or 24-hour ambulatory BP monitoring is recommended to determine if the hypertension occurs only in the physician's office (white coat hypertension) and rarely to identify masked hypertension, in which BP elevations occur only outside the physician's office. White coat and masked hypertension can be associated with end-organ disease, including left ventricular hypertrophy (LVH) and microalbuminuria; diagnosis should be followed by assessment of CV risk factors and frequent reevaluation of BP.

The history should investigate the onset and duration of hypertension and the presence of a family history of hypertension or cardiorenal disease. The history should identify risk factors for hypertension (obesity, diabetes, physical activity, gout, alcohol, smoking, diet, emotional or work-related stress, over-the-counter and prescribed medications) and any hypertension-related morbidity. Hypertension is often asymptomatic, but studies have found that even childhood-associated hypertension can be associated with impaired memory and mental performance, and hypertension remains a major risk factor for vascular dementia. Good BP control improves mental performance and decreases the risk for developing dementia.[26] Hypertension, especially stage 2 (see Table 34.1),

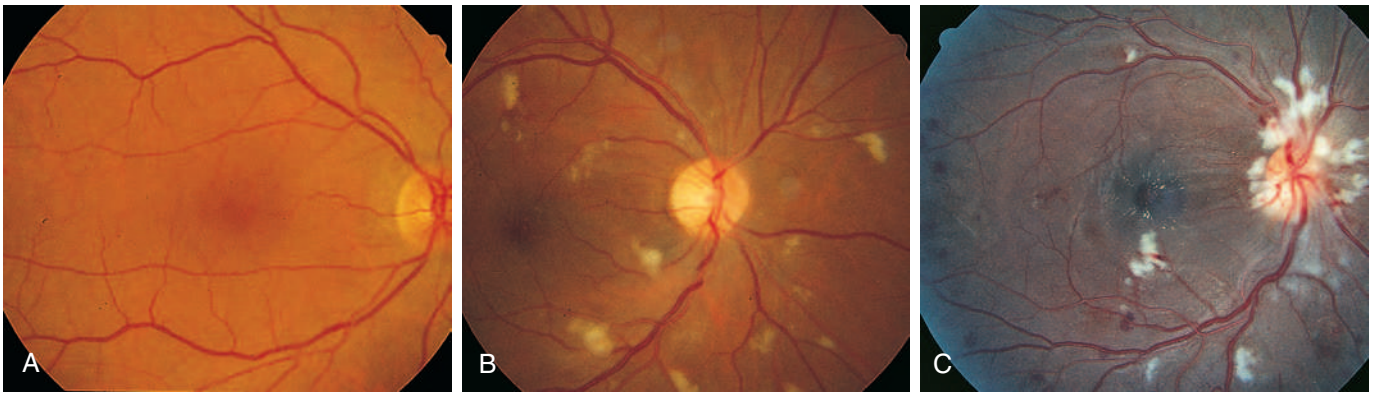

Fig. 34.5 Different grades of hypertensive retinopathy. (A) Mild hypertensive retinopathy, with arteriolar narrowing and arteriovenous nicking. (B) Moderate hypertensive retinopathy, with cotton-wool spots (nerve fiber layer infarcts) and arteriovenous nicking. (C) Papilledema, cotton-wool spots, macular yellow exudates (star formation pattern), and retinal hemorrhages in a subject with hypertensive emergency. (Provided by J. Kinyoun, University of Washington.)

also may be associated with headache, classically occipital and pulsatile. In hypertensive emergency, encephalopathy may rarely occur, with an acute decline in mental status and seizures. In addition, rarely, patients may lose vision from papilledema. Stage 2 hypertension also places individuals at acute risk for myocardial infarction (MI), congestive heart failure (CHF) with pulmonary edema, aortic dissection, cerebrovascular accident (stroke), and renal failure.

Physical examination includes BP measurement in both arms and a careful cardiac examination. Attention should be focused on both the large vessels (by both palpation and listening for bruits) and the retina to grade the severity of disease in the microvasculature (Fig. 34.5). Laboratory tests should include hematocrit, electrolytes, creatinine (and estimated GFR), calcium and phosphate (to look for primary hyperparathyroidism), fasting lipid profile (cholesterol and triglycerides), uric acid, and urinalysis. A chest x-ray film and electrocardiogram should be performed to assess cardiac size and look for aortic dilation.

Additional tests include assessment of 24-hour urine sodium and potassium excretion. Urinary Na^+ and K^+ excretion correlates with intake if the patient is in steady state (desirable values are <100 mmol/l Na^+ and >100 mmol/l K^+ in 24 hours). A spot urine albumin-creatinine and an echocardiogram may uncover additional evidence of end-organ damage (Fig. 34.6). Note that a spot urine albumin-creatinine is recommended only for those with diabetes or stage 2 or higher CKD. Echocardiography is not recommended for routine use in patients with hypertension because of its cost, although appropriate for those with cardiac problems.

PATHOLOGY

Primary hypertension is characterized by disease of the preglomerular arterial vessels, primarily the afferent arteriole and interlobular artery. The classic lesion, seen in 90% of patients, is arteriolosclerosis, in which smooth muscle cells of the media in the afferent arteriole are replaced by connective tissue[10] (Fig. 34.7). Often, hyaline material (plasma proteins) accumulates in the subintima (hyalinosis). In addition to the arteriolar disease, there is often evidence of glomerular and tubulointerstitial ischemia with shrinkage of the glomerular tuft, tubular atrophy, and interstitial fibrosis. Occasionally, glomerulosclerosis and severe tubulointerstitial injury are seen. In cases of hypertensive emergency, a proliferative arteriolopathy occurs, occasionally with fibrinoid necrosis. Concentric layers of connective tissue and cells may give an onion-skin appearance to the intima, which may progress to a total obliteration of the lumen.

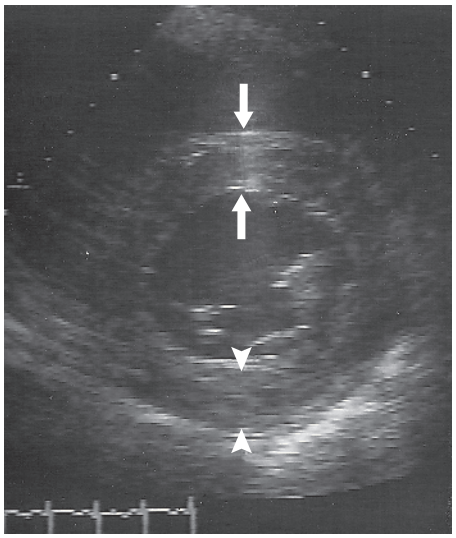

Fig. 34.6 Echocardiogram showing concentric left ventricular hypertrophy. Septal thickness *(between large arrows)* and posterior wall thickness *(between arrowheads)* are increased (to 16 mm) in a patient with primary hypertension (normal is 11 mm or less). (Provided by A. Pearlman, University of Washington.)

DIAGNOSIS

The diagnosis of primary hypertension requires the elimination of secondary causes, of which the more common include medications (nonsteroidal antiinflammatory drugs, corticosteroids, sympathomimetics, oral contraceptives), recreational drugs (excessive alcohol intake, cocaine), intrinsic renal parenchymal disease, renovascular disease, and primary aldosteronism from adrenal hyperplasia or tumors. Table 33.10 provides a more complete list along with the recommended evaluation for secondary causes.

NATURAL HISTORY

The major long-term risk of hypertension is cardiovascular disease (CVD), which can be separated into pressure-related (stroke, CHF), atherosclerotic (MI), and renal (CKD) causes. Hypertension is the most common cause of stroke and CHF, and the risk increases linearly with BP[27] (Fig. 34.8).

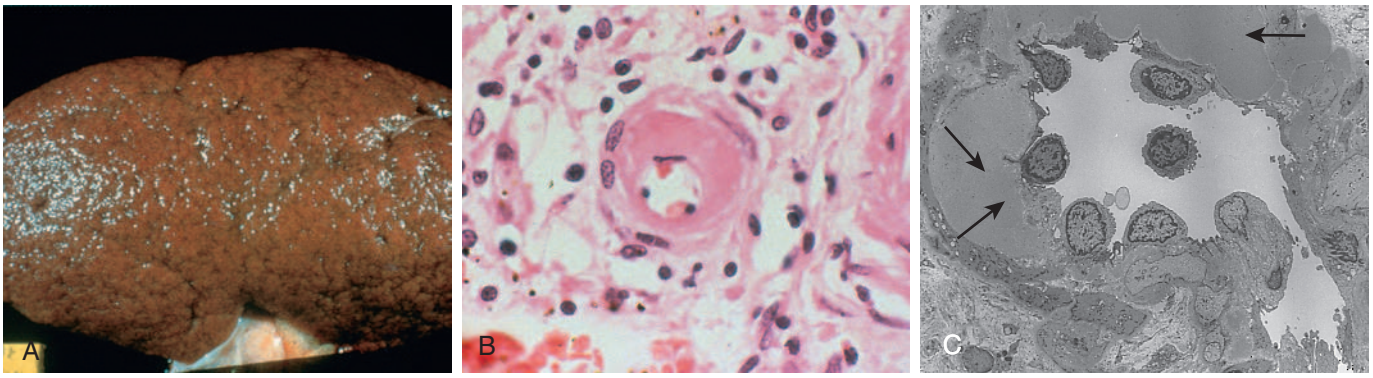

Fig. 34.7 Renal pathology in primary hypertension. (A) A granular pitted kidney in a subject with chronic primary hypertension. (B) Arteriolosclerosis with subintimal hyalinosis. (C) Electron micrograph showing hyalinosis with the accumulation of insudative plasma proteins in the subendothelium of an arteriole. Fig. 34.8 Relative risk for stroke and coronary heart disease increases with increased diastolic blood pressure. (A) Cerebrovascular accident (stroke) data are from seven prospective observational studies and 843 events. (B) Coronary heart disease data are from nine studies and 4856 events. Size of *squares* is proportional to the number of events in each category; *vertical lines* indicate 95% confidence intervals. (Modified from reference 27.)

Other rarer pressure-related morbidities include aortic dissection and cerebral and aortic aneurysms. Increased systolic, diastolic, and pulse pressure all confer risk, although the SBP and the pulse pressure (in particular when associated with low DBP) are the more important determinants of risk for the pressure-related morbidities. This increased risk depends on age (increases with age), gender (greater in males), ethnic origin (greater in African Americans), and other conditions (especially diabetes).

Cardiac consequences of poor hypertension control begin with concentric LVH associated with supernormal systolic function. Over time, impaired diastolic dysfunction may occur, as manifested by slow diastolic filling, which reflects decreased diastolic relaxation. This may progress to CHF. Almost 90% of patients with CHF have a history of hypertension.

Hypertension also confers risk for atherosclerotic-associated morbidities, including coronary heart disease,[27] peripheral vascular disease, and carotid atherosclerosis with or without cerebral emboli. In addition to an increased prevalence of hypertension, African Americans also have a 50% greater risk for heart disease.

Kidney Disease

Most patients with newly diagnosed primary hypertension have normal renal function, stage 1 CKD (GFR >90 ml/min/1.73 m^2 with microalbuminuria) or stage 2 CKD (GFR 60 to 90 ml/min/1.73 m^2) with elevated renal vascular resistance.[28] Despite relatively normal renal function, renal biopsy, if done, usually shows arteriolosclerosis and hyalinosis (see Fig. 34.7).

Before use of effective antihypertensive agents, proteinuria developed in up to 40% of hypertensive patients and as many as 18% developed renal impairment over time. Microalbuminuria, which is a marker of vascular disease and CV risk, occurs in 15% to 30% of patients, whereas non-nephrotic proteinuria is uncommon and nephrotic-range proteinuria is rare.[29] Microalbuminuria is associated with salt-sensitive hypertension, the loss of nocturnal dipping in BP, and increased target organ damage, especially LVH. Elevations in serum creatinine develop in 10% to 20% of patients with poorly controlled BP, and the risk is greater in African Americans, elderly persons, patients with hyperuricemia, and those with higher SBP (>160 mm Hg).[30,31] In 2% to 5% of those with poorly controlled SBP (>160), progression to renal failure will occur over the subsequent 10 to 15 years (Figs. 34.9 and 34.10). Despite the relative infrequency for hypertension to progress to end-stage renal disease (ESRD), hypertension is recorded as the second most common cause of ESRD after diabetes in the United States and Europe. Furthermore, almost all patients with diabetes have hypertension when they start dialysis.

The incidence of ESRD in African Americans with hypertension is fourfold to sixfold greater than in Whites.[31,32] Renal biopsies of African

Americans with hypertension show more severe hypertensive injury, with more prominent vascular changes and increased frequency of segmental and global glomerulosclerosis. Although some of these vascular changes may relate to the presence of certain transforming growth factor-β (TGF-β) polymorphisms or the higher uric acid levels that are common in this population, recent studies suggest that the increased frequency of glomerulosclerosis may be caused by a polymorphism in apolipoprotein L1 (APOL1), the product of which is expressed in the podocyte.[33] The mechanism by which *APOL1* polymorphisms increase the risk for progression of renal disease is unclear but may relate to effects on the podocyte or on the microvasculature.

Effect of Antihypertensive Therapy on Natural History of Hypertensive Cardiovascular Disease and Kidney Disease Progression

The specific pharmacologic approach to treatment of hypertension is discussed in Chapter 36, whereas the effect of antihypertensive therapy on CV and renal outcomes is discussed here. As of 2012, only 71% of patients with hypertension in the United States are receiving treatment and only 48% have their BP under adequate (<140/90 mm Hg) control.[34]

TABLE 34.4 Meta-Analysis of Effect of Antihypertensive Agents on Cardiovascular Outcomes in Hypertensive Patients

Outcome	No. of Trials	Effects Model	RR (95% CI)	P Value for Heterogeneity
Coronary heart disease	24	Fixed	0.86 (0.80-0.93)	.55
		Random	0.87 (0.80-0.94)	.55
Stroke	23	Fixed	0.69 (0.64-0.74)	.004
		Random	0.68 (0.61-0.76)	.004
CHF	7	Fixed	0.54 (0.45-0.66)	.66
		Random	0.60 (0.49-0.74)	.80
Major CVD events	28	Fixed	0.78 (0.74-0.81)	<.001
		Random	0.73 (0.62-0.87)	<.001
CVD mortality	23	Fixed	0.84 (0.78-0.90)	.10
		Random	0.84 (0.78-0.90)	.10
Total mortality	25	Fixed	0.90 (0.85-0.95)	.58
		Random	0.90 (0.85-0.95)	.59

From reference 35.
CHF, Congestive heart failure; *CI,* confidence interval; *CVD,* cardiovascular disease; *RR,* relative risk.
Analysis was based on 42 clinical trials that included 192,478 patients randomized to seven major treatment strategies, including placebo.

Although age-adjusted mortality for stroke and coronary artery disease has been significantly reduced since the early 1980s as a result of better BP control (and better treatment of other risk factors such as hyperlipidemia), heart disease and stroke remain the first and third leading causes of death in Western countries. This emphasizes the importance of identifying and treating patients with hypertension.

Antihypertensive therapy reduces stroke, heart failure, and CV complications in patients with hypertension, although historically there were fewer data to support benefit for stage 1 hypertension (see Table 34.4).[35] Recently, the Systolic blood PRessure INTervention (SPRINT) trial documented significant reduction in CV events and mortality in nondiabetic hypertensive subjects in whom SBP was targeted to 120 mm Hg systolic compared with 140 mm Hg in the group with standard treatment.[36] A consequence of the more intensive treatment was a higher risk for complications, including hypotension, syncope, and acute kidney injury. The SPRINT trial is consistent with other studies suggesting the best overall BP control has the best outcome.[37] One exception comes from the recent ACCOMPLISH trial, in which both groups had similar BP control, but the group initially randomized to an ACE inhibitor with a calcium antagonist had a 20% CV risk reduction compared with the ACE inhibitor plus diuretic group.[38] Note that almost all people with some level of kidney disease will require two or more medications.

The effect of antihypertensive therapy on the progression of renal disease secondary to hypertension is more controversial. In subjects with CKD the use of diuretics (e.g., chlorthalidone) is commonly needed and provides greater initial reductions in BP than most antihypertensive agents, although they are not considered agents of first choice for treatment of primary hypertension by any except U.S. guidelines. In the Multiple Risk Factor Intervention Trial (MRFIT), in which diuretics and β-blockers were primarily used to control BP, slowing or stabilization of renal function was not seen in African American men, but was seen in all other racial groups studied.[39] In the African American Study of Kidney Disease, use of an ACE inhibitor (ramipril) was more effective at slowing CKD progression than either the dihydropyridine calcium channel blocker amlodipine (Fig. 34.11) or metoprolol.[40,41] However, both studies, as well

Ramipril Is Superior to Amlodipine in Reducing Renal Events in Hypertensive African Americans with Renal Impairment

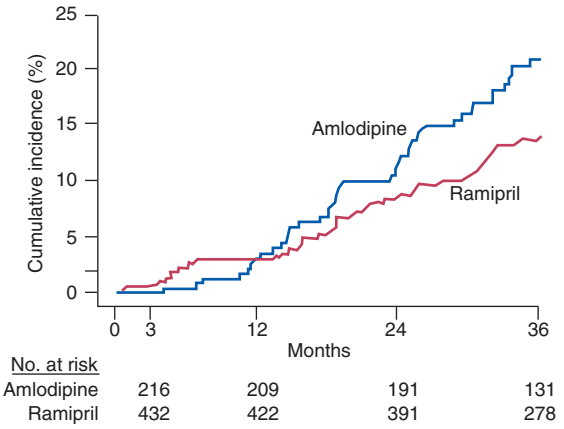

Fig. 34.11 Ramipril is superior to amlodipine in reducing renal events in hypertensive African Americans with mild to moderate renal impairment. The angiotensin-converting enzyme (ACE) inhibitor ramipril resulted in fewer renal end-points (proteinuria, decline in renal function, ESRD, death) compared with the dihydropyridine calcium channel blocker amlodipine, in the African American Study of Kidney Disease. (From reference 41.)

as the recent SPRINT study, failed to show superior protection with tight BP control compared with conventional BP targets in patients with renal disease secondary to hypertension.[40,42] Masked hypertension may be a confounder to these results; a subanalysis of ambulatory BP showed inadequate 24-hour BP control in more than 70% of the cohort. Masked hypertension and nondipping (i.e., lack of BP decrease with sleep) were the two most common reasons for poor BP control.[43]

Further studies are being performed regarding the dosing and timing of antihypertensive treatment to evaluate changes in overall BP control. In contrast, post hoc analyses of trials show that patients with diabetic renal disease or proteinuric (>300 mg/day) renal disease, including that caused by hypertension, appear to benefit from lower BP goals in terms of renal protection. Based on current evidence, achieved BP levels should be less than 140 mm Hg systolic for nonproteinuric hypertensive renal disease and less than 130/80 mm Hg in those with diabetes and hypertension.[44] However, because all of the prospective randomized CKD outcome trials have failed to show a benefit, the updated Kidney Disease: Improving Global Outcomes (KDIGO) guidelines recommend a BP goal of less than 140/90 mm Hg in those with CKD, as backed with the highest level of evidence. The previous goal of less than 130/80 mm Hg in the presence of very high albuminuria (>300 mg/day) has a much lower level of evidence and is not endorsed.[45]

Some studies also suggest that thiazide diuretics are associated with worsening of renal function in patients with hypertension. In the European Working Party on High Blood Pressure in the Elderly trial, a significantly higher incidence of impaired renal function was found in those receiving diuretics than with placebo.[46] In the Systolic Hypertension in the Elderly trial, serum creatinine increased significantly in those treated with thiazide diuretics compared with placebo.[47] In the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), the chlorthalidone-treated group showed statistically worse renal function than either the amlodipine or the lisinopril group, at both 2- and 4-year end-points.[48] This could likely be accounted for by volume depletion in many cases, but diuretics have been shown to induce mild renal injury in various animal models, possibly because of hypokalemia, hyperuricemia, and stimulation of the renin-angiotensin-aldosterone system (RAAS) related to decreased renal perfusion pressure.[49]

Can Primary Hypertension Spontaneously Remit?

In those under age 60, as many as 15% to 20% of patients with prehypertension may become normotensive spontaneously. Furthermore, in patients with established hypertension who have good BP control for 5 years under treatment, as many as 20% to 40% can be withdrawn from therapy successfully, especially if they have stage 1 hypertension and adhere to salt restriction and weight reduction. This suggests that the processes that mediate hypertension are at times reversible.

SELF-ASSESSMENT QUESTIONS

1. Primary hypertension is characterized by all of the following except:
   - **A.** Primary hypertension is more common in older patients.
   - **B.** Salt sensitivity is less common in older patients.
   - **C.** Primary hypertension is associated with a reduction in renal blood flow and usually mild reduction in glomerular filtration rate (GFR).
   - **D.** Primary hypertension is more common in individuals with low birth weight and low nephron number
   - **E.** The presence of the APOL1 polymorphism is associated with more rapid progression of kidney disease in hypertensive African American subjects.
2. The renal pathology in patients with primary hypertension may consist of all of the following except which feature?
   - **A.** Arteriolosclerosis with arteriolar fibrosis or hyalinosis.
   - **B.** Evidence of tubular ischemia change is commonly present.
   - **C.** Glomerulosclerosis may be present, especially in African Americans.
   - **D.** Renal histologic studies can rarely appear normal.
   - **E.** Transmural necrosis of medium-sized vessels can occasionally be observed.
3. Which of the following is not a dietary risk factor for primary hypertension?
   - **A.** Sodium
   - **B.** Potassium
   - **C.** Sugar
   - **D.** Alcohol
   - **E.** Coffee

Nonpharmacologic Prevention and Treatment of Hypertension

Brian Rayner, Karen E. Charlton, Wayne Derman

Lifestyle changes, including a combination of increased fat and refined carbohydrate intake and reduced physical activity, have resulted in a worldwide epidemic of obesity, type 2 diabetes mellitus, and hypertension that is most pronounced in underserved and indigenous populations. Adoption of healthy lifestyles is critical preventing and managing high blood pressure (BP). According to the American Society of Hypertension (ASH) and International Society of Hypertension (ISH) Practice Guidelines, lifestyle interventions lower BP, enhance efficacy of antihypertensive medication, and lower overall cardiovascular (CV) risk.[1] The lifestyle changes that are widely agreed to lower BP and CV risk are (1) smoking cessation, (2) weight reduction, (3) moderation of alcohol intake, (4) physical exercise, (5) reduction of salt intake, (6) increase in fruit and vegetable intake, and (7) decrease in saturated and total fat intake. Interventions may have efficacy similar to that of single-drug therapy (Table 35.1). However, lifestyle changes should not delay the initiation of drug therapy in patients at higher CV risk.

PREVENTION

The importance of primary prevention has been underscored by the recognition that hypertension is common, treatment is lifelong, the control of BP in hypertensive individuals does not restore CV risk to normal, and the majority of hypertensive individuals do not reach goal BP readings. The most important individuals to target are those with *prehypertension* (defined by JNC 7 as 120-139/80-89 mm Hg).[2] Those with prehypertension have increased prevalence of early vascular damage, increased risk for incident hypertension, and increased risk for CV events compared with those who have optimal BP levels (<120/80 mm Hg).[3] The World Health Organization (WHO) Global NCD (Non-Communicable Disease) Alliance Action Plan advocates the following voluntary global targets for country member states: 10% reduction in harmful use of alcohol, 10% reduction in insufficient physical activity, 30% reduction in mean population intake of salt, and 30% reduction in current tobacco use. Up to 80% of cardiovascular disease (CVD) can be prevented through lifestyle measures that include maintenance of healthy weight, adequate physical activity, a healthy diet, and avoidance of tobacco.[4] These targets align with *The Lancet's* Commission on Hypertension (2016) that identifies key actions to prevent elevated BP, at both the population and individual level.[5] A life course approach is recommended, which focuses on early lifetime programming. Exposure to CV risk factors in early childhood have been shown to promote adverse vascular damage in early adulthood and increase the trajectory of vascular ageing.[6]

WEIGHT LOSS

Obesity is epidemic throughout the world, and, for example, 65% of the adult population in the United States is either overweight, with a body mass index (BMI) of 25.0 to 29.9 kg/m^2, or obese, with BMI of ≥30 or higher. Obese individuals have a threefold increased prevalence of hypertension. Possible mechanisms for obesity-induced hypertension include overactivity of the sympathetic nervous system (SNS), hyperinsulinemia (which may increase renal sodium reabsorption), increased leptin, hyperuricemia, activation of the renin-angiotensin system, and sleep apnea. Abdominal or visceral obesity is a greater predictor of both hypertension and CV risk than other types of body fat distribution. *Abdominal obesity* is defined as a waist circumference greater than 88 cm (>35 inches) in women and greater than 102 cm (>40 inches) in men. These reference values were developed in White populations and may need to be modified for other ethnic groups.

In obese hypertensive patients or those with high-normal BP, weight loss of as little as 4 to 5 kg (~9 to 11 lb) is often associated with a significant reduction in BP. A meta-analysis has demonstrated that a weight reduction of 5.1 kg reduced systolic BP (SBP) by 4.4 mm Hg and diastolic BP (DBP) by 3.6 mm Hg.[7] A rule of thumb is that for every kilogram lost, there is a reduction of 1 mm Hg in both SBP and DBP. To minimize the risk for relapse and maintain sustainability of the weight loss program, the initial target should be 5% to 10% of current weight, or 1 to 2 BMI units. Marked oscillations in weight should be avoided because this increases the risk for development of hypertension in obese, normotensive persons.[8] A randomized trial of the effectiveness of four popular diets on sustained weight loss and CV disease risk reduction concluded that a variety of diets can similarly reduce weight and BP, but only a minority of individuals can sustain high dietary adherence.[9]

Very-low-carbohydrate weight-loss diets, such as the Atkins Diet and others with a carbohydrate content below 20% of energy, are not recommended because they result in a greater increase in low density lipoprotein cholesterol, despite resulting in a greater weight loss over the short term, as compared with a low-fat diet.[10] The Pan-European Diet and Obesity, and Genes (DiOGenes) study found that BP reduction after weight loss is better maintained when the intake of protein is increased at the expense of carbohydrates, to around 23% to 28% energy from protein, as compared with lower protein intakes of between 10% and 15% energy.[11]

Weight reduction should be accompanied by recommendations to increase physical activity unless it is contraindicated. Bariatric surgery

TABLE 35.1 Lifestyle Modifications for Prevention and Management of Hypertension (JNC 7)

Modification	Recommendation	Average Systolic BP Reduction Range Achieved With Intervention*
Weight reduction	Maintain normal body weight (BMI = 18.5-24.9 kg/m^2)	5-20 mm Hg/10 kg
DASH eating plan	Adopt a diet rich in fruits, vegetables, and low-fat dairy products with reduced content of saturated and total fat	8-14 mm Hg
Dietary sodium restriction	Reduce dietary sodium intake to 100 mmol/day (2.4 g sodium or 6 g sodium chloride)	2-8 mm Hg
Aerobic physical activity	Regular aerobic physical activity (e.g., brisk walking) at least 30 min/day, most days of the week	4-9 mm Hg
Moderation of alcohol consumption	Men: Limit to 2 drinks† per day; women and lighter weight persons: limit to 1 drink per day	2-4 mm Hg

Modified from reference 2.
*Effects are dose and time dependent.
†One drink = ½ oz or 15 ml ethanol (e.g., 12 oz [360 ml] beer, 5 oz [150 ml] wine, 1.5 oz [45 ml] 80-proof whiskey).
BMI, Body mass index; *BP,* blood pressure; *DASH,* Dietary Approaches to Stop Hypertension.

and pharmacologic interventions for weight loss (e.g., orlistat) may be useful to achieve weight loss in some patients, but always as an adjunct rather than a substitute for lifestyle modification.

PHYSICAL ACTIVITY

Physical inactivity may account for 5% to 13% of the risk for developing hypertension.[12] In addition, physical inactivity accounts for 5.5% to 25.1% of the population attributed risk for coronary heart disease.[13] Regular physical activity lowers all-cause morbidity and mortality and provides the basis for public health recommendations to exercise at least 30 minutes per day. A recent review reported that patients with high BP who participated in any level of physical activity had a reduced risk (by 16% to 67%) of CV mortality, whereas a greater than twofold increase in CV mortality risk was observed in nonactive individuals.[14]

Exercise Training Dose Response

In a meta-analysis of studies involving more than 1500 patients, exercise training in normotensive individuals has been shown to reduce SBP and DBP by 3.0 ± 1 and 1.7 ± 1 mm Hg, respectively.[15] However, in hypertensive patients, the effect of exercise training is even more marked. In a meta-analysis involving 27 randomized controlled trials (RCTs) and 1480 patients, aerobic activity was shown to reduce BP on average by 10.8 ± 4.7 mm Hg in hypertensive patients.[16] Studies in hypertensive patients have shown that the benefit of exercise on BP is maximal with 90 minutes of exercise per week, after which there was no further improvement.[17] Furthermore, only a modest amount of exercise was needed to reduce BP in patients with hypertension (>30 min/week). There is no consensus whether high intensity interval is superior to low-intensity continuous aerobic training on BP response.[18,19] Regular exercise prevents the development of left ventricular hypertrophy that is independent of BP in young patients with stage 1 hypertension.[20]

However, there is no benefit to increasing exercise intensity on BP reduction with exercise training, as long as intensity ranges between 40% and 70% of maximal, age-predicted heart rate.[15] Exercise of higher intensity (75% maximum) is associated with a more marked and prolonged reduction in postexercise BP in the postexercise window compared with lower intensity exercise (50% maximum).[21] Despite these promising results, a recent review highlights important limitations in the literature regarding the effects of exercise on BP. These include lower methodologic quality, selective reporting as to BP outcomes, and lack of including participants with hypertension.[22]

Mechanisms

The reduction in BP immediately after exercise has been linked to a sympathetic inhibition and increased release of vasodilator substances. The mechanisms by which exercise lowers BP over the longer term are less well understood, but possibilities include reductions in systemic vascular resistance secondary to neurohumoral and structural adaptations. It has been further suggested that physical inactivity negatively affects brain areas associated with sympathetic outflow. SNS overdrive is thought to account for more than 50% of all cases of hypertension, and a lack of balance between parasympathetic and sympathetic modulation has been observed in hypertensive subjects.[23] Chronic exercise is also associated with a loss of weight and a reduction of serum uric acid levels, both of which could reduce BP.

Antihypertensive Medication and Guidelines for Exercise

Box 35.1 provides exercise guidelines for patients with hypertension.[24] β-Blockers decrease exercise tolerance. β-Blockers and diuretics also may alter thermoregulation in hot environments and provoke hypoglycemia. Patients using these medications should be educated about exercising in the heat, clothing, adequate hydration, and methods to prevent hypoglycemia.[25] However, the use of β-blockers is not the first-line treatment for physically active hypertensive patients. Angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and calcium channel blockers may be better suited for patients who exercise frequently or athletes with hypertension.

For patients undergoing supervised exercise training, the monitoring of postexercise BP may be helpful so medications may be adjusted to avoid postexercise hypotension, especially with calcium channel blockers or in patients exercising in a hot environment.

DIET

Salt Intake

Epidemiologic studies demonstrate that the prevalence of hypertension is directly related to dietary salt intake in all societies in which Na intake is above 50 to 100 mmol/day (3 to 6 g salt or NaCl) (Fig. 35.1).[26] In societies in which daily intake is below that range, hypertension is rare. Salt intake also plays an important role in age-related increase in BP (Fig. 35.2).[27] Not all individuals respond similarly to high salt intake. "Salt sensitivity" describes a group of individuals who significantly decrease or increase their BP during periods of salt restriction or loading, respectively. Risk factors for salt sensitivity include Black ethnicity, older age, obesity, elderly people, patients with type 1 or 2 diabetes, treatment with calcineurin inhibitors, and patients with chronic kidney disease (CKD).

Salt Intake and Hypertension

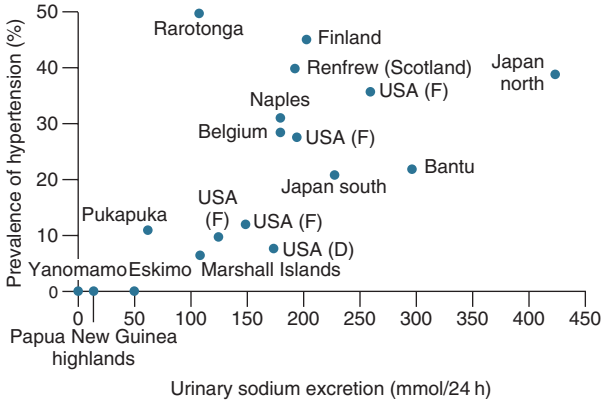

Fig. 35.1 Relationship of salt intake with prevalence of hypertension in different populations. *D,* Data from Dahl; *F,* data from Framingham study from different time periods. (Modified from reference 26.)

Blood Pressure Changes with Age and Salt Intake

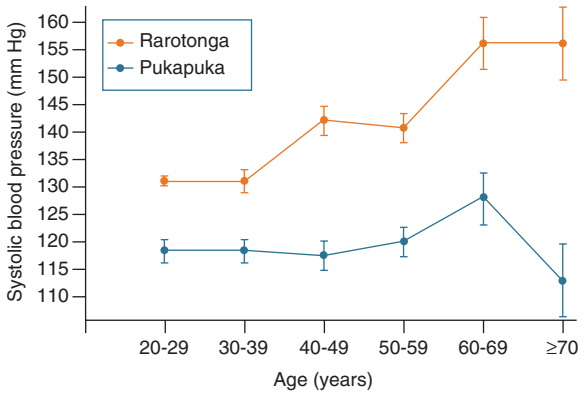

Fig. 35.2 Blood pressure changes with age and salt intake. The increase in systolic blood pressure (SBP) with age correlates with a higher salt intake in two Polynesian populations. In men of Rarotonga Island, where the sodium intake averages 130 mmol/day, SBP increases with age. In contrast, it remains constant in men from Pukapuka Island, where the sodium intake averages 50 to 70 mmol/day. (Modified from reference 27.)

BOX 35.1 Practical Guidelines for Exercise in Patients With Hypertension

All apparently healthy individuals should undergo preexercise screening to determine health risk status. The American College of Sports Medicine (ACSM) recognizes that two or more of the following risk factors increase the risk associated with exercise, and individuals should undergo preexercise graded exercise testing. Risk factors include male gender (older than age 45 years) or female gender (older than 55 years), serum cholesterol concentrations greater than 5.2 mmol/l, impaired glucose tolerance or diabetes mellitus, smoking, obesity (body mass index ≥30), inactivity, and family history of cardiovascular disease.

Patients with uncontrolled hypertension should embark on exercise training only after evaluation and initiation of therapy. Furthermore, patients should not participate in an exercise training session if resting systolic blood pressure is above 200 mm Hg or diastolic blood pressure is above 115 mm Hg.

Many patients with hypertension are overweight and should therefore be encouraged to follow a program that combines both exercise training and restricted calorie intake.

Type of exercise: This should be predominantly endurance physical activity, including walking, jogging, cycling, swimming, or dancing. This should be supplemented by resistance exercise that can be prescribed according to the ACSM or American Heart Association guidelines.

Frequency of exercise: Most or preferably every day.

Intensity of exercise: Moderate intensity at 40% to 60% of maximal oxygen consumption ($\dot{V}O_2$ peak).

Duration of exercise: More than 30 minutes of continuous or accumulated moderate physical activity daily.

Modified from references 22 and 23.

Putative mechanisms for salt sensitivity are alterations in circulating levels of (or renal responses to) atrial natriuretic factor, kallikrein, prostaglandins, and nitric oxide (NO); increased levels of norepinephrine; abnormal suppression of both renin and aldosterone; genetic mechanisms; congenital reduction in nephron number; and acquired renal microvascular and tubular injury.

In a Cochrane systematic review of 34 trials the effect of modest salt reduction on BP was studied. The pooled mean change in urinary sodium (Na) was −75 mmol/24 h (equivalent to reduction of 4.4 g of salt) resulting in a mean reduction in SBP of −4.18 mm Hg and DBP of −2.06 mm Hg, respectively. Meta-regression analysis showed that older age, Black ethnicity, hypertensive status, and change in 24-hour urinary Na were associated with a greater fall in BP.[28]

In the Dietary Approaches to Stop Hypertension (DASH)–Sodium Trial, the additional benefits of salt restriction over and above the DASH diet were investigated (Fig. 35.3).[29] Reduction of sodium intake from a high (150 mmol/day, or 9 g salt) to either an intermediate (100 mmol/day, or 6 g salt) or a low (65 mmol/day, or 4 g salt) intake resulted in a stepwise reduction in BP, which was approximately twice as great in participants receiving the control than receiving the DASH diet (see Fig. 35.3). In those following the DASH diet, the addition of salt restriction resulted in a relatively small additional decrease in BP (3.0 and 1.6 mm Hg for SBP and DBP, respectively). Thus the greatest benefits of salt restriction are seen in those with typical Westernized high-fat, low-nutrient diet.

Most hypertension guidelines recommend a reduction of salt intake to about 100 mmol or 6 g of salt. The U.S. Department of Agriculture and U.S. Department of Health and Human Services Joint Dietary Guidelines for Americans calls for stricter reduction in salt intake to no more than 65 mmol/day, or 4 g salt in African Americans, people over age 51, and patients with hypertension, diabetes mellitus, or CKD.[30] WHO recommends less than 5 g salt daily (2 g or 90 mmol/day Na) as a population goal.

A recent meta-analysis has stirred controversy by suggesting potential harm from salt restriction, especially in normotensive individuals, and spurred calls to abandon population-based salt restriction.[31] In this analysis, although increased Na intake was associated with increases in BP, hypertensive subjects in the high Na (>7 g/day) and low Na intake (<3 g/day) had increased risk for CV events and death compared with those with a Na intake of 4 to 5 g/day. In normotensive subjects, high salt intake had no adverse effect and low salt intake was associated with increased risk for CV events. However, this study has been heavily criticized[32] because a single spot urine sample was used to estimate Na intake. Currently only multiple 24-hour urine collections are considered reliable to account for day-to-day variability in Na intake.[33] There was

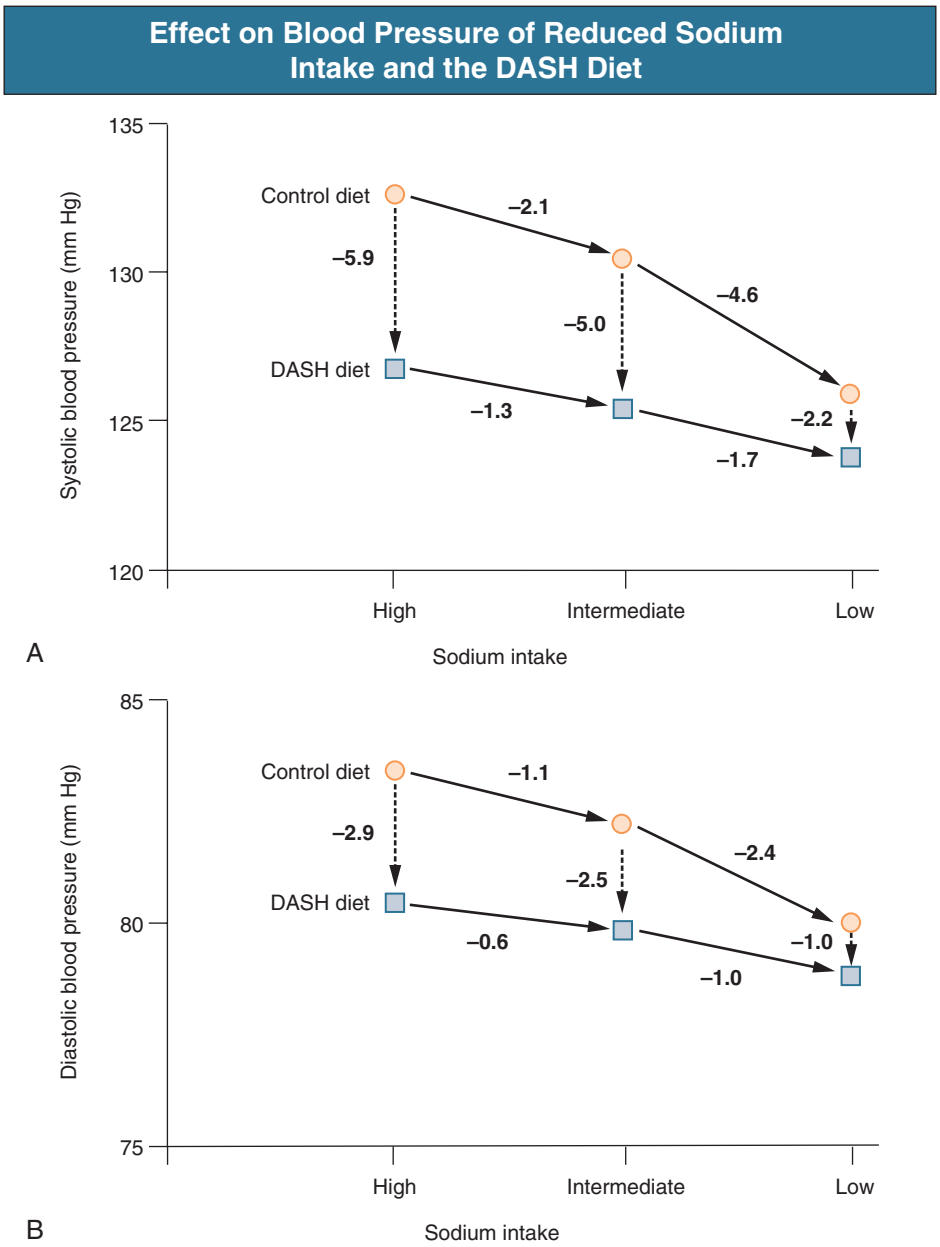

Fig. 35.3 Reduced sodium intake and DASH diet. Effect on (A) systolic blood pressure and (B) diastolic blood pressure. (**B,** Modified from reference 29.)

also the question of reverse causality with patients included in the study with significant CV disease in whom there may have been reduced food intake (and hence Na intake) and Na retention by the kidney. In countries where population-based reduction in salt intake has occurred (Finland, United Kingdom, and Japan) there has been an accompanying fall in BP and CV mortality. A recent American Heart Association (AHA) Presidential Advisory review concluded that the evidence supporting the effectiveness of population-level salt reduction to prevent hypertension and reduce the incidence of CV disease and stroke remains robust and persuasive for policy development.[30]

Avoiding added salt and salt-rich processed foods can reduce salt intake from 9 g/day to about 6 g/day. Further reduction in salt requires specialized dietary counseling. Despite these recommendations, long-term studies have reported only small reductions in BP associated with salt restriction (average of only 1.1/0.6 mm Hg).[34] These results undoubtedly reflect limited compliance, but this can be improved by regular contact with the patient, dietetic counseling, and educational sessions.

One of the most cost-effective ways to lower salt intake in the general population is to reduce salt in processed foods. This approach was effective in lowering the BP in patients with drug-treated hypertension in a middle-income community in South Africa through the modification of the salt content of a small number of commonly consumed foods, including bread.[35] In Belgium, the reduction in the salt content of bread between the mid-1960s and the early 1980s was accompanied by marked reductions in 24-hour urinary sodium excretion. In recognition of the need for a concerted global effort to reduce population-wide salt intake, a WHO Forum and Technical meeting in 2006 recommended an integrated approach incorporating a commitment by the food industry to product reformulation, increased consumer awareness, and social marketing around salt and health issues.

The United Kingdom was the first country to set voluntary sodium reduction targets for categories of foods, through its Food Standards Agency (2009), closely followed by Australia, the United States, and Canada. South Africa is the first country to adopt mandatory regulation

for maximum sodium levels in food categories that are major contributors to salt intake in that population: bread, margarine and spreads, savory snacks, processed meats, soup powders, and stock cubes. It is estimated that reducing the sodium content of bread by 50%, along with other proposed reductions in margarine, soups, and gravies, would decrease salt intake by 0.85 g/day, resulting in 7000 fewer deaths from CVD and 4000 fewer nonfatal strokes in the country per year, as well as save about $40 million (U.S.) each year in health care costs associated with nonfatal strokes alone. In the United States, as in most developed nations, a major challenge to sodium intake reduction efforts is the widespread use of sodium in the food supply, with more than 75% of total sodium intake from packaged and restaurant foods.[36]

Potassium Intake

One of the confounding factors of the relationship of salt and BP has been the inverse relationship between the intake of salt and that of potassium. Typically, diets with a high salt content are relatively deficient in potassium (and calcium); but in persons who consume little salt, the potassium (and calcium) intake is high.

In normotensive individuals with an average potassium intake above 1.95 g/day (50 mmol/day), potassium supplementation has no significant effect on BP. However, among hypertensive patients who are potassium deficient because of diuretic treatment or low potassium intake, potassium supplementation lowers BP (Fig. 35.4).[37] The DASH diet lowers BP and is high in potassium because of the high fruit and vegetable content and inclusion of low-fat dairy products (Table 35.2). However, the synergistic effect of the various food groups in the DASH diet makes it difficult to ascertain the contribution of the individual nutritional components. The mechanisms by which a low-potassium diet may contribute to hypertension are complex and poorly understood but may relate to stimulation of intrarenal angiotensin II (Ang II), oxidants, and endothelin; inhibition of intrarenal NO and prostaglandins; and induction of renal ischemia.

In the Trials of Hypertension Prevention (TOHP) I and II, a higher sodium-potassium excretion ratio (implying a high-salt and low-potassium intake) was more strongly associated with subsequent CV events than either urinary Na^+ or K^+ excretion alone.[38] Overall, it appears to be beneficial to optimize potassium intake in hypertensive patients to

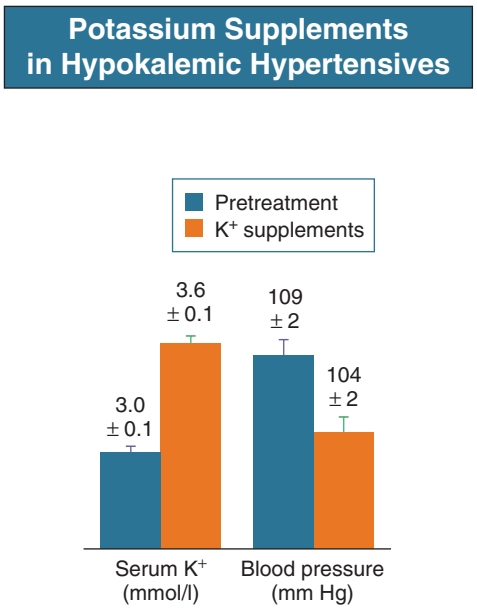

Fig. 35.4 Potassium supplementation lowers blood pressure in hypokalemic hypertensive patients. Treatment with potassium chloride (60 mmol/day potassium for 6 weeks) resulted in an increase in serum potassium concentration and a decrease in mean arterial pressure in hypertensive patients taking thiazide diuretics. (Redrawn from reference 37.)

TABLE 35.2 Dietary Approaches to Stop Hypertension (DASH) Diet*

Food Group	Daily Servings	Serving Sizes	Examples and Notes	Contribution to the DASH Diet Pattern
Grains and grain products	7-8	1 slice bread ½ cup dry cereal ½ cup cooked rice, pasta, or cereal	Whole-wheat bread, muffin, pita bread, bagel, cereals, oatmeal	Major sources of calories and fiber
Vegetables	4-5	1 cup raw, leafy vegetables ½ cup cooked vegetables 6 oz vegetable juice	Tomatoes, potatoes, carrots, peas, squash, broccoli, turnip greens, kale, spinach, artichokes, green beans, sweet potatoes	Rich sources of potassium, magnesium, and fiber
Fruits	4-5	1 medium fruit ¼ cup dried fruit 6 oz fruit juice ½ cup fresh, frozen, or canned fruit	Apricots, bananas, dates, oranges, orange juice, grapefruit, grapefruit juice, mangoes, melons, peaches, pineapples, prunes, raisins, strawberries, tangerines	Important sources of potassium, magnesium, and fiber
Low-fat or nonfat dairy foods	2-3	8 oz milk 1 cup yogurt 1.5 oz cheese	Skim or low-fat (2%) milk, skim or low-fat buttermilk, nonfat or low-fat yogurt, nonfat or low-fat cheeses	Major sources of calcium and protein
Meats, poultry, and fish	≤2	3 oz cooked meats, poultry, or fish	Select only lean meats; trim away visible fats; broil, roast, or boil instead of frying; remove skin from poultry.	Rich sources of protein and magnesium
Nuts, seeds, and legumes	4-5/wk	1.5 oz or ⅓ cup nuts ½ oz or 2 tbsp seeds ½ cup cooked legumes	Almonds, mixed nuts, peanuts, walnuts, sunflower seeds, kidney beans, lentils, split peas	Rich sources of calories, magnesium, potassium, protein, and fiber

*The DASH eating plan shown is based on 2000 kcal/day. Depending on energy needs, the number of daily servings in a food group may vary from those listed.

minimize hypokalemia, being careful to avoid the risk for hyperkalemia, especially in those with renal impairment. If renal function is normal, optimal potassium intake is 80 to 120 mmol/day. For CVD prevention, the WHO recommends a potassium intake that will keep the urine Na/K ratio close to 1 (i.e., 70 to 80 mmol/day if Na guidelines are met).

Calcium, Vitamin D, and Dairy Food Intake

Cross-sectional population surveys of self-reported nutrient intake suggest an inverse relationship between calcium intake and BP. The relationship is more convincing at low levels of calcium consumption (<300 to 600 mg/day). There may be a threshold of 700 to 800 mg/day, above which any further reduction in BP is attenuated. A meta-analysis of randomized calcium supplementation trials (mostly with 1 or 1.5 g calcium daily) demonstrated reductions in SBP (−0.9 to −1.7 mm Hg) that are of little clinical importance.[39] Although calcium in milk may contribute to BP lowering, dairy products may lower BP by other mechanisms. Biologically active peptides formed during the milk fermentation process, such as the casein-derived tripeptides isoleucine-proline-proline and valine-proline-proline, have ACE-inhibiting properties. Vitamin D, which is often added to milk, also may help reduce BP by reducing renin expression, but in a randomized controlled clinical trial vitamin D had no effect on BP compared with placebo.[40] At present, the AHA does not recognize dairy consumption as a dietary approach to the prevention and management of hypertension. Nevertheless, low-fat dairy products are recommended as an integral part of the DASH diet.

Magnesium Intake, Other Micronutrients, and Bioactive Food Components

A weak inverse relationship has been reported between dietary intake of magnesium and BP, but in a meta-analysis of 34 RCTs, magnesium supplementation with a median dose of 368 mg/day was associated with a 2 mm Hg and 1.78 mm Hg reduction in SBP and DBP, respectively.[41]

In contrast, the inverse association between fruit and vegetable intake and BP and other CV risk factors is well established. Epidemiologic evidence suggests that polyphenol compounds found in fruit may explain in part the cardioprotective properties of fruits. Intervention trials have shown that fruits containing relatively high concentrations of flavonols, anthocyanins, and procyanidins, such as pomegranate, purple grapes, and berries, were effective at reducing CVD risk factors. Regular consumption of flavonol-rich foods, cocoa products, tea, and red wine may reduce BP.

Dietary Sugars and Fats

Added sweeteners, such as table sugar and high-fructose corn syrup, have been linked with the epidemics of obesity, hypertension, metabolic syndrome, diabetes, and CV disease.[42] Experimental studies suggest that the fructose component of sugar may increase the risk for obesity and diabetes because of its unique ability to reduce intracellular adenosine triphosphate levels and generate uric acid.[43] One study has reported that reducing soft drink intake by one drink per day is associated with a decrease of 1.8 mm Hg SBP.[44]

Interestingly, whole fruits appear to be beneficial despite containing fructose, possibly as a result of the high content of protective nutrients such as vitamin C, antioxidants, flavanols, potassium, and fiber. Possibly because of this, a systematic review and meta-analysis of three prospective cohort studies in 37,375 men and 185,855 women reported no association of fructose consumption with the incidence of hypertension.[45] However, although there was no effect of fructose at average levels of consumption over time, a positive association was identified with high intakes of fructose.

Supplementation with omega-3 fatty acids reduces the risk for myocardial infarction (MI) and sudden cardiac death, but their effect on BP is small. In a meta-analysis, omega-3 supplementation significantly reduced DBP by a mean of 1.8 mm Hg but had no effect on SBP, fibrinogen level, or heart rate.[46] About 10 portions of oily fish per week or 9 or 10 fish oil capsules per day are required (equivalent to ~3 g/day long chain n-3 fatty acids), and this is not tolerated by most because of belching and fishy taste. Concerns about the cholesterol content as well as dioxin and polychlorinated biphenyl content (environmental pollutants that have carcinogenic potential and, being fat soluble, can accumulate in the body) of some fish oil supplements also raise questions about the safety of very large doses. As a guideline for overall health, individuals with hypertension should aim to consume about 2 to 3 portions (200 to 400 g) of oily fish (e.g., herring, kippers, mackerel, pilchards, sardines, salmon, trout, fresh tuna, swordfish) per week.

Dietary Approaches to Lower Blood Pressure

Although individual nutrients and components of foods can have an impact on BP, it is necessary to consider these within the context of a total dietary approach because of potential synergistic effects. A meta-analysis of 17 randomized controlled trials showed that a dietary pattern that was rich in fruits, vegetables, whole grains, legumes, nuts, seeds, dairy, and fish and low in processed foods and red meat reduced SBP and DBP by 4.06 mm Hg and 2.30 mm Hg, respectively.[47] These dietary patterns included the DASH diet, the Mediterranean diet, and the Nordic diet, and the key factor is that they all emphasize plant-based foods.

SMOKING

Cigarette smoking is a well-established major risk factor for CV disease, but its role in the development of hypertension is not well elucidated and not routinely included in recommendations for prevention and treatment of hypertension. The relationship with hypertension may be confounded by changes in weight during and after the cessation of smoking. In a large epidemiologic study of middle-aged and older men from the United States, smoking was associated with a modest but important risk for development of hypertension.[48] In addition, smoking increases the risk for CKD progression as well as morbidity and mortality from multiple causes, so all smokers should be advised to stop.

ALCOHOL

There is a linear relationship between alcohol consumption, BP levels, and prevalence of hypertension. In Japan, alcohol intake above 300 g/wk (about three drinks daily) was associated with significantly greater increases of BP during a 7-year period, and baseline BP was higher in drinkers consuming 200 g/wk.[49] Heavy drinking is associated with increased risk for stroke, increase in BP after alcohol withdrawal, and attenuation of antihypertensive efficacy. Paradoxically, alcohol has a J-shaped relationship with coronary heart disease, with moderate consumption (one to two drinks daily) having the lowest risk. In a large epidemiologic study, modest alcohol consumption was protective against first MI.[50] Alcohol may increase BP through activation of the SNS, whereas its protective effects include increasing high density lipoprotein cholesterol, lowering fibrinogen, and inhibiting platelet activation. The JNC 7 guidelines recommend limiting alcohol consumption to no more than two drinks per day (24 oz [720 ml]) beer, 10 oz [300 ml] wine, or 3 oz [90 ml] 80-proof whiskey) in most men and no more than one drink per day in women or lighter weight men (see Table 35.1).[2]

CAFFEINE

Caffeine is the most widely used psychoactive substance worldwide. Caffeine stimulates the CV system through the blockade of vascular

adenosine receptors. In a meta-analysis of RCTs of coffee ingestion, there was no effect on BP or risk for hypertension, although the quality of the evidence was low.[51] Caffeine tablets may have a greater effect on BP than coffee. The ASH/ISH guidelines do not address the issue of caffeine, but it seems reasonable to propose that coffee consumption is safe, but that pharmacologic ingestion of caffeine and the use of "smart drinks" supplemented with caffeine should be avoided.

PSYCHOLOGICAL STRESS

Chronic psychological stress is a contributor to the development and maintenance of hypertension. Men exposed to job strain had a 10.7 mm Hg and 15.4 mm Hg higher work and home ambulatory SBP than did controls, respectively.[52] The INTERHEART study showed that psychosocial stress was associated with a twofold increase in the risk for the first MI.[50] Although stress reduction techniques may be beneficial for other reasons, there are few long-term data on efficacy in reducing BP and as a result they are not recommended by ASH/ISH for the management of hypertension.

ADOPTING LIFESTYLE MODIFICATIONS

Maintaining adherence to lifestyle changes has always been challenging. The Prevention of Myocardial Infarction Early Remodeling (PREMIER) trial evaluated the effects of implementing JNC 7 lifestyle recommendations and the DASH diet.[53] Adults with prehypertension or untreated stage 1 hypertension were randomly assigned to one of three groups for 6 months: advice only, JNC recommendations, and JNC recommendations plus DASH diet. At 6 months, the JNC and JNC plus DASH groups had significantly reduced BP compared with the advice-only group, but there was little additional benefit in adding the DASH diet to JNC recommendations. However, participants purchased their own foods in the PREMIER study, instead of being provided with foods as in the DASH and DASH low-salt diet studies. Similarly, in the DASH low-salt diet study, the BP-lowering effect attributable to salt reduction was −6.7/−3.5 mm Hg,[29] whereas in meta-analyses of 34 salt restriction trials in which participants mostly prepared their own low-salt meals, this effect was only −4.18/−2.06 mm Hg.[28] Thus, in the outpatient setting, even highly motivated individuals usually cannot meet DASH dietary goals unless their meals are provided.

The Trials of Hypertension Prevention (TOHP) II study demonstrated the problems of sustainability of dietary intervention and the need for regular counseling.[54] The effect of adding salt restriction to weight loss appeared to offer no further decrease in BP. Assessed by urinary sodium excretion, adherence to lower dietary sodium was poor in the long term. At 36 months of follow-up, mean urinary sodium was 40 mmol/24 h lower than baseline in the sodium-restricted group and only 21% achieved the target of less than 80 mmol/24 h. A higher attendance at counseling sessions was associated with a greater reduction in urinary sodium. At 36 months, a decrease of 84 mmol/day of sodium from baseline levels could be achieved only in those who attended more than 80% of the counseling sessions. In summary, the sustainability of long-term lifestyle interventions remains problematic, but it appears that regular and long-term counseling can improve adherence.

SELF-ASSESSMENT QUESTIONS

1. Which of the following is *not* a lifestyle recommendation of the American Society of Hypertension and International Society of Hypertension (ASH/ISH)?
   A. Reduction in alcohol intake
   B. Reduction in salt intake
   C. Stress reduction
   D. Weight reduction
2. For every kilogram reduction in weight, it is estimated that the systolic blood pressure will be reduced by:
   A. 0.5 mm Hg.
   B. 1 mm Hg.
   C. 2 mm Hg.
   D. 3 mm Hg.
3. Which of the following patients should not be targeted for stricter sodium reduction, according to U.S. Department of Agriculture and Department of Health and Human Services?
   A. African Americans
   B. Patients with chronic kidney disease
   C. Hypertensive individuals
   D. People younger than 40 years
4. Supplementation of vitamin D in hypertensive patients:
   A. Has little or no effect on BP.
   B. Causes a slight reduction in BP.
   C. Causes a slight increase in BP.
   D. Causes a marked reduction in BP.

36

Pharmacologic Treatment of Hypertension

Bryan Williams, Megan Borkum

Successful lifestyle interventions can delay the development of hypertension (see Chapter 35), but the majority of patients with confirmed hypertension require lifelong treatment, usually with more than one drug. This has resulted in a multibillion-dollar industry, in which numerous pharmacologic agents have been introduced (Table 36.1). In turn, this has made it more difficult for clinicians to decide which drugs should be used in specific patient groups. Further, recommended treatment targets are constantly evolving and there are a number of international guidelines, which are discussed in this chapter.

DEFINING WHO SHOULD RECEIVE PHARMACOLOGIC TREATMENT

Blood pressure (BP) follows a normal distribution within populations, and thus "hypertension" is arbitrarily defined by diagnostic thresholds subject to change as new evidence from clinical trials emerges. Hypertension is best defined as *that level of blood pressure at which treatment to lower blood pressure results in significant clinical benefit*. The BP at which treatment results in "significant clinical benefit" for any individual will depend on their absolute cardiovascular (CV) risk.[1-3] This varies because some people will be more vulnerable than others to end-organ damage at a given BP. Differential BP targets and thresholds have emerged, grouping patients into categories defining their threshold BP for therapeutic intervention and optimal BP goals. In some cases, specific drug classes have been given "compelling indications" and "compelling contraindications" for specific groups of patients. This has been useful in tailoring therapy from a wide range of drug classes but must not be misinterpreted as indicating that the specific drug is more important than the achieved BP, which is not the case. The primary objective of therapy is to lower BP as effectively as possible while minimizing side effects from therapy.[4-6]

Blood Pressure Thresholds for Intervention (Office Blood Pressure)

Treating a seated "office" BP above 160/100 mm Hg reduces the risk for stroke, myocardial infarction (MI), heart failure, and mortality.[4-9] There is also evidence that treating pressures above 140/90 mm Hg, especially in high-risk patients, is beneficial. Consequently, most recent guidelines define hypertension as an office BP of 140/90 mm Hg or higher.[7,8] The exception is the recent U.S. American Heart Association/American College of Cardiology (AHA/ACC) hypertension guideline,[9] which recommends a reclassification of hypertension, with stage 1 hypertension defined as a BP of 130/80 mm Hg or greater. Note that the U.S. hypertension guidelines refers to "stages" of hypertension, whereas other guidelines refer to "grades" of hypertension. The U.S. guideline recommends lifestyle advice for such patients and drug treatment to lower BP to less than 130/80 mm Hg if there is coexisting CV disease or an estimated 10-year risk for CV disease greater than 10%.[9] This is a major change, especially the diagnosis of "hypertension" when BP is 130/80 mm Hg or greater, because this will lead to as many as 50% more people being diagnosed as "hypertensive," with the majority recommended for drug treatment. Other international guidelines have adopted a treatment threshold of 140/90 mm Hg for adults and a higher threshold of 150/90 mm Hg in the elderly (variously defined as aged 65 years to 80 years and older), and it is most unlikely that the 140/90 mm Hg definition for hypertension will change outside of the United States.

Table 36.2 provides the contrast between the new U.S. guidance and the various grades of hypertension according to the current European guidelines, which are representative of most international guidelines. All guidelines identify a category of patient with "high normal BP" (often referred to as borderline hypertension or prehypertension), which is designed to highlight people at high risk for progression to hypertension and in whom lifestyle changes can be beneficial by reducing the transition to grade 1 hypertension. Importantly, high normal BP is not benign; data from the Framingham Heart Study show that people with a high normal BP experience a doubling in risk for CV complications (Fig. 36.1).[10] This principle was, in part, the basis for the recent U.S. guidelines to reclassify high-normal BP as stage 1 hypertension, encouraging the wider use of lifestyle interventions and drug therapy in this group of patients.

Clinical Dilemma of End-Organ Damage and "Normal" Blood Pressure

It is not known how best to treat people with high normal BP who already have evidence of end-organ damage, such as left ventricular hypertrophy (LVH), or microalbuminuria. This could be an example of the insensitivity of the defined thresholds for diagnosis of hypertension. Clearly, such a patient has a BP that is causing damage but considered below the usual threshold for intervention. Consequently, clinical understanding of the disease process is critical to enable the optimal use of guidelines for treatment decisions. There remains considerable uncertainty in the evidence base, and clinical judgment cannot be replaced by guidelines. The reclassification of BP in the United States means that many would now be classified as "stage 1 hypertension" and recommended for treatment.

Blood Pressure Thresholds for Intervention (Ambulatory and Home Blood Pressure Monitoring)

Diagnostic thresholds for hypertension vary according to the method of measurement. Ambulatory blood pressure monitoring (ABPM) and home BP monitoring are increasingly advocated and used. When ABPM or home BP are used to classify hypertension, the diagnostic thresholds are lower than office BP because they represent the average of a greater number of measurements under different conditions. The National Institute for Health and Clinical Excellence (NICE) guidelines[8] in the United Kingdom recommends that ABPM be routinely used to confirm the diagnosis of hypertension because of high rates of white coat and masked hypertension (www.guidance.nice.org.uk/CG127). The new U.S. guidance also advises the wider use of "out of office" BP measurement by ABPM or home BP monitoring to confirm the diagnosis of hypertension and monitor the quality of BP control in treated patients. Table 36.3 summarizes the diagnostic thresholds for hypertension according to different methods of measurement (see Chapter 33).

TABLE 36.1 Development of Therapeutic Strategies for Hypertension

Year	Nondrug Therapy
1920s	Strict low-sodium diet
1929	Lumbar sympathectomy
1944	Kempner rice diet
Year	**Drug Therapy**
1930s	Veratrum alkaloids
1940s	Thiocyanates
1948	Reserpine, phenoxybenzamine
1950	Ganglion blockers
1951	Monoamine oxidase inhibitors
1958	Thiazide diuretics (chlorothiazide)
1960s	Central α_2-receptor agonists, nondihydropyridine calcium channel blockers, and β-blockers
1970s	Angiotensin-converting enzyme (ACE) inhibitors, α_1-receptor blockers
1980s	Dihydropyridine calcium channel blockers
1990s	Angiotensin receptor blockers (ARBs)
2000s	Renin inhibitors, angiotensin receptor neprilysin inhibitor (ARNI)

BLOOD PRESSURE TREATMENT GOALS

The ideal BP treatment goal is likely to be patient specific, but guidelines must be generalizable to populations. Guidelines should therefore be conservative and pragmatic, should curb the zeal of specialists to advocate ever lower BP goals, and should only make recommendations supported by solid evidence. Until recently, there was international consensus that two BP goals were appropriate: less than 140/90 mm Hg for those with "uncomplicated hypertension" and a lower goal of less than 130/80 mm Hg for those at higher risk, that is, patients with diabetes, established CV or cerebrovascular disease, or chronic kidney disease (CKD). The SPRINT trial recently challenged this consensus when it showed that more intensive BP lowering (targeting a systolic BP <120 mm Hg), was more effective at reducing major cardiovascular events and mortality than the current less intensive systolic BP goal of less than 140 mm Hg.[11] Importantly, BP was measured in SPRINT using an automated device after 5 minutes of seated rest in a quiet room followed by three oscillometric measurements without an observer in the room. Automated office BP eliminates the white coat effect and, in patients with CKD, automated BP has been shown to be considerably lower than daytime ambulatory BP. Consequently the BP achieved in SPRINT would likely correspond to higher office BP.[12] This trial included a high proportion of patients aged 75 years and older and a high proportion with CKD. The "more intensive" treatment strategy was well tolerated, and there was no evidence of excess falls or reduction in gait speed.[13] However, although there was no difference in the composite end-point of all serious adverse events, the intensive therapy arm was associated with more nonorthostatic hypotension, syncope, electrolyte abnormalities, and acute kidney injury. These findings strongly influenced the recent U.S. guideline recommendation to lower the systolic

High Normal Blood Pressure and the Risk of Cardiovascular Disease

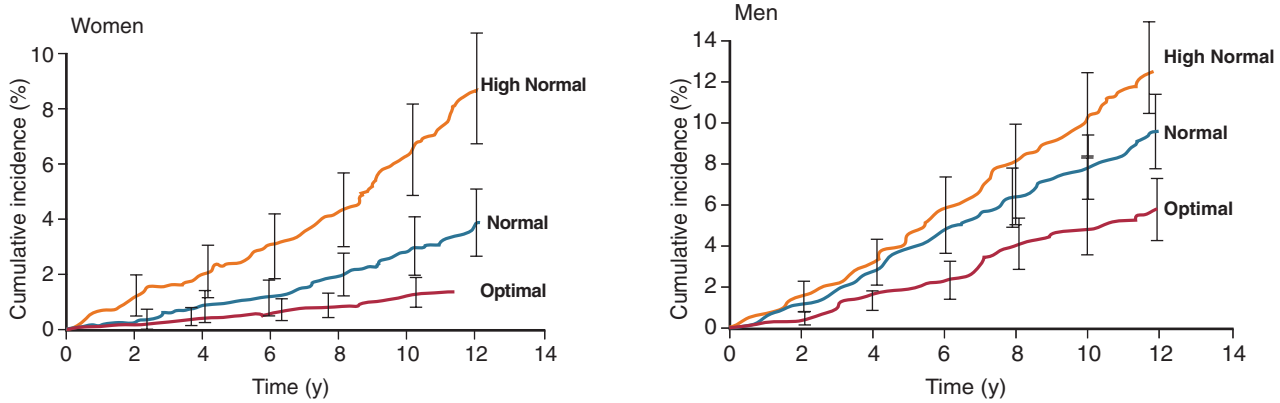

Fig. 36.1 "High Normal" blood pressure (BP) and risk for cardiovascular disease. Cumulative incidence of cardiovascular events in women (left) and men (right) without hypertension, according to BP category at the baseline examination, showing 95% confidence intervals. For this analysis, "optimal" BP was defined as systolic pressure of less than 120 mm Hg and diastolic pressure less than 80 mm Hg; "normal" BP as systolic 120 to 129 or diastolic 80 to 84 mm Hg; and "high normal" BP as systolic 130 to 139 or diastolic 85 to 89 mm Hg. (Modified from reference 10.)

TABLE 36.2 Blood Pressure Treatment Thresholds, Goals, and Initial Therapy Choices According to Most Recent Major International Guidelines

ESH/ESC CLASSIFICATION OF HYPERTENSION (2013)

Category	Systolic (mm Hg)		Diastolic (mm Hg)
Optimal	<120	and	<80
Normal	120-129	and/or	80-84
High-normal	130-139	and/or	85-89
Grade 1 hypertension	140-159	and/or	90-99
Grade 2 hypertension	160-179	and/or	100-109
Grade 3 hypertension	≥180	and/or	≥110
Isolated systolic hypertension	≥140	And	<90

USA CLASSIFICATION OF HYPERTENSION (2017)

BP Category	SBP		DBP
Normal	<120 mm Hg	and	<80 mm Hg
Elevated	120-129 mm Hg	and	<80 mm Hg
Hypertension			
Stage 1	130-139 mm Hg	or	80-89 mm Hg
Stage 2	≥140 mm Hg	or	≥90 mm Hg

INTERNATIONAL GUIDELINE BP THRESHOLDS AND BP GOALS

Guidelines	BP Threshold (mm Hg)	BP Goal (mm Hg)	Initial Therapy
U.S. 2017	130/80 if existing CV disease or 10-y CVD risk >10% 140/90 in all others	<130/80	ACEi or ARB, or CCB, or thiazide/thiazide-type diuretic, usually as a two-drug combination
ESH/ESC 2013	Age <80 y: 140/90 Age ≥80 y: 160/90	<140/90 <150/90	Thiazide/thiazide-type diuretic, ACEi, ARB, CCB, or β-blocker, usually as monotherapy
NICE U.K. 2011	Age <80 y: 140/90 Age ≥80 y: 160/90	<140/90 <150/90	ACEi or ARB, or CCB, or thiazide/thiazide-type diuretic: Usually as monotherapy

ACE, Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *BB,* β-blocker; *CCB,* calcium channel blocker; *ESH/ESC,* European Society of Hypertension/European Society of Cardiology; *DBP,* diastolic blood pressure; *SBP,* systolic blood pressure.
Hypertension grades or stages replace the older terminology of mild, moderate, and severe.

BP goal to less than 130 mm Hg for almost all patient groups (including the elderly) providing they are independent and well functioning.[9,13] This recommendation also has been supported by recent systematic reviews and meta-analysis but with the caveat that some of these analyses point to an increased risk for harm if the systolic BP goal is below 120 mm Hg.[14,15] The SPRINT trial did not include patients with prior stroke or diabetes, but the systematic reviews show consistent benefit, especially for stroke reduction, in these patients when systolic BP is lowered to less than 130 mm Hg.[3-5] The impact of lower BP goals (i.e., systolic BP <130 mm Hg) on the progression of CKD seems less well established in the same meta-analyses.

It is likely that the decision to lower the systolic BP target to below 130 mm Hg for most patients in the U.S. guideline will be replicated by many future guidelines. It is certainly less controversial than the U.S. guideline decision to reclassify hypertension and begin treating low-moderate risk patients with a systolic BP threshold of 130 mm Hg or more. There still will be concern about over aggressive treatment of older patients aged 65 years and older and especially the very old at 80 years and older. People age at different rates and have different levels of comorbidities, mobility, and independence, so a systolic BP treatment goal of less than 130 mm Hg may be too low for some. That said, the previous systolic BP goal of less than 150 mm Hg was almost certainly too conservative. A reasonable first goal in older patients would be to achieve a systolic BP below 140 mm Hg, with the option of reducing the BP further if treatment is well tolerated. However, there will be benefit from BP lowering even when these goals cannot be achieved. Table 36.4 summarizes the new BP thresholds and treatment goals recommended by the 2017 U.S. hypertension guideline.

There is less evidence available on diastolic BP treatment goals. Concern has been expressed that overaggressive lowering of diastolic BP may compromise coronary artery perfusion in particular and lead to adverse outcomes. Interpretation of the impact of diastolic pressure reduction in trials is complex, especially when conducted post hoc, and is confounded by the fall in diastolic BP with ageing, reflecting arteriosclerosis, and arterial stiffening. Thus a low diastolic BP is often a marker of vascular disease rather than the cause of it. Expert consensus regards a diastolic BP in the range of 70 to 80 mm Hg as optimal. However, some older patients have much lower and sometimes unmeasurably low diastolic BP levels. This should not be a barrier to effective lowering of systolic BP, provided the patient is tolerating the treatment well and is asymptomatic. Some of the most impressive benefits of drug treatment of hypertension have occurred in patients with isolated systolic hypertension (ISH) in whom baseline diastolic pressure has been lower than 70 mm Hg.

GUIDE TO SELECTION OF ANTIHYPERTENSIVE AGENTS

Key Principles From Clinical Trials

BP lowering undoubtedly reduces morbidity and mortality, but there has been much debate about "how low to go." Many large randomized controlled trials (RCTs) have compared different drug classes with placebo and different treatment strategies with each other (see references 4 to 6 for overviews). Table 36.5 and Fig. 36.2 present detailed analyses, reporting the effectiveness of specific drug classes on major CV events and mortality. The differences among the various drug classes on clinical outcomes are primarily driven by differences in BP control. Analysis of trials has provided some important guiding principles with regard to treatment strategies for hypertension, as follows:

1. Effective BP lowering is overwhelmingly important in reducing the risk for major CV events in people with hypertension. Thus the first priority in treatment is to control BP.
2. Early studies focused primarily on diastolic BP as the treatment target, but systolic BP is invariably more difficult to control and more closely linked to CV outcomes and should now be the primary but not the sole focus of treatment.
3. Monotherapy is rarely sufficient to control BP, and the majority of patients will require more than one drug as part of their treatment strategy, especially if lower BP targets, as advocated by the recent U.S. guidelines, are more widely adopted.
4. The response to any class of BP-lowering medication is heterogeneous, with important effects of age and ethnicity.

TABLE 36.3 Diagnostic Thresholds for Hypertension According to Different Methods of Blood Pressure Measurement

	BLOOD PRESSURE (mm Hg)	
Measurement	**Systolic**	**Diastolic**
Office or clinic	140	90
24-hour	125-130	80
Day	130-135	85
Night	120	70
Home	130-135	85

Clinic	HBPM	Daytime ABPM	Nighttime ABPM	24-Hour ABPM
120/80	120/80	120/80	100/65	115/75
130/80	130/80	130/80	110/65	125/75
140/90	135/85	135/85	120/70	130/80
160/100	145/90	145/90	140/85	145/90

ABPM, Ambulatory BP monitoring; *HBPM,* home BP monitoring. 24-Hour, day or night refer to ambulatory blood pressure (BP) averages over these periods. Home refers to an average of at least 4 days of seated readings at home, usually two readings, twice per day, that is, an average of ~16 readings. The top panel shows BP thresholds according to the current ESH/ESH 2013 Guidelines. The bottom panel shows the corresponding values of SBP and DBP for Clinic, HBPM, Daytime, Nighttime and 24 hr ABPM measurements according to the U.S. 2017 Guidelines.

TABLE 36.4 Summary of Blood Pressure Thresholds and Treatment Goals (Office Blood Pressure) Recommended by the U.S. 2017 Hypertension in Adults Treatment

Clincal Condition(s)	BP Threshold (mm Hg)	BP Goal (mm Hg)
General		
Clinical CVD or 10-year ASCVD risk ≥10%	≥130/80	<130/80
No clinical CVD and 10-year ASCVD risk <10%	≥140/90	<130/80
Older persons (≥65 years of age; noninstitutionalized, ambulatory, community-living adults)	≥130 SBP	<130 SBP
Specific Comorbidities		
Diabetes mellitus	≥130/80	<130/80
Chronic kidney disease	≥130/80	<130/80
Chronic kidney disease after renal transplantation	≥130/80	<130/80
Heart failure	≥130/80	<130/80
Stable ischemic heart disease	≥130/80	<130/80
Secondary stroke prevention	≥140/80	<130/80
Secondary stroke prevention (lacunar)	≥130/80	<130/80
Peripheral arterial disease	≥130/80	<130/80

ASCVD, Atherosclerotic cardiovascular disease; *BP,* blood pressure; *CVD,* cardiovascular disease; *SBP,* systolic BP.

TABLE 36.5 Relative Risk and Benefit of Antihypertensive Drug Classes

Outcome	Thiazide Diuretics (D)	Calcium Channel Blockers (C)	β-Blockers (B)	ACE/ARBs* (A)
Unstable angina	0.89	0.88	0.98	0.97
Myocardial infarction	0.78	0.79	0.85	0.81
Diabetes	0.98	0.80	1.13	0.72
Stroke	0.69	0.65	0.85	0.73
Heart failure	0.53	0.73	0.76	0.64
Death	0.91	0.88	0.93	0.90

Modified from data at www.nice.org.uk/CG034guidance.
*Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) were grouped as a single class for the purposes of this analysis.
Effectiveness of drugs: 1.0 = no benefit/harm, <1.0 = benefit, and >1 = potential harmful effect, from a meta-analysis of major blood pressure (BP)-lowering trials conducted for the U.K. National Institute for Health and Clinical Excellence (NICE) Hypertension Guideline Development Group, 2006.

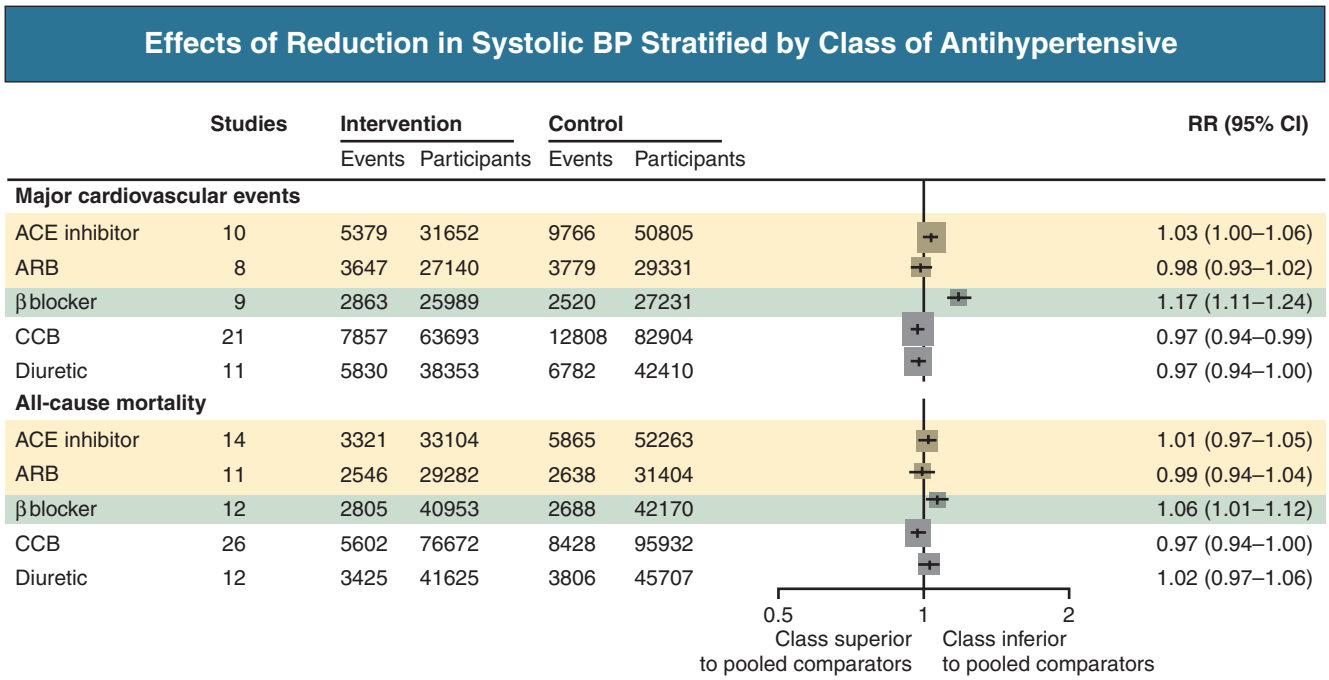

Fig. 36.2 Effects of reductions in systolic blood pressure (BP) stratified by class of BP-lowering drug. *ACE,* Angiotensin-converting enzyme; *ARB,* angiotensin receptor blockers; *CCB,* calcium channel blocker; *CI,* confidence interval; *RR,* relative risk. (From reference 4.)

5. Some trials have indicated that certain comorbidities (e.g., diabetes) and target organ damage (e.g., LVH, CKD) provide compelling indications for inclusion of specific classes of drug therapy in the treatment regimen, but this consideration should not override the importance of BP control and has become less relevant now that most patients are treated with combinations of drugs.
6. There are inadequate clinical outcome data for treatment studies of younger patients. Most studies, especially the more recent, have been conducted in patients older than 55 years and typically with a mean age older than 65 years.
7. On average, lowering of BP by 20/10 mm Hg in hypertensive patients will reduce the risk for major CV events by half.
8. The reduction in stroke risk and heart failure appears to follow the predicted reduction in risk based on the epidemiologic association between these morbidities and BP.
9. The observed benefits of BP lowering on coronary events are lower than expected based on epidemiologic predictions, which is best addressed by attention to concomitant risk factors, especially statin therapy.
10. Another important objective of antihypertensive therapy is reducing the progression of CKD. Some but not all RCTs have shown a protective effect of BP-lowering on progression of CKD toward end-stage renal disease, in both diabetic and nondiabetic nephropathy.[16,17]
11. The risk reduction associated with BP lowering is continuous across a wide range of BP, with the benefit from treatment greatest in those with the highest absolute CVD risk. This provides the rationale for advocating the use of complementary strategies to reduce CVD risk (e.g., statins and antiplatelet therapy in those with established vascular disease, with target organ damage, or at high calculated CVD risk, i.e., ≥20% during 10 years).

Selection of Drug Therapy

The major classes of BP-lowering therapies are summarized here. International guidelines have recommended certain indications and contraindications for the use of specific classes of BP-lowering therapy in specific clinical situations (Box 36.1 and Table 36.6). These lists are

BOX 36.1 Clinical Indications Favoring Use of Specific Antihypertensive Medications

ACE Inhibitors
Heart failure
LV dysfunction
Post-MI
Diabetic nephropathy
Nondiabetic nephropathy
LV hypertrophy
Carotid atherosclerosis
Proteinuria/microalbuminuria
Atrial fibrillation
Metabolic syndrome

Angiotensin Receptor Blockers
Heart failure
Post-MI
Diabetic nephropathy
Proteinuria/microalbuminuria
LV hypertrophy
Atrial fibrillation
Metabolic syndrome
ACE inhibitor–induced cough

β-Blockers
Angina pectoris
Post-MI
Heart failure
Tachyarrhythmias
Glaucoma
Pregnancy

Calcium Antagonists (Verapamil, Diltiazem)
Angina pectoris
Carotid atherosclerosis
Supraventricular tachycardia

Calcium Antagonists (Dihydropyridines)
Isolated systolic hypertension (elderly)
Angina pectoris
LV hypertrophy
Carotid/coronary atherosclerosis
Pregnancy
Hypertension in Blacks

Thiazide Diuretics
Isolated systolic hypertension (elderly)
Heart failure
Hypertension (Blacks)

Diuretics (Antialdosterone)
Heart failure
Post-MI

Loop Diuretics
End-stage renal disease
Heart failure

ACE, Angiotensin-converting enzyme; *LV,* left ventricular; *MI,* myocardial infarction.

TABLE 36.6 Contraindications to Specific Blood Pressure–Lowering Therapies

Pharmacologic Therapy	CONTRAINDICATIONS	
	Compelling	Possible
Thiazide diuretics	Gout	Metabolic syndrome Glucose intolerance Pregnancy
β-Blockers	Asthma A-V block (grade 2 or 3)	Peripheral artery disease Metabolic syndrome Glucose intolerance Athletes, physically active patients COPD Asthma (use cardioselective β-blocker)
Calcium antagonists (dihydropyridines)		Tachyarrhythmias Heart failure
Calcium antagonists (verapamil, diltiazem)	A-V block (grade 2 or 3) Heart failure β-Blocker therapy	
Angiotensin-converting enzyme inhibitors	Pregnancy Angioneurotic edema Hyperkalemia Bilateral renal artery stenosis	
Angiotensin receptor blockers	Pregnancy Hyperkalemia Bilateral renal artery stenosis	
Diuretics (antialdosterone)	CKD stages 4 and 5 Hyperkalemia	
Direct renin inhibitors	Pregnancy Hyperkalemia Bilateral renal artery stenosis	

A-V, Atrioventricular; *CKD, chronic kidney disease; COPD,* chronic obstructive pulmonary disease.

TABLE 36.7 Common Side Effects Associated With Various Classes of Antihypertensive Drugs

Drug Class	Side Effects
ACE inhibitors	Cough, hyperkalemia
ARBs	Much less frequent hyperkalemia compared with ACE inhibitors
CCBs	
DHP CCBs	Pedal edema, headache
Non-DHP CCBs	Constipation (verapamil), headache (diltiazem)
Diuretics	Frequent urination, hyperglycemia, hyperlipidemia, hyperuricemia, sexual dysfunction
Central α-agonists	Sedation, dry mouth, rebound hypertension, sexual dysfunction
α-Blockers	Pedal edema, orthostatic hypotension, dizziness
β-Blockers	Fatigue, bronchospasm, hyperglycemia, sexual dysfunction
Potassium [K^+] channel openers	Hypertrichosis (minoxidil); lupus-like reactions, pedal edema (hydralazine)

ACE, Angiotensin-converting enzyme; *ARBs,* angiotensin receptor blockers; *CCBs,* calcium channel blockers; *DHP CCBs,* dihydropyridine calcium channel blockers; *non-DHP CCBs,* nondihydropyridine calcium channel blockers.

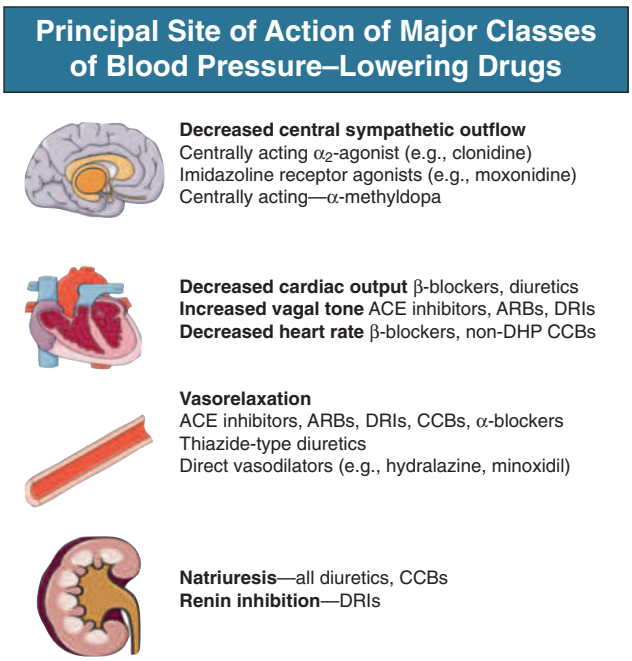

Fig. 36.3 Principal site of action of major classes of blood pressure–lowering drugs. *ACE,* Angiotensin-converting enzyme; *ARBs,* angiotensin receptor blockers; *CCBs,* calcium channel blockers; *DRIs,* direct renin inhibitors; *non-DHP CCBs,* nondihydropyridine calcium channel blockers.

not comprehensive and are subject to change as new evidence emerges. Moreover, the compelling indications have become less important now that few patients are treated with monotherapy and most patients will receive renin-angiotensin-system (RAS) inhibitors with an angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB), along with a calcium channel blocker (CCB) or thiazide or thiazide-type diuretic as part of their treatment strategy. Table 36.7 outlines the more common adverse effects associated with the major classes of BP-lowering drug therapies. Fig. 36.3 shows their sites of action.

Thiazide and Thiazide-Like Diuretics

The class of diuretics includes the traditional thiazide diuretics such as hydrochlorothiazide and bendroflumethiazide, as well as thiazide-like diuretics such as chlorthalidone and indapamide. The latter are termed *thiazide-like* because, like the thiazides, they act primarily by inhibiting the Na^+-Cl^- cotransporter in the distal tubule, promoting sodium excretion, which is integral to their antihypertensive effect. However, the thiazide-like diuretics have different structure than the thiazides and differing actions on other aspects of renal tubular function, such as carbonic anhydrase inhibition in the proximal tubule. Thiazide and thiazide-like diuretics remain an important therapeutic option for the treatment of hypertension. The early changes in salt and water balance they induce are usually accompanied by counteractivation of several

vasoconstrictor mechanisms, including the RAS, which may transiently raise peripheral vascular resistance (PVR) and attenuate BP lowering. Subsequently, a gradual reduction in PVR and a new steady state of reduced total body sodium and BP are established, usually after about 2 months of treatment.

The sustained actions of these diuretics on the kidney make them preferable to loop diuretics for the control of BP. Although loop diuretics are more potent promoters of acute sodium and water loss, their shorter duration of action can result in compensatory sodium retention during the latter part of the dosing interval, thereby reducing their BP-lowering efficacy. Loop diuretics have no place in the routine management of primary hypertension in patients with well-preserved glomerular filtration rate (GFR). However, thiazide and thiazide-like diuretics lose efficacy in patients with GFR below 30 ml/min. In such patients, loop diuretics are often required for effective BP lowering, especially when there is clinical evidence of sodium and water retention.

The main adverse effects of thiazide and thiazide-like diuretics are metabolic: hypokalemia, hyponatremia (less frequently), impaired glucose tolerance, and small increments in blood levels of low-density lipoprotein (LDL) cholesterol and triglycerides. These diuretics also elevate serum uric acid levels and should be avoided in patients predisposed to gout, as well as in those receiving lithium because of a high risk for lithium toxicity. Lithium reabsorption is similar to sodium in the proximal tubule, and thus distal sodium loss caused by thiazide and thiazide-like diuretics can promote proximal reabsorption of sodium and lithium; because lithium has a narrow therapeutic window, this can lead to lithium toxicity. An incidental advantage of thiazide and thiazide-like diuretics may be reduction in osteoporosis, especially in women, as a result of calcium retention.

There has been a trend during recent years to reduce the recommended dose of these diuretics to minimize their adverse metabolic effects. The dose-response for BP to thiazide and thiazide-like diuretics is flat (unlike the adverse effect profile); however, some patients respond well to higher doses, which they tolerate. Moreover, when thiazide or thiazide-like diuretics are combined with drugs that block the RAS, such as ACE inhibitors or ARBs, the dose-response curve is steeper and higher doses (e.g., hydrochlorothiazide 25 to 50 mg or chlorthalidone 25 mg) may be especially effective in patients with more resistant hypertension. The most recent NICE hypertension guidelines recommend the preferential use of thiazide-like diuretics such as chlorthalidone and indapamide, rather than traditional thiazides such as hydrochlorothiazide because there are limited outcome data with the latter when used at low dose.[8]

Potassium-Retaining Diuretics

This class of agents includes spironolactone, eplerone, and amiloride. Spironolactone is an aldosterone receptor antagonist that acts in the distal tubule and collecting ducts, decreasing the reabsorption of sodium and water and decreasing the excretion of potassium. The main action of spironolactone is to decrease tubular expression of epithelial sodium channels (ENaC) and renal outer medullary potassium (ROMK) channels, and thus it has a relatively slow onset and offset of action. Because its main site of action is on sodium and water handling in distal tubule and collecting ducts, spironolactone is a relatively weak diuretic. Nevertheless, it is effective as a BP-lowering agent although rarely used as initial therapy for hypertension. Spironolactone has the advantage over thiazide-like diuretics that it does not cause hypokalemia or hyperuricemia and it does not impair glucose tolerance. However, spironolactone has antiandrogen activity by binding to the androgen receptor and preventing it from interacting with dihydrotestosterone. Consequently, it can cause nipple tenderness and gynecomastia in some male patients (~6%) that is dose dependent and can limit its use. Another concern with potassium-sparing diuretics in general is the risk for hyperkalemia in people with substantially reduced GFR (see later discussion).

Eplerenone is more selective for the aldosterone receptor than spironolactone and consequently avoids its antiandrogen effects. There is very limited experience with use of eplerenone for the routine management of hypertension. Empirically, milligram per milligram, eplerenone is less potent than spironolactone and less effective at lowering BP.

Amiloride is an antagonist of ENaC in the distal convoluted tubules and collecting ducts, decreasing sodium and water reabsorption and promoting potassium excretion. Previously, amiloride was a popular treatment of primary hypertension, when, like spironolactone, it was often used in combination with thiazide-like diuretics. Amiloride is less used now even though it shares the advantage of spironolactone over thiazide-like diuretics of not causing hypokalemia, hyperuricemia, or impaired glucose tolerance.[18] Amiloride is the treatment of choice in patients with Liddle syndrome who have hypertension caused by a gain-of-function mutation of ENaC.

The reason for the decline in popularity of potassium-sparing diuretics for the initial treatment of primary hypertension is not clear; it may reflect the increasing use of ACE inhibitors and ARBs for the routine management of hypertension and the increased risk for hyperkalemia when these are combined with spironolactone or amiloride, especially in patients with renal impairment. Spironolactone and amiloride are, however, increasingly used as additional diuretic therapy in multidrug strategies for the treatment of resistant hypertension, when these drugs can be very effective.[19,20]

β-Adrenoceptor Blockers

β-Blockers reduce BP and CV events in patients with hypertension. Most β-blockers, with the exception of those with strong intrinsic sympathomimetic activity, reduce cardiac output by their negative chronotropic and inotropic effects. As with diuretics, short-term hemodynamic responses can be offset by counteractivation of vasoconstrictor mechanisms, which may limit initial BP lowering. Longer term reduction in arterial pressure occurs because PVR is restored to pretreatment levels. Partial blockade of renin release from the kidney may contribute to the later hemodynamic response.

β-Blockers differ in their duration of action, selectivity for β_1 receptors, lipophilicity, and partial agonist activity. Side effects include lethargy, aches in the limbs on exercise, impaired concentration and memory, aggravation of depression and psoriasis, erectile dysfunction, vivid dreams, and exacerbation of symptoms of peripheral vascular disease and Raynaud syndrome. Nonselective β-blockers are contraindicated in asthma patients and can cause adverse metabolic effects, including impaired glucose tolerance and worsening of dyslipidemia, notably reduced high-density lipoprotein (HDL) cholesterol and raised triglyceride levels. There is accumulating evidence that β-blockers increase the likelihood of new-onset diabetes, particularly in combination with thiazide-type diuretics.[21,22] Moreover, recent meta-analyses suggest that there is a shortfall in CV protection with β-blocker–based treatment of hypertension (especially in stroke reduction) compared with treatment with other major drug classes[4,23,24] (see Table 36.5 and Fig. 36.2). As a consequence, the U.K. guidelines and recent U.S. guidelines both state that β-blockers are not preferred as initial therapy for routine hypertension and should be used only when there is a compelling indication other than BP control (e.g., in patients with angina or chronic heart failure as well as hypertension).[8,9]

Another exception is in younger women in whom β-blockers are often effective at lowering BP and are safer than ACE inhibitors or ARBs in women anticipating pregnancy. The good BP-lowering efficacy in younger people most likely reflects higher renin levels, and the BP-lowering

action of β-blockers, at least in part, relates to suppression of renin release. Newer β-blockers have associated α-blocking activity, such as carvedilol and nebivolol. However, there are no clinical outcome trial data for the treatment of hypertension with these agents. The European Society of Hypertension/European Society of Cardiology (ESH/ESC) guideline did not come out quite so strongly against β-blockers but did not specifically endorse these agents as a preferred initial treatment or as an ideal drug in combination with other treatments.[7]

Calcium Channel Blockers

CCBs effectively reduce BP and have extensive evidence supporting their use for the treatment of hypertension[4,6]; they are also effective antianginal agents. They are metabolically neutral with regard to glucose tolerance and lipid parameters. More recent data have highlighted that CCBs are especially effective at smoothing BP variability, which is an independent risk factor for stroke. This may explain why systematic reviews have shown CCBs (particularly amlodipine) to be the most cost-effective treatment option for hypertension, mainly because they are the most effective agent at preventing stroke.[4,25] BP response to CCBs is largely determined by the magnitude of BP elevation, more so than with other drugs. Thus patients with higher baseline BP experience greater BP lowering with CCBs than those with only modest elevations of BP. This property also may explain the smoothing effect of CCBs on BP variability.

There are two main groups of CCBs, the dihydropyridines (e.g., amlodipine, nifedipine) and the nondihydropyridines (e.g., diltiazem, verapamil). The dihydropyridine (DHP) CCBs act mainly by inducing relaxation of arterial smooth muscle by blocking L-type calcium channels, thereby inducing a fall in PVR and arterial pressure. Nondihydropyridine (non-DHP) CCBs block calcium channels in cardiac muscle and reduce cardiac output. Verapamil has an additional antiarrhythmic action through its effects on the atrioventricular node. DHP and non-DHP CCBs have occasionally been combined, but no robust data are available on the BP-lowering efficacy or clinical outcomes of this approach and it is not a recommended combination therapy in international guidelines.

Earlier formulations of some DHP CCBs, such as capsular nifedipine, had a rapid onset and a short duration of action, with unpredictable effects on BP. These responses were often accompanied by reflex sympathetic stimulation and tachycardia. These shorter acting oral preparations of CCBs have no place in the routine management of hypertension. Longer acting formulations of DHP CCBs produce more sustained and predictable responses.

Side effects of DHP CCBs include dose-dependent peripheral edema, which is not caused by fluid retention but by transudation of fluid from the vascular compartments into the dependent tissues as a result of preapillary arteriolar dilation. This edema does not respond to diuretic therapy but is alleviated by limb elevation. There is emerging evidence that this edema may be reduced by coadministration of an ACE inhibitor or ARB because of their effects on venous capacitance. Gum hypertrophy can occur with DHP CCBs but is rarely seen with non-DHP CCBs. Non-DHP CCBs cause less peripheral edema but are negatively inotropic and negatively chronotropic and should therefore be avoided in patients with compromised left ventricular function and in combination with β-blockers. Verapamil use is commonly accompanied by constipation.

Blockade of Renin-Angiotensin System

Inhibition of RAS is predictably effective at lowering BP by inhibiting the various central and peripheral pressor effects of angiotensin II (Ang II). Blockade of RAS also may lower BP by other mechanisms involving improvements in endothelial function, vagal tone, and baroreceptor function and through inhibition of the renal tubular reabsorption of sodium. In addition, RAS inhibition has been popularized by clinical trial evidence that treatment with RAS inhibition reduced morbidity and mortality in patients with heart failure, delayed progression of renal disease, and reduced CV events in those at high CV risk.[6] Three classes of drugs are now available that directly target the RAS (Fig. 36.4): ACE inhibitors, ARBs, and the direct renin inhibitors (DRIs).[26] However, the DRIs are not recommended for routine treatment of hypertension in international guidelines because of a lack of evidence on their impact on CV outcomes.

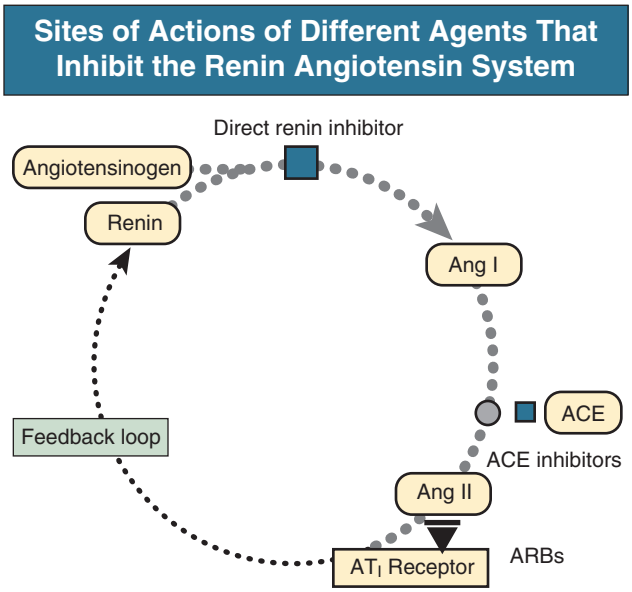

Fig. 36.4 Sites of actions of different agents that inhibit the renin-angiotensin system. The resulting neurohumoral profile is also shown. *ACE,* Angiotensin-converting enzyme; *Ang,* angiotensin; *ARB,* angiotensin receptor blocker; *DRI,* direct renin inhibitor.

Angiotensin-converting enzyme inhibitors. ACE inhibitors block the conversion of Ang I to Ang II by inhibiting ACE. The resulting reduction in levels of Ang II leads to vasodilation and a fall in BP. Ang II has many additional actions that are potentially harmful to the CV system and has been implicated in the pathogenesis of structural changes in the heart, blood vessels, and kidneys in hypertension. Sharp falls in BP after the introduction of ACE inhibitors may occur when the RAS is activated, for example, in patients who are dehydrated, in heart failure, or with accelerated hypertension. This is rarely a problem when therapy is initiated in uncomplicated hypertensive patients.

Side effects of ACE inhibitors include the development of a persistent dry cough in about 20% of users. This is more common in women and in people from East Asia and the Pacific Rim. The cough disappears only after discontinuation of the drug. Another rare but important complication is angioedema, which occurs in about 1% and is much more common in the Black population (~4%). ACE inhibitors should be avoided in women of childbearing potential because of the danger of fetal malformation, especially from exposure in the first trimester, when women may be unaware they are pregnant. ACE inhibitors should not be used in patients with significant bilateral renal artery disease because they may precipitate deterioration in renal function and renal failure. Careful monitoring of renal function and serum potassium concentration is also required in patients with more advanced renal impairment of any cause, because of the risk for hyperkalemia.

Angiotensin receptor blockers. ARBs are highly selective inhibitors of the Ang II type 1 receptor (AT_1). In common with ACE inhibitors, ARBs inhibit the actions of Ang II on the CV system and kidney. ARBs reduce BP as effectively as ACE inhibitors and generally have

a longer duration of action. ACE inhibitors and ARBs appear to be equally effective in reducing albuminuria and preserving GFR,[27] and have similar efficacy for preventing major CV events in patients with established CVD.[4,28] Because of their selectivity and specificity for the AT_1 receptor, the ARBs are well tolerated, with a placebo-like adverse effect profile. Cough and angioedema are much less likely to occur with ARBs than with ACE inhibitors, and most guidelines recommend switching patients to an ARB when an ACE-induced cough occurs. Cautions and contraindications are similar to those outlined for ACE inhibitors.

Direct renin inhibitor. The first nonpeptide, orally active DRI, is aliskiren.[26] which has high specificity for renin and is a potent inhibitor of plasma renin activity with a long half-life (~24 hours). Aliskiren inhibits the rate-limiting step in angiotensin production, the renin-dependent conversion of angiotensinogen to Ang I. DRIs have BP-lowering efficacy similar to that of ACE inhibitors and ARBs but with fewer side effects than ACE inhibitors.[26] The contraindications to use are similar to those for ACE inhibitors and ARBs. The main differentiating factor is that ACE inhibitors or ARBs activate plasma renin activity, whereas the DRI inhibits plasma renin activity. Aliskiren also has a much longer duration of action than the other forms of RAS blockade. The ALTITUDE trial tested the efficacy of aliskiren at reducing CV and renal events when added to preexisting RAS blockade in patients with type 2 diabetes and high CVD risk.[29] The study was discontinued for futility, and there was a signal for increased risk for harm when aliskiren was combined with another RAS blocker in this group of high-risk patients. The use of DRIs for the treatment of hypertension continues to decrease because of the absence of evidence for benefit of DRIs on outcomes in hypertensive patients and the lack of any guideline endorsement of their use.

α-Adrenergic Blockers

The original members of the α-adrenergic blocking class (e.g., prazosin) were short-acting drugs that blocked the activation of α_1-adrenoceptors in the vasculature, leading to vasodilation. Initially, the recommended dosage was too high, and postural hypotension and syncope were frequent. The use of lower doses and the development of longer acting agents (e.g., doxazosin) have largely overcome this problem. Blockade of sphincteric receptors improves symptoms in patients with benign prostatic hypertrophy. On occasion, these same sphincteric effects can worsen symptoms of stress incontinence in women. Uniquely among antihypertensive drugs, the α_1-antagonists produce modest favorable changes in plasma lipids, with a reduction in total and LDL cholesterol and triglyceride levels and an increase in HDL cholesterol. Despite the beneficial effects of α_1-antagonists in specific circumstances (e.g., prostatic outflow obstruction), they do not form part of the routine treatment strategy for hypertension in modern guidelines and are largely reserved for their specific indications (e.g., prostatic outflow obstruction), or as "add-on" treatment for resistant hypertension when alternative treatments are not tolerated.

Combined α-Adrenergic and β-Adrenergic Blocker

The use of β-blockers with vasodilatory properties has increased in recent years. Drugs in this class include carvedilol, nebivolol, and labetalol. Carvedilol and nebivolol have been shown to improve outcomes in RCTs in heart failure.[30] Labetalol has a rapid onset of action, making it a useful intravenous medication for the treatment of hypertensive emergencies. Labetalol is also safe in pregnancy and in patients with coronary disease because it does not increase heart rate. Labetalol should not be used without prior adequate α-blockade in patients with hyperadrenergic states, such as pheochromocytoma, because unopposed, inadequately blocked α-adrenergic activity can increase BP if β-blockade is not complete.

Centrally Acting Sympatholytic Drugs

Some of the earliest drugs developed to treat hypertension targeted the activation of the sympathetic nervous system (SNS) at various levels, including the CV regulatory nuclei in the brainstem, the peripheral autonomic ganglia, and the postganglionic sympathetic neuron. Few of these agents have any residual role to play in the modern treatment of hypertension because side effects are common.

Methyldopa reduces sympathetic outflow from the brainstem and frequently causes sedation, impaired psychomotor performance, dry mouth, and erectile dysfunction. Its unfavorable impact on quality of life resulted in methyldopa being gradually replaced by more effective drugs, although it is still extensively used in the management of hypertension of pregnancy, which is now its main indication.

Clonidine is now rarely used because of its short duration of action and risk for withdrawal syndrome, which occurs when sudden discontinuation results in a rebound rise in catecholamines with features that may resemble those of pheochromocytoma, such as severe hypertension, tachycardia, and sweating. This is exacerbated when patients are also receiving nonselective β-blockers such as propranolol. The syndrome is treated by readministration of the drug and then gradual discontinuation or the intravenous infusion of labetalol in an emergency. Clonidine is still used occasionally and can be effective in some patients with resistant hypertension. Longer-acting preparations of clonidine are being developed.

A newer centrally acting agent, *moxonidine* is an imidazoline receptor agonist that reduces sympathetic outflow and BP. It has a lower incidence of side effects and is better tolerated than other centrally acting agents. Moxonidine has no clinical trial evidence to support its use as a preferred first-line agent but is used empirically in some patients with resistant hypertension.

Direct Vasodilators

Hydralazine is no longer recommended as a first-line agent for hypertension management. The main disadvantages of hydralazine are sympathetic activation and the development of a lupus-like syndrome, particularly in patients with the slow acetylator genotype. Also, multiple daily dosing was required. It is still occasionally used in severe hypertension and hypertension associated with pregnancy.

Minoxidil is a potent vasodilator, and its use is largely confined to specialist centers for the treatment of severe and resistant hypertension. Its side effect profile includes stimulation of body hair growth; tachycardia and severe fluid retention reflect its potent vasodilator action and concomitant reflex SNS activation. For this reason, minoxidil is usually combined with a potent loop diuretic and a β-blocker as part of a triple-therapy approach to severe hypertension. Long-term use can be associated with insidious development of peritoneal and pericardial effusions (especially in patients with impaired renal function), which usually respond to treatment withdrawal.

Treatment Strategies

Given the multiple drug classes for the treatment of hypertension, there is a need for a treatment strategy that identifies the preferred drugs for initial therapy and preferred combinations for patients requiring more than monotherapy to control their BP. The use of drug therapy to lower BP should usually follow a period of observation and repeated measures of BP to ensure there is a sustained elevation of BP that merits treatment. The duration of the observation period is inversely related to the severity of hypertension. This ranges from immediate treatment to repeated measurement over days or months.

Lifestyle interventions should be initiated during this period of observation and continued even if treatment with drug therapy is initiated

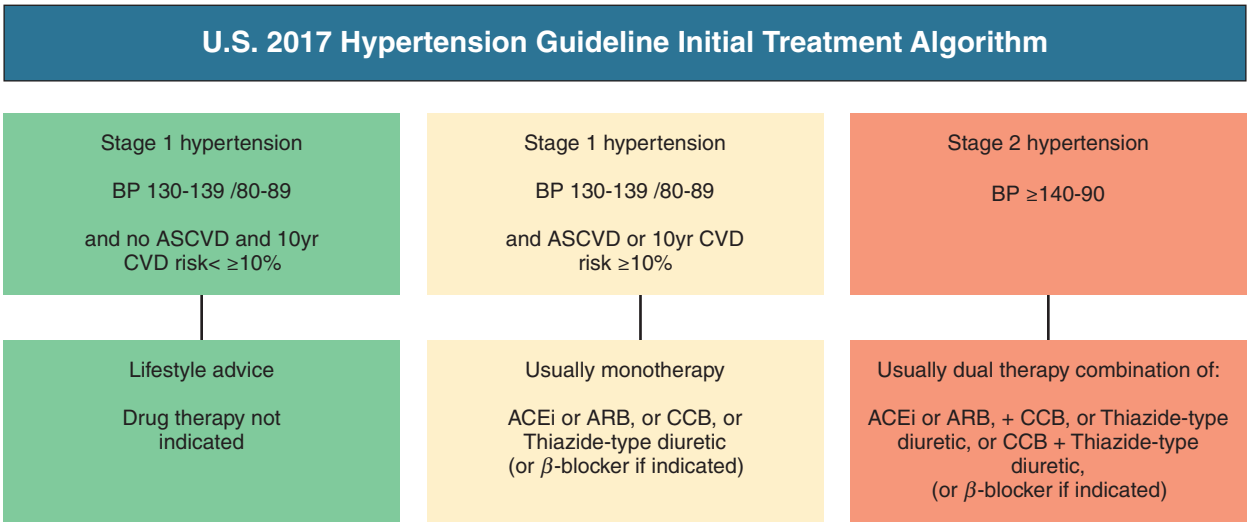

Fig. 36.5 U.S. Hypertension Guideline Initial Treatment Algorithm. All patients in these categories of blood pressure *(BP)* should receive lifestyle advice to aid reduction of their BP and CV risk. Patients with stage 1 hypertension and established atherosclerotic cardiovascular disease *(ASCVD)* or calculated to be at least 10% 10-year risk for a cardiovascular disease event *(CVD),* also should receive drug therapy, usually as a monotherapy. Patients with stage 2 hypertension also should receive drug therapy, usually as a dual therapy combination as initial therapy. *ACEi,* Angiotensin-converting enzyme inhibitor; *ARB,* angiotensin receptor blocker; *CCB,* calcium channel blocker.

(see Chapter 35). This is important because the actions of drug therapy often can be potentiated by concomitant lifestyle changes, especially body weight reduction and reduction in dietary sodium intake.[31] Furthermore, lifestyle changes are also important to improve the overall health and CV risk profile of the patient, beyond the impact on BP. Another key aspect of the initial assessment of patients is to identify concomitant risk factors, comorbidities, and target organ damage, all of which might influence the selection of drug therapies to improve BP control.

Initial Drug Therapy

The most important change in emphasis in the treatment of hypertension has been a shift toward recommending initiating therapy with a two-drug combination of treatment. This is because monotherapy is rarely sufficient to control BP, and this will be especially true if BP targets are universally lowered to less than 130/80 mm Hg. This was exemplified by the recent U.S. guideline that recommends initial dual therapy for most patients with hypertension, except those with stage 1 (i.e., systolic BP 130 to 139 mm Hg) (Fig. 36.5). Other guidelines recommend initiation with monotherapy and a stepped care approach for most patients, except those with grade 2 hypertension (i.e., BP ≥160/100 mm Hg) or those with grade 1 hypertension and high or very high CV risk, in whom initial dual therapy should be considered.

Choice of initial therapy. There is variation in international guidelines with regard to the preferred initial therapy for primary hypertension. In 2001 the U.S. JNC VII report recommended low-dose thiazide diuretics as initial therapy for all, unless contraindicated. The 2017 U.S. guidelines recommend an ACE-inhibitor or ARB as initial therapy, with the addition of a CCB or thiazide-type diuretic for patients with stage 2 hypertension. For stage 1 hypertension, any of these drugs are recommended as monotherapy. β-Blockers are reserved for specific indications, such as angina, after MI, and heart failure.

The current European guideline (2013) recommend that ACE-inhibitors, ARBs, low-dose thiazide-like diuretics, CCBs, or β-blockers were all suitable as initial therapy, usually as monotherapy, guided by the specific indications shown in Fig. 36.6.[7] The U.K. NICE guidelines

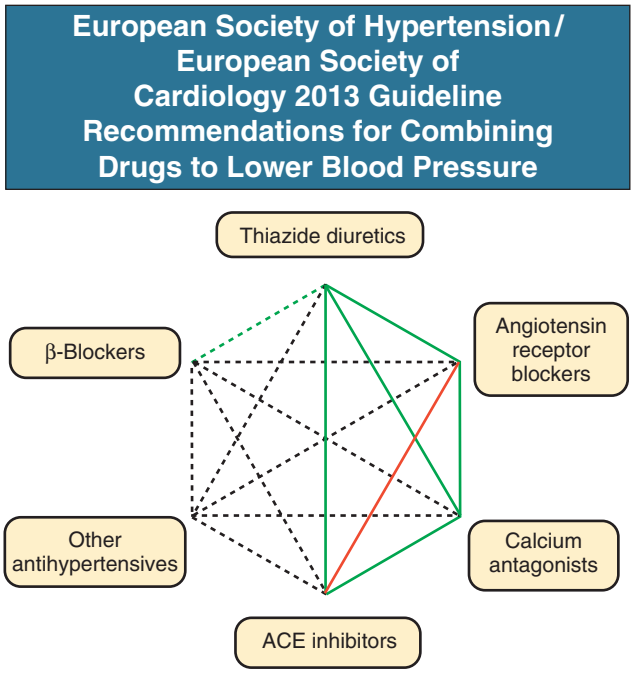

Fig. 36.6 ESH/ESC recommendations for combining drugs to lower blood pressure. *Green continuous lines* are the preferred combinations, *green dashed line* is considered a useful combination but with some limitations, *black dashed line* is possible but less well-tested combinations; and the *red line* is not recommended as a combination treatment for hypertension. *ACE,* Angiotensin-converting enzyme. (From reference 7.)

(2011) adopted a different approach and suggested that both age and ethnicity are important determinants of the BP response to initial therapy (Fig. 36.7).[8] The rationale for this approach is that the RAS is usually more active in younger people and Black people at any age. The U.K. NICE guidelines recommend initial therapy with an ACE

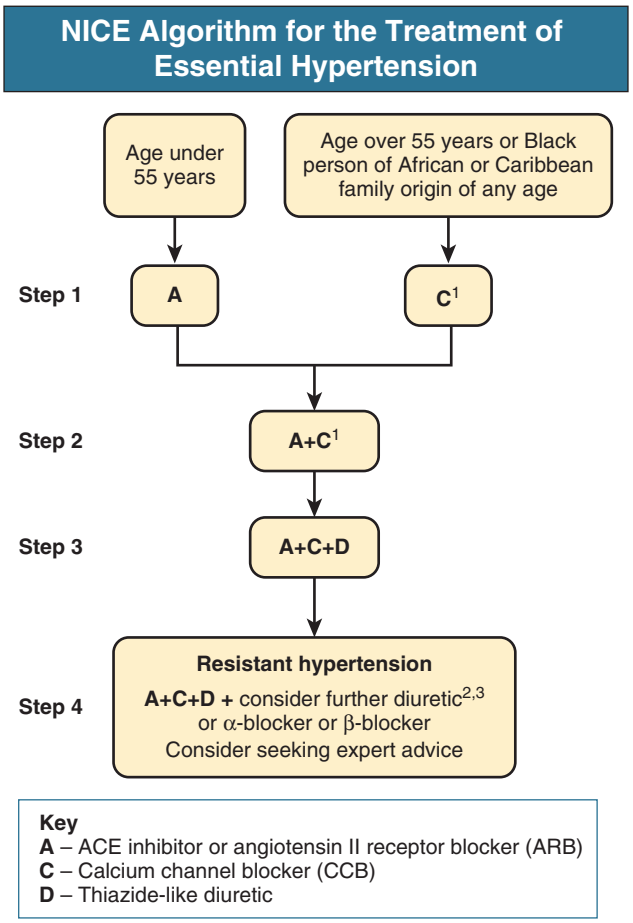

Fig. 36.7 Algorithm for treatment of essential hypertension. U.K. National Institute for Health and Clinical Excellence (NICE) guidelines: [1]CCB is preferred, but consider a thiazide-like diuretic (chlorthalidone or indapamide) if a CCB is not tolerated or the patient has edema or heart failure or is at high risk for developing heart failure; [2]consider low-dose spironolactone; [3]higher doses of the thiazide-like diuretic. (Modified from reference 8.)

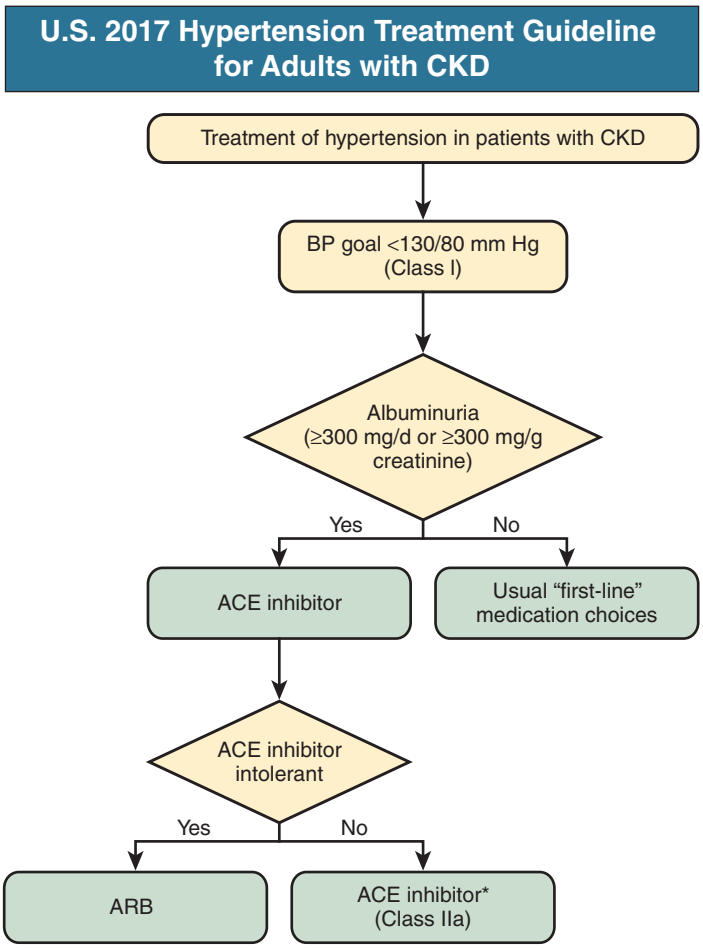

Fig. 36.8 U.S. 2017 hypertension treatment guideline for adults with chronic kidney disease *(CKD).* *ACE,* Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *BP,* blood pressure.

inhibitor or ARB in non-Black patients younger than 55 years and a CCB as the preferred initial therapy for most patients aged 55 and older. For Black patients of any age, the U.K. NICE guideline recommends a CCB as the preferred initial therapy. The caveats to these recommendations are (1) that a thiazide-type diuretic may be preferred to a CCB where a CCB is not tolerated or in those with signs of heart failure or at high risk for heart failure (e.g., the very elderly) and (2) that an ACE inhibitor or ARB should not be used in women of childbearing potential, when instead a β-blocker may be preferred. Thus the U.S. 2017 guideline has moved much closer to U.K. NICE guidance with regard to choice of drug therapy for routine treatment of hypertension (Fig. 36.5). The reason for the nonroutine use of β-blockers in the U.K. and recent U.S. guidance is that they (1) appear less effective than alternative drugs at reducing the risk for stroke; (2) were no more effective than other drugs at preventing incident coronary events; (3) were more likely to increase the risk for developing type 2 diabetes, especially when combined with diuretic therapy; and (4) were, as a consequence, the least cost-effective option for the initial treatment of primary hypertension.[8,24]

The U.S. 2017 guideline made specific recommendations for drug treatment in patients with CKD, recommending a BP goal of less than 130/80 mm Hg and a drug treatment strategy that included an ACE-inhibitor (or an ARB if ACE inhibitor intolerant), specifically when there was albuminuria greater than 300 mg/day (Fig. 36.8).

Combination Therapy

There is an emerging consensus in guidelines that the usual combination of drug treatment for hypertension should comprise an ACE inhibitor or ARB with CCB and/or thiazide or thiazide-type diuretic, for the preferred dual or triple therapy combinations. The U.K. NICE guidelines were the first to give explicit guidance for the use of ACE inhibitor or ARB with a CCB (A+C) as the preferred two-drug combination for most people, while accepting that an ACE inhibitor or ARB with a low-dose thiazide or thiazide-like diuretic is a suitable alternative (Fig. 36.7). The recommendation for the preferred use of A+C is supported by the ACCOMPLISH trial, which compared two different single-pill combinations (an ACE inhibitor with a CCB vs. the same ACE inhibitor combined with a low-thiazide diuretic) in a high-risk group of patients.[32] There was a significant (~20%) reduction in the primary end-point of CV morbidity and mortality in favor of the ACE inhibitor and CCB combination, with no difference in BP control between the two treatment groups. These data from ACCOMPLISH, along with the wealth of data from ACE inhibitor or ARBs in combination with low-dose thiazide diuretic therapy, provide evidence-based options to combine with either an ACE inhibitor or ARB as a two-drug combination therapy (i.e., A+C or A+D), with the use of A+C+D when a three-drug combination is required. The preferred combinations are now similar in European, U.S., and U.K. guidance

(i.e., A+C or A+D, and A+C+D when required) (Fig. 36.8). The only difference is that the European guidelines also endorse the combination of CCB plus a thiazide-type diuretic, which has been effective in some trials but is rarely used because it excludes RAS blockade, which many would consider complementary to either a CCB or thiazide-type diuretic, lowering BP and preventing reflex activation of the RAS system, which would otherwise occur with a C+D combination. What is clear is that all guidelines have converged and are closer than they have ever been with regard to preferred combination therapies.

Initial therapy with a two-drug combination. "Low-dose" two-drug combination therapy is recommended in the European and American hypertension guidelines when BP is more than 20/10 mm Hg above goal and therefore unlikely to be controlled with monotherapy. The recommendation of a two-drug combination is in part driven by concern that the upward titration of treatment in people at high risk may be too slow and leave them at risk for too long. A two-drug combination is also logical because the response to a single drug is often limited by counteractivation of pressor systems. This also explains why many BP-lowering drugs in monotherapy have a relatively flat dose-response curve. For example, sodium and water loss caused by diuretics or vasodilation with CCBs will activate RAAS, which limits the BP lowering. Thus a two-drug combination therapy is likely to (1) produce much greater BP lowering, (2) reduce heterogeneity in the BP-lowering response, and (3) have a more effective dose-response to upward titration of either component. The main concern has been adverse events related to potentially large initial BP falls in treatment-naïve patients. If the lower BP targets recommended in the recent U.S. hypertension guideline (i.e., <130/80 mm Hg) are replicated by other guidelines, it seems inevitable that low-dose combinations will become necessary for the majority of patients as initial therapy, with the preferred combinations likely to be RAS blockade plus diuretic and RAS blockade plus CCB.

Combining Renin-Angiotensin System Blockade

The view that RAS blockade may help prevent or regress hypertension-mediated structural and functional damage led to the use of dual RAS blockers. However, data from the ONTARGET and ALTITUDE trials demonstrated that dual RAS blockade in high-risk patients with an ACE inhibitor plus ARB combination in ONTARGET,[28] or an ACE inhibitor or ARB plus a DRI in ALTITUDE,[29] was no more effective than RAS blocker monotherapy at preventing major CV events in a high-risk population, including those with diabetes. Moreover, in both studies, the risk for adverse events, especially renal impairment, was greater with dual RAAS blockade. These findings have prompted all international guidelines to state that dual RAAS blockade should not be used for the management of hypertension.

Resistant Hypertension

Resistant hypertension has been defined as BP that remains above target despite the concurrent use of three antihypertensive agents of different classes. The U.S., European, and U.K. guidance all suggest that one of the three agents should be a thiazide-type diuretic and that all agents should be prescribed at optimal doses.[7,9,22] The NICE guidelines state that the three agents should usually comprise A+C+D in best tolerated doses.[8] White coat hypertension should be excluded by 24-hour ABPM. Most of these people will be older, often obese, and invariably with evidence of target organ damage. Other causes of resistant hypertension also should be considered (Table 36.8).[17,33,34]

Most patients with drug-resistant hypertension are likely to be retaining sodium and will respond to further diuretic therapy. A recent study (PATHWAY-2) demonstrated that low-dose spironolactone 25 to 50 mg/day, when added to A+C+D, was more effective at lowering BP than placebo, a β-blocker (bisoprolol), or an α-blocker (modified-release doxazosin).[19] Thus spironolactone has the best evidence for the treatment of resistant hypertension. However, the PATHWAY-2 study was conducted in patients with normal renal function, and careful monitoring for hyperkalemia is required, especially in patients with reduced GFR. Moreover, approximately 6% of men will develop gynecomastia with longer term use of spironolactone, necessitating its withdrawal. Alternatives to spironolactone include eplerenone, higher doses of thiazide-type diuretics, or high-dose amiloride 10 to 20 mg/day. For patients with reduced GFR (<45 ml/min/1.73 m^2), replacing the thiazide-type diuretic with a loop diuretic is usually necessary. For some patients, it may be necessary to use a combination of minoxidil, loop diuretic, and β-blocker to improve BP control.

TABLE 36.8 Considerations in the Patient With Resistant Hypertension

Patient Factors	Secondary Causes of Resistant Hypertension	Concomitant Medications That May Raise BP	Causes of "Pseudoresistant Hypertension"
Demographics Older age, especially over 75 Obesity Women > men More common in Blacks Excess dietary sodium High baseline BP and chronicity of uncontrolled hypertension	**Common Causes** Primary hyperaldosteronism (Conn adenoma) Atherosclerotic renovascular disease Sleep apnea CKD	**Prescription** Oral contraceptives NSAIDs Sympathomimetics (e.g., decongestants in cold remedies) Cyclosporine Erythropoietin Corticosteroids (e.g., prednisone, hydrocortisone)	**Poor Patient Adherence to Medications** Check BP response to directly observed medication
Concomitant Disease Target organ damage: LVH or CKD Diabetes Atherosclerotic vascular disease Aortic stiffening	**Uncommon Causes** Pheochromocytoma Aortic coarctation Cushing disease Hyperparathyroidism	**Nonprescription** Drug abuse (e.g., cocaine, amphetamines) Excess licorice ingestion Herbal remedies (e.g., ephedra, also known as ma huang)	**Errors in BP Measurement** Including BP cuff too small for arm circumference **White Coat Hypertension** Check BP with ABPM or home BP measurements.

Modified from reference 20.

ABPM, Ambulatory blood pressure monitoring; *BP,* blood pressure; *CKD,* chronic kidney disease; *LVH,* left ventricular hypertrophy; *NSAIDs,* nonsteroidal antiinflammatory drugs.

Medication to Reduce Cardiovascular Risk

Treating hypertension should be considered part of a more comprehensive strategy to reduce CVD risk. Patients at high risk are those with established CVD, target organ damage, or diabetes and those with a high calculated CVD risk; they should be considered for additional interventions to reduce risk. Various tools to assess CVD risk, usually over a 10-year time frame are available. The proposed level of CVD risk considered sufficient to warrant additional interventions has varied; it was typically 20% CVD risk over 10 years but is being progressively reduced toward 10% CVD risk over 10 years. Patients at increased risk, because of established atherosclerotic cardiovascular disease (ASCVD), diabetes, target organ damage, or an elevated 10-year CVD risk score, should receive reinforcement of lifestyle advice, especially smoking cessation, and treatment with statin therapy to further reduce the risk for stroke and coronary heart disease. Routine use of statins to reduce total cholesterol values by 40 mg/dl (~1 mmol/l) has been associated with a reduction in the risk for coronary events by about one third and for stroke by about one fifth, over and above the benefit already accrued from BP lowering.[35,36] Moreover, the relative risk reduction associated with statin therapy in higher risk hypertensive patients is not dependent on a high baseline cholesterol value. Higher risk hypertensive patients should be considered for treatment with antiplatelet drugs once BP has been controlled.

Follow-Up

In the early stages of treatment, the frequency of monitoring will be determined by the patient's response to therapy, the comorbidities, and the complexity of the treatment regimen required to control the BP. After initiating therapy, patients should be reviewed frequently to adjust treatment, monitor for adverse effects, and establish BP control. Once BP is controlled, patients should be reevaluated at least annually for a formal review, and most will be reevaluated every 6 months. Patients are increasingly monitoring their own BP in the intervening periods, and this trend is likely to increase.

Withdrawal of Therapy

Most patients with hypertension require lifelong therapy. Some with grade 1 hypertension who make major adjustments to their lifestyle may obtain sufficient fall in their BP to warrant safe withdrawal of monotherapy. However, patients with target organ damage or those at high CVD risk usually should not have their therapy withdrawn unless there is a compelling clinical reason to do so.[7-9] In patients with previously severe hypertension that has subsequently been well controlled, treatment withdrawal may not always result in an immediate increase in BP, which can sometimes take many months to rise progressively back to dangerously high pretreatment values. Any patient who discontinues therapy must remain under review with regular BP monitoring. All but a very few will require treatment again.

Indications for Specialist Referral

Referral to a specialist center is sometimes indicated for the patient in management of hypertension. Indications include uncertainty about the decision to treat, investigations to exclude secondary hypertension, severe and complicated hypertension, and resistant hypertension (see Table 36.8).

Hypertension in People of Black African Origin

Hypertension is more prevalent in Black patients, is associated with more target organ damage, and carries a worse prognosis, with a particularly high risk for stroke.[37] Black patients tend to respond better to diuretics, CCBs, and dietary salt restriction than White patients. ACE inhibitors, ARBs, and β-blockers are generally less effective as initial therapy in Black patients but become more effective in combination with diuretics or CCBs. When a RAS blocker is used as part of the treatment strategy, an ARB may be preferred because of the increased risk for angioedema with ACE inhibitors in Black patients.

Hypertension in Older People

If a BP of 140/90 mm Hg or higher is used to define hypertension, more than 70% of people older than 60 years will be hypertensive, the majority of these patients having ISH.[38] The lower BP threshold in the new U.S. guidelines means that almost all older patients, and especially those older than 70 years, will be classified as hypertensive. Surveys suggest that physicians consistently underestimate the risks and undertreat hypertension in older people. However, important considerations in treating older people include the following:

1. The arterial wall stiffening that gives rise to systolic hypertension and increased pulse pressure (ISH) is also associated with impaired baroreflex sensitivity with increased risk for orthostatic hypotension. Thus it is important to record lying and standing BP readings in elderly patients.
2. Estimated GFR declines with age, with impaired renal conservation of sodium and fluid in the face of depletion. Elderly patients are therefore more subject to volume depletion as a result of diuretic therapy.
3. Clearance of drugs and their active metabolites is decreased as a result of declining hepatic and renal function.
4. Cardiac function and reserve are often reduced, and patients are therefore much more likely to develop cardiac failure. Trials in elderly patients have consistently shown that treatment of hypertension reduces morbidity and mortality from cardiac failure.
5. Multiple comorbidity is much more common in elderly patients.
6. Communication and adherence with therapy may be more difficult with decline in cognitive function. Some evidence from clinical trials suggests that this decline may be slowed by antihypertensive treatment.

Despite these considerations, elderly patients generally tolerate BP-lowering medications well, and BP reduction leads to substantial benefits in the risk for stroke, coronary events, and heart failure. As a general rule, drug regimens should be as simple as possible and dosages increased more gradually. The greatest danger results from lowering of BP too rapidly. The benefits of treating hypertension in people older than 80 years was illustrated by the Hypertension in the Very Elderly Trial (HYVET), which confirmed that treatment was well tolerated and associated with impressive reductions in the risk for stroke, heart failure, and mortality.[39] Furthermore, approximately one third of patients in the SPRINT study were older than 75 years and there was no evidence that these older patients experienced more harm or received less benefit from more intensive BP lowering.[13] Thus there is no reason to manage very elderly patients any differently from those who are not as old. The recent U.S. guideline has recommended that ambulant, independent, and noninstitutionalized elderly patients should be treated with medication when their systolic BP is 130 mm Hg or higher and treated to a systolic BP of less than 130 mm Hg. This is a very dramatic reduction in both BP thresholds and targets, a recommendation that has been strongly influenced by the outcome of the SPRINT study.[13] This magnitude of BP reduction may be too aggressive for many elderly patients, especially those with a high baseline BP. Moreover, elderly participants in clinical trials such as SPRINT tend to be fitter and more independent than the many millions of elderly patients to whom this guideline will be applied. It seems likely that this recommendation will not be endorsed by other international guidelines that are more likely to consider

initiating treatment when systolic BP is 140 mm Hg or greater and target systolic BP to less than 140 mm Hg but not less than 130 mm Hg. Finally, there remains a dilemma, compounded by a paucity of data, with regard to treatment strategies for the more frail and dependent elderly patients, often with limited life expectancy, which in many cases is unlikely to be influenced by treatment of hypertension. Treatment decisions for such patients have to be individualized, in consultation with the patient, family, and carers.

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements is true of calcium channel blockers (CCBs) for the treatment of hypertension?
   - **A.** Nondihydropyridine CCBs have the strongest evidence base and are the most widely used for treatment of hypertension.
   - **B.** CCBs are not a cost-effective treatment for hypertension.
   - **C.** The peripheral edema associated with CCBs is often improved when combined with renin-angiotensin–blocking drugs.
   - **D.** CCBs are less effective at reducing the risk for stroke compared with other antihypertensives.
   - **E** CCBs are less effective at reducing blood pressure (BP) variability.
2. Which of the following statements is true of recommended BP targets for treated hypertensive patients?
   - **A.** 2017 U.S. hypertension guidelines have recommended a BP target similar to those of other international guidelines, that is, the BP target for most people should be less than 140/90 mm Hg.
   - **B.** Similar targets have been recommended in all guidelines (<140/90 mm Hg) for people 80 years and older.
   - **C.** The evidence for optimal BP targets is stronger for systolic versus diastolic BP.
   - **D.** All guidelines recommend the routine use of ambulatory or home BP monitoring for checking BP control.
   - **E.** The BP targets are similar for office, home, and ambulatory BP measurements.
3. Which of the following statements is true of combination therapies for high BP?
   - **A.** Guidelines acknowledge that combination of two or more drugs are rarely required to control BP in most patients.
   - **B.** Combinations of two or more renin-angiotensin system (RAS)–blocking drugs are no longer recommended for the treatment of hypertension.
   - **C.** RAS-blocking drugs are suitable treatment for women of childbearing potential, either alone or as part of combination treatment, as long as they are discontinued by the third trimester in pregnant women.
   - **D.** β-Blockers are especially effective as part of combination therapy in reducing the risk for stroke in older patients
   - **E.** There is good clinical trial evidence that starting treatment with a combination of two drugs is more effective than a standard "stepped care" approach in reducing CV events.
4. Which of the following statements are true for resistant hypertension?
   - **A.** Resistant hypertension is common, affecting approximately 30% of treated patients.
   - **B.** When patients are thoroughly investigated, resistant hypertension is usually found to be due to a secondary cause of hypertension.
   - **C.** Resistant hypertension is more common in younger patients.
   - **D.** It is only rarely possible to control BP in resistant hypertension with additional drug therapy.
   - **E.** Resistant hypertension is most effectively treated with further diuretic therapy.
5. The 2017 U.S. guidelines recommend which of the following for treatment of patients with chronic kidney disease (CKD)?
   - **A.** Recommend a similar treatment strategy for hypertension irrespective of the presence of proteinuria
   - **B.** Recommend an optimal BP treatment target of less than 140/90 mm Hg
   - **C.** Recommend the use of ACE-inhibitors in preference to angiotensin receptor blockers in patients with proteinuria
   - **D.** Recommend the use of ARBs in preference to ACE inhibitors in patients with proteinuria

Evaluation and Treatment of Hypertensive Emergencies and Urgencies

Pantelis A. Sarafidis, George L. Bakris

The term *malignant hypertension* first appeared in 1928 and described patients with extremely high blood pressure (BP) values, to emphasize that because of rapid target organ damage, their average prognosis was similar to that of most cancer patients.[1] Subsequently, malignant (or accelerated) hypertension was used to describe patients with greatly elevated BP and vascular damage that could manifest as retinal hemorrhage/exudate and papilledema, usually associated with encephalopathy, acute kidney injury, and microangiopathic hemolytic anemia.[2,3] However, dramatic advances in both in-hospital and outpatient treatment of hypertensive emergencies have led to an improved prognosis: a decrease in 1-year mortality from 80% in 1928 to 50% in 1955 and to less than 10% after 1990.[4,5] Thus terms such as *malignant* and *accelerated hypertension* have been progressively replaced by the terms *hypertensive emergency* and *hypertensive urgency*.

Marked elevations in systolic BP (SBP) and diastolic BP (DBP) (usually above 180/120 mm Hg) can be classified as either emergencies or urgencies.[6,7] A *hypertensive emergency* is defined as a marked elevation in BP complicated by evidence of acute target organ damage, such as coronary ischemia, dissecting aortic aneurysm, pulmonary edema, hypertensive encephalopathy, cerebral hemorrhage, and eclampsia. In most hypertensive emergencies, BP should be reduced usually by 20 to 40 mm Hg (or no more than 25%) within minutes to an hour using parenteral drug therapy in an intensive care unit (ICU) to limit end-organ damage.[6] *Hypertensive urgency* is a clinical setting of significant BP elevation without acute target organ dysfunction. The approach to hypertensive urgency is a gradual BP reduction within hours, usually with oral medications.[4,6-9] Recently, the American College of Emergency Physicians proposed the term *asymptomatic markedly elevated BP* to be used instead for the term *hypertensive urgency* for patients presenting in the emergency department (ED) with BP above 160/100 mm Hg.[10]

ETIOLOGY AND PATHOGENESIS

Hypertensive emergencies and urgencies can develop de novo in normotensive individuals or can complicate underlying primary or secondary hypertension[4,9,11]; Box 37.1 shows the most common causes. In some hypertensive emergencies, an underlying condition is the clear cause of acute BP elevation. In acute glomerulonephritis, renal crisis in patients with systemic sclerosis, or renal artery stenosis, severe BP elevations are evoked through increased activity of the renin-angiotensin system (RAS). In pheochromocytoma, cocaine intoxication, or spinal cord injury, acutely elevated BP is the result of excess catecholamine release. In other patients, acute sustained elevations in BP itself are the etiologic factor, resulting in conditions such as hypertensive encephalopathy or severe hypertension with acute left ventricular failure and pulmonary edema. In some cases, however, it may be difficult to differentiate whether BP elevation is the cause or the result of a hypertensive emergency. For example, in a patient with intracerebral hemorrhage an acute marked BP increase may be the primary cause; alternatively a hemorrhage of other etiology (i.e., coagulation deficit) may have occurred, followed by BP elevation to preserve cerebral tissue blood supply. Thus a careful diagnostic evaluation of hypertensive emergencies and urgencies is essential to guide proper treatment.

A hypertensive emergency can occur in various clinical settings, but the most common is chronic hypertension (often untreated or poorly controlled) in a patient whose usual BP is above 180/120 mm Hg.[11] In many of these patients, chronically elevated BP does not affect target organ perfusion because of autoregulation. *Autoregulation* is the ability of blood vessels to dilate or constrict in response to changes in perfusion pressure and thereby maintain normal organ perfusion. This mechanism is present in the brain and kidneys and involves L-type calcium channels.[7] Arteries from normotensive individuals can maintain flow over a wide range of mean arterial pressures, 70 to 150 mm Hg, associated with SBP of around 90 to 180 mm Hg. Chronic BP elevations cause compensatory functional and structural changes in the arteriolar circulation and shift the autoregulatory curve to the right, which allows hypertensive patients to maintain normal perfusion and avoid excessive blood flow at higher BP levels.[3,12] Over time, the structural and functional changes in cerebral and renal arterioles may lead to a progressive inability of the arterioles to autoregulate properly (Fig. 37.1).[9,13]

The factors that lead to the severe and rapid BP elevation causing a hypertensive emergency are poorly understood. The rapidity of the onset suggests a triggering factor (i.e., release of a humoral vasoactive factor) superimposed on preexisting hypertension; however, the hypertensive emergency is likely a nonspecific consequence of chronically elevated BP.[3,7] In any case, target organ damage associated with hypertensive emergency results from the inability of autoregulatory mechanisms to maintain normal perfusion pressures in certain vascular beds (especially of brain and kidney) when BP rises above the autoregulatory range.[12] The resultant endothelial injury causes a loss of endothelial antithrombotic properties, with activation of platelets and the coagulation cascade, increased vascular wall permeability, and vascular smooth muscle cell proliferation culminating in an increase of tissue ischemia and ultimately fibrinoid necrosis. This is coupled with activation of hormonal systems and release of vasoactive substances (RAS, catecholamines, endothelin, vasopressin) that maintain a vicious cycle of elevated BP and vascular injury.[3,9] According to recent studies of patients with hypertensive emergency, the typical structural kidney changes are

BOX 37.1 Common Hypertensive Emergencies and Urgencies

Acceleration of Chronic Hypertension
- With papilledema ± encephalopathy ± renal failure
- With features of thrombotic microangiopathy (thrombocytopenia, hemolytic anemia, renal failure, ± papilledema, ± encephalopathy)

Cardiovascular Conditions
- Acute myocardial ischemia/infarction caused by coronary artery disease
- Acute left ventricular failure/pulmonary edema
- Acute aortic dissection
- Severe hypertension after coronary bypass or other vascular surgery
- Epistaxis unresponsive to anterior/posterior packing

Renal Conditions
- Acute or rapidly progressive glomerulonephritis
- Renovascular hypertension
- Renal crises from scleroderma or collagen vascular disease
- Severe hypertension after kidney transplantation

Neurologic Conditions
- Hypertensive encephalopathy
- Intracerebral hemorrhage
- Subarachnoid hemorrhage
- Cerebral embolism or atherothrombotic cerebral infarction
- Severe hypertension after thrombolysis for atherothrombotic stroke
- Acute head trauma
- Guillain-Barré syndrome

Excess Circulating Catecholamine Conditions
- Pheochromocytoma crisis
- Interactions of tyramine-containing foods with monoamine oxidase inhibitors
- Rebound hypertension after sudden withdrawal of centrally acting α_2-agonists (clonidine, methyldopa, or other)
- Use of sympathomimetic drugs (phencyclidine, phenylpropanolamine, cocaine, or other)
- Automatic hyperreflexia after spinal cord injury

Pregnancy-Related Condition
- Eclampsia

Surgical Conditions
- Severe hypertension in patients requiring immediate surgery
- Perioperative hypertension
- Postoperative bleeding from vascular suture lines
- Hypertension after organ transplantation

Hypertension Associated With Severe Burns

onion-skin appearances of small arteries and arterioles and glomerular collapse (Fig. 37.2) with electron-lucent widening of the subendothelial zone and wrinkling of the glomerular capillary walls, with fibrinoid necrosis of small arteries being less common.[14] Other findings include injury of the affected organs (e.g., cerebral edema).[3,12] Hypertensive emergency may rarely present as a thrombotic microangiopathy, for example, in patients with scleroderma renal crisis (see Chapter 28). Although direct observations on acute kidney dysfunction in hypertensive crises are rare, a recent study reported that patients presenting with hypertensive emergency had lower glomerular filtration rate and increased biomarkers of early kidney injury, such as urine neutrophil gelatinase-associated lipocalin (NGAL), compared with patients with hypertensive urgency or controls.[15]

In normotensive or minimally hypertensive individuals, such as children or pregnant women, the symptoms and signs of a hypertensive emergency occur at lower BP levels than in hypertensive patients because adaptive chronic vascular changes are absent. However, most hypertensive emergencies occur in patients with chronic hypertension. This may relate to other mechanisms contributing to impaired autoregulation, such as progressive arteriolar disease (in both cerebral and renal circulation) and pharmacologically impaired autoregulation (e.g., use of dihydropyridine calcium channel blockers [CCBs], or furosemide).

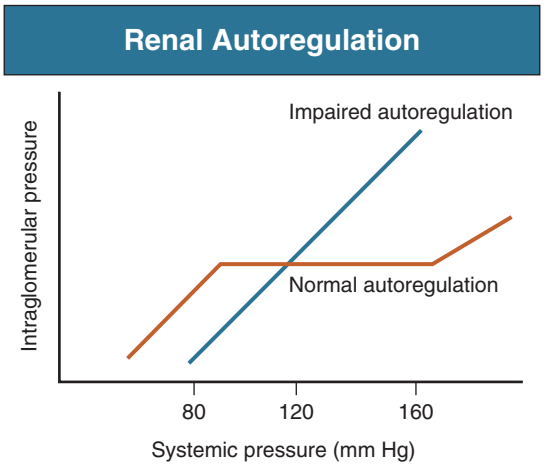

Fig. 37.1 Renal autoregulation. Relationship of systemic to glomerular pressure in the setting of normal or abnormal renal autoregulation.

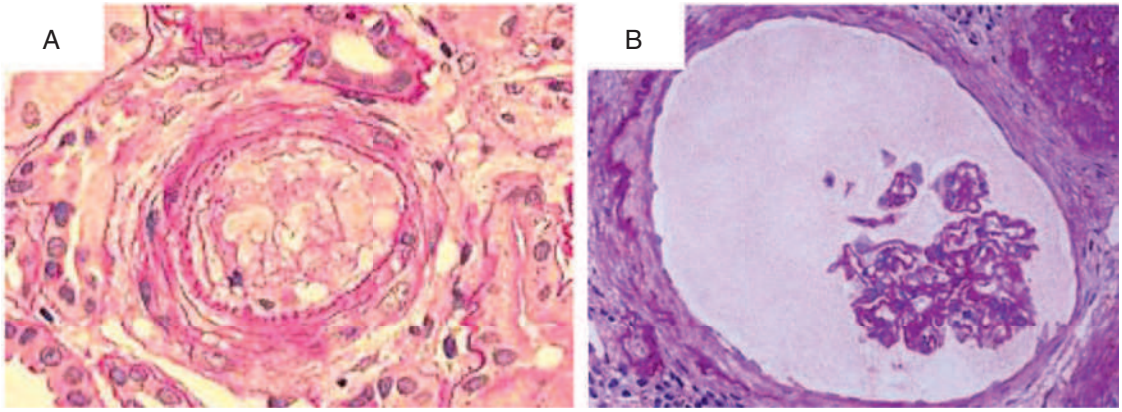

Fig. 37.2 Common kidney biopsy findings in patients with hypertensive emergency–related renal dysfunction. (A) Concentric subendothelial edematous thickening (onion-skin appearance) of an arteriole. (B) Collapsed glomerulus. (Periodic acid–Schiff staining). (Reprinted with permission from reference 14.)

EPIDEMIOLOGY

The exact incidence of hypertensive emergencies and urgencies or the demographic distribution is not known, but an estimated 1% to 2% of individuals with hypertension develop a hypertensive emergency.[16] One study reporting on more than 14,000 ED visits showed that hypertensive urgencies accounted for 76% and emergencies for 24% of hypertension-related visits, which in turn represented 3% of total visits.[17] In this study, the most common manifestations of hypertensive emergency were associated with cerebral infarction (24.5%), acute pulmonary edema (22%), hypertensive encephalopathy (16%), and acute heart failure (14%), followed by myocardial infarction (12%), cerebral hemorrhage (5%), eclampsia (5%), and aortic dissection (2%). In a different series of 435 ED visits for hypertension, 40% were hypertensive urgencies, almost all with some degree of preexisting kidney disease, and 60% were emergencies.[18] Hospitalization for hypertensive emergency occurs at a rate of 1 or 2 cases per 1 million population per year in the United States.[12]

In developed countries, widespread use of antihypertensive agents has reduced the incidence of hypertensive emergencies, as supported by previous indirect observations.[12] Use of any antihypertensive drug reduces the risk for hypertensive emergency because poor treatment compliance and outpatient BP control are predictors of subsequent hypertensive urgency and or emergency.[19] A recent retrospective study on the incidence, cause, and prognosis of hypertensive emergencies in an academic medical center covering a 20-year period documented that 80.3% of patients had been previously diagnosed with hypertension and were undertreated, and the incidence of hypertensive emergency was reduced from 12.7 per 100,000 admissions during 1991 to 1995 to 6.2 per 100,000 admissions during 2006 to 2010, and 1-year mortality decreased from 16.7% to 3.6% over the same periods.[20] With regard to long-term renal prognosis, another study in 120 patients with malignant hypertension showed that during a median follow-up of 67 months, 24% of patients developed end-stage renal disease and started dialysis and another 7% had a greater than 40% decline in estimated glomerular filtration rate.[21] Hospitalization for hypertensive emergency is more common in developing countries, ethnic minorities of developed countries,[5] and individuals of low socioeconomic status, that is, in patients who often have poor BP control.

DIAGNOSTIC EVALUATION

The primary goal of the diagnostic process is to differentiate a true hypertensive emergency from a hypertensive urgency, because of the different therapeutic approaches. The second goal is rapid assessment of the type and severity of ongoing target organ damage. In some hypertensive emergencies, the history (e.g., acute head trauma, preeclampsia, scleroderma) or overt symptoms and signs (e.g., chest/back pain, dyspnea, throbbing abdominal mass) may guide the diagnosis; whereas in other cases (e.g., severe hypertension with altered mental status), the evaluation must be more comprehensive.

The diagnostic approach begins with the patient's history, with attention to duration, severity, and treatment of preexisting hypertension and associated conditions[8,9,11] (Box 37.2). BP measurements should be performed in both arms (if possible, in both sitting and standing positions) and a leg[2] (see Chapter 33). A careful examination and assessment of cardiac, pulmonary, peripheral vascular, and neurologic systems with assessment of mental status should follow, along with a thorough funduscopic (ophthalmoscopic) examination for hemorrhages, exudates, and papilledema.

Signs of secondary hypertension should not be missed in this initial examination. For example, an abdominal bruit may indicate renovascular hypertension; a palpable abdominal mass suggests abdominal aneurysm or polycystic kidneys; a radial-femoral pulse delay suggests aortic coarctation; abdominal striae and central obesity are observed with Cushing syndrome; and exophthalmos may indicate hyperthyroidism.

The initial laboratory studies in a hypertensive emergency include a complete blood count with peripheral smear, urinalysis, creatinine and urea concentrations, and electrolyte values.[8,9,11] Comparison of kidney function with a patient's recent measurement is important. Severe hypertension accompanied by acute deterioration in kidney function, microscopic hematuria with red blood cell casts, or nephritic urine sediment suggests acute glomerulonephritis. Patients with features of hemolytic anemia and thrombocytopenia should be evaluated for causes of thrombotic microangiopathy. If a secondary form of hypertension is suspected, samples for plasma renin activity, aldosterone concentration, and plasma free catecholamines and metanephrines also should be drawn *before* initiation of treatment. Testing should be performed with the patient supine, and ideally the patient should not be receiving β-blockers, especially labetalol, because of false-positive metanephrine and total catecholamine values. Electrocardiography to rule out myocardial ischemia and left ventricular strain or hypertrophy, as well as chest radiography, should be performed in every patient.[8] Renal ultrasound, if available, is also useful to rule out abnormalities such as differences in size or perfusion, especially in patients with altered renal function or with abnormalities on urinalysis.

Neurologic syndromes associated with hypertension, including subarachnoid hemorrhage, intracerebral hemorrhage, thrombotic stroke, and hypertensive encephalopathy, are difficult to distinguish from one another. Computed tomography (CT) or magnetic resonance imaging (MRI) provides a definite diagnosis of a hemorrhagic or thrombotic stroke. Echocardiography, thoracoabdominal CT or MRI, or abdominal

BOX 37.2 Diagnostic Evaluation for Hypertensive Emergencies and Urgencies

History
- Previous diagnosis and treatment of hypertension
- Symptoms, previous diagnoses, and treatment of cardiac, cerebral, renal, and visual damage
- Intake of pressor agents: Sympathomimetics, illicit substances

Repeated Blood Pressure Measurements (First Measurement in Both Arms)

Physical Examination
- Cardiac
- Vascular
- Pulmonary
- Neurologic
- Optic fundi

Laboratory Studies
- Complete blood count urinalysis, creatinine, urea, electrolytes
- Plasma renin activity, aldosterone, and catecholamines if secondary hypertension is suspected

Electrocardiography

Chest Radiograph

Further Investigations (According to Clinical Presentation)
- Renal ultrasound
- Brain CT scan or MRI
- Echocardiography (transthoracic, transesophageal)
- Thoracoabdominal CT scan or MRI

CT, Computed tomography; *MRI,* magnetic resonance imaging.

ultrasound may be needed in patients with suspected aortic dissection or pheochromocytoma.[8]

TREATMENT

General Principles for Managing Hypertensive Emergencies

Although therapy with parenteral antihypertensive agents may be initiated in the ED, patients with a hypertensive emergency should be admitted to an ICU for continuous BP monitoring, clinical surveillance, and continued parenteral administration of an appropriate agent (Tables 37.1 and 37.2). Specific BP levels do not determine the severity and the emergency of the situation because the autoregulatory structural and functional changes may vary among individuals, such that some may develop target organ damage at lower BP.

Understanding of autoregulation as well as cardiovascular (CV) comorbidities such as age and extent of vascular disease are crucial for therapeutic decisions; sudden lowering of BP into a normal range could lead to inadequate tissue perfusion.[12] Clinical data document that lowering BP in hypertensive emergencies is beneficial: papilledema and exudates regress, hypertensive encephalopathy vanishes, pulmonary edema resolves, and renal function improves. However, there is also evidence that abrupt lowering of BP can be harmful. For example, the use of sublingual nifedipine with potent but unpredictable BP lowering may shunt blood away from the penumbra of the brain (ischemic penumbra), resulting in a vascular infarct.[22] Thus the goal of antihypertensive therapy is not to normalize BP rapidly, but rather to prevent target organ damage by gradually reducing BP while minimizing the risk for hypoperfusion.

For most patients with hypertensive emergency, the mean BP should be reduced by no more than 20% to 25% within the first hour.[6,8] A DBP target between 100 and 110 mm Hg or a reduction of 25% compared with the initial baseline, whichever is higher, is an appropriate goal within the next 2 to 6 hours. Reduction of DBP to less than 90 mm Hg or by 35% of the initial mean BP has been associated with major organ dysfunction, coma, and death. Similarly SBP should be reduced to levels around 160 mm Hg within the first hour and slowly over the next 24 hours reduced to levels around 140 mm Hg. If the degree of BP reduction is well tolerated and the patient is clinically stable, further gradual reductions toward levels below 140/90 mm Hg should be implemented within the next 24 to 48 hours.

An important consideration before initiation of intravenous therapy is assessment of the patient's volume status. With the exception of patients presenting with volume overload and pulmonary edema, some patients with a hypertensive emergency may be volume depleted because of pressure natriuresis, and diuretics should not be used; rather, fluid administration may help restore organ perfusion and prevent a precipitous fall in BP.[9] Diuretics especially should be avoided in hypertensive emergencies because of catecholamine excess states (pheochromocytoma, monoamine oxidase inhibitor crisis, cocaine intoxication), because these patients are usually volume depleted.

Major exceptions to these treatment recommendations include patients with acute stroke; in ischemic stroke there is no clear evidence to support immediate BP lowering, and a more cautious approach is needed (see Chapter 40), but the recent INTERACT2 trial in patients who presented with a *hemorrhagic* stroke showed that lowering SBP to less than 140 mm Hg within an hour is safe and may improve functional outcome.[23] This observation has led to changes in relevant guidelines.[24] In patients with aortic dissection, SBP should be lowered to less than 100 mm Hg if tolerated; another group of patients who would benefit from BP being lowered to levels between 100 and 110 systolic are those who require thrombolytic agents.[8,16]

After BP has been controlled for a suitable period, typically 12 to 24 hours, allowing autoregulation to reestablish, the intravenous medication is gradually reduced and replaced by oral agents. Typically, a CCB, α- and β-blocker, or RAS blocker can be used, depending on the suspected cause and possible ongoing investigations for secondary hypertension.[12]

Specific Aspects of Antihypertensive Drug Use for Hypertensive Emergencies

The need for gradual and tightly controlled BP reduction requires the use of short-acting intravenous drugs (see Table 37.1), the effects of which can be promptly reversed if the response is excessive. Previous systematic reviews and meta-analyses showed minor differences in the degree of BP lowering and no differences in morbidity or mortality among these agents, because of the relative paucity of large, randomized controlled trials (RCTs) with appropriate follow-up.[25,26] Thus treatment practices were mainly empiric. Recent evidence, however, suggests benefits of novel agents, a result expected to change clinical practice.

For several years, *sodium nitroprusside* was considered the first-choice drug for almost all hypertensive emergencies. It is easily titrated, is inexpensive, and has a long record of effectiveness.[8,12,27] It also has several drawbacks, including accumulation of toxic metabolites (thiocyanate and cyanide) when used for more than 48 hours, especially in patients with renal or hepatic dysfunction, and the need for invasive BP monitoring and an administration system that protects it from light. High-dose nitroprusside increases intracranial pressure. It also obliterates cerebral autoregulation and reduces regional coronary blood flow. These attributes of nitroprusside limit its usefulness in patients with neurologic complications or acute coronary syndromes.[9,16]

Clevidipine butyrate is a new, ultra-short-acting (within 1 to 2 minutes) third-generation CCB that acts through inhibition of extracellular calcium influx via the L-type channel and reduces peripheral vascular resistance without affecting venous vascular tone or cardiac filling pressure. Clevidipine is rapidly hydrolyzed by blood esterases, and thus its metabolism is not affected by renal or hepatic function.[9,16,28] In clinical studies, clevidipine was shown to be effective and safe in the control of perioperative hypertension and hypertensive emergencies.[28,29] The Evaluation of Clevidipine in the Perioperative Treatment of Hypertension Assessing Safety Events (ECLIPSE) report included three randomized trials with more than 1500 patients with perioperative acute hypertension and compared clevidipine, nitroglycerin, sodium nitroprusside, and nicardipine.[30] In this study, no difference was observed among clevidipine, nitroglycerin, or nicardipine in the primary end point of death, myocardial infarction, stroke, or renal dysfunction at 30 days, but clevidipine was more effective in maintaining BP within the prespecified target range and, most important, was associated with lower mortality than nitroprusside.[30] In view of these data, nitroprusside should be used in hypertensive emergencies only when no other intravenous antihypertensive drug is available.[7,16]

Nicardipine is a dihydropyridine CCB with intermediate onset and duration of effect, prolonged half-life, and strong cerebral and coronary vasodilatory activity. It is useful for most hypertensive emergencies, especially in patients with coronary artery disease. Nicardipine potentiates curare effects and interacts with inhalant anesthetics.[12,27] In an RCT of 226 patients with acute SBP of 180 mm Hg or higher, those receiving nicardipine reached physician-specified target range slightly more often (92% vs. 83%, $P = .039$) than those receiving labetalol.[31] In a subsequent post hoc multivariate analysis, treatment with labetalol (odds ratio [OR] 2.7, 95% confidence interval [CI] 1.1-6.7), history of stroke (OR 5.4, 95% CI 1.6-18.5), and being male (OR 3.3, 95% CI 1.4-8.1) were associated with failure to achieve target BP in this study.[32]

TABLE 37.1 Pharmacologic Agents for Treatment of Hypertensive Emergencies

Drug	Mechanism of Action	Dose	Onset of Action	Duration of Action	Adverse Effects*	Special Indications
Vasodilators						
Nicardipine hydrochloride	Calcium channel blocker	5-15 mg IV every hour	5-15 min	15-30 min, may exceed 4 hr	Tachycardia, headache, flushing, nausea, vomiting, local phlebitis	Most hypertensive emergencies except acute heart failure
Fenoldopam mesylate	Dopamine-1 receptor agonist	0.1-0.3 mcg/kg/min IV infusion	>5 min	30 min	Tachycardia, headache, nausea, flushing	Most hypertensive emergencies; caution with glaucoma
Clevidipine butyrate	Calcium channel blocker	1-2 mg/hr IV infusion; increase every 5-10 min up to 16 mg/h	2-4 min	5-15 min	Tachycardia, headache, flushing, heart failure deterioration	Most hypertensive emergencies; caution with severe aortic stenosis
Sodium nitroprusside	↑ Cyclic GMP, blocks intracellular Ca^{2+} increase	0.25-10 mcg/kg/min IV infusion†	Immediate	1-2 min	Nausea, vomiting, muscle twitching, thiocyanate and cyanide intoxication, impaired cerebral autoregulation, coronary steal syndrome	Caution in situations associated with CNS manifestations, hepatic or renal failure; probably should be avoided if given other agents, especially fenoldopam
Nitroglycerin	↑ Nitrate receptors	5-100 mcg/min IV infusion	2-5 min	5-10 min	Headache, vomiting, methemoglobinemia, tachyphylaxis, tolerance with prolonged use	Coronary ischemia, pulmonary edema
Enalaprilat	ACE inhibitor	1.25-5 mg every 6 hr IV	15-30 min	6-12 hr	Precipitous fall in BP in high-renin states, variable response, acute renal failure	Acute left ventricular failure; avoid in acute myocardial infarction
Isradipine	Calcium channel blocker	0.15 mcg/kg/min IV, increase by 0.0025 mcg/kg/min every 15 min. Maintenance infusion 0.15 mcg/kg/min	1-10 min	1-2 hr	Headache, flushing, peripheral edema, dizziness, tachycardia	Perioperative, pregnancy
Hydralazine hydrochloride	Opens K^+ channels	10-20 mg IV	10-20 min	1-4 hr	Tachycardia, flushing, headache, vomiting, aggravation of angina	Must be given with concomitant IV β-blockers to avoid precipitation of angina but *not* a preferred initial choice or treatment
Adrenergic Inhibitors						
Labetalol hydrochloride	α_1-, β-Blocker	20-80 mg IV bolus every 10 min *or* 0.5-2 mg/min IV infusion	5-10 min	3-6 hr	Nausea, vomiting, scalp tingling, bronchoconstriction, dizziness, heart block, heart failure	Most hypertensive emergencies except acute heart failure
Esmolol hydrochloride	β_1-Blocker	0.5-2 mg/min IV infusion *or* 250-500 mcg/kg/min IV bolus, then 50-100 mcg/kg/min by infusion; may repeat bolus after 5 min or increase infusion to 300 mcg/min	1-2 min	10-30 min	Nausea, asthma, first-degree heart block, heart failure, thrombophlebitis, COPD	Aortic dissection, perioperative, increased heart output or heart rate
Urapidil	α_1-Blocker, serotonin ($5\text{-}HT_{1A}$) receptor agonist	12.5-25 mg IV bolus followed by 5-40 mg/hr IV infusion	3-5 min	4-6 hr	Headache, dizziness	Perioperative
Phentolamine	α-Blocker	5-15 mg IV bolus	1-2 min	10-30 min	Tachycardia, flushing, headache	Catecholamine excess

*Hypotension may occur with all agents.
†Requires light-resistant delivery system.
ACE, Angiotensin-converting enzyme; *BP,* blood pressure; *CNS,* central nervous system; *COPD;* chronic obstructive pulmonary disease; *GMP,* guanosine monophosphate; *IV,* intravenous(ly).

TABLE 37.2 Management of Specific Types of Hypertensive Emergencies

Type of Emergency	First-Choice Drug(s)	Second-Choice or Additional Drug(s)	Drugs to Avoid	Aim of BP Reduction
Cardiac				
Coronary ischemia/ infarction	Nitroglycerin, nicardipine, clevidipine, labetalol	Sodium nitroprusside, esmolol if heart failure absent	Diazoxide, hydralazine	Improvement in cardiac perfusion
Heart failure, pulmonary edema	Nitroglycerin, fenoldopam, clevidipine	Sodium nitroprusside, enalaprilat; loop diuretics	Diazoxide, hydralazine; β-blockers	Decrease in afterload
Aortic dissection	Labetalol or combination of esmolol with sodium nitroprusside or fenoldopam or nicardipine		Diazoxide, hydralazine	Decrease of aortic wall stress with systolic BP reduction <100-120 mm Hg in 20 min (if possible)
Renal				
Acute glomerulonephritis, collagen vascular renal disease, or renal artery stenosis	Fenoldopam	Nicardipine, labetalol, clevidipine; diuretics for volume overload	Sodium nitroprusside; ACE inhibitors and ARBs	Reduction in vascular resistance and volume overload without compromise of renal blood flow or glomerular filtration rate
Scleroderma crisis	Enalaprilat or other ACE inhibitor	Angiotensin receptor blocker, fenoldopam	Corticosteroids,* diuretics	Decrease in BP to <140/90 mm Hg with long-term goal of <130/85
Neurologic				
Hypertensive encephalopathy	Nicardipine, fenoldopam, labetalol, clevidipine	Nitroprusside, esmolol, urapidil		20%-25% reduction in mean BP over 1-2 hr
Ischemic stroke	Nicardipine, labetalol, clevidipine	Nitroprusside, nimodipine, esmolol, urapidil		Reduction of BP if above 220/120 mm Hg (mean BP >130) by no more than 10%-15% within first 24 hr to avoid impairing cerebral blood flow in penumbra
Intracerebral hemorrhage	Nicardipine, labetalol, clevidipine	Fenoldopam, nitroprusside, esmolol, urapidil, nimodipine for subarachnoid hemorrhage		For patients presenting with SBP 150-220 mm Hg and without contraindication to acute BP treatment, decrease SBP to 140 mm Hg, as it is safe and can improve functional outcome. For patients presenting with SBP >220 mm Hg, it may be reasonable to consider aggressive reduction of BP with a continuous intravenous infusion and frequent BP monitoring. For subarachnoid hemorrhage in normotensive patients, reduction to systolic BP of 130-160 mm Hg
Catecholamine Excess States				
Pheochromocytoma	Phentolamine or labetalol	β-Blocker in the presence of phentolamine, sodium nitroprusside	Diuretics, β-blockers alone	Control of BP paroxysms from sympathetic stimulation
Ingestion of cocaine or other sympathomimetic	Phentolamine or labetalol	β-Blocker in the presence of phentolamine, sodium nitroprusside	Diuretics	Control of BP paroxysms from sympathetic stimulation
Perioperative/Postoperative Hypertension				
Coronary artery surgery	Nitroglycerin, nicardipine, clevidipine	Esmolol, labetalol, fenoldopam, isradipine, urapidil		Protection against target organ damage and surgical complications (keep BP <140/90 or mean BP <105 mm Hg)
Non-cardiac surgery	Esmolol, labetalol, fenoldopam, nicardipine, clevidipine, urapidil, nitroglycerin			Protection against target organ damage and surgical complications

Continued

TABLE 37.2 Management of Specific Types of Hypertensive Emergencies—cont'd

Type of Emergency	First-Choice Drug(s)	Second-Choice or Additional Drug(s)	Drugs to Avoid	Aim of BP Reduction
Pregnancy Related				
Eclampsia	Labetalol, urapidil	Nifedipine isradipine, nicardipine, $MgSO_4$, methyldopa, hydralazine	Nitroprusside, ACE inhibitors, ARBs	Control BP (typically <90 mm Hg diastolic but often lower) and protect placental blood flow

*Corticosteroids may worsen hypertension in scleroderma renal crisis.
ACE, Angiotensin-converting enzyme; *ARBs,* angiotensin receptor blockers; *BP,* Blood pressure; *SBP,* systolic blood pressure.

Fenoldopam mesylate is a selective agonist of dopaminergic 1 receptors located mainly in the renal and splanchnic arteries, with lesser density in the coronary and cerebral arteries.[9,12,27] Intravenous fenoldopam does not cross the blood-brain barrier and has no central nervous system activity because it is a poorly lipid-soluble molecule. In clinical studies, compared with sodium nitroprusside, fenoldopam demonstrated similar BP-lowering efficacy and beneficial renal effects (increased diuresis, natriuresis, creatinine clearance).[33] Thus fenoldopam is mostly useful for BP reduction in patients with renal impairment, those with heart failure, and those undergoing vascular surgery. Fenoldopam must be administered with caution, if at all, to patients with glaucoma because it increases intraocular pressures.[12,27]

Labetalol is a nonselective α_1- and β-blocker (in 1:7 ratio) given intravenously that can be used in many hypertensive emergencies because it has rapid onset of action, potent and sustained effect, and low toxicity. Labetalol reduces peripheral vascular resistance without a reflex increase in systolic volume, while cerebral, renal, and coronary blood flow is maintained. Its main indications are aortic dissection, acute coronary syndromes, hypertensive encephalopathy, and adrenergic crisis. Labetalol can be used in pregnancy-induced hypertensive crisis because little placental transfer occurs as a result of its negligible lipid solubility.[8,9,16] *Esmolol* is a β_1-blocker with an immediate onset and a short duration of action, whose metabolism is not dependent on renal or hepatic function. Esmolol is used particularly in patients with severe postoperative hypertension, and it can be useful in those with increased cardiac output and heart rate.[9,27] Labetalol may be used in chronic obstructive pulmonary disease if the patient has no history of an asthmatic component.[34]

Table 37.1 provides pharmacologic characteristics and adverse effects of other agents that have been used in the treatment of hypertensive emergencies. Table 37.2 includes a general guide for use of these drugs according to the type of hypertensive emergency.[7,11]

Treatment of Hypertensive Urgencies

Although hypertensive urgencies are particularly common, quality studies on the value of extensive diagnostic testing for target-organ damage, the need of hospitalization, the type of treatment and the optimal follow-up in asymptomatic patients with BP elevation are clearly missing.[10] A recent retrospective cohort study with propensity matching that included all patients presenting with hypertensive urgency (BP >180/110) to an office in a large health care system in the United States showed that patients sent home compared with those sent to the ED had an equally low risk for major CV events (0.9%) and equal chance to have uncontrolled hypertension (65% vs. 67%) at 6 months.[35]

Because there is no proven benefit from rapid BP reduction in asymptomatic patients without evidence of acute target organ damage, most agree that BP lowering should occur over a longer time than for a hypertensive emergency. BP reduction to levels below 160/100 mm Hg may be accomplished within 2 to 4 hours in the ED with the oral drugs described later. This may be particularly important for patients without ongoing target-organ damage, who are judged to be at high risk for CV events over the next days because of severe hypertension (e.g., those with known history of aortic aneurysm, repeated pulmonary edema, etc.). However, there are many different types of patients who may present as a hypertensive urgency, the most common of which is the hypertensive patient with low compliance and chronically elevated BP levels. Thus less aggressive lowering of BP (over several hours to days) is also proposed by some, using strategies such as resumption of antihypertensive therapy (in nonadherent patients), initiation of antihypertensive therapy with long-acting agents (if patients are treatment naive), and treatment modification or addition of another antihypertensive drug (in patients who are currently treated). In short, the most important aspect of treatment of hypertensive urgency is not achieving a BP goal but rather ensuring adequate follow-up, generally within 1 week, to an appropriate site of care for chronic hypertension to optimize care and improve BP control of uncontrolled hypertensive patients.[8,9,12] There are data, however, suggesting that most of these patients do not receive medications or instructions in the ED as traditionally described in the literature and providers overestimate how often they refer patients for follow-up, resulting in questionable improvement in long-term outpatient BP control.[10]

Patients with hypertensive urgency should be provided a quiet room in which to rest because this maneuver was associated with BP fall of 20/10 mm Hg or greater in one third of such patients.[36]

Another major factor to consider before prescribing medication is assessment of pain. Patients with severe pain not secondary to cardiac or cerebral origin should be given analgesics first to improve pain. If such patients present with hypertensive urgency and are given acute-acting medications such as clonidine or labetalol, they could become hypotensive once pain is alleviated with nonsteroidal agents, opioids, or steroids.

The choice of drugs for treatment of hypertensive urgencies is much broader than for emergencies, because almost all antihypertensives lower BP effectively given sufficient time. Captopril, clonidine, labetalol, and other short-acting drugs have been used most often (Table 37.3).[8,9] A careful history to assess chronic antihypertensive treatment and patient adherence to medication is critical for drug and dose selection, and clinical surveillance is always advisable during the first few hours after drug administration. In an acute situation, if uncertain whether the patient may have a pheochromocytoma, it is advisable to avoid β-blockers because they can increase BP. This includes labetalol because its α-blocking effect is very small. An α-blocker such as doxazosin or prazosin should always be a first-line drug in these patients.

Oral captopril is typically given in a 12.5- to 25-mg dose; angiotensin-converting enzyme (ACE) inhibitors must be used with caution because they can cause or exacerbate renal impairment in the occasional patient

TABLE 37.3 Pharmacologic Agents for Treatment of Hypertensive Urgencies

Drug	Mechanism of Action	Dose	Onset of Action	Duration of Action	Adverse Effects
Captopril	ACE inhibitor	12.5-25 mg PO every 1-2 hr	15-30 min	4-6 hr	Angioedema, cough, acute renal failure
Clonidine	Central α_2-agonist	0.1-0.2 mg PO every 1-2 hr	30-60 min	6-8 hr	Sedation, dry mouth, bradycardia, rebound hypertension after withdrawal
Labetalol	α_1-, β-Blocker	200-400 mg PO every 2-3 hr	30-120 min	6-8 hr	Bronchoconstriction, heart block, congestive heart failure
Furosemide	Loop diuretic	20-40 mg PO every 2-3 hr	30-60 min	8-12 hr	Volume depletion, hyponatremia, hypokalemia
Isradipine	Calcium channel blocker	5-10 mg PO every 4-6 hr	30-90 min	8-16 hr	Headache, tachycardia, flushing, peripheral edema

PO, Taken orally.
Shown are short-acting agents commonly used in the emergency room setting. However, as noted in the text, sometimes longer-acting drugs can be used.

with critical renal artery stenosis.[3,8] A recent study suggested that sublingual captopril had a more pronounced BP lowering effect than oral captopril at 10 and 30 minutes, but similar at 60 minutes after dosing.[37] Oral clonidine, 0.1 to 0.2 mg, is one of the most common agents used in this setting. However, patients should not be discharged on clonidine if they have a history of nonadherence to drug regimens, because of the risk for rebound hypertension if clonidine is abruptly stopped. Furosemide also can effectively lower BP if elevated pressure is related to volume overload, especially if renal dysfunction is present. However, a common physiologic response of the kidney to elevated BP is natriuresis, so many patients, especially those with normal renal function, are volume depleted rather than volume expanded.[8,9] Further, furosemide is not considered a drug choice for primary hypertension because of its short duration of action.

Sublingual short-acting nifedipine, although once frequently used, is now contraindicated secondary to a higher incidence of stroke, myocardial infarction, and death related to precipitous hypotensive episodes after ED release.[22] However, intermediate-acting dihydropyridine CCBs, such as intravenous nicardipine, may be used. A possible exception to this rule is pregnant patients with acute BP elevations, in whom oral nifedipine was shown in randomized studies to reduce BP faster than intravenous labetalol and without safety concerns.[38] Longer acting CCBs, such as once-daily nifedipine or nifedipine XL, amlodipine, and sustained-release isradipine, do not have a role in reducing BP in the ED. However, these and long-acting agents from other major antihypertensive classes are valuable tools for long-term BP control, which, as mentioned previously is the most important aspect of management in these patients.

SELF-ASSESSMENT QUESTIONS

1. A patient being evaluated for a routine history and physical is noted to have a blood pressure (BP) of 220/130 mm Hg. He states he feels fine except for nightly reflux. Examination shows fundi with atrioventricular nipping and normal heart sounds. Chest x-ray film is normal; serum creatinine 1.3 mg/dl and urinalysis show rare RBCs. Management should include which of the following?
   - **A.** Immediate hospitalization to intensive care unit with administration of intravenous labetalol
   - **B.** Stat electrocardiogram, cardiac enzymes, and admission to the cardiac care unit
   - **C.** Start oral isradipine 5 mg, let the patient rest in a quiet room, and observe for some hours.
   - **D.** Perform a full workup for secondary causes with plasma metanephrines and catecholamines and aldosterone-renin ratio. Start clonidine, 0.4 mg twice daily
2. A patient presents with an acute hemorrhagic stroke and has a BP of 180/120 mm Hg. You are asked to consult on the patient. Which of the following is the *best* strategy?
   - **A.** Give hydralazine (10 mg IV) to bring the BP down as rapidly as possible.
   - **B.** Initiate nitroprusside therapy and titrate BP down to 140/90 mm Hg over a 1-hour period.
   - **C.** Start nicardipine infusion and reduce BP to 160/90 mm Hg within an hour.
   - **D.** Do not treat the hypertension because it may worsen the stroke.
3. A patient presents with acute chest pain. On examination, BP in the right arm is 190/120 mm Hg but in the left arm is only 160/90 mm Hg. The chest x-ray film shows a widened mediastinum. What is the best initial treatment to lower the BP?
   - **A.** Start a nitroprusside infusion, targeting BP of 140/90 mm Hg in the right arm.
   - **B.** Start a labetalol infusion, targeting blood pressure of 100 mm Hg systolic in the right arm.
   - **C.** Start an esmolol infusion, targeting BP of 120 mm Hg systolic in the left arm.
   - **D.** Do not treat the BP because it is important to preserve cerebral perfusion.

Endocrine Causes of Hypertension
Aldosterone

I. David Weiner, Charles S. Wingo

Recent advances in the diagnosis of aldosterone-induced hypertension have led to the recognition that primary aldosteronism is more common than previously thought. Effective diagnostic strategies are available, and treatment regimens are highly efficacious.

ETIOLOGY AND PATHOGENESIS

Aldosterone is a steroid hormone normally produced by the zona glomerulosa of the adrenal glands (Fig. 38.1). Aldosterone synthase, which is encoded by the gene *CYP11B2,* is the generally accepted rate-limiting enzyme in adrenal aldosterone production. Table 38.1 summarizes factors known to stimulate or inhibit aldosterone synthesis. There is circadian variation in serum aldosterone concentrations, greatest in the late morning with peak values about 50% greater than the average concentration. The physiologically most important regulators of aldosterone production include angiotensin II (Ang II), which stimulates aldosterone production through activation of the AT1 receptor, atrial natriuretic peptide (ANP), which is inhibitory, and extracellular potassium concentration (hyperkalemia is stimulatory and hypokalemia is inhibitory).[1,2] A high-salt diet, particularly in the presence of chronic kidney disease (CKD), can suppress aldosterone production; this likely occurs through changes in ANP and renin-dependent Ang II production.

Pathogenesis of Aldosterone-Dependent Hypertension

Aldosterone increases blood pressure (BP) through several mechanisms involving effects on the kidneys, vasculature, central and peripheral nervous system (CNS), and other endocrine hormones (Fig. 38.2). These multiple effects explain why primary aldosteronism can cause refractory hypertension.

First, aldosterone stimulates renal sodium chloride (NaCl) retention by increasing expression of the amiloride-sensitive epithelial sodium channel (ENaC), in the collecting duct, and the chloride-reabsorbing protein, pendrin, in the cortical collecting duct.[3-5] Aldosterone also can acutely stimulate sodium reabsorption in these segments through nongenomic mechanisms.[6] Aldosterone also stimulates NCC, the sodium-chloride cotransporter that is present in the distal convoluted tubule (4). Together, these effects on multiple Na^+ and Cl^- transporters lead to NaCl retention, intravascular volume expansion, and volume-dependent hypertension.

Second, aldosterone alters BP through generation of hypokalemia. Aldosterone increases extrarenal cellular potassium uptake by stimulating the ubiquitous Na^+,K^+-ATPase. As discussed in Chapter 9, potassium depletion raises BP through a variety of mechanisms, including expression of the of the thiazide-sensitive NaCl cotransporter in the distal convoluted tubule, induction of renal interstitial injury, and direct vascular effects.

Third, aldosterone has multiple effects on the vasculature. Aldosterone increases both basal vascular tone and vascular reactivity to circulating vasoconstrictors, including norepinephrine, epinephrine, Ang II, and vasopressin.[7] Aldosterone decreases flow-mediated vasodilation, possibly by decreased nitric oxide (NO) production resulting from decreased endothelial NO synthase expression.[8] In the CNS, aldosterone stimulates CNS-mediated sympathetic nervous tone, which further increases BP.[9] Finally, aldosterone causes perivascular fibrosis and stimulates vascular endothelin expression.[10]

Aldosterone mediates its physiologic and pathophysiologic effects predominantly by activating the mineralocorticoid receptor (MR).[11] The MR is located in the inactive state in the cytoplasm in selectively aldosterone-responsive tissue; aldosterone binding to MR promotes a conformational change and translocation to the nucleus, where it regulates gene transcription.

Other Hormones That Can Cause Hypertension Through Mineralocorticoid Receptor Activation

Cortisol is a naturally synthesized glucocorticoid with an affinity for MR similar to that of aldosterone, but is present in plasma at levels about 100-fold greater than aldosterone. The enzyme 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2) is expressed in the aldosterone-sensitive distal nephron and collecting duct and metabolizes cortisol to cortisone, which does not effectively bind to MR, thereby preventing glucocorticoid-dependent MR activation. Either the genetic deficiency of 11β-HSD or the ingestion of inhibitors of this enzyme can result in excessive activation of the MR and development of severe hypertension (see Chapter 47).[12] Aldosterone also has nongenomic effects, but their role in mineralocorticoid-dependent BP regulation remains unclear.[13]

Types of Primary Aldosteronism

Primary aldosteronism can result either from an aldosterone-producing adenoma (APA) or from hyperplasia of the zona glomerulosa (Fig. 38.3). Typically, unilateral disease results from adenoma and bilateral disease from hyperplasia. This association is not absolute, and about 10% of patients with primary aldosteronism have either bilateral APA, which may be microscopic, or unilateral hyperplasia. In general, an APA causes more severe primary aldosteronism than does adrenal hyperplasia, but this association is not sufficiently strong to solely guide clinical decision making.

Most APAs are unilateral and are large enough (≥1 cm) to be identified by computed tomography (CT) (Fig. 38.4). However, APAs also may be microscopic and may be bilateral. Hyperplasia is typically bilateral but occasionally is unilateral, and it may develop asynchronously in the two adrenal glands. Because unilateral adrenal hyperplasia is potentially curable with adrenalectomy, the absence of an identifiable adrenal

*Acutely, only.
Both extracellular potassium and numerous hormones exert significant effects on aldosterone release. The primary effectors under most clinical circumstances are angiotensin II, potassium, and adrenocorticotropic hormone, and are noted in italics.

adenoma on CT or magnetic resonance imaging does not exclude the possibility of surgically treatable primary aldosteronism.

Familial Forms of Primary Aldosteronism

Multiple familial forms of primary aldosteronism have been identified. In some cases, the clinical presentation suggests the presence of a familial etiology, and in some the presentation is indistinguishable from sporadic forms. With the exception of familial hyperaldosteronism type 1, identification of these familial forms, beyond allowing specific genetic testing of family members of affected individuals, does not alter treatment decisions at this time,

Familial Hypertension Type I

The first identified was *familial hypertension type I* (FH-I), which also is known as *glucocorticoid-remediable aldosteronism* (GRA). In FH-I there is crossover between the *CYP11B1* and *CYP11B2* genes, resulting in a chimeric aldosterone synthase gene, whose expression is regulated by adrenocorticotropic hormone (ACTH), leading to excessive aldosterone release.[14,15] FH-I is transmitted in an autosomal dominant pattern and should be considered in children or young adults with refractory hypertension or in whom there is a family history of hypertension at a young age or history of premature hemorrhagic stroke.[16] If a genetic cause is suspected, genetic testing is the preferred diagnostic approach because of improved sensitivity and specificity over measurement of steroid metabolites or dexamethasone suppression testing.[16] When FH-I is identified, administering corticosteroids at the lowest dose necessary to suppress ACTH release often dramatically improves BP control (see Chapter 47).

Familial Hyperaldosteronism Type II

The clinical presentation of FH-II does not differ from that observed with sporadic forms of primary aldosteronism.[17] Genetic studies have not identified any causative mutations. At present, FH-II is identified by its autosomal dominant clinical presentation and absence of mutations in *CYP11B2, KCNJ5,* or *CACNA1H,* the genes responsible for other familial hyperaldosteronism syndromes.

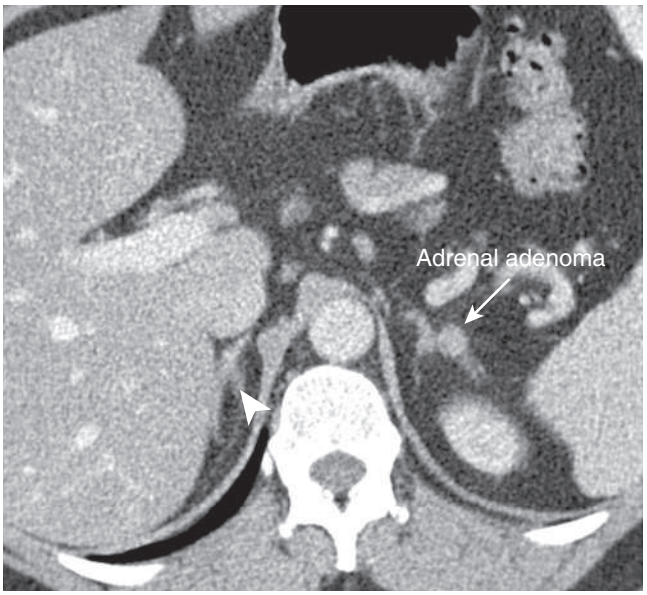

Fig. 38.4 Adrenal adenoma by computed tomography scan. A normal linear image of the right adrenal gland *(white arrowhead)* and expansion of the left adrenal with aldosterone-producing adenoma (~1 cm) *(white arrow).*

Familial Hyperaldosteronism Type III

FH-III was first reported in 2008.[18] Although initial studies characterized FH-III as having a severe, often childhood onset of hypertension, subsequent studies suggest the presentation is more variable.[17] FH-III is the result of germline mutations in the *KCNJ5* gene.[19,20] The *KCNJ5* gene encodes a K^+ channel that is a major determinant of adrenal cortical cell membrane voltage. Mutations observed in FH-III result in loss of K^+ selectivity, leading to Na^+ influx, and membrane depolarization. Consequently, there is voltage-gated Ca^{2+} channel activation, increased cytosolic calcium, and stimulation of aldosterone production and adrenal cell proliferation.

Familial Hyperaldosteronism Type IV

FH-IV is the most recently identified genetic form of primary aldosteronism and generally presents with hypertension and primary aldosteronism before 10 years of age.[21] FH-IV appears to result from mutations in the *CACNA1H* gene, which encodes for a T-type calcium channel ($Ca_V3.2$). These mutations appear to lead to increased Ca^{+2} entry, increased cytosolic calcium, and stimulation of aldosterone production and adrenal cell proliferation. Clinical penetrance of the mutation is incomplete.

Sporadic Forms

Substantial advances have been made recently in our understanding of the factors that lead to sporadic forms of primary aldosteronism. In particular, mutations in the potassium channel gene *KCNJ5* are now recognized as a frequent cause of primary aldosteronism. Somatic mutations are present in about 40% of aldosterone-producing adenomas and may occur in as many as 65% to 80% in certain regions, such as China, Taiwan, and Japan.[19,22] Somatic mutations in the genes *ATP1A1* (encoding the α-subunit of Na^+,K^+-ATPase), *ATP2B3* (encoding a Ca^{2+}-ATPase), and *CACNA1D* (encoding a voltage-gated calcium channel subunit) also have been identified in about 7% of APAs.[17,23] These mutations increase intracellular calcium in adrenal cortical cells, and the increased intracellular calcium is believed to initiate the development of hyperplasia, lead to adenoma formation, and increase expression of the specific genes involved in aldosterone synthesis. Each of these mutations appears to alter intracellular calcium regulation, leading to stimulation of aldosterone production.

Recent advances also have been made in understanding the pathogenesis of primary aldosteronism from bilateral adrenal hyperplasia. Activating autoantibodies directed against the Ang II type I (ATI) receptor may activate the ATI receptor, both directly stimulating adrenal aldosterone secretion and contributing to the hypertension through an aldosterone-independent mechanism involving ATI receptor activation in vascular tissue.[24,25] To date, the presence of these antibodies has been examined in only a limited number of patients. Additional studies are needed to examine how widespread this mechanism is found and what proportion of cases of bilateral adrenal hyperplasia results from this mechanism.

EPIDEMIOLOGY

The apparent incidence of primary aldosteronism varies with the patient population and the diagnostic criteria used. Early studies, which recognized only severe cases, suggested that primary aldosteronism was rare, with an incidence less than 1% to 2%. More accurate diagnosis has now led to the recognition that primary aldosteronism is relatively common. Patients with treatment-resistant hypertension—inadequately controlled hypertension despite treatment with three medications at appropriate dosages, including a diuretic—are highly likely to have primary aldosteronism, with rates typically of 20% to 40% and as high as 67% in some studies (Fig. 38.5).[26]

CLINICAL MANIFESTATIONS

Identifying patients with primary aldosteronism purely on clinical characteristics is difficult. Some patients with primary aldosteronism have features suggestive of secondary hypertension, such as early onset of hypertension or the need for multiple drugs for BP control. Others present with either frank or easily provoked hypokalemia. But many have no distinguishing characteristics that differentiate them from individuals with essential hypertension. The incidence of primary aldosteronism in a hypertensive population parallels the severity of hypertension, although 1% to 2% of those with primary aldosteronism are normotensive (see Fig. 38.5).[27] Table 38.2 summarizes characteristics of those with primary aldosteronism.[28]

Because of this wide variety of presentations, we recommend testing all patients who have characteristics of secondary hypertension, have baseline or easily provoked hypokalemia, or have hypertension not effectively controlled with routine antihypertensive therapy for primary aldosteronism. It is important to recognize that both hypokalemia and metabolic alkalosis are no longer considered hallmarks of primary aldosteronism and are absent in the majority of patients.

Primary aldosteronism also causes adverse effects that are independent of hypertension and hypokalemia. Untreated primary aldosteronism causes cardiovascular events at rates greater than attributable solely to the hypertension. This includes an increased risk for cardiac arrhythmias, both atrial and ventricular, cerebrovascular events, and coronary heart disease.[29] Diagnosing and treating the primary aldosteronism, whether with adrenalectomy or with MR blockers, as clinically appropriate, substantially reduces, and may even fully correct, this increased risk.[29] Finally, primary aldosteronism is associated with a variety of neuropsychiatric disorders, ranging from depression and anxiety to lethargy, fatigue, and difficulties with concentration. Appropriate treatment of the primary aldosteronism appears to reverse these symptoms.[17]

Incidence of Primary Hyperaldosteronism in Patients with Differing Degrees of Hypertension

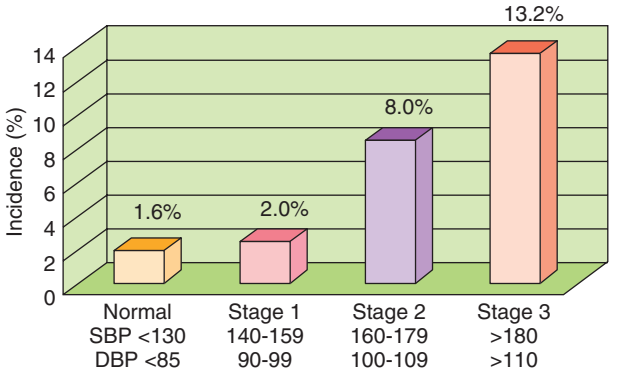

Fig. 38.5 Incidence of primary aldosteronism in patients with differing degrees of hypertension. *DBP,* diastolic blood pressure; *SBP,* Systolic blood pressure. (From reference 27.)

TABLE 38.2 Typical Characteristics of Patients at Diagnosis of Primary Aldosteronism

Patient Factor	Measured Value
Gender (female/male)	43 : 57 (%)
Age (yr)	52 ± 1 (range 29-74)
Hypertension duration (yr)	10 ± 1
Number of hypertensive medications	2.4 ± 0.1 (range 0-4)
Percentage requiring three or more medications	54%
Blood pressure controlled with current medical regimen	20%
Neither hypokalemic nor receiving three or more medications	52%
Plasma aldosterone (ng/dl)	
<15	37%
15-40	54%
>40	9%
Plasma renin activity (ng Ang I/ml/h)	0.39 ± 0.04

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Who to Screen for Primary Aldosteronism

We recommend that screening for primary aldosteronism should be performed in several groups of patients. The first is the patient with refractory hypertension. The incidence of primary aldosteronism is increased in patients with hypertension and increases with increasing severity of hypertension. The second is the patient with spontaneous or easily provoked hypokalemia. Hypokalemia has significant long-term adverse effects, and identification and treatment of the underlying cause is beneficial. Finally, the patient found to have an adrenal adenoma on abdominal imaging should be considered for screening if under the age of 40 years, where the incidence of a nonfunctional adrenal adenoma is low. In the patient older 40 years, we recommend screening for primary aldosteronism if hypertension requiring therapy with multiple medications is present.

The question as to whether to screen patients with refractory hypertension at all for primary aldosteronism before initiating therapy with MR blockers is not a simple one. MR blockers, when used for the treatment of refractory hypertension, improve BP to a similar extent in those who do and those who do not have primary aldosteronism.[30] Thus screening is not needed to determine whether MR blocker therapy will be effective treatment of the hypertension. We recommend screening for primary aldosteronism before initiating MR blocker therapy because significant diagnostic problems occur if a patient treated with an MR blocker who was not screened for primary aldosteronism is found at a later time to have an adrenal adenoma. Determining whether this is an APA or a nonfunctional adenoma is very difficult in this case because MR blocker treatment can cause false-negative screening test results for primary aldosteronism. If withholding an MR blocker, the length of time it should be withheld to enable effective serologic screening has not been determined; we recommend holding therapy for at least 2 weeks, and preferably 4 weeks. Otherwise, the only way to differentiate a nonfunctional adenoma from an APA is through adrenal vein sampling, with the risks and significant costs associated with this procedure. Accordingly, we recommend screening for primary aldosteronism before initiating antihypertensive therapy with MR blockers. If the screening result is negative, MR blocker therapy should still be used, but there is no need to evaluate for an APA should an adrenal adenoma be identified at a later time.

Evaluation of Suspected Primary Aldosteronism

Evaluation of patients with suspected primary aldosteronism is directed at (1) identifying those who have autonomous aldosterone release and then (2) determining whether treatment should be based on a medical or a surgical approach (Fig. 38.6).

Use of the Aldosterone-Renin Ratio (ARR)

Evidence of Ang II–independent aldosterone release is used to indicate autonomous aldosterone release and therefore primary aldosteronism. Because Ang II cannot be assayed by routine clinical tests, renin is used as a surrogate. A random blood sample is used to measure the ratio of plasma aldosterone to renin (ARR). This sample should be obtained in early morning because of diurnal variations in plasma aldosterone and plasma renin activity. The question as to whether to hold medications that can alter the renin-angiotensin-aldosterone system (RAAS) and, if so, for how long before testing is complex and is discussed in detail later. If the ARR is elevated, this suggests that there is significant Ang II–independent aldosterone release, providing presumptive evidence of autonomous aldosterone production consistent with primary aldosteronism.

Currently, two types of renin assays are in routine clinical use. One measures renin activity, assayed as the rate of conversion of angiotensinogen to Ang I, and the second measures the amount of immunoreactive renin. These two techniques yield results that correlate well with each other, but the units and numerical values obtained differ. For the plasma renin activity, the normal range is 1.9 to 3.7 ng Ang I/ml/h, and the lower level of detectability is 0.1 ng Ang I/ml/h in most clinical laboratories. For the direct renin assay, the normal range is typically 13 to 44 IU/ml and lower level of detectability is 6 to 8 IU/ml. Therefore the typical ARR, for a patient with primary hypertension not receiving drugs that alter the renin-angiotensin system (RAS), is about 10 : 1 when using the plasma renin activity and 1 : 1 with the direct renin assay.

Although an elevated aldosterone value in combination with an elevated ARR strongly suggests primary aldosteronism, an elevated ARR can occur even with suppressed plasma aldosterone production if plasma renin activity (or concentration) is substantially suppressed. In this event, the ARR represents a false-positive screening result. We recommend that the combination of an elevated ARR and a "nonsuppressed" aldosterone level should be used for case-screening for primary aldosteronism. The minimal plasma aldosterone level that may be associated with aldosteronism is unclear. We recommend using a minimal value of 8 ng/dl to make a diagnosis of primary aldosteronism.[31] Others recommend using a cut-off of 15 or even 20 ng/dl.[32,33] We recommend the lower cut-off because about 40% of patients with primary aldosteronism have plasma aldosterone levels between 9 and 16 ng/dl,[27,34] and about 20% of those with unilateral autonomous adrenal aldosterone production have levels less than 15 ng/dl.[34]

Effect of Drugs on Screening for Primary Aldosteronism

Many medicines commonly used for the treatment of hypertension can alter either plasma aldosterone or renin release and thereby alter the ARR.[33,35] β-Adrenergic receptor antagonists (β-blockers) suppress renin release, typically by about 50%. However, β-blockers generally will not result in complete renin suppression that is typically seen in primary aldosteronism.[35] Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs), along with diuretics, can increase renin release in normal individuals, which theoretically might decrease the sensitivity of ARR measurement. However, the effect of ACE inhibitors and ARBs to increase renin release also can be an advantage. In patients using either an ACE inhibitor or an ARB, suppressed renin in combination with nonsuppressed aldosterone (>8 ng/dl) is highly specific for primary aldosteronism. MR antagonists such as spironolactone and eplerenone can elevate the plasma renin activity and impair the sensitivity of testing. Direct renin inhibitors have been reported to both increase and decrease plasma renin activity in patients who presumably have essential hypertension and decrease plasma aldosterone. Their effect on plasma renin activity and ARR in patients with primary aldosteronism is not known.

When to Withold Drugs That Affect the Renin-Angiotensin-Aldosterone System Before Screening

The decision whether to discontinue drugs that directly interact with the RAAS requires the clinician to balance competing priorities. Doing so can improve the diagnostic accuracy of measurement of aldosterone and plasma renal activity. However, in the patient with poorly controlled hypertension, discontinuing all diuretics, β-blockers, ACE inhibitors, ARBs, and direct renin inhibitors and attempting to control the BP solely with calcium channel blockers (CCBs), α-adrenergic blockers, and direct vasodilators can be problematic because of the risk for worsening already poor BP control. Moreover, the amount of time drugs should be discontinued to completely reverse all of their effects on the adrenal gland is not clear. Acute effects of these drugs will be reversed

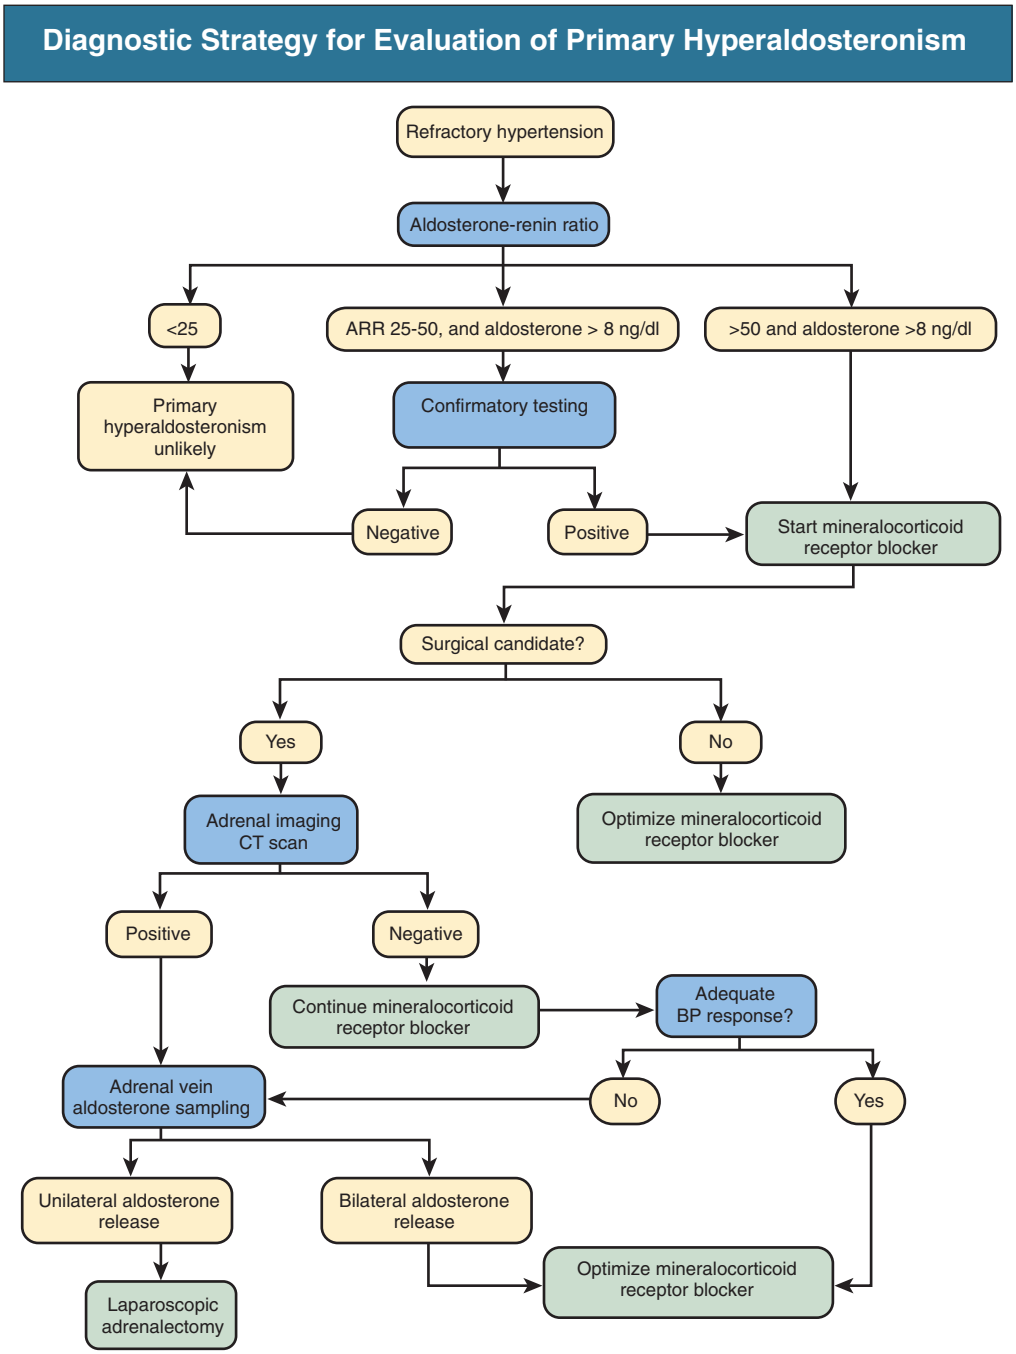

Fig. 38.6 Diagnostic strategy for evaluation of primary aldosteronism. Aldosterone-renin ratio *(ARR)* is calculated using measurement of plasma renin activity. If direct renin immunoassay is used, the resulting ARR calculation should be multiplied by 10 for use with this diagnostic algorithm. *BP,* Blood pressure; *CT,* computed tomography.

once they are fully metabolized. However, chronic effects that involve AT1 receptor–mediated changes in expression of proteins involved in aldosterone synthesis may be more long-lasting. Finally, requiring discontinuation of these drugs for at least several days, and optimally several weeks, before testing substantially complicates the use of ARR as an easy screening test in patients who may be at only modest risk for primary aldosteronism.

Our practice as to whether to withhold drugs before testing depends on clinical situation. For patients evaluated because of refractory hypertension, we think the time, expense, and risks for more severe hypertension associated with discontinuation of all drugs that can affect the RAS and treatment of the refractory hypertension solely with CCBs, direct vasodilators, and α-blockers, is significant, and that the risk may exceed the benefit of eliminating concern regarding these drugs on the ARR. Indeed, in this population, whether the patient has primary aldosteronism does not predict whether MR blockers will improve BP control; patients with refractory hypertension regardless of whether they have primary aldosteronism respond equally well treatment to MR blockers. The diagnosis of primary aldosteronism is important primarily to direct decisions regarding whether to evaluate further for a potentially

surgically curable APA. Because an APA is typically associated with more severe primary aldosteronism, the risk for false-negative testing if medications are not held may be less.

In patients being evaluated because they have an adrenal adenoma and who have minimal clinical symptoms related to possible primary aldosteronism, that is, do not have resistant hypertension and who do not have substantial hypokalemia, our approach is different. In this patient population, we think discontinuation of medications that alter the renin-angiotensin-aldosterone pathway and substitution with CCBs and direct vasodilators, as needed for BP control, is appropriate. In this latter group, the clinical difficulty and risks to the patient from making this medication change is much less substantial.

Confirmatory Testing

If the diagnosis of primary aldosteronism is in doubt, several confirmatory tests can be used. Table 38.3 summarizes the various confirmatory testing methods in routine use. Both the risks and the benefits of confirmatory testing must be considered.[31] None of the confirmatory tests has 100% sensitivity or specificity. Moreover, confirmatory testing has complicating issues associated with its performance. Salt loading, if used for testing, can raise BP and worsen hypokalemia and is problematic in the patient who already has poorly controlled hypertension. Testing requires the patient to not use any medications that interact with the RAAS, which means discontinuation of β-blockers, ACE inhibitors, ARBs, MR blockers, direct renin inhibitors, and diuretics, and this can lead to significant worsening of hypertension control.[31] How long these medications should be held is not clear. Acute effects will dissipate within days as the medications are metabolized, but chronic effects on expression of proteins involved in adrenal aldosterone metabolism may persist longer.

We recommend that confirmatory testing should be used if it will substantially alter management. Patients with resistant hypertension respond well to MR antagonists with significant BP improvement even if they do not have primary aldosteronism.[36,37] Because of this, we do not routinely perform confirmatory testing before initiating treatment with MR blockers in this population. We reserve confirmatory tests for patients with an adrenal adenoma found for unrelated reasons who have minimal clinical symptoms and are being evaluated for possible adrenalectomy. In this latter patient population, the benefits of MR blocker therapy are less clear and the clinical risks associated with holding RAS blockers, discussed earlier, are substantially less. Accordingly, we believe that confirmatory testing before adrenal vein sampling procedure and possible adrenalectomy is appropriate.

Differentiation of Etiology

Selection of Patients for Further Testing

Once primary aldosteronism is diagnosed, the clinician should determine whether there is primarily unilateral aldosterone release, in which case adrenalectomy may be curative. However, this step is important only if the patient is both an appropriate surgical candidate and desires possible surgical intervention. If either condition is not met, further evaluation is not necessary, and the patient can be treated with MR blocker therapy.

Imaging Approaches

Primary aldosteronism most commonly results either from an APA, which is typically unilateral, or from hyperplasia of the zona glomerulosa, which is typically bilateral (see Fig. 38.3). Most APAs are large enough (>1 cm) to be identified by CT (see Fig. 38.4). Adrenal hyperplasia, as a cause of primary aldosteronism, is not detectable with current CT or MR imaging techniques. It is important when imaging for a possible APA to use CT or MR imaging with distances of only 1 to 3 mm between slices. Conventional abdominal CT imaging, which often uses 10-mm slices, can miss small adrenal adenomas. However, the presence or absence of an adrenal adenoma should not be equated with the presence or absence of unilateral or bilateral aldosterone production, respectively. About 10% of patients with primary aldosteronism have either bilateral APA, which may be microscopic and not identifiable by CT or MR imaging, or unilateral hyperplasia. In addition, nonfunctional adrenal adenomas are common and the frequency increases as the patient's age increases. Consequently, the presence of an adenoma on imaging studies does not necessarily indicate the presence of an APA. Overall, an adrenal adenoma in a patient with primary aldosteronism has an approximately 70% to 80% chance that it is functional, that is, that an APA is present, and a 20% to 30% chance that it is a nonfunctional adenoma. In the patient younger than 40 years of age,

TABLE 38.3 Confirmatory Testing for Primary Aldosteronism

Test	Method	Evaluation	Limitations
Oral sodium chloride (NaCl) loading	Oral NaCl intake >200 mmol/day for 3 days, with oral KCl as needed to prevent hypokalemia, with subsequent 24-hr urine aldosterone measurement	Urine aldosterone <10 μg/day, diagnosis unlikely; >12 μg/day, diagnosis likely	Avoid if severe uncontrolled hypertension, CKD, CHF, cardiac arrhythmias, or severe hypokalemia
Saline infusion test	Patient in recumbent position for 1 hr before testing and then throughout entire test Begin test between 8 and 9:30 AM. Measure plasma aldosterone, plasma renin activity, cortisol, and potassium at beginning of test and then after infusing 2 l NS IV over 4 hr.	Plasma aldosterone at end of infusion <5 ng/dl, diagnosis unlikely; >10 ng/dl, diagnosis likely; 5-10 ng/dl, indeterminate	Avoid if severe uncontrolled hypertension, CKD, CHF, cardiac arrhythmias, or severe hypokalemia
Fludrocortisone suppression test	Oral fludrocortisone, 0.1 mg every 6 hr for 4 days, plus oral NaCl, 30 mmol 3×/day, and high-salt diet combined with sufficient KCl to avoid hypokalemia	Upright plasma aldosterone on day 4 >6 ng/dl and plasma renin activity <1 ng/ml/h, diagnosis likely	Requires very close follow-up to monitor blood pressure and potassium
Captopril challenge test	Oral captopril, 20-50 mg, given with plasma aldosterone, and plasma renin activity obtained immediately before captopril and then 1-2 hr afterward, with patient seated throughout test	Plasma aldosterone decrease >30%, diagnosis unlikely	Probably more false-positive and false-negative results than other tests

From reference 39.

the likelihood of a nonfunctional adenoma is less and the likelihood of an APA is greater. If a detectable adrenal adenoma is not found on imaging, the likelihood of unilateral autonomous aldosterone production is substantially less, probably close to 10%.

Adrenal Vein Sampling

Adrenal vein sampling is considered the definitive test for determining whether autonomous aldosterone release is due to unilateral or bilateral disease. Adrenal vein sampling should be used in the patient who has a high pretest likelihood of unilateral disease. This generally means the patient with primary aldosteronism known to have an adrenal adenoma or the patient with severe primary aldosteronism not responsive to medical therapy.

When interpreting adrenal vein sampling results, the first step is to confirm sampling of both the right and left adrenal veins. Because of the small caliber of both adrenal veins and the variable insertion point of the right adrenal vein into the inferior vena cava, successful cannulation is difficult. Confirmation of successful cannulation, particularly of the right adrenal vein, solely on radiologic criteria is unreliable. Accordingly, biochemical confirmation of successful adrenal vein sampling should be employed. Typically this is done by measuring the concentration of a hormone produced in the adrenal gland and demonstrating that the observed concentration is significantly greater than present in the inferior vena cava; cortisol is the most frequently measured analyte, and acute stimulation of cortisol production with ACTH or an analogue is often used. The selectivity index, the ratio of adrenal vein to inferior vena cava (sampled below the renal veins) cortisol concentration, should be determined and should be at least 5:1 for each adrenal vein sample to confirm successful adrenal vein cannulation. Alternative approaches using metanephrine levels also may be used.[38] If the selectivity index is not adequate to confirm successful adrenal vein cannulation, results of the aldosterone value in that adrenal vein sample may not be interpretable.

After confirming successful adrenal vein sampling, the lateralization index is calculated to determine whether there is unilateral or bilateral excessive aldosterone production. The ratio of adrenal vein aldosterone to adrenal vein cortisol is calculated for each adrenal vein. The lateralization index is calculated by dividing the greater adrenal vein ratio by the lesser adrenal vein ratio. A lateralization index greater than 2.0 supports a diagnosis of an APA, but it should be noted that this cut-off is not 100% specific. Our practice is to use a lateralization index greater than 2.0 to indicate an APA if this is concordant with the presence of an adrenal adenoma on the same side. If the lateralization index findings are discordant with imaging, then because of the possibility of a false-positive test result with a lateralization index between 2 and 4, we generally do not refer the patient for adrenalectomy unless the lateralization index is greater than 4.0.

Other Testing Options

Many other diagnostic tests have been suggested in the evaluation of primary aldosteronism to differentiate unilateral from bilateral disease, but none has widespread acceptance. Noninvasive physiologic tests, such as the saline suppression test and postural stimulation tests, rely on the association that APA-mediated aldosterone release is typically not stimulated by Ang II, whereas in hyperplastic lesions Ang II–dependent stimulation is generally retained. All medicines that affect the RAS, including diuretics, β-blockers, ACE inhibitors, and ARBs, must be discontinued before testing, but the difficulty in controlling BP in these patients without these medicines often limits the utility of this test. In addition, the association of Ang II–stimulated aldosterone production is discordant with whether aldosterone release is unilateral or bilateral in as many as 20% of cases, leaving this test result insufficiently accurate to determine whether surgical therapy should be used in most cases. Its main role may be in the evaluation of the patient with an adrenal adenoma and unsuccessful adrenal vein sampling.[39]

NATURAL HISTORY

The natural history of untreated primary aldosteronism leads to a variety of significant complications. Clearly, it is a major cause of worsening hypertension, and it also increases the incidence of hypokalemia, with its adverse chronic effects. In addition, it leads to a wide variety of end-organ complications. These end-organ effects include increased risks for coronary heart disease, atherosclerotic peripheral vascular disease, cardiac arrhythmias, left ventricular hypertrophy, low bone mineral density, and development of CKD.[29,40,41] The incidence of these complications appears to be substantial, and twofold to threefold, greater than in patients with essential hypertension of the same magnitude. These effects appear to be related to excessive activation of MRs in these end-organ tissues and therefore reflect a direct and BP-independent disease association. Effective treatment of primary aldosteronism appears to substantially improve these risks. Therefore treatment either with MR blockers or with adrenalectomy is recommended for all patients with primary aldosteronism.

TREATMENT

Adrenalectomy

The appropriate treatment of patients with primary aldosteronism depends on two factors: whether they are candidates for and would consider surgical therapy, and for those who are, whether they have unilateral or bilateral autonomous aldosterone production. This is because patients with unilateral autonomous aldosterone production, typically from an APA, who are acceptable surgical candidates, can have a dramatic response to adrenalectomy. Patients with an APA who undergo adrenalectomy have a 30% to 60% chance of hypertension cure.[42,43] Patients most likely to have their hypertension cured are younger than 50 years of age and have few family members with primary hypertension. Those not cured have a greater than 95% chance for BP improvement.[42,43] The lack of complete cure may reflect microvascular disease that developed as a consequence of the poorly controlled hypertension. Adrenalectomy performed using a laparoscopic approach is associated with a relatively short hospital stay, low postoperative morbidity, and a rather quick return to normal health, at least as compared with a nonlaparoscopic surgical approach. Adrenalectomy should not be performed in patients with bilateral autonomous aldosterone production because unilateral adrenalectomy is not curative and bilateral adrenalectomy is associated with unacceptable long-term complications secondary to the induction of deficiency of other adrenal hormones, such as glucocorticoids and catecholamines.

Mineralocorticoid Receptor Antagonists

Patients who are not candidates for surgical adrenalectomy or who have bilateral aldosterone production should be treated with MR antagonists. Current MR antagonist treatment options are spironolactone and eplerenone. These should be started at modest doses and titrated slowly. Most patients find that the responses are delayed, and monthly dose adjustments should be done until an optimal dose is identified.

The choice of which MR blocker to use involves consideration of effectiveness and side effects. Importantly, the treatment efficacy of these two agents is quite different. Spironolactone appears to be more effective than eplerenone at improving BP, yielding almost twice as great a BP reduction and a substantially greater proportion of patients

experiencing a significant BP improvement.[44] Spironolactone has off-target effects on sex-steroid hormone receptors, which can lead to breast enlargement (gynecomastia) in men and breast tenderness (gynecodynia) and menstrual irregularities in women. These side effects are dose-dependent and are typically mild or not present at doses of 100 mg/day or less. Eplerenone is more selective than spironolactone for the MR, and the risk for these side effects is less, but not eliminated.

Based on its greater treatment efficacy, we recommend spironolactone as the preferred initial agent for medical treatment of primary aldosteronism. Treatment can begin with low doses; we typically recommend initial therapy with oral spironolactone 25 to 50 mg/day, with dose titration on a 2- to 4-week basis. Most patients can be treated with maximum dose of 100 mg/day, but occasional patients may require 200 to 400 mg/day, often administered twice a day. Eplerenone can be used at similar doses and with a similar dose escalation pattern, with the exception that the general maximum recommended dose is only 100 mg/day.

Many of the side effects of MR blockers can be easily managed. Muscle cramps occur with both spironolactone and eplerenone. Changing from one MR blocker to the other often allows resolution of the muscle cramps. MR blockers can cause neuropsychiatric side effects that are often nonspecific and can include symptoms of feeling out of touch with reality, difficulty thinking, and decreased attention and performance in various memory tasks.[44,45] In general, these effects are temporary and resolve within a few weeks. Hyperkalemia is common when MR blockers are used for conditions other than primary aldosteronism, such as congestive heart failure,[46,47] but relatively uncommon in patients with primary aldosteronism. However, hyperkalemia can occur late in therapy, often after years of MR blocker administration, and may require either a decrease in the MR dose or addition of diuretics to increase renal potassium excretion.

Treatment with an MR antagonist usually results in dramatically improved BP control. Many patients will respond to a low dose of spironolactone (25 to 50 mg daily) as initial therapy. Both systolic BP and diastolic BP frequently decrease by about 25 mm Hg over a few weeks to months. Dosage of the MR antagonists can be increased as necessary but generally should not be changed more than every 2 to 4 weeks. If present, hypokalemia and metabolic alkalosis typically improve. Potassium supplements often can be discontinued when MR therapy is initiated, or the dose can be tapered rapidly. Because changes in potassium supplement requirement to avoid either hypokalemia or hyperkalemia exhibit significant inter-patient variability after MR initiation, we suggest close follow-up of serum potassium after initiating MR therapy, particularly in patients previously treated with large doses of potassium. With time, BP can be controlled in many patients with an MR antagonist and a single alternative agent. We typically use ACE inhibitors or ARBs because renin activity, which is suppressed initially, typically increases after starting MR antagonist therapy. Synergistic use of an ACE inhibitor or ARB may prevent development of a renin-stimulated, Ang II–dependent component of hypertension. However, many antihypertensive combinations can be used successfully with the MR antagonist.

Other MR blockers are in development and may become available for use in the near future. Finerenone is a novel, selective, nonsteroidal MR blocker that may have less effect on serum potassium.[48] This may make this medication particularly useful in treatment of a number of patients, such as those with CKD and primary aldosteronism, with CKD and glomerular disease, and with CKD and congestive heart failure (CHF), in whom MR blocker–induced hyperkalemia is often a limiting factor in MR blocker therapy. Multiple other nonsteroidal MR blockers are also in development.

Non–Mineralocorticoid Receptor Blocker Therapy

In occasional patients, high doses of MR blockers will not be sufficient to block the effects of aldosterone on BP and potassium. In this case, addition of a medication that specifically blocks aldosterone's effect on renal NaCl reabsorption can be helpful. Aldosterone specifically stimulates the distal epithelial cell Na^+ transporter, ENaC, which contributes to the volume expansion and resulting hypertension. Use of ENaC inhibitors, such as amiloride or triamterene, in combination with MR blockers may be helpful. We typically use oral amiloride, starting at 5 mg/day and titrating as needed.

Aldosterone synthase inhibitors are a new treatment option in development.[49] These medications directly inhibit adrenal aldosterone synthesis, leading to decreased plasma aldosterone levels and leading to improvements in BP control. Because they do not target MR, their side-effect profile is likely to differ from that observed with MR blockers, although the development of hyperkalemia is not likely to differ.

SELF-ASSESSMENT QUESTIONS

1. The most common genetic cause of primary aldosteronism resulting from an aldosterone-producing adenoma (APA) is related to a mutation in which protein?
   - **A.** Aldosterone synthase
   - **B.** Mineralocorticoid receptor
   - **C.** AT1 receptor
   - **D.** Potassium channel (KCNJ5)
   - **E.** Sodium channel
2. Based on recent comparative studies, which of the following mineralocorticoid receptor (MR) antagonists for primary aldosteronism is preferred and for what reason?
   - **A.** Eplerenone, because of greater efficacy
   - **B.** Eplerenone, because of fewer side effects and less drug discontinuation
   - **C.** Spironolactone, because of greater efficacy
   - **D.** Spironolactone, because of fewer side effects and less drug discontinuation
3. Which of the following is the preferred first-line test for identification of primary aldosteronism?
   - **A.** Serum potassium
   - **B.** Plasma aldosterone
   - **C.** Plasma renin activity
   - **D.** Aldosterone-renin ratio (ARR) in combination with absolute level of plasma aldosterone
   - **E.** Urinary sodium and potassium excretion rate

Other Endocrine Causes of Hypertension

A. Mark Richards

Endocrine hypertension often remains undiagnosed. However, primary aldosteronism may be present in 10% of patients with newly diagnosed hypertension, and, overall, an endocrine contribution to high blood pressure (BP) may be present in more than 12% of all hypertension cases.[1]

Endocrine hypertension frequently occurs in the absence of readily observed signs and symptoms or abnormalities in routine biochemical tests. However, certain features should trigger consideration of endocrine hypertension (Fig. 39.1) because diagnosis may offer the chance for cure and simple therapies that ameliorate other elements of the disease beyond BP control. Chapter 38 discusses aldosteronism; this chapter describes other types of endocrine hypertension.

CUSHING SYNDROME

Definition

This syndrome of sustained glucocorticoid excess is most often secondary to production of adrenocorticotropic hormone (ACTH) by a pituitary adenoma (Cushing disease). Less frequently, Cushing syndrome is the result of cortisol overproduction from an adrenal adenoma, adrenal nodular hyperplasia, or carcinoma, and rarely it may be secondary to ectopic ACTH (corticotrophin) secretion from tumors.[1-3] Approximately 0.5% of patients with bronchogenic carcinoma (more common in men than women) develop ectopic ACTH syndrome. The Carney complex, an autosomal dominant disorder featuring cardiac myxomas and pigmented skin/mucosal lesions is a rare cause of Cushing syndrome. Ectopic corticotropin-releasing hormone (CRH) from tumors is a rare cause of hypercortisolism. Cushing syndrome also can result from exogenous corticosteroid administration. The incidence of endogenous Cushing syndrome is 5 to 10 cases per 1 million population per year. Cushing disease and cortisol-secreting adrenal tumors are four times more common in women than in men.

Etiology, Pathogenesis, and Epidemiology

Hypertension is present in 80% of patients with Cushing syndrome (less often when caused by exogenous synthetic corticosteroid administration) and results from an increase in both cardiac output and total peripheral resistance. The mechanisms underlying these hemodynamic changes are complex.[4]

In some patients, Cushing syndrome may be caused by concurrent overproduction of mineralocorticoids such as aldosterone, 11-deoxycorticosterone, and corticosterone. Although cortisol can bind the mineralocorticoid receptor (MR), usually it does not because of the renal enzyme 11β-hydroxysteroid dehydrogenase type 2 (β-HSD2), which inactivates cortisol to corticosterone, thereby preventing its binding to the MR. However, in the patient with low β-HSD2 activity or extremely high cortisol levels (e.g., ectopic ACTH syndrome), there may be sufficient excess cortisol that MR binding occurs. Furthermore, alterations in oxidation-reduction (redox) status, potentially triggered by metabolic disturbance and cytokines, may alter the effects of corticosteroids at the MR function, converting cortisol from its receptor antagonist role in health to an agonist in inflammation.[5]

Subsequent cardiac and vascular MR activation may foster cardiovascular inflammatory, hypertrophic, and fibrotic changes. Inhibition of the vasodilator nitric oxide (NO) by cortisol may contribute to the hypertension, along with enhanced pressor responsiveness to catecholamines and angiotensin II (Ang II), heightened cardiac inotropic sensitivity to β-adrenergic stimulation, and increased plasma volume.[4] The sympathetic nervous system and renin-angiotensin system (RAS) may be suppressed, even though circulating levels of renin substrate are increased.[,] Adipokines, including leptin and resistin, plus release of pro-inflammatory cytokines (tumor necrosis factor α, interleukin-6) also may contribute to the increased cardiovascular (CV) risk observed in Cushing syndrome.[1-3,6-8]

Successful treatment of Cushing disease or removal of an underlying adrenal adenoma usually results in BP reduction and partial return of the previously impaired nocturnal fall in arterial pressure, although hypertension persists in a sizable minority of patients.[8]

Clinical Manifestations

Clinical features in Cushing disease result from elevated circulating levels of pro-opiomelanocortin hormones, including ACTH (increased pigmentation) and cortisol (central adiposity, insulin resistance or diabetes, muscle wasting/weakness, plethoric facies, purple striae [Fig. 39.2], easy bruising, osteoporosis, psychological problems). In some patients, androgen effects are observed (hirsutism, acne, virilization) and may be striking in those with adrenal adenoma or carcinoma. Ectopic ACTH syndrome caused by small cell bronchial carcinoma or other tumors (e.g., bronchial or thymic carcinoid) manifests typically as a wasting disease, often with hyperpigmentation and hypokalemia. Hypertension is often associated with left ventricular hypertrophy, which can be disproportionate to BP, and frank cardiac failure is occasionally the presenting feature.[1,4] In up to 15% of patients with Cushing syndrome, clinical features occur only periodically; this is known as *cyclical Cushing syndrome*.[1]

Differential Diagnosis

Pseudo–Cushing syndrome can occur with a sustained high intake of alcohol by inducing augmented cortisol secretion and reduced cortisol metabolism caused by hepatic damage. Routine diagnostic tests are

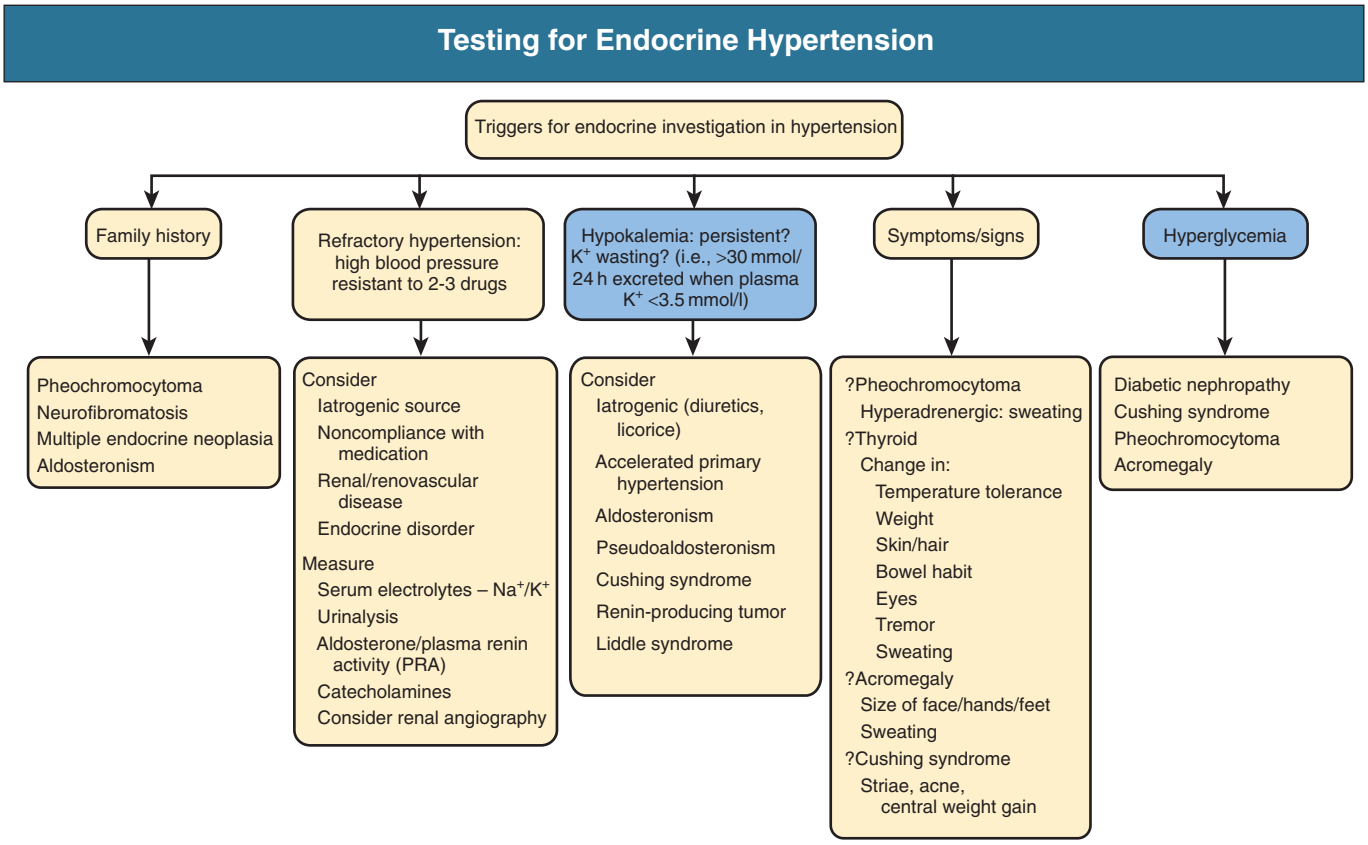

Fig. 39.1 Testing for endocrine hypertension. Clinical observations suggesting investigation into endocrine causes of hypertension in hypertensive patients.

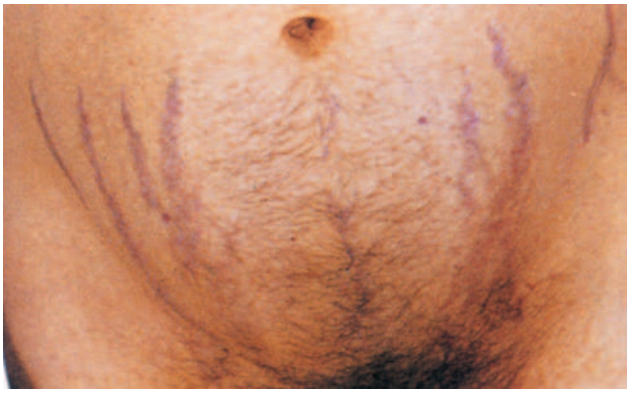

Fig. 39.2 Striae and central obesity in a patient with Cushing syndrome.

unable to distinguish alcoholic pseudo–Cushing syndrome from true Cushing syndrome, and reassessment after alcohol withdrawal may be required.[9] Depression is associated with an increased cortisol level. Careful psychological and physical evaluation will usually differentiate these patients from those with Cushing syndrome.

Diagnosis

Initial evaluation should test for one or more of the following: (1) an elevated 24-hour urinary free cortisol excretion (at least two samples), (2) increased late night salivary cortisol, (3) absence of suppression of 8 AM plasma cortisol after a dose of dexamethasone (1 mg at midnight), and (4) failure of suppression of cortisol on low-dose dexamethasone (0.5 mg four times daily) for 48 hours. Random plasma cortisol measurements are not reliable.

A positive test result should trigger involvement of an endocrinologist. Further key investigations include computed tomography (CT) and magnetic resonance imaging (MRI) of the pituitary and adrenal glands and plasma ACTH (suppressed in cortisol-secreting adrenal tumors but elevated in pituitary adenoma and ectopic ACTH syndrome). Further tests may include a high-dose dexamethasone suppression test that partially suppresses ACTH in patients with pituitary tumors but not with ectopic ACTH. The response of plasma ACTH to a dose of corticotrophin-releasing hormone (≥20% rise in response to CRH points to a pituitary source) may help distinguish pituitary from adrenal or ectopic tumors. Simultaneous bilateral inferior petrosal sinus sampling for ACTH measurements is useful in differentiating Cushing disease from ectopic ACTH syndrome, when the previous tests give equivocal results. Imaging of the thorax, abdomen, and pelvis is indicated when ACTH-producing carcinoid tumors are suspected. When other tests are equivocal, an indium-111 octreotide radio-ligand scan, highlighting tissue with somatostatin receptors, may secure the location of ectopic ACTH production.

Treatment and Prognosis

Untreated patients with Cushing syndrome have 50% 5-year mortality because of CV risk from hypertension, along with glucose intolerance, insulin resistance, hyperlipidemia, and obesity.[4,10]

Cure rates in treatment of Cushing disease are 80% to 90% by selective removal of a pituitary microadenoma and 50% for pituitary macroadenomas. Cushing syndrome caused by adrenal adenoma is almost always cured by unilateral adrenalectomy. However, in adrenal

carcinoma, median survival is less than 2 years. The prognosis is also poor when Cushing syndrome results from ectopic ACTH syndrome caused by small cell bronchial carcinoma. If the ACTH-producing tumor is benign and can be located, however, complete removal usually leads to cure and reduction of mortality to match that in the general population. After cure of Cushing syndrome, approximately 30% of patients have persistent hypertension.[11]

No evidence supports the use of any antihypertensive class over another. Potassium-losing diuretics can exacerbate both hypokalemia and glucose intolerance, whereas potassium-sparing diuretics, usually in combination with other antihypertensive agents, may correct hypokalemia and reduce edema while lowering BP.

PHEOCHROMOCYTOMA

Definition

Pheochromocytoma can mimic a wide spectrum of other disorders, and the diagnosis is frequently delayed or missed altogether.[12]

Pheochromocytoma refers to a dusky tumor whose cells stain brown with chromium salts. Such tumors arise most frequently within the adrenal glands (Fig. 39.3), but approximately 10% are extra-adrenal (paraganglioma). Although the majority of pheochromocytomas are benign, 10% to 15% of adrenal pheochromocytomas and 20% to 50% of paraganglionomas are malignant. Histologic features are not a reliable guide to malignant behavior. The tumors secrete norepinephrine, epinephrine, and dopamine, with patterns differing among patients. Few paragangliomas produce epinephrine. Very high dopamine production is associated with malignant disease or a large tumor mass.

Etiology, Pathogenesis, and Epidemiology

The prevalence of pheochromocytoma in patients with hypertension in general medical outpatient clinics is 0.1% to 0.6%.[13] However, the prevalence may be considerably higher because the diagnosis is often made postmortem.[12,13]

Pheochromocytomas can be sporadic or familial.[14] Whereas sporadic cases are usually unicentric and unilateral, familial pheochromocytomas are often multicentric and bilateral. At least one third of all pheochromocytomas result from germ-line gene mutation; 14 genes have been identified thus far.[12,15] Variants in the *RET* gene result in multiple endocrine neoplasia (MEN) type 2; in the *VHL* gene, the von Hippel–Lindau syndrome; in the neurofibromatosis type 1 *(NF1)* gene in von Recklinghausen disease; and variants in the genes encoding the B and D subunits of mitochondrial succinate dehydrogenase (*SDHB* and *SDHD*) are associated with familial paragangliomas and pheochromocytomas. The high prevalence of inherited disease and the fact that the *SDHB* variants lead to metastatic disease in 40% of cases, makes genetic testing important once pheochromocytoma is diagnosed.[12,15] For patients with apparently sporadic pheochromocytomas, an underlying germ-line mutation of the genes mentioned may be present in about 20% of cases and should be considered in younger patients (<50 years) and those with multifocal or extra-adrenal tumors.[12,15,16] Patients with a germ-line mutation should be identified for appropriate guidance of medical management for them and their families.

Fig. 39.3 Large adrenal pheochromocytoma with areas of hemorrhagic necrosis.

Clinical Manifestations

Table 39.1 outlines clinical features of syndromes associated with pheochromocytoma. Clinical features of pheochromocytoma reflect episodic or continuous overproduction of catecholamines and depend in part on which catecholamine dominates. Symptoms include headache, sweating, palpitations, anxiety, and pallor (Fig. 39.4).[17] Hypertension or diabetes mellitus, with or without symptoms, may be the initial manifestation. Less than 1% of resistant hypertension cases are due to pheochromocytoma. Pheochromocytoma also may manifest as a tumor mass, usually an enlarging primary lesion in the abdomen or a paraganglioma in the neck, ear, thorax, or abdomen. On occasion, a metastatic lesion may be the presenting sign. About 4% of adrenal incidentalomas are pheochromocytomas. Physical examination may reveal labile (66%) or persistent (33%) hypertension, sometimes with strikingly reciprocal changes in BP and heart rate when the tumor secretes predominantly norepinephrine.[18] The patient may have cool, mottled extremities and a low-grade fever with tachycardia and postural hypotension. Hypertensive crisis with or without heart failure may be precipitated by emergency surgery, general anesthesia, or on exposure to radiocontrast material. This also may occur after minor or major trauma, at delivery, and apparently from sudden spontaneous release of catecholamines from the tumor or on hemorrhage into it. Pheochromocytoma in pregnancy presents particular difficulties in diagnosis and management.[19]

Diagnosis

Diagnosis of pheochromocytoma is based on clinical suspicion and biochemical confirmation (Fig. 39.5). Measurement of plasma free metanephrines or urinary fractionated metanephrines is the investigation of choice for diagnosis or exclusion of pheochromocytoma. Levels are relatively independent of renal function and provide some guidance for tumor size and location.[12] When analysis of plasma free metanephrines is not available, plasma or urinary catecholamines or their other metabolites may be used and typically are 5- to 10-fold greater than normal. When catecholamine levels are less than 3 to 4 times the upper limit of normal, it is useful to undertake a suppression test with clonidine, which suppresses plasma norepinephrine into the normal range in health but fails to do so in patients harboring a pheochromocytoma.[20]

Once the biochemical diagnosis is secured, the lesion must be localized (see Fig. 39.5). MRI or CT scan (with nonionic contrast) of the abdomen and pelvis, concentrating first on the adrenals, is successful in most patients, but additional investigations may be required if no lesion is detected. These may include metaiodobenzylguanidine (MIBG) scanning, In-111–labeled octreotide scanning, or positron emission tomography (PET); with any of these imaging modes potentially coupled with selective venous sampling from vena cava (or veins draining specific organs) to detect a step-up in catecholamine levels (preferably including measurements of plasma free metanephrines.[21] MIBG scanning is generally recommended to corroborate the diagnosis and exclude multisite

TABLE 39.1 Clinical Features of Syndromes Associated With Pheochromocytoma

Associated Syndrome	Clinical Manifestations
Von Hippel–Lindau Syndrome	
Type 1 (no pheochromocytoma)	Renal cell cysts and carcinomas
	Retinal and CNS hemangioblastomas
	Pancreatic neoplasms and cysts
	Endolymphatic sac tumors
	Epididymal cystadenomas
Type 2 (with pheochromocytoma)	2A. Retinal and CNS hemangioblastomas
	Pheochromocytomas
	Endolymphatic sac tumors
	Epididymal cystadenomas
	2B. Renal cell cysts and carcinomas
	Retinal and CNS hemangioblastomas
	Pancreatic neoplasms and cysts
	Pheochromocytomas
	Endolymphatic sac tumors
	Epididymal cystadenomas
	2C. Pheochromocytomas only
Multiple Endocrine Neoplasia (MEN) Type 2*	
Type 2A (MEN-2A)	Medullary thyroid carcinoma
	Pheochromocytoma
	Hyperparathyroidism
	Cutaneous lichen amyloidosis
Type 2B (MEN-2B)	Medullary thyroid carcinoma
	Pheochromocytoma
	Multiple neuromas
	Marfanoid habitus
Other Syndromes	
Neurofibromatosis type 1	Multiple fibromas on skin and mucosa
	Café-au-lait skin spots
	Pheochromocytomas
Paraganglioma syndromes	Head and neck tumors (carotid body tumors; vagal, jugular, and tympanic paragangliomas)
	Pheochromocytomas
	Abdominal or thoracic paragangliomas (or both)

*A third type of MEN type 2 consists of familial medullary thyroid carcinoma only (without pheochromocytoma).
CNS, Central nervous system.

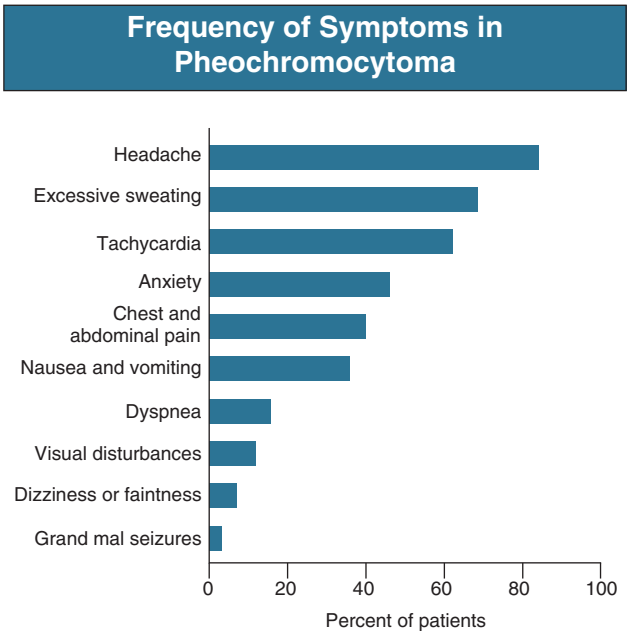

Fig. 39.4 Frequency of symptoms in 324 patients with pheochromocytoma. (Modified from reference 17.)

or metastatic disease. Removal of a pheochromocytoma-containing adrenal gland can result in compensatory medullary hyperplasia in the contralateral adrenal gland, potentially giving a false-positive MIBG scan on follow-up scanning, so the clinician must be cautious with interpretation.[22] Diagnosis of a pheochromocytoma should trigger exclusion of associated syndromes, including von Hippel–Lindau syndrome, von Recklinghausen disease, and familial paraganglioma.

Treatment

Once the pheochromocytoma has been localized, the patient should be prepared for surgery with a collaborative team approach by the surgeon, anesthesiologist, and physician. Traditionally, preoperative management has included 7 to 21 days of α-adrenoceptor blockade (usually with phenoxybenzamine), repletion of salt and water volume, and the later addition of β-blockade (if necessary to control BP and tachycardia). β-Blocker monotherapy is contraindicated because unopposed α-adrenergic stimulation can cause hypertensive crisis. Alternative drugs that have been used successfully before surgery include prazosin (α-blocker) and labetalol (combined α- and β-blocker). Metyrosine, a tyrosine hydroxylase inhibitor, blocks catecholamine synthesis; frequent side effects have led to limitation of its use for large tumors or where other measures have failed to achieve control of the BP.

Longer preoperative treatment has been recommended in cases with cardiomyopathy, myocardial infarction, and/or vasculitis. However, the need for prolonged presurgical pharmacologic control is still debated, with an emerging view that improved anesthetic management, skilled use of short-acting vasoactive drugs, and careful intraoperative handling of the tumor usually will allow safe progression to early surgery, with perioperative mortality close to zero in recent series.[12,14,23]

A laparoscopic approach to surgical removal of adrenal pheochromocytomas and some extra-adrenal tumors has gained widespread acceptance, but open adrenalectomy is preferred for large tumors, difficult dissection, invasion, adhesions, or surgical inexperience.[24] Laparoscopic surgery also has been used successfully for hereditary bilateral or recurrent pheochromocytoma. Intraoperative manipulation of the tumor causes volatile elevations in BP. Agents used to achieve intraoperative BP control include phentolamine, sodium nitroprusside, and magnesium sulfate.

Hypotension and hypoglycemia are potential postoperative problems. In most patients, surgical removal of pheochromocytoma normalizes plasma catecholamine levels and previously suppressed central sympathetic outflow. Plasma or urinary metanephrines should be checked no sooner than 10 days after surgery. Follow-up should include life-long biochemical monitoring at least annually and in the event of symptoms suggestive of recurrence.

BP usually improves with removal of a pheochromocytoma, but especially in those with persistent hypertension versus episodic, BP will remain elevated in 25% of cases, necessitating long-term antihypertensive therapy. For malignant pheochromocytoma, consideration should be given to aggressive surgical resection, particularly when there is a single

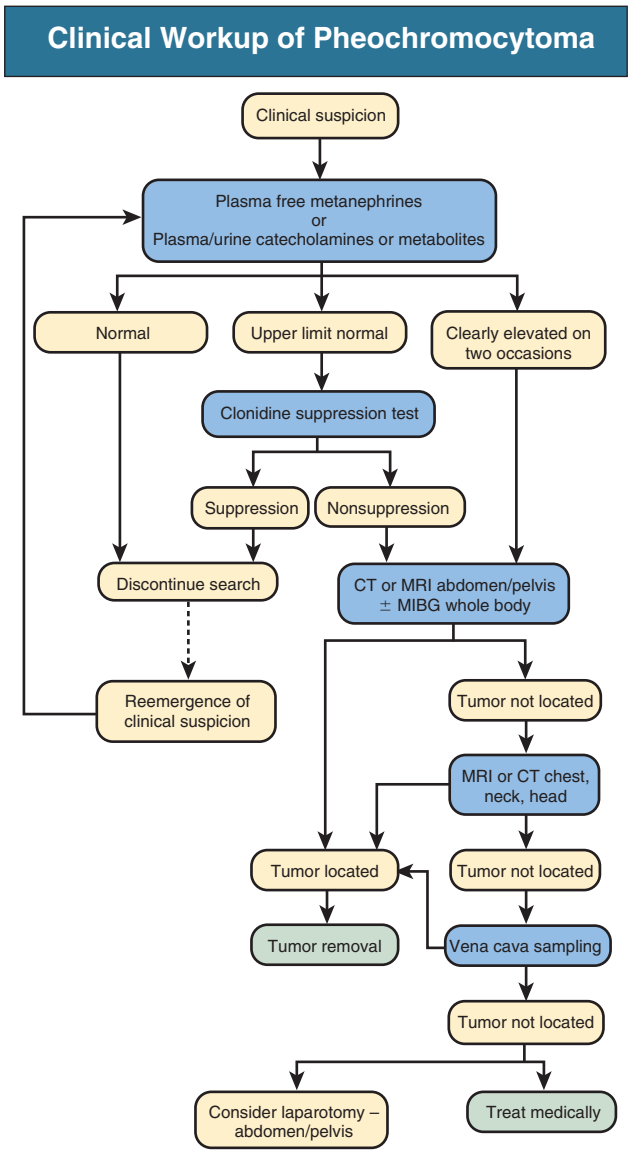

Fig. 39.5 Clinical workup of pheochromocytoma. *CT,* Computed tomography; *MIBG,* metaiodobenzylguanidine; *MRI,* magnetic resonance imaging.

metastatic lesion. Hepatic metastases are readily resected. The standard chemotherapeutic regimen for malignant pheochromocytoma includes cyclophosphamide, vincristine, and dacarbazine. Other chemotherapeutic options include doxorubicin, cisplatin, VP-16, etoposide, carboplatin, ifosfamide, temozolomide, imatinib, tamoxifen, bevacizumab, sorafenib, and prednisone. Targeted molecular treatment includes the antiangiogenic tyrosine kinase receptor inhibitor sunitinib. Everolimus inhibits the pro-proliferative, proangiogenic mammalian target of rapamycin (mTOR) pathways.

Several other treatment options are available. Radionuclide treatment with I-131 MIBG at high dose offers treatment targeted to the tumor. Somatostatin-like drugs coupled with radioisotopes such as yttrium-90 and letetium-177 offer alternative modes of radiotherapy.

External beam radiation therapy can be useful for bone metastases. Tumor embolization and ablation procedures using radiofrequency ablation, cryoablation, and ethanol injection have been successful as palliation or for longer term control of metastatic disease in selected cases.[14]

Progression of malignant pheochromocytoma is extremely variable. Although median survival is approximately 5 years, survival for decades has been recorded in some cases.

ADRENAL INCIDENTALOMA

Definition and Epidemiology

Incidentaloma refers to the incidental discovery of an adrenal mass of 1 cm or greater in diameter in the course of investigation for other conditions in the absence of any prior suspicion of adrenal disease.[25] The increasing use and sophistication of abdominal imaging for a wide range of indications frequently leads to the incidental discovery of an adrenal mass. Current prevalence of unsuspected adrenal masses is reported in 4% to 7% of adults undergoing high-resolution CT or MRI abdominal studies (<1% in those younger than 30 years, rising to 7% in those older than 70 years).[25-27]

Hypertension is more common in those with incidentalomas (40%) than in the general population. In a substantial series of more than 1000 incidentalomas, about 75% proved to be nonsecretory benign adenomas. However, an important minority show endocrine activity, including aldosteronoma (frequently normokalemic), pheochromocytoma (>4%, with half normotensive), and, most often, cortisol-secreting tumors. Between 5% and 30% of patients with incidentalomas have subclinical hypercortisolism, which is more common among those with bilateral rather than unilateral incidentaloma.[28,29] The formal definition of subclinical Cushing syndrome (SCS) is yet to be finally agreed upon but will include plasma cortisol after dexamethasone suppression over a threshold at some level between 1.8 and 5.0 μg/dl and a basal ACTH value below 10 pg/ml. SCS is frequently complicated by hypertension (~65% of cases), diabetes (~33%), obesity, and osteoporosis and carries increased risk for CV events and related mortality.[30] Adrenal carcinoma accounted for 4% of cases in a large, well-documented series of incidentalomas. Although a rare malignancy in the general population at 3 to 17 per million, 2% of masses up to 4 cm in diameter, 6% of those 4 to 6 cm in diameter, and 25% of those larger than 6 cm are adrenal carcinomas. Adrenal carcinomas may or may not be functional. The prognosis is poor, with 5-year survival of less than 20%.

Management

Investigation and management should address two key issues: whether the tumor is malignant and whether it is hormonally active. CT appearances consistent with malignancy and tumors greater than 4 cm in diameter without benign imaging features should be surgically resected.[25,29,31] Biochemical screening should be undertaken for pheochromocytoma (plasma free metanephrines or urinary free metanephrines), glucocorticoid excess (ratio of urinary free cortisol to creatinine and early-morning plasma cortisol concentration after 1 mg dexamethasone given the night before), or primary aldosteronism (plasma and 24-hour urinary potassium levels and ratio of plasma renin to aldosterone), as outlined here and in Chapter 38. It is reasonable to resect functional tumors. In nonfunctional tumors of benign appearance, annual biochemical follow-up for 5 years together with repeat imaging has been recommended if the tumor is larger than 3 cm. Incidentalomas increasing in size by more than 0.8 cm per year should be considered for resection.[27,30,31]

RENIN-SECRETING TUMOR

Definition

Primary renin-secreting tumors are rare, and fewer than 200 cases have been reported.[32] Diagnostic criteria include an elevated plasma renin or prorenin level, which decreases on removal of the tumor, and demonstration of renin within the tumor. Most renin-secreting tumors are caused

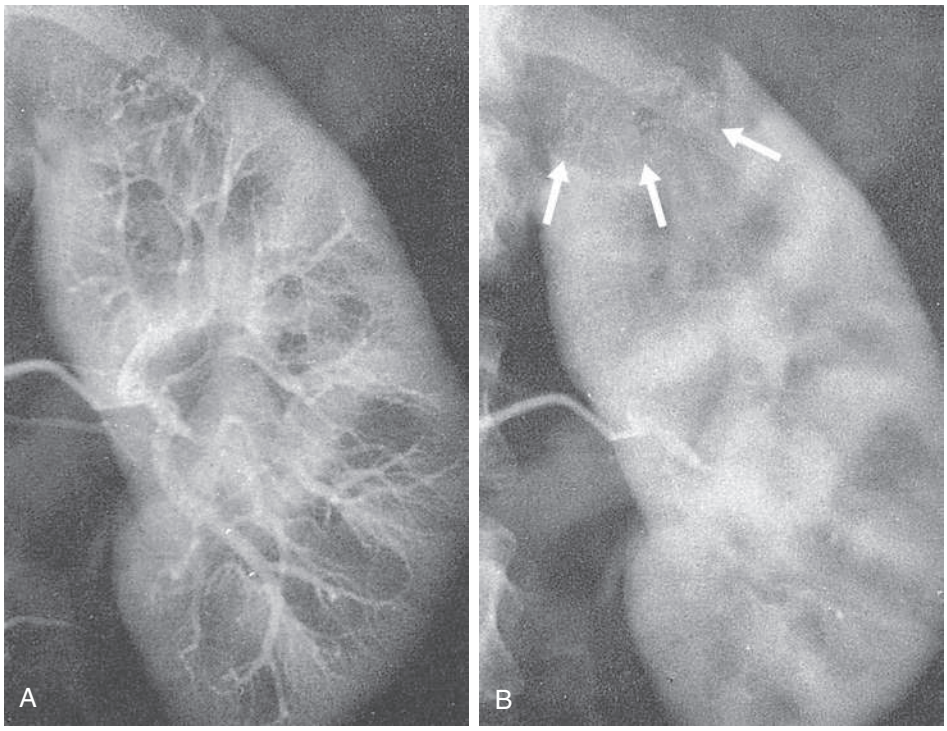

Fig. 39.6 Renin-secreting tumor. Left renal angiography arterial (A) and (B) phases revealing a 2.5-cm juxtaglomerular cell tumor with a circumscribed and relatively avascular appearance at the upper pole *(arrows)*. (Modified from reference 34.)

by benign renal juxtaglomerular cell tumors (JGCT) ranging from 5 mm to 6 cm in diameter (typically 2 to 4 cm). These tumors occasionally occur with nephroblastomas, renal cell carcinomas, and extrarenal neoplasms (bronchial or pancreatic carcinoma, ovarian tumors, carcinoma of ileum or colon, soft tissue sarcomas, orbital hemangiopericytoma).

Etiology and Pathogenesis

Autonomous hypersecretion of renin results in high circulating levels of Ang II that increase arterial pressure. Secondary hyperaldosteronism and hypokalemia result from stimulation of the adrenal glomerulosa by Ang II. High Ang II levels also induce hyponatremia in a minority of patients, by stimulation of thirst and arginine vasopressin (AVP) secretion, together with a direct renal water-retaining action of the peptide.[32]

Clinical Manifestations

Cases show female predominance; 75% of patients are younger than 30 years, presenting usually with severe, occasionally paroxysmal hypertension (average 206/131 mm Hg), hypokalemia (<3.0 mmol/l in ~70% of cases), proteinuria (>0.4 g/day in ~50% of patients), and in a minority, hyponatremia.[33] Glomerular filtration rate (GFR) is normal or high. BP may decrease substantially with the first dose of angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB).

Pathology

Renin-secreting tumors are encapsulated and tan or grayish yellow, with scattered hemorrhages. These masses consist largely of polygonal or spindle cells in close contact with capillary and sinusoidal vessels and contain cytoplasmic renin granules.[32]

Diagnosis and Differential Diagnosis

Patients presenting with hypertension and hypokalemia together with elevated renin (and prorenin) and aldosterone levels may harbor a renin-secreting tumor, most often a JGCT.

CT or MRI angiography or renal arteriography typically identify JGCTs as radiolucent, expansile, homogeneous, solid renal cortical neoplasms that typically measure 2 to 4 cm in diameter (Fig. 39.6).[33] CT and MRI scans showing an isodense or hypodense lesion with little or no enhancement after injection of contrast material have proved helpful in the provisional localization of these tumors. Bilateral, simultaneous renal vein sampling may enable lateralization of the tumor. Because renal blood flow to the culprit kidney is not impaired, however, a renin ratio of more than 1.2:1 between the two renal veins may not be present, in contrast to unilateral renal artery stenosis, in which reduced blood flow to the stenosed kidney and renin oversecretion often lead to an elevated renal vein renin ratio. Selective segmental renal vein renin sampling may help localize the tumor. When no renal lesion can be visualized and lateralization of renin secretion is not evident, an extrarenal renin-secreting lesion must be considered and sought by appropriate radiographic investigations and venous sampling for renin measurements.

Apart from renal artery stenosis or occlusion, it may be necessary to exclude other renin-producing lesions, including Wilms tumor, renal carcinoma, neuroblastoma, hepatocellular carcinoma, and pheochromocytoma, which can either secrete renin or stimulate renal renin production.

Treatment

Preoperative control of arterial pressure is based on an ACE inhibitor or ARB, introduced with caution to avoid first-dose hypotension. For JGCTs, local excision, where possible, is advisable to preserve nephrons. When doubt exists, an intraoperative frozen section will differentiate a benign JGCT from malignant lesions and guide surgery. Removal of a JGCT results in the return of renin and aldosterone levels to normal. BP decreases rapidly, but not always to normal if there is a background of primary hypertension or established hypertensive vascular damage.[34]

ACROMEGALY

Definition and Epidemiology

Acromegaly is caused by excessive circulating growth hormone (GH) originating sporadically from a somatotroph adenoma of the pituitary in over 95% of cases. Rare causes of acromegaly include hypothalamic or neuroendocrine tumors secreting GH-releasing factor (GHRH) and, rarely, hemopoietic, breast, bronchial, and abdominal tumors secrete GH. MEN syndrome type 1 may feature GH-secreting tumors. Acromegaly may appear in other familial settings (e.g., McCune-Albright syndrome, Carney complex) or as an isolated disorder in familial isolated pituitary adenoma.[35]

Acromegaly is rare, with an incidence of 5 cases per 1 million population per year and a prevalence of 36 to 60 cases per million. Hypertension is more common (~40%) in persons with acromegaly than in the general population, with an estimated 35% of patients with acromegaly having diastolic BP above 100 mm Hg with higher frequencies in female and older patients.[36] Patients with acromegaly who have additional hypopituitarism or advanced cardiomyopathy may have BP reduction masking prior hypertension. Most pituitary adenomas causing acromegaly are macroadenomas resulting in some pituitary destruction and one or more hypopituitary features in 75% of cases.

The pathogenesis of hypertension in acromegaly is complex but reflects sodium retention and volume expansion associated with an inappropriate response of hormonal systems to counteract these effects. Total exchangeable sodium, total body water, and extracellular fluid volume are increased. Volume expansion should suppress plasma renin levels, but although levels are low, they are not consistent with the sodium status. Aldosterone levels are also normal or only slightly suppressed. The kidneys are enlarged and GFR is increased, but sodium balance is not corrected unless the acromegaly is cured.

Clinical Manifestations

Excess circulating GH stimulates production of insulin-like growth factor 1 (IGF-1) from the liver. IGF-1 mediates the biologic effects of GH. Acromegaly is characterized by enlargement of the skull (Fig. 39.7), hands (Fig. 39.8), and feet. Other symptoms result from local effects of an expanding pituitary tumor and include visual field defects and headache. The manifestations of disease are gradual, slowly progressing over many years, and diagnosis may be delayed until dysmorphic features are well developed, typically in the fourth to fifth decade. Other signs and symptoms include headache (40%), excessive sweating (50%), loss of libido (35%), amenorrhea (45%), carpal tunnel syndrome (25%), diabetes mellitus (19%), and visual field defects (5%).[35] Thyroid enlargement occurs in 50% of patients and thyrotoxicosis in 6%. Hirsutism occurs in 24% of women and galactorrhea in 10%. Other complications of acromegaly include cardiac hypertrophy, systolic and diastolic dysfunction, heart failure, arrhythmia, sleep apnea, osteoarthritis and osteopenia, and disturbed calcium metabolism.[37] Through uncertain mechanisms, acromegaly is associated with increased rates of subsequent neoplasia, best demonstrated in a twofold increase in colorectal cancer.

Diagnosis

Clinical suspicion should be raised by symptoms and signs. Box 39.1 lists appropriate tests for acromegaly. Elevated plasma levels of IGF-1 and GH, especially with lack of suppression of GH on oral glucose tolerance testing, are strongly suggestive of the diagnosis. Visual field assessment and MRI of the pituitary fossa are necessary to define the tumor and exclude supra-tentorial extension.

Treatment

Trans-sphenoidal adenomectomy is the treatment of choice. Surgery is curative for microadenoma in 80% to 90% of cases. At least half of macroadenomas are not cured surgically. Surgical cure (defined by normalization of plasma IGF-1 and a nadir oral glucose tolerance test GH of <2 μg/l) is achieved in 81% to 100% of microadenomas and

BOX 39.1 Diagnostic Tests for Acromegaly

- Serum growth hormone
- Serum growth hormone responses to glucose tolerance test
- Serum insulin-like growth factor 1
- Lateral skull x-ray film
- Magnetic resonance imaging of the pituitary fossa
- Visual field measurements
- Assessment of other pituitary functions (e.g., thyroid function tests, thyroid-stimulating hormone, prolactin level, adrenocorticotropic hormone, and cortisol)

Fig. 39.7 Facial features of acromegaly with enlargement of brow, nose, and jaw.

Fig. 39.8 Radiograph of the hand in acromegaly. "Arrowhead" distal phalanges, expanded joint spaces, and increased soft tissue can be seen.

45% to 68% of macroadenomas.[35] Irradiation and drug therapy are valuable when complete removal of tumor tissue is not possible (approximately one third of acromegalic cases overall) and when surgery is contraindicated. Dopaminergic agents, such as bromocriptine and cabergoline, and the somatostatin analogue octreotide, reduce serum GH in acromegaly. Bromocriptine may induce tumor shrinkage and improve diabetes. The GH receptor antagonist pegvisomant also has been shown to be safe and effective.[35,38] In view of long-term side effects, radiation therapy is employed only when necessary in cases with persistent active disease despite all other treatment. Radiotherapy may not exert its full effect for months or years. Hypopituitarism may occur late after treatment and necessitate endocrine replacement for ACTH, thyroid-stimulating hormone (TSH), or gonadotropin deficiency. Therefore regular monitoring of pituitary function is required after treatment. Overall, 75% to 94% of cases are controlled.[35]

Management of Hypertension in Acromegaly

Surgical removal of the pituitary adenoma with normalization of GH levels may reduce BP to some extent, but most patients with acromegaly will continue to require antihypertensive therapy. Antihypertensive treatment requires a diuretic, given the volume-expanded state. Additional antihypertensive agents are frequently required, and both calcium channel blockers and ACE inhibitors may be effective. β-Blockers also may be used, although theoretically such agents may increase GH concentration.

HYPOTHYROIDISM

Definition and Epidemiology

It is estimated that hypertension is 1.5 to 2 times more common in hypothyroid patients than in the general population.[39] The pathogenesis of the hypertension is multifactorial and associated with both increased total body sodium and increased peripheral vascular resistance. Even in euthyroid patients, serum free thyroxine index (FTI) is lower and TSH is higher in hypertensive than in normotensive patients and FTI also independently predicts BP response to increments in dietary sodium in both normotensive and hypertensive individuals.[40]

Hypothyroidism is associated with increased aortic stiffness, loss of sensitivity to vasoconstrictors, and impaired endothelial function with loss of endothelial-dependent vasodilation plus reduced vasodilatory responses to NO donors.[41] Observations of short-term hypothyroidism have confirmed increases in arterial pressure, plasma catecholamines, aldosterone, and cortisol, all reversible with thyroid hormone treatment.[42,43,44] The relationship between plasma catecholamine levels and BP is enhanced in hypothyroidism.[45] Hypertension develops despite a low cardiac output.

Thyroid replacement therapy corrects the electrolyte, hemodynamic, and hormone changes and cures the hypertension in most patients.

Clinical Features

Symptoms and signs can be protean. Bradycardia, mild hypertension with narrowed pulse pressure, and muffled heart sounds are the most frequent signs in overt hypothyroidism. Other features include weakness, dry skin, lethargy, slow slurred speech, cold intolerance, thick tongue, facial puffiness (Fig. 39.9), coarse and thinning hair, failing memory, constipation, and weight gain with reduced appetite. In extreme cases, myxedema and coma ensue. Coronary heart disease is common, with dyslipidemia and hypertension accelerating the atherogenic process.

Diagnosis

Hypothyroidism should be considered in any patient with hypertension. Because the clinical manifestations of hypothyroidism are often difficult to elicit, especially in elderly patients, thyroid function tests, including TSH when FTI is equivocal, should be performed. In patients with primary hypothyroidism in whom normotension is not achieved by full thyroxine replacement therapy, primary hypertension is a likely concomitant disorder. For those with gross or long-standing hypothyroidism, replacement thyroxine therapy should be cautious to minimize the chances for exacerbating latent myocardial ischemia.

Fig. 39.9 Hypothyroid facies.

HYPERTHYROIDISM

Definition and Epidemiology

Hypertension is common in hyperthyroidism, with a prevalence of 60% in toxic adenoma and approximately 30% in Graves disease.[1]

Clinical Features

The clinical features depend on the underlying cause of the hyperthyroidism, severity of the disorder, rapidity of onset, age of the patient, and concomitant disease. Abnormalities may be evident in the cardiovascular system (tachyarrhythmias, heart failure), skin (increased sweating, increasing pigmentation with vitiligo), eyes (lid lag, exophthalmos), nervous system (hypertension, nervousness), alimentary system (increased appetite yet weight loss, diarrhea), and muscles (proximal weakness).

Hypertension in hyperthyroidism is associated with an increased pulse pressure with elevated systolic BP and normal or low diastolic BP. It may be observed in both postpartum thyrotoxicosis and neonatal thyrotoxicosis. Elevation of diastolic BP is unusual unless there is concomitant primary hypertension.

The hemodynamic characteristics in hypertension of thyrotoxicosis are an increased cardiac output (by 50% to 300%), increased myocardial contractility, tachycardia, decreased peripheral vascular resistance, and expanded blood volume. These indices return to normal in most patients on achieving the euthyroid state. Interestingly, catecholamine levels tend to be low (inversely to hypothyroid hypertension) and there is no heightened activity of the sympathetic system. The RAS tends to be activated and the aldosterone levels increased in hyperthyroidism, which may contribute to the development of systolic hypertension. Suspicion of hyperthyroidism should be high in the elderly patient with hypertension and a high pulse pressure, particularly if there is also atrial fibrillation. Such patients are prone to developing cardiac failure, in which

case the increased systolic arterial pressure will diminish, masking previous hypertension. Hypertension with a high pulse pressure, although typical of hyperthyroidism, is observed in many elderly patients with primary hypertension because of the loss of compliance of the aorta with aging.

Diagnosis and Treatment

Diagnosis of hyperthyroidism is confirmed by thyroid function tests, including measurement of TSH. β-Blockers are often effective first-line therapy for hyperthyroidism-associated hypertension. Treatment of hyperthyroidism, whether by antithyroid drugs, surgery, or radioiodine, often will promptly normalize the increased systolic arterial pressure, although not necessarily in elderly patients with concomitant primary hypertension.

PRIMARY HYPERPARATHYROIDISM

The incidence of primary hyperparathyroidism (PHPT) is approximately 20 per 100,000 person-years.[1,46] Full-blown PHPT may feature severe hypercalcemia, nephrolithiasis, acute and chronic renal disease, and fractures, but more commonly patients are asymptomatic. The prevalence of hypertension is increased in PHPT, approaching 50% with an independent association between plasma ionized calcium levels and the presence of hypertension. Generally, mild PHPT is not an indication for parathyroidectomy and management comprises serial follow-up in an endocrine service with monitoring of plasma calcium, renal function, and bone density. Coincident hypertension is not an accepted indication for parathyroidectomy and is managed according to standard guidelines with the notable difference that thiazide diuretics (which may increase plasma calcium) should be avoided. There is some evidence that surgical cure of PHPT and restoration of eucalcemia restores vascular function and BP toward normal.[46]

SELF-ASSESSMENT QUESTIONS

1. Each form of endocrine hypertension:
   - **A.** Always manifests typical signs and symptoms
   - **B.** Can always be cured if correct specific therapies are applied
   - **C.** Is usually familial
   - **D.** May present as hypertension resistant to multiple drugs
2. Initial screening tests for Cushing syndrome include which of the following?
   - **A.** Computed tomography or magnetic resonance imaging of pituitary and adrenal glands
   - **B.** Measurement of late night salivary cortisol
   - **C.** High-dose dexamethasone suppression test
   - **D.** Bilateral inferior petrosal sinus sampling for ACTH
3. Adrenal incidentalomas are:
   - **A.** Usually hormonally active
   - **B.** Associated with subclinical hypercortisolism in about 30% of cases
   - **C.** Adrenal carcinomas in over 5% of cases
   - **D.** Are not associated with any higher prevalence of hypertension than in the general population without incidentaloma

Neurogenic Hypertension, Including Hypertension Associated With Stroke or Spinal Cord Injury

Venkatesh Aiyagari, Mohamed Osman, Philip B. Gorelick

An intimate relationship exists between the nervous system and blood pressure (BP).[1] It is well recognized that the elevated BP response to stressors is mediated by the sympathetic nervous system (SNS). However, the role of the SNS in long-term regulation of BP and the initiation and maintenance of hypertension is now better delineated. Several studies of serum catecholamine levels, renal norepinephrine spillover, microneurography, and heart rate variability suggest that sympathetic activation plays a major role in hypertensive patients.[2] The SNS also has an important role in hypertension after neurologic injury. In this chapter, we discuss the physiology and management of hypertension in such injury.

PHYSIOLOGY AND PATHOPHYSIOLOGY

Neural Control of Blood Pressure

The brainstem, especially the ventral medulla, has a key role in the maintenance of BP (Fig. 40.1). BP is controlled by the nucleus tractus solitarius, which receives inhibitory baroreceptor afferents, and the rostral ventrolateral medulla and rostral ventromedial medulla, which are the source of excitatory descending bulbospinal pressor pathways. In addition, a depressor center in the caudal ventrolateral medulla composed of γ-aminobutyric acid (GABA)-containing neurons receives afferents from the nucleus tractus solitarius and projects to the rostral ventral medulla. These inhibitory GABA-containing neurons are tonically active, and reduced activity of these neurons leads to hypertension.[3-5]

The ultimate effector units are the sympathetic neurons located in the intermediolateral cell column of the spinal cord and the parasympathetic neurons found in the dorsal motor nucleus of the vagus and nucleus ambiguus located in the medulla. In addition, impulses from the limbic system, cerebral cortex, and hypothalamus directly or indirectly project to the intermediolateral cell column of the spinal cord and influence BP regulation.

The factors that lead to increased sympathetic activation in hypertension are poorly understood. However, there is strong evidence linking hypertension with increased levels of circulating inflammatory markers such as tumor necrosis factor α, interleukin-6, C-reactive protein, monocyte chemoattractant protein 1, and adhesion molecules such as P-selectin and intercellular adhesion molecule 1. Angiotensin II (Ang II) and aldosterone also play a crucial role in vascular inflammation, and treatment with both candesartan and mineralocorticoid antagonists decrease the levels of inflammatory markers. In addition, Ang II–mediated hypertension is associated with brain microglial activation and increased brain levels of inflammatory cytokines and reactive oxygen species. An increase in reactive oxygen species may directly activate or sensitize sympathetic neurons and scavenge nitric oxide, which tonically inhibits sympathetic outflow. Thus a dysfunction of the neural-immune-vascular triad leading to an increase in central oxidative stress may drive sympathetic activation, which then increases Ang II and promotes further inflammation and vascular dysfunction.[6]

Cerebrovascular Autoregulation

Under normal conditions, cerebral blood flow (CBF) of the adult brain is 50 ml/100 g/min. CBF is regulated by the relationship between cerebral perfusion pressure (CPP) and cerebrovascular resistance (CVR):

$$CBF = CPP/CVR$$

CPP is the difference between the mean arterial blood pressure (MAP) and the intracranial pressure (ICP). If ICP is increased, systemic BP must also increase to maintain CPP and CBF.

Cerebrovascular autoregulation maintains a constant blood flow over a wide range of CPP. Normally, changes in CPP have little effect on CBF because of compensatory changes in CVR. An increase in CPP produces vasoconstriction and a decrease produces vasodilation, thus keeping the CBF constant (Fig. 40.2). Autoregulation is effective for a range of CPP from about 60 to 150 mm Hg. In chronically hypertensive individuals, the cerebral arterioles develop medial hypertrophy and lose the ability to dilate effectively at lower pressures. This leads to a shift of the autoregulatory curve to the right.[7] In these individuals, a rapid reduction of BP may lead to a drop in CBF even though the BP might still be "normal." With effective control of hypertension for several months, the normal range for autoregulation can be reestablished.[8]

Above the upper limit of autoregulation, there is breakthrough vasodilation leading to damage of the blood-brain barrier, cerebral edema, and possibly cerebral hemorrhage. Below the lower limit of autoregulation, decreases in CPP lead to a decrease in CBF. Under these circumstances, increased extraction of oxygen and glucose maintains normal cerebral metabolism and brain function. When the CBF decreases to less than 20 ml/100 g/min, increases in oxygen extraction are no longer able to supply the metabolic needs of the brain, leading to impairment of brain function.

SPECIFIC SYNDROMES

Hypertension After Stroke

Epidemiology

BP is commonly elevated in patients with stroke. In a large retrospective analysis that examined 276,734 patients presenting to the emergency department with acute ischemic stroke, the incidence of elevated BP was 76.5%.[9] The Chinese Acute Stroke Trial (CAST) and the International Stroke Trial (IST), each enrolling approximately 20,000 patients with

Neural Pathways Involved in the Control of Blood Pressure

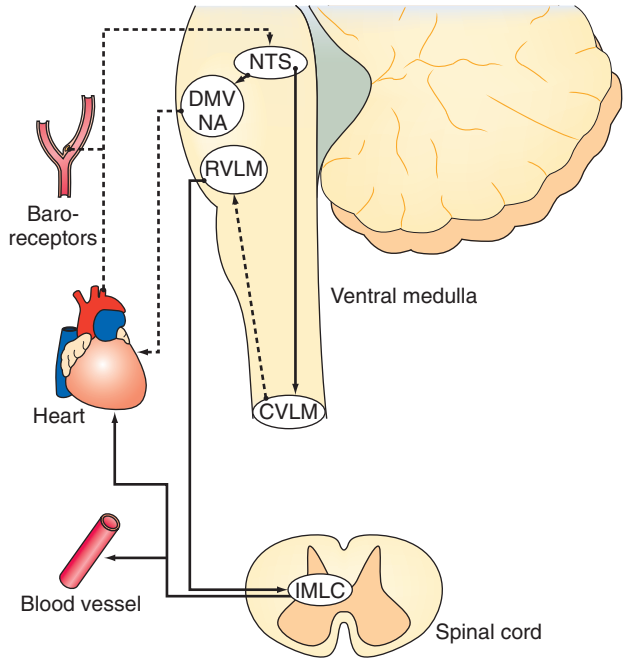

Fig. 40.1 Neural pathways involved in the control of blood pressure. The ventral medulla has a key role in generating both excitatory *(solid line)* and inhibitory *(dotted line)* pathways, largely through the rostral ventrolateral medullary neurons *(RVLM)* and nucleus tractus solitarius *(NTS),* respectively. Ultimate effector control is provided by sympathetic activation originating in the intermediolateral cell column *(IMLC)* and parasympathetic action through the nucleus ambiguus *(NA)* and dorsal motor nucleus of the vagus nerve *(DMV). CVLM,* Caudal ventrolateral medullary neurons.

ischemic stroke, reported systolic BP (SBP) above 140 mm Hg in 75% and 80% of patients and severely elevated SBP of greater than 180 mm Hg in 25% and 28%, respectively.[10,11]

Hypertension is the most important modifiable risk factor for stroke, and reduction in BP is effective in the primary prevention of both ischemic and hemorrhagic stroke; BP reduction also decreases the risk for a recurrent ischemic or hemorrhagic stroke.[12] Combined data from 40 trials show that a 10% reduction in SBP lowers stroke risk by one third.[13] A 5-mm reduction in diastolic pressure together with a 9-mm lower SBP confers a 33% lower risk for stroke, and a 10-mm lower diastolic BP (DBP) together with an 18- to 19-mm lower SBP confers more than a 50% reduction in stroke risk.[14] In patients who have had a stroke, the Perindopril Protection Against Recurrent Stroke Study (PROGRESS) showed that BP reduction was associated with reductions of 28% in stroke recurrence and 26% in major coronary and vascular events, even in normotensive subjects. This study also demonstrated a reduction of absolute rates of hemorrhagic stroke from 2% to 1% over a mean of 3.9 years of follow-up.[15]

However, the management of BP in the immediate aftermath of a stroke is controversial.[16] A high proportion of patients have elevated BP immediately after a stroke, but BP spontaneously decreases over 1 to 2 weeks to the prestroke baseline in most patients. Some of the postulated causes of elevated BP are listed in Box 40.1. An increased BP after stroke is associated with a higher mortality. Nonetheless, it is uncertain whether this increase directly contributes to poor outcome and whether immediate lowering of BP will lead to better outcomes.

Cerebral Autoregulation Curve

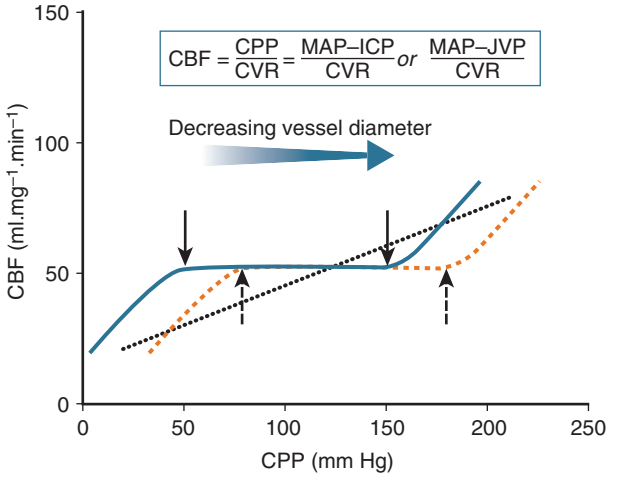

Fig. 40.2 Cerebral autoregulation curve. In the normal state *(solid line),* the cerebral blood flow *(CBF)* is held constant across a wide range of cerebral perfusion pressure *(CPP)* (60 to 150 mm Hg). In chronic hypertension *(dashed line),* the autoregulation curve shifts to the right. In the presence of acute cerebral ischemia *(dotted line),* cerebral autoregulation may be impaired, and the CBF becomes dependent on the CPP. *CVR,* Cerebral venous resistance; *ICP,* intracranial pressure; *JVP,* jugular venous pressure; *MAP,* mean arterial pressure. (Reproduced with permission from reference 17.)

BOX 40.1 Postulated Causes of Hypertension After Stroke

- Preexisting hypertension
- "White coat" effect
- Stress of hospitalization
- Cushing reflex*
- Catecholamine and cortisol release
- Lesion of brainstem or hypothalamus
- Nonspecific response to brain damage

*A hypothalamic response to raised intracranial pressure or ischemia consisting of hypertension with bradycardia.

SBP variability is significantly associated with the risk for cerebrovascular events independent of the mean BP. Home BP monitoring and ambulatory BP monitoring are useful in monitoring BP variability. Normally, BP is highest in the morning and gradually falls to reach its lowest level during sleep. Several alterations in this pattern, including a lack of nighttime decline in BP (nondippers), a rise in nighttime BP (reverse dippers), and a more than 20% fall in nighttime BP (extreme dippers), are associated with increased risk for vascular complications, including stroke. These findings also have a bearing on the choice of the antihypertensive agent for stroke prevention. Calcium channel blockers (CCBs) and nonloop diuretics appear to decrease SBP variability, whereas β-blockers, angiotensin receptor blockers (ARBs), and angiotensin-converting enzyme (ACE) inhibitors have the opposite effect.

Pathophysiology

An understanding of cerebrovascular pathophysiology is essential to understand the pros and cons of treating hypertension in these patients (Table 40.1).

TABLE 40.1 Acute Treatment of Hypertension in Stroke: Advantages and Disadvantages

Advantages	Disadvantages
Acute Ischemic Stroke	
Might lower mortality	BP decreases on its own
Might decrease stroke progression	No proven benefit
Might decrease hemorrhagic transformation (especially after tPA)	Ongoing ischemia around infarct (ischemic penumbra)
Might decrease cerebral edema formation	Altered autoregulation from chronic hypertension, ischemia
Might be helpful for systemic reasons (e.g., associated myocardial ischemia)	Large-vessel stenosis might have resulted in reduction of perfusion
	Chance of propagating thrombus
Patients likely to be more compliant with antihypertensive use if treatment initiated in hospital	Anecdotal case reports and trial results demonstrating deterioration with BP decrease
	Principle of "do no harm" *(primum non nocere)*
Acute Intracerebral Hemorrhage	
Might lower mortality	BP decreases on its own
Might decrease hematoma expansion	No proven benefit
Might decrease cerebral edema formation	Possible zone of ischemia around intracerebral hematoma
Might be helpful for systemic reasons (e.g., associated myocardial ischemia)	Chronically hypertensive patients require higher CPP, because of shift in autoregulatory curve.
Patients likely to be more compliant with antihypertensive use if treatment initiated in hospital	ICP may be elevated, and lowering BP reduces what could be marginal CPP
	Principle of "do no harm" *(primum non nocere)*
Aneurysmal Subarachnoid Hemorrhage	
Might decrease rebleeding rate	No proven benefit
Might help if there is cardiac ischemia (stunned myocardium)	ICP may be elevated, and lowering BP reduces what could be marginal CPP. Might lead to cerebral ischemia in presence of vasospasm.

BP, Blood pressure; *CPP,* cerebral perfusion pressure; *ICP,* intracranial pressure; *t-PA,* tissue plasminogen activator.

In patients with an ischemic stroke, vascular occlusion leads to a central region of irreversibly ischemic brain surrounded by an ischemic zone where blood flow is reduced but brain tissue is still viable. After 2 or 3 days, the ischemic areas either recover completely or undergo infarction. In the first few days, perfusion of the area surrounding that destined to infarction is marginal and a further decrease in blood flow might lead to infarction there as well. Because cerebral autoregulation is impaired with acute ischemic stroke, a fall in BP could lower blood flow and extend infarction. On the other hand, a very high BP could exacerbate cerebral edema or lead to hemorrhagic transformation, especially if thrombolytic agents have been given.

In patients with intracerebral hemorrhage (ICH), the considerations are different.[17] Hematoma expansion occurs in 73% of patients within 24 hours, and significant expansion (>33% increase in volume) occurs in nearly 40% of patients.[18] Hematoma expansion is frequently associated with decline in neurologic status and is an independent predictor of mortality and poor functional outcome. Therefore BP is often lowered in these patients in the hope that this might decrease hematoma expansion. However, it is not often clear if the elevation in BP is the cause or the consequence of hematoma expansion. The suggestion that there may be perihematomal ischemia around an ICH has not been supported by recent studies.[19] Furthermore, some patients with ICH might have increased ICP because of the hematoma volume or associated hydrocephalus. In such a situation, lowering of BP is not warranted because it might critically lower CPP. Monitoring of ICP and CPP may be helpful in choosing the appropriate BP target in these circumstances.

In patients with aneurysmal subarachnoid hemorrhage (SAH), there is a significant risk for rebleeding from aneurysmal re-rupture and therefore early BP control is recommended to decrease the re-bleeding risk. Some patients with SAH have associated myocardial dysfunction ("stunned myocardium"), in which case high BP might worsen myocardial function. Similar to patients with ICH, in patients with hydrocephalus or an associated ICH, ICP and CPP monitoring can help guide BP management. However, many patients develop vasospasm of the intracranial arteries at 4 to 12 days after SAH, and reduction of BP may lead to worsening of cerebral ischemia in this situation. Therefore, once the aneurysmal rupture has been adequately treated with surgical clipping or coiling, BP is usually maintained at a normal or slightly elevated level in these patients.

Diagnosis and Treatment

Acute management of hypertension in stroke is highly dependent on the type of stroke (ischemic vs. hemorrhagic) and for ischemic stroke the use of thrombolysis. The benefits of lowering BP to prevent hematoma expansion in the setting of ICH or hemorrhagic transformations of ischemic stroke should be balanced with the risk for abrupt reduction of CBF in chronically hypertensive patients with shifted cerebrovascular autoregulation, especially if increased ICP and cerebral edema are present.

It is important to distinguish between hypertensive encephalopathy, in which lowering of BP is clearly indicated, and ischemic stroke with hypertension, in which urgent lowering of BP may not be warranted. The level of consciousness, the presence of focal neurologic deficits, and the funduscopic examination can help in making this distinction. Hypertensive encephalopathy is a syndrome of global neurologic dysfunction, usually with papilledema. Focal neurologic deficits are usually less prominent. In acute ischemic stroke, the focal neurologic deficit is prominent and the symptoms and neurologic signs often can be mapped to the vascular territory supplied by a specific cerebral blood vessel. Early alterations of consciousness are less common except with brainstem strokes or when there is "malignant" brain edema secondary to a massive hemispheric infarction.

Several recent studies assess the benefits and risks of BP lowering after ischemic and hemorrhagic stroke. A Cochrane review on this topic concluded that more research is needed to evaluate and identify the candidates most likely to benefit from management of BP in the acute phase of stroke, and the timeframe for such intervention.[20]

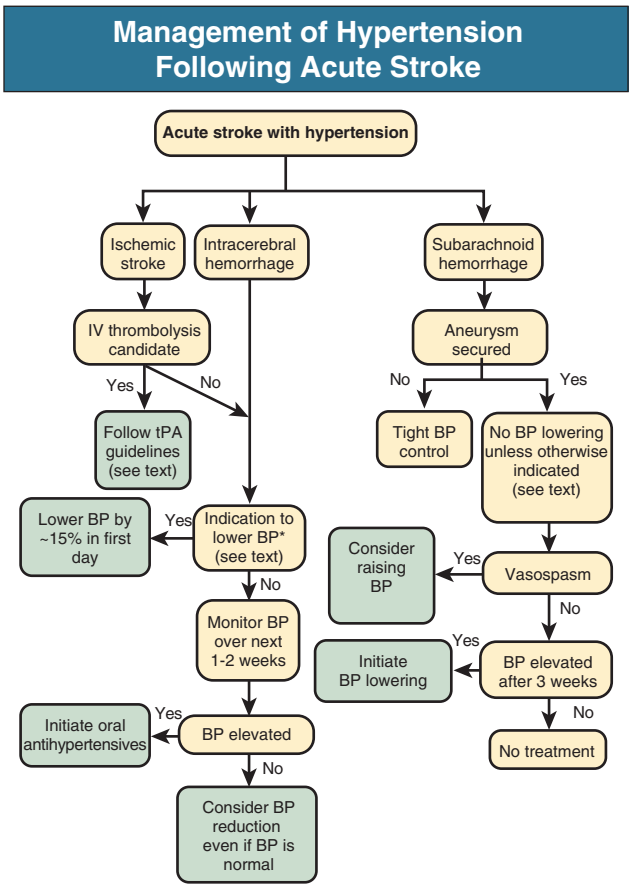

Fig. 40.3 Management of hypertension after acute stroke. *Indication for treatment includes systolic BP above 220 mm Hg or diastolic BP above 120 mm Hg for ischemic stroke, the presence of associated conditions such as aortic dissection or myocardial infarction, and, in cases of cerebral hemorrhage, systolic BP above 180 mm Hg or mean arterial pressure above 130 mm Hg. *BP,* Blood pressure; *IV,* intravenous; *tPA,* tissue plasminogen activator.

An overview of recommendations for treating BP in different clinical situations is outlined in Fig. 40.3.

Acute ischemic stroke. Several large prospective trials of BP lowering in acute ischemic stroke have been completed and are summarized in Table 40.2.[21-29]

The current guidelines of the American Heart Association/American Stroke Association (AHA/ASA) and the European Stroke Organisation (ESO) for BP management in acute ischemic stroke recommend a cautious approach to lowering BP in acute ischemic stroke. Patients receiving thrombolytic therapy should have their BP lowered to less than 185/110 mm Hg before the administration of the thrombolytic agent and maintained at a level of less than 180/105 mm Hg for at least the first 24 hours after thrombolytic treatment. Patients not receiving thrombolytic agents should have antihypertensive medications withheld unless the SBP is greater than 220 mm Hg or the DBP is greater than 120 mm Hg, in which case a 15% reduction in BP in the first 24 hours appears reasonable. Recommendations are summarized in Table 40.3.

Thus the available evidence does not support immediate BP reduction after an acute ischemic stroke. Based on the limited data and natural history of BP after ischemic stroke, treatment of newly diagnosed previously untreated hypertension or resumption of long-term antihypertensive medication can be initiated or resumed gradually after the first 24 hours. Reduced dosage and/or number of agents from the prestroke regimen should be used to avoid rapid reduction of BP in the case of prior outpatient noncompliance.

Intracerebral hemorrhage. Hypertension is the most important modifiable risk factor for ICH. Although long-term benefit in lowering BP in patients with ICH is widely accepted, it remains unclear if elevated BP should be lowered in the acute phase. In recent years, a few randomized trials have attempted to address the issue of acute BP lowering in ICH and are summarized in Table 40.4.[30-34]

The currently recommended guidelines of the AHA/ASA and the European Stroke Initiative (ESI) for BP management in acute ICH are summarized in Table 40.5.[35,36] It should be noted that these guidelines were published before the publication of the results of Antihypertensive Treatment of Acute Cerebral Hemorrhage 2 (ATACH 2). Similar to the case in acute ischemic stroke, the current evidence does not demonstrate lower rates of mortality or severe disability with aggressive BP reduction in patients with cerebral hemorrhage. If elevated ICP is of concern, such as in patients with large hemorrhages or with hydrocephalus, ICP should be monitored to ensure that the CPP is appropriate before significant BP reduction. In other instances, it is reasonable to keep the SBP below 180 mm Hg. Definitive evidence to support lower BP targets (e.g., <140 mm Hg) in the acute setting is currently lacking.

Subarachnoid hemorrhage. Before definitive treatment of the ruptured aneurysm, SBP is usually kept below 160 mm Hg, although there is no conclusive evidence that higher BPs increase rebleeding rates. In patients with suspected elevation of ICP, it is important to monitor ICP and keep the CPP above 70 mm Hg. The AHA/ASA guidelines recommend monitoring and control of BP to balance the risk for stroke, hypertension-related bleeding, and maintenance of CPP. An SBP goal of less than 160 mm Hg is considered reasonable.[37] The ESO recommends keeping the SBP below 180 mm Hg but keeping the MAP greater than 90 mm Hg.[38] After the ruptured aneurysm has been secured, aggressive treatment of BP should be avoided, and in the setting of cerebral vasospasm, BP is usually elevated using vasopressors until the neurologic deficits resolve, often as high as an SBP of 200 to 220 mm Hg.

Hypertension After Carotid Endarterectomy and Endovascular Procedures

Definition, Incidence, and Clinical Features

Hemodynamic disturbances such as hypotension, bradycardia, and hypertension are common (10% to 40%) after carotid endarterectomy and endovascular procedures such as angioplasty and stenting. A small percentage of these patients develop carotid hyperperfusion (or reperfusion) syndrome. This syndrome occurs in the first week after surgery or angioplasty-stenting and manifests as transient or permanent contralateral neurologic signs, ipsilateral pulsatile headache, seizures, ICH, or reversible cerebral edema.[39-41] Some subjects with postrevascularization cerebral hyperperfusion may not manifest clinical signs acutely but may later develop cortical neuronal loss and cognitive impairment.[42]

After carotid endarterectomy, the incidence of postoperative severe hypertension is reported as 19% and that of carotid hyperperfusion syndrome as 1%. Most cases occurred in the first week and the average time to symptoms was the fifth postoperative day. Seizures (36%), hemiparesis (31%), or both (33%) were the common presenting features, and 59% of patients had headache.[43]

Pathophysiology

Preexisting hypertension, baroreceptor impairment after surgical manipulation, and elevated catecholamine levels after cerebral hypoperfusion during intraoperative cross-clamping may contribute to postoperative hypertension that contributes to cerebral hyperperfusion. The hyperperfusion syndrome may be due, in part, to impaired autoregulation from chronic vasodilation of the distal vascular bed ipsilateral to a hemodynamically significant internal carotid artery stenosis.[44] Other postulated mechanisms include activation of the trigeminovascular axon reflex and derangement of the carotid baroreceptors.[45] Subjects at risk

TABLE 40.2 Major Trials of Acute Blood Pressure Reduction in Ischemic Stroke

Trial	Study Design	Study Arms	Number of Patients	Results
Acute Candesartan Cilexetil Evaluation in Stroke Survivors (ACCESS)[21]	Prospective, double-blind, placebo-controlled, randomized, multicenter, phase 2	Candesartan versus placebo	342	Lower 12-month mortality and vascular events in the candesartan group, but no significant difference in BP between the two arms
Scandinavian Candesartan Acute Stroke Trial (SCAST)[22]	Prospective, double-blind, placebo-controlled, randomized, multicenter	Candesartan versus placebo	2029 (274 had cerebral hemorrhage)	During 6 months of follow-up, the risk of the composite vascular end-point did not differ between treatment groups. Analysis of functional outcome suggested a higher risk for poor outcome in the candesartan group.
Controlling Hypertension and Hypotension Immediately Post-Stroke (CHHIPS)[23]	Prospective, double-blind, placebo-controlled, randomized, multicenter	Labetalol versus lisinopril versus placebo	179 (25 had cerebral hemorrhage)	No difference in death or dependency at 2 weeks, early neurologic deterioration, or serious adverse event.
Continue Or Stop post-Stroke Antihypertensive Collaborative Study (COSSACS)[24]	Prospective, open, multicenter, randomized, blinded-end-point trial	Continue versus stop preexisting antihypertensive drugs	763 (38 had cerebral hemorrhage)	Continuation of antihypertensive drugs did not reduce 2-week death or dependency, cardiovascular event rate, or mortality at 6 months.
Glycine Antagonist in Neuroprotection (GAIN International)[25]	Prospective, double-blind, placebo-controlled, randomized, multicenter	Gavestinal versus placebo	1445	A 30% drop in mean arterial pressure from baseline was not associated with poor outcome.
Intravenous Nimodipine West European Stroke Trial (INWEST)[26]	Prospective, double-blind, placebo-controlled, randomized, multicenter	Placebo versus low-dose versus high-dose nimodipine	265	Patients with a DBP reduction of ≥20% in the high-dose group had a significantly increased adjusted odds ratio for the compound outcome variable death or dependency.
Chinese Antihypertensive Trial in Acute Ischemic Stroke (CATIS)[27]	Prospective, single-blind, randomized, blinded end-point, multicenter	Antihypertensive treatment versus discontinuing all antihypertensives	4071	BP reduction with antihypertensive medications, compared with the absence of hypertensive medication, did not reduce the likelihood of death and major disability at 14 days or hospital discharge.
Efficacy of Nitric Acid in Stroke (ENOS)[28]	Prospective, multicenter, randomized, placebo-controlled, patient-masked, outcome-assessor-masked, parallel-group trial	Glyceryl trinitrate versus no treatment; subset taking antihypertensive medications on admission randomized to taking versus stopping them	4011 (629 had cerebral hemorrhage)	Transdermal glyceryl trinitrate lowered BP and had acceptable safety but did not improve functional outcome. There was no evidence to support continuing prestroke antihypertensive drugs in patients in the first few days after acute stroke.
Valsartan Efficacy on Modest Blood Pressure Reduction in Acute Ischemic Stroke (VENTURE)[29]	Prospective, multicenter, randomized, open-label, blinded-end-point trial	Valsartan versus no treatment	393	Early reduction of BP with valsartan did not reduce death or dependency and major vascular events at 90 days, but increased the risk for early neurologic deterioration.

BP, Blood pressure; *DBP,* diastolic blood pressure.

for development of this syndrome are those with extensive microvascular disease, preoperative hypoperfusion and impaired autoregulation, or postoperative hyperperfusion.

Diagnosis and Treatment

Cerebral hyperperfusion represents a postoperative increase in CBF of more than 100% compared with preoperative flow. However, this increase in blood flow may be only approximately 20% compared with the contralateral side.[46] Making a diagnosis based on CBF doubling alone may lead to a significant overestimation of the incidence, and the following four criteria have been suggested: (1) Occurrence within 30 days post–carotid endarterectomy; (2) evidence of hyperperfusion (on transcranial Doppler, single-photon emission computed tomography, or computed tomography (CT)/magnetic resonance (MR) perfusion imaging) or SBP greater than 180 mm Hg; (3) clinical features such as new headache, seizures, hemiparesis, Glasgow coma scale less than 15, or radiologic features such as cerebral edema or ICH; and (4) no evidence of new cerebral ischemia, postoperative carotid occlusion, or metabolic or pharmacologic cause to explain the findings.[43]

Because of the risk for development of carotid hyperperfusion syndrome after carotid endarterectomy or stenting, all patients should have continuous intraoperative and postoperative BP monitoring. Most authors advocate strict BP control (SBP <120 mm Hg) from the time of intraoperative internal carotid artery unclamping or angioplasty, particularly in high-risk patients.[47] If high-risk features are absent, aiming for SBP of 140 to 160 mm Hg or preoperative SBP (if lower) in the postoperative period is reasonable. Elevated BP should be treated with intravenous labetalol or clonidine. Vasodilators such as nitroglycerin

TABLE 40.3 Guidelines for Blood Pressure Management After Acute Ischemic Stroke

AHA/ASA	ESO
Patients Eligible for Thrombolytic Therapy ***Before Thrombolytic Therapy*** Lower BP if SBP >185 or DBP >110 mm Hg. ***After Thrombolytic Therapy*** Lower BP if SBP >180 or DBP >105 mm Hg.	Routine BP lowering is not recommended. Cautious BP lowering is recommended in patients with extremely high BP (>220/120 mm Hg) on repeated measurements, or with severe cardiac failure, aortic dissection, or hypertensive encephalopathy. Abrupt BP lowering should be avoided. BP must be below 185/110 mm Hg before, and for the first 24 hours after, thrombolysis.
Patients Not Eligible for Thrombolytic Therapy Patients with markedly elevated BP may have their BP lowered. Lowering BP by ~15% in these patients is reasonable. Antihypertensive drugs should be withheld unless SBP >220 or DBP >120 mm Hg.

TABLE 40.5 Guidelines for Blood Pressure Management After Acute Cerebral Hemorrhage

AHA/ASA	ESO
For ICH patients presenting with SBP between 150 and 220 mm Hg and without contraindication to acute BP treatment, acute lowering of SBP to 140 mm Hg is safe (Class I; Level of Evidence A) and can be effective for improving functional outcome (Class IIa; Level of Evidence B).	In acute ICH within 6 hours of onset, intensive BP reduction (SBP target <140 mm Hg in <1 hour) is safe and may be superior to SBP target of <180 mm Hg. No specific agent can be recommended. (Quality of evidence: Moderate; Strength of recommendation: Weak).
For patients with ICH presenting with SBP >220 mm Hg, it may be reasonable to consider aggressive reduction of BP with a continuous intravenous infusion and frequent BP monitoring (Class IIb; Level of Evidence C).

TABLE 40.4 Major Trials of Acute Blood Pressure Reduction in Cerebral Hemorrhage

Trial	Study Design	Study Arms	Number of Patients	Results
Koch et al.[30]	Prospective, randomized	Target MBP <110 or 110-130 mm Hg	42	No significant differences in early neurologic deterioration, hematoma and edema growth, and clinical outcome.
INTERACT[31]	Prospective, randomized, blinded end-point assessment	Target SBP <140 or <180 mm Hg	404	No significant difference in hematoma growth between the two tiers after adjustment for baseline hematoma volume and time to CT scan.
INTERACT 2[32]	Prospective, randomized, blinded end-point assessment	Target SBP <140 or <180 mm Hg	2839	No significant reduction in the rate of primary outcome of death or severe disability with intensive lowering of BP. Improved functional outcomes with lower BP target on ordinal analysis of modified Rankin Scale score.
ATACH[33]	Prospective, Phase I dose-escalation	Target SBP 110-140 or 140-170 or 170-200 mm Hg	60	Observed proportions of neurologic deterioration and serious adverse events below the prespecified safety thresholds; 3-month mortality rate lower than expected in all tiers.
ATACH 2[34]	Prospective, randomized, multicenter, open-label trial	Target SBP 110-140 or 140-179 mm Hg	1000	BP reduction to a target SBP of 110 to 139 mm Hg did not result in a lower rate of death or disability than a target of 140 to 179 mm Hg. The rate of renal adverse events within 7 days after randomization was significantly higher in the group with the lower BP target.

BP, Blood pressure; *CT,* computed tomography; *MAP,* mean arterial blood pressure; *SBP,* systolic BP.

and sodium nitroprusside should be avoided. Because this syndrome may occur after patients have been discharged from the hospital, it is important for physicians to ensure that BP is appropriately controlled even after the immediate postoperative period.

Hypertension After Spinal Cord Injury

Definition and Epidemiology

Autonomic dysreflexia occurs in up to 70% of persons after spinal injury, most often during the first 2 to 4 months after injury. It is defined as an increase in SBP by at least 20%, associated with a change in heart rate and accompanied by at least one sign (sweating, piloerection, facial flushing) or symptom (headache, blurred vision, stuffy nose).[48] If it is unrecognized, it can result in serious sequelae, such as posterior leukoencephalopathy, ICH, SAH, seizures, arrhythmia, pulmonary edema, retinal hemorrhage, and, rarely, coma or death.[49]

Pathophysiology and Diagnosis

Autonomic dysreflexia is most commonly seen in patients with complete spinal cord injury in which there is loss of all neurologic function below the level of the lesion. The spinal cord lesion is typically at or above the sixth thoracic spinal level. Immediately after the injury, there is initial loss of supraspinal sympathetic control similar to the initial period

of muscle flaccidity. This often leads to hypotension and bradycardia (spinal shock). After a few weeks to months, there is extrajunctional sprouting of the α-receptors, denervation hypersensitivity, and impaired presynaptic uptake of norepinephrine. In addition, there may be derangement of spinal glutaminergic interneurons. Noxious stimuli below the neurologic level of the lesion trigger a spinal reflex arc that results in increased sympathetic tone and hypertension.[50] The most common inciting events are an overdistended urinary bladder and fecal impaction. However, it may be secondary to other precipitants, including infections, pressure ulcers, urologic and endoscopic procedures, sympathomimetic medications, and sildenafil citrate used for sperm retrieval.[51]

Clinical symptoms include pulsatile headache, blurred vision, anxiety, nasal congestion, nausea, and sweating above the involved spinal level. The flushed, sweaty skin above the lesion level is due to brainstem parasympathetic activation. At and below the lesion, the skin remains pale, cool, and dry. Heart rate can be quite variable from bradycardia to tachycardia. The hallmark physical finding is elevated BP. However, because BP may normally be quite low after spinal cord injury, baseline BP readings may be within the normal range but elevated for a given individual, making clinical suspicion and reliance on other clinical signs and symptoms paramount in the diagnosis if baseline BP is not known.[50]

Treatment

Vigilant preventive measures for autonomic dysreflexia include proper bowel, bladder, and skin care. However, expeditious treatment of elevated BP is critical to avoid the potentially life-threatening consequences. Placement of the patient upright with the legs lowered to reduce BP and removal of any possible noxious stimuli (such as binding clothing and devices) are the initial treatments. It is also important to look for and appropriately treat other common triggers such as urinary retention or constipation.

Pharmacologic treatment with rapid-acting, short-lived agents may be indicated for SBP elevation of 150 mm Hg or greater that persists after the preceding interventions. Nitroglycerin is often used to treat hypertension associated with autonomic dysreflexia. However, to avoid precipitating hypotension, nitrate-containing agents should not be given for 24 hours before the use of sildenafil or similar agents to facilitate sperm retrieval or treat erectile dysfunction in spinal cord injury. CCBs and ACE inhibitors also have been reported to be effective.[52] However, these agents might exacerbate resting hypotension and therefore should be used with caution. Prazosin has been reported to be effective in reducing the severity of autonomic dysreflexia without significantly lowering the resting BP. If the bladder is empty and the BP is below 150 mm Hg, fecal disimpaction with topical anesthetic should be attempted. If dysreflexia is refractory or associated with severe clinical presentation, other precipitants should be sought and hospitalization may be indicated.[53]

Up to 90% of pregnant women with upper spinal cord injury experience autonomic dysreflexia during labor and delivery. Appropriate epidural or spinal anesthesia techniques can ameliorate the risk.[54]

Cerebrovascular Effects of Antihypertensive Agents

Different classes of antihypertensive agents have different direct effects on the CBF, ICP, and autoregulation. The ideal drug would not increase ICP or decrease blood flow to ischemic regions. In addition, in treatment of hypertension in the acute setting, drugs that can be given intravenously, have a short half-life and do not cause sedation are preferable. In the chronic phase after a stroke, adequate BP lowering is key and there is no clear evidence favoring one class of antihypertensive agent over another; however, one may consider avoiding the use of nonselective β-blockers that may increase SBP variability.

The advantages and disadvantages of various classes of antihypertensive agents after acute stroke are summarized in Table 40.6.

β-Adrenergic antagonists (e.g., esmolol) and combined α- and β-adrenergic receptor antagonists (e.g., labetalol) do not increase ICP or affect cerebral autoregulation. They are suitable for treatment of hypertension in the setting of acute cerebral ischemia or increased ICP. However, bradycardia secondary to increased ICP is a relative contraindication.

Vasodilators (e.g., hydralazine, sodium nitroprusside, nitroglycerin) cause cerebral arterial dilation and venodilation and can theoretically

TABLE 40.6 Preferred Antihypertensive Agents in the Treatment of Stroke-Associated Hypertension

Drug	Mechanism of Action	Intravenous Dose	Advantages	Disadvantages
Labetalol	α_1-, β_1-, and β_2-Receptor antagonist	Test dose 5 mg, then 20- to 80-mg bolus every 10 min up to 300 mg; IV infusion 0.5-2 mg/min	Does not lower CBF Does not increase ICP	May exacerbate bradycardia
Esmolol	β_1-Receptor antagonist	500-mcg/kg bolus, then 50-300 mcg/kg/min	Does not lower CBF Does not increase ICP	May exacerbate bradycardia
Sodium nitroprusside	Vasodilator	0.25-10 mcg/kg/min	Potent antihypertensive	May increase ICP Can cause cerebral steal Potential for cyanide toxicity
Nitroglycerin	Vasodilator	5-200 mcg/min	Can be helpful for concomitant cardiac ischemia	May increase ICP Can cause cerebral steal
Hydralazine	Vasodilator	2.5- to 10-mg bolus	Can be given as IV bolus when labetalol is contraindicated because of bradycardia	May increase ICP Can cause cerebral steal
Nicardipine	L-type CCB	5-15 mg/h	Does not decrease CBF	May increase ICP Long duration of action
Enalaprilat	ACE inhibitor	0.625-1.25 mg every 6 hr	Does not decrease CBF	Variable response Long duration of action

ACE, Angiotensin-converting enzyme; *CBF,* cerebral blood flow; *CCB,* calcium channel blocker; *ICP,* intracranial pressure.

increase ICP and cause a cerebral steal phenomenon in patients with acute cerebral ischemia. Other disadvantages of sodium nitroprusside are tachyphylaxis, the need to shield the medication from light because of its photosensitivity, and the danger of cyanide and thiocyanate toxicity that may be difficult to detect in patients with brain injury. However, they may be used in patients with small and moderate-sized ICH and in patients with SAH if increased ICP is not a concern.

CCBs have varying effects on cerebral autoregulation. Nifedipine can lead to severe reduction in BP and is not recommended. Nimodipine is used routinely in patients with SAH because it has been shown to improve outcome, possibly due to a neuroprotective effect. Nicardipine has been used in patients with acute ICH without any change in CBF and is often used in patients with SAH. It is becoming quite popular in neurocritical care units because of its efficacy, ease of titration, predictable response, and favorable cerebral hemodynamic effects.

ACE inhibitors and the ARB candesartan have been used in patients with acute cerebral ischemia and have no effect on CBF. However, short-acting parenteral forms of these drugs are not available. ACE inhibitors and ARBs shift the lower limit of cerebral autoregulation toward lower BP in rats and humans. However, these agents have a long half-life, which is not desirable in treatment of hypertension in the acute phase.

Similarly, because of its long half-life and sedative effect, the α_2-adrenergic agonist clonidine is not preferred.

The cerebrovascular effects of the newer parenteral antihypertensives such as fenoldopam, a peripheral dopamine-1 receptor agonist, and clevedipine, a CCB, have not been extensively studied. However, in small studies, fenoldopam has been shown to decrease global CBF and increase ICP in patients with impaired intracranial compliance.[55] In a small single-center study, clevedipine was found to be safe and effective in perioperative neurosurgical patients with hypertension.[56]

SELF-ASSESSMENT QUESTIONS

1. A 55-year-old man with long-standing hypertension presents with acute right hemiplegia. The onset of symptoms was 45 minutes before presentation. His blood pressure (BP) on presentation is 200/110 mm Hg and his noncontrast head CT scan is normal. He is given 10 mg labetalol and his BP is now 175/105 mm Hg. Intravenous tPA is administered for acute ischemic stroke. An hour later, his BP is noted to be 170/110 mm Hg. Which of the following statements best characterizes BP management in this case?
   - **A.** The patient should not have been given intravenous tissue plasminogen activator (tPA) because his BP (175/105 mm Hg) was too high.
   - **B.** The patient's current BP of 170/110 mm Hg needs to lowered with intravenous labetalol or nicardipine.
   - **C.** Sublingual nifedipine is the drug of choice in the acute management of elevated BP in the setting of an acute stroke.
   - **D.** BP should be increased using vasopressors to augment cerebral perfusion.
   - **E.** None of the above.
2. A 60-year-old man with poorly controlled BP presents to the emergency department with left hemiparesis that was first noticed 2 days ago. He is awake, fully alert, and oriented. His strength on the right side is normal. His head CT scan shows a 2- × 2-cm right putaminal hemorrhage with no hydrocephalus or intraventricular extension. His BP is 150/85 mm Hg. Which of the following statements best characterizes BP management in this case?
   - **A.** This patient has a >50% chance of clinically significant expansion of his ICH over the next 48 hours if his BP is not lowered acutely.
   - **B.** BP should be lowered immediately to <120/80 mm Hg with intravenous nicardipine to prevent hematoma expansion.
   - **C.** He should have an intracranial pressure monitor inserted to measure intracranial pressure.
   - **D.** There is an area of ischemia surrounding an ICH that may increase in size with additional BP lowering.
   - **E.** None of the above.
3. Which of the following features best characterizes carotid hyperperfusion syndrome after a carotid endarterectomy?
   - **A.** Headache
   - **B.** Intracerebral hemorrhage
   - **C.** Increase in cerebral blood flow ipsilateral to the endarterectomy
   - **D.** Seizures
   - **E.** All of the above

Renovascular Hypertension and Ischemic Nephropathy

Barbara A. Greco, Kausik Umanath

NORMAL RENOVASCULAR ANATOMY

The clinical presentations of renovascular disease are influenced by the acuity, nature, and site of renal vascular compromise. In most individuals, the kidney has a single renal artery (RA) with a lumen diameter of 3 to 7 mm. The main RA branches in a double or triple fork pattern or, less commonly, a ladder pattern.[1] The incidence of multiple RAs is about 31%, with bilateral supernumerary arteries in 11%.[2] The right RA usually passes posterior to the inferior vena cava (IVC), but rarely can be precaval. The collaterals to the kidney, depicted in Fig. 41.1, can maintain renal parenchymal viability in the face of main RA occlusion. The factors determining the development and caliber of these vessels are poorly understood but include individual anatomy, status of the aorta, rate of progression of main RA narrowing, and condition of the intrarenal perforating arteries.

CLINICAL SYNDROMES ASSOCIATED WITH RENAL VASCULAR DISEASE

Reduction or loss of renal arterial or venous blood flow is associated with one or more distinct clinical syndromes. These are summarized in Box 41.1. Discussion of these syndromes as distinct entities is meant to help with recognition and understanding. However, more often in clinical practice there is significant overlap. The first section will focus on the three most common clinical presentations of RA stenosis: renovascular hypertension (RVH), ischemic renal disease (IRD), and unstable cardiac syndromes. The second section will address the distinct clinical presentations of renal infarction, atheroembolic disease, and renal vein thrombosis.

RENOVASCULAR HYPERTENSION

A seminal observation in blood pressure (BP) regulation is the observation that a reduction in renal perfusion pressure activates a series of hormonal and neuronal responses that raise systemic arterial pressure to restore RA perfusion pressures.[3] RVH is defined as a syndrome of elevated BP (systolic and/or diastolic) produced by any condition that leads to reduced perfusion of the kidneys.

Central to the pathogenesis of RVH is activation of the renin-angiotensin-aldosterone system (RAAS) with release of renin from the juxtaglomerular apparatus. This is mediated in part by stimulation of neuronal nitric oxide (NO) synthase and cyclooxygenase-2 in the macula densa. Blockade of RAAS during creation of an experimental RA stenosis prevents development of hypertension.[4] Studies in transgenic mice without receptors for angiotensin confirm that development of RVH requires an intact RAAS.[5] In the absence of RAAS blockade, systemic arterial pressures increase until renal perfusion is restored. Studies in experimental models and humans indicate that additional mechanisms contribute to long-term BP elevation in the presence of RA stenosis, including activation of the sympathetic nervous system, impairment of NO generation, release of endothelin, and hypertensive microvascular injury to the kidney.[6]

Mechanisms responsible for sustained RVH differ depending on whether one or both kidneys are affected and have been studied in animal models in which RA perfusion is reduced by clipping the vessel proximally. The nomenclature distinguishes between a situation in which one clip is present with a normal contralateral unclipped kidney ("1-clip–2-kidney hypertension") and a situation in which the entire renal mass is affected ("1-clip–1-kidney hypertension"). Both these situations begin with impaired renal perfusion and initial activation of RAAS with sodium retention. However, in the 1-clip–2-kidney hypertension model, the elevated pressure generated by RAAS activation mediates a pressure natriuresis in the nonstenotic kidney. This restores plasma volume and results in sustained hypoperfusion of the poststenotic kidney and RAAS activation. This sequence of events produces angiotensin II (Ang II)-dependent hypertension (Fig. 41.2A).

By contrast, 1-clip–1-kidney hypertension represents a model in which the entire renal mass is exposed to reduced perfusion pressure. As a result, sodium retention leads to expanded blood volume and sustained elevation in pressure, which then restores renal perfusion pressure beyond the stenosis and inhibits RAAS activation (see Fig. 41.2B).

Box 41.2 lists causes of RVH based on these mechanisms. Some screening tests for RVH rely on comparison of the different physiologic responses of the two kidneys to maneuvers and are less sensitive in the setting of bilateral renovascular disease. Also, 1-clip–1-kidney hypertension is typically more volume than Ang II dependent. It may be less responsive to RAAS blockade than 1-clip–2-kidney hypertension.

A fall in renal perfusion pressure sufficient to activate the RAAS occurs when luminal stenosis is relatively severe, usually in the range of at least 60% to 80% cross-sectional diameter reduction (Fig. 41.3). In experimental models, the relative importance of pressor mechanisms, including measurable activation of the RAAS, changes with time. Levels of circulating plasma renin activity tend to decrease. Several mechanisms have been proposed to explain such changes, including a slowly developing pressor action of Ang II, transition to alternative

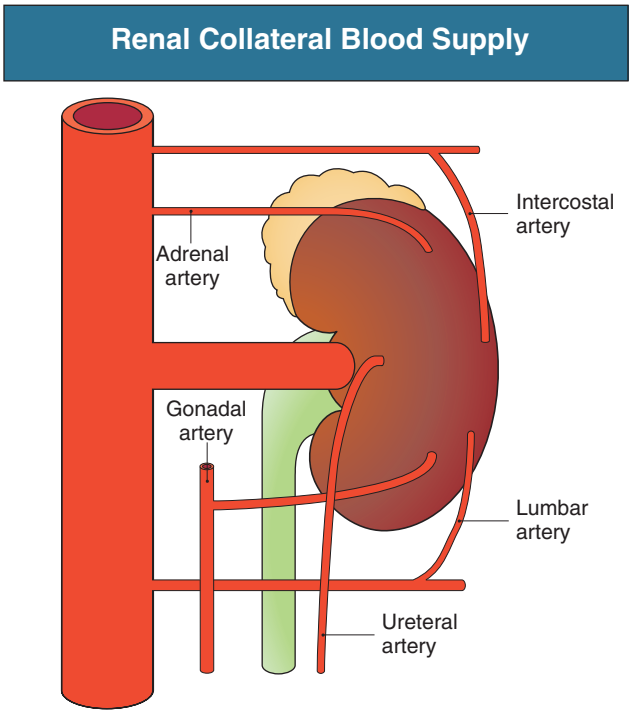

Fig. 41.1 Renal collateral circulation. Diagrammatic representation of the potential collateral arterial vessels to the kidney.

pressor mechanisms, and hypertensive injury to the nonstenotic kidney. In experimental models, this translates into a time limit for reversibility of RVH by removal of the clip. Clinically, this makes it difficult to determine when patients are most likely to benefit from endovascular or surgical RA revascularization.

Recent guidelines emphasize the need for effective population-wide BP control while limiting the cost of evaluation and management. As a result, most patients with hypertension simply are treated and subjected to few laboratory investigations. For those who reach target BP, no further studies are performed. Widespread application of RAAS blockers in the management of hypertension, congestive heart failure (CHF), and diabetic and other proteinuric nephropathies has increased the exposure of individuals with undetected RVH to these agents. Therefore many cases of RVH go undiagnosed unless hypertension becomes more difficult to control or kidney dysfunction develops. Patients who typically undergo diagnostic evaluation for RA stenosis are a subset of patients with more severe or resistant hypertension or those presenting with unstable renal or cardiac syndromes.

BOX 41.1 Clinical Syndromes Associated With Renovascular Disorders

- Renovascular hypertension
- Ischemic renal disease
- Unstable cardiac syndromes
- Renal infarction
- Atheroembolic renal disease
- Renal vein thrombosis

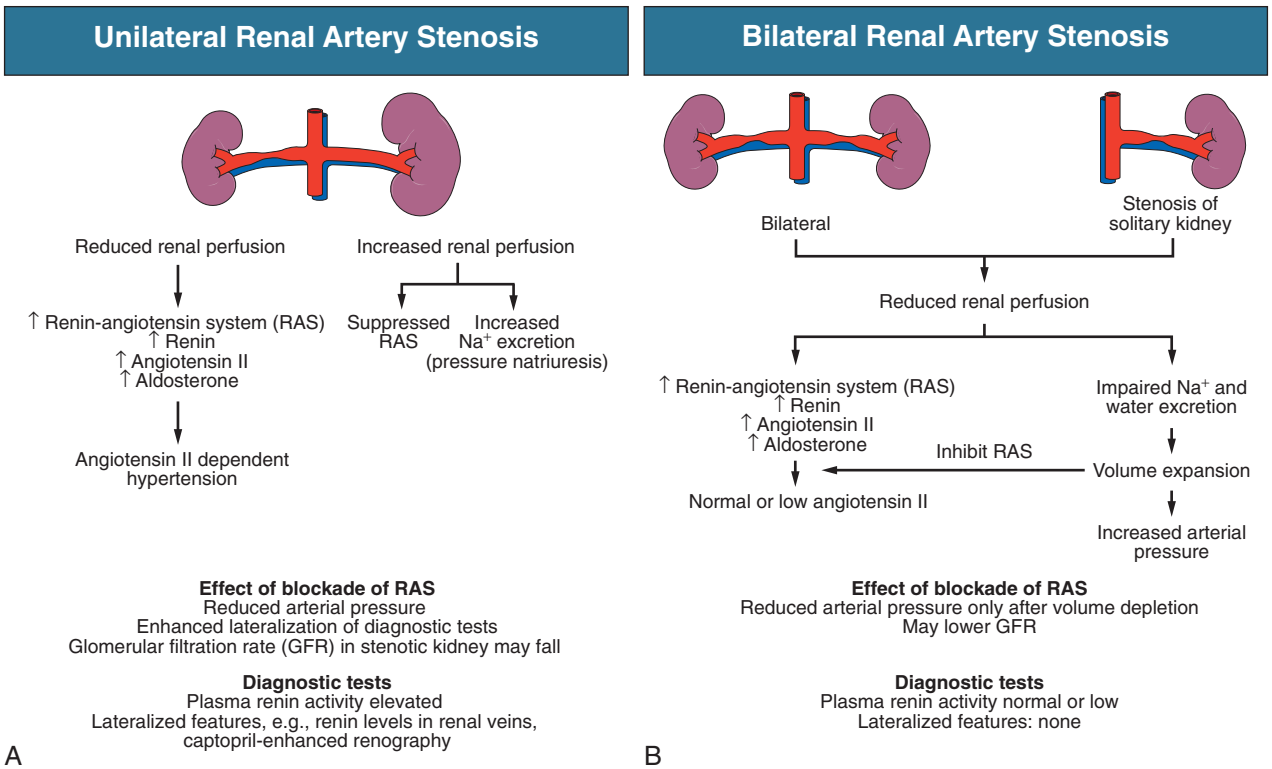

Fig. 41.2 Pathogenesis of renovascular hypertension in one-kidney versus two-kidney model. (A) In unilateral stenosis with two kidneys, opposing forces between the stenotic kidney, which has reduced perfusion pressures, and the nonstenotic contralateral kidney, which has increased perfusion pressures, result in laboratory and clinical features of angiotensin-dependent hypertension. (B) In unilateral stenosis with a solitary functioning kidney or in a patient with bilateral critical renal artery stenosis, reduced perfusion pressure to the stenotic kidney in the absence of a normal kidney excreting sodium leads to sodium and volume retention, ultimately associated with hypertension without persistent activation of the RAS.

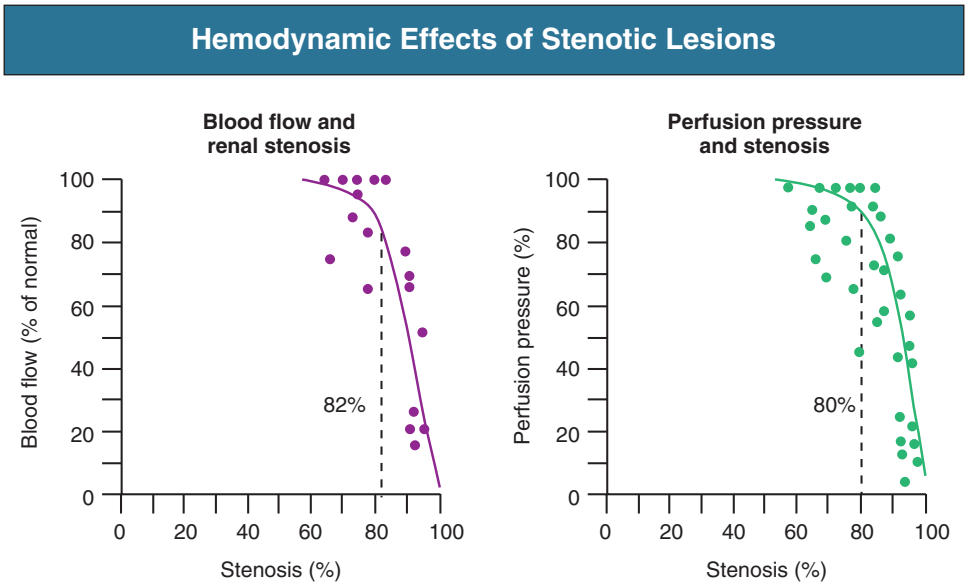

Fig. 41.3 Hemodynamic effects of stenotic lesions. Changes in blood flow and arterial pressure across a carefully quantitated arterial lesion are barely detectable until cross-sectional area diminishes by 75% to 80%.

BOX 41.2 Classification of Renovascular Hypertension

Two-Kidney Hypertension*
- Unilateral fibromuscular dysplasia
- Unilateral atherosclerotic renovascular disease
- Renal artery aneurysm
- Renal artery embolism and infarction
- Traumatic arterial occlusion
- Arteriovenous fistula
- Renal artery dissection or thrombosis
- Aortic dissections with compromise to renal ostium
- Page kidney
- Takayasu arteritis
- Metastatic tumor compressing renal parenchyma
- Pheochromocytoma compressing renal artery
- Phakomatosis pigmentovascularis type IIb
- Neurofibromatosis
- Behçet disease
- Covering of origin of renal artery by aortic stent graft
- Renal artery spasm

One-Kidney Hypertension†
- Stenosis to solitary kidney
- Bilateral arterial stenosis or dissection
- Coarctation of the aorta
- Vasculitis involving renal arteries
- Congenital vascular anomalies
- Atheroembolic renal disease

*Two-kidney hypertension implies that a contralateral, nonaffected kidney is present.
†One-kidney hypertension implies that the entire renal mass is beyond the vascular lesion, either bilateral disease or a solitary functioning kidney.

BOX 41.3 Clinical Features of Renovascular Hypertension

- Activation of renin angiotensin system (early)
- Early-onset (<30 years) or late-onset (>60 years) hypertension
- Activation of sympathetic nervous system
- Abnormal circadian rhythm: Loss of nocturnal fall
- Secondary aldosteronism: Hypokalemia
- Accelerated target organ damage
- Microvascular disease
- Left ventricular hypertrophy
- Renal injury
- Hyponatremic hypertensive syndrome
- Unstable cardiac syndromes
- Rarely, nephrotic range proteinuria

Clinical differentiation of RVH and primary hypertension is difficult, and they may be superimposed. RVH secondary to unilateral RA stenosis, for example, often can be easily controlled with the use of RAAS blockers. Certainly, some cases of RVH present with accelerated, resistant, or hypertension urgency or emergency. Clinical studies suggest that for any level of BP, patients with RVH have higher nocturnal pressures ("nondippers") and have more severe target organ manifestations such as left ventricular hypertrophy (LVH) and albuminuria, than patients with essential hypertension.[7] Patients with RVH may present with hypokalemia and metabolic alkalosis, clues to secondary aldosteronism. Clinical suspicion for RVH arises when hypertension develops either very early (<30 years) or later in life (>70) or when BP that was previously easily or well controlled becomes more resistant. Some cases of RVH may rarely be associated with renin-mediated and hemodynamically induced nephrotic range proteinuria that regresses with treatment. A syndrome of polydipsia associated with hyponatremia attributed to the dipsogenic action of Ang II also has been observed in patients with RVH. Clinical features of RVH are summarized in Box 41.3.

Renal Artery Stenosis

The most common cause of RVH is RA stenosis. RA fibromuscular dysplasia (FMD) and atherosclerotic disease are the two most common causes of RVH. The unique clinical presentations of inflammatory arteritides as exemplified by Takayasu arteritis (TA) and aortic coarctation also will be discussed.

Fibromuscular Dysplasia

FMD is a noninflammatory, nonatherosclerotic arteriopathy characterized by arterial medial smooth muscle cell proliferation and fibrosis. It is the most common cause of RVH in children and young adults. FMD is defined by pathognomonic arteriographic aberrancies involving the middle to distal RA or branches. The vascular distribution of FMD involves primarily the renal and cerebral arteries. RAs are involved with FMD in 65% to 80% of cases. Bilateral RA involvement is seen in 25% to 35% of adult cases, in up to 78% of syndromic childhood FMD, and in most familial cases.[8] Cerebrovascular involvement is present in up to 65% of adult cases with renovascular FMD.[9] Less common extrarenal sites of involvement with FMD include coronary, mesenteric, celiac, splenic, aortic, and peripheral vasculature.

The prevalence of clinically apparent renovascular FMD is estimated at 4 in 1000.[10] Data from screening angiography in potential kidney donors suggest that the prevalence may be higher, with FMD observed in 3.8% to 6.6% of individuals.[11] About 90% of FMD cases occur in women. Of those enrolled in the U.S. registry of patients with FMD, 95% are White, and the mean age of onset of hypertension is 43 years.[12] This racial predilection could represent recruitment or geographical bias. Familial FMD occurs in approximately 10% of patients and has been associated with subclinical evidence of carotid flow abnormalities in first-degree relatives, consistent with an autosomal dominant inheritance pattern.[13] FMD also may complicate hereditary and collagen vascular syndromes.

The pathophysiology of FMD is unknown. It is likely that numerous disturbances in vascular collagen and structural processes can result in the FMD angiographic phenotypes. No unifying genetic mutation has been identified. Other factors implicated in the etiology of FMD include cigarette smoking, hormonal influences (based on the female predilection), and vascular trauma or stretching of the RA during development.[14]

Histologically, abnormal vascular wall structure is associated with irregular bands of collagen deposits and in some cases disruption of the elastic membrane. In up to two thirds of cases more than one arterial wall layer is involved. The histologic features coincide with the arteriographic phenotypes outlined in Table 41.1. The most common variant of FMD is medial fibroplasia, accounting for 85% to 100% of cases. Here, alternating thin and thick ridges of collagen and elastic tissue deposits result in discrete stenoses alternating with aneurysmal sections characterized by fragmented internal elastic lamina. This produces the recognizable "string of beads" appearance on angiography as shown in Fig. 41.4. The loss of elastic structural integrity leads to ballooning or beading of the vessels such that the diameter of the beaded segment is larger than the diameter of the artery lumen. RA aneurysms may develop in patients with FMD, and 17% of patients with an aneurysm at any vascular site have more than one vascular site involved, with some having up to four. FMD generally involves the segment of RA beyond the first 2 cm from the ostium. FMD and atherosclerotic renovascular disease may coexist.[15]

The most common adult clinical presentation is early-onset hypertension in young to middle-aged women. Cerebrovascular lesions may manifest with headaches, pulsatile tinnitus, and bruits over the carotid arteries, epigastrium, or femoral regions. FMD should be considered in younger patients presenting with hypertension and stroke, transient ischemic attacks, subarachnoid hemorrhage, or amaurosis fugax. Clinical presentations of FMD and associated disorders are shown in Box 41.4.

The natural history of FMD has not been adequately studied. Progression of disease may manifest with new focal lesions within the same arterial bed, worsening arterial luminal narrowing within a specific lesion, involvement of a new vascular territory, or development or enlargement of arteriovenous fistulas or aneurysms. Up to 37% of patients may demonstrate angiographic progression of FMD.[16] This appears to be limited to younger patients, with few patients developing new or progressive lesions after the age of 40 years. Progression may be associated with kidney cortical thinning, but rarely causes advanced kidney failure.

Atherosclerotic Renal Artery Stenosis

Atherosclerotic RA stenosis is the most common cause of RVH in patients over the age of 50. Estimates of the prevalence of atherosclerotic RA stenosis depend on the population screened. One population-based study of 870 patients older than 65 screened with RA duplex ultrasound found a 6.8% prevalence of atherosclerotic RA stenosis defined as greater than 60% stenosis.[17] Autopsy series report an overall prevalence of 4% to 20%, with progressively higher rates for those older than 60 years (25% to 30%) and 75 years (40% to 60%). It has been estimated that atherosclerotic RA stenosis is a contributor to the development of end-stage renal disease (ESRD) in up to 22% of incident ESRD. Among patients with chronic CHF, RA stenosis has been reported in up to 50%.[18]

Atherosclerotic RA stenosis generally occurs in patients with more generalized atherosclerosis involving the aorta, peripheral vasculature, and coronary arteries.[19] In patients undergoing coronary angiography, coexistent RA stenosis is found in 11% to 16% and in up to 42% of

TABLE 41.1 Histologic Classification of Fibromuscular Dysplasia and Angiographic Phenotypes

Type	Frequency (%)	Histology	Angiographic Appearance
Medial			"String of beads"
Medial fibroplasia	85-100, most common	Alternating ridges of collagen/loss of elastic membrane	Medial: Bead diameter is larger than lumen diameter
Perimedial fibroplasia	Rarer (10-15)		Perimedial: Bead diameter is smaller than lumen diameter
Medial hyperplasia	Rarest	True smooth muscle hyperplasia: No fibrosis	Medial hyperplasia: Smooth stenosis without beads
Intimal	<10	Circumferential deposition of collagen in intima: Fragmented or duplicated internal elastic lamina	Concentric smooth stenosis: Long smooth narrowing
Adventitial	<1	Dense collagen replaces fibrous tissue in adventitia and surrounding tissue	Smooth stenosis or diffuse attenuation of vessel lumen

BOX 41.4 Clinical Manifestations and Disorders Associated With Fibromuscular Dysplasia

Clinical Manifestations

- Incidental finding (e.g., living kidney donors)
- Renovascular hypertension
- Renal infarction
- Loin or flank pain
- Hematuria
- Retroperitoneal hemorrhage
- Cerebrovascular accident (stroke)
- Transient ischemic attack
- Headaches
- Pulsatile tinnitus
- Horner syndrome
- Neck pain
- Dizziness
- Imaging finding of aneurysm dissection
- Amaurosis fugax
- Myocardial infarction
- Ischemic chest pain/dyspnea
- Postprandial abdominal pain
- Weight loss
- Hemobilia
- Claudication

Associated Disorders

- Tuberous sclerosis
- Marfan syndrome
- Ehlers-Danlos syndrome
- Cystic medial necrosis
- Coarctation of the aorta
- Alport syndrome
- Renal agenesis or dysgenesis
- α_1-Antitrypsin deficiency
- Medullary sponge kidney
- Pheochromocytoma
- Infantile myofibromatosis
- Ergotamine preparation, methysergide
- Cigarette smoking
- Collagen III glomerulopathy
- Atherosclerotic renovascular disease
- Alagille syndrome
- Ask-Upmark kidney
- Celiac disease
- Cocaine exposure—intrauterine
- Crohn disease
- Homocystinuria
- Macrophagic myofasciitis
- Neurofibromatosis
- Williams syndrome

patients undergoing peripheral angiograms.[20] Predictors of RA stenosis include a history of hypertension, presence of CKD, coexisting peripheral vascular or coronary artery disease, the presence of abdominal bruits, and a history of smoking. Atherosclerotic RA stenosis is bilateral in 20% to 40% of patients. In many of these cases, the degree of stenosis is below the threshold to cause activation of RAAS or have other clinical implications. Given its association with older age and more diffuse atherosclerosis, atherosclerotic RA stenosis is associated with increased cardiovascular and mortality risk.[21] Accordingly, the identification of atherosclerotic disease should prompt clinical attention to cardiovascular risk factors, including the use of high-dose statin therapy, efforts to promote smoking cessation, and optimal control of BP and metabolic syndrome.

Some patients with atherosclerotic RA stenosis will experience progressive RA luminal narrowing and develop RVH or other clinical syndromes described later. Progression is usually defined as a greater than 25% further luminal diameter narrowing or progression to vascular occlusion. Prospective studies between 1990 and 1997 using Doppler ultrasound in patients with atherosclerotic RA stenosis indicated progression in 30% over 3 years, varying by degree of initial stenosis, with progression more common in those with more than 60% stenosis. Total occlusion is rare, reported in only 3%.[22] Statins appear to reduce the risk for progression and occasionally induce regression of stenosis.[23] There are few prospective data assessing progression in patients treated with optimal medical therapy targeting atherosclerotic risk factors in the modern era. Atherosclerotic RA stenosis often presents as RVH but also is associated with other clinical syndromes that will be described later.

Takayasu Arteritis

Initially described in 1761, TA, often termed *pulseless disease*, is one of several inflammatory disorders involving the renal vasculature causing

RVH. Though rare in the United States, its prevalence varies geographically, with reports as high as 1 in 3000 in Japan.[24] TA usually presents between the ages of 25 and 41 years but, like FMD, can present in childhood. It most often presents as RVH and should be considered in any child or young adult with hypertension and/or asymmetric peripheral pulses or bruits. Concomitant inflammatory aortic coarctation may be present. In half of cases, identification of arterial stenosis is preceded by a prodromal illness characterized by fever, night sweats, malaise, and weight loss. Inflammatory markers are often elevated during this phase. After this active inflammatory phase, vascular stenoses can lead to sequelae including RVH, kidney dysfunction, stroke, cerebral hemorrhage, myocardial infarction, or CHF, depending on sites of involvement.

Diagnostic criteria are still somewhat controversial. The diagnosis requires arteriographic narrowing or occlusion of a vascular territory of the aorta, its branches, or large arteries not attributable to atherosclerosis, middle aortic syndrome, or FMD. One distinguishing angiographic feature of TA is the presence of inflammatory thickening or edema of the vascular wall seen on magnetic resonance angiography (MRA), computed tomographic angiography (CTA), or duplex or positron emission tomography.[25]

The pathophysiology of TA is unclear. Theories include autoimmunity and hypersensitivity response to a variety of proposed antigens, including heat shock protein and *Mycobacterium tuberculosis*. Histologically, granulomatous inflammation involves all layers of the vessel wall during the active phase of disease, followed by fibrotic stenosis.

Treatment is controversial but generally starts with corticosteroids or other immunomodulatory therapy during the inflammatory phase of disease followed by medical or interventional treatment to reduce organ ischemic injury.[24,26]

Coarctation and Middle Aortic Syndrome

Coarctation occurs in about 1 in 1550 births and accounts for about one third of all causes of RVH in infants. Yet, only 35% of isolated coarctation cases present during the first year of life, and milder forms may be missed in childhood. Furthermore, cases treated in childhood can develop restenosis of the coarct segment later in life. It is estimated that 1 in 150 adults have congenital heart disease, with aortic coarctation comprising 5% to 10%.

Adult presentations of RVH associated with coarctation include signs and symptoms of collateral development. Bruits may be heard over the carotids, and intercostal pulses may be palpable. A radial-femoral pulse delay is a sensitive physical examination finding. Present in only about 50% of cases, a harsh systolic blowing murmur is heard best over the posterior thorax. Although echocardiography with Doppler flow analysis with special attention to the aortic arch provides excellent diagnostic accuracy in infants, MRA or CTA is necessary to confirm coarctation in adults. Indications for the treatment of coarctation in adults include upper limb hypertension and a greater than 20 mm Hg systolic BP gradient across the stenosis with evidence of significant collateral flow. These patients have a fivefold risk for cerebral aneurysms, and screening cerebrovascular CTA or MRA is recommended. Current guidelines recommend multispecialty consultation among cardiologists, interventionalists, and surgeons to determine the optimal approach (endovascular vs. surgical) to repair. Success rates in terms of cure of hypertension range from 69% to 80%, with highest chance for cure and best survival data when treated in childhood under the age of 10. In adults with prior coarctation, the risk for late-onset hypertension exceeds that in the general population. Causes of this late hypertension include vascular noncompliance, reduced aortic arch baroreceptor sensitivity, early kidney injury with sustained RAAS activation, and, in some cases, development of restenosis of the repaired coarct segment.[27]

Fig. 41.5 Middle aortic syndrome. Angiogram showing typical smooth narrowing of the aorta. Bilateral stenosis of paired renal arteries is present. (From Panayiotopoulos YP, Tyrrell MB, Koffman G, et al. Mid-aortic syndrome presenting in childhood. Br J Surg. 1996;83:235-240.)

A rare entity, middle aortic syndrome is a segmental or diffuse narrowing of the abdominal or distal descending aorta, causing RVH usually noted in infancy (Fig. 41.5). Concomitant proximal RA stenosis occurs in up to 80% of cases, with variants including RA atresia, hypoplasia, or dysplasia.[28] The cause is congenital in many cases, but associations with FMD, congenital anomalies, neurofibromatosis, Williams syndrome, and TA have been reported and these cases can present later in life. Middle aortic syndrome can cause claudication of the lower extremities as well as mesenteric ischemia. Angioplasty and stenting of stenotic segments, surgical bypass grafting, and autotransplantation of ischemic organs are among the approaches to treatment of this disorder.

Renal Artery Aneurysms

RA aneurysms are a rare cause of RVH that is present in up to 75% of cases. Aneurysms are associated with atheromatous, fibromuscular, and vasculitic RA disease. Thrombosis within an aneurysm can lead to distal emboli and renal infarcts. Aneurysms with diameters of more than 1.5 cm have a higher risk for rupture. Elective repair of large renal aneurysms should be considered in women of childbearing age because of the risk for rupture during the third trimester of pregnancy. Other complications of RA aneurysms include vessel dissection and arteriovenous fistula formation.

ISCHEMIC RENAL DISEASE

Activation of the RAAS can occur without loss of kidney function. However, a common clinical scenario in patients with atherosclerotic RA stenosis is the presence of both hypertension and kidney dysfunction. In recent randomized controlled trials evaluating treatment options for atherosclerotic RA stenosis, 40% to 50% of the enrolled patients had concomitant CKD. In clinical practice, it remains difficult to distinguish CKD secondary to hypertensive nephrosclerosis from reduced kidney function resulting from atherosclerotic RA stenosis, sometimes called IRD.

The term IRD has been used to describe both the hemodynamic and structural consequences of reduced RA perfusion on the kidney. Critical RA stenosis or occlusion can lead to reduced glomerular filtration rate (GFR) by reducing renal blood flow and hence glomerular capillary pressure below the level of renal autoregulatory compensation. GFR improves once perfusion pressure is restored. The term *ischemic* is a misnomer in this context. Indeed, basal kidney energy requirements are met with less than 10% of renal blood flow. When there is reduced perfusion to a kidney, energy delivery tends to match filtration and transport functions. Reductions in GFR and associated energy-dependent solute transport allow adaptation to reduced blood flow without development of tissue hypoxia. Studies using blood oxygen level–dependent magnetic resonance imaging (MRI) indicate that, despite reductions in blood flow and GFR, many patients with RA stenosis maintain normal renal cortical and medullary tissue oxygenation.[29] Thus many poststenotic kidneys have no more ischemia than normal kidneys. These observations explain the relative stability and infrequent progression of kidney injury in prospective trials of medically treated patients with atherosclerotic RA stenosis.

However, under more chronic conditions of reduced blood flow with persistent filtration and tubular function, levels of deoxygenated hemoglobin may increase in the renal medulla, representing true medullary hypoxia beyond that which is physiologic.[30,31] When more severe vascular occlusion develops beyond the limits of functional adaptation, ischemia develops.

Reduced renal perfusion and ischemia ultimately activate numerous mechanisms of tissue injury.[32] This results in macrophage accumulation with progressive tubular cell loss and fibrosis.[33] Glomeruli are usually preserved but often appear collapsed. The ischemic kidney develops microvascular rarefaction contributing to ongoing irreversible structural and functional changes.[34] Often, the kidney atrophies with time. The term IRD comprises both the potentially reversible hemodynamic component and these adaptive and structural changes, some of which will not be reversible by merely revascularizing the kidney.

Clinical presentations that should prompt consideration of the presence of IRD are outlined in Box 41.5. IRD can present as CKD or acute kidney injury (AKI). IRD should be considered in the setting of unexplained CKD in patients with generalized atherosclerosis, resistant or accelerated hypertension, or small or asymmetric kidneys. Unilateral atherosclerotic RA stenosis may lead to atrophy of the poststenotic kidney. The contralateral kidney with a patent RA often hypertrophies and compensates with hyperfiltration. However, over time, this kidney develops parenchymal injury mediated by the combined effects of high pressure and Ang II. In some cases, the kidney with the patent RA has worse function than the poststenotic kidney.[35]

The diagnosis of IRD always should be considered in patients with known RA stenosis who present with rapidly declining renal function or episodes of AKI. In patients with high-grade RA stenosis, AKI can follow normalization of systemic BP with any agent. The sudden reduction in systemic BP can reduce RA pressure below levels needed to sustain GFR. With the use of RAAS inhibitors, these alterations in glomerular hemodynamics may be more common or pronounced.[36] Normally, activation of Ang II causes efferent arteriolar vasoconstriction, which preserves transcapillary filtration pressures at the glomerulus when preglomerular pressures are reduced, thereby maintaining GFR. The loss of this compensatory mechanism induced by agents that inhibit or block the RAAS can result in functional AKI. This typically occurs within a few days from the start of therapy and is usually, but not always, reversible. This change in GFR after initiation of RAAS inhibitors is not specific for the presence of RA stenosis and is seen frequently in patients with cardiac or hepatic dysfunction or patients with intravascular volume depletion because, in these settings, maintenance of GFR is also Ang II dependent.[37]

BOX 41.5 Clinical Presentations of Ischemic Renal Disease Associated With Atherosclerotic Renal Artery Stenosis

- Acute kidney injury with control of blood pressure: angiotensin-converting enzyme inhibitors or angiotensin receptor blockers
- Acute kidney injury with aggressive diuresis in patients with congestive heart failure
- Chronic kidney disease otherwise unexplained in atherosclerotic age range
- Chronic kidney disease with asymmetric renal size
- Acute or chronic kidney disease and renovascular hypertension
- Acute on chronic kidney injury with episodes of "flash" pulmonary edema
- Unexplained rapid decline in glomerular filtration rate in chronic kidney disease
- Oligo-anuric kidney failure not otherwise explained in a patient with atherosclerosis and hypertension

HEART FAILURE AND UNSTABLE CARDIAC CONDITIONS

Some patients with RA stenosis present with recurrent episodes of relatively sudden onset "flash" pulmonary edema.[38] This has been attributed in part to rapid loss of contractile strength of the left ventricle caused by sudden increases in afterload. Many of these patients have hypertensive urgency or emergency, hypervolemia resulting from aldosterone excess and effects of Ang II on sodium reabsorption, and echocardiographic evidence of diastolic dysfunction.[39] Such patients have increased mortality and hospitalization rates compared with those who have CHF without renovascular disease.[40] Case series and retrospective reviews suggest that renal revascularization can facilitate fluid volume management, reduce hospitalizations, and improve GFR and cardiac function in this high-risk subgroup of patients with atherosclerotic RA stenosis.[41,42] However, in two large prospective trials comparing medical therapy to RA stenting in atherosclerotic RA stenosis, endovascular treatment did not confer a protective effect on cardiovascular endpoints, including hospitalizations for CHF.[43,44] However, this cohort of patients was underrepresented in randomized controlled trials. Some believe that chronic stimulation of the RAAS secondary to RA stenosis contributes to the abnormal left ventricular remodeling in patients with chronic systolic heart failure as well as the frequency of episodes of decompensation.[45]

Finally, some patients with RA stenosis and LVH can present with chest pain syndromes with no significant lesions in the coronary arteries (although microvascular disease may be present).

IMAGING RENOVASCULAR HYPERTENSION AND RENAL ARTERY STENOSIS

Conventional direct angiography remains the reference standard to define the RA anatomy against which other screening modalities are compared. Noninvasive screening options include RA duplex (or Doppler) ultrasound, CTA, and MRA, each with their limitations and strengths.

RA duplex scanning is often used to identify and follow hemodynamic effects of RA stenoses. It is relatively inexpensive and carries no risk. It is most effective in detecting lesions of the main RA near the ostium and thus is better for identifying atherosclerotic RA stenosis than FMD. The reliability of duplex ultrasound depends on the skill and experience of the operator and the body habitus of the patient.

Duplex ultrasound provides little functional information regarding the kidney beyond the vascular lesion, although structural features such as kidney size and echogenicity can be determined. The duplex diagnostic criteria for hemodynamically significant RA stenosis consider the comparative rates of blood flow in the stenotic area to that in the remaining segments of the RA and the aorta. Parameters measured include peak systolic velocity (PSV) at various sites along the RA and in the suprarenal aorta; the renal aortic ratio (RAR), which compares the PSVs at these segments; acceleration time and index, which help evaluate the RA wave form; and the intrarenal resistive index (see Chapter 5). The resistive index has been associated with intrinsic small vessel renal disease, and a value greater than 80 has a strong negative predictive value on likelihood of BP response to intervention.[46] Normal PSV in the RA will depend on the lumen diameter of the vessel and ranges from about 120 to 160 cm/sec. PSV readings greater than 200 to 220 cm/sec and a RAR greater than 3.5 usually indicate RA stenosis of greater than 60% narrowing.[47,48] Clinicians should be aware of the significant heterogeneity among vascular laboratories in terms of how the data are reported. Most laboratories provide assessment of whether parameters support at least 60% luminal diameter narrowing. More precise assessments are not usually provided. Generally, the higher the PSV, the more severe is the stenosis. Clinicians should be familiar with aortic and RA velocities and waveforms to evaluate the validity of these interpretations. For example, a very blunted RA waveform can represent critical RA stenosis in the absence of an elevated PSV. RA duplex allows for serial testing, hence monitoring for progression and changes in kidney size. It is the preferred test for evaluating for restenosis of a stented RA segment.

Three-dimensional MRA with gadolinium enhancement provides excellent visualization of the arteries and functional information about the kidneys (Fig. 41.6). Limitations include interobserver variability, a tendency to overestimate luminal narrowing, interference by motion and breathing artifact, and limited sensitivity for middle and distal vascular lesions and small accessory vessels. MRA is less sensitive than CTA for the diagnosis of FMD.[49] It has the advantage of avoiding radiation exposure. Caution is advised in the use of gadolinium agents in patients with reduced GFR, based on reports of nephrogenic systemic fibrosis in patients with advanced CKD exposed to these agents. Some centers have reported success in the use of modified steady-state free precession MRA pulse sequences without contrast for visualization of RA stenoses.

CTA with vascular reconstruction provides imaging definition nearly equal to that of conventional angiography but requires significantly more contrast, usually 100 to 125 ml. Focal vascular calcification often obscures accurate assessment of stenoses. CTA is highly sensitive for identifying lesions in the mid and branch vessels often associated with FMD and is a good screening test for these patients who generally have good kidney function.

Angiography remains the gold standard for defining the degree of stenosis associated with atherosclerotic RA stenosis and for confirmation of FMD or other arteritides. It is the most reliable modality for identifying distal and branch or small vessel disease, which may be missed by other screening modalities. Aortography provides the opportunity to measure pressure gradients across a stenosis, an aide in determining the hemodynamic significance of a lesion. When there is complete proximal arterial occlusion, direct aortography can identify distal reconstitution by collateral and a renal "blush" confirming parenchymal viability. Limited selective renal angiography can be performed with as little as 20 ml of contrast. In cases at highest risk for contrast-induced AKI, carbon dioxide can be used instead of nonionic iodinated contrast.

In cases of unilateral RA disease, captopril renography provides functional information regarding the size and excretory capacity of the kidney and demonstrates the rate of isotope appearance as an index of renal blood flow and filtration. It detects the presence of a differential role of Ang II on GFR between the kidneys. This test has a high negative predictive value for the presence of RVH when completely normal.[50] Fig. 41.7 illustrates a captopril-enhanced renogram in a patient with RA stenosis. This examination provides no direct image of the renal vessel. Many intrinsic renal abnormalities unrelated to the main RA may change these curves, which limits its value in the presence of reduced kidney function.

Renal vein renin measurements may help predict the BP response to renal revascularization. Previous studies indicated that lateralization of renal vein levels (>1.5:1 stenotic-to-nonstenotic kidney ratio) predicts a favorable BP response for more than 90% of patients. Because failure to lateralize also carried a favorable response in almost half of patients, the negative predictive value is limited. Some clinicians use these measurements to verify the role of a pressor kidney before undertaking nephrectomy.

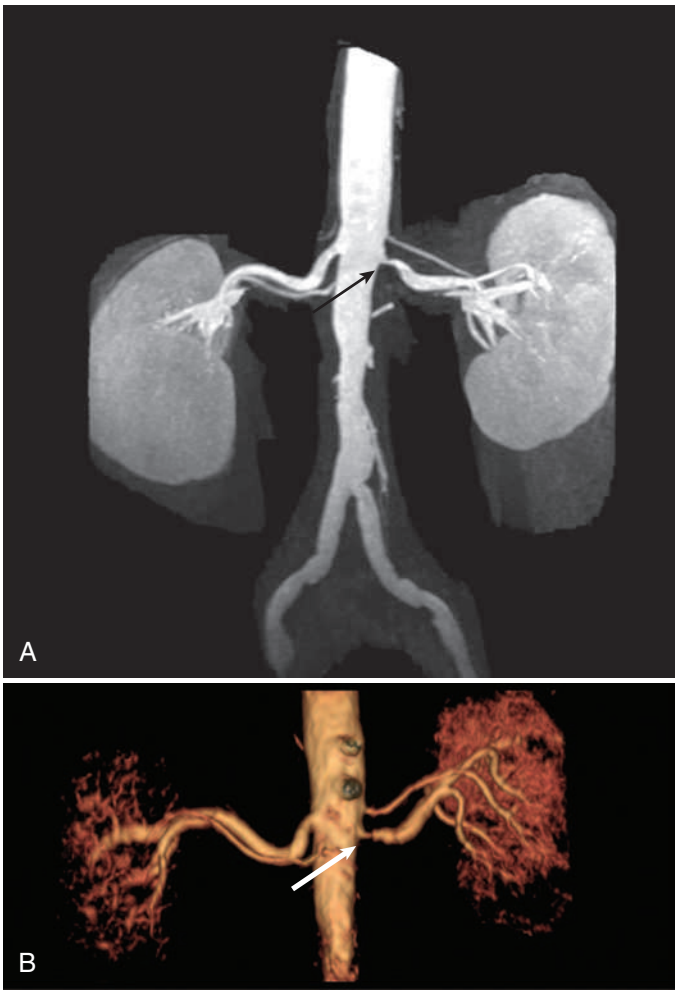

Fig. 41.6 Magnetic resonance angiogram with and without gadolinium contrast enhancement. (A) High-grade stenosis affecting the left inferior renal artery is evident, with functioning kidney tissue as reflected by gadolinium nephrogram *(arrow)*. Concerns about the role of gadolinium in the development of nephrogenic systemic fibrosis have greatly reduced the use of this contrast agent. (B) As a result, methods to image the vasculature without contrast material are being developed that produce excellent reconstructed images *(arrow)*.

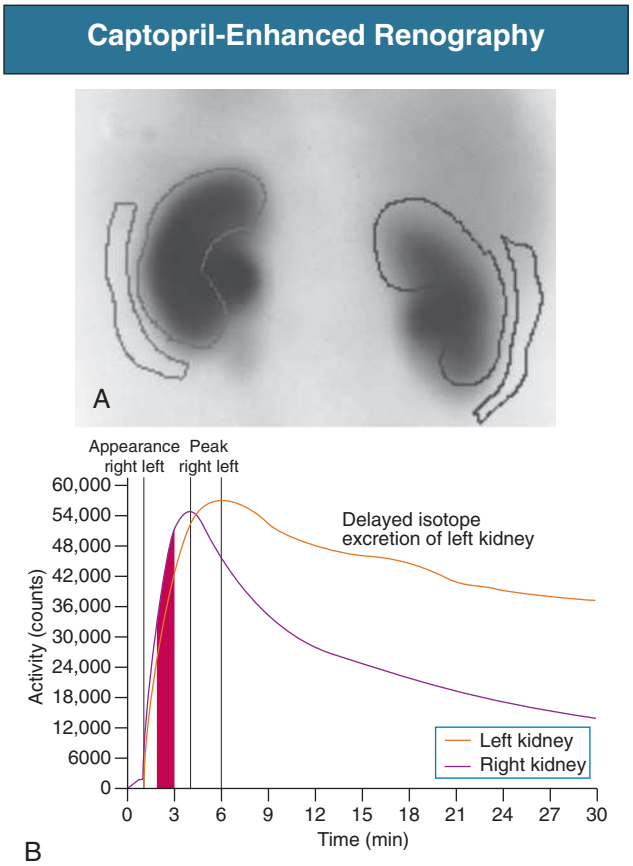

Fig. 41.7 Captopril-enhanced renography. (A) Scan in a patient with newly developing hypertension. (B) Renogram demonstrates delayed arrival and excretion of isotope (MAG3) in the affected left kidney.

TREATMENT OF ATHEROSCLEROTIC RENAL ARTERY STENOSIS AND FIBROMUSCULAR DYSPLASIA

Because RA FMD usually presents early in life and endovascular therapy has a high rate of cure of hypertension, FMD of hemodynamic significance should be treated with revascularization. The treatment of choice for FMD is percutaneous renal artery angioplasty (PTRA) usually without stenting. Successful PTRA results in disruption of the abnormal collagen bands in the lumen of the artery and the vascular wall leading to larger lumen diameter and less turbulent RA blood flow. Complete cure, defined as normalization of BP without the need for medications, occurs in 35% to 45% of cases. In over 85% of cases of FMD treated with PTRA, BP is improved with reduction in the number of antihypertensive medications.[51] Predictors of response to intervention include lower preintervention systolic BP, younger age at treatment, shorter duration of hypertension, and a positive pretreatment captopril renogram.[52] Primary technical success rates are high (>90%). Inadequate initial treatment or restenosis has been reported in up to 34% of treated cases. This is most common with the string of beads angiographic variant, which is multifocal and can require more than one procedure to adequately address all areas of stenosis. Some interventionalists recommend the use of intravascular ultrasound to guide adequate endovascular treatment of these lesions. The intimal and adventitial variants of FMD are associated with higher rates of PTRA failure and may require surgical revascularization for optimal management. When FMD is associated with aneurysmal dilatations exceeding 1.5 cm in diameter, surgical revascularization may be required. Endovascular management can sometimes be achieved by use of covered stents. Women of childbearing age with RA aneurysms should be treated before pursuing pregnancy because of the risk for rupture during pregnancy or delivery.

The optimal treatment of atherosclerotic RA stenosis presenting with RVH or other clinical syndromes has been the subject of much controversy. In the early 1990s, before the widespread use of RAAS blockade in the treatment of RVH, endovascular approaches to treating atherosclerotic RA stenosis emerged as an option for managing RA stenosis. Initially application of PTRA was associated with unacceptable rates of early restenosis. Subsequently, primary percutaneous renal artery stenting (PTRS) became standard treatment in many centers. Target vessel patency rates using PTRS regularly exceeds 95%. Between 1996 and 2005, enthusiastic application of PTRS in the treatment of atherosclerotic RA stenosis led to a marked rise in stent placement in these patients. Most case series and observational studies reported stabilization of BP and renal function in half of patients undergoing PTRS, improvement in up to 25%, and a decline in kidney function after PTRS in 25%.

The relative effectiveness of endovascular treatment of RA stenosis compared with medical therapy has now been studied in several randomized controlled trials. These are summarized in Table 41.2. The two largest trials, the Angioplasty and Stent for Renal Artery Lesions (ASTRAL) and Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL), comparing medical therapy and stenting to medical therapy alone demonstrated no differences in the primary end-points between groups.[43,44,53] The end-points were different for the two studies. In ASTRAL, 806 subjects with hypertension, many with CKD, were randomized to PTRS versus medical therapy and followed for a mean of 33.6 months. Of the enrolled patients, 53% had bilateral RA stenosis; the mean degree of luminal narrowing was 75.5%. ASTRAL reported no difference in the primary end-point of change in kidney function as measured by reciprocal creatinine. CORAL investigators enrolled 947 patients, all treated with well-defined medical therapy addressing all cardiovascular risk factors, used RAAS blockade as the cornerstone of antihypertensive therapy, and randomized half the group to medical therapy plus stent. CORAL had an imaging oversight laboratory and allowed enrollment based on angiographic as well as CTA, MRA, and duplex ultrasound definition of RA stenosis greater than 60%. At a median of 43 months of follow-up, there were no differences in the composite end-point of mortality, cardiovascular and renal events, or any of the individual components between the treatment groups.

Based on these data, the current consensus opinion is that the initial treatment of patients with RVH and CKD associated with atherosclerotic RA stenosis should be a focused medical management approach to addressing all cardiovascular and renal risk factors, including hypertension. Most patients with RVH secondary to RA stenosis can achieve BP control by applying antihypertensive algorithms that include the use of RAAS blockade. In CORAL, there was no difference in number of medications required to control BP between groups. For those patients with diabetes and CKD, attention to achieving hemoglobin A_{1c} as well as CKD mineral bone disease and anemia targets are important therapeutic goals associated with their general care. Statins are usually recommended in these patients both for cardiovascular risk reduction and with the goal of slowing progression of the RA lesion; there are also experimental data suggesting that statins attenuate renal parenchymal injury associated with atherosclerotic renovascular disease.[23,54]

Whether all patients with RA stenosis should be treated with RAAS blockade remains controversial.[55] RAAS blockers pose the risk for inducing AKI, and this risk is higher in patients with bilateral RA stenosis or stenosis to a single functioning kidney.[56] Although the unique properties of RAAS blockers allow more effective BP control in patients

TABLE 41.2 Randomized Controlled Trials Comparing Medical Therapy to Medical Therapy With Renal Artery Stenting for Renal Artery Stenosis

Year Study	2009 ASTRAL[43]	2009 STAR[44]	2014 CORAL[53]
Cohort	Hypertension	Hypertension and CKD	Hypertension and/or CKD
Entry BP	No BP threshold required	BP <140/90 mm Hg and stable for 1 month and eGFR <80 mL/min	SBP >155 mm Hg on two or more medications or eGFR <60 mL/min
Stenosis	>50% by MRA, CTA, angiography	>50% by MRA, CTA, or angiography	>60% by MRA, CTA, angiography, DUS
Excluded	Clinician certain patient would benefit from stent or require stent within 6 months	Malignant hypertension Pulmonary edema with bilateral RAS Intolerance to ACEI/ARBs as evidenced by >20% drop in CrCl	Entry creatinine >4 mg/dl Kidney Length <7 cm
% Stenosis	75.5 mean %	NA	67.3%/66.2%
CKD	Mean creatinine 2.0 mg/dl	Mean creatinine 1.7 mg/dl	Mean eGFR 58 mL/min
% Bilateral	53.5%	47.9%	22%
Subjects per arm (N/N)	403/403	76/64	459/472
F/u	33.6 months	24 months	43 months
Treatment	Stent	Stent	Stent
Medical treatment	At discretion of sites BP control with or without ACEI or ARB No specified target BP	BP target <140/90 mm Hg ACEI/ARB last resort ASA Statin Smoking cessation counseling	BP target <140/90 mm Hg 130/80 mm Hg for DM and CKD ACE/ARB first-line ASA Statin goal LDL <70 mg/dl, HbA_{1c} <7.0% for DM Smoking cessation counseling
End-point	Rate of progression of CKD based on reciprocal creatinine over time	≥20% decrease in CrCl	Composite cardiovascular and renal events
Outcome	No significant difference	No significant difference	No significant difference

with RVH, there is the potential for early loss of filtration pressure in patients with critical RA stenosis.

Clinical experience with RAAS blockers in the treatment of RVH is reassuring, however. Registry data and prospective follow-up studies in patients with atherosclerotic RA stenosis indicate that blockade of the RAAS is usually well-tolerated.[57,58] In the CORAL Trial, most patients received an ARB or ACE inhibitor. The lack of differences in renal end-points suggests that this was generally well tolerated. However, it is strongly advised that patients with atherosclerotic RA stenosis who are prescribed these agents have electrolytes and creatinine measured within 2 to 4 weeks after starting these agents and frequently (at least quarterly) over the course of follow-up.

Indications to Consider Renal Revascularization in Atherosclerotic Renal Artery Stenosis

Despite the lack of randomized controlled data and the risks, some patients may benefit from RA revascularization when medical therapy falls short. Indications to consider renal revascularization are listed in Box 41.6. First, uncontrolled hypertension despite all efforts to optimize pharmacologic and dietary interventions and to enhance adherence should prompt evaluation for all potential causes of resistance. Some patients will be intolerant of the very medications they need to control BP. Others may present with hypertensive urgency or emergency despite therapy. Some of these patients may respond to PTRS. Second, when RA stenosis critically reduces glomerular capillary pressure such that there is a rapid decline in GFR, renal revascularization may improve or retrieve renal function and avoid the need for dialysis. In these cases,

BOX 41.6 Clinical Indications to Consider Renal Artery Revascularization

- Worsening kidney function due to ischemic renal disease
- Uncontrolled hypertension failing medical therapy
- Intolerance to medical therapy
- Recurrent hospitalizations for pulmonary edema without other obvious cause
- while on optimal medical therapy
- Other unstable cardiac or renal trajectories
- Progressive renal atrophy (controversial)
- Potentially reversible dialysis dependence due to ischemic renal disease

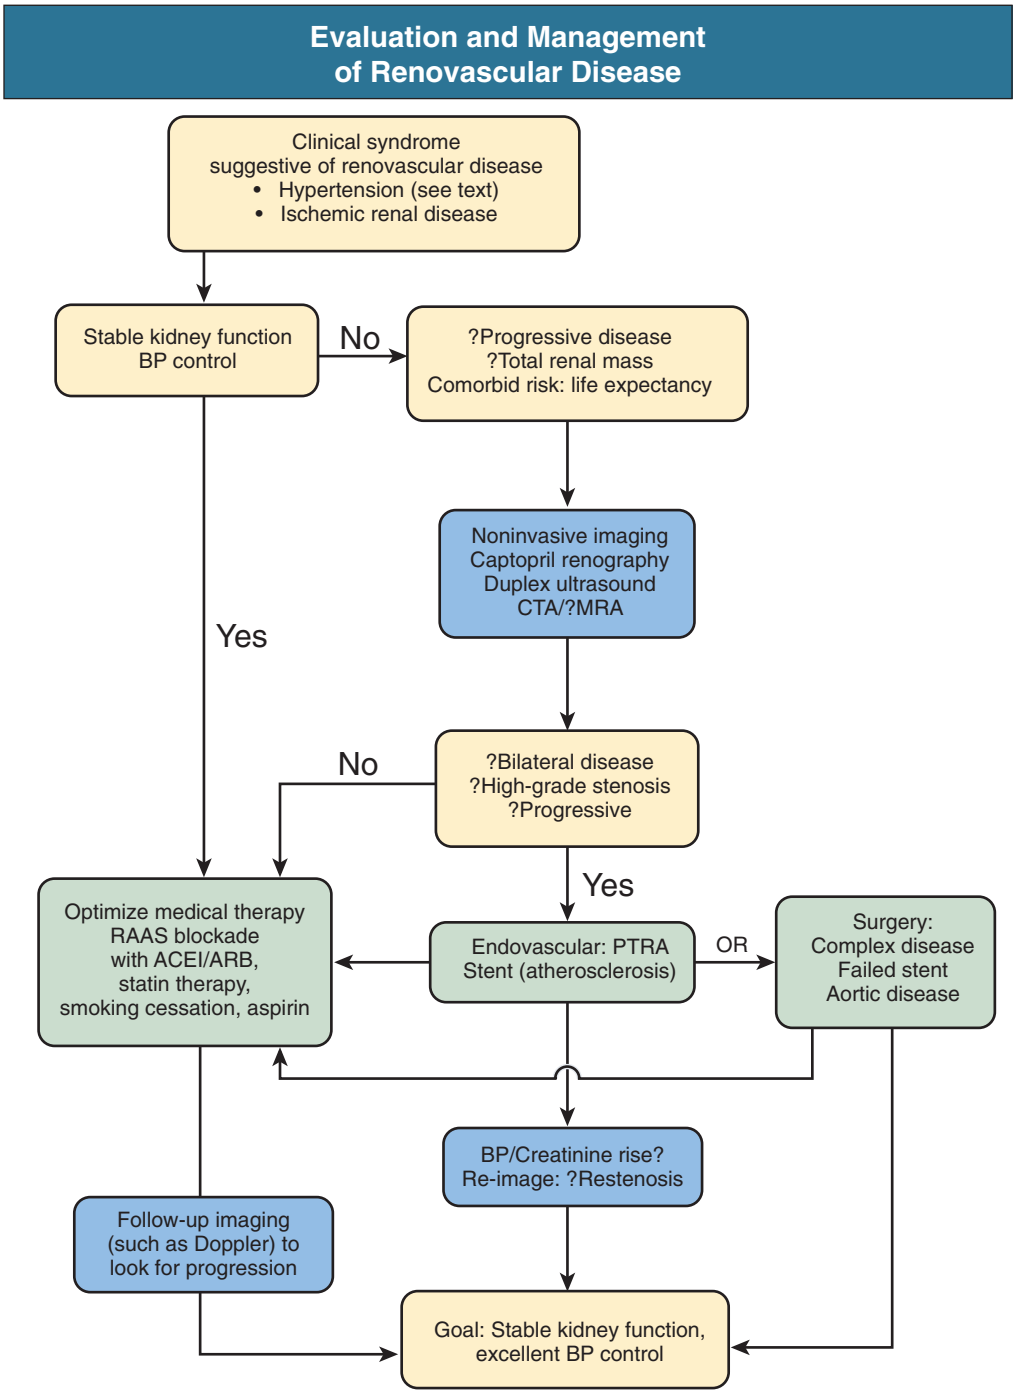

Fig. 41.8 Evaluation and management of renovascular disease. The intensity of imaging and revascularization depends on both the level of kidney function and the blood pressure *(BP),* in addition to the comorbid disease risks for the individual patient. The overall goal should focus on stable kidney function and BP levels. As with any other vascular disease, monitoring for disease progression and recurrence is an important element of long-term management. *ACEI,* angiotensin-converting enzyme inhibitor; *ARB,* angiotensin receptor blocker; *CTA,* computed tomographic angiography; *F/U,* follow-up; *MRA,* magnetic resonance angiography; *PTRA,* percutaneous transluminal renal angioplasty; *RAAS,* renin-angiotensin-aldosterone system.

there are often multiple other potential contributors to declining GFR that need to be considered. Given the risks for interventions in these patients, it is advised that a multidisciplinary group of clinicians with expertise in this area provide recommendations when interventions are considered. Finally, some patients with recurrent hospitalizations for flash pulmonary edema not resulting from other causes and attributed to medically resistant RA stenosis may benefit from RA revascularization.[59]

Fig. 41.8 outlines a proposed clinical algorithm for managing patients with atherosclerotic RA stenosis.

Surgical Renal Revascularization

Before the introduction of PTRA and PTRS, surgical revascularization was the standard treatment for patients with IRD and RVH. Such procedures carry considerable risk, cost, and morbidity. As a result, surgical intervention for renovascular disease is generally reserved for patients

failing best medical therapy and in whom endovascular therapy is not feasible or who have associated aortic disease that is not amenable to endovascular therapy. Despite these caveats, successful surgical revascularization in well-selected cases provides durable restoration of kidney blood supply with good long-term patient survival.[60] Overall, the effects of surgical revascularization on BP and renal function response in patients with atherosclerotic RA stenosis mirror those for PTRS. Surgical revascularization in the modern era may provide more durable patency than PTRS with lower complication rates and risk for restenosis.[61]

Surgical revascularization should be considered in patients with total occlusion of the RA and abrupt loss of GFR for retrieval of kidney function. Some dialysis-dependent patients and some with advanced CKD with IRD experience recovery of kidney function after revascularization.[62] Treatment involves assessment of the risks versus potential benefits of heroic revascularization procedures. The status of the contralateral kidney and overall residual kidney function should be weighed against the potential retrievable function from the underperfused kidney, as well as the perioperative risk associated with surgical thrombectomy or bypass. Predictors of GFR recovery with revascularization in the setting of critical RA occlusion include preserved kidney size, evidence of a renal blush or nephrogram by imaging, recent decline in GFR, and recent baseline creatinine concentration below 3 mg/dl.[63]

When considerable renal atrophy with poor function and RVH refractory to optimal medical therapy are present, nephrectomy of the ischemic kidney may improve BP control with minimal impact on total GFR.

TRANSPLANT RENAL ARTERY STENOSIS

Transplant RA stenosis is a common post-transplantation complication occurring most often in the period between 3 months and 2 years after transplantation. The incidence ranges from 1.3% to 23% depending on the screening tests used.[64] In many cases, anastomotic stenoses are not hemodynamically significant. Renovascular complications, including RA stenosis, are more common in deceased donor than in living donor transplants and in allografts with multiple renal vessels.[65] The use of pediatric kidneys in adult recipients is associated with a higher rate of stenosis because of smaller donor vessel size, leading to greater turbulences and mismatch between donor and recipient vessels. As the transplant population ages, there has been increasing recognition of another subset of patients with pseudo–transplant RA stenosis, in which vascular disease proximal to the allograft artery, particularly involving the iliac vessel, results in reduced kidney perfusion.

The pathophysiologic basis for transplant RA stenosis may include atheromatous disease in the donor artery, intimal scarring, and hyperplasia in response to trauma to the vessel during harvesting, and anastomotic stenosis, which is most commonly associated with end-to-end anastomoses and may be related to suture technique. In end-to-side anastomoses, stenosis is typically postanastomotic, suggesting that turbulence or other hemodynamic factors play a role. Immunologic causes of transplant RA stenosis also have been proposed on the basis of histologic similarities with chronic vascular rejection and association with prior acute rejection. Other proposed pathogenic mechanisms include calcineurin inhibitor toxicity and cytomegalovirus infection. RA stenosis occurring many years after transplantation most often represents atherosclerotic disease.

Patients typically present with new-onset or worsening hypertension with or without decline in allograft function. Patients may present with IRD with rapid decline in GFR or episodes of AKI. When pseudo–transplant RA stenosis occurs, the patient often presents with ipsilateral lower extremity claudication associated with hypertension and worsening function in the allograft.[66] Risk factors for the development of transplant RA stenosis include male gender, diabetes mellitus, hyperlipidemia, smoking, and elevated serum creatinine at discharge from transplantation.

Renal duplex ultrasound is the screening test of choice for transplant RA stenosis because the vessel is superficial and easy to interrogate; the sensitivity and specificity range from 90% to 100% and 87% to 100%, respectively.[67] MRA provides excellent anatomic definition but is associated with clip artifact at the anastomosis and high false-positive rates. CTA is comparable to renal arteriography but requires a large amount of contrast material.

PTRA with or without stenting is the preferred initial approach to transplant RA stenosis.[68] Surgical renal revascularization of allografts is difficult and associated with high complication rates. Extensive fibrosis develops around the allograft and often involves the renal vessels, making surgical access to the renal vessels risky. Complications include graft loss (in 15% to 30% of cases), ureteral injury (14%), and death (5%).

RENAL INFARCTION

Abrupt interruption of blood flow to the kidney without adequate collateral blood supply can result in renal infarction. Small areas of the cortex or medulla or the entire kidney may be involved. Autopsy series suggest the incidence is between 0.5% and 1.5%. The most common presenting symptoms include loin, flank, or abdominal pain with nausea and/or vomiting. Urinalysis often demonstrates microhematuria and proteinuria. Transient or accelerated hypertension (i.e., RVH) may occur as a result of release of renin from the infarcted portion of the kidney. Transient elevations of the serum creatinine are not uncommon. Systemic signs of renal infarction may be present and include leukocytosis and fever. Up to one quarter of cases are asymptomatic, identified only by enhancement or functional defects on renal imaging. When bilateral occlusion of the renal arteries or infarction of a single functioning kidney occurs, the patient will present with oliguric or anuric AKI. Tissue injury results in elevations of serum enzymes, most commonly lactate dehydrogenase, however transaminases, creatine kinase, and alkaline phosphatase may also be elevated.[69-71]

A high clinical suspicion is required for the diagnosis of renal infarction because the presenting symptoms are common to those of a number of other disorders. CT with intravenous contrast administration is the imaging modality of choice for demonstrating areas of renal cortex that are not perfused. CT findings can include focal wedge-shaped areas of decreased attenuation or global infarction with or without a rim sign indicating intact collateral circulation to the renal cortex as demonstrated in Fig. 41.9. Perinephric stranding also may be seen. Simultaneous infarcts in the liver and spleen are not uncommon. Other potential imaging techniques include MRA with gadolinium or nuclear scintigraphy with dimercaptosuccinic acid (DMSA). When the entire kidney is not perfused well, it is often difficult to determine if there is any salvageable renal parenchyma. Studies in experimental animals with acute RA occlusion have shown that the collateral circulation can maintain renal viability for up to 3 hours after occlusion.[72] Patients with atherosclerotic RA disease may have developed collateral vessels, resulting in the maintenance of renal viability for days to weeks. In these patients, urgent arteriography to identify the location of the arterial thrombosis or embolus may allow renal salvage via percutaneous or surgical revascularization.

Causes of renal infarction are listed in Box 41.7. The most common are trauma, RA embolism from cardiac thrombus, dissection, and iatrogenic complications of endovascular procedures. Spontaneous RA thrombosis or dissection is most often associated with atherosclerotic disease of the aorta or RAs, but other inflammatory vascular disorders can lead to infarction.

Renal infarction secondary to traumatic RA injury occurs in 1% to 4% of all nonpenetrating abdominal trauma. Types of injuries

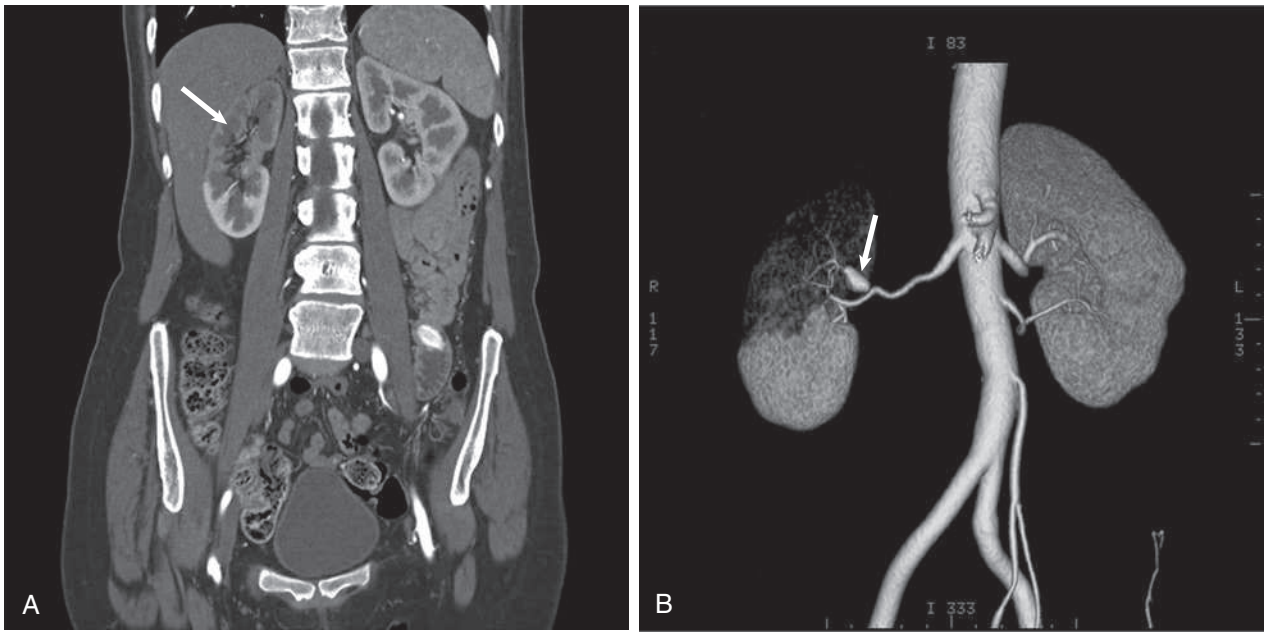

Fig. 41.9 Computed tomography angiogram of renal artery aneurysm with area of renal infarction in right kidney. (A) Coronal image demonstrates area of intact tissue with no blood perfusion within the kidney parenchyma *(white arrow)*. (B) Reconstructed view with vascular aneurysm *(arrow)* and minimal flow in the distribution beyond this segment, consistent with near-total occlusion. This patient presented with accelerated renovascular hypertension treated primarily with renin-angiotensin system (RAS) blockade.

BOX 41.7 Causes of Renal Infarction

Renal Artery Thrombosis

Spontaneous

- Renal artery atherosclerosis or fibromuscular dysplasia
- Renal artery or aortic dissection
- Renal or aortic aneurysms

Traumatic

- Postprocedure
- Endovascular stents
- Renal transplantation
- Hypercoagulable disorders
- Malignancy
- Antiphospholipid syndrome
- Renal artery vasculitis
- Vascular rejection
- Thrombotic microangiopathies
- Genetic
- Ehlers-Danlos vascular variant

Renal Embolism

- Atrial fibrillation
- Cardiac mural thrombi
- Valvular heart disease
- Paradoxical embolism
- Tumor or fat embolism
- Atheroemboli

Renal Vein Thrombosis

- Nephrotic syndrome
- Post–renal transplantation
- Traumatic

associated with RA or kidney injury include deceleration injury and direct blunt trauma to the loin or flank regions. Evidence of lumbar vertebral injury should raise suspicion in the emergency department for renovascular trauma. Traumatic renal vascular occlusion often leads to renal infarction within 3 to 6 hours. The success rate for revascularization of RA thrombosis after trauma remains low, even when diagnosed early.[73]

A common cause of renal infarction is RA embolism. The kidneys are frequently the target for emboli from thrombi originating in the heart. In one series, 1.4% of the general population had RA embolism at autopsy, of which only 2 of 205 cases (1%) were diagnosed clinically.[74] Emboli to the right and left RA occur with equal frequency, with 12% of cases being bilateral. Atrial fibrillation, cardiac thrombus after myocardial infarction, atrial myxoma or other cardiac tumors, endocarditis, paradoxical emboli, and aortic thrombus represent most of the conditions associated with renal embolism. Atrial fibrillation is the most common cause, with a rate of embolism four times higher than that of the general population; the highest risk is during the first year after the diagnosis of atrial fibrillation and when anticoagulation is subtherapeutic.[75] When echocardiography is performed, cardiac thrombus is only rarely detected. Other causes of renal emboli include fiber or foam related to cardiac bypass procedures, calcium from valve annuli, and even "bullet emboli" in the setting of trauma. Aortic endovascular stenting has been associated with a 10% incidence of new renal infarcts, presumably of embolic origin.[76] There is a 30-day mortality rate of 10% to 13% among patients experiencing renal embolism in the setting of atrial fibrillation. Up to 40% of cases of renal embolic events have at least transient reduction in kidney function.

Paradoxical RA embolism may occur in patients with right-to-left cardiac shunts most commonly due to atrial septal defects present in up to 9% to 35% of the general population. The diagnosis of paradoxical embolism requires clinical, angiographic, or pathologic evidence of systemic embolism, as well as the presence of a venous thrombus along with an abnormal communication between the right and left circulations with a favorable pressure gradient (typically diagnosed by "bubble" echocardiography) for the passage of clot from the right to the left side of the heart.

Less common causes of infarction include hypercoagulable states, inflammatory diseases of the retroperitoneum, and thrombotic microangiopathies. Antiphospholipid antibody syndrome is associated with both arterial and venous thrombotic events and is the most common cause of spontaneous arterial thrombosis.[77] Rare causes of renal infarction include autoimmune diseases and drug abuse, such as intravenous injection or nasal insufflation of cocaine or even marijuana smoking. The exact mechanism involved in the pathogenesis of renal infarction in some of these conditions is unclear.

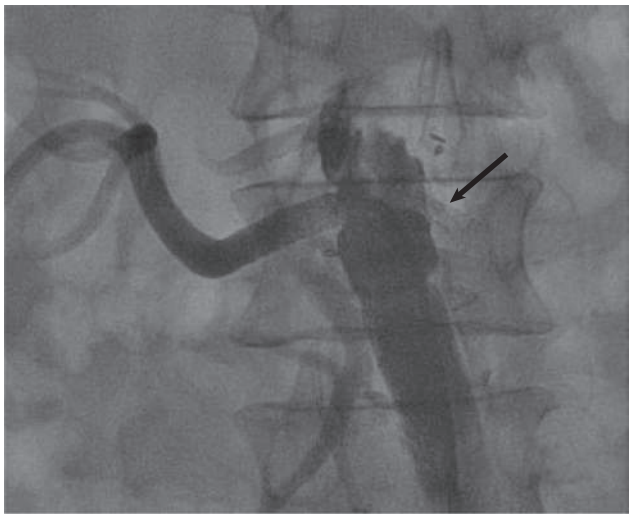

Fig. 41.10 Thrombosis of renal artery complicating renal artery stenting. Right and left renal artery stents. The left renal stent *(arrow)* is triangular, indicating crimping of the proximal portion, which in this patient was associated with thrombosis of the renal artery, seen here as no contrast entering the vessel. The right renal stent is patent.

Aortic dissection can lead to RA occlusion, reduced renal blood flow, or infarction. In this setting the predictors of renal salvage are the same as those for occlusion caused by atherosclerotic RA stenosis and include preserved renal size, collateral circulation permitting renal viability, and blush on imaging studies. Aortic dissection occurs most commonly in association with atheromatous aneurysmal vascular disease of the thoracic aorta, but it can occur in collagen disorders, such as Ehlers-Danlos type IV or Marfan syndrome, and with arteritis, such as TA.

RA thrombosis, dissection, laceration, or embolism can occur secondary to vascular interventions, especially those involving placement of endovascular stents. Endovascular aortic stents commonly used to treat infrarenal abdominal aortic aneurysms can cross the RA orifice, impair renal perfusion or cause RA thrombosis.[78,79] RA stent placement similarly may cause intimal dissection, atheroembolism, and thrombosis of the RA. Stent fracture also can be associated with thrombosis, as demonstrated in Fig. 41.10.

In-stent stenosis remains a significant complication occurring in up to 33% of post-PTRS cases and can occur at any time after stent placement, with the highest risk within the first year after PTRS. Whether duplex surveillance should be performed at various intervals after PTRS is unclear, but clinicians should be aware that RA stenosis and occlusion can occur within stents, sometimes without clinical clues. Clinicians need to inform patients with atherosclerotic RA stenosis regarding the risk and uncertain benefits of PTRS.[80]

Treatment of Acute Renal Infarction

Investigations should be done to determine whether the infarction is embolic or thrombotic. Treatment of the infarction itself is usually conservative and includes pain control and treatment of associated RVH, which can be labile. If RA occlusion is caused by thrombosis associated with a hypercoagulable state or an embolism from a central source, systemic anticoagulation is indicated. Salvage of the kidney by acute thrombolytic therapy also has been attempted, with limited success. There is no evidence that thrombolytic therapy can limit infarct size if it is administered in the acute setting.

When an embolism from a central source results in renal infarction or RA occlusion, a search for the source should be undertaken. An echocardiogram is usually indicated to evaluate for intracardiac or aortic arch thrombi and valvular abnormalities. Systemic anticoagulation is indicated to prevent recurrent embolic events, except when the source is septic emboli.

Thrombosis of atherosclerotic RAs (because of prior collateral development in most cases) often results in marked ischemia but not overt infarction of the kidney; in this setting surgical and, sometimes, percutaneous endovascular revascularization can restore kidney function.[81,82]

ATHEROEMBOLIC RENAL DISEASE

Atheroembolic renal disease is common and is estimated to account for up to 10% of unexplained renal failure in the elderly. It is typically associated with arterial manipulation that occurs during arteriography, vascular surgery, angioplasty, and stent placement. Spontaneous atheroemboli may occur in patients with extensive atherosclerosis and unstable plaques, especially after administration of oral or intravenous anticoagulants or thrombolytic agents. Atheroembolism may be expected to occur in up to 30% of patients with extensive aortic atherosclerosis after endovascular intervention. Careful studies using filters to capture embolic material confirm that PTRA and PTRS release thousands of atheromatous particles of various sizes in 70% to 100% of cases.[83] Preprocedure treatment with antiplatelet agents and intraprocedural use of embolic protection devices during PTRS is under investigation, with some positive results as means of reducing the frequency of this underdiagnosed cause of renal infarction and CKD.[84,85]

Ipsilateral RA stenosis may be present in up to 80% of patients with renal cholesterol embolization. Cholesterol embolization may contribute to the loss of renal function in patients with atherosclerotic IRD; cholesterol emboli were found in the kidneys of 36% of patients undergoing surgical revascularization.[86]

Most patients are older than 50 years with generalized atherosclerosis and have a history of recent endovascular procedures or signs and symptoms of atherosclerotic vascular disease. These signs and symptoms can include claudication or ischemic ulcers, abdominal pain, angina, myocardial infarction, transient ischemic attacks, amaurosis fugax, stroke, abdominal aortic aneurysm, RVH, or IRD. Most patients have atherosclerotic risk factors, including hypertension, hypercholesterolemia, diabetes, and smoking.

Clinical Presentation

Acute or subacute renal impairment caused by renal microinfarctions developing as long as 6 months after the atheroembolic insult is the most common presentation leading to the diagnosis of cholesterol embolization. The clinical picture is multisystemic and involves the kidneys in about 75% of patients.

If a large atheroembolic shower induces significant renal tubular damage, the resulting AKI may manifest with an oliguric phase characterized by a high fractional excretion of sodium. More often, the renal failure is nonoliguric. A slowly progressive, often stair-stepping subacute renal impairment is common. Some patients will have only moderate impairment in renal function, whereas others progress to ESRD. Urinalysis findings are nonspecific but may include mild proteinuria, microhematuria, pyuria, and eosinophiluria. Renin release by ischemic zones in areas of embolization can lead to labile hypertension early in the course, sometimes associated with transient marked proteinuria. Fever, often low grade, is characteristic.

Although the kidneys are the organs most commonly involved, extrarenal cholesterol embolization will provide clues to aid in the diagnosis. Cutaneous findings are seen in up to 60% of patients during initial presentation. These findings include blue or purple toes, mottled

Fig. 41.11 Livedo reticularis. The mottled skin changes associated with peripheral cholesterol embolization may be seen over the legs, buttocks, back, or flank and may be transient.

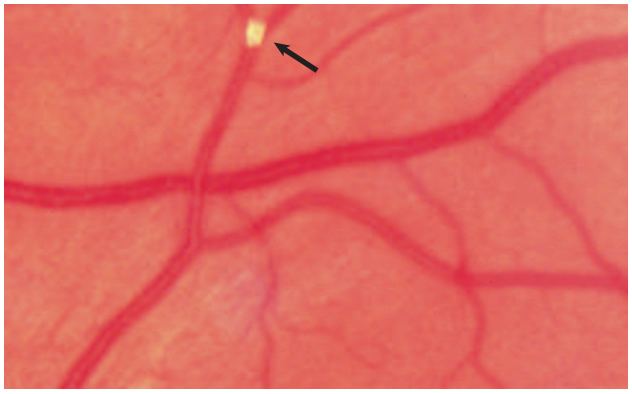

Fig. 41.12 Hollenhorst bodies. Cholesterol embolus of a retinal arteriole *(arrow)*. (Courtesy Richard Mills, University of Washington, Seattle, Wash.)

serpiginous rash (livedo reticularis; Fig. 41.11), petechiae, and purpura or necrotic ulceration in areas of skin embolization, such as the lower back, buttocks, lower abdomen, legs, feet, or digits.

Other organs often involved include the spleen (in 55% of cases), pancreas (52%), gastrointestinal tract (31%), liver (17%), and brain (14%). This involvement can result in a number of associated clinical symptoms, including abdominal or muscle pain, nausea, vomiting, ileus, gastrointestinal bleeding, ischemic bowel, hepatitis, angina, Hollenhorst plaques (Fig. 41.12), and visual and neurologic deficits.

Diagnosis

Atheroembolic renal disease should be suspected when renal failure develops after a vascular intervention in the presence of livedo reticularis.

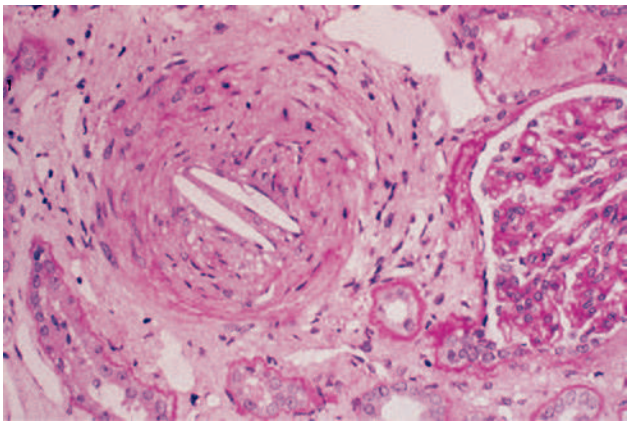

Fig. 41.13 Cholesterol emboli in kidney biopsy specimen. Biconvex cholesterol clefts with giant cell reaction and recanalization of the lumen of a medium-sized renal vessel. (Periodic acid–Schiff stain.) (Courtesy Dr. R. Horn, Vanderbilt University, Nashville, Tenn.)

Many laboratory abnormalities indicative of tissue injury are associated with cholesterol embolization, including elevated erythrocyte sedimentation rate (in 97% of cases), elevated serum amylase (60%), leukocytosis (57%), anemia (46%), hypocomplementemia (especially low C3) (25% to 70%), and elevated lactate dehydrogenase and creatine kinase (38% to 60%). Peripheral eosinophilia, which may be transient, is seen in up to 57% of patients. The presence of eosinophilia should raise suspicion for atheroembolic renal disease in the appropriate clinical setting. Serum lactate elevation is usually seen only if concomitant ischemic bowel is present. In most circumstances, the diagnosis is made clinically. However, a definitive diagnosis can be made by biopsy of an involved organ or tissue. A skin or muscle biopsy in an involved area may preclude the need for kidney biopsy.

Differential Diagnosis

In this setting, often after vascular interventions, other considerations include contrast nephropathy, acute tubular necrosis, renal infarction, or vascular occlusion. Peripheral eosinophilia and eosinophiluria, rash, fever, and renal dysfunction may also be misdiagnosed as acute interstitial nephritis. Acute cholesterol embolization syndrome may mimic vasculitis, occult infection, neoplasm, or thrombotic microangiopathy. Chronic cholesterol embolization syndrome may appear similar to hypertensive nephrosclerosis or IRD. In the kidney transplant recipient, renal atheroembolism may mimic acute rejection or chronic allograft nephropathy.

Pathology and Pathophysiology

If clinical or other pathologic evidence has not secured the diagnosis, kidney biopsy may be helpful. Diagnosis is based on the presence of birefringent, biconvex, elongated cholesterol crystals or biconcave clefts within the lumina of small vessels left behind in formalin-fixed tissue Fig. 41.13. Due to the patchy nature of this disorder, open wedge kidney biopsy has a higher likelihood of successful diagnosis relative to a percutaneous approach because it allows visualization and direct sampling of areas of ischemic infarction of the cortex. The pathologist should be alerted by the clinician that cholesterol embolization is in the differential diagnosis before the biopsy specimen is processed. In frozen sections of tissue, the cholesterol material can be identified with polarized light microscopy. The pathologic findings also may include intimal thickening and concentric fibrosis of vessels, giant cell reaction to the cholesterol particles, vascular recanalization, endothelial proliferation, tubulointerstitial fibrosis with both eosinophil and mononuclear cell

infiltrates, glomerular ischemia, and even focal segmental glomerulosclerosis. In the kidney, the most commonly affected vessels are the arcuate and interlobular arterioles, leading to patchy ischemic changes distal to these vessels.

Natural History

The natural history is determined by the extent of organ involvement and the degree of the embolization. In one series of cases, renal function declined rapidly in 29%, with a more slowly progressive course seen in 61%.[87] Among the latter group, the decline in renal function was thought to result from a combination of cholesterol embolization and IRD. Patients also may manifest acute or subacute renal impairment followed by partial recovery of renal function. Conversely, the outcome can be dismal, particularly when cerebral embolization occurs or when there is a large unstable atheromatous burden. Some patients with cholesterol embolization may develop ESRD.

Treatment

There is no specific therapy for the cholesterol embolization syndrome. Therefore its risk should be considered before angiographic and vascular surgical procedures are undertaken in patients with diffuse, extensive atherosclerotic disease. Prevention is the most effective management strategy, so patients with extensive aortic atherosclerosis should be considered for alternative approaches to cardiac catheterization, such as through the brachial artery. When it is feasible, distal embolic protection devices should be used to trap embolic material for removal from the circulation to avoid end-organ damage by embolic debris.

Once the diagnosis of cholesterol embolization has been established, further endovascular interventions should be avoided. Poor outcomes have been reported in patients with cholesterol emboli who subsequently undergo coronary artery bypass surgery. When clinical factors dictate the need for aortic, renal, or peripheral arterial surgery, optimal timing and surgical approach are critical. Conversely, there is a growing surgical experience with segmental aortic replacement to remove the source of emboli, particularly when atheroembolic disease occurs spontaneously. Transesophageal echocardiography is often used to identify mobile ulcerative plaque in the aorta to guide intervention.

ACE inhibitors are effective in managing the labile hypertension seen early in the course of cholesterol embolization. Corticosteroids have been used with some success in patients with systemic cholesterol embolization and associated inflammatory symptoms.[88] There also have been several reports documenting improvement or stabilization of skin signs of cholesterol embolization after administration of statins,[89] which should be part of the treatment of the generalized atherosclerosis in these patients. Cholesterol embolization also has occurred after treatment with anticoagulants. Although direct causality between anticoagulants and cholesterol embolization has not been established, the proposed mechanism is that anticoagulants prevent thrombus organization over the ulcerative plaques. Therefore anticoagulation should be avoided in the acute setting of cholesterol embolization unless a critical life-threatening indication for anticoagulation is present. This has implications for the delivery of renal replacement therapy, if indicated.

RENAL VEIN THROMBOSIS

Renal veins begin in the subcapsular region of the kidney. These stellate veins communicate with perirenal and cortical venous channels and empty into interlobular and then arcuate veins. The venae rectae drain the pyramids and join the arcuate veins, which leave the renal parenchyma through interlobar vessels, converging into four to six trunks near the hilum of the kidney. Two or more renal veins have been described in up to 20% of people; this is more common on the right. The main renal veins empty into the IVC. The left renal vein is three times longer than the right (7.5 vs. 2.5 cm) and traverses behind the splenic vein and body of the pancreas before it crosses in front of the aorta near its termination at the IVC. About 25% of people have retro-aortic or circumaortic renal veins.

Renal vein thrombosis is rare and primarily observed in children with severe dehydration (with an incidence in neonates of 0.26% to 0.7%) or in adults with nephrotic syndrome, renal tumors, or hypercoagulable states and after surgery or trauma to the renal vessels.[90] When it occurs in adults, the diagnosis is often never considered.

Thrombosis of the longer left renal vein also may involve the ureteral, gonadal, adrenal, and phrenic branches that drain into the left vein, whereas on the right side, the adrenal and gonadal veins drain directly into the IVC. The renal veins also communicate with perirenal veins outside of the Gerota fascia as part of the retroperitoneal collateral venous network: tributaries of the portal system, lumbar, azygos, and hemiazygos. Because of this network of venous complexes, occlusion of the left renal vein results in enlargement of the systemic collateral vessels and provides some protection against infarction (Fig. 41.14).

Acute Versus Chronic Renal Vein Thrombosis

Experimentally, acute RVT is associated with immediate enlargement of the kidney, with a marked increase in renal vein pressure, leading to a significant decrease in renal arterial flow. Complications include hemorrhagic infarction, kidney rupture, and retroperitoneal hemorrhage. In the dog, the kidney enlarges over the course of a week, then proceeds to atrophy as a result of progressive fibrosis. In contrast, slow, progressive (chronic) thrombosis may allow collateral formation, resulting in minimal symptoms.

Clinical Presentation

Acute RVT is usually symptomatic and associated with loin, testicular, or flank pain and even the development of scrotal swelling or hydrocele. The patient may present with fever, leukocytosis, and, in the setting of a single kidney or renal transplant, oliguric AKI. Acute RVT is associated with renal edema and swelling. Nausea and vomiting often accompany acute RVT, and symptoms might be confused with those of acute pyelonephritis. Hematuria is nearly universal and most often is microscopic. The high venous pressures result in a marked increase in proteinuria. Urinalysis sometimes reveals evidence of proximal tubule dysfunction, such as glycosuria. In some patients, RVT is diagnosed only after the patient has developed an acute pulmonary embolus and the source of the embolus is investigated or with worsening of renal function in the setting of proteinuric CKD.

Chronic RVT may be asymptomatic. Extensive venous collaterals may allow for minimal impairment of kidney function and structure. Often, however, microhematuria, proteinuria, and evidence of reduced GFR or tubular dysfunction are present, particularly when indices of differential renal function are sought, such as with nuclear studies.

When RVT causes renal infarction, the distribution of the hypoperfused region tends to be medullary or subcortical. The renal impairment tends to be patchy and subtotal. These patients can develop severe hypertension acutely. The swollen kidney can rupture the capsule and result in massive retroperitoneal hemorrhage.

Etiology

The causes of RVT are listed in Box 41.8. Renal vein thrombosis occurs in neonates in situations of dehydration and thrombophilia. The classic presentation triad includes a palpable abdominal mass, hematuria, and thrombocytopenia. Proteinuria, tubular dysfunction, reduced GFR, and hypertension may be associated. There is a greater predilection for development of RVT in male infants, with 67% of the reported cases

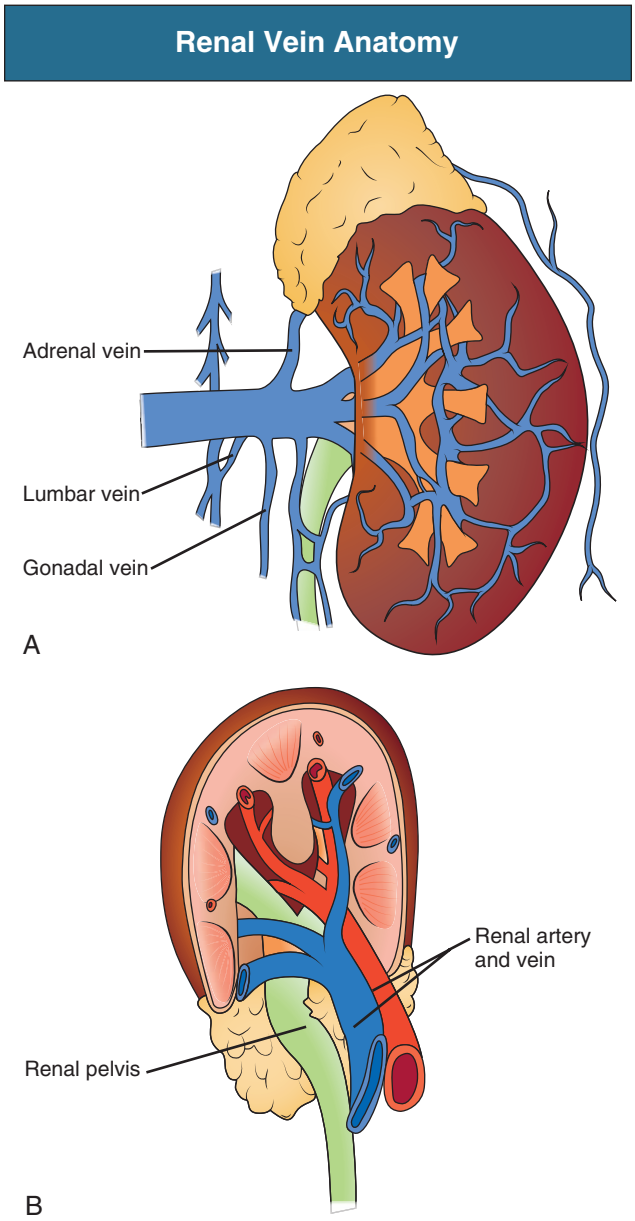

Fig. 41.14 Renal vein anatomy. (A) There is extensive communication between the renal venous plexus and lumbar, gonadal, and adrenal veins, which provide alternative outflow in the setting of renal vein thrombosis, particularly on the left. (B) Transverse section of the kidney showing relative position of vascular structures in the renal pelvis. (Redrawn from Graham SD, Keane TE, Glenn JF, eds. Glenn's Urologic Surgery. 7th ed. Philadelphia: Wolters Kluwer/Lippincott Williams & Wilkins Health; 2010.)

occurring in boys.[91] Most cases are unilateral, with the left renal vein more commonly affected. In neonates, the diagnosis is made by renal ultrasound and Doppler study of the renal veins. The strongest predictor of poor renal outcome is marked decrease in perfusion detected on initial Doppler ultrasound.[92] The optimal treatment approach to neonatal RVT is controversial. Fibrinolytic therapy may be associated with bleeding complications, including adrenal hemorrhage, and is usually not successful in restoring renal function unless it is undertaken within 24 hours of the thrombotic event.[93]

Patients with nephrotic syndrome have increased risk for venous thromboembolism. The prevalence of RVT in nephrotic syndrome is unclear because it is largely undiagnosed; studies report frequencies from 5% to 62%.[94] Numerous abnormalities promoting a prothrombotic state occur secondary to heavy proteinuria. It is interesting to note that RVT appears to be more common in membranous nephropathy and lupus nephritis, but RVT can complicate any cause of proteinuric renal

BOX 41.8 Causes of Renal Vein Thrombosis

- **Malignant neoplasia**
  - Direct invasion of tumor into the renal vein
  - Retroperitoneal adenopathy, fibrosis, or tumor compressing the renal vein
  - Extension of inferior vena cava (IVC) obstruction by tumor invasion
  - Hypercoagulable state associated with malignant disease
- **Complication of IVC filters**
- **Complication of PICC lines**
- **Nephrotic Syndrome**
  - Membranous nephropathy
  - Lupus Nephritis
- **Acute pyelonephritis**
- **Complicating inflammatory bowel disease**
- **Acute Pancreatitis**
- **Inflammatory aortic aneurysm**
- **Neonatal**
  - Congenital
  - Dehydration
  - Thrombophilia
  - Complication of umbilical vein catheterization
  - Transmission of maternal procoagulant factors
- **Hypercoagulable states**
  - Antiphospholipid antibody syndrome
  - Factor V Leiden mutation
  - Antithrombin III deficiency
  - Protein S and C abnormalities
  - Hyperhomocysteinemia
  - Elevated levels of clotting factors VIII, IX, and XI
  - Heparin-induced thrombocytopenia
  - Birth control pill
- **Thrombophilia**
- **Chuvash polycythemia**
- **Post Renal Transplantation**
  - Acute rejection, OKT3
  - Vascular rejection
  - Compression or kinking of renal vein
  - Hypercoagulable disorders
  - Sticky platelet syndrome
  - Calcineurin inhibitors
  - Viral infection of the allograft
- **Complication of surgical compression**
  - After aortic aneurysm surgery
  - After pyeloplasty
  - After partial nephrectomy
- **Traumatic renal vein thrombosis**
- **Pregnancy**
  - Compression
  - Preeclampsia, eclampsia
- **Complication of embolization of gastric varices**
- **Budd-Chiari syndrome**
- **Behcet's disease**

PICC, peripherally inserted central catheter

disease. In this setting, RVT can lead to an increase in baseline proteinuria and present with AKI superimposed on CKD.

RVT after transplantation is rare and occurs in less than 0.5% to 4% of transplants, usually within the first week after transplantation.[95] It usually leads to graft infarction, but rupture of the allograft also can occur. Causes include technical issues related to the anastomosis, compression of the renal vein by fluid collections, volume depletion, acute rejection, and hemostatic and hypercoagulable states. Factor V Leiden mutation, which occurs in 2% to 5% of the population, is a risk factor for transplant RVT and should be sought when it occurs. Another prothrombotic syndrome known as *sticky platelet syndrome* can result in post-transplant RVT. There are some data supporting the protective effects of low-dose aspirin in this population. Renal salvage is possible with early diagnosis, surgical exploration, and thrombectomy.

Pregnancy and the postpartum state are hypercoagulable states. There have been reports of spontaneous RVT in the postpartum period associated with renal infarction. RVT complicating pregnancy should be suspected when clinical clues such as flank pain, proteinuria, and hematuria are present.

Malignancy accounts for the greatest number of cases of RVT.[96] RVT can result from invasion of tumor of renal origin into the renal vein. About half of renal cell carcinomas are associated with RVT at autopsy. In addition, neoplasia originating in the renal vein or IVC, such as leiomyosarcoma or cavernous hemangioma, can cause RVT. Extrinsic compression of the renal vein by a tumor or retroperitoneal fibrosis also may cause this syndrome.

Diagnosis

Diagnosis of RVT requires imaging. Conventional ultrasound may demonstrate alterations in size and echogenicity. Sonographic findings in neonatal RVT include renal enlargement, loss of corticomedullary differentiation, and linear echogenicities radiating from the renal hilum as a result of interlobular and interlobar venous clot. Later scans may show linear, punctuate, or lace-like calcifications in these regions, representing calcified thrombi. Renal duplex ultrasound may show increases in resistive indices and can directly visualize the filling defect. In patients with renal transplant RVT, the duplex waveform pattern demonstrates reversal of diastolic flow, which is not pathognomonic or specific for RVT. Imaging of the renal vein by MRI or CT venography is needed to confirm transplant RVT. In adults, these modalities have much greater sensitivity than renal vein duplex studies for the diagnosis of RVT. Fig. 41.15 is a CT venogram demonstrating unilateral RVT.

Treatment

Treatment is controversial and depends on the setting, acuteness, and renal consequences. If there is no contraindication, most patients are treated acutely with systemic anticoagulation. In adults with acute RVT that is compromising renal function, catheter-directed thrombolytic therapy with urokinase or tissue plasminogen activator with or without percutaneous mechanical thrombectomy can restore vessel patency.[97] The long-term benefit of this approach is unclear, and it is less successful when the thrombotic process begins in the small intrarenal venules rather than in the major veins, as is often the case when primary renal disease or a hypercoagulable state initiates the process. In neonatal RVT, which often results in renal nonfunction, thrombolytic therapy and anticoagulation have been used with variable results.

Surgical interventions include nephrectomy, thrombectomy, and retroperitoneal surgery for non–renal-associated abnormalities, such as tumor, retroperitoneal fibrosis, aortic aneurysm, and acute pancreatitis. Surgery tends to be reserved for situations in which the RVT results in hemorrhage from renal capsular rupture or for long-term consequences of RVT, such as hypertension or infection of a nonfunctioning kidney.

A conservative approach may be favored when left RVT occurs because of the extensive collateral venous supply on that side, ultimately allowing venous drainage and delayed improvement in renal function. Systemic anticoagulation is indicated acutely to prevent extension of thrombus into the IVC and prevent pulmonary emboli. Anticoagulation should be continued indefinitely in patients with a persistent hypercoagulable state after RVT.

SELF-ASSESSMENT QUESTIONS

1. A 24-year-old woman presents with hypertension and bruits over her carotid arteries. She does not know the onset of her hypertension, which was discovered during a regular gynecologic check-up. In evaluating her, you discover the presence of a heart murmur heard loudest over the posterior thorax. She has no abdominal bruits. There is no difference between blood pressure (BP) measurements taken in each arm. She has a radial-femoral delay, and otherwise her pulses are equal and present. Which of the following is the most likely cause of her hypertension?
   A. Takayasu arteritis
   B. Fibromuscular dysplasia of the renal artery
   C. Coarctation of the aorta
   D. Vasculitis
   E. Atherosclerotic renal artery (RA) stenosis
2. A 76-year-old woman comes to see you because her primary care doctor has had difficulty getting her BP controlled. She tells you she never had hypertension until about 4 or 5 years ago. She has a history of smoking one pack per day of cigarettes for 40 years. She had coronary artery bypass grafting 8 years ago and has been well without chest pain or dyspnea since then. Examination is notable for systolic BP of 180. She has a left carotid bruit audible and diminished dorsalis pedis pulses. Her creatinine is 1.3 mg/dl and potassium is 3.4 mg/dl. A renal duplex shows normal velocities in the left RA but a peak systolic volume of 350 cm/sec in the proximal portion of the right RA. She is on the following antihypertensive medications: metoprolol 50 mg twice daily, amlodipine 5 mg/day, hydrochlorothiazide 25 mg/day, and atorvastatin 80 mg/day and is taking aspirin. What is the most appropriate next action?
   A. Refer right for RA stent
   B. Start angiotensin-converting enzyme (ACE) inhibitor and follow BP response and potassium and creatinine closely
   C. Refer to vascular surgery for RA bypass
   D. Stop aspirin and atorvastatin
   E. Add doxazocin
3. A 32-year-old woman with lupus nephritis class V is currently being treated with induction therapy with mycophenolate mofetil 1500 mg twice daily and oral steroids. She continues to have proteinuria, and her last 24-hour quantitative protein concentration was 6 g. Fortunately, her creatinine has remained normal at 0.8 mg/dl. She presents to the emergency department with pleuritic chest pain. A ventilation/perfusion ($\dot{V}/\dot{Q}$) scan shows high probability for pulmonary embolism. When you see her, you note that her creatinine is 1.8 and urine protein/creatinine is 30 g/g. She is started on anticoagulation therapy and admitted. As the renal consult, which of the following tests would you recommend the team order?
   A. Antiphospholipid antibody
   B. Renal vein Doppler study and renal ultrasound
   C. Computed tomographic angiography (CTA) of pulmonary arteries
   D. Both a and b
   E. None of the above
4. An 83-year-old woman presents with congestive heart failure and hypertension. She has a history of peripheral vascular disease and chronic kidney disease with a baseline creatinine of 1.5 mg/dl and a single kidney because she donated one to her son with diabetic nephropathy 30 years earlier. She is admitted and treated with diuretics and achieves a net negative fluid balance of 6 liters over 3 days. Her BP, which was 180/90 on admission, is now 120/80. An echo shows left ventricular hypertrophy with diastolic dysfunction, preserved ejection faction, and no valvular abnormalities. Over the past 24 hours her creatinine has risen to 3.8 and she has produced almost no urine. She has no flank pain. Despite stopping her diuretics, her creatinine does not improve over the next 72 hours and she is oliguric. She appears euvolemic and does not respond to empiric intravenous fluids for 24 hours. Her medications are reviewed, and she is receiving no nephrotoxic agents and all diuretics and antihypertensives are on hold. An ultrasound and Doppler examination show a blunted waveform concerning for possible critical renal artery stenosis. What test would be best to rule out critical RA stenosis?
   A. MRA of renal arteries
   B. CTA of RAs
   C. Captopril renography
   D. Direct renal angiography with carbon dioxide
   E. Peripheral renin level
5. A 62-year-old man with a history of hypertension presents with acute left flank pain with no dysuria. Urinalysis shows hematuria without pyuria. He has a temperature of 99.8° F and a white blood cell count of 12,000. He is in new-onset atrial fibrillation. His creatinine is noted to be 1.3, above his recent normal level of 0.9 mg/dl 1 month previously. An abdominal ultrasound is done, and the kidneys appear normal. Which of the following tests would help sort out the cause of his flank pain?
   A. Echocardiogram
   B. CT without contrast
   C. CT with and without contrast and serum lactate dehydrogenase (LDH)
   D. Urine culture
   E. Brain natriuretic peptide
6. A 60-year-old White man with a history of hypertension and diabetes undergoes cardiac angiography with stent placement after presenting to the emergency department with symptoms consistent with unstable angina. Three days later he is noted to have a rise in serum creatinine from a baseline of 0.8 to 1.9. Along with this rise he is noted to have a slight increase in eosinophils on his complete blood count. On examination the patient is noted to have a serpiginous rash on the bilateral lower extremities to the level of the ankles. Which of the following is the likely cause for the AKI?
   A. Cardiorenal syndrome
   B. Cholesterol emboli
   C. Contrast-induced nephropathy
   D. Acute interstitial nephritis
   E. Renal infarction

Renal Physiology and Complications in Normal Pregnancy

Shikha Aggarwal, Mark A. Brown

RENAL PHYSIOLOGY IN NORMAL PREGNANCY

Renal physiology changes significantly in normal pregnancy. Marked volume expansion and vasodilation result in alterations in systemic and renal hemodynamics, renal size, and volume, with physiologic hydronephrosis being common. Renal plasma flow (RPF) increases by approximately 80% and glomerular filtration rate (GFR) by 50%.[1] Renal tubular function responds to these changes with alterations in water and electrolyte handling, with the predominant findings being lower serum osmolality, mild hyponatremia, and increased urinary glucose and protein (Fig. 42.1).

ANATOMY

Renal size increases by 1 to 1.5 cm bilaterally during pregnancy,[1] and there is progressive dilatation of the renal pelvis, calyces, and ureter, more prominent on the right (Fig. 42.2). These changes are thought to be due to ureteral compression by iliac vessels and/or impaired peristalsis from increased progesterone production. The dilated collecting system can hold 200 to 300 ml of urine, promoting urinary stasis and increasing the risk for pyelonephritis in women with asymptomatic bacteriuria. Renal volume increases by up to 30%, thought to be secondary to increased vascular volume rather than nephron size.[2]

HEMODYNAMIC CHANGES

Systemic

Plasma volume increases until 32 to 34 weeks of gestation, by as much as 1.25 liters. Despite an increase in red blood cells (RBCs) there is a disproportional increase in plasma causing physiologic anemia of normal pregnancy.[3] Cardiac output increases by 40% to 50% secondary to increased heart rate, stroke volume, and venous return.[4] Despite this, systemic blood pressure decreases as a result of reductions in systemic vascular resistance (SVR) thought to be due to vasodilatory factors, including prostacyclin, nitric oxide (NO), relaxin, and progesterone.

Renal

Systemic vasodilation, increased arterial compliance, and decreased vascular resistance result in increased renal perfusion and increased GFR as early as 4 weeks of gestation that peaks at 40% to 50% above baseline by the second trimester, after which there is a mild decline until term.[1] These changes result in decreased serum creatinine concentrations to a normal range of 0.4 to 0.8 mg/dl (35 to 70 µmol/l). Although a value above 0.8 mg/dl (70 µmol/l) may be normal in the nonpregnant state, in pregnancy this indicates renal dysfunction. Most clinicians view a serum creatinine value greater than 1.0 mg/dl (>90 µmol/l) as being abnormal in pregnancy. RPF increases by approximately 80% above the increment in GFR, thereby resulting in a decreased filtration fraction. Despite increased RPF, there is no change in glomerular pressure because of equal dilation of the preglomerular and postglomerular resistance vessels.

Mechanisms of Increased Glomerular Filtration Rate

The exact mechanisms behind increased GFR are not completely understood.

$$GFR = (\Delta P - \pi_{GC}) x Kf$$

where ΔP is the net hydraulic pressure in the glomerulus, π_{GC} is the oncotic pressure in the glomerulus, and Kf is the glomerular ultrafiltration coefficient. As a result of plasma volume expansion, π_{GC} is decreased in pregnancy, contributing to the rise in GFR. Changes in hydraulic permeability and the surface area for filtration may cause minor changes in Kf, and it is unclear whether ΔP changes in pregnancy.

Measuring Glomerular Filtration Rate

Estimation of GFR in pregnancy can be challenging because the Modification of Diet in Renal Disease (MDRD) and Chronic Kidney Disease–Epidemiology Collaboration (CKD-EPI) formulas significantly underestimate true GFR.[5] The true GFR can be measured in pregnancy only by using inulin or creatinine clearance. More recent biomarkers such as cystatin C cannot yet be recommended for clinical use. However, change in GFR for an individual woman as pregnancy advances is more useful for measuring renal function than an absolute value.

Renin-Angiotensin-Aldosterone System

In early gestation, vasodilation and decreased SVR activate the renin-angiotensin-aldosterone system (RAAS) to increase renin, angiotensin II (Ang II), and aldosterone. This allows for an aldosterone-dependent increase in plasma volume, which is essential to maintain adequate uteroplacental blood flow. Maternal blood pressure (BP), however, does not increase, perhaps because of reduced responsiveness to the pressor effect of Ang II through reduced sensitivity of arterial smooth muscle and downregulation of AT1 receptors. Angiotensin (1-7) is elevated in pregnancy and may contribute to vasodilation through activation of

Fig. 42.1 Hydronephrosis in normal pregnancy. Intravenous urogram at 36 weeks of gestation. Note bilateral hydronephrosis, more marked on the right side.

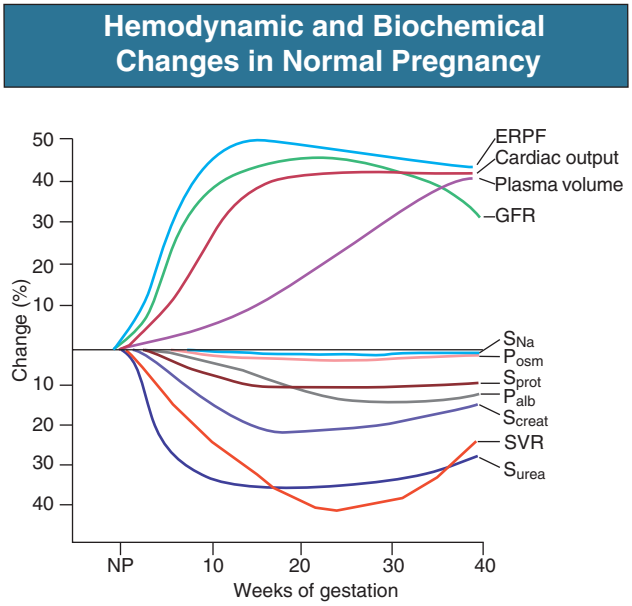

Fig. 42.2 Hemodynamic alterations induced by normal pregnancy. Increments and decrements in hemodynamic and biochemical parameters shown as percentage of change from nonpregnant baseline. *ERPF,* Effective renal plasma flow; *GFR,* glomerular filtration rate; *NP,* nonpregnant state; *S,* serum; *SVR,* systemic vascular resistance.

the Mas receptor. The ovarian hormone and vasodilator relaxin is a key mediator for enhanced NO signaling in pregnancy[6] and probably contributes to the vasodilated state of normal pregnancy. Relaxin is produced in the corpus luteum and in pregnancy is secreted in large amounts by the placenta in early gestation, peaking at 6 weeks and then returning to normal by 6 weeks postpartum.

TABLE 42.1 Changes in Some Common Indices During Pregnancy

	Nonpregnant	Pregnant
Hematocrit (%)	41	33
Serum protein (g/dl)	7.0	6.0
Plasma osmolality (mOsm/kg)	285	275
Serum sodium (mmol/l)	140	135
Serum creatinine (mg/dl, μmol/l)	0.8 (73)	0.5 (45)
Blood urea nitrogen (mg/dl)	12.7	9.3
Serum urea (mmol/l)	4.5	3.3
pH	7.40	7.44
Arterial P_{CO_2} (mm Hg)	40	30
Serum bicarbonate (mmol/l)	25	20
Serum uric acid (mg/dl, μmol/l)	4.0 (240)	3.2 (190) early 4.3 (260) late
Systolic BP (mm Hg)	115	105
Diastolic BP (mm Hg)	70	60

Mean values compiled from reference 56.
BP, Blood pressure, *PCO_2, carbon dioxide partial pressure.*

RENAL TUBULAR CHANGES

The elevated GFR means that the filtered solute load is increased, though tubular reabsorption is proportionally increased. The renal handling of common solutes is discussed later (Table 42.1).

Sodium Handling and Osmoregulation

In early gestation, serum osmolality decreases by approximately 10 mOsm/kg to a new set point of about 270 mOsm/kg, with a reduction in serum sodium concentration by 4 to 5 mmol/l below nonpregnant states.[1] In pregnancy the physiologic vasopressin (AVP) release response mechanisms of thirst and are reset to recognize this new set point in osmolality; β-human chorionic gonadotrophin (β-hCG) and relaxin may play a role in this resetting. The decrease in serum sodium is thought to be secondary to systemic vasodilation, arterial underfilling, and subsequent release of AVP.[7] In addition, the natriuretic effects of increased GFR and elevated progesterone promote sodium excretion, which is balanced by increased aldosterone and Ang II directly increasing sodium reabsorption, increased deoxycorticosterone promoting sodium retention, and upregulation of the epithelial sodium channel (ENaC) sodium channel.[8] Although there is a gradual gain in total body sodium during pregnancy of about 900 to 1000 mmol, there is greater water gain (Table 42.2).

Potassium

Despite increased aldosterone and mild alkalosis in pregnancy, hypokalemia does not occur, although typical pregnancy serum K^+ concentration is at the lower limit of normal. This may be partly due to the anti-mineralocorticoid effect of progesterone and the capacity of progesterone to inhibit K^+ excretion independent of anti-mineralocorticoid effects.

Calcium

There is increased urinary excretion of calcium but also of magnesium, citrate, acidic glycoproteins, and nephrocalcin that help prevent calcium oxalate stone formation associated with calcium super-saturation.

TABLE 42.2 Antinatriuretic and Natriuretic Factors Influencing Sodium Excretion During Pregnancy

Antinatriuretic	Natriuretic
Aldosterone	Increased glomerular filtration rate
Angiotensin II	Progesterone
Estrogen	Atrial natriuretic peptide
Deoxycorticosterone	Nitric oxide
Epithelial sodium channel	Prostaglandins
Supine posture	
Upright posture	
Decreased blood pressure	
Increased urethral pressure	
Placental shunting	

Uric Acid

Serum uric acid falls early in pregnancy to 2.0 to 3.0 mg/dl (119 to 178 µmol/l). After 22 to 24 weeks, uric acid levels start to rise as uric acid production increases secondary to trophoblast breakdown, ischemia, and the release of cytokines. Renal tubular absorption of urate also increases.[9] By 37 weeks of gestation, serum uric acid can reach nonpregnant levels.

Acid-Base

In pregnancy there is typically chronic mild respiratory alkalosis secondary to hyperventilation that lowers arterial carbon dioxide tension. Increased minute ventilation probably results from direct stimulation of the respiratory centers by progesterone.

Urine Protein

There is a rise in urine protein excretion in normal pregnancy. The mechanisms and clinical implications of proteinuria in pregnancy are discussed later.

Glucose

Glycosuria in pregnancy occurs secondary to increased glucose filtration coupled with decreased tubular reabsorption, thought to be secondary to increased plasma volume. Once the filtered load of glucose has reached the maximum reabsorptive capacity of the proximal tubule, there is physiologic glycosuria, although serum glucose concentrations typically remain normal.

RENAL COMPLICATIONS IN NORMAL PREGNANCY

The most common renal tract problem in pregnancy in an otherwise well woman is urinary tract infection (UTI), and the most common *de novo* "renal disease" in the second half of pregnancy is preeclampsia.

URINALYSIS AND MICROSCOPY

Many young women have urinalysis and urine microscopy performed for the first time during pregnancy, leading to the detection of hematuria, proteinuria, and pyuria, either related to or coincidental to the pregnancy.

Hematuria

Definition and Epidemiology

Microhematuria is detected at some time during pregnancy in about 20% of women.[10] Clinically significant *microhematuria* is defined as three or more RBCs per high-power field on microscopic evaluation of urinary sediment from two of three properly collected (clean-catch, midstream) urine specimens,[11] or greater than 2500 RBCs/ml. Microhematuria disappears in about 75% of women after delivery, but if secondary to glomerulonephritis (GN), it persists after the pregnancy and can be further investigated postpartum.

Etiology and Outcome

Dysmorphic microhematuria (defined by phase contrast microscopy, see Chapter 4) during pregnancy is most frequently caused by primary GN or lupus nephritis but is occasionally associated with preeclampsia. *Isomorphic* hematuria is more likely to be caused by bladder infection or bladder compression by the fetal head. Isolated microhematuria has no adverse effects on pregnancy; there is similar gestational age at delivery and no difference in birth weight, gestational hypertension, or preeclampsia.[12]

Macrohematuria (gross hematuria) in pregnancy is most often the result of vaginal bleeding or hemorrhagic bacterial cystitis. Other, less common causes include renal calculi, renal arteriovenous malformations, renal vein thrombosis, polycystic kidneys, and, rarely, bladder or kidney neoplasms.

Differential Diagnosis

When microhematuria is found, a urine culture is required to exclude infection. If there is no proteinuria, and BP and serum creatinine values are normal, further investigations can be delayed until 3 months postpartum, when microscopy to determine RBC morphology, serologic tests including antinuclear antibody (ANA) testing, and renal ultrasound can be performed. When there are significant numbers of dysmorphic urinary RBCs in pregnancy and BP is normal, the most likely cause is GN, for example, thin basement membrane nephropathy, IgA nephropathy, or lupus nephritis. As in nonpregnant women, ultrasound will exclude the presence of stones in only two thirds of pregnant women with calculi but may demonstrate other abnormalities such as polycystic kidneys and in rare cases neoplasms. For persistent isomorphic microhematuria, we do not recommend cystoscopy during pregnancy. This microhematuria often disappears spontaneously after pregnancy, and the likelihood of urothelial tumors is very low in this age group.

Treatment

The treatment of associated UTI and calculi is discussed later. There is no specific treatment for GN during pregnancy, provided renal function is normal and nephrotic syndrome and lupus are absent.

Proteinuria

Proteinuria during pregnancy warrants investigation and will most often be associated with preeclampsia, but renal disease secondary to GN or systemic conditions such as diabetes or essential hypertension may be detected first in pregnancy and present with proteinuria. *Gestational proteinuria* (isolated *de novo* proteinuria with no features of preeclampsia) also may develop, and this has no adverse effects for fetus or mother.

Definition

There is a rise in urine protein excretion in normal pregnancy that may continue into the postpartum period and may take 5 to 6 months to resolve.[13] The increase is greater in twin pregnancy. Some studies suggest this results from a combination of increased GFR and increased

permeability of the glomerular basement membrane, whereas other studies implicate increased tubular proteinuria.

Abnormal urine protein excretion is defined as greater than 150 mg/day in nonpregnant women, and proteinuria in pregnancy is generally defined as total urine protein greater than 300 mg/day, though more than 95% of pregnant women excrete less than 200 mg/day.[14]

Proteinuria is most frequently detected in pregnancy by dipstick urinalysis, but this method is notoriously unreliable, with a significant proportion of false-positive and false-negative results.[15] These false results are usually secondary to the variable osmolality of a random urine specimen. Other causes of false-positive results include macrohematuria, alkaline urine (pH >7.0), and the presence of radiocontrast agents or additives in the urine collection container. False-negative results may occur with acidic urine, low specific gravity (<1.001) or high salt concentration. A negative dipstick result is generally reliable, although not perfect, for confirming the absence of proteinuria or true proteinuria when dipstick readings are 3+ (>3 g/l) or 4+ (>20 g/l). At intermediate levels, false-positive rates are as high as 50%. Detection may be improved using an automated urinalysis device, thereby reducing observer error.

The 24-hour urine collection remains the gold standard for quantitation but is impractical when a quick assessment of proteinuria is required, as in preeclampsia. A reliable alternative is the ratio of urine protein to creatinine (uPCR); a ratio greater than 30 mg protein/mmol creatinine (~0.3 mg/mg) correlates reasonably well for urine protein greater than 300 mg/24 h.[16]

The albumin-to-creatinine ratio correlates with the uPCR but offers no greater clinical advantage, and clinicians should continue to use the protein-to-creatinine ratio until further data are available.[16]

Differential Diagnosis

Proteinuria arising *de novo* in pregnancy should be quantitated and further investigated according to the clinical situation. The course of pregnancy in women with proteinuria present before pregnancy is discussed in Chapter 43.

Persistent proteinuria associated with preeclampsia usually arises in the second half of pregnancy (>20 weeks) and generally but not always after the development of hypertension. The severity of the proteinuria is not indicative of the severity of preeclampsia and should not be used to guide management. Furthermore, proteinuria may be absent in up to 25% of women with other clinical manifestations of preeclampsia and is no longer mandatory for a diagnosis of preeclampsia. In the absence of preeclampsia, isolated proteinuria in an otherwise asymptomatic pregnant woman usually reflects gestational proteinuria or new-onset renal disease such as primary GN. Alternatively, proteinuria may appear because pregnancy has unmasked renal disease secondary to systemic disorders such as diabetes mellitus, systemic lupus, or chronic hypertension.

We limit investigation of *de novo* non-preeclamptic, non-nephrotic proteinuria during pregnancy to a renal ultrasound and the measurement of serum creatinine concentration, electrolyte concentrations, albumin, and ANA titers. A renal biopsy is not indicated. When underlying renal disease has been unmasked by pregnancy, appropriate investigations usually can be delayed until the postpartum period. The exceptions to this are women with nephrotic syndrome or renal impairment in whom prompt delivery is not desired (i.e., <24 weeks of gestation). In these patients, full investigation should be undertaken quickly, often including a renal biopsy, to determine whether specific treatment (e.g., corticosteroids) may be of benefit.

Natural History

Proteinuria occurring as a complication of preeclampsia invariably resolves in the postpartum period. Gestational proteinuria (i.e., new-onset proteinuria without features of preeclampsia) also resolves postpartum. Tradition holds that in both cases, proteinuria disappears within 3 months postpartum, but many cases take longer. In the absence of impaired renal function, we do not investigate non-nephrotic proteinuria unless it persists after 12 months postpartum.

Treatment

For women with nephrotic syndrome, an inverse correlation exists between serum albumin and birth weight, although no studies have examined whether reducing proteinuria can reverse reduced fetal growth. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are contraindicated in pregnancy because of their unwanted effects on the fetus.

Intravenous albumin has little role in managing nephrotic syndrome during pregnancy unless there is progressive deterioration in renal function. We recommend intravenous albumin infusion when serum creatinine rises above 100 µmol/l (1.2 mg/dl) with no other explanation, acknowledging that this may provide only a temporary benefit. Diuretics and sodium restriction should be avoided unless the woman has severe, intractable edema; the concern is that diuretics will lead to a further reduction in plasma volume and reduced uteroplacental perfusion. The pregnant woman with nephrotic syndrome is at high risk for venous thromboembolism and should receive prophylactic anticoagulation therapy during pregnancy and until the nephrotic syndrome has resolved postpartum.

Pyuria

Isolated pyuria without UTI is common in normal pregnancy, usually from contamination by vaginal secretions. There is also an increased white blood cell excretion rate in normal pregnancy. It requires no further follow-up other than ensuring it disappears, usually by 3 months postpartum.

URINARY TRACT INFECTION

Definitions

In asymptomatic bacteriuria (ASB), the urinary tract is colonized by a single species of bacteria in the absence of specific symptoms. Outside of pregnancy, ASB usually should not be treated with antibiotics. The traditional view is that ASB can lead to serious complications in pregnancy (e.g., pyelonephritis), and there is a cost benefit from its screening and treatment.[17] This view has recently been challenged,[18] but for now we recommend it is safest to continue to adopt concern about the risks for ASB in pregnancy until further trials examine this issue. Although the gold standard for diagnosis is detection of more than 10^5 organisms per milliliter, without epithelial cells, in a midstream urine specimen on two or more occasions, in practice, bacteriuria is usually detected by a single routine bacterial culture early in pregnancy. As many as 1% to 2% of pregnancies are complicated by *acute bacterial cystitis,* defined as an acute bacterial UTI accompanied by symptoms such as frequency, dysuria, or strangury. Although more than 10^5 organisms per milliliter defines ASB, as few as 10^2 organisms per milliliter is sufficient to diagnose cystitis if accompanied by pyuria and characteristic symptoms. In *acute pyelonephritis* there are generally more than 10^5 organisms per milliliter in the urine, in association with parenchymal bacterial infiltration. This is usually diagnosed clinically by fever, loin pain, and sometimes systemic sepsis.

Epidemiology

ASB affects 2% to 10% of all pregnant women. The prevalence is higher in women from lower socioeconomic groups and increases with age, parity, coexistent genital tract infection, and sickle cell trait. ASB is

BOX 42.1 Organisms Typically Causing Urinary Tract Infection in Pregnancy

- *Escherichia coli* (>70% of infections)
- *Klebsiella* spp.
- *Proteus* spp. (particularly in diabetic women or urinary tract obstruction)
- Enterococci
- Staphylococci, especially *Staphylococcus saprophyticus*
- *Pseudomonas*

more common in women with urinary tract abnormalities such as reflux nephropathy and neurogenic bladder, in diabetic patients, and in women with previous UTIs.

The overall incidence of acute pyelonephritis in pregnancy is approximately 1%, but it may occur in up to 30% of women with ASB. It is thought that about 70% of women who develop acute pyelonephritis have preceding covert bacteriuria, but this is difficult to prove. With treatment of ASB, it has been estimated that the incidence of pyelonephritis would be reduced by more than 80%. When possible, urethral catheters should be avoided, even in women having cesarean section, because the incidence of UTI in these women is twice that of those not catheterized.

Pathogenesis

Certain host characteristics may increase the risk for UTI or pyelonephritis (see Chapter 51). Women, such as those who do not express the antibody to the O antigen of *Escherichia coli,* may have ASB that predates pregnancy (i.e., are chronically colonized). Pregnancy is a state of relative urinary tract stasis; the calyces, pelves, and ureters dilate, particularly on the right, and this contributes to ASB developing into ascending acute pyelonephritis. The most common mechanism of infection is through the urethra from perineal bacteria. Box 42.1 lists common organisms causing UTI in pregnancy. Some strains of *E. coli* are particularly virulent and are associated with both ASB and pyelonephritis. They possess fimbriae, which enable the bacteria to attach themselves to the uroepithelial cells with pili, allowing them to ascend the urinary tract from the perineum. Unfortunately, infection with multi-resistant organisms is becoming more common.

Clinical Manifestations

Asymptomatic Bacteriuria

A Cochrane systematic review has indicated that treatment of ASB during pregnancy reduces the incidence of pyelonephritis, low birth weight, and preterm delivery.[19] More recent evidence challenges this. The mechanism by which UTI may cause premature labor is not fully understood, but proinflammatory cytokines secreted in response to bacterial endotoxins likely initiate labor in these women.

Most maternity units operate a policy of screening all pregnant women at least once, whether by dipstick urinalysis for leukocytes or nitrites or by urine culture. Both dipstick and urine culture appear cost-effective compared with no screening when the prevalence of ASB is 2% to 6%. Because isolated pyuria on dipstick testing is very common in normal pregnancy, we recommend screening by primary urine culture rather than the dipstick method.

Pyelonephritis

Pyelonephritis most often presents between 20 and 28 weeks of gestation. Not all women will have had lower urinary tract symptoms, and pyelonephritis also can manifest in pregnancy as acute abdominal pain or may be detected only after presentation with premature labor. Pyelonephritis is more common in pregnant women with urologic abnormalities or diabetes and more often affects the right kidney, probably because the ureter is generally more dilated on that side.

The diagnosis of pyelonephritis is usually made on clinical grounds. Definitive diagnosis requires positive urine culture, but this may take about 2 days, and treatment should not be delayed. *E. coli* is the most common infecting organism (>85% of cultures).

Bacteremia is a common and usually transient complication of pyelonephritis. Occasionally, however, women become septicemic and may develop endotoxemia with shock, with sequelae including respiratory failure, disseminated intravascular coagulation (DIC), and acute kidney injury (AKI). Pyelonephrosis and perinephric abscess are rare complications but should be suspected when treatment fails.

Without treatment, the complications of acute pyelonephritis during pregnancy can be severe, probably more so than in nonpregnant women. In the preantibiotic era, maternal mortality was 3% to 4%; death from pyelonephritis is now rare in developed countries.

Treatment

Asymptomatic Bacteriuria

For now we agree that antibiotic treatment of ASB significantly reduces the incidence of pyelonephritis in pregnancy and thereby reduces the risk for preterm delivery.[19]

In choosing treatment, the clinician must consider the safety of the antibiotic in pregnancy. In most women, treatment with cephalexin, amoxicillin–clavulanic acid, or nitrofurantoin is first-line therapy. Overall, trials demonstrate that longer duration of treatment is likely to be more effective than single-dose therapy, although data are limited.[20] Until evidence from new trials is available, a 3- to 7-day treatment regimen is recommended.

Without treatment, ASB will persist in 80% of women, and even with treatment 20% will still have ASB. Those with persistent colonization are difficult to treat, with eradication achieved in only 40% after a second course of antibiotics. Where eradication is not achieved, we recommend prophylactic antibiotics, usually cephalexin 250 mg at night, throughout pregnancy to prevent pyelonephritis and its consequences; however, no studies specifically address this situation. The incidence of pyelonephritis after effective treatment of ASB is reduced from about 30% to 3%, comparing favorably with a 1% prevalence of pyelonephritis for the overall pregnant population.

Cystitis

Treatment of cystitis at the first presentation should be for 5 days with an appropriate antibiotic. As for ASB, it is important to obtain a follow-up urine culture to be certain infection has been eradicated.

Pyelonephritis

It is usual practice to admit pregnant women with pyelonephritis to hospital, although a trial has reported successful outpatient management for milder cases.[20] Treatment may occasionally require resuscitation with intravenous (IV) fluids, but usually a short course of IV antibiotics followed by oral antibiotics, once the woman is afebrile, is adequate therapy.

A cephalosporin is usual first-line treatment with addition of an aminoglycoside in more severe cases, used for 24 to 48 hours while awaiting urine cultures, provided maternal renal function is satisfactory. The risk for irreversible fetal ototoxicity precludes prolonged use, and aminoglycosides are not recommended in the first trimester. The full duration of treatment is generally 2 weeks, and it is imperative to repeat urine culture 1 week after treatment to ensure eradication. We then recommend prophylactic antibiotics such as cephalexin 250 mg at night until delivery, to prevent further episodes and preterm labor. Periodic urine culture is also recommended to monitor the risk for antibiotic

TABLE 42.3 Antibiotic Regimens for Treatment for Urinary Tract Infections in Pregnancy*

Antibiotic	Dose	Duration
Acute Cystitis		
Amoxicillin	500 mg three times daily	3-5 days
Nitrofurantoin	100 mg four times daily	3-5 days
Cephalexin	500 mg three times daily	3-5 days
Asymptomatic Bacteriuria		
Cephalexin	500 mg three times daily	3 days
Amoxicillin	500 mg three times daily	3 days
Amoxicillin–clavulanic acid	500 mg three times daily	3 days
Nitrofurantoin	50 mg four times daily	3 days
Fosfomycin	3 g single dose	
Recurrent Bacteriuria or Cystitis		
Cephalexin	250 mg nighttime (or postcoital)	
Nitrofurantoin	50 mg nighttime (or postcoital)	
Amoxicillin	250 mg nighttime (or postcoital)	
Pyelonephritis (Initial Intravenous Therapy)		
Ceftriaxone	1 g daily	
Cephazolin	1g every 8 hours	
Ampicillin (with gentamicin)	1 g every 6 hours	
Gentamicin	3 mg/kg daily	
Ticarcillin	3.2 g every 8 hours	
Piperacillin	4 g every 8 hours	

*Avoid tetracyclines at all stages and sulfamethoxazole (in the third trimester) and use aminoglycosides only when other drugs are not suitable.

resistance and to decrease the risk for prematurity resulting from recurrent infection.

Renal ultrasound is generally not indicated during an initial infection, because urinary tract dilation is common, and cannot be distinguished from urinary tract obstruction. However, if infection persists, ultrasound is indicated to help exclude pyelonephritis, perinephric abscess, and renal calculi. If pyelonephritis persists despite adequate antibiotic therapy and urinary tract dilation is confirmed, percutaneous nephrostomy should be performed under ultrasound guidance. In our experience, this is rarely necessary, but nephrostomy is the only way to be certain that urinary tract obstruction and pyelonephritis have been properly treated.

Clinicians also should remain alert for premature labor in the presence of pyelonephritis and institute appropriate treatment while aggressively treating the infection. When more than two UTIs have occurred in pregnancy, prophylaxis is indicated until delivery with either nitrofurantoin 50 mg or cephalexin 250 mg at night. Table 42.3 outlines some antibiotic regimens suitable for use in pregnancy.

RENAL CALCULI

Epidemiology

Despite normal pregnancy being an ideal environment for renal stone formation, the incidence of renal calculi remains similar in pregnant and nonpregnant women, in the range of 0.03% to 1%.

Pathogenesis

The majority of stones are formed from calcium oxalate and calcium phosphate. Struvite stones are the next most common, usually when the urinary tract is infected with organisms such as *Proteus* spp. Small proportions of renal stones are formed from uric acid or cystine. Although pregnancy is a physiologic state of relative urinary stasis and increased calcium and uric acid excretion, this is balanced against enhanced excretion of inhibitors of stone formation, such as magnesium, citrate, and the glycoprotein nephrocalcin.

Clinical Manifestations

Symptomatic stones during pregnancy are rare, usually presenting in the second or third trimester with acute flank pain radiating to the groin or lower abdomen and hematuria. However, clinical features of renal calculi may be more difficult to interpret in pregnancy because frequent episodes of diffuse, poorly localized abdominal pain and lower urinary tract symptoms are relatively common in normal pregnancy.

Approximately 75% to 85% of stones will pass spontaneously during pregnancy, and some women with calculi will have a concomitant UTI. Pregnant women with renal calculi are at greater risk for superimposed pyelonephritis and complications including preterm labor, hypertensive disorders, gestational diabetes, and cesarean deliveries.[21]

The diagnosis of renal calculi in pregnancy is difficult because of the risk for radiation to the fetus if investigating the urinary tract with computed tomography (CT). Ultrasound will detect hydronephrosis (usually as part of normal pregnancy) and will often detect calculi within the kidney, but ultrasound rarely finds ureteral stones and is less accurate than CT for this purpose. If pain persists, transvaginal ultrasound should be performed when transabdominal ultrasound is uninformative, to detect distal ureteral stones. If symptoms persist and further diagnosis is required, magnetic resonance (MR) urography or low-dose CT (in second or third trimester) can be used, although in our experience, this is rarely needed.

Treatment

Initial management of renal calculi is conservative, with appropriate hydration, antiemetics, and analgesia. The woman should lie on her side, with the symptomatic side up, enabling relief of pressure on the ureter from the gravid uterus. Calcium intake should not be limited, but women in whom calcium oxalate stones form persistently can limit foods high in oxalate, such as spinach, rhubarb, and chocolate. Urine should always be cultured and appropriate antibiotics administered when a UTI is suspected.

Quantitation of urine calcium, uric acid, or other mineral excretion is not necessary in pregnancy, because specific pharmacologic agents to modify excretion (including thiazides and allopurinol) are contraindicated. Investigations can be completed postpartum.

Surgical intervention is considered only when stones cause persistent obstruction, deteriorating renal function, intractable pain or infection, or premature labor unresponsive to other treatment. This is a rare situation. Both cystoscopy with ureteral stenting and ureteroscopic removal of stones have been reported.[22] Lithotripsy is generally contraindicated during pregnancy because of the presumed adverse effect of the shock waves on the fetus; however, some centers have used ureteroscopic laser lithotripsy in pregnant women.[22] Although not recommended for routine use, extracorporeal shock wave lithotripsy has been reported as an inadvertent procedure in six women in the first month of pregnancy, all of whom subsequently delivered normal infants.[22]

Postpartum follow-up is important. In the absence of ongoing symptoms, we perform a CT scan of kidney, ureters, and bladder 3 months later. This delay is necessary because calyceal and ureteral dilation may persist well after delivery and may cause confusion. Women planning a further pregnancy should be assessed for idiopathic hypercalciuria or other causes of renal calculi after a minimum of 3 months postpartum.

HYPERTENSION IN PREGNANCY

Definitions

There are four major hypertensive disorders related to pregnancy (Fig. 42.3).

Hypertension in pregnancy is defined as BP of 140 mm Hg or greater systolic or 90 mm Hg diastolic. Normal pregnancy is characterized by a decrease in BP, beginning in the first trimester and reaching a nadir in the second trimester. BP rises toward preconception levels near the end of the third trimester. A BP increment of 30 mm Hg or greater systolic and/or 15 mm Hg diastolic but still below 140/90 mm Hg warrants increased frequency of follow-up. By itself, this BP increase does not diagnose gestational hypertension or preeclampsia, but in the presence of proteinuria, this may signify preeclampsia in some women.

The development of newly elevated BP after 20 weeks of gestation without evidence of maternal organ dysfunction is known as *gestational hypertension.* This should usually resolve by 12 weeks postpartum. If hypertension persists beyond that, the diagnosis is likely chronic/preexisting hypertension that has been masked by the physiologic decrease in BP that occurs in early pregnancy. However, some women with preeclampsia or gestational hypertension may take longer for their high BP to resolve.

Preeclampsia is hypertension developing in the second half of pregnancy, but this more serious disorder includes accompanying evidence of maternal renal, cerebral, hepatic, cardiac dysfunction, or clotting abnormalities and fetal growth restriction. Neither proteinuria nor edema are now considered necessary for a diagnosis of preeclampsia. The International Society for the Study of Hypertension in Pregnancy (ISSHP)[23] defines preeclampsia as *de novo* hypertension manifesting after 20 weeks of gestation combined with one or more of the following:

1. Proteinuria (spot urine protein/creatinine >30 mg/mmol [0.3 mg/mg] or >300 mg/day or at least 1 g/l [2+] on dipstick testing)
2. Other maternal organ dysfunction: Renal impairment (serum creatinine ≥90 µmol/l [1 mg/dl]), liver involvement (elevated transaminases—at least twice the upper limit of normal ± right upper quadrant or epigastric abdominal pain), neurologic complications (e.g., eclampsia, altered mental status, blindness, stroke, or, more commonly, hyperreflexia with clonus, severe headaches with hyperreflexia, persistent visual scotomata), hematologic complications (thrombocytopenia—platelet count below 150×10^9/l, DIC, hemolysis)
3. Uteroplacental dysfunction: Fetal growth restriction

Chronic/preexisting hypertension is BP greater than 140/90 mm Hg that antedates pregnancy or is present before the 20th week of pregnancy

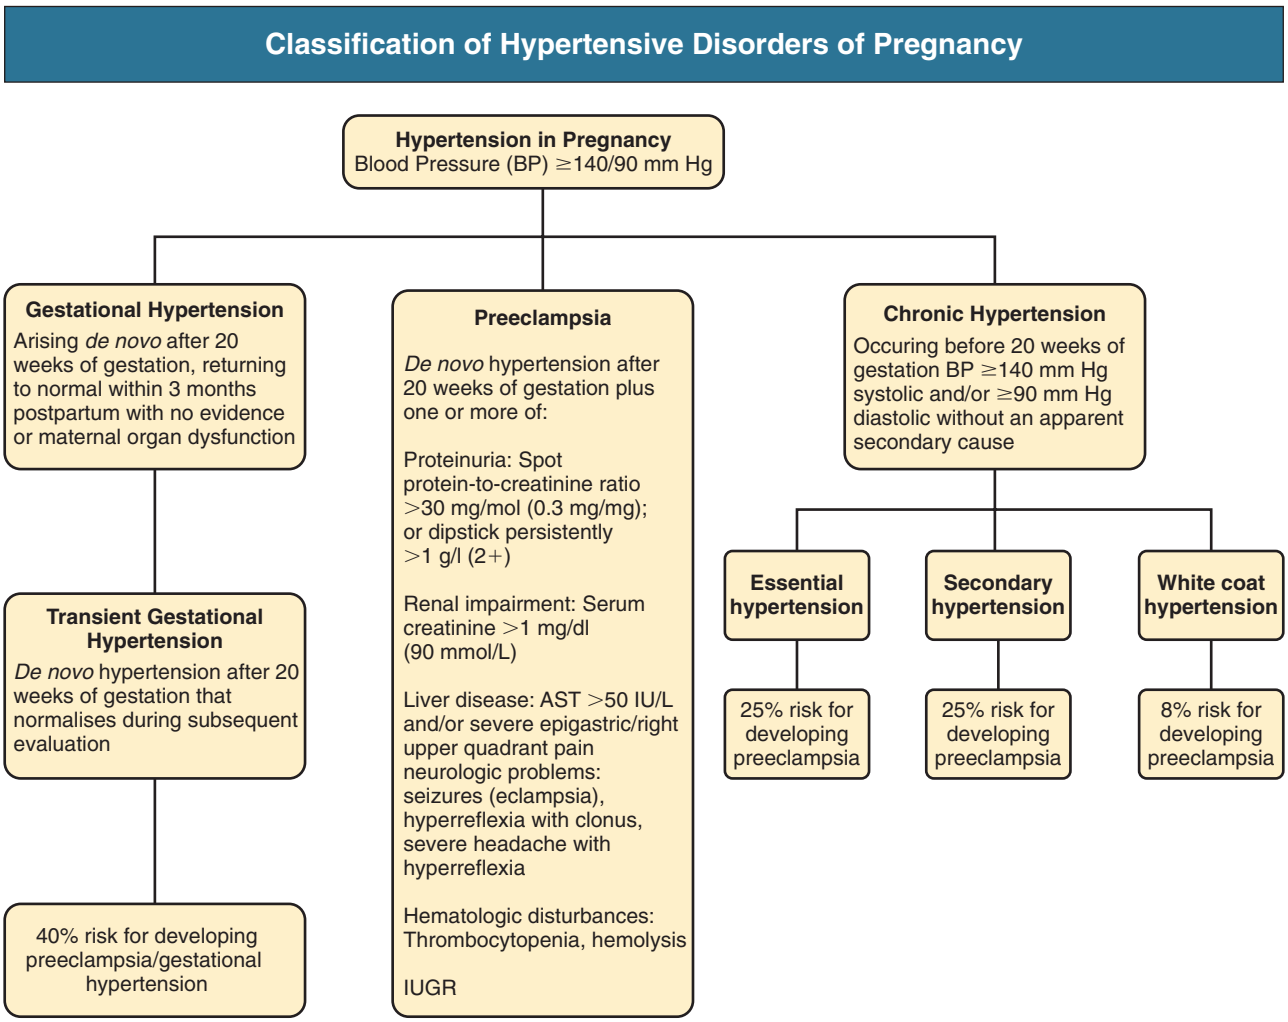

Fig. 42.3 Classification of hypertensive disorders of pregnancy. *AST,* Aspartate aminotransferase; *BP,* blood pressure; *IUGR,* intrauterine growth restriction.

(on at least two occasions) or persists beyond 12 weeks postpartum. This should be confirmed by 24-hour ambulatory BP monitoring or home self-monitoring, to exclude *white coat hypertension,* which is common in pregnancy.[24] Superimposed preeclampsia is the development of new proteinuria or new renal dysfunction, thrombocytopenia, neurologic features, or abnormal liver function after 20 weeks of gestation in a woman with chronic/preexisting hypertension.

Eclampsia (seizures) is now uncommon in developed countries, with a prevalence of about 0.3% of hypertensive pregnancies. In developing countries, eclampsia is much more common, with greater risks for maternal mortality and morbidity, as well as perinatal mortality.

Epidemiology

Hypertensive disorders of pregnancy are the second most common cause for maternal death worldwide, after hemorrhage.[24] Hypertension affects 10% to 12% of all pregnancies, and tertiary referral units tend to have a higher proportion of severe preeclamptic cases. In general, primary chronic hypertension accounts for about 20% and preeclampsia and gestational hypertension each about 40% of cases. About one in four women with apparent primary hypertension early in pregnancy have white coat hypertension, and their outcomes are better than those with true chronic hypertension. Women with white coat hypertension may be managed without medication through regular home BP monitoring. A small proportion will go on to develop preeclampsia.[24]

PREECLAMPSIA

Epidemiology

Preeclampsia follows no recognized racial patterns, and no specific genotype-phenotype relation has been associated with this disorder.[25] It remains a major contributor to maternal, fetal, and neonatal mortality worldwide.[26] Box 42.2 lists risk factors for preeclampsia. The risk is highest in those with a history of preeclampsia, with rates ranging from 15% to 65% depending on the gestation at onset of the preeclampsia and in women with assisted reproduction, antiphospholipid syndrome, diabetes, obesity, and chronic hypertension.[27] Risk for preeclampsia is usually higher in a first pregnancy. The reduced risk for preeclampsia in subsequent pregnancies is intriguing. However, the risk returns to that of a first pregnancy in women who have a new partner. This observation, combined with an increased likelihood of preeclampsia in women who have used barrier methods of contraception, raised the possibility of an impaired immunologic response to paternal antigens in such pregnancies. However, this may be explained simply by a longer interpregnancy interval rather than a change of partners, with the incidence increasing after about 7 years between pregnancies.

Smoking reduces the risk for preeclampsia by a third, but increases the risk for preterm labor, intrauterine growth restriction (IUGR), and placental abruption.[28]

Pathogenesis

The pathogenesis of preeclampsia is complex. The placenta likely causes preeclampsia, with other maternal organs (e.g., kidney) amplifying the disease process (Fig. 42.4). This is supported by the observation that preeclampsia can occur in hydatidiform mole, where the fetus is absent, with the condition resolving when the placenta is removed. Preeclampsia is considered a maternal endothelial disorder made up of two stages: (1) placental ischemia and/or hypoxia secondary to abnormal placental implantation or a placental oxygen demand mismatch and (2) ischemia-reperfusion injury resulting in a maternal inflammatory syndrome. The following key mechanisms are involved in the progression to the clinical preeclamptic syndrome:

BOX 42.2 Risk Factors for Preeclampsia

Maternal Obstetric Factors
- Nulliparity
- Multiple-gestation pregnancy
- History of previous preeclampsia
- Prior intrauterine growth restriction
- Prior placental abruption
- Artificial reproductive technology
- Molar pregnancy
- Trisomy 13 or fetal hydrops
- Gestational diabetes

Obstetric Paternal Factors
- Father born from preeclamptic pregnancy
- Family history of preeclampsia

Maternal Comorbid Conditions
- Chronic hypertension
- Chronic kidney disease
- Pregestational diabetes
- Obesity (body mass index >30 kg/m^2)
- Antiphospholipid antibody
- Systemic lupus erythematosus
- Polycystic ovarian syndrome

Maternal Genetic Factor
- Thrombophilia
- Preeclampsia in pregnancy of first-degree relative

Other Maternal Factors
- Age older than 40 years
- Having been born small for gestational age
- Pregnancy interval greater than 10 years

Maternal risk factors determined at 16 weeks of gestation
Modified from reference 27.

- *The immune response at the placental-maternal interface.* The fetal-maternal immunologic interaction at placentation involves maternal natural killer (NK) cells, immunoglobulin-like receptors, and fetal human leukocyte antigen (HLA-C and HLA-G) molecules. This interaction fails in preeclampsia, leading to an abnormal interaction among uterine NK cells, trophoblastic cells, and macrophage-derived tumor necrosis factor α (TNF-α).
- *Superficial placentation with insufficient remodeling of spiral arteries.* In normal pregnancy, invasive cytotrophoblasts penetrate the walls of the spiral arteries, where they replace maternal endothelium, converting them to capacitance vessels capable of carrying greater blood flow through the placenta and reducing their capacity for vasoconstriction. In preeclampsia the spiral arteries often fail to undergo this transformation resulting in uteroplacental ischemia and making them more prone to the lesion of acute atherosis and inflammation. There is also a hypoxic microenvironment, indicated by the finding of hypoxia-inducible factor 1 α (HIF-1α), a marker of cellular oxygen deprivation, in placentas of women with preeclampsia.[29] It remains unclear how commonly this is due to structural changes in the spiral arteries or an oxygen demand-supply mismatch in the placenta.
- Imbalance of angiogenic factors and Ang II type 1 receptor autoantibodies.
  Angiogenic and anti-angiogenic factors implicated in the pathogenesis of preeclampsia include placental growth factor (PlGF), vascular

(Modified from reference 29.)

endothelial growth factor (VEGF-A), the VEGF receptor soluble fms-like tyrosine kinase 1 (sFlt-1), transforming growth factor-β (TGF-β), and soluble endoglin (sEng).[30] There is an excess of syncytiotrophoblast-derived anti-angiogenic factors, such as sEng and sFlt-1, thought to be triggered by placental ischemia or hypoxia. In the serum, sFlt-1 binds to VEGF and PlGF, preventing their interaction with endothelial receptors on the cell surface, inducing endothelial dysfunction and increasing sensitivity to pro-inflammatory factors such as TNF-α (Fig. 42.5). In addition, sEng, a cell surface coreceptor of TGF-β induces proliferation and migration of endothelial cells. High concentrations as seen in preeclampsia result in interference with NO signaling, vasoconstriction, and increased vascular permeability. Ang II type 1 receptor autoantibodies (AT1AA), often present in preeclampsia, may contribute to the hypertension, increased production of reactive oxygen species (ROS), increased thrombin generation, impaired fibrinolysis, endothelial cell damage, and impaired trophoblast invasiveness seen in preeclampsia.[29] However, further study is required to identify the exact role of AT1AA in preeclampsia pathogenesis.

- *Oxidative stress that triggers inflammation.* Maternal blood enters the intervillous space at higher pressure and faster rate when there is impaired arterial remodeling of the spiral arteries. This exposes the placental villi to fluctuating oxygen concentrations, leading to oxidative stress and activation of nuclear factor-κB, a transcription factor central to the inflammatory response. Increase in necrotic trophoblast shedding occurs and may be important in the pathogenesis of preeclampsia through systemic endothelial cell activation by secretion of interleukin-6 (IL-6). Microparticles derived from placental syncytiotrophoblasts in maternal plasma interact with leukocytes and monocytes and stimulate production of proinflammatory cytokines.

Thus abnormal placentation leads to an imbalance in angiogenic factors and oxidative stress that triggers inflammation. The resulting insufficient placental function, release of placental factors into the

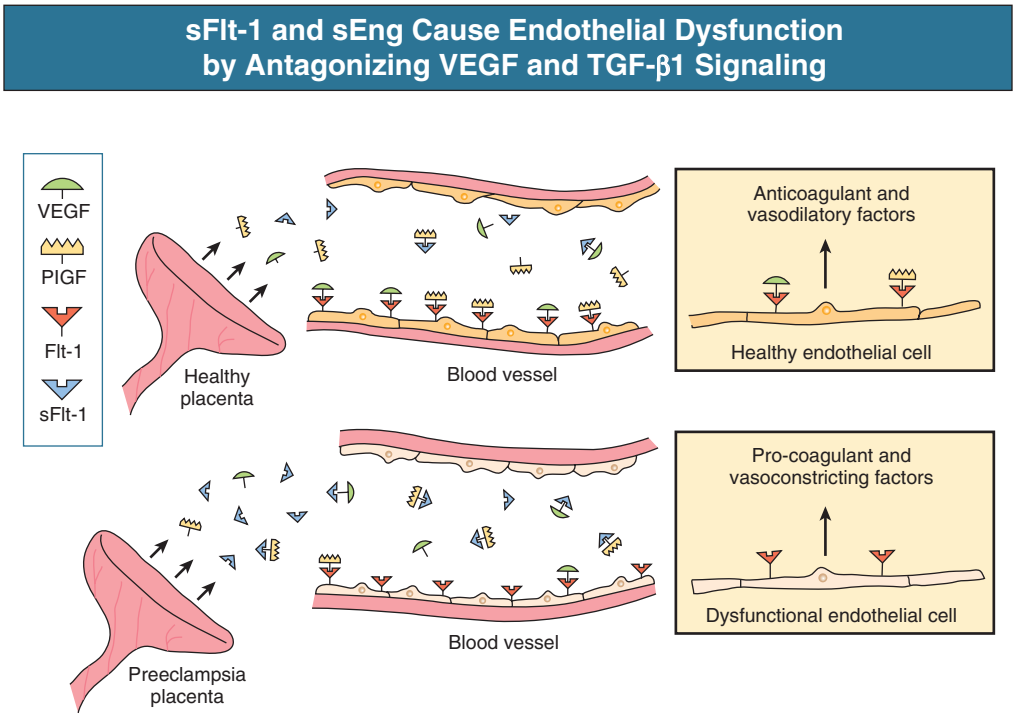

Fig. 42.5 Proteins sFlt-1 and sEng cause endothelial dysfunction by antagonizing vascular endothelial growth factor (*V*EGF) and transforming growth factor β1 (TGF-β) signaling. There is mounting evidence that VEGF and TG-β1 are required to maintain endothelial health in several tissues, including the kidney and perhaps the placenta. During normal pregnancy, vascular homeostasis is maintained by physiologic levels of VEGF and TGF-β1 signaling in the vasculature. In preeclampsia, excess placental secretion of sFlt-1 and sEng (two endogenous circulating antiangiogenic proteins) inhibits VEGF and TGF-β1 signaling, respectively, in the vasculature. This results in endothelial cell dysfunction, including decreased prostacyclin, nitric oxide production, and release of pro-coagulant proteins. *PlGF,* Placental growth factor; *sEng,* soluble endoglin; *sFlt-1,* soluble fms-like tyrosine kinase 1. (Modified from reference 54.)

maternal circulation, and exaggerated maternal inflammatory response cause a generalized endothelial dysfunction with leukocyte and clotting activation.

Regardless of cause, preeclampsia is characterized by vasoconstriction, platelet activation with intravascular coagulation (usually local but occasionally disseminated), and maternal plasma volume contraction associated with capillary leak.

These abnormalities lead to further impairment of blood flow through the placenta as well as through the maternal kidneys, liver, and brain. It is unknown why these organs are most often affected in preeclampsia or why other vascular beds (e.g., gut) are unaffected, even in severe cases.

The clinical presentation of preeclampsia will depend on the extent to which maternal organ systems and the placenta have been affected by this process, but once begun, preeclampsia runs a progressive course until delivery, the only definitive cure.

Renal Abnormalities in Preeclampsia

Several abnormalities of renal function and structure occur in preeclampsia (Fig. 42.6). Characteristic pathologic changes in preeclampsia include diffuse *glomerular endotheliosis,* characterized by swelling and vacuolization of endothelial cells, capillary lumen occlusion, and glomerular enlargement. The swollen endothelial cytoplasm encroaches on glomerular capillary lumina, contributing to the tuft ischemia (Fig. 42.7). Immunofluorescence may reveal fibrin deposits. These changes are infrequently seen in clinical practice because renal biopsy is rarely performed in preeclamptic women.

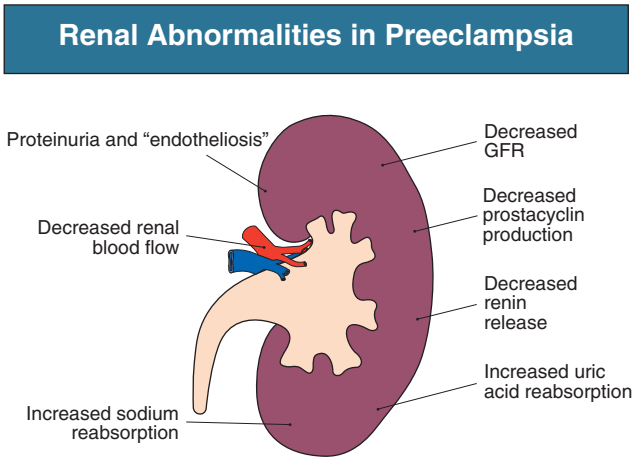

Fig. 42.6 Renal abnormalities in preeclampsia. *GFR,* Glomerular filtration rate.

Proteinuria

The urine sediment is usually bland. Both tubular and glomerular patterns of proteinuria have been reported in preeclampsia. Glomerular proteinuria is nonselective and may vary from a few hundred milligrams per day up to the nephrotic range. Levels of proteinuria in women with preeclampsia do not seem to correlate with maternal and fetal outcomes,[31] and women with mild or no proteinuria should be managed with the same caution as those with nephrotic-range proteinuria.

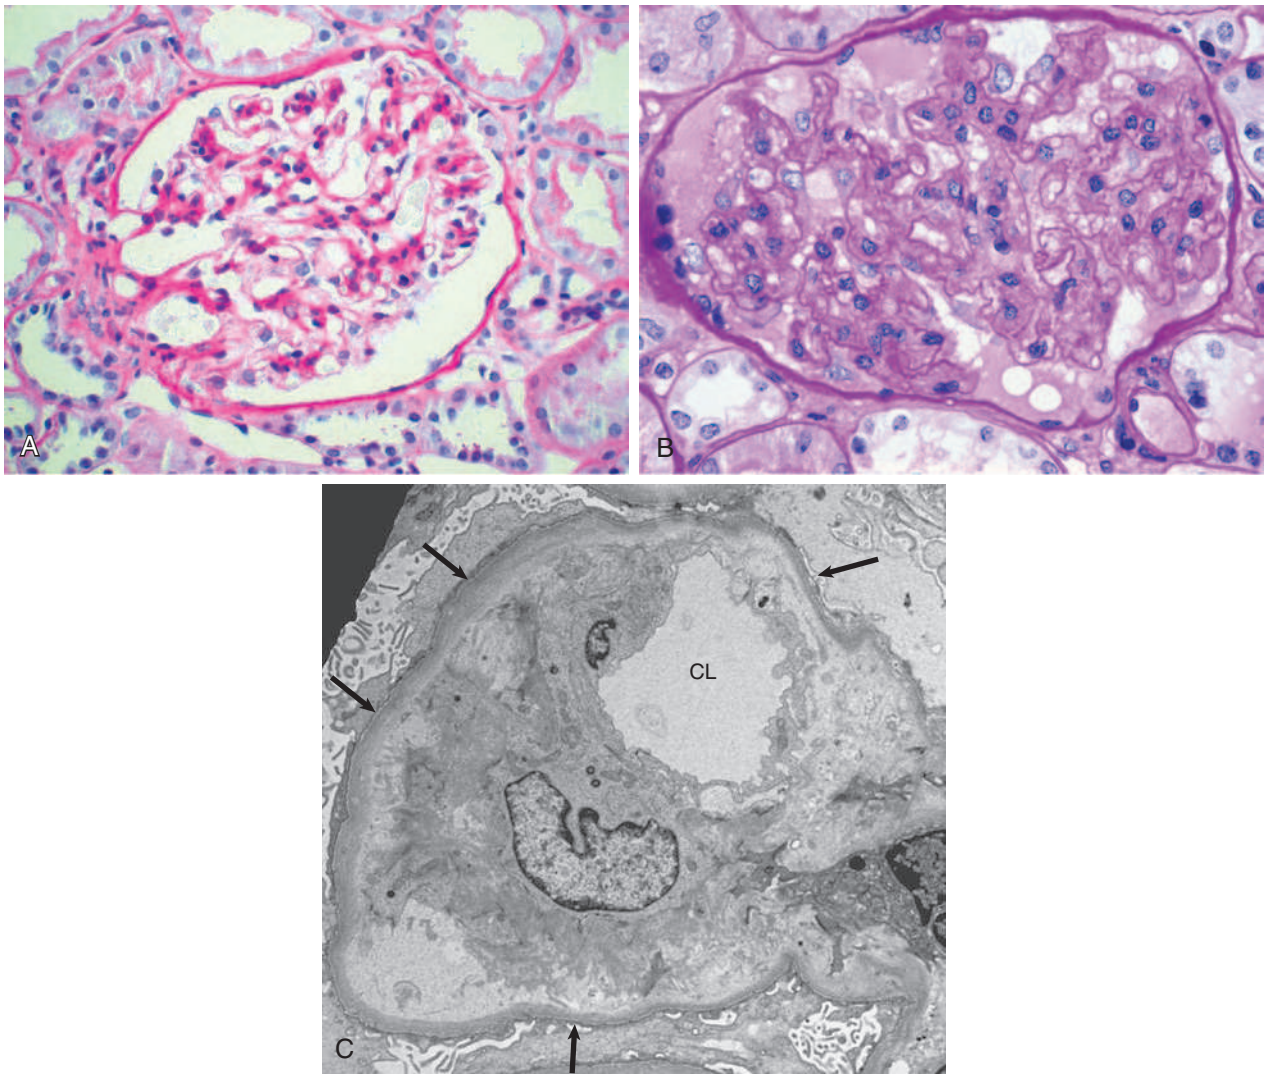

Fig. 42.7 Glomerular endotheliosis. (A) Normal glomerulus on light microscopy. (B) Glomerulus from a patient with preeclampsia on light microscopy. (*A* and *B,* Periodic acid–Schiff reaction; magnification ×40; *C,* original magnification ×7500.) (Courtesy Prof. P. Furness, University of Leicester, UK.)

Proteinuria may be part of the general capillary leak of preeclampsia or may be, in part, a consequence of glomerular endotheliosis.

Decreased Glomerular Filtration Rate

A fall in the GFR may be partly caused by the decrease in renal blood flow (in turn caused by vasoconstriction, plasma volume loss, and decreased cardiac output). Other factors may be involved, including impaired placental production of the vasodilator relaxin, impaired renal prostacyclin or NO production, or the glomerular morphologic changes themselves.

Acute Tubular Necrosis

Acute tubular necrosis (ATN) is the most common cause of AKI in preeclampsia. Impaired GFR (serum creatinine ≥90 µmol/l [1.2 mg/dl]) is only sometimes corrected by BP control and plasma volume restoration, and delivery is indicated if renal function continues to deteriorate.

Sodium Retention

Avid sodium retention occurs in preeclampsia, as a renal tubular response to perceived reduction in renal perfusion and perhaps also to increased sympathetic nervous system activity or alterations in expression of epithelial sodium channels. This is a normal renal response to the hemodynamic changes and may lead to oliguria; in the absence of an elevated serum creatinine, oliguria should not itself be an indication for delivery.

Renin-Angiotensin-Aldosterone System

Plasma renin and aldosterone concentrations are reduced in preeclampsia, compared with their elevation in normal pregnancy, and their levels correlate inversely with the severity of the disorder. This has little direct clinical relevance; however, it may be explained by a mineralocorticoid receptor mutation, *MRL810,* which allows factors normally antagonistic to aldosterone, such as progesterone, to bind and activate this receptor leading to inappropriate sodium retention, hypertension, and subsequent

TABLE 42.4 Gestation-Corrected Serum Uric Acid During Pregnancy

Gestational Age	Serum Uric Acid (μmol/l)	Serum Uric Acid (mg/dl)
<32 wk	>240	>4.0
32-35 wk	>270	>4.5
36-37 wk	>290	>4.9
≥38 wk	>330	>5.6

Concentrations above these levels should prompt review for associated adverse pregnancy outcomes, even in patients with gestational hypertension alone. Data are from 1610 hypertensive pregnant women.
From reference 34.

suppression of renin and aldosterone release.[32] There is a general upregulation of the systemic and placental RAAS systems in normal pregnancy. However, it seems that in preeclampsia, placental RAAS is upregulated, possibly because of agonistic AT1AA, whereas systemic RAAS components are lower, possibly as a result of increased epithelial sodium channel activation.[33]

Increased Uric Acid Reabsorption

Uric acid may be involved in the pathogenesis of preeclampsia. Hyperuricemia in preeclampsia results largely from renal uric acid retention, although there is probably also a component of increased uric acid production, perhaps by the placenta.[9] Serum uric acid is a not a useful test in the diagnosis of hypertensive pregnant women, but the degree of hyperuricemia correlates with fetal risk, even in women with gestational hypertension alone, and should alert clinicians to seek evidence of fetal growth restriction (Table 42.4).[34]

Clinical Manifestations

Preeclampsia is initially detected in most women by the onset of hypertension, typically after the 20th week of pregnancy (Box 42.3). Symptoms are not always present, but may include severe headaches, seizures, stroke, repeated visual scotomata (all manifestations of cerebral involvement), severe epigastric or right upper quadrant pain (reflecting hepatic ischemia), oliguria, bleeding caused by DIC, lower abdominal pain caused by placental abruption, or reduced fetal movements. Neurologic complications include eclampsia (see later discussion), stroke/reversible ischemic deficit, retinal detachment, cortical blindness, and posterior reversible encephalopathy. Hepatic complications include subcapsular hematoma and in rare cases liver rupture. Renal involvement can result in AKI requiring dialysis, and cardiorespiratory complications include myocardial ischemia and pulmonary edema.

Routine evaluation should include assessment of fetal growth, fetal heart rate patterns measured by cardiotocography (CTG), and assessment of the maternal reflexes because clonus can be a warning sign of impending eclampsia. The following investigations should be performed in all patients:

- Urine dipstick testing for proteinuria, with quantitation by measuring the uPCR if the dipstick is 1+ (30 mg/dl) or higher
- Hemoglobin, platelet count
- Serum creatinine, electrolytes, uric acid
- Serum transaminases
- Ultrasound assessment of fetal growth, amniotic fluid volume, and umbilical artery flow

BOX 42.3 Clinical Features of Preeclampsia

Primary Manifestation
- Hypertension

Renal Involvement
- Significant proteinuria: Dipstick positive confirmed by spot ratio of urine protein to creatinine >30 mg/mmol (about >300 mg/g creatinine)
- Acute kidney injury: Serum or plasma creatinine >90 mmol/l
- Oliguria

Hematologic Involvement
- Thrombocytopenia
- Hemolysis
- Disseminated intravascular coagulation

Liver Involvement
- Raised serum transaminases
- Severe epigastric or right upper quadrant pain

Neurologic Involvement
- Seizures (eclampsia)
- Hyperreflexia with sustained clonus
- Severe headache with hyperreflexia
- Persistent visual disturbances (photopsia, scotomata, cortical blindness, retinal vasospasm)
- Cerebrovascular accident (stroke)

Other Major Features
- Pulmonary edema
- Fetal growth restriction
- Placental abruption

Eclampsia

Eclampsia is the occurrence of tonic-clonic seizures in a woman who is pregnant or has recently delivered that cannot be attributed to other causes. Of these women, the majority, but not all, have premonitory signs and symptoms present during the week before the first eclamptic seizure: headache (56%), visual disturbances (23%), epigastric pain (17%), hypertension (48%), proteinuria (46%), or concurrent hypertension and proteinuria (38%).[35] Risk for eclampsia is not directly related to BP level. Although some view this as a form of hypertensive posterior reversible encephalopathy syndrome eclampsia may occur with relatively low BP and can occur in the absence of proteinuria. Importantly, about half the cases of eclampsia occur after delivery, usually within the first 5 days postpartum.

HELLP Syndrome

The HELLP syndrome—hemolysis, elevated liver enzymes, and low platelet count—is a variant of preeclampsia. Although sometimes regarded as a separate entity, HELLP simply refers to a severe form of preeclampsia in which the hepatic and platelet abnormalities dominate, with thrombotic microangiopathy. The diagnosis of HELLP syndrome is based on the following laboratory criteria:

- Microangiopathic hemolytic anemia: schistocytes in a blood film, elevated serum bilirubin or lactate dehydrogenase, low haptoglobin
- Increased liver transaminases: aspartate transaminase (AST) >70 U/l
- Platelet count: Less than 100×10^9/l

Maternal mortality from severe HELLP syndrome is about 1% and perinatal mortality between 7% and 34%, largely depending on gestational age.[36] It is best to consider this as a variant of preeclampsia and

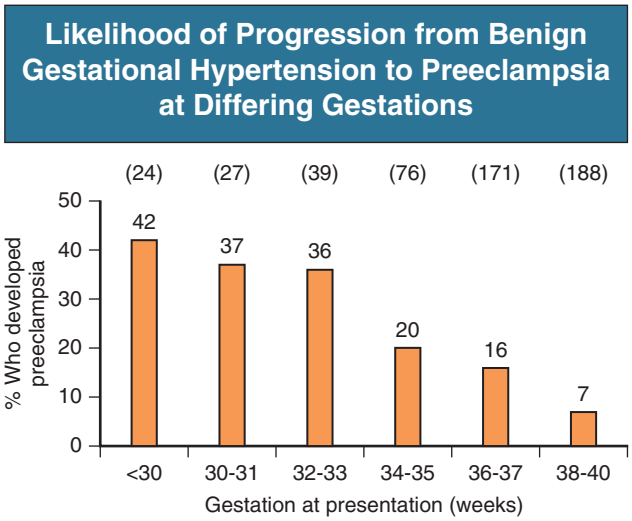

Fig. 42.8 Likelihood of hypertension progressing to preeclampsia at various weeks of gestation. The earlier the presentation with gestational hypertension, the greater is the likelihood of progression to preeclampsia. (Modified from reference 55.)

continue to seek and manage all the features of preeclampsia as these arise.

Natural History

Women with gestational hypertension have a 10% risk for developing preeclampsia if they present after 36 weeks of gestation, but a greater than one third risk if they present before 32 weeks (Fig. 42.8).

In general, the prognosis is favorable for women with preeclampsia but complications include abnormal liver function or thrombocytopenia (10% to 20%), pulmonary edema (<0.5%), AKI (1% to 5%), placental abruption (1% to 4%), fetal growth restriction (10% to 25%), neurologic damage (<1%), preterm birth, and perinatal death.[37] After delivery, all clinical and laboratory derangements of preeclampsia resolve but may be delayed by several days; thus it is critical to remain vigilant until the patient's clinical picture improves. Some patients require antihypertensives for the first time in the postnatal period, which we recommend is commenced when BP exceeds 140/90 mm Hg. Hypertension may persist for days, weeks, or months but will eventually resolve if preeclampsia is responsible for the elevated BP.

Prediction and Prevention

Despite numerous studies, including measurement of circulating angiogenic factors, no test has been found that can reliably predict the development of preeclampsia. Recently copeptin, a glycopeptide component of prepro–arginine vassopressin (prepro-AVP) that is the precursor protein of vasopressin (AVP), also has been suggested as a new biomarker,[38] but this requires further confirmation. Combination screening with maternal risk factors, late first-trimester uterine artery Doppler ultrasound, and various biomarkers has been shown in some studies to predict early-onset preeclampsia with high sensitivity and specificity[39,40]; but these models require further validation before adoption into routine clinical practice. Once preeclampsia has developed, or is suspected clinically, measuring the sFlt-1/PlGF ratio may be predictive of women needing delivery in the next 2 weeks, or, conversely, if the ratio is low, of women not needing intervention in the next week. However, it is too early to recommend this become part of standard practice.

The observation that preeclampsia is associated with increased platelet turnover and increased platelet-derived thromboxane levels led to several trials investigating the effect of aspirin in prevention of preeclampsia. It has subsequently been found that aspirin has other effects, perhaps on angiogenic factor production. Regardless, aspirin reduces the risk for developing early preeclampsia, particularly in high-risk women has been shown many times, most recently in the large Aspirin Vs Placebo in pregnancies at high risk for preterm preeclampsia (ASPRE) trial.[40a] We advocate starting aspirin at 12 to 14 weeks of gestation because the pathophysiologic features of preeclampsia develop at this time, and we typically recommend cessation at 37 weeks.[41] Bleeding is not significantly increased, even for women in labor while taking aspirin. Women who have already developed preeclampsia do not benefit from aspirin in preventing progression to more severe disease.

Oral calcium supplementation appears to halve the risk for preeclampsia in women at high risk and in communities with low dietary calcium intake.[42] The World Health Organization recommends calcium supplementation (1.5 to 2 g/day) after 20 weeks of gestation only in women with low dietary calcium intake. Nutritional supplements, including magnesium, folic acid, fish oils, antioxidants, and garlic, have been extensively studied and do not seem to be effective in preventing preeclampsia.[41] In particular, combined use of vitamins C and E has been associated with worse maternal and fetal outcomes. L-Arginine (a precursor of NO) has been shown to reduce the risk for preeclampsia when given in combination with antioxidants in high-risk populations[41]; however, its role in low-risk women is still being evaluated. Currently, anti-coagulation is not recommended for reducing the risk for preeclampsia except in rare cases related to lupus/antiphospholipid syndrome. Maternal obesity is associated with an increased risk for preeclampsia, and weight loss has been shown to reduce that risk.

Antihypertensive drugs do not reduce the risk for preeclampsia, but do reduce the incidence of severe hypertension with its associated maternal risks, particularly stroke.

Treatment

The only definitive treatment for preeclampsia is delivery of the placenta. The disorder may occur in the absence of the fetus (e.g., hydatidiform mole), and thus it is removal of the placenta that is important. Therefore preeclampsia that continues to worsen several days postpartum should prompt evaluation for retained placental products.

Indications for delivery are:

- Progressive evidence of maternal organ dysfunction: Worsening renal or hepatic function, worsening thrombocytopenia, and development of neurologic symptoms or signs
- Inability to control BP
- Failure of fetal growth or concern about fetal status
- Gestational age beyond 37 weeks

Timing of delivery should be based on optimizing perinatal outcomes while avoiding maternal risks. This requires assessment of fetal well-being with ultrasound and CTG, as well as assessment of the likely benefit of further intrauterine time. Antenatal corticosteroids for fetal lung maturation should be given to all women at risk for delivery at less than 34 weeks of gestation; many obstetricians also give steroids at later gestation if cesarean birth is likely.

There is consensus after the hypertension and preeclampsia intervention trial at near term (HYPITAT) trials that women with preeclampsia at later than 37 weeks of gestation should be delivered and that below 37 weeks such women can be managed expectantly to hope for further fetal growth and maturation, with delivery if any of the previously listed indications arise.[43,44]

General Management

All women with preeclampsia should be admitted at the initial diagnosis. If the condition then appears stable, outpatient care is reasonable

provided appropriate resources and expertise are available. Reviews should include once- or twice-weekly laboratory evaluation of platelet count, serum creatinine, and AST, as well as CTG. Repeated quantification of proteinuria is not required once the protein-to-creatinine ratio has risen to 30 mg/mmol, because the amount or rate of increase of proteinuria is not associated with maternal or perinatal outcome. Ultrasound estimation of fetal weight, looking for growth restriction, and oligohydramnios, along with umbilical artery Doppler flow should be done at diagnosis and every 2 to 3 weeks if initially normal.

Blood Pressure Management

The major indication for antihypertensive therapy in preeclampsia is prevention of maternal cerebrovascular accident (stroke) and other sequelae of severe hypertension, such as placental abruption. Treatment does not affect the course of preeclampsia because the primary pathogenic process is related to the maternal response to abnormal placental function. However, lowering BP removes one maternal indication for delivery and therefore allows pregnancy to be prolonged, with further fetal maturation.

Antihypertensive medications are always recommended for systolic BP 160 mm Hg or greater and/or diastolic BP 100 mm Hg or greater, although it is controversial whether treatment is required at lower BP. Treatment of hypertension in the range 140 to 160 mm Hg systolic and 90 to 100 mm Hg diastolic is a reasonable approach and will reflect local practice. For such chronic treatment, the first-line agents are oxprenolol, labetalol, and methyldopa (Table 42.5). When additional treatment is required, hydralazine, nifedipine, or prazosin may be added. ACE inhibitors and ARBs should be avoided, because they cause fetal renal abnormalities in the latter half of pregnancy and possibly fetal cardiac or other abnormalities with first-trimester exposure. Diuretics should be avoided because they reduce an already-impaired maternal blood volume, although there are no convincing data about harm of diuretics in pregnancy.

Target BP is controversial; the control of hypertension in pregnancy (CHIPS) trial found better maternal outcomes without adverse fetal consequences at a target diastolic BP of 85 mm Hg in women with chronic hypertension or new-onset hypertension in pregnancy.[45] Our practice is to target BP between 110 to 140/80 to 85 mm Hg, trying to reduce the risk for maternal stroke while ensuring placental perfusion.

BP of 160/110 mm Hg or higher always requires acute treatment to prevent maternal stroke and eclampsia. In such a patient, oral short-acting nifedipine 10 mg tablets, IV hydralazine bolus 5 mg every 20-30 minutes to a maximum dose of 20 mg followed by an IV infusion at 5-10 mg/h, or labetalol 50 mg every 20 minutes to a maximum dose of 300 mg is typically used.

Magnesium sulfate 4 g over 10 to 15 minutes, followed by an infusion (1 to 2 g/h) is used as seizure prophylaxis and after a seizure; it should be continued for at least 24 hours. Magnesium sulfate is renally excreted, so caution is required in women with oliguria or renal failure. It is not usually necessary to monitor serum magnesium, but all women should be monitored with electrocardiogram, respiratory rate, oxygen saturation, and examination of the reflexes. The recurrence rate of seizures despite appropriate magnesium therapy is 10% to 15%.[46] In our view, seizure prophylaxis should usually be reserved for preeclamptic women who either have severe disease or already have clinical evidence of cerebral involvement, such as hyperreflexia with clonus, severe headaches, and visual scotomata. Withholding seizure prophylaxis in the remainder is associated with an extremely low likelihood of fits and avoids the potential for drug toxicity in a large number of pregnant women.[47] However, in low- and middle-income countries, we recommend routine magnesium prophylaxis because the rate of eclampsia is higher and the cost benefit much greater.

Although preeclampsia is a volume-contracted state, the increased capillary permeability makes intravenous volume expansion a potentially harmful procedure, with the ever-present risk for pulmonary edema. Therefore volume expansion should be used only in select patients, such as before parenteral treatment of acute severe hypertension (when rapid vasodilation may occur) and as initial treatment in the persistently oliguric woman. No more than 1 liter of crystalloid or colloid should be given in such women, usually over 4 to 6 hours. This will restore the average plasma volume deficit in most preeclamptic women, but careful clinical observation is required for the possibility of pulmonary edema, particularly if oliguria persists.

Platelet transfusion is generally given for platelet counts less than 20×10^9/l, but in some cases at higher levels (e.g., 20 to 40×10^9/l) if hypertension is difficult to control and the risk for intracerebral hemorrhage is therefore high. Fresh-frozen plasma is indicated only if there is accompanying microangiopathy and thrombocytopenia, when it may be difficult to differentiate preeclampsia from hemolytic uremic syndrome (HUS), or when hepatic disease leads to impaired coagulation in preeclamptic women. We do not recommend plasma exchange or corticosteroids for HELLP syndrome. Adsorption of sFlt-1 by dextran column apheresis is the subject of ongoing study but is not part of standard practice at present.[48] Fig. 42.9 summarizes management of preeclampsia.

Postpartum Management

Recovery should be anticipated over 5 to 7 days in most women after delivery. In many women, the condition may worsen in the first 3 days after delivery, and they should be monitored and treated as vigorously as antepartum. Some women may require up to 3 months for all the features to resolve, and a few will have proteinuria that takes up to 1 year to disappear completely.

TABLE 42.5 Medications Typically Used in the Treatment of Hypertension in Women With Preeclampsia

Drug	Treatment Regimen
Acute Hypertension	
Hydralazine	5-mg IV bolus every 20-30 min, to maximum of 20 mg, then infusion at 5-10 mg/h
Labetalol	50 mg IV every 20 min, to maximum 300 mg
Nifedipine	10 mg oral (tablets, not capsules)
Chronic Hypertension	
First-Line Choice	
Methyldopa	500-2000 mg/day PO
Clonidine	0.2-0.8 mg/day PO
Oxprenolol	80-480 mg/day PO
Labetalol	200-1200 mg/day PO
Second-Line Choice	
Hydralazine	25-200 mg/day PO
Prazosin	1-15 mg/day PO
Nifedipine SR	40-120 mg/day PO

Diuretics and propranolol are not recommended. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers are contraindicated.
IV, Intravenously; *PO,* orally; *SR,* sustained release. All medications for chronic hypertension are given as divided doses.

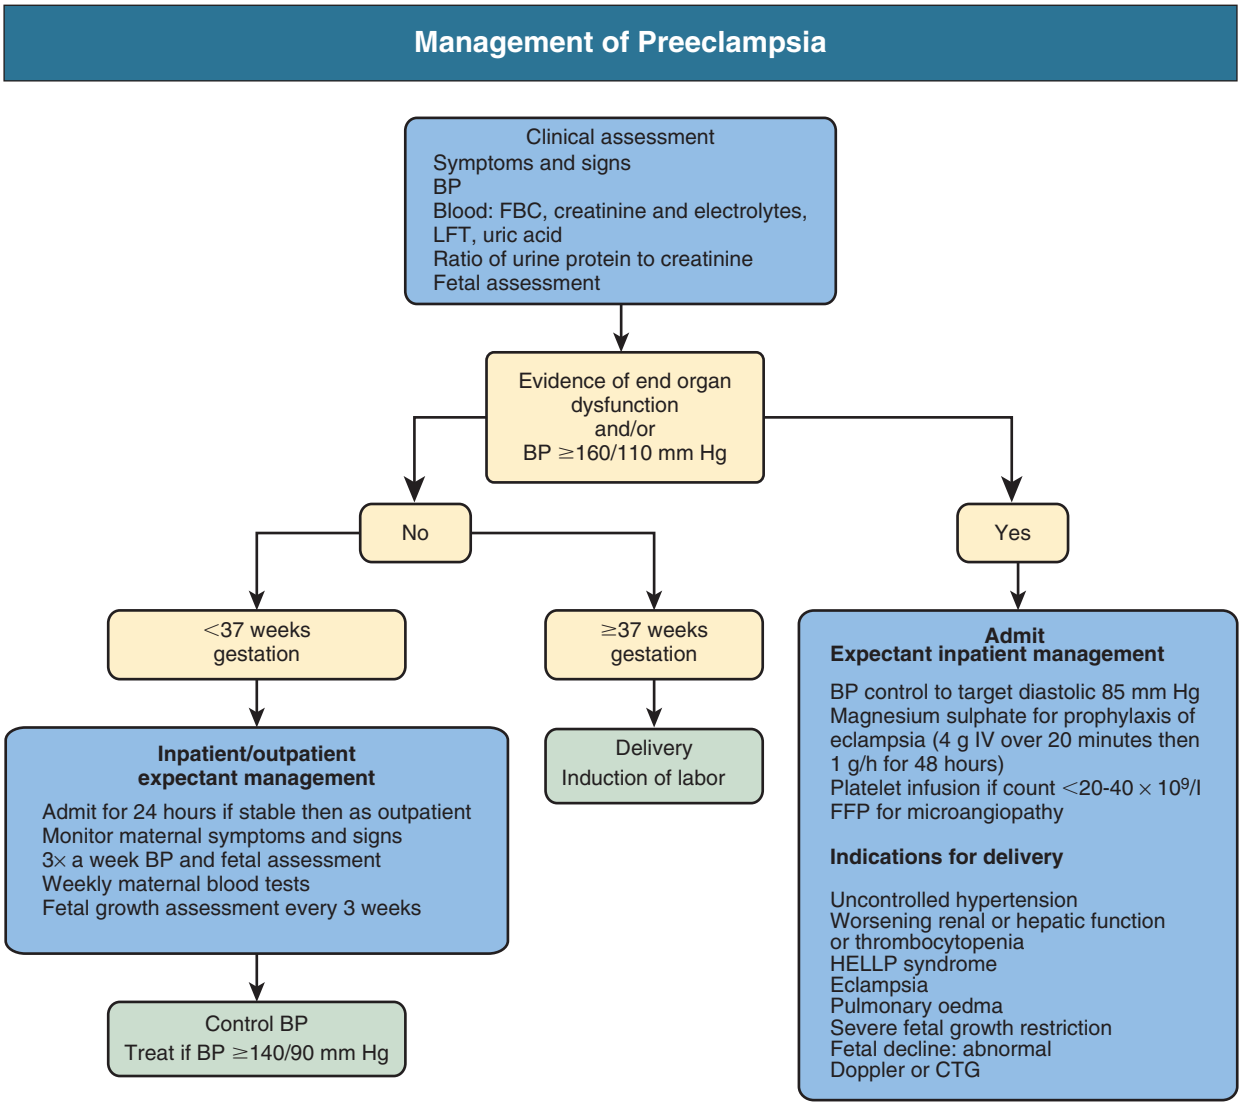

Fig. 42.9 Management of preeclampsia. Management depends on disease severity and gestational age of diagnosis. Prompt and adequate treatment can reduce the risk for adverse maternal and fetal outcomes. *BP,* blood pressure; *CTG,* cardiotocography; *FBC,* full blood count; *FFP,* fresh frozen plasma; *HELLP,* hemolysis, elevated liver enzymes, and low platelet count; *LFTs,* liver function tests. (Modified from reference 41.)

Assessment of the preeclamptic woman several months postpartum is mandatory. The BP should have returned to normal within 3 months in most women, and, if not, this should prompt a search for underlying primary or secondary hypertension. Urinalysis and urine microscopy should be normal by 12 months postpartum, and, if not, a primary underlying renal disease should be sought.

Women with recurrent preeclampsia, or severe early-onset preeclampsia (in whom recurrence is more likely) should be tested for underlying connective tissue, renal, thrombophilic and antiphospholipid or autoimmune disorders.

Preeclampsia and the more benign gestational hypertension will recur in only about 15% of women in a subsequent pregnancy. However, women who have presented at or before 28 weeks of gestation have at least a 25% risk for recurrence.

Especially if it occurs before 37 weeks of gestation, preeclampsia has well-recognized long-term implications, including an increased risk for primary hypertension, coronary heart disease, stroke, venous thromboembolism, and end-stage renal disease (Box 42.4). The mechanism for these increased risks appears to be a tendency to metabolic syndrome.[49] It is appropriate to counsel women who develop hypertension in pregnancy on cardiovascular risk factor lifestyle modifications, along with periodic BP, serum lipid, and blood glucose checks. All such women should also receive counseling before embarking on another pregnancy.

ACUTE FATTY LIVER OF PREGNANCY

Acute fatty liver of pregnancy (AFLP) presents in the third trimester and has an incidence of 1 per 7000 to 20,000 pregnancies,[50] but many milder cases may go undiagnosed. The incidence is higher in primigravid women, multiple gestations, and pregnancies with male fetuses. AKI is a common complication of AFLP, although the exact incidence is unclear.

BOX 42.4 Long-Term Consequences of Preeclampsia

After preeclampsia, there is long-term increased likelihood of:

- Fatal and nonfatal coronary heart disease
- Cerebrovascular accident (stroke)
- Hypertension
- Thromboembolism
- End-stage renal disease
- Diabetes
- Cognitive dysfunction and white matter lesions on cerebral computed tomography scan
- Death from any cause

Pathogenesis and Pathology

The disease is frequently associated with an autosomal recessive genetic error that causes a functional defect in long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD), an enzyme involved in mitochondrial fatty acid β-oxidation. This causes excessive fetal fatty acid accumulation, which is released into the maternal circulation, deposits in liver tissue, and leads to maternal hepatic dysfunction. The hallmark of the hepatic pathologic process is lipid microvesicle infiltration of the hepatocytes without inflammation or necrosis.

The renal involvement in AFLP is nonspecific, and the pathophysiology is unclear. It may be caused by hemodynamic changes similar to those seen in the hepatorenal syndrome or by a thrombotic microangiopathy. Coexisting preeclampsia may also contribute to the renal injury. Renal biopsy and autopsy studies have shown mild glomerular hypercellularity with thick, narrow capillary loops and tubular free fatty acid accumulation, suggesting that abnormal fatty acid oxidation also may contribute to renal dysfunction.

Clinical Manifestations

Patients with AFLP present with any combination of fever, malaise, epigastric pain, nausea, vomiting, and jaundice and 50% present with symptoms and signs of preeclampsia. The severity of liver involvement in women with AFLP is highly variable, ranging from a moderate isolated increase in transaminases to fulminant hepatic failure with encephalopathy and coagulopathy. Characteristic laboratory abnormalities include hyperbilirubinemia, increased transaminases, hypoglycemia, leukocytosis, and evidence of coagulopathy (hypofibrinogenemia, prolonged prothrombin time, depressed antithrombin III levels).

Differential Diagnosis

Viral hepatitis and biliary obstruction should be excluded before confirming the diagnosis of AFLP. Distinguishing AFLP from severe preeclampsia can be challenging because the two disorders share many pathophysiologic and clinical features. Indeed, some suspect that these are part of the same spectrum of disease. Nevertheless, distinguishing between preeclampsia and AFLP is important to guide whether offspring should be assessed for the LCHAD mutation.

Treatment and Outcome

Early diagnosis, supportive care (reversal of coagulopathy, correction of hypoglycemia, and fluid status management), and prompt delivery are critical in the management of AFLP. In most women, there is complete liver and kidney recovery after delivery. However, AFLP is associated with maternal and perinatal mortality of up to 18% and 55%, respectively.[51] Renal recovery typically follows delivery, but dialysis may be needed.

THROMBOTIC MICROANGIOPATHY

Pregnancy-associated thrombotic microangiopathy (TMA) is defined by the presence of fibrin and platelet thrombi in the microcirculation of multiple organs, microangiopathic hemolysis, and thrombocytopenia. Manifestations of pregnancy-associated TMA include the HELLP syndrome, HUS, and thrombotic thrombocytopenic purpura (TTP). Pregnancy-associated TMA is further discussed in Chapter 29.

Clinical Manifestations and Differential Diagnosis

Women with HUS typically present with AKI (often with hypertension) in the postpartum period, although this can occur at any time during pregnancy, even as early as the first trimester. TTP often presents antepartum, usually before 28 weeks of gestation. Coagulation studies and liver function tests are usually normal in HUS and TTP, unlike cases of severe preeclampsia or AFLP. One study suggests that a high ratio of lactate dehydrogenase to AST (25:1) indicates that HUS is a more likely diagnosis than preeclampsia/HELLP in the third trimester.

In practice, it is difficult to distinguish HUS and TTP from preeclampsia without renal biopsy, which often must be delayed until thrombocytopenia is resolving. If renal injury is progressive, biopsy becomes more important to guide ongoing therapy, including plasma exchange or eculizumab.

Natural History

The maternal mortality in pregnancy-associated TMA has declined in recent years and is now between 10% and 20%. However, perinatal mortality is high (30% to 80%), mainly from growth restriction and placental infarction caused by thrombosis of decidua arterioles.[52]

Treatment

The mainstay of treatment of TTP in pregnancy is plasma exchange/infusions. Delivery is indicated in cases of fetal distress or progressive maternal clinical features. Treatment for HUS is supportive, and the use of eculizumab (monoclonal C5 inhibitor) in pregnancy has been described in a few case reports.

ACUTE KIDNEY INJURY

Definition

The diagnosis of AKI in pregnancy is based on the serum creatinine increase. The usual formulas for estimating GFR are not validated in pregnancy, nor are systems for defining AKI (e.g., Acute Kidney Injury Network [AKIN]; Risk, Injury, Failure, Loss of kidney function, and End-stage kidney disease [RIFLE]; Kidney Disease: Improving Global Outcomes [KDIGO]; see Chapter 68). Unfortunately, there is still no agreed definition of AKI in pregnancy, but we suggest investigating women with a serum creatinine of 90 µmol/l (>1 mg/dl) or greater or an increase within 48 hours of 44 µmol/l (0.5 mg/dl) above baseline.

Epidemiology

AKI necessitating dialysis in developed countries occurs in about 1 of 20,000 pregnancies, so a typical obstetric unit (with 2000 to 3000 unselected deliveries per year) will only see one case every 6 to 10 years; the incidence will be greater in tertiary referral centers but is still very low. The development of AKI in pregnancy follows a bimodal distribution with two incidence peaks: the first and third trimesters. Prerenal causes are more common in the first trimester because of hyperemesis gravidarum, ATN in the context of septic abortion, or AKI associated with viral or bacterial infections or sepsis. Common causes in the later stages of pregnancy are preeclampsia, AFLP, TMA, or ATN/acute cortical

TABLE 42.6 Common Causes of Acute Kidney Injury in Pregnancy

Category	Specific Causes
Prerenal	Antepartum or postpartum hemorrhage Hyperemesis gravidarum Sepsis Congestive heart failure (rare)
Renal	Acute tubular necrosis Pyelonephritis Renal cortical necrosis Thrombotic microangiopathy Preeclampsia/HELLP syndrome Acute fatty liver of pregnancy Glomerulonephritis Medication toxicity
Post-renal	Urinary tract obstruction Gravid uterus (rare) Calculi

HELLP, Hemolysis, elevated liver enzymes, and low platelet count.

necrosis secondary to hemorrhage. Obstructive uropathy is an uncommon cause of AKI in pregnancy.

Etiology and Pathogenesis

The causes of AKI in pregnancy are best classified as prerenal, renal, and postrenal (Table 42.6).

Prerenal AKI in pregnancy is associated with volume contraction and vasoconstriction as well as intravascular coagulation, each of which reduce renal perfusion, leading to renal ischemia. It is generally believed that a pregnant woman is more likely to develop AKI than a nonpregnant woman exposed to the same set of conditions that threaten renal perfusion, although there are no confirmatory data for this view. The best explanation for this would be that many of the renal "protective" mechanisms (e.g., increased prostacyclin production to enhance renal blood flow) are already activated maximally in normal pregnancy and may not be augmented in the setting of prerenal AKI.

It is also a common view that subsequent bilateral renal cortical necrosis is more likely than if AKI had developed outside of pregnancy. The risk for cortical necrosis is estimated at 20% when AKI follows septic abortion. This contrasts with a lower incidence of cortical necrosis (~2%) after other causes of AKI in pregnancy. Irreversible renal damage follows 10% to 25% of such cases of cortical necrosis, mostly after preeclampsia or antepartum hemorrhage. Septic abortion is now an uncommon problem in developed countries; hence cortical necrosis is a less common cause of AKI than in the past, although this risk remains higher in developing countries where opportunities to prevent AKI are fewer.

Antepartum Hemorrhage, Prolonged Intrauterine Fetal Death, or Amniotic Fluid Embolism

In these conditions, DIC and severe renal ischemia (leading to endothelial damage and secondary fibrin deposition) are the initiating events. Local release of NO normally minimizes the degree of thrombus formation by diminishing platelet aggregation, but if endothelial injury is too great, NO release is impaired, accelerating the tendency to thrombosis. Renal cortical necrosis or ATN (in less severe cases) may then occur, manifesting as abrupt-onset oliguria or anuria with gross hematuria, flank pain, and often hypotension caused by the initiating disorder.

Sepsis

In septic conditions in pregnancy, AKI is probably the result of cytokine-induced changes in vascular permeability and a loss of effective RPF, sometimes with accompanying hemolysis or DIC. Common causes of sepsis in pregnancy include pyelonephritis, chorioamnionitis, and pneumonia.

Preeclampsia, Acute Fatty Liver of Pregnancy, and Thrombotic Microangiography

Preeclampsia and HELLP syndrome accounts for 40% of AKI, usually later in pregnancy. The pathogenesis of renal impairment in these conditions is a combination of volume depletion, vasoconstriction, and activation of the inflammatory and coagulation cascades.

Clinical Manifestations and Differential Diagnosis

Most cases of AKI in pregnancy are associated with oliguria, and the clinical manifestations in the mother are the same as for AKI in general (see Chapter 68). However, there is the added concern of fetal death because the fetus does not survive in an environment of prolonged uremia.

Preeclampsia

Oliguria in the context of preeclampsia is a worrying sign but of itself may represent a normal renal response to volume contraction. The rise in serum creatinine can sometimes be prevented by good BP control and judicious volume expansion in these women. AKI is more likely to develop in the HELLP syndrome. Table 42.7 outlines the differential clinical features of preeclampsia/HELLP syndrome, HUS, and AFLP.

Obstructive Uropathy

Although compression of the renal system resulting in urinary stasis is common in pregnancy, obstruction as a cause of AKI in pregnancy is rare. Usually, there are no specific clinical features; renal failure is discovered when serum creatinine is measured because a pregnant woman is progressively unwell or is oliguric. Ureteral dilation in normal pregnancy makes the use of ultrasound to diagnose obstructive uropathy difficult. In cases of obstructive uropathy with progressive renal failure and delay in initiating delivery, percutaneous nephrostomy may rarely be required. The diagnosis is then confirmed if serum creatinine falls.

Natural History

Maternal mortality after AKI in pregnancy is reported as 6% and 30%.[53] Fetal mortality rates are much higher but vary enormously depending on the availability of perinatal care.

Treatment

The mainstay of treatment for AKI in pregnancy is restoration of fluid volume deficits and in later gestations, delivery of the baby and placenta, because this is likely to remove the stimulus for AKI. Treatment is easier to initiate when AKI develops late in pregnancy, but if fetal viability is uncertain and the maternal condition stable, dialysis and specific treatment of the underlying condition are commenced. Albumin infusions have not been shown to improve renal function. Pharmacotherapies specific for cause such as antihypertensives in preeclampsia and antibiotics in sepsis should be administered promptly.

Dialysis

The absolute indications for dialysis are the same as for the general population with severe AKI: uremic symptoms (encephalopathy or pericarditis), volume overload, hyperkalemia, and metabolic acidosis unresponsive to medical treatment. However, it is generally recommended

TABLE 42.7 Differential Clinical and Laboratory Features of Syndromes That Cause Acute Kidney Injury in Pregnancy

Clinical Features	PE	HUS/TTP	HELLP	AFLP

AFLP, Acute fatty liver of pregnancy; *ALT,* alanine aminotransferase; *AST* aspartate aminotransferase; *CNS,* central nervous system; *HELLP,* hemolysis, elevated liver enzymes, and low platelet count; *HUS,* hemolytic uremic syndrome; *PE,* preeclampsia; *TTP,* thrombotic thrombocytopenic purpura.

to start dialysis earlier than in nonpregnant patients (i.e. blood urea nitrogen (BUN) >42 mg/dl (serum urea >15 mmol/l) despite volume restoration, because the uremic environment has a negative effect on fetal survival. Both peritoneal dialysis and hemodialysis have been used in pregnancy with success. Peritoneal dialysis requires dialysis catheter insertion under direct vision and has the potential advantage of maintaining fairly constant maternal hemodynamics without threatening uteroplacental blood flow, but carries the risk for peritonitis. Hemodialysis is required more frequently than in nonpregnant patients and has the risk for impairing uteroplacental perfusion if sudden fluid shifts occur. Neither peritoneal dialysis nor hemodialysis has been proven superior, and there is only limited experience with continuous renal replacement therapy in pregnancy. Dialysis in pregnancy is discussed in more detail in Chapter 43.

OVARIAN HYPERSTIMULATION SYNDROME

Definition and Epidemiology

Ovarian hyperstimulation syndrome (OHSS) is an exaggerated response to ovulation induction associated with *in vitro* fertilization therapy. OHSS manifests as increased capillary permeability and fluid retention, with inflammatory mediators.

Pathogenesis

After treatment with gonadotropin-releasing hormone analogues, massive follicular luteinization occurs, which can lead to excessive release of factors, including VEGF, cytokines, prostaglandins, histamine, and Ang. These factors increase vascular permeability, causing loss of fluid into the third space, resulting in ascites, pleural and pericardial effusions, and edema. The hemoconcentration, hypovolemia, and elevated estrogen increase susceptibility to thromboembolic events, oliguric AKI, hyperkalemia, hyponatremia, and acidosis. The majority of patients with severe OHSS will have at least one febrile episode over 24 hours.

Clinical Manifestations and Investigations

Early-onset OHSS occurs 3 to 7 days typically after the administration of the ovulatory dose of human chorionic gonadotropin (hCG), and late-onset OHSS is defined as occurring more than 1 week after hCG administration. Pregnancy-related OHSS is usually clinically severe and more prolonged than OHSS that occurs before embryo implantation. Patients should be investigated with full blood count and hematocrit, serum creatinine, electrolytes, liver function tests (albumin), β-hCG, and coagulation studies. An abdominal ultrasound will help confirm the diagnosis. Abdominal pain must be investigated thoroughly because the enlarged, fragile ovaries are prone to torsion and rupture. Intra-abdominal infection and ectopic pregnancy also must be considered.

Management

OHSS is self-limiting, with an average duration of 7 days in nonpregnant patients and 10 to 20 days in pregnant patients. Treatment is mainly supportive. In the woman with moderate to severe OHSS, hospital admission is required for correcting volume depletion, monitoring and correcting electrolyte abnormalities (particularly hyperkalemia), providing analgesia, offering nutrition and psychological support, preventing deep vein thrombosis, and supporting respiratory function. The ideal fluid replacement is not clear. Our practice is to give only 2 liters of crystalloid over 24 hours to correct intravascular volume depletion, recognizing that some of this will be lost into third-space fluid. Paracentesis may be necessary to improve symptoms and respiratory function in the short term. Simultaneous albumin infusion should be given to avoid protein depletion, hypotension, and rapid reaccumulation of fluid within the pleural and peritoneal spaces. Diuretics are contraindicated because they will not reduce third-space fluid and may worsen hypovolemia and hemoconcentration and precipitate AKI. Prophylactic anticoagulation with heparin is required due to the risk for thromboembolism.

SELF-ASSESSMENT QUESTIONS

1. Which of the following does not occur in normal pregnancy?
   A. Lower serum osmolality
   B. Hypernatremia
   C. Elevated glomerular filtration rate
   D. Glycosuria
2. Which of the following antibiotics should be avoided for use in treatment of urinary tract infections in pregnancy?
   A. Cephalexin
   B. Nitrofurantoin
   C. Amoxicillin–clavulanic acid
   D. Trimethoprim
3. Which of the following factors have been implicated in the pathogenesis of preeclampsia?
   A. Soluble fms-like tyrosine kinase 1
   B. Angiotensin II type 1 receptor antibodies
   C. Tumor necrosis factor α
   D. Reactive oxygen species
   E. All of the above
4. Which of the following is not an indication for delivery in preeclampsia?
   A. Proteinuria 2 g/day
   B. Gestation ≥ 37 weeks
   C. Pulmonary edema
   D. Worsening renal function
5. Which of the following syndromes causing acute kidney injury are least likely to recover after delivery?
   A. Preeclampsia
   B. HELLP syndrome
   C. Thrombotic thrombocytopenic purpura/hemolytic uremic syndrome
   D. Acute fatty liver of pregnancy

Pregnancy With Preexisting Kidney Disease

Kate Bramham, Mark A. Brown

Historically, renal disease was considered a contraindication to pregnancy but now many pregnant women with chronic kidney disease (CKD) have successful outcomes. However, adverse pregnancy outcomes remain more frequent in women with CKD than healthy controls; thus nephrologists and obstetricians need to be skilled in disease optimization before pregnancy, counseling regarding possible pregnancy outcomes, and antenatal and postpartum management of such women. In this chapter we will consider the current evidence for maternal and fetal complications for women with CKD, including management of those with normal renal function, those with renal transplants, and women with end-stage renal disease (ESRD) requiring dialysis.

THE ADVERSE EFFECTS OF CHRONIC KIDNEY DISEASE ON PREGNANCY

CKD affects up to 6% and 9% of women of child-bearing age in high- and low-income countries, respectively, approximately a third of whom have stages 3 to 5 CKD.[1] Available data on pregnancy outcomes in women with CKD are mainly from studies published 10 to 20 years ago and probably overestimate risk compared with modern practice, particularly with improvements in neonatal intensive care. The following key prepregnancy factors are the main predictors of pregnancy outcome:

- Degree of renal impairment
- Severity of hypertension
- Degree of proteinuria

In most circumstances, these features are more important in predicting outcome than the mother's specific renal disease.

The traditional view was that most women with mild renal impairment (serum creatinine <1.5 mg/dl [130 µmol/l]) and controlled hypertension have a successful pregnancy outcome, with preexisting hypertension being the main predictor of pregnancy outcome in women with mild renal impairment. However, even CKD stages 1 and 2 are associated with a higher rate of preeclampsia and perinatal mortality, preterm delivery, and small for gestation age rates; the development of superimposed preeclampsia appears higher in women with a preconception creatinine value of 1.4 mg/dl (125 µmol/l) but greater than 0.9 mg/dl (100 µmol/l) in early pregnancy and indeed even in women with normal glomerular filtration rate (GFR) but dipstick-positive proteinuria and one or more other risk factors for preeclampsia.[2] Those with moderate (serum creatinine 1.5 to 2.5 mg/dl [130 to 220 µmol/l]) to severe (>2.5 mg/dl [220 µmol/l]) renal impairment, particularly when accompanied by hypertension and heavy proteinuria, have a lower chance of having a live baby and a greater risk for maternal complications, including progression of their renal disease. Outcomes according to severity of renal function are presented in Boxes 43.1 and 43.2.

Severity of Hypertension

Preexisting hypertension is associated with significantly higher risk for adverse pregnancy outcomes than the general population,[3] and in pregnant women with CKD, the presence of secondary hypertension is an important predictor of adverse events. For example, a retrospective analysis of 358 pregnant women with CKD found an association between diastolic BP greater than 90 mm Hg (treated or untreated) and neonatal death, which compounded the risk for preterm birth that arises because of renal impairment alone.[4] Preexisting hypertension conferred an approximate doubling of risk for severe neonatal outcome (early preterm delivery, requirement for neonatal intensive care and/or small for gestational age infant) in a recent large prospective Italian cohort study.[5]

Proteinuria

Preexisting proteinuria as a risk factor for poor pregnancy outcome is variably reported, with some studies reporting no influence and others have identified an association among preterm delivery, cesarean section rates, and need for neonatal intensive care, particularly if baseline proteinuria was more than 1 g/day.[6]

MANAGEMENT COMMON TO ALL PREGNANCY WITH PREEXISTING KIDNEY DISEASE

The general principles of management of pregnancy in women with CKD are summarized in Box 43.3.

Prepregnancy Counseling

It has long been known that any woman with stage 3 to 5 CKD should receive prepregnancy counseling. Studies from Italy have found that preterm delivery, cesarean section rates, and need for neonatal intensive care were higher than in the general population, even in women with stage 1 CKD without systemic disease, hypertension, or proteinuria.[5] Another meta-analysis included older studies but also many women with stage 1 CKD; the presence of any form of CKD was associated with worse maternal and fetal outcomes,[7] and thus prepregnancy counseling should be provided for all women with CKD. Issues that should be covered in counseling are shown in Box 43.4. This counseling should include the relevant information on pregnancy outcomes in CKD shown in Boxes 43.1 and 43.2.

Pregnancy may be unplanned in women with CKD, and detailed discussion regarding maternal and fetal outcomes should be provided in early pregnancy. Furthermore, pregnancy may be the first opportunity for identification of CKD; for example, in a prospective cohort study 16% of women with CKD were diagnosed in pregnancy,[8] and similarly these women should be informed of potential pregnancy-related risks.

BOX 43.1 Maternal Renal Outcomes According to Prepregnancy Serum Creatinine*

Creatinine <1.5 mg/dl (130 μmol/l)
- Permanent loss of GFR in <10% of women
- Greatest risk if GFR is <40 ml/min and proteinuria is >1 g/day
- Major determinant of ESRD progression is hypertension
- 40% risk for preeclampsia if baseline proteinuria is >500 mg/day

Creatinine 1.5 to 2.5 mg/dl (130-220 μmol/l)
- Decline or permanent loss of GFR in 30% of women
- Increased to 50% if uncontrolled hypertension
- 10% ESRD soon after pregnancy

Creatinine >2.5 mg/dl (220 μmol/l)
- Progression to ESRD highly likely during or soon after pregnancy

*Note that Modification of Diet in Renal Disease or Chronic Kidney Disease–Epidemiology Collaboration or CKD-EPI formula for estimation of GFR are not valid for pregnancy.
ESRD, End-stage renal disease; *GFR,* glomerular filtration rate.

BOX 43.2 Fetal Outcomes According to Maternal Prepregnancy Serum Creatinine*

Outcomes after accounting for first-trimester miscarriage:

Creatinine <1.5 mg/dl (130 μmol/l)
- Live births in >90% of women
- Up to 50% preterm delivery, 60% small for gestational age if baseline proteinuria >500 mg/day

Creatinine 1.5 to 2.5 mg/dl (130 to 220 μmol/l)
- Live births in about 85% of women unless uncontrolled hypertension (mean arterial pressure >105) at conception
- 60% prematurity, mainly iatrogenic (preeclampsia/fetal growth restriction)

Creatinine >2.5 mg/dl (220 μmol/l)
- Fetal loss high; estimates uncertain

*Note that Modification of Diet in Renal Disease (MDRD) formula and Chronic Kidney Disease-Epidemiology (CKD-Epi) formula for estimation of GFR are not valid for pregnancy.

BOX 43.3 Principles of Antenatal Care With Preexisting Chronic Kidney Disease

- Management of hypertension aiming for BP 110 to 140/80 to 85 mm Hg*
- Aspirin (75-150 mg daily) for all women with CKD
- Regular medication review: Discontinue statins, ACE inhibitors, ARBs
- Correct interpretation of changes in serum creatinine
- Clinical assessment and maintenance of volume homeostasis
- Interpretation and management of proteinuria, including nephrotic syndrome
- Identification of superimposed preeclampsia
- Identification and management of urinary tract infection
- Consideration of the primary renal disease
- Assessment for fetal well-being and consider if delivery is indicated (see Box 43.5)

*See text for further discussion.
ACE, Angiotensin-converting enzyme; *ARBs,* angiotensin receptor blockers; *BP,* blood pressure.

BOX 43.4 Prepregnancy Counseling for Women With Chronic Kidney Disease

Maternal Risks
- Accelerated decline in glomerular filtration rate, sometimes precipitating dialysis during pregnancy or soon after
- Severe maternal hypertension with risk for stroke
- Superimposed preeclampsia with renal, hepatic, thrombotic, or bleeding and neurologic risks
- Nephrotic syndrome with risks for thrombosis or sepsis and iron or vitamin D deficiency

Fetal Risks
- Fetal growth restriction or intrauterine fetal death from placental insufficiency
- Prematurity, with both short-term and long-term consequences
- Complications of drug therapy for renal disease during pregnancy
- Inheritance of a renal disorder

Fertility Assessment

Fertility is reported to be reduced in women with moderate to severe CKD, but there is limited study of underlying mechanisms; however, raised prolactin and luteinizing hormone concentrations are reported.[9] With the advent of assisted conception overcoming natural fertility barriers to conception in women with CKD, nephrologists may be approached for advice regarding hormone stimulation therapies and embryo transfer. There is no evidence so far to suggest that hormonal manipulation has additional adverse consequences in women with CKD unless they develop ovarian hyperstimulation syndrome (see Chapter 42), which may further compromise kidney function. Single embryo transfer is recommended because of the additional maternal and neonatal risk for multiple fetal pregnancies.

Contraception should be offered to women with CKD of childbearing age who do not wish to conceive, including those on dialysis. For the majority of patients with CKD, estrogen-containing preparations are contraindicated because of exacerbation of hypertension or thrombotic risk and progesterone methods are preferred. Women taking immunosuppression have historically been advised against intrauterine devices because of concerns related to failure and pelvic inflammatory disease, although there is no robust evidence to support this recommendation, and case series of women with renal transplants suggest that contraceptive performance is comparable to that in the general population.[10]

Volume Homeostasis

Adequate intravascular volume is essential to preservation of GFR and good pregnancy outcome for mother and baby. Peripheral edema is a common finding even in healthy pregnancy; thus it is not a useful tool for assessing volume status in pregnant women with CKD. Hematocrit should be measured in women with underlying CKD at the initial first-trimester visit, along with serum albumin. A rise in either value strongly suggests intravascular volume contraction, though there is no absolute discriminant value. Conversely, a significant fall in either value does not by itself diagnose excessive volume expansion because both hematocrit and albumin are influenced by other factors (e.g., estimated GFR [eGFR], albuminuria).

When there is concern about fetal growth or deteriorating GFR in women with CKD and reduced intravascular volume is suggested by

the change in hematocrit and albumin from baseline, a trial of intravenous normal saline (no more than 1 L) under observation in hospital is a reasonable clinical approach.

Urinalysis: Proteinuria

Any woman with 1+ (0.3 g/l) proteinuria or above should have protein excretion quantified with a spot ratio of urine protein creatinine (uPCR) or 24-hour urine collection. The upper limit of normal protein excretion during pregnancy is defined as 300 mg/day. In a mid-stream specimen of urine, uPCR greater than 30 mg/mmol (0.27 mg/mg) correlates with more than 300 mg/day proteinuria. Although the spot uPCR in pregnancy is a reasonably reliable method of determining whether protein excretion is abnormal, it is not recommended that serial measurements of uPCR be used to reliably predict *changes* in proteinuria. When there is a true increase in protein excretion during pregnancy in women with underlying renal disease there are few therapeutic options apart from ensuring BP control (see later discussion).

Isolated non-nephrotic proteinuria may develop *de novo* during pregnancy, which usually indicates one of the following scenarios and usually does *not* require antenatal renal biopsy:

1. Developing preeclampsia (after 20 weeks of gestation).
2. No pregnancy complications occur, and proteinuria resolves postpartum (known as *gestational proteinuria*).
3. Intrinsic glomerular disease has developed and remains postpartum (uncommon).

Because serum albumin falls in most pregnancies as a result of volume expansion and may be below 30 g/l, hypoalbuminemia is not a reliable indicator of nephrotic syndrome. Similarly, peripheral edema and a rise in serum cholesterol are commonly seen in healthy pregnancy. A spot uPCR greater than 230 mg/mmol generally indicates protein excretion is above 3 g/day and this should be confirmed by 24-hour urine collection. Diuretic therapy is rarely needed, but is indicated if edema is causing blistering and skin infections. Dietary sodium restriction should be avoided in pregnancy.

Nephrotic syndrome in pregnancy may be associated with urinary loss of vitamin D binding protein, transferrin, immunoglobulins, antithrombin III (accompanied by increased hepatic synthesis of clotting factors), and a propensity for intravascular volume contraction that may lead to reduced uteroplacental blood flow with fetal growth restriction or death and worsening renal function. Treatment requires oral calcium, vitamin D, and iron supplementation, subcutaneous heparin for thrombosis prophylaxis, and reassessment of maternal serum creatinine on a regular basis. Thresholds for commencing thromboprophylaxis are undefined, but most clinicians initiate treatment at higher serum albumin and/or lower proteinuria concentrations than in the nonpregnant state because of the prothrombotic nature of pregnancy, with consideration for additional risk factors such as dehydration secondary to hyperemesis, or obesity. We recommend this for all pregnant women with nephrotic syndrome and for women with nephrotic range proteinuria but serum albumin above 20 g/l if they have a body mass index above 35, dehydration, or another known clinical risk factor for thrombosis. Warfarin should not be used during pregnancy because of increased risk for fetal anomalies. Low-molecular-weight heparin is safe during pregnancy and does not cross the placenta. Dose adjustment should be made for increased renal clearance in pregnancy and weight. Unfractionated heparin is recommended in women with GFR less than 30 ml/min/1.73 m^2 to avoid accumulation.

Data comparing pregnancy outcomes in women with different glomerular diseases associated with nephrotic syndrome are limited. Nonetheless there are no data to suggest that any particular glomerular disease is associated with worse outcomes independent from the severity of renal disease and hypertension.

Hypertension

Many pregnant women with CKD will not exhibit the usual first-trimester fall in BP, and, in many women, BP increases as the pregnancy progresses. Normal pregnancy is accompanied by significant volume expansion, which does not usually induce hypertension. However, in CKD there is often inability to excrete a sodium load with accompanying hypertension, and it is likely that this mechanism contributes in pregnancy. Other potential contributory factors include stimulation of the renin-angiotensin and sympathetic nervous systems; alterations in endothelial factors such as prostacyclin, nitric oxide, and endothelin; and drugs such as calcineurin inhibitors and corticosteroids. Regardless of its cause, persistence of hypertension is an adverse factor in pregnancy outcome and inadequate use of antihypertensives in pregnancy has been associated with poorer pregnancy outcomes, at least in women with renal transplants.[11] BP often will rise significantly soon after delivery and should be measured diligently postpartum and treated if necessary.

Hypertension in pregnancy is defined as BP of 140/90 mm Hg or greater and has historically been the threshold for commencing treatment. A large randomised controlled trial comparing tight BP control (target diastolic blood pressure [DBP], 85 mm Hg) or less tight control (target DBP, 100 mm Hg) reported no difference in neonatal outcomes but a reduction in episodes of severe maternal hypertension including requirement for intravenous antihypertensive treatment, in those with more tight BP control[12]; thus stricter hypertension control is now generally recommended for pregnant women with hypertension.

Target BP for nonpregnant women with CKD are lower in the presence of proteinuria; therefore pregnant women with proteinuric CKD may have a prolonged period when BP is above the usual target if standard pregnancy targets are used, which may contribute to progressive renal impairment, and thus strict BP control is imperative for women with CKD. Although there is no direct evidence for optimum BP thresholds in women with CKD, the authors recommend aiming for 110 to 140/80 to 85 mm Hg. Nevertheless, if a pregnant woman develops BP below 110/80 mm Hg, it is the authors' practice to reduce antihypertensives so as to avoid the potential risk for fetal hypoperfusion.

There is limited understanding of the role of nonpharmacologic interventions for treatment of hypertension in pregnancy. However, salt restriction is not recommended because of the increased net requirement of sodium in pregnancy to facilitate plasma volume expansion. Suitable antihypertensive agents include methyldopa, labetalol, oxprenolol, hydralazine, prazosin, and nifedipine, and they all may be used in conventional doses. There is no evidence to prioritize these agents, and choice of first-line agent is based on clinician preference and experience. The frequency of dosing often needs to be increased because of altered drug metabolism in pregnancy. Diltiazem may have a small benefit in reducing proteinuria, but this has not been addressed specifically for pregnancy. Diuretics are not recommended during pregnancy because any reduction in maternal plasma volume may have adverse effects on uteroplacental or renal perfusion, but may be used in extreme circumstances such as pulmonary edema or substantial peripheral edema leading to skin breakdown. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) must be discontinued as soon as pregnancy is diagnosed, because of increased risk for fetal growth restriction, oligohydramnios, neonatal renal failure, and probably cardiac and neurologic development abnormalities. Although it remains usual practice to cease ACE inhibitors or ARBs before pregnancy, it is acceptable to continue these until the time of conception for some women, often those with heavy proteinuria, provided the woman understands the need to cease these on learning she is pregnant. Aldosterone antagonists also should be avoided, and atenolol has been associated

with fetal growth restriction. Enalapril or captopril may be used in women after delivery for those who wish to breastfeed.

RENAL BIOPSY IN PREGNANCY

It is rare to require renal biopsy in pregnancy. Situations in which biopsy may inform treatment that could significantly affect the pregnancy outcome for mother and baby are as follows:

1. *De novo* onset of nephrotic syndrome or unexplained impaired GFR with abnormal urine sediment before fetal viability, that is, before 24 weeks of gestation. Nephrotic syndrome after this stage can generally be managed conservatively until delivery, usually at about 32 to 34 weeks; most such cases are due to preeclampsia.
2. Situations before 32 weeks of gestation in which clinician and patient have agreed that immunosuppression and/or plasma exchange will be used if necessary, while prolonging the pregnancy to about 32 weeks.
   a. Rapidly declining GFR without apparent reversible cause in women with underlying primary glomerulonephritis (GN).
   b. Acute kidney injury with active urine sediment.
   c. Declining GFR or increasing proteinuria in a woman with lupus nephritis or lupus without previously known nephritis.
3. Deteriorating GFR before 32 weeks of gestation without obvious cause in a woman with a kidney transplant, to exclude acute rejection.

Complication rates of renal biopsy in pregnancy are probably comparable to those in general nephrology practice, but one systematic review reported complications in 7% of biopsies performed in pregnancy compared with 1% performed postpartum.[13]

SUPERIMPOSED PREECLAMPSIA

Preeclampsia (see Chapter 42) is a placental disorder of unknown cause that is rarely diagnosed before 20 weeks of gestation that has several predisposing risk factors, including an association with increasing severity of CKD. Superimposed preeclampsia in a woman with underlying renal impairment frequently will lead to exaggerated hypertension and proteinuria with risks for nephrotic syndrome, short-term and long-term progression of maternal renal impairment, fetal growth restriction, prematurity and perinatal mortality.

Superimposed preeclampsia may be challenging to diagnose in a woman with preexisting hypertension, renal impairment, and/or proteinuria. However, when these features are accompanied by additional features such as hyperreflexia with clonus, abnormal liver transaminases, or new-onset thrombocytopenia (except in systemic lupus), superimposed preeclampsia is likely, although relatively few patients with superimposed preeclampsia present with extrarenal manifestations.[8]

It has been proposed that an elevated ratio of soluble fms-like tyrosine kinase 1 to placental growth factor (sFlt-1/PlGF) is diagnostic of preeclampsia and distinguishes this condition from pregnant women with CKD[14]; a prospective cohort study reported comparable diagnostic performance for superimposed preeclampsia and preeclampsia without preexisting disease[8]; although these data are promising, measurement of the sFlt-1/PlGF ratio is not yet recommended for routine clinical practice. Confirmation of superimposed preeclampsia in women with CKD is to some extent unnecessary because clinicians should be vigilant for changes in maternal and fetal condition in all cases and the indications for delivery in women with preeclampsia are comparable to those for progressive underlying renal disease (Box 43.5).

Limited studies suggest that aspirin is of benefit in reducing superimposed preeclampsia and perinatal death in women with underlying renal disease.[15] Our practice is to use low-dose aspirin 75 to 150 mg/day for all women with CKD, giving reassurance regarding safety for both fetus and maternal renal disease. We also use calcium 1200 mg/day as prophylaxis against preeclampsia when there is no concern about hypercalcemia; data for calcium as prophylaxis are less convincing than for aspirin, but this causes little harm and may have some benefit.

BOX 43.5 Indications for Delivery in Women With Preeclampsia or Chronic Kidney Disease

- Inability to control blood pressure
- Deteriorating glomerular filtration rate
- Neurologic abnormalities, such as eclampsia, headaches with accompanying clonus and hyperreflexia, or repeated visual scotomata
- Worsening thrombocytopenia
- Increasing liver transaminase levels
- Failure of fetal growth
- Reversed or absent end diastolic flow on cardiotocography

The decision to deliver is based on a global clinical assessment rather than on specific thresholds for each parameter.

ASSESSMENT OF FETAL WELL-BEING

Prematurity, fetal growth restriction, and stillbirth are the major concerns for neonatal outcomes of women with renal impairment, particularly if superimposed preeclampsia develops. Avoidance of prematurity is not just for the immediate effects on the baby but the association with higher mortality in later life.

Early pregnancy ultrasound (before 12 weeks) is advised to estimate accurately the expected date of delivery, followed by a nuchal translucency scan at 12 weeks, and then fetal morphology scan at 18 to 20 weeks of gestation to screen for fetal anomalies, assess fetal well-being, and check placental function and position. An important point is that blood human chorionic gonadotropin (hCG) levels are often elevated in women with renal impairment and may overestimate the risk for a fetal abnormality.[16]

In women with stages 3 to 5 CKD and all women with hypertension, additional ultrasound scans should be done at 2- to 4-weekly intervals to assess fetal growth and amniotic fluid volume, with Doppler studies of umbilical artery blood flow from 28 weeks of gestation. Asymmetric intrauterine growth restriction (IUGR) in which the abdominal measurements are more decreased than the fetal head and femur measurements is characteristic of IUGR related to maternal CKD and reflects reduced placental function.

Amniotic fluid volume correlates well with perinatal outcome, and reduced volume helps distinguish babies who are small due to IUGR from those who are constitutionally small. However, women with diabetes and severe renal impairment may have disproportionately increased amniotic fluid because of excess urine fetal urine excretion.

Absent end diastolic flow on umbilical artery velocimetry is usually an indication for delivery, depending on gestation. The development of reversed end diastolic flow indicates a high risk for fetal hypoxia, acidosis, and death.

TIMING OF DELIVERY

In women with stable CKD and no evidence of fetal compromise, pregnancies should be continued to term and spontaneous labor awaited. The method of delivery, either vaginal or by cesarean section, is determined

by obstetric issues rather than CKD. Indications for delivery are described in Box 43.5.

The goal is to time delivery such that the risks of delivery (to both mother and fetus) are less than the risks of the pregnancy continuing, which often requires consultation among nephrologist or obstetric medicine physician, obstetrician, midwife, and neonatologist. The following issues should be considered:

1. *Gestational age:* Decisions are difficult to make at the borderlines of viability (23 to 25 weeks of gestation). Although outcome data vary from country to country, approximate survival rates increase from 30% at 23 weeks to 75% at 25 weeks to 95% at 28 weeks of gestation. Babies born at less than 30 weeks of gestation have significant risk for long-term morbidity, including chronic lung disease and cerebral palsy.
2. *Prevention of respiratory distress syndrome:* Maternally administered antenatal corticosteroids, generally intramuscular betamethasone 12 mg two doses 12 hours apart ideally at least 24 hours before delivery, which has been shown to reduce respiratory distress syndrome by 50%.
3. *Transfer to a unit with neonatal support:* There is less neonatal morbidity and mortality if babies are born in hospitals where there is appropriate neonatal care rather than being transferred after delivery.

The final pregnancy outcome in most cases is successful for both mother and baby, albeit with long-term implications for both. Clinicians can take a positive approach, at all times emphasizing the need for diligence and assessment for potential complications, and aim to relieve some of the stress that accompanies pregnancy for women with CKD.

COURSE OF CHRONIC KIDNEY DISEASE DURING AND AFTER PREGNANCY

The risk for progression of renal disease during pregnancy depends on severity of renal disease, hypertension, increasing proteinuria, or onset of superimposed preeclampsia, rather than underlying cause of CKD.

Rapid deterioration during a pregnancy is unlikely in women with mild CKD, other than lupus, which may flare. However, 50% of women with moderate baseline renal impairment (serum creatinine >1.5 mg/dl [130 µmol/l]) or worse have a significant rise in serum creatinine in the third trimester or early postpartum and almost 1 in 5 of these will progress to ESRD within 6 months.[17] In a series of 49 women with stage 3 to 5 CKD before conception whose pregnancy proceeded beyond 20 weeks, GFR was lower after pregnancy than before conception, and this fall was predicted by the combination of preconception GFR less than 40 ml/min/1.73 m^2 and proteinuria greater than 1 g/day, but not by GFR alone.[18]

The course of renal disease postpartum is unpredictable. Even some women with stable renal function throughout their pregnancy develop an acute deterioration postpartum. Surveillance by the nephrologist therefore should be just as diligent in the first 3 to 6 months postpartum as during pregnancy. ACE inhibitors or ARBs should be commenced soon after delivery for their antiproteinuric effect if GFR is stable.

A Norwegian study showed that women with biopsy-proven kidney disease had slightly faster progression to ESRD if their pregnancy required preterm delivery but not if they had preeclampsia.[19] A neglected issue is the association between preterm birth, low birth weight, and later life cardiovascular and renal disease; because many women with CKD are delivered prematurely, this in turn may transmit an increased risk for renal disease to their offspring even if the renal disease is not hereditary. On balance it is prudent to consider both preeclampsia and preterm delivery as risk factors for later kidney disease. It is imperative that women with CKD have close attention postpartum, with a strong emphasis on BP control.[20]

MANAGEMENT OF SPECIFIC RENAL DISORDERS DURING PREGNANCY

The most common CKDs predating pregnancy are primary GN, diabetic nephropathy, lupus nephritis, and reflux nephropathy.

IgA Nephropathy

Pregnancy outcomes for women with IgA nephropathy are generally good, with outcomes comparable to those with other causes of CKD. Long-term follow-up of women with IgA nephropathy diagnosed in childhood showed that pregnancy was complicated by hypertension in half the cases and premature delivery in one third.[21] Pregnancy in IgA nephropathy does not appear to cause accelerated renal dysfunction, at least in those with CKD stage 1 or 2, compared with nulliparous women,[22] but proteinuria may increase in the third trimester.[23] However, there is limited evidence that women with proteinuria before pregnancy have a more rapid decline in function postpartum.[24] Visible hematuria is not more likely during pregnancy unless there is intercurrent upper respiratory tract or gastrointestinal tract infection.

Diabetic Nephropathy

Studies in the United Kingdom reported that 8% of pregnant women with type 1 diabetes and 5% with type 2 diabetes had nephropathy. Diabetes *per se* increases risks for preterm birth, cesarean section, and perinatal mortality. The presence of overt nephropathy more than doubles the risk for fetal death after 20 weeks. There is an added risk for congenital abnormalities if blood sugar was not adequately controlled at the time of conception, and a large cohort study reported that the presence of nephropathy also was an independent risk factor for congenital abnormalities.[25]

The Diabetes Control and Complications Trial and EURODIAB trial both concluded that pregnancy does not increase the progression of diabetes to early diabetic nephropathy (microalbuminuria). Although microalbuminuria alone did not correlate with increased perinatal risk, both prematurity and superimposed preeclampsia rates were higher than in women with type 1 diabetes without microalbuminuria. It is likely that women with diabetic nephropathy have worse pregnancy outcomes than women with other causes of CKD and comparable renal function. For example, a recent Finnish retrospective cohort study of women with type 1 diabetes and nephropathy (median prepregnancy serum creatinine 0.8 mg/dl [68 µmol/l]) reported high complication rates (e.g., preeclampsia 42%, preterm before 34 weeks 21%, neonatal care admission 49%).[26]

The outcome of established diabetic nephropathy during pregnancy depends on the usual factors of severity of renal impairment and hypertension. Meticulous control of blood glucose and BP during pregnancy is required in all women with diabetic nephropathy. One study showed that failure to achieve mean arterial pressure below 100 mm Hg was associated with increased risk for early delivery even after adjusting for glucose control.[27] Risk for permanent decline in renal function for women with more severe diabetic nephropathy has not been formally evaluated, but the incidence of CKD progression is likely to be comparable, if not higher, than for women with CKD without diabetes. Ideally, ACE inhibitors (enalapril or captopril if breastfeeding) should be introduced soon after delivery for prevention of progression of diabetic nephropathy.

Having gestational diabetes mellitus (GDM) without developing overt diabetes after the pregnancy is still associated with about a 10% risk for microalbuminuria by age 50, an intermediate risk between that of nondiabetic and diabetic women.[28] This means that women with a history of GDM, not just those with type 1 or 2 diabetes, should be followed after pregnancy assessing renal function and urine albumin excretion because of their risk for later developing diabetes.

Lupus Nephritis

Ideally, women with lupus should be in remission for at least 6 months before conception and on maintenance corticosteroids in doses less than prednisolone 20 mg/day, with or without azathioprine; all such women should receive aspirin and hydroxychloroquine during pregnancy.[29] Women with active disease at conception have a higher likelihood of developing acute lupus nephritis during pregnancy that is then associated with high fetal risk, about 20% having miscarriage, stillbirth, or neonatal death[30]; thus it is important to establish remission before pregnancy. This assessment may include cessation of ACE inhibitors and repeat renal biopsy to exclude active disease in women with persistent proteinuria more than 1 g/24 h. If such a woman has worsening proteinuria (at least >1 g/day) and there is ongoing delay to conception, we now advocate continuing ACE or ARB therapy until conception because the first-trimester risks of these drugs are small. We discuss the rationale for this approach clearly with each woman.

Lupus nephritis may flare during pregnancy in about 30% or postpartum in 15%,[31] but a prophylactic postpartum increase in corticosteroid dosing in those who have not had a flare during the pregnancy is not indicated. The major cause of maternal death in lupus nephritis is sepsis, and immunosuppression should be used with care in pregnant women.[32] New onset or a flare of lupus nephritis, evidenced by increasing proteinuria, active urine sediment, and rising serum creatinine, is a major concern, and such cases have sometimes been associated with maternal death. These women should be treated by increasing doses of prednisolone and early introduction of azathioprine. Some prefer to undertake renal biopsy at this point to confirm the histologic changes before introducing immunosuppression. Either approach is reasonable, but our approach is to introduce steroids and azathioprine and reserve biopsy for after delivery.

Cyclophosphamide and mycophenolate mofetil (MMF) are contraindicated in pregnancy because of teratogenicity, including (for MMF) microtia (underdeveloped external ear), auditory canal atresia, cleft lip and palate, and micrognathia; although cyclophosphamide has been used successfully in a few cases of lupus nephritis in later pregnancy, its use is not recommended. Tacrolimus is an alternative agent that has been used with increasing success in women with active lupus nephritis in pregnancy.[33]

Prior histologic class of lupus nephritis has no influence on pregnancy outcome. Predictors of poor pregnancy outcome include baseline creatinine greater than 0.9 mg/dl (100 µmol/l), proteinuria greater than 0.5 g/24 h, antiphospholipid syndrome, hypertension, non-White ethnicity, and maternal disease flare.[34] A prospective cohort study of women with lupus, including those with mild nephritis, recently reported that pregnancy outcomes were favorable for women without adverse risk factors (including lupus anticoagulant, antihypertensive use, active disease, or low platelets), with 92% having uncomplicated pregnancies. However, when counseling about future pregnancies women should be advised that even if their lupus nephritis has been well treated, they appear to have a greater risk for maternal complications and lupus flare in their next pregnancy than do women with systemic lupus erythematosus (SLE) who have never had nephritis; this appears only partly explained by increased activity of the SLE at conception. Fortunately, fetal outcomes are not affected adversely in this group and postpartum renal function appeared unaffected.[35] This means that such women need more surveillance during pregnancy than usual, to detect a renal flare or preeclampsia, their two biggest maternal risks.

Women with anti-Ro and anti-La antibodies should be counseled regarding the risk for fetal heart block and neonatal cutaneous lupus, respectively. Hydroxychloroquine may reduce the risk for recurrent fetal heart block in women with a previously affected infant, and this should be encouraged.[36]

Reflux Nephropathy

Pregnancy outcome in women with reflux nephropathy depends on preexisting renal function and BP control rather than the disorder itself, as for other renal diseases. There is an increased incidence of gestational hypertension, preeclampsia, and fetal morbidity in women with reflux with renal scarring but not in those without scarring compared with the general population.[37] These women are more predisposed to urinary tract infection (UTI) throughout pregnancy, as are women who have had surgically corrected reflux in childhood. Around 20% of women with reflux nephropathy will develop UTI in pregnancy, with about 6% of these due to acute pyelonephritis. This is important because UTI can be associated with premature labor or spontaneous rupture of membranes; hence regular urine culture should be performed throughout pregnancy in women with underlying reflux nephropathy. Management of UTI in pregnancy is further discussed in Chapter 42. About 40% of offspring have vesicoureteral reflux, and testing of offspring is recommended offspring is recommended.

Inherited Renal Disorders

Inherited renal disorders are likely to have been diagnosed before the pregnancy, and the specific implications of this for the offspring will have been discussed, for example, autosomal dominant polycystic kidney disease and Alport syndrome. For single-gene disorders preimplantation diagnosis may be available, and referral to a specialist is recommended.

DIALYSIS IN PREGNANCY

Significant improvements in outcomes of pregnant women requiring dialysis during pregnancy have occurred over the past two decades, with fetal survival rising from less than 50% to almost 85%.[38] Enhanced outcomes have been associated with more intensive dialysis regimens and advances in neonatal care enable survival for premature and growth-restricted infants. Evidence for the benefit of increased dialysis in pregnancy came from a Canadian cohort study that reported significant improvement in birth weight and length of gestation in women with ESRD who received prolonged dialysis (43 ± 6 h/wk) compared with those with a more modest increment (17 ± 5 h/wk).[39] A meta-analysis of 574 pregnancies in 543 patients, reported that fewer dialysis hours per week was strongly associated with preterm delivery before 37 weeks.[40] Recommendations for managing hemodialysis during pregnancy are listed in Box 43.6.

Women of childbearing age undergoing dialysis have around a 1 in 20 chance of conceiving,[38] but increments in dialysis dose also appear to be associated with increased fertility, for example, nocturnal home dialysis.[39] Women of childbearing age on maintenance dialysis therefore need to be counseled about adequate contraception.

Initiating Dialysis for Progressive Chronic Kidney Disease

Dialysis should be commenced for the standard indications of hyperkalemia, acidosis, and/or fluid overload. In addition, it is generally recommended to commence dialysis at a blood urea nitrogen (BUN)

BOX 43.6 Managing Hemodialysis During Pregnancy

Prepregnancy

- Discuss risks of pregnancy (miscarriage, fetal death, fetal growth restriction, prematurity, preeclampsia).
- Ensure all medications safe in pregnancy.
- Aspirin: 75 to 150 mg daily.
- Folic acid: 5 mg daily.

During Pregnancy

Dialysis	20 h/wk in four or more sessions. Aim for predialysis BUN <40 mg/dl (serum urea 15 mmol/l). Heparin requirement may increase because of hypercoagulability of pregnancy.
Anemia	Intravenous iron to maintain iron stores. Dose ESA to achieve hemoglobin 10 to 11 g/dl.
Bicarbonate	Adjust oral and dialysate bicarbonate to achieve normal serum bicarbonate for pregnancy (18 to 22 mmol/l).
Nutrition	Dietician advice to ensure adequate protein and nutrient intake. Supplement oral or dialysate phosphate to maintain postdialysis serum phosphate in normal range.
Calcium	Maintain normal serum calcium with additional oral calcium and vitamin D, as well as increased dialysate calcium. Hypercalcemia occasionally provoked by placental PTHrP and vitamin D–like substances.
Phosphate	Supplement oral or dialysate phosphate to maintain postdialysis serum phosphate in normal range.

After Pregnancy

- Return to usual dialysis schedule immediately.
- Readjust dry weight and antihypertensives weekly for 6 weeks.

BUN, Blood urea nitrogen; *ESA,* erythropoiesis-stimulating agents; *PTHrP,* parathyroid hormone–related protein.

>40 mg/dl (serum urea >15 mmol/l) and aim for predialysis blood urea below 10 mmol/l (BUN 28 mg/dl).[38] Dialysis initiated during pregnancy is probably associated with greater likelihood of successful pregnancy than for those on maintenance dialysis, perhaps because of the benefits of residual renal function,[41] although this is not a consistent finding.[39]

Dialysis Regimens in Pregnancy

In addition to augmentation of dialysis dose as practically possible, ensuring the above biochemical goals are achieved, and weekly surveillance, the following also should be considered:

- Control of maternal blood pressure, generally to 110 to 140/80 to 90 mm Hg. This is difficult to achieve in many cases. There still appears to be volume expansion in women on maintenance hemodialysis who become pregnant, as evidenced by anemia and fall in serum albumin. As yet there are no data to recommend assessment of volume status in pregnant women on dialysis using ultrasound measurement of inferior vena cava diameter or bioimpedance.
- Intravenous iron and erythropoiesis-stimulating agents aiming for a hemoglobin level of 10 to 11 g/dl. No adverse consequences in pregnancy have been reported with either intravenous iron or erythropoiesis-stimulating agents, although there is a theoretic risk for exacerbation of hypertension with the latter agents.
- Detection and early treatment of sepsis, which may precipitate premature labor or premature rupture of membranes.
- Phosphate monitoring if supplementary phosphate in the dialysate is required.
- Fetal monitoring with at least 2- to 4-weekly ultrasound scanning from the time of fetal viability, around 24 weeks of gestation.

Peritoneal Dialysis and Pregnancy

There is little information concerning specific requirements of women on peritoneal dialysis (PD) during pregnancy. A systematic review and meta-analysis compared pregnancy outcomes in women on hemodialysis (HD) with PD and reported a higher incidence of infants who are small for gestational age in those receiving PD,[40] although successful pregnancies have been reported. A major risk is that PD peritonitis may provoke premature labor or premature rupture of membranes. Although some women have had successful outcomes remaining on PD throughout pregnancy, we recommend switching to HD to augment dialysis dose in a controlled manner. This recommendation is predicated on the greater available evidence for HD in pregnancy and may change when more data emerge about PD in pregnancy.

RENAL TRANSPLANTATION AND PREGNANCY

Successful renal transplantation is an excellent way of restoring fertility in women with ESRD. It is surprising therefore that the pregnancy rate amongst female transplant recipients more than halved between 1990 and 2003, which is unexplained by a change in age of women being transplanted, but may be related to the introduction of MMF, which is teratogenic.[42] Women with transplants appear less likely to conceive if ESRD is caused by diabetes compared with women without diabetes and in those with preemptive transplants compared with those on dialysis for 3 or more years before transplant.

Timing of Pregnancy

Women are recommended to wait at least 12 months after a successful renal transplant before embarking on pregnancy, to ensure stable transplant function and maintenance immunosuppression, although evidence is conflicting. A meta-analysis of pregnancy outcomes in women with renal transplants reported that live-birth rates were higher if conception occurred within 2 years of transplantation compared with 4 years or more, but in a study in the United States, rates of preeclampsia, gestational diabetes, caesarean section, and preterm delivery also were higher than for the general population in those who conceived within 2 years.[43] One to two years after transplantation seems a practical time for ensuring clinical stability and having optimal BP control and stable immunosuppression.

Immunosuppression in Pregnancy

There are usually opportunities to ensure that conception is carefully planned, immunosuppression optimized, and folic acid commenced, but, unfortunately, many pregnancies in women with renal transplants are still unplanned. Immunosuppressive drugs considered safe in pregnancy include prednisolone, azathioprine, and cyclosporine. Tacrolimus has been associated with neonatal hyperkalemia, but overall data support its safety. MMF is associated with embryotoxic effects and should be avoided in pregnancy, as should sirolimus and everolimus. We suggest ceasing such drugs 6 months before pregnancy.

Gestational diabetes occurs in 3% to 12% of pregnancies of women with renal transplants but no more frequently in tacrolimus-treated women than in those receiving cyclosporine. Screening for gestational diabetes is recommended for all transplant recipients at 12 and 28 weeks.

Dosing of tacrolimus in pregnancy remains problematic until assays for free tacrolimus become readily available. Tacrolimus pharmacokinetics alter during pregnancy with increased metabolism but altered

protein binding. Our practice is to change dose from prepregnancy doses only if trough levels fall very low.

Azathioprine, tacrolimus, and prednisone appear safe to use for women who are breastfeeding, but the decision to breastfeed remains an individual one. Women should be informed that effects on the baby are not completely known but that breastfeeding may have considerable advantages, particularly in premature and growth-restricted babies.

Pregnancy Outcomes

A favorable view of pregnancy in women who have undergone successful renal transplantation was supported early on by observations in over 3000 pregnancies from 2000 women mostly receiving azathioprine and prednisone.[44] About 15% of these pregnancies miscarried spontaneously, and of those going past the first trimester, pregnancy was successful in over 90% of cases, provided that hypertension or a decline in renal function had not occurred before 28 weeks of gestation, in which case successful pregnancy outcome was reduced to about 70%. Women with preconception serum creatinine of 1.4 mg/dl (125 µmol/l) had 96% pregnancy success, whereas those with higher serum creatinine had a 75% success rate. In keeping with the data for all women with CKD, long-term decline in renal function occurred significantly more often (27%) in those with preconception serum creatinine greater than 1.4 mg/dl.

Hypertension, either accelerated from preexisting hypertension or *de novo* during pregnancy, is present in 58% to 72% of cases. Even with these relatively good outcomes, somewhere between 30% and 70% of women will have hypertension requiring treatment as the pregnancy progresses (sometimes superimposed preeclampsia), fetal growth restriction occurs in 40% to 50% of cases, and preterm delivery occurs in as many as 40% to 50%, with attendant long-term risks for prematurity. Cesarean section is necessary in approximately half of cases.[43,44]

The United States National Transplantation Pregnancy Registry (NTPR) reported in 2014 on the outcomes of 1742 pregnancies from 986 women who had received kidney transplants.[45,46] Because this is a voluntary registry, there is potential for reporting bias. Data are reported according to immunosuppression taken during pregnancy and include azathioprine without calcineurin inhibitor (26.4%), cyclosporine (48.4%), or tacrolimus (25.2%). Overall live birth rates were about 76%, 30% of women had preeclampsia, 51% of live births required delivery before 37 weeks of gestation, and 41% of babies weighed less than 2500 g. Biopsy-proven acute rejection occurred in 1% of pregnancies, and 4.4% of babies had a birth defect, a figure not dissimilar to that of the general population. Graft loss within 2 years after delivery occurred in approximately 6% of women. Maternal and fetal risks for pregnancy in women with a renal transplant are summarized in Box 43.7.

Graft and patient survival are similar in those with and without any pregnancy over follow-up as long as 15 to 20 years. This was observed in data from 577 pregnancies in the Australian and New Zealand Data registry, most of whom had GN or reflux nephropathy as their primary diagnosis[47] and in most single-center cohort studies.

A postpregnancy increase in serum creatinine has been associated with cyclosporine use, possibly because cyclosporine doses were increased during pregnancy as blood concentrations fell. Thus it is very important to check tacrolimus or cyclosporine levels frequently in the early postpartum period.

Acute transplant rejection is uncommon—reported in fewer than 1 in 20 cases.[43] Presentation as acute graft dysfunction is not different in pregnancy; renal biopsy is required to confirm the diagnosis. Treatment is limited to intravenous methylprednisolone and increments in oral immunosuppression, because safety of more potent agents (e.g., antithymocyte globulin) is unproven in pregnancy and likely to cause harm to the developing fetus.

BOX 43.7 Maternal and Fetal Outcomes in Renal Transplant Pregnancies

Maternal

- Long-term decline in glomerular filtration rate if preconception serum creatinine below 1.4 mg/dl (125 µmol/l); rate of decline not usually different from transplant women without pregnancy
- Graft loss in 5% to 10% at 2 years postpartum
- Hypertension in about two thirds
- Rejection risk in 2% to 4%
- Infection in 20% to 35%
- Gestational diabetes mellitus in 10%

Fetal

- Overall live birth rate: 75% to 80%
- Spontaneous miscarriage: 15%
- Prematurity: 50%
- Fetal growth restriction: 50%
- Birth defects in about 5%, probably no more than in the general population
- Long-term consequences of prematurity, although most infants have normal postnatal growth and development

Infection in Pregnant Transplant Recipients

There is an increased risk for infection (20% to 35%), particularly UTI but also cytomegalovirus (CMV) infection with attendant maternal and fetal risks. The consequences of any infection can include premature labor and preterm rupture of membranes. CMV can cause congenital malformations and fetal demise, but delay in conception to after at least 1 year post-transplantation makes new infection or reactivation unlikely. Valganciclovir prophylaxis is not advised because of teratogenicity in animals, but there are case reports of successful use in women with severe CMV infection in pregnancy.

Recommendations for management of pregnancy in women with a renal transplant are summarized in Box 43.8.

Male Transplant Recipients

Outcomes of pregnancies fathered by male transplant recipients showed mean gestational age and mean birth weight similar to those of the general population. There have been recent concerns about teratogenicity of MMF in the offspring of fathers with renal transplants, and the manufacturers have advised switching to a different agent before conception. We agree with this approach for stable grafts, but because these recommendations are largely theoretical, this should be balanced against the risk for inadequate immunosuppression for a prolonged period in men with higher risk transplants.

PREGNANCY IN THE KIDNEY DONOR

It is usually stated that being a kidney donor does not adversely affect future pregnancy outcomes in terms of fetal birth weight, stillbirth, or prematurity; although recent studies suggest there may be an increased risk for preeclampsia in pregnancy after organ donation, and some reports suggest that fetal outcomes also may be slightly worse.[48,49] A Canadian population study also reported a higher incidence of preeclampsia and gestational hypertension in women after donation compared with controls. Importantly, there were no differences in neonatal outcomes, including gestation at delivery or birth weight, and thus placental insufficiency is unlikely to be severe.[50] These studies have some limitations, and pregnancy should not be discouraged in women

BOX 43.8 Management of Renal Transplant Patients During Pregnancy

Prepregnancy

- Stable graft function at least 1 year after transplantation.
- Discuss risks with transplant recipient and her partner.
- Best pregnancy outcome will occur if:
  - Prepregnancy serum creatinine is less than 1 mg/dl (125 μmol/l)
  - Proteinuria <500 mg/day
  - Blood pressure <140/90 mm Hg
- Aspirin 75 to 150 mg/day if creatinine is ≥1.5 mg/dl (130 μmol/l) or 0.9 to 1.5 mg/dl (100 to 130 μmol/l) and proteinuria is >1 g/day.
- Replace all medications that are not safe in pregnancy.
- Eradicate UTI before pregnancy; prophylactic antibiotics indicated if there has been recurrent UTI since transplant.
- Stable cyclosporine or tacrolimus blood levels.
- Test for and control diabetes.

During Pregnancy

- Visits every 2 weeks until 24 weeks of gestation (alternating between obstetrician and nephrologist), then weekly.
- Assess fetal growth by ultrasound at least every 4 weeks from 24 weeks of gestation.
- Do not adjust CNI dose during pregnancy unless there are extreme variations from stable prepregnancy levels.
- Screen for gestational diabetes at 28 weeks of gestation with 1-hour 50-g glucose challenge test.
- At each visit, assess BP (goal 110 to 140/80 to 90 mm Hg), proteinuria (dipstick, then uPCR if dipstick result is positive), urine culture (if history of recurrent UTI, otherwise at 24, 28, and 32 weeks of gestation), electrolytes, creatinine, full blood count, CNI level, and fetal growth.
- Reassess at each visit whether there is an impending indication for delivery (see Box 43.5).

During Delivery

- Vaginal delivery is usually possible despite pelvic kidney.
- Prophylactic antibiotics are not required routinely.

Postpartum

- Monitor CNI and serum creatinine levels daily in hospital.
- Breastfeeding appears safe with CNI drugs, azathioprine, and corticosteroids, but discuss individual case with neonatologist.
- Review weekly or every other week for the first 3 months.

ACE, Angiotensin-converting enzyme; *BP,* blood pressure; *CNI,* calcineurin inhibitor; *uPCR,* urine protein-to-creatinine ratio; *UTI,* urinary tract infection.

who have been kidney donors; rather, the key message is that all such women should be treated as "at risk" pregnancies and have a higher number of clinical reviews, focusing on maternal BP and urinalysis and fetal growth, than in normal low-risk pregnancies.

SUMMARY

A summary of factors to be considered in managing a pregnant woman with renal disease is shown in Box 43.9. Attention to these issues from preconception through to postpartum can result in good pregnancy outcomes with preservation of maternal health. These women and in many cases their offspring require lifelong assessment for progressive renal and/or cardiovascular disease.

BOX 43.9 Managing Women With Preexisting Renal Disease During Pregnancy

1. Women with chronic kidney disease should be managed by a team comprising obstetrician, nephrologist, and experienced midwife or specialty nurse, preferable in a high-risk pregnancy clinic.
2. Main determinants of pregnancy outcome are prepregnancy GFR, proteinuria, and BP. These should be the focus in counseling.
3. GFR should be estimated using serum creatinine and proteinuria using changes in spot uPCR after calculation of initial ratio on 24-hour urine collection.
4. Low-dose aspirin should be given to reduce risk for preeclampsia or perinatal death. Subcutaneous heparin if nephrotic syndrome develops.
5. Primary issues during pregnancy are BP control, watching for emerging preeclampsia, and regular assessment of fetal well-being.
6. An appropriate schedule of visits is every 2 weeks until 24 weeks of gestation (alternating between obstetrician and nephrologist) and then weekly until delivery.
7. Appropriate laboratory evaluations are:
   Initial visit at 12 weeks of gestation: Full blood count, serum creatinine and electrolytes, liver function, 24-hour uPCR if proteinuria on dipstick testing.
   If baseline GFR is normal, repeat at 24 weeks of gestation.
   If baseline GFR is abnormal, repeat every 4 weeks.
   Mid-stream urine culture at 24, 28, and 32 to 34 weeks of gestation (monthly throughout pregnancy if woman has history of UTI).
8. Fetal assessment by ultrasound, in those with impaired GFR, or with heavy proteinuria.
   At 20 weeks: Uterine artery pulsatility index.
   Monthly from 24 weeks: Fetal growth, blood flow, amniotic fluid index.
9. Obstetric review at 6 weeks postpartum, nephrology review within the first 4 weeks because impairment of renal function can occur after delivery. Transplant patients should be seen more often.

GFR, Glomerular filtration rate; *uPCR,* urine protein-to-creatinine ratio.

SELF-ASSESSMENT QUESTIONS

1. A 32-year-old woman with autosomal dominant polycystic kidney disease (ADPKD) wishes to become pregnant. Her estimated glomerular filtration rate (eGFR) is 110 ml/min/1.73 m^2. Her blood pressure (BP) is 142/89 mm Hg, and she has no proteinuria. She is taking amlodipine 5 mg once daily. Which of the following is correct advice about a future pregnancy?
   A. Her pregnancy will be low risk.
   B. She should have preimplantation genetic testing.
   C. She should take aspirin daily.
   D. She should stop amlodipine when she becomes pregnant.
2. A 39-year-old woman with end-stage renal disease secondary to lupus nephritis received a kidney transplant from her partner 9 months ago and wishes to conceive. She has had no episodes of rejection. Her eGFR is 84 ml/min/1.73 m^2, and her BP is 124/77 mm Hg. She is currently taking prednisolone, tacrolimus, mycophenolate mofetil (MMF), and aspirin. What would you recommend to have the best outcome?
   A. She should not conceive until at least 24 months after transplantation.
   B. Breastfeeding is not recommended with immunosuppressant medication.
   C. Her steroid dose should be increased and MMF stopped.
   D. Anti-Ro and La antibody should be assessed to inform fetal monitoring.
3. A 28-year-old woman with immunoglobulin A (IgA) nephropathy is at 32 weeks of gestation. Her prepregnancy GFR is 45 ml/min/1.73 m^2 and ratio of urine protein to creatinine (uPCR) is 120 mg/mmol. She presents with headache and peripheral edema; her BP is 166/100 mm Hg and uPCR is 245 mg/mmol. Her serum creatinine has increased from 70 µmol/l 4 weeks ago to 84 µmol/l. What is the best approach to management?
   A. Admit for BP control and assess by fetal artery Doppler to determine timing of delivery.
   B. Admit for BP control and urgent cesarean section delivery to preserve renal function.
   C. Give intravenous magnesium sulfate to prevent eclampsia, then plan delivery within 24 hours.
   D. Start aspirin 75 mg daily and labetalol 200 mg three times daily with escalation to intravenous antihypertensives if no response.

Autosomal Dominant Polycystic Kidney Disease

Vicente E. Torres, Peter C. Harris

DEFINITION

Autosomal dominant polycystic kidney disease (ADPKD) is a multisystem disorder characterized by multiple, bilateral renal cysts and associated with cysts in other organs, such as liver, pancreas, and arachnoid membranes.[1] It is a genetic disorder caused by mutations in either of two major genes and is inherited in an autosomal dominant pattern, with variable expression. Although benign (nongenetic) renal cysts are common with aging, an underlying inherited disease should be suspected in patients with multiple bilateral renal cysts, even if the renal function is normal.

ETIOLOGY AND PATHOGENESIS

The common ADPKD proteins, polycystin-1 and polycystin-2, play a critical role in the normal function of the primary cilium that is essential to maintaining the differentiated phenotype of tubular epithelium.[2]

Genetic Mechanisms

ADPKD is genetically heterogeneous with two common genes identified (Fig. 44.1), *PKD1* (chromosome 16p13.3) and *PKD2* (4q21). Recently, mutations in a third gene, *GANAB,* have been identified in families with mild polycystic kidney and more variable polycystic liver disease (PLD).[3] Autosomal dominant polycystic liver disease (ADPLD) also exists as an independent entity and is genetically heterogeneous; the first two genes identified (*PRKCSH* in chromosome 19 and *SEC63* in chromosome 6) account for about one third of isolated ADPLD cases, with *GANAB,* also an ADPLD gene.

Evidence from animal models of ADPKD and analysis of cystic epithelia has shown that renal cysts may develop from loss of functional polycystin with somatic inactivation of the normal allele. However, cysts can develop even if the protein is not completely lost, as demonstrated by animal models expressing incompletely penetrant alleles.[4] Furthermore, transgenic rodents overexpressing *Pkd1* or *Pkd2* develop renal cystic disease, which suggests that multiple genetic mechanisms causing an imbalance in expression of polycystins can lead to the development of cysts.[2]

Polycystic Kidney Disease Proteins

Polycystin-1 (PC1; PKD1 protein) and polycystin-2 (PC2; PKD2 protein) belong to a subfamily of transient receptor potential (TRP) channels. PC1 (TRPP1; ~440 kDa) has the structure of a receptor or adhesion molecule and contains a large extracellular N region, 11 transmembrane regions, and a short intracellular C region (see Fig. 44.1). PC1 interacts with PC2 through a coiled-coil domain in the C-terminal portion and with multiple other proteins at different extracellular and intracellular sites. PC1 is found in the primary cilia, plasma membrane at focal adhesions, desmosomes, adherens junctions, and possibly endoplasmic reticulum and nuclei. PC1 may regulate the mechanical strength of adhesion between cells by controlling the formation of stabilized, actin-associated adherens junctions. PC2 (TRPP2; ~110 kDa) contains a short N-terminal cytoplasmic region, six transmembrane domains, and a short C-terminal portion. PC2 is localized predominantly to the endoplasmic reticulum but also to the plasma membrane, primary cilium, centrosome, and mitotic spindles in dividing cells.[2] PC1 and PC2 are also found at high concentrations in exosomes, which are shed into the urine and physically interact with primary cilia, possibly exerting a urocrine function of cell-cell communication.

Mechanisms of Cyst Formation

Experimental data indicate that the timing of ciliary loss or *Pkd1* inactivation determines the rate of development of cystic disease. Inactivation in the developing kidney results in rapid progression.[5] Interestingly, the loss of *Pkd1* and cilia results in less severe PKD than loss of *Pkd1* alone.[6]

The polycystins are involved in the detection of extracellular cues at primary cilia, cell-cell contacts, and cell-matrix contacts and are essential to maintain the differentiated phenotype of the tubular epithelium. Reduction in one of the polycystins below a critical threshold results in inability to maintain planar polarity, increased rates of proliferation and apoptosis, expression of a secretory phenotype, and remodeling of the extracellular matrix.[2] PC1 and PC2 in the primary cilium may be required for the increase in cytosolic calcium that occurs in response to ciliary bending.[7] PC2 is a TRP channel (TRPP2) and functions as a calcium release channel in the endoplasmic reticulum.[8] PC1 interacts with and modulates the maturation and function of PC2, and vice versa.[9] PC1 and PC2 also interact with additional calcium channel proteins. Precisely how intracellular calcium homeostasis is altered in ADPKD remains uncertain, but many studies show reduced resting intracellular calcium, endoplasmic reticulum calcium stores, and store-operated calcium entry in primary cell cultures or microdissected samples from human and rodent polycystic tissues[2] (Fig. 44.2).

Intron–exon sequences of *PKD1 (upper left)* and *PKD2 (upper right)*. Diagram of proposed structural features of the polycystin-1 and polycystin-2 proteins *(center)*.

A common finding in animal models of PKD is increased levels of cyclic adenosine monophosphate (cAMP), not only in the kidney but also in the liver and vascular smooth muscle.[10] Tissue levels of cAMP are determined by the activities of membrane-bound and soluble adenylyl cyclases and cAMP phosphodiesterases (PDEs), themselves subject to complex regulatory mechanisms. Reduced intracellular calcium in PKD may activate calcium inhibitable AC6 or AC5, directly inhibit calcium/calmodulin-dependent PDE1, and indirectly inhibit cGMP inhibitable PDE3, thereby accounting for the accumulation of cAMP and activation of protein kinase A (PKA), which in turn contributes to the development and progression of PKD by stimulating cystic fibrosis transmembrane conductance regulator (CFTR)-driven chloride and fluid secretion and cell proliferation (see Fig. 44.2).

Chloride enters across basolateral Na-K-2Cl cotransporters, driven by the sodium gradient generated by basolateral Na^+,K^+-ATPase, and exits across apical PKA–stimulated CFTR. Basolateral recycling of potassium occurs through the KCa3.1 channel.

cAMP exerts opposite effects on cell proliferation in different cell types. cAMP and PKA signaling enhance several pro-proliferative pathways (extracellular signal–regulated kinase [ERK]) in cells derived from polycystic kidneys, while inhibiting proliferation in cells derived from normal human kidney cortex.[11,12] Treatment of normal human kidney or murine collecting duct cells with calcium channel blockers replicates the proliferative response of the ADPKD cells to cAMP, thus linking this response to the reduction in intracellular calcium that results from disrupting the polycystin pathway.[13] Conversely, treatment of ADPKD cyst–derived cells with calcium channel activators or calcium ionophores restores the normal antimitogenic response to cAMP (see Fig. 44.2).

Liver Cyst Development

Liver cysts arise by excessive proliferation and dilation of biliary ductules and peribiliary glands. Estrogen receptors, insulin-like growth factor 1 (IGF-1), IGF-1 receptors, and growth hormone receptor are expressed in the epithelium lining the hepatic cysts, and estrogens and IGF-1 stimulate hepatic cyst–derived cell proliferation. Cyst growth is also promoted by growth factors and cytokines secreted into the cyst fluid.

Hypertension

Hypertension is a major clinical manifestation and predictor of outcome in ADPKD (see Clinical Manifestations in this chapter). Several factors contribute to the development of hypertension in ADPKD. Activation of the intrarenal renin-angiotensin system (RAS) likely plays an important role, but whether the circulating RAS is inappropriately activated is controversial. The expression of PC1 and PC2 in vascular smooth muscle and endothelium, along with enhanced vascular smooth muscle contractility and impaired endothelium-dependent vasorelaxation in ADPKD, suggest that disruption of polycystin function directly contributes to hypertension. Other factors include increased sympathetic nerve activity and plasma endothelin-1 levels and insulin resistance.[1]

Endothelial vasodilation and constitutive nitric oxide synthase activity are reduced in subcutaneous resistance vessels from patients with ADPKD and normal glomerular filtration rate (GFR). Flow-induced vasodilation of the brachial artery is inconsistently impaired, whereas pulse wave reflection is amplified, suggesting a predominant involvement of small resistance vessels. Reduced coronary flow velocity reserve and increased carotid intima-media thickness in normotensive patients

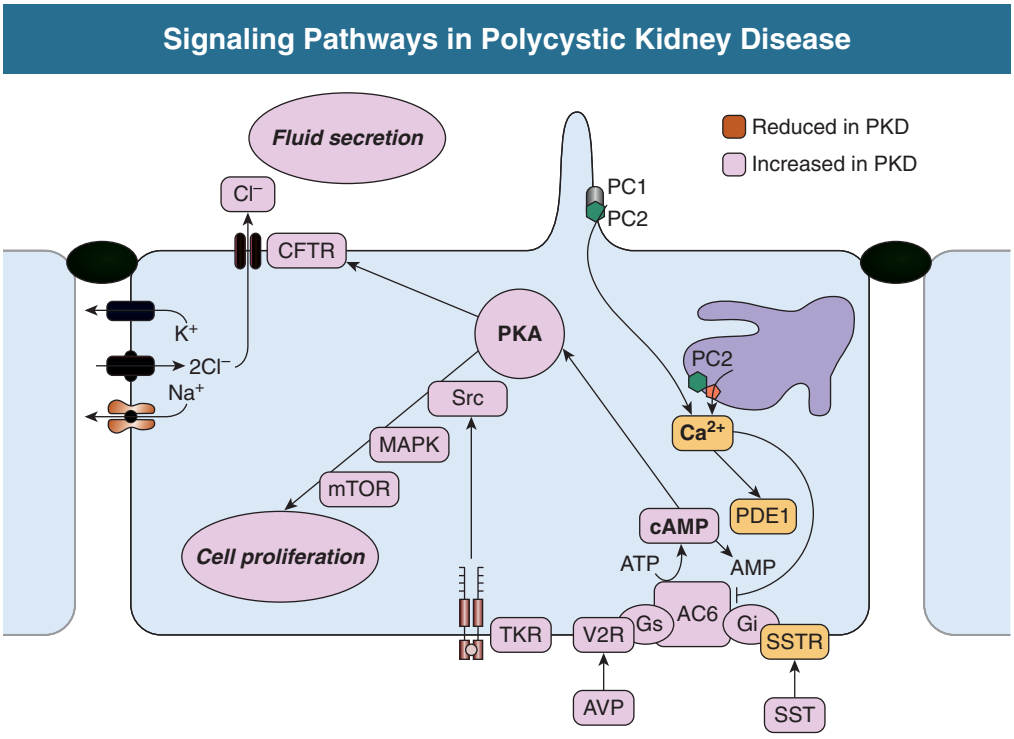

Fig. 44.2 Signaling pathways in polycystic kidney disease (PKD). Pathways that are upregulated or downregulated in polycystic kidney disease and rationale for potential therapies. Dysregulation of intracellular calcium homeostasis leads to intracellular accumulation of cyclic adenosine monophosphate *(cAMP),* activation of protein kinase A *(PKA),* cystic fibrosis transmembrane conductance regulator *(CFTR)* phosphorylation, and stimulation of chloride-driven fluid secretion. In the setting of reduced intracellular calcium, PKA activates Src, mitogen-activated protein kinase *(MAPK)*/extracellular signal–regulated kinase (ERK), and mammalian target of rapamycin *(mTOR)* signaling. Activation of tyrosine kinase receptors *(TKR)* for several growth factors contributes to the activation of Src and downstream pro-proliferative pathways. Therapies currently under clinical investigation target G protein–coupled receptors (modulating activity of adenylyl cyclase 6 *[AC6]* and generation of cAMP), Src, mTOR, and TKRs. *AVP,* Arginine vasopressin; *PDE1,* phosphodiesterase-1; *SST,* somatostatin; *SSTR,* somatostatin receptor.

with normal GFR suggest that atherosclerosis starts early in the course of ADPKD.

Reduced nitric oxide endothelium-dependent vasorelaxation in ADPKD may be caused by increased plasma levels of asymmetric dimethylarginine, a mechanism common to all hypertension associated with kidney disease.

Altered polycystin function in cardiac fibroblasts likely accounts for the increased frequency of valvular heart disease in ADPKD.

EPIDEMIOLOGY

ADPKD occurs worldwide and in all races, with a prevalence of genetically affected individuals at birth estimated at 1 in 400 to 1 in 1000. In most patients the diagnosis is made decades later, and some patients are never diagnosed. Therefore, at any point in time, only a fraction of genetically affected individuals are aware of having the disease. Clinical registry data suggest point prevalence rates of diagnosed cases ranging from 1 in 543 to 1 in 4000. The proportion of end-stage renal disease (ESRD) caused by ADPKD is less among African Americans than among Whites because of a higher incidence of other causes of ESRD. Yearly incidence rates for ESRD caused by ADPKD in men and women, respectively, are 8.7 and 6.9 per 1 million (1998 to 2001, United States), 7.8 and 6.0 per million (1998 and 1999, Europe), and 5.6 and 4.0 per million (1999 and 2000, Japan). Age-adjusted gender ratios greater than unity (1.2 to 1.3) and recent genotype/phenotype studies suggest more progressive disease in men than in women.[14,15] In recent studies, the age of onset of ESRD has increased in both genders; and all-cause mortality has decreased, possibly because of improved detection and control of hypertension.[1]

PHENOTYPIC VARIABILITY

Genic, allelic, and gene-modifier effects contribute to the high phenotypic variability of ADPKD. *PKD1*-associated disease is more severe than *PKD2*-associated disease (age at ESRD, 58 years vs. 79 years for *PKD1* and *PKD2,* respectively).[16] The greater severity of *PKD1* is caused by development of more cysts at an early age, not faster cyst growth.[1] Both *PKD1* and *PKD2* can be associated with severe PLD and vascular abnormalities.[17] Because of the lesser severity of the renal involvement, the prevalence of *PKD2*-associated disease has likely been underestimated in clinical studies.

Mutations in *PKD1* and *PKD2* are highly variable and often "private" (unique to a kindred). The ADPKD Mutation Database (www.pkdb.mayo.edu) lists 1273 likely pathogenic *PKD1* mutations identified in 1895 families with a total of 2323 variants, including silent polymorphisms. Also, 202 likely pathogenic *PKD2* mutations are listed in 438 families, with a total of 278 different variants. So far 9 families (20 patients) with *GANAB* mutations have been described.[3]

Allelic factors have an effect on the severity of ADPKD. Recent studies in large cohorts have shown that the type of *PKD1* mutation, but not its position, correlates strongly with renal survival. The median age at onset of ESRD was 55 years for carriers of a truncating mutation and 67 years for carriers of a nontruncating mutation.[16] Hypomorphic or incompletely penetrant *PKD1* or *PKD2* alleles have been described. These alleles alone may result in mild cystic disease; two such alleles cause typical to severe disease and in combination with an inactivating allele, may be associated with early-onset disease that mimics ARPKD.[1] A new prognostic score (PRO-PKD score) based on the gene mutated and type of mutation helps predict renal outcomes and enable the personalization of therapeutic management in patients with ADPKD.[2,18]

The large intrafamilial variability of ADPKD highlights a role for genetic background in disease presentation. Age at clinical manifestations in ADPKD is less variable within than between families, which suggests a common familial modifying background for early and severe disease expression (e.g., mutations or variants in genes encoding other cystoproteins). The contiguous deletion of the adjacent *PKD1* and *TSC2* is characterized by childhood PKD with additional clinical signs of tuberous sclerosis complex. Other modifying loci are likely to account for more common and subtle intrafamilial variability.

DIAGNOSIS

Only individuals who have been properly informed about the advantages and disadvantages of screening should be offered presymptomatic screening. If ADPKD is diagnosed, the patient should receive appropriate genetic counseling, and risk factors such as hypertension can be identified and treated early. If ADPKD is absent, the patient can be reassured. Disadvantages of presymptomatic screening relate to insurability and employability. Presymptomatic screening of children is not recommended until more effective therapy for the disease becomes available.

Renal Ultrasound

Renal ultrasound is used for presymptomatic testing because of cost and safety. Revised criteria have been proposed to improve the diagnostic performance of ultrasound in ADPKD (Table 44.1). At least three (unilateral or bilateral) renal cysts are sufficient for diagnosis of at-risk individuals 15 to 39 years of age; two cysts in each kidney sufficient for diagnosis for ages 40 to 59 years.[19] For at-risk individuals age 60 and older, four or more cysts in each kidney is required.

The specificity and positive predictive value (PPV) of ultrasound are high using these criteria, but their sensitivity and negative predictive value (NPV) when applied to PKD2 patients age 15 to 59 are low. This is a problem in the evaluation of potential kidney donors, in which exclusion of the diagnosis is important. Different criteria have therefore been proposed to exclude a diagnosis of ADPKD in an individual at risk from a family with an unknown genotype. An ultrasound finding of normal kidneys or one renal cyst in an individual age 40 or older has an NPV of 100%. The absence of any renal cysts provides near certainty that ADPKD is absent in at-risk individuals age 30 to 39, with a false-negative rate of 0.7% and NPV of 98.7%. A normal or indeterminate ultrasound scan does not exclude ADPKD with certainty in an at-risk individual younger than 30 years. A recent study of 73 affected and 82 nonaffected individuals suggested that finding fewer than five cysts by magnetic resonance imaging (MRI) is sufficient to exclude the diagnosis of ADPKD in potential living related kidney donors.[20] Contrast-enhanced computed tomography (CT) scanning with thin slices likely provides similar information, but this has not been proven.

TABLE 44.1 Ultrasound Criteria for the Diagnosis of Autosomal Dominant Polycystic Kidney Disease

Age (y)	Criteria	PPV	NPV
Original Ravine's PKD1 Diagnostic Criteria			
15-29	≥2 cysts, unilateral or bilateral	99	88
30-39	≥2 cysts in each kidney	100	88
40-59	≥2 cysts in each kidney	100	95
≥60	≥4 cysts in each kidney	100	100
Revised Unified Diagnostic Criteria			
15-29	≥3 cysts, unilateral or bilateral	100	86
30-39	≥3 cysts, unilateral or bilateral	100	86
40-59	≥2 cysts in each kidney	100	95
≥60	≥4 cysts in each kidney	100	100
Revised Diagnostic Criteria (when diagnosis needs to be excluded)			
15-29	≥1 cyst	97	91
30-39	≥1 cyst	94	98
40-59	≥2 cysts	97	100
≥60	≥3 cysts in each kidney	100	100

NPV, Negative predictive value; *PPV,* positive predictive value.

Genetic Testing

Genetic testing can be performed when a precise diagnosis is needed and the results of imaging are indeterminate. Molecular diagnosis of ADPKD is complicated by duplication of the *PKD1* gene, which means it may not be efficiently screened by whole-exome sequencing. For diagnostic purposes, direct mutation screening by Sanger or next-generation sequencing of the *PKD1* and *PKD2* genes is generally performed with multiplex-dependent probe amplification to identify larger rearrangements. However, next-generation sequencing panels of PKD genes are increasingly being employed that have the potential for higher throughput screening and lower costs.[21] Molecular testing by direct DNA sequencing is now informative in about 90% of patients. However, because many mutations are unique and up to one third of *PKD1* changes are missense, the pathogenicity of some changes is difficult to prove. *De novo* mutations and mosaicism also can complicate interpretation of results.

In preimplantation genetic diagnosis (PGD), genetic analysis is performed on single blastomeres from preimplantation embryo biopsy specimens obtained after in vitro fertilization (IVF), and only embryos unaffected by the disease are selected for transfer. PGD for ADPKD is complicated by the genetic heterogeneity of the disease and the large size and complex structure of the *PKD1* gene but has been performed for ADPKD. PGD should be included in the discussion of reproductive choices with patients with ADPKD, but it is only available in certain countries and the acceptance of this technique is influenced by personal values as well as the severity of the disease.[1]

DIFFERENTIAL DIAGNOSIS

Renal cysts can be a manifestation of many other systemic diseases. Conditions to consider when presentation is not typical of ADPKD include autosomal recessive PKD, tuberous sclerosis complex, von Hippel–Lindau disease, renal cysts and diabetes from *HNF1β* mutations, and orofaciodigital syndrome type I, as well as medullary sponge kidney and simple renal cysts. These are discussed further, including differential

diagnosis, in Chapter 45. If the patient has ESRD, acquired cystic disease also should be considered (see Chapter 88).

CLINICAL MANIFESTATIONS

ADPKD is a multisystem disorder. Multiple renal and extrarenal manifestations of ADPKD have been described that cause significant complications.

Renal Manifestations

A number of clinical features that result from renal damage can be identified (Box 44.1). Reduction in urinary concentrating capacity and glomerular hyperfiltration are early functional abnormalities that can be observed in some children and adolescents with ADPKD.

Renal Size

Renal size increases with age, and renal enlargement eventually occurs in 100% of patients with ADPKD. The severity of the structural abnormality correlates with the manifestations of ADPKD, such as pain, hematuria, hypertension, and renal impairment.[1] Massive renal enlargement can lead to compression of local structures, resulting in such complications as inferior vena cava (IVC) compression and digestive symptoms. Most manifestations are directly related to the development and enlargement of renal cysts. The Consortium for Radiologic Imaging Studies of Polycystic Kidney Disease (CRISP), a prospective study of 241 patients by annual MRI, has shown that total kidney volume and cyst volumes increased exponentially.[22] Rates of growth were relatively constant, averaging 5.3% per year, but highly variable from patient to patient. Baseline total kidney volume predicted the subsequent rate of increase in renal volume and decline in GFR.[23] An imaging classification of ADPKD based on height adjusted total kidney volume and age has been proposed to facilitate the selection of patients for enrollment into clinical trials and for treatment when one becomes available.[24]

BOX 44.1 Renal Manifestations of Autosomal Dominant Polycystic Kidney Disease

Functional Manifestations
- Concentrating defect
- Reduced renal blood flow

Hypertension → Target Organ Damage
- Cardiac
- Cerebrovascular
- Arteriolosclerosis and glomerulosclerosis
- Peripheral vascular disease

Pain, Caused by
- Cyst hemorrhage
- Gross hematuria
- Nephrolithiasis
- Infection
- Renal enlargement

Reduced Glomerulat Filtration Rate, Possible Caused by
- Interstitial inflammation
- Apoptosis of tubular epithelial cells
- Hypertensive glomerulosclerosis
- Compression atrophy

Pain

Episodes of acute renal pain are seen frequently; causes include cyst hemorrhage, infection, stone, and, rarely, tumor, and these must be investigated thoroughly. A few patients with ADPKD with renal enlargement and structural distortion develop chronic flank pain without specifically identifiable cause.

Hematuria and Cyst Hemorrhage

Visible hematuria may be the initial presenting symptom and occurs in up to 40% of patients with ADPKD over the course of the disease. Many have recurrent episodes. Differential diagnosis includes cyst hemorrhage, stone, infection, and tumor. Cyst hemorrhage is a frequent complication and produces gross hematuria when the cyst communicates with the collecting system. Frequently, the cyst does not communicate with the collecting system, and flank pain without hematuria occurs. It can manifest with fever, raising the possibility of cyst infection. On occasion, a hemorrhagic cyst will rupture, resulting in a retroperitoneal bleed that can be significant, potentially requiring transfusion. In most patients, cyst hemorrhage is self-limited, resolving within 2 to 7 days. If symptoms of hematuria or flank pain last longer than 1 week or if the initial episode of hematuria occurs after age 50 years, neoplasm should be excluded.

Urinary Tract Infection and Cyst Infection

Urinary tract infection (UTI) is common in ADPKD, but its incidence may have been overestimated because sterile pyuria is common in these patients. UTI presents as cystitis, acute pyelonephritis, cyst infection, and perinephric abscesses. As in the general population, women are affected more frequently than men. Most infections are caused by *Escherichia coli, Klebsiella* and *Proteus* species, and other Enterobacteriaceae. The route of infection in acute pyelonephritis and cyst infection is usually retrograde from the bladder; therefore cystitis should be promptly treated to prevent complicated infections.

Both CT and MRI are sensitive to detect complicated cysts and can provide anatomic definition, but the findings are not specific for infection. Nuclear imaging, especially indium-labeled white blood cell scanning, is useful, but false-negative and false-positive results are possible. F-Labeled fluorodeoxyglucose (FDG) positron emission tomography (PET) has recently been used for detection of infected cysts.[1] FDG is taken up by inflammatory cells because of their high metabolic rate but is filtered by the kidneys, is not reabsorbed, and appears in the collecting system, which may limit its use in diagnosis of renal cyst infections; its present role is for diagnosis of infected liver cysts. FDG-PET is expensive and not widely available, but it provides rapid imaging with high spatial resolution, high target-to-background ratio, low radiation burden, and high interobserver agreement.

When there is fever and flank pain with suggestive diagnostic imaging but blood and urine cultures are negative, cyst aspiration under ultrasound or CT guidance should be undertaken to culture the organism and inform the selection of antimicrobial therapy.

Nephrolithiasis

Renal stone disease occurs in about 20% of patients with ADPKD. Most stones are composed of uric acid, calcium oxalate, or both. Uric acid stones are more common in ADPKD than in stone formers without ADPKD. Urinary stasis secondary to distorted renal anatomy may play a role in the pathogenesis of nephrolithiasis. Predisposing metabolic factors include decreased ammonia excretion, low urinary pH, and low urinary citrate concentration.

Stones can be difficult to diagnose on imaging in ADPKD because of cyst wall and parenchymal calcification. The distorted anatomy can cause difficulty in localizing stones to the collecting system on plain

radiographs. Intravenous (IV) urography has the advantage of specifically localizing stone material to the collecting system and may provide clues to stone composition. IV urography also can detect precalyceal tubular ectasia, found in 15% of patients with ADPKD. CT urography has replaced IV urography in many centers; it is more sensitive in detecting small or radiolucent stones and for differentiating stones from tumor, clot, and cyst wall or parenchymal calcification. Dual-energy CT is increasingly used to distinguish between calcium and uric acid stones.

Hypertension

Hypertension is the most common manifestation of ADPKD and a major contributor to renal disease progression and cardiovascular morbidity and mortality (Fig. 44.3). Microalbuminuria, proteinuria, and hematuria, which are independent risk factors for renal functional decline, are more common in hypertensive patients with ADPKD. Hypertension also may increase morbidity from valvular heart disease and intracranial aneurysms, which are common in ADPKD.

Ambulatory blood pressure (BP) monitoring of children or young adults without diagnosed hypertension often reveals elevated BP, attenuated nocturnal BP dipping, and exaggerated BP response during exercise. A study stratified 65 children by BP into three cohorts: hypertensive (≥95th percentile), borderline hypertensive (75th to 95th percentile), and normotensive (≤75th percentile).[25] Both the hypertensive and the borderline hypertensive children had significantly higher left ventricular mass indices than the normotensive children. Among normotensive children, indices were significantly higher in those within the upper quartile of normal BP. These observations suggest that target organ damage develops early in ADPKD and that antihypertensive treatment may be indicated in children with ADPKD and borderline hypertension.

End-Stage Renal Disease

In most patients, renal function is maintained within the normal range, despite relentless growth of cysts, until the fourth to sixth decade of life. By the time renal function starts declining, the kidneys usually are greatly enlarged and distorted with little recognizable parenchyma on imaging studies. At this stage, the average rate of GFR decline is 4.4 to 5.9 ml/min per year. Nevertheless, ESRD is not inevitable in ADPKD. Up to 77% of patients are alive with preserved renal function at age 50 years, and 52% at age 73. Men tend to progress to renal failure more rapidly and require renal replacement therapy at a younger age than women. Other risk factors for renal failure include Black race, diagnosis of ADPKD before age 30, first episode of hematuria before age 30, onset of hypertension before age 35, hyperlipidemia, low level of high-density lipoprotein cholesterol, sickle cell trait, and *PKD1* truncating mutations. Recently, a post hoc analysis of the HALT PKD clinical trials showed an association of dietary sodium with the rate of kidney growth in patients with ADPKD with estimated GFR (eGFR) over 60 ml/min/1.73 m^2 and with the rate of decline in kidney function in those with eGFR between 25 and 60 ml/min/1.73 m^2.[26]

Several mechanisms account for renal function decline. The CRISP study confirmed that kidney and cyst volumes are the strongest predictors of renal functional decline.[23] CRISP also found that renal blood flow (or vascular resistance) is an independent predictor.[27] This points to the importance of vascular remodeling in the progression of the disease and may account for cases in which the decline of renal function seems disproportionate to the severity of the cystic disease. Other factors, such as heavy use of analgesics, may contribute to chronic kidney disease progression in some patients.

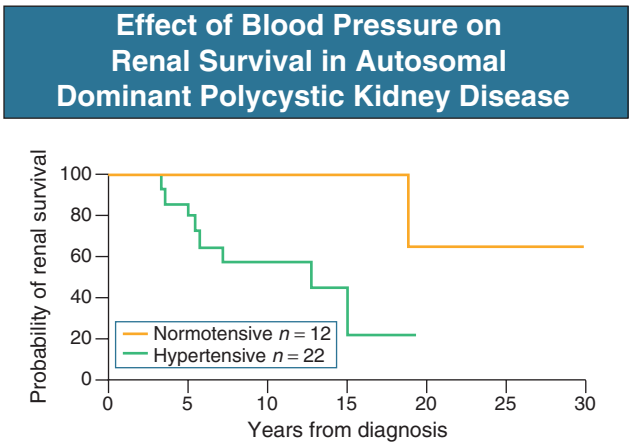

Fig. 44.3 Patients with polycystic kidney disease and hypertension at diagnosis have less probability of renal survival than those with normal blood pressure.

Extrarenal Manifestations

Polycystic Liver Disease

PLD is the most common extrarenal manifestation of ADPKD. PLD is associated with both *PKD1* and *PKD2* genotypes. In contrast to the renal phenotype, the ADPKD genotype is not associated with the severity or growth rate of PLD in patients with ADKPD.[17] In addition, PLD also occurs as a genetically distinct disease in the absence of renal cysts (ADPLD). Most simple hepatic cysts are solitary, and PLD should be suspected when four or more cysts are present in the hepatic parenchyma. The liver in PLD contains multiple microscopic or macroscopic cysts that result in hepatomegaly (Fig. 44.4), but typically there is preservation of normal hepatic parenchyma and liver function.

Hepatic cysts are exceedingly rare in children with ADPKD. Their frequency increases with age and may have been underestimated by ultrasound and CT studies. Their prevalence by MRI in the CRISP study was 58%, 85%, and 94%, respectively, in participants age 15 to 24, 25 to 34, and 35 to 44 years. Women develop more cysts at an earlier age than men. Women who have multiple pregnancies or who have used oral contraceptives (OCs) or estrogen replacement therapy (ERT) in the postmenopausal period may have worse disease. After menopause the volume of polycystic livers often remains stable or may even decrease.[17]

Typically, PLD is asymptomatic, but reported symptoms have become more frequent as the life span of patients with ADPKD is prolonged with dialysis and transplantation. Symptoms result from mass effect or from complications related to the cysts themselves.[28] Symptoms include dyspnea, orthopnea, early satiety, gastroesophageal reflux, mechanical low back pain, uterine prolapse, and even rib fracture. Other complications caused directly by mass effect include hepatic venous outflow obstruction, IVC compression, portal vein compression, and bile duct compression presenting as obstructive jaundice. Hepatic venous outflow obstruction is an uncommon condition caused by severe extrinsic compression of the intrahepatic IVC and hepatic veins by cysts, rarely with superimposed thrombosis. Symptomatic cyst complications include cyst hemorrhage, which occurs less frequently than renal cyst hemorrhage, cyst infection, and the rare occurrence of torsion or rupture of cysts. Hepatic cyst infection can be a serious complication and typically presents with localized pain, fever, leukocytosis, elevated sedimentation rate, and often elevated alkaline phosphatase. Enterobacteriaceae are the most common microorganisms causing cyst infection. The same imaging techniques discussed for the investigation of renal cyst infections may be useful for the localization of infected cysts in the liver.

Congenital hepatic fibrosis, always found in association with autosomal recessive PKD, can, rarely, coexist with ADPKD. Contrary to PKD, which affects members of several generations in these families, congenital hepatic fibrosis is seen in only one generation and is not

transmitted vertically, suggesting the importance of modifier genes. These patients present with manifestations of portal hypertension, but hepatocellular function is normal.

Intracranial Aneurysms

Intracranial aneurysms occur in about 8% of patients with ADPKD. There is some familial clustering; intracranial aneurysms occur in 6% of patients with a negative family history and 16% of those with a positive family history. Most are asymptomatic. Focal findings, such as cranial nerve palsy and seizure, may result from compression of local structures by an enlarging aneurysm (Fig. 44.5). Yearly rupture rates increase with size, ranging from less than 0.5% for aneurysms smaller than 5 mm in diameter to 4% for aneurysms larger than 10 mm. Rupture carries a 35% to 55% risk for combined severe morbidity and mortality. The mean age at rupture in ADPKD is 39 years (vs. 51 years in the general population), with a range of 15 to 69 years. Most patients have normal renal function, and up to 29% have normal BP at rupture.

Screening is not indicated for all patients with ADPKD because most intracranial aneurysms found by presymptomatic screening are small, have a low risk for rupture, and require no treatment because the risks of intervention exceed any risk for rupture.[29] Indications for screening in patients with a good life expectancy include family history of intracranial aneurysm or subarachnoid hemorrhage, previous aneurysmal rupture, preparation for elective surgery with potential hemodynamic instability, high-risk occupations (e.g., airline pilots), and significant patient anxiety despite adequate information about the risks. Magnetic resonance angiography is the diagnostic imaging modality of choice for presymptomatic screening because it is noninvasive and does not require IV contrast administration. CT angiography is a satisfactory alternative if there is no contraindication to IV contrast. Repeated screening of patients with a strong family history of intracranial aneurysms or aneurysmal rupture after 5 to 10 years is recommended.

Other Vascular Abnormalities

In addition to intracranial aneurysms, ADPKD is associated with other vascular abnormalities, such as thoracic aortic and cervicocephalic arterial dissections, coronary artery aneurysms, and retinal artery and vein occlusions (Fig. 44.6). Thoracic aortic dissection is seven times more common in ADPKD than in the general population in autopsy series, but reported cases are rare. Rare patients with coronary aneurysms can present with cardiac ischemia and thrombus in the aneurysm in the absence of atherosclerotic disease. Several case reports describe abdominal aortic aneurysms in ADPKD. However, a prospective ultrasound study showed neither a wider aortic diameter nor a higher prevalence of abdominal aortic aneurysms in patients with ADPKD compared with an unaffected kindred in any age group.

Valvular Heart Disease and Other Cardiac Manifestations

Mitral valve prolapse is the most common valvular abnormality and has been demonstrated in up to 25% of patients with ADPKD by echocardiography. Mitral regurgitation, tricuspid regurgitation, and tricuspid prolapse also occur more frequently in ADPKD than in unaffected kindred. Aortic regurgitation may be associated with dilation of the aortic root. On histologic examination, valvular tissue shows myxoid degeneration with disruption of collagen, as seen in Marfan and Ehlers-Danlos syndromes. Although the lesions may progress with time, they rarely require valve replacement. Screening echocardiography is not indicated unless a murmur is detected on physical examination. Small, hemodynamically insignificant pericardial effusion can be detected by CT scanning in up to 35% of patients with ADPKD.

Other Associated Conditions

Cyst formation has been described in such diverse organs as the pancreas, seminal vesicles, and arachnoid membrane (Fig. 44.7). Seminal

(A) Gross specimen demonstrating bilateral aneurysms of the middle cerebral arteries *(arrows).* (B) Gross specimen demonstrating a thoracic aortic dissection extending into the abdominal aorta in a patient with ADPKD.

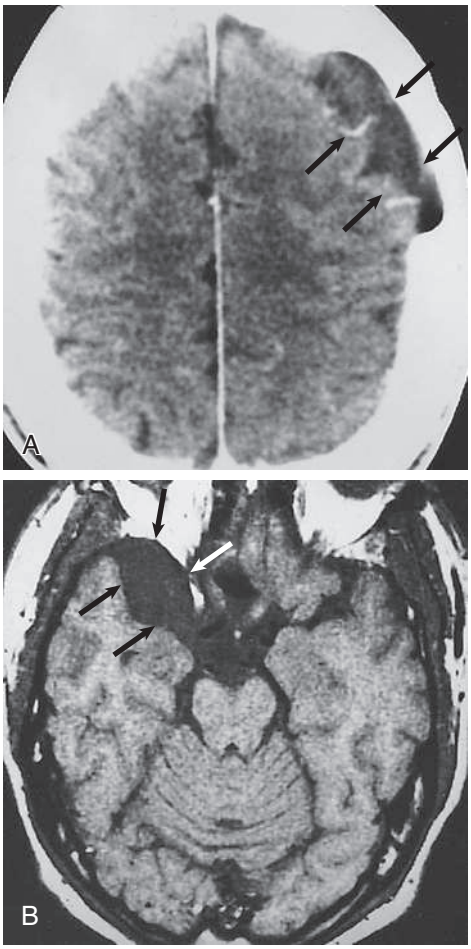

Fig. 44.7 Extrarenal manifestations of autosomal dominant polycystic kidney disease (ADPKD). Computed tomography (A) and magnetic resonance imaging (B) scans demonstrate cysts in the arachnoid membrane *(arrows)* in ADPKD.

vesicle cysts, usually multiple and bilateral, are found in 40% of ADPKD compared with 2% of nonaffected males. Ovarian cysts are not associated with ADPKD. Pancreas and arachnoid membrane cysts are present in 5% and 8% of patients, respectively. Pancreatic cysts are almost always asymptomatic, with rare occurrences of recurrent pancreatitis and possibly chance associations of intraductal papillary mucinous tumor or carcinoma. Epididymal and prostate cysts also may occur with increased frequency. Sperm abnormalities with defective motility are common in ADPKD and rarely may be a cause of male infertility. Spinal meningeal diverticula may occur with increased frequency and rarely manifest with intracranial hypotension (orthostatic headache, diplopia, hearing loss, ataxia) caused by cerebrospinal fluid leak. The prevalence of colonic and duodenal diverticula also may be increased.

PATHOLOGY

Polycystic kidneys are diffusely cystic and enlarged (Fig. 44.8). Size varies from normal to weighing more than 4 kg. The outer and cut surfaces show numerous spherical cysts of varying size, which are distributed evenly between cortex and medulla. The collecting system typically is distorted. The epithelium lining the cysts is characterized by hyperplastic changes, including flat nonpolypoid hyperplasia, polypoid hyperplasia, and microscopic adenomas (Fig. 44.9), as well as increased rates of cell proliferation and apoptosis. Despite the frequency

Fig. 44.8 Polycystic kidneys. Greatly enlarged polycystic kidneys from a patient with autosomal dominant polycystic disease compared with a normal kidney *(middle).*

of hyperplastic lesions and microscopic adenomas, the incidence of renal cell carcinoma is not increased.

Cysts arise from all segments of the nephron and collecting ducts. As they grow, cysts dissociate from the parent tubule and eventually become isolated, fluid-filled sacs. There is no agreement on whether

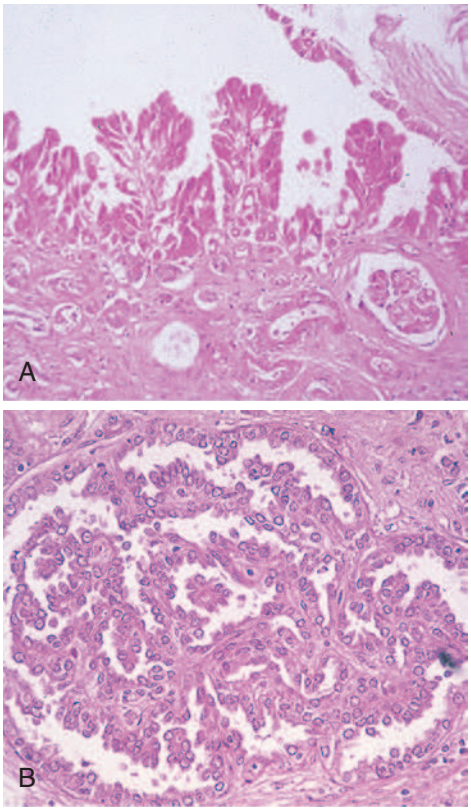

Fig. 44.9 Renal cyst histology in autosomal dominant polycystic kidney disease (ADPKD). (A) Papillary hyperplasia of cyst epithelium. (B) Papillary microscopic adenoma in kidney of patient with ADPKD. (Magnification ×200.)

the cysts originate preferentially from particular tubular segments. Most studies indicate that cysts are predominantly of distal nephron and collecting duct origin. Studies in advanced renal disease showing proximal tubular cysts may be confounded by the effects of obstruction and acquired renal cystic disease.

Polycystic kidneys demonstrate advanced sclerosis of preglomerular vessels, interstitial fibrosis, and tubular epithelial hyperplasia, even in patients with normal renal function or early renal failure. Sclerosis involves both afferent arterioles and interlobular arteries. Interstitial fibrosis is also prominent, even in early disease. It is associated with an interstitial infiltrate of macrophages and lymphocytes.

TREATMENT

Current therapy is directed toward the renal and extrarenal complications of ADPKD in an effort to limit morbidity and mortality. Advances in the understanding of the genetics of ADPKD and mechanisms of cyst development and growth have raised hopes for treatments specifically directed toward limiting the development and progression of the disease, and some of these treatments are now being evaluated in clinical trials (see Novel Therapies in this chapter).

Flank Pain

Causes of flank pain that may require intervention, such as infection, stone, and tumor, should be excluded. Care should be taken to avoid long-term administration of nephrotoxic agents, such as combination analgesics and nonsteroidal antiinflammatory drugs. Narcotic analgesics should be reserved for the management of acute pain. Patients with chronic kidney pain are at risk for narcotic and analgesic dependence, and a psychological evaluation and a supportive attitude by the physician are essential. Reassurance, lifestyle modification, and avoidance of aggravating activities may be helpful. Tricyclic antidepressants are helpful as in other chronic pain syndromes, with a generally well-tolerated side effect profile. Splanchnic nerve blockade with local anesthesia or corticosteroids results in pain relief prolonged beyond the duration of the local anesthetic.

When distortion of the kidneys by large cysts is deemed responsible for the pain and conservative measures fail, cyst decompression should be considered. Cyst aspiration, under ultrasound or CT guidance, is a relatively simple procedure. To prevent the reaccumulation of cyst fluid, sclerosing agents such as 95% ethanol, acidic solutions of minocycline, or sodium tetradecyl sulfate may be used. Minor complications include microhematuria, localized pain, transient fever, and systemic absorption of the alcohol. More serious complications, such as pneumothorax, perirenal hematoma, arteriovenous fistula, urinoma, and infection, are rare. Complications from aspiration of centrally located cysts are more common, and the morbidity of the procedure is proportional to the number of cysts treated.

If multiple cysts are contributing to pain, laparoscopic or surgical cyst fenestration may be of benefit. Surgical decompression is effective in 80% to 90% of patients at 1 year, and 62% to 77% have sustained pain relief for more than 2 years (Fig. 44.10A). Surgical intervention does not accelerate the decline in renal function, as once thought, but does not appear to preserve declining renal function either (see Fig. 44.10B). Laparoscopic fenestration is as effective as open surgical fenestration in short-term follow-up in patients with limited disease, and there is a shorter, less complicated recovery period compared with open surgery. Previous abdominal surgery with possible adhesion formation is a relative contraindication to the procedure.

Other interventions are available for the management of pain in ADPKD whose roles have not been fully defined. Laparoscopic renal denervation has been used in combination with cyst fenestration and may be considered, particularly in polycystic kidneys without large cysts. Thoracoscopic sympatho-splanchnicectomy is effective in some patients but has significant morbidity. Catheter-based renal denervation has been reported to be successful in a few patients, but a prospective protocolized evaluation of this approach is needed. Laparoscopic and retroperitoneoscopic nephrectomy and arterial embolization have been used to treat symptomatic polycystic kidneys in patients with ADPKD who have ESRD.

Cyst Hemorrhage

Episodes of cyst hemorrhage are self-limited, and patients respond well to conservative management with bed rest, analgesics, and increased fluid intake to prevent obstructing clots. Rarely, bleeding is more severe, with extensive subcapsular or retroperitoneal hematoma causing significant decrease in hematocrit and hemodynamic instability. This requires hospitalization and transfusion. The antifibrinolytic agent tranexamic acid has been successfully used in some patients, but no controlled studies have been performed.[30] The dose should be reduced in the presence of renal impairment. Potential adverse effects of tranexamic acid therapy include glomerular thrombosis and ureteral obstruction from clots. In patients with unusually severe or persistent hemorrhage, segmental arterial embolization can be successful. If not, surgery may be required to control bleeding.

Urinary Tract and Cyst Infection

Because most renal cyst infections begin as cystitis, prompt treatment of symptomatic cystitis and asymptomatic bacteriuria is indicated to prevent retrograde seeding of the renal parenchyma. Antibiotics that require glomerular filtration, such as highly polar aminoglycosides, are

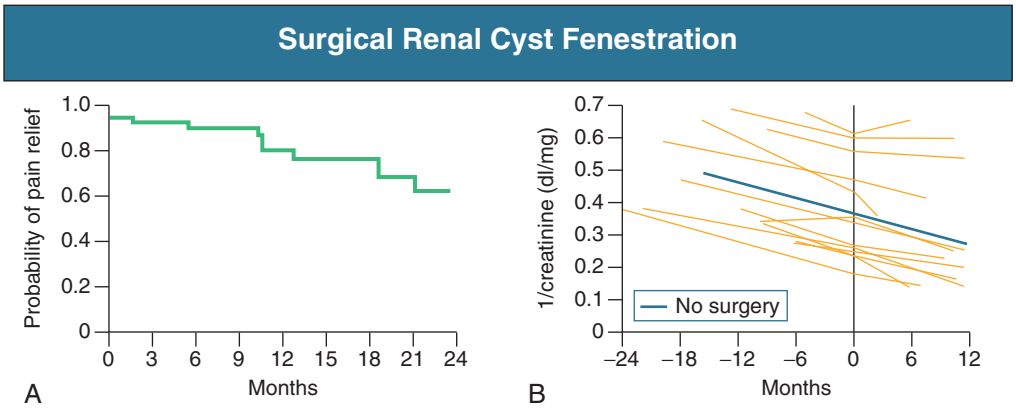

Fig. 44.10 Surgical cyst fenestration for symptomatic autosomal dominant polycystic kidney disease. (A) Effects on relief of pain. (B) Rate of decline of renal function. *Orange lines* indicate the course of renal function in individual patients who underwent cyst fenestration at month 0.

not effective for upper UTI in severe renal impairment. Cyst infection is often difficult to treat despite prolonged therapy with an antibiotic to which the organism is susceptible. Treatment failure occurs if antibiotics do not penetrate the cyst epithelium and achieve therapeutic concentrations within the cysts. Lipophilic agents have been shown to penetrate cysts reliably and have an acid dissociation constant (pK_a) that allows favorable electrochemical gradients into acidic cyst fluid. Therapeutic agents of choice include trimethoprim-sulfamethoxazole and fluoroquinolones, both of which have favorable intracystic therapeutic concentration gradients at physiologic pH in gradient and nongradient cysts.

If fever persists after 1 to 2 weeks of appropriate antimicrobial therapy, infected cysts should be drained percutaneously or surgically. In the case of end-stage polycystic kidneys, nephrectomy should be considered. If fever recurs after stopping antibiotics, complicating features such as obstruction, perinephric abscess, and stone should be excluded. If no such complicating features are identified, the antibiotic course should be extended and may require several months to fully eradicate infection.

Nephrolithiasis

Treatment of nephrolithiasis in patients with ADPKD is the same as that in patients without ADPKD (see Chapter 57). Potassium citrate is the treatment of choice in the three stone-forming conditions associated with ADPKD: uric acid lithiasis, hypocitraturic calcium oxalate nephrolithiasis, and distal acidification defects. Extracorporeal shock wave lithotripsy and percutaneous nephrostolithotomy are reported to be 82% and 80% successful, respectively, without increased complications compared with patients without ADPKD.[1] Flexible ureterorenoscopy with laser fragmentation also has been used safely and effectively and cannot cause traumatic nephron loss.[1]

Hypertension

Control of hypertension is essential because uncontrolled hypertension accelerates the decline in renal function and aggravates extrarenal complications. Antihypertensive agents of choice and optimal BP targets in ADPKD have not been established. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) increase renal blood flow in ADPKD, have a favorable side effect profile, and may have renoprotective properties that go beyond BP control. The HALT PKD study, a recent double-blind, placebo-controlled randomized clinical trial (RCT), examined the role of RAS blockade in both early and advanced ADPKD.[31,32] Monotherapy with ACE inhibitors gave good BP control in the majority of patients. In early ADPKD (15 to 49 years of age, GFR >60 ml/min/1.73 m^2), rigorous BP control (target range 95 to 110/60 to 75 mm Hg) was associated with slower increase in total kidney volume, faster eGFR decline during the first 4 months of treatment followed by a slower eGFR decline thereafter without an overall eGFR effect, a lesser increase in renal vascular resistance, and a greater decline in left ventricular mass index, after a follow-up of 8 years.[33] Patients with more severe ADPKD determined by age-adjusted kidney volume were more likely to benefit from rigorous BP control.[33] Dual RAS blockade with lisinopril and telmisartan had no beneficial effect compared with lisinopril alone in these patients, nor in more advanced ADPKD (18 to 64 years of age with GFR between 25 and 60 ml/min/1.73 m^2). The HALT PKD study therefore supports the use of an ACE inhibitor or ARB as the antihypertensive medication of choice in most patients with ADPKD and a rigorous BP target (95 to 110/60 to 75 mm Hg) in young patients with ADPKD with normal renal function and without other significant comorbidities.

Progressive Renal Failure

General strategies to delay progression of CKD are discussed in Chapter 79. Hypertension plays an important role in the progression of ADPKD to ESRD. In addition to the HALT PKD clinical trials, long-term follow-up of participants in the Modification of Diet in Renal Disease (MDRD) study suggested that individuals with ADPKD randomized to a low BP target (mean arterial pressure [MAP] <92 mm Hg) experienced significantly less ESRD and combined ESRD/death than those randomized to the usual BP target (MAP <107 mm Hg).[1]

Preclinical studies, and evidence suggesting increased vasopressin effect on the kidney and cAMP levels are involved in cyst progression, have led to the ingestion of supplemental water sufficient to achieve a urinary osmolality below 250 mOsm/kg H_2O (~3 liters in most patients) being recommended for patients with ADPKD with an eGFR greater than 30 ml/min, although there are no RCTs to support this approach.[34] Exclusions would include severe protein or sodium restriction, volume contraction, or reduced effective intravascular volume, taking diuretics or drugs enhancing the release of arginine vasopressin (AVP), or presenting abnormal voiding or urologic problems. Serum sodium concentration should be monitored.

Patients with ADPKD have reduced morbidity and mortality on dialysis compared with patients with ESRD from other causes. Women appear to do better than men. The good outcome in ADPKD may result from higher endogenous erythropoietin production, better maintenance of hemoglobin, or lower comorbidity. Rarely, hemodialysis can be

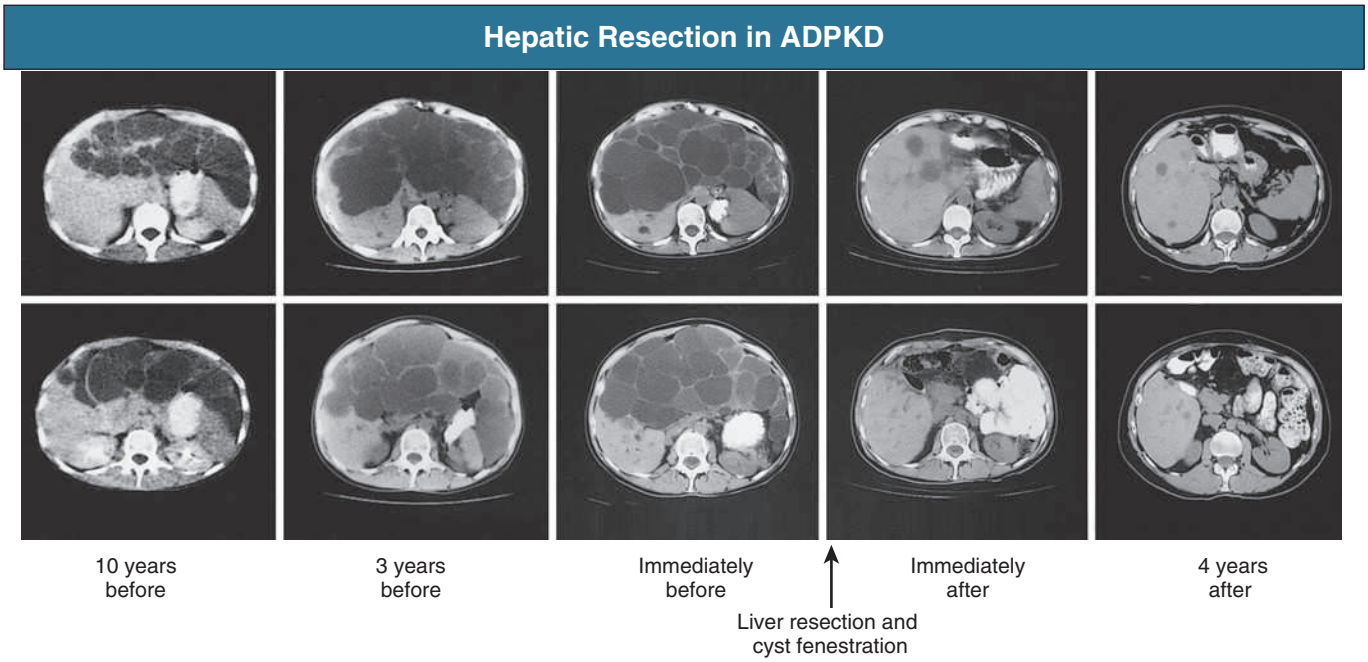

Fig. 44.11 Hepatic resection in autosomal dominant polycystic kidney disease. Computed tomography scans of the abdomen 10 years before *(column 1),* 3 years before *(column 2),* immediately before *(column 3),* immediately after *(column 4),* and 4 years after *(column 5)* liver resection and cyst fenestration, demonstrating long-term, sustained reduction in liver size after the procedure.

complicated by intradialytic hypotension if there is IVC compression by a medially located renal cyst. Despite renal size, peritoneal dialysis can usually be performed in ADPKD, although there is increased risk for inguinal and umbilical hernias, which require surgical repair.

Polycystic Liver Disease

Usually asymptomatic, PLD requires no treatment. When symptomatic, therapy is directed toward reducing cyst volume and hepatic size. Noninvasive measures include avoiding excessive use of ethanol, other hepatotoxins, and possibly cAMP agonists (e.g., caffeine), which have been shown to stimulate cyst fluid secretion *in vitro*. Histamine-2 blockers and somatostatin have been suggested to reduce secretion of secretin and secretory activity of cyst walls. Estrogens are likely to contribute to cyst growth, but the use of OCs and postmenopausal ERT are contraindicated only if the liver is significantly enlarged and the risk for further hepatic cyst growth outweighs the benefits of estrogen therapy. Rarely, symptomatic PLD may require invasive measures to reduce cyst volume and hepatic size. Options include percutaneous cyst aspiration and sclerosis, laparoscopic fenestration, and open surgical fenestration. Cyst aspiration is the procedure of choice if symptoms are caused by one or a few dominant cysts or by cysts that are easily accessible to percutaneous intervention. To prevent the reaccumulation of cyst fluid, sclerosis with minocycline, 95% ethanol, or sodium tetradecyl sulfate is often successful. Laparoscopic fenestration can be considered for large cysts that are more likely to recur after ethanol sclerosis, or if several cysts are present that would require multiple percutaneous passes to be treated adequately. Partial hepatectomy with cyst fenestration is an option because PLD often spares a part of the liver with adequate preservation of hepatic parenchyma and liver function[35] (Fig. 44.11). In the rare case in which no segments are spared, liver transplantation may be necessary.

When a hepatic cyst infection is suspected, any cyst with unusual appearance on an imaging study should be aspirated for diagnostic purposes. The best management is percutaneous cyst drainage in combination with antibiotic therapy. Long-term oral antibiotic suppression or prophylaxis should be reserved for relapsing or recurrent cases. Antibiotics of choice are trimethoprim-sulfamethoxazole and the fluoroquinolones, which are effective against the typical infecting organisms and concentrate in the biliary tree and cysts.

Intracranial Aneurysm

Ruptured or symptomatic intracranial aneurysm requires surgical clipping of the neck of the aneurysm. Asymptomatic aneurysms measuring less than 5 mm, diagnosed by presymptomatic screening, can be observed with repeated magnetic resonance angiography at 6 months, then annually and less frequently after stability of the aneurysm has been established. If the size increases, surgery is indicated. Definitive management of aneurysms between 6 and 9 mm remains controversial. Surgical intervention is usually indicated for all unruptured aneurysms 10 mm in diameter or larger. For patients with high surgical risk or technically difficult lesions, endovascular treatment with detachable platinum coils may be indicated.[29]

NOVEL THERAPIES

A better understanding of the pathophysiology and the availability of animal models have facilitated the development of promising candidate drugs for clinical trials (see Fig. 44.2). Of the candidates, only tolvaptan has so far entered clinical practice in some countries outside trials.

Vasopressin Antagonists

The effect of vasopressin, through V_2 receptors, on cAMP levels in the collecting duct, the major site of cyst development in ADPKD, and the role of cAMP in cystogenesis provided the rationale for successful preclinical trials of vasopressin V_2 receptor antagonists.[2] High water intake by itself also exerted a protective effect on the development of PKD in

a rat model of PKD (PCK rat), probably because of suppression of vasopressin. Genetic elimination of AVP in these rats yielded animals born with normal kidneys that remained relatively free of cysts unless an exogenous V_2 receptor agonist was administered.[36]

In a large, phase III parallel-arm RCT in patients with ADPKD with estimated creatinine clearance above 60 ml/min, a split daily dose of the V_2 receptor antagonist tolvaptan administered over 3 years slowed the increase in kidney volume and decline in kidney function and lowered the frequency of ADPKD-related adverse events (kidney pain, hematuria, UTI).[37] However, tolvaptan was associated with a higher frequency of aquaresis-related adverse events (polyuria, thirst, urinary frequency, nocturia) that led to drug discontinuation in 8.3% of tolvaptan-treated patients. In addition, clinically significant increases in liver enzymes (>2.5 times the upper limit of normal) were seen in 4.9% of tolvaptan-treated versus 1.2% of placebo-treated patients and led to discontinuation of the drug in 1.8% of patients taking tolvaptan and 0.2% of the placebo group. Moderate increases in serum sodium and uric acid levels were also seen more frequently in the patients taking tolvaptan. At present, tolvaptan is approved for the treatment of rapidly progressive ADPKD in Japan, Canada, the European Union, Switzerland, and South Korea, but not in the United States. A hierarchical decision algorithm using a sequence of risk-factor assessments has been proposed to select patients with rapidly progressive disease and therefore most likely to benefit from tolvaptan.[38] A large RCT (**R**eplicating **E**vidence of **P**reserved **R**enal Function: An **I**nvestigation of Tolvaptan **S**afety and **E**fficacy in ADPKD or REPRISE) in patients with more advanced ADPKD (eGFR 25 to 65 ml/min/1.73 m^2) will be completed in 2017. Patients taking tolvaptan should have easy access to and be able to tolerate water. Liver function should be monitored closely during therapy. Serum sodium and uric acid require monitoring.

Somatostatin Analogues

Somatostatin acting on somatostatin receptors inhibits cAMP accumulation not only in the kidney but also in the liver. Somatostatin has a half-life of approximately 3 minutes, so more stable synthetic peptides (octreotide, lanreotide, pasireotide) have been developed for clinical use, which vary in stability and receptor affinity. In preclinical studies, these drugs reduced cAMP levels and proliferation of cholangiocytes in vitro, expansion of liver cysts in three-dimensional collagen culture, and development of kidney and liver cysts and fibrosis in animal models orthologous to ARPKD and ADPKD. Three small RCTs of octreotide or lanreotide have been completed[39-41] and extended as open-label, uncontrolled studies,[42-44] with similar results. Kidney growth is halted during the first year of treatment and then resumes, possibly at a lower rate than without treatment. Liver volume decreases by 4% to 6% during the first year of treatment, and this reduction is sustained during the second year. Similar results were obtained in a larger RCT of patients (Alpha-Lipoic Acid in Diabetic Neuropathy [ALADIN]) in which a trend toward stabilization of GFR was observed after the first year.[45] Several additional studies of somatostatin analogues in patients with more advanced ADPKD are in progress. Octreotide and lanreotide are generally well tolerated. Self-resolving abdominal cramps and loose stools are common in the first few days after the injections. Other adverse effects include injection site granuloma and pain, cholelithiasis, steatorrhea, weight loss, and, rarely, hair loss.

Mammalian Target of Rapamycin (mTOR) Inhibitors

The mammalian target of rapamycin (mTOR) is activated in animal models of PKD. Patients with the contiguous *PKD1/TSC2* gene syndrome have a more severe form of PKD than those with ADPKD alone. This observation suggests a convergence of signaling pathways downstream from PC1 and the TSC proteins tuberin and hamartin that control the activity of mTOR. Studies in rodent models of PKD showed that the mTOR inhibitors sirolimus and everolimus significantly prevent cyst expansion and protect renal function. However, two large randomized trials using everolimus and sirolimus for 18 to 24 months have shown no benefit.[46,47]

Other Investigational Therapies

Pravastatin, an HMG-CoA reductase inhibitor, slowed the rate of kidney growth in a small RCT in children and young adults with ADPKD.[48] A phase II, multicenter, double-blind RCT of the Src inhibitor bosutinib reduced the rate of kidney growth, with a trend to worsen renal function (ClinicalTrials.gov NCT01233869). Clinical trials of the multikinase inhibitor KD019, metformin, pioglitazone, nicotinamide, and triptolide are ongoing (ClinicalTrials.gov) (see Fig. 44.2).

TRANSPLANTATION

Transplantation is the treatment of choice for ESRD in patients with ADPKD. There is no difference in patient or graft survival between patients with ADPKD and other ESRD populations. Living donor transplants also have graft survival no different from that of non-ADPKD populations. However, living related transplantation has only recently been widely practiced in the ADPKD population. In 1999, 30% of kidney transplants for patients with ADPKD were from living donors in the United States, compared with 12% in 1990.

Complications after transplantation are no greater in the ADPKD population than in the general population, and specific complications directly related to ADPKD are rare. Cyst infection is not increased after transplantation, and there is no significant increase in the incidence of symptomatic mitral valve prolapse or hepatic cyst infection. One study showed an increased rate of diverticulosis and bowel perforation in ADPKD. Whether ADPKD increases the risk for development of new-onset diabetes mellitus after transplantation is controversial.

Although practiced routinely in the past, pretransplantation nephrectomy has fallen out of favor. By 1 and 3 years after renal transplantation, kidney volumes decrease by 37.7% and 40.6% whereas liver volumes increase by 8.6% and 21.4%, respectively.[49] Indications for nephrectomy include a history of infected cysts, frequent bleeding, severe hypertension, and massive renal enlargement with extension into the pelvis. There is no evidence of an increased risk for development of renal cell carcinoma in native ADPKD kidneys after transplantation. When nephrectomy is indicated, hand-assisted laparoscopic nephrectomy is associated with less intraoperative blood loss, less postoperative pain, and faster recovery compared with open nephrectomy and is increasingly being used.

SELF-ASSESSMENT QUESTIONS

1. Age of end-stage renal disease (ESRD) onset in the patient with autosomal dominant polycystic kidney disease (ADPKD) depends on:
   - **A.** Mutated gene (*PKD1* vs. *PKD2*)
   - **B.** Type of mutation
   - **C.** Modifier genes
   - **D.** Environmental factors
   - **E.** All of the above
2. Which of the following statements about ADPKD and intracranial aneurysm is true?
   - **A.** All ADPKD patients should be screened for intracranial aneurysms.
   - **B.** Most intracranial aneurysms rupture.
   - **C.** The risk for rupture of an intracranial aneurysm depends on its size and location.
   - **D.** Magnetic resonance angiography to screen for intracranial aneurysms is contraindicated in advanced chronic kidney disease (CKD) because it requires administration of gadolinium.
   - **E.** None of the above.
3. Which of the following is the most common risk factor for nephrolithiasis in ADPKD?
   - **A.** Low urine citrate
   - **B.** Hypercalciuria
   - **C.** Hyperuricosuria
   - **D.** Hyperoxaluria
   - **E.** Renal tubular acidosis
4. Which of the following statements about ADPKD and hypertension is true?
   - **A.** Angiotensin-converting enzyme (ACE) inhibitors have been shown to be superior to β-blockers to treat hypertension and protect renal function in patients with ADPKD.
   - **B.** Rigorous blood pressure (BP) control has been shown to be superior to standard BP control in prospective studies to protect renal function in patients with ADPKD and CKD stage 3.
   - **C.** Both A and B are true.
   - **D.** Both A and B are false.

45

Other Cystic Kidney Diseases

Lisa M. Guay-Woodford

Numerous single-gene disorders share renal cysts as a common feature (Box 45.1).[1] These disorders may be inherited or acquired; their manifestations may be confined to the kidney or expressed systemically. They may manifest at a wide range of ages, from the perinatal period to old age (Fig. 45.1). The renal cysts may be single or multiple, and the associated renal morbidity may range from clinical insignificance to progressive parenchymal destruction with resultant renal insufficiency.

The clinical context often helps distinguish these renal cystic disorders from one another. Echogenic, enlarged kidneys in a neonate or infant should raise suspicion about autosomal recessive polycystic kidney disease (ARPKD), autosomal dominant polycystic kidney disease (ADPKD, see Chapter 44), tuberous sclerosis complex (TSC), or one of the many congenital syndromes associated with renal cystic disease. Renal impairment in an adolescent suggests ARPKD or nephronophthisis as possible causes. The finding of a solitary cyst in a child of 5 years of age may indicate a calyceal diverticulum, whereas this finding in a 50-year-old person is most compatible with a simple renal cyst. Renal stones occur in ADPKD and medullary sponge kidney (MSK). For those disorders with systemic manifestations, such as ADPKD, TSC, and von Hippel–Lindau (VHL) disease, the associated extrarenal features may provide other important differential diagnostic clues.

For an increasing number of the single-gene disorders, genetic testing is available in expert laboratories around the world. Genetic testing resources are listed at Gene Tests (http://www.genetests.org) and the NIH Genetic Testing Registry (http://www.ncbi.nlm.nih.gov/gtr).

AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE

Definition

ARPKD is a severe, typically early-onset form of cystic disease that primarily involves the kidneys and biliary tract. Affected patients have a spectrum of clinical phenotypes that depend in part on the age at presentation.

Etiology and Pathogenesis

Genetic Basis

All typical forms of ARPKD are caused by mutations in a single gene, *PKHD1,* that encodes multiple alternatively spliced isoforms predicted to form both membrane-bound and secreted proteins. The largest protein product of *PKHD1,* the fibrocystin/polyductin complex (FPC), contains one membrane-spanning domain and an intracellular C-terminal tail. FPC localizes, at least in part, to the primary cilium and the centrosome in renal epithelial cells. The basic defects observed in ARPKD suggest that FPC mediates the terminal differentiation of the collecting duct and biliary tract. However, the exact function of the numerous isoforms has not been defined and the widely varying clinical spectrum of ARPKD may depend in part on the nature and number of splice variants that are disrupted by specific *PKHD1* mutations.

Pathogenesis

ARPKD typically begins *in utero*, and the renal cystic lesion appears to be superimposed on a normal developmental sequence. The tubular abnormality involves nonobstructive, fusiform and/or saccular dilatation of the renal collecting ducts. In the liver, defective remodeling of the ductal plate *in utero* results in persistence of primitive bile duct configurations and progressive portal fibrosis evolves.[2] The remainder of the liver parenchyma develops normally. The defect in ductal plate remodeling is accompanied by abnormalities in the branching of the portal vein. The resulting histopathologic pattern is referred to as *congenital hepatic fibrosis*.

ARPKD is one of a number of renal cystic diseases associated with congenital hepatic fibrosis, prompting these disorders to be described as hepatorenal fibrocystic diseases.[3] The primary cilium appears to play a central role in the pathogenesis of ARPKD and other hepatorenal fibrocystic diseases, so the broader term *ciliopathies* is used for these disorders, in which dysfunction of the cilia-centrosome complex appears to underpin the development of a wide array of phenotypes, including renal cystic disease.[2]

Epidemiology

The estimated incidence of ARPKD is 1 per 20,000 live births. It occurs more frequently in Whites than in other ethnic populations.

Clinical Manifestations

The clinical spectrum of ARPKD is variable. The majority of cases are identified either *in utero* or at birth. The most severely affected fetuses have enlarged echogenic kidneys and oligohydramnios as a result of poor fetal urine output. These fetuses develop the Potter phenotype, with pulmonary hypoplasia, a characteristic facies, and deformities of the spine and limbs. At birth, these neonates often have a critical degree of pulmonary hypoplasia that is incompatible with survival. The estimated perinatal mortality is about 30%. Renal function, though frequently compromised, is rarely a cause of neonatal death.

For those who survive the first month of life, the reported mean 5-year patient survival rate is 85% to 90%. Morbidity and mortality results from severe systemic hypertension, renal impairment, and portal hypertension secondary to portal-tract hyperplasia and fibrosis.[4] Hypertension usually develops in the first few months and ultimately affects 70% to 80% of patients. Individuals with ARPKD have defects in both

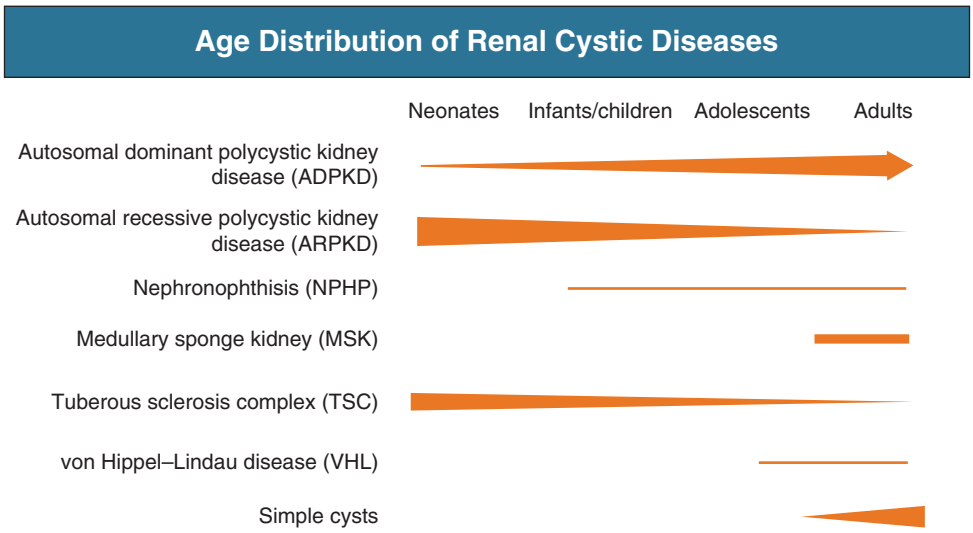

Fig. 45.1 Age distribution of patients with renal cystic disorders.

urinary diluting capacity and concentrating capacity. Newborns can have hyponatremia, presumably resulting from defects in free water excretion.[4] Although net acid excretion may be reduced, metabolic acidosis is not a significant clinical feature. Retrospective studies have noted an increased incidence of pyuria on urinalysis, as well as culture-confirmed urinary tract infection (UTI).

In the first 6 months of life, infants with ARPKD may have a transient improvement in glomerular filtration rate (GFR) as a result of renal maturation. Subsequently, a progressive but variable decline in renal function occurs, with patients presenting in the first month of life progressing more rapidly to end-stage renal disease (ESRD) than those presenting at more than 1 month of age.[5] With advances in effective therapy for ESRD, prolonged survival is common, and for many patients the hepatic complications become the predominant clinical issue.

On average, those infants with serum creatinine values greater than 2.2 mg/dl (200 µmol/l) progress to ESRD within 5 years, but this is highly variable. In longitudinal studies, the probability of renal survival without ESRD is approximately 85% at 1 year, approximately 70% at 10 years, approximately 65% at 15 years, and approximately 40% at 20 years.[6]

In children who present later in childhood or in adolescence, portal hypertension is frequently the predominant clinical abnormality, with hepatosplenomegaly and bleeding esophageal or gastric varices, as well as hypersplenism with consequent thrombocytopenia, anemia, and leukopenia. Hepatocellular function is usually preserved. Ascending suppurative cholangitis is a serious complication and can cause fulminant hepatic failure.[7,8]

Other associated features include growth retardation, although the mechanism is not yet defined and very rarely, intracranial aneurysms.

Pathology

Kidney

The renal involvement is invariably bilateral and largely symmetric. The histopathology varies depending on the age of presentation and extent of cystic involvement (Fig. 45.2A and B).

In the affected neonate, the kidneys can be 10 times normal size, but retain the typical kidney contour. Dilated, fusiform collecting ducts extend radially through the cortex. On histopathologic sections, the dilated medullary collecting ducts are often cut tangentially or transversely, resulting in a more spheroid appearance. Up to 90% of the collecting ducts are involved. Associated interstitial fibrosis is minimal in neonates and infants but increases with progressive disease.

In patients diagnosed later in childhood, the kidney size and extent of cystic involvement tend to be more limited. Cysts can expand up to 2 cm in diameter and become more spherical. Progressive interstitial fibrosis is probably responsible for secondary tubular obstruction. In older children, medullary ductal ectasia is the predominant finding.

Cysts are lined with a single layer of nondescript cuboidal epithelium. The glomeruli and nephron segments proximal to the collecting ducts are initially structurally normal, but are often crowded between ectatic collecting ducts or displaced into subcapsular wedges. The presence of cartilage or other dysplastic elements indicates a diagnosis other than ARPKD, such as cystic dysplasia.

Liver

The liver lesion in ARPKD is characterized by ductal plate malformation. The liver can be either normal in size or somewhat enlarged. Bile ducts are dilated (biliary ectasia), and marked cystic dilatation of the entire intrahepatic biliary system (Caroli syndrome) is well described.[7] In neonatal ARPKD, the bile ducts are increased in number, tortuous in configuration, and often located around the periphery of the portal tract. In older children, the biliary ectasia is accompanied by increasing portal tract fibrosis and hypoplasia of the small portal vein branches (see Fig. 45.2C). The hepatic parenchyma may be intersected by delicate fibrous septa that link the portal tracts, but the hepatocytes themselves are seldom affected.

Diagnosis

Imaging

A number of other hepatorenal fibrocystic diseases can resemble, or "phenocopy," ARPKD (Table 45.1). Although most of these disorders are characterized by large, echogenic kidneys in the fetus and neonate, these usually can be distinguished by ultrasound. ARPKD kidneys *in utero* are hyperechogenic and display *decreased* corticomedullary differentiation due to the hyperechogenic medulla (Fig. 45.3A). With high-resolution ultrasound, the radial array of dilated collecting ducts may be imaged. In comparison, ADPKD kidneys *in utero* tend to be moderately enlarged with a hyperechogenic cortex and relatively hypoechogenic medulla causing *increased* corticomedullary differentiation.

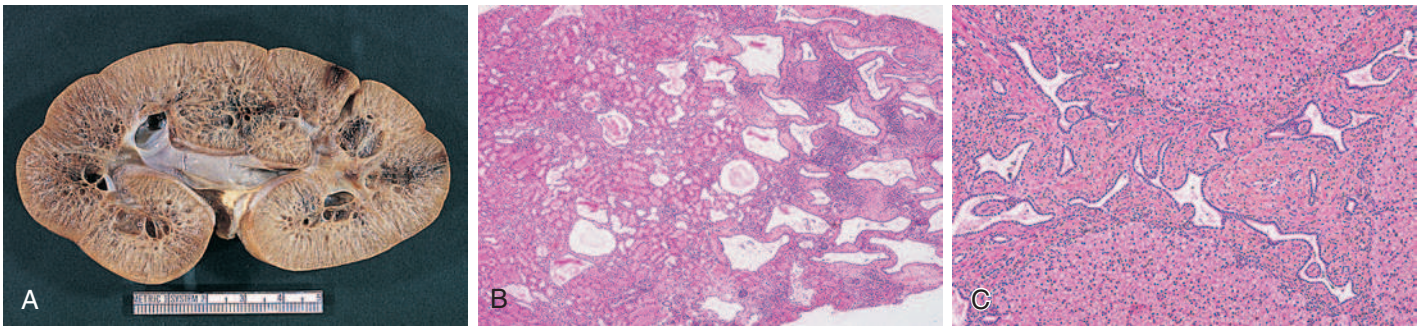

Fig. 45.2 Pathologic features of autosomal recessive polycystic kidney disease. (A) Cut section of autosomal recessive polycystic kidney disease (ARPKD) kidney from 1-year-old child shows discrete medullary cysts and dilated collecting ducts. (B) Light microscopy shows later onset ARPKD kidney with prominent medullary ductal ectasia (hematoxylin-eosin [HE] stain; magnification, ×10). (C) Light microscopy of congenital hepatic fibrosis shows extensive fibrosis of the portal area with ectatic, tortuous bile ducts and hypoplasia of the portal vein (HE stain, ×40).

Kidney size typically peaks at 1 to 2 years of age, then gradually declines relative to the child's body size, and stabilizes by 4 to 5 years. With age, there is increased medullary echogenicity with scattered small cysts, measuring less than 2 cm in diameter. These cysts and progressive fibrosis can alter the usual kidney contour, causing ARPKD in some older children to be mistaken for ADPKD. Contrast-enhanced computed tomography (CT) can be useful in delineating the renal architecture (Fig. 45.3B). Bilateral pelvicaliectasis and renal calcifications have been reported in 25% and 50% of patients with ARPKD, respectively. In adults with medullary ectasia alone, the cystic lesion may be confused with MSK.

The liver may be either normal in size or enlarged. It is usually less echogenic than the kidneys. Prominent intrahepatic bile duct dilatation suggests associated Caroli syndrome. With age, the portal fibrosis tends to progress and, in older children, ultrasound typically shows hepatosplenomegaly and a patchy increase in hepatic echogenicity.[7,8]

Genetic Testing

With the identification of *PKHD1* as the principal disease gene, genetic testing is available as a clinical diagnostic tool. The mutation detection rate is 80% to 87%. Current diagnostic approaches include gene-specific analysis and multigene testing panels using next-generation sequencing.[9] Genetic testing is primarily applied in the context of prenatal testing and preimplantation genetic diagnosis. Although patients with two truncating mutations are said to have a higher risk for perinatal death, the demonstration of a large homozygous deletion in an 8-year-old boy confounds this proposed association.[4] Patients with ARPKD have a high frequency of unique, missense changes in *PKHD1,* which can complicate the unequivocal interpretation of gene-based testing. Moreover, about 20% of ARPKD siblings have discordant clinical phenotypes. Taken together, these data complicate genetic counseling, and caution must be exercised in predicting the clinical outcome of future affected children.[9]

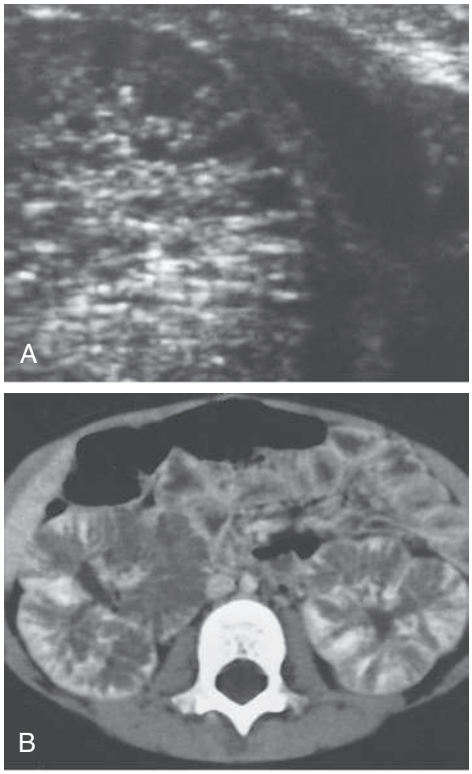

Fig. 45.3 Radiologic findings associated with autosomal recessive polycystic kidney disease. (A) Autosomal recessive polycystic kidney disease (ARPKD) in a neonate. High-resolution ultrasound reveals radially arrayed dilated collecting ducts. (B) ARPKD in symptomatic 4-year-old girl. Contrast-enhanced CT shows striated nephrogram and prolonged corticomedullary differentiation.

Treatment

The survival of neonates with ARPKD has improved significantly in the last two decades because of advances in mechanical ventilation for neonates and other supportive measures. Aggressive interventions such as unilateral or bilateral nephrectomies and continuous hemofiltration have been advocated in neonatal management, but prospective, controlled studies have yet to be performed.[4]

For those children who survive the perinatal period, blood pressure (BP) control is a major clinical issue. Angiotensin-converting enzyme inhibitors, angiotensin receptor blockers (ARBs), adrenergic antagonists, and loop diuretics are effective antihypertensive agents. The management of children with ARPKD and declining GFR should follow the standard guidelines established for chronic kidney disease in children.

Given the relative urinary concentrating defect, children with ARPKD should be monitored for dehydration during intercurrent illnesses associated with fever, tachypnea, nausea, vomiting, or diarrhea. In those infants with severe polyuria, thiazide diuretics may be used to decrease

Genetic testing	Yes	Most	Most	Yes	Yes	Yes

*Meckel-Gruber syndrome (MKS) is a severe, often lethal, autosomal recessive disorder characterized by bilateral renal cystic dysplasia, biliary ductal dysgenesis, bilateral postaxial polydactyly, and variable CNS malformations. The triad of renal cystic disease, occipital encephalocele, and polydactyly is most common. Genes disrupted in MKS have also been identified in patients with NPHP and Joubert syndrome, suggesting a phenotypic spectrum.

†GCKD: Glomerulocystic kidney disease can occur as the infantile manifestation of autosomal dominant polycystic kidney disease (ADPKD). Familial hypoplastic GCKD, resulting from mutations in *HNF1B*, the gene encoding hepatocyte nuclear factor (HNF-1β), can be associated with maturity-onset diabetes of the young, type 5 (MODY5).

‡A contiguous germ-line deletion of both the *PKD1* and *TSC2* genes (the PKDTS contiguous gene syndrome) occurs in a small group of patients with features of tuberous sclerosis complex (TSC), as well as massive renal cystic disease reminiscent of ADPKD, severe hypertension, and a progressive decline in renal function with the onset of end-stage renal disease in the second or third decade of life.

§Joubert syndrome is a genetically heterogeneous, autosomal recessive disorder characterized by developmental defects in the cerebellum (cerebellar vermis aplasia) and the eye (coloboma), as well as retinitis pigmentosa, congenital hypotonia, and either ocular motor apraxia or irregularities in breathing patterns during the neonatal period. The disease can be associated with NPHP, and mutations in several *NPHP* genes have been described in patients with Joubert syndrome.

Testing is available for most *NPHP* and *MKS* genes.

C-M, corticomedullary junction; *CNS,* central nervous system, *NPHP,* nephronophthisis; *PKDTS,* infantile severe polycystic kidney disease with tuberous sclerosis.

distal nephron solute and water delivery. Acid-base balance should be closely monitored, and supplemental bicarbonate therapy initiated as needed.

Close monitoring for portal hypertension is warranted in all patients with ARPKD. There is no correlation between the severity of the kidney and liver disease.[8] Recent studies suggest that the platelet count combined with serial abdominal ultrasound (assessing liver and splenic size) and Doppler flow studies provide good surrogate markers for the portal hypertension severity.[8] Medical management may include sclerotherapy or variceal banding.[7] Surgical approaches such as portocaval or splenorenal shunting may be indicated in some patients. Although hypersplenism is fairly common, splenectomy is seldom warranted. Unexplained fever with or without elevated transaminase levels suggests bacterial cholangitis and requires meticulous evaluation to make the diagnosis and guide aggressive antibiotic therapy.

Effective management of systemic and portal hypertension, coupled with successful renal replacement therapy, has allowed long-term patient survival. Therefore the prognosis in ARPKD, particularly for children who survive the first month of life, is far less bleak than popularly thought and aggressive medical therapy is warranted.

Although current treatment of ARPKD is entirely supportive, preclinical studies suggest future benefit from new, targeted therapies.[10]

Transplantation

A prolonged period of dialysis in childhood has been associated with both cognitive and educational impairment.[11] Therefore renal

transplantation is the treatment of choice for ESRD in patients with ARPKD. ARPKD is a recessive disorder, and therefore either parent may be a suitable kidney donor. However, the identification of subtle renal and liver abnormalities on ultrasound in ARPKD *parents*[12] mandates more extensive post-transplant follow-up. Native nephrectomies may be warranted in patients with massively enlarged kidneys to allow allograft placement.

In some patients, combined kidney-liver transplantation may be appropriate.[4] Indications include the combination of renal failure and either recurrent cholangitis or significant complications of portal hypertension, such as recurrent variceal bleeding, refractory ascites, and the hepatopulmonary syndrome. In addition, liver transplantation may be a consideration for patients with a single episode of cholangitis in the context of Caroli syndrome.[7]

NEPHRONOPHTHISIS: AUTOSOMAL DOMINANT TUBULOINTERSTITIAL KIDNEY DISEASE

Definitions

Nephronophthisis (NPHP) and autosomal dominant tubulointerstitial kidney disease (ADTKD) (formerly known as *medullary cystic kidney disease*) share a triad of histopathologic features: tubular basement membrane irregularities, tubular atrophy with cyst formation, and interstitial cell infiltration with fibrosis. These histopathologically similar disorders differ in their mode of transmission, age of onset, and genetic defects. NPHP is an autosomal recessive disorder that manifests in childhood, whereas ADTKD occurs in adults. NPHP is more common than ADTKD and has been reported both as an isolated renal disease and in association with a wide range of systemic manifestations, including retinitis pigmentosa, congenital hepatic fibrosis, oculomotor apraxia, and skeletal anomalies.

Nephronophthisis

NPHP is an autosomal recessive tubulointerstitial nephropathy and one of the most frequently inherited causes of ESRD in children and adolescents.[13] The term *nephronophthisis* derives from Greek, meaning "progressive loss of nephrons."

Genetic Basis

Multiple disease-causing genes have been identified. Defects in *NPHP1* account for 21% of NPHP with large, homozygous deletions detected in 80% of affected family members and in 65% of sporadic cases. Mutations in each of the remaining NPHP genes cause no more than 4% of NPHP-related disease.[14] Clinical disease expression seems to be exacerbated by oligogenic inheritance, that is, patients carrying two mutations in a single *NPHP* gene, as well as a single-copy mutation in an additional *NPHP* gene. In addition, multiple allelism, or distinct mutations in a single gene, appears to explain the continuum of multiorgan phenotypic abnormalities observed in NPHP-related disorders, which include Meckel syndrome, Joubert syndrome, and Bardet-Biedl syndrome.[15]

Most of the protein products of the NPHP-associated genes are expressed in the cilia- centrosome complex,[2] and NPHP is considered a ciliopathy.

Clinical Manifestations

Renal Disease. Three distinct forms of NPHP (infantile, juvenile, and adolescent) were initially described, based on the age of onset of ESRD. In the infantile form, ESRD occurs before 5 years of age, whereas in juvenile NPHP (the most common form), ESRD occurs at a mean age of 13 years. However, recent studies have demonstrated that there is no clear genotype-phenotype correlation for this spectrum of presentations, and these disorders should be referred to with the single designation NPHP.

Decreased urinary concentrating capacity is invariable in NPHP and usually precedes the decline in renal function, with typical onset between 4 and 6 years of age. Polyuria and polydipsia are common. Salt wasting develops in most patients with renal impairment, and sodium supplementation is often required until the onset of ESRD. One third of patients become anemic before the onset of renal impairment, and this has been attributed to impaired regulation of erythropoietin production by peritubular fibroblasts. Growth retardation (out of proportion to the degree of renal impairment) is common.

Slowly progressive decline in renal function is typical of NPHP. Although symptoms can begin after the age of 2 years, they may progress insidiously, so that 15% of affected patients present with ESRD. There is no specific treatment. The disease is not known to recur in renal allografts.

Children with the infantile variant develop symptoms in the first few months of life and rapidly progress to ESRD, usually before the age of 2 years, but invariably by 5 years of age. Severe hypertension is common in this disorder.[16]

Unlike patients with polycystic kidney disease (PKD) or MSK, those with NPHP rarely develop flank pain, hematuria, hypertension, UTI, or renal calculi.

Associated Extrarenal Abnormalities. Extrarenal abnormalities have been described in approximately 15% of patients with NPHP,[13] the most frequent of which is retinal dystrophy due to tapetoretinal degeneration (Senior-Loken syndrome). Severely affected patients present with coarse nystagmus, early blindness, and a flat electroretinogram (Leber amaurosis); those with moderate retinal dystrophy typically have mild visual impairment and retinitis pigmentosa. Other extrarenal anomalies include oculomotor apraxia (Cogan syndrome), cerebellar vermis aplasia (Joubert syndrome), and cone-shaped epiphyses of the bones. Congenital hepatic fibrosis occurs on occasion in patients with NPHP, but the associated bile duct proliferation is mild and qualitatively different from that found in ARPKD.

Pathology

In classic NPHP, the kidneys are moderately contracted, with parenchymal atrophy causing a loss of corticomedullary demarcation. Histopathologic findings include tubular atrophy with thickened tubular basement membrane, diffuse and severe interstitial fibrosis, and cysts of variable size distributed in an irregular pattern at the corticomedullary junction and in the outer medulla. However, up to 25% of NPHP kidneys have no grossly visible cysts.

In the typical NPHP renal lesion, clusters of atrophic tubules alternate either with groups of viable tubules showing dilation or with marked compensatory hypertrophy. Multilayered thickening of tubular basement membranes is a prominent histopathologic feature (Fig. 45.4). This pattern is not unique, but the abrupt transition from one type of tubular profile to another suggests NPHP. Moderate interstitial fibrosis, usually without a significant inflammatory cell infiltrate, is interspersed among the atrophic tubules. Spherical, thin-walled cysts lined with a simple cuboidal epithelium may be evident at the corticomedullary junction, in the medulla, and even in the papillae. Microdissection studies indicate that these cysts arise from the loop of Henle, distal convoluted tubules, and collecting ducts. Glomeruli may be normal, although some may be completely sclerosed, others show periglomerular fibrosis, and still others have dilatation of Bowman space suggestive of glomerulocystic kidney disease.[17]

In comparison, the infantile form has features of both classic NPHP (such as tubular cell atrophy, interstitial fibrosis, and tubular cysts) and PKD, including enlarged kidneys and widespread cystic involvement.

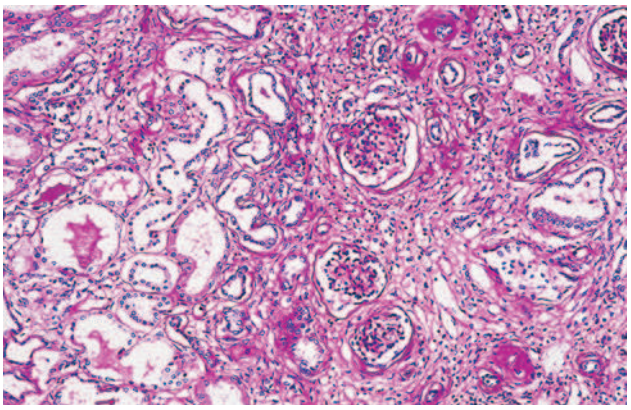

Fig. 45.4 Renal pathology in nephronophthisis. Light microscopy shows tubulointerstitial nephropathy. Atrophic tubules with irregularly thickened basement membranes are surrounded by interstitial fibrosis. Dilated tubules are evident at the corticomedullary junction. (HE stain, ×40.)

Diagnosis

In a child with NPHP and renal impairment, ultrasound typically reveals normal-sized or small kidneys with increased echogenicity and loss of corticomedullary differentiation. On occasion, cysts can be detected at the corticomedullary junction or in the medulla. Thin-section CT scanning may be more sensitive than ultrasound in detecting these cysts.

The pathologic findings in NPHP are not unique; hence in the early stages of the disease, neither renal imaging nor histopathology can confirm the clinical diagnosis. Molecular testing can be useful; newer strategies using multigene panels and next-generation sequencing technologies allow high-throughput mutation detection for known *NPHP* genes, but to date defects in these genes explain disease in only up to 40% of patients with NPHP-related disorders.[14,15]

Treatment

Current treatment of NPHP is entirely supportive. However, preclinical studies suggest that targeted therapies may have benefit for these patients. For example, treatment with a vasopressin receptor 2 antagonist remarkably attenuated renal cystic disease progression in a mouse model of *NPHP*-related disease.[10] Other investigators have proposed that therapeutic strategies should target the renal fibrosis rather than cystic disease in NPHP and note that low-dose paclitaxel has shown promising results in rodent models of renal fibrosis.[18]

Autosomal Dominant Tubulointerstitial Kidney Disease

The term *autosomal dominant tubulointerstitial kidney diseases* (ADTKD) has been proposed for the set of disorders previously described as medullary cystic kidney disease, *UMOD*-related kidney disease, familial juvenile hyperuricemic nephropathy (HNFJ1; MIM 162000), and familial glomerulocystic disease with hyperuricemia (MIM 609886).[19] ADTKD is less common than NPHP, and the renal pathologic findings are indistinguishable, although the progressive tubulointerstitial fibrosis resulting in ESRD is slower in ADTKD. Some patients have phenotypically unaffected parents, but an affected second- or third-degree relative, suggesting disease is poorly recognized in affected family members and/or there is variable penetrance.

ADTKD manifests in adults with familial renal disease characterized by bland urinalysis (i.e., little or no proteinuria or hematuria) and slowly progressive renal failure. There may be hyperuricemia or gout. Ultrasound shows normal or small kidneys, sometimes with medullary cysts.

Disease-causing mutations in four genes: *MUC1*, *UMOD*, *REN,* and *HNF1B,* are responsible for most cases.[19] Hyperuricemia is a key feature of *UMOD*-related disease.

Uremia typically occurs after 60 years of age in ADTKD-*MUC1* (MCKD1, MIM 174000), but disease progression is highly variable. In ADTKD-*UMOD* (MCKD2, MIM 603860), progression to ESRD occurs between the fourth and seventh decades of life.

MEDULLARY SPONGE KIDNEY

Definition

MSK is characterized by dilated medullary and papillary collecting ducts that give the renal medulla a spongy appearance. It is associated with nephrocalcinosis, recurrent calcium nephrolithiasis, abnormalities in renal tubular acidification and urinary concentration, bone mineralization defects, and an increased risk for UTI.[20]

Etiology and Pathogenesis

Histopathologic observations of embryonal tissue in the affected papillae, coexistence of renal tubular defects, and evidence of defects in the genes encoding the *RET* proto-oncogene and the glial cell line–derived neurotrophic factor (GDNF)[21] suggest that MSK results from a developmental defect in the ureteral bud–metanephric mesenchyme interaction. In addition, MSK occurs more frequently in individuals with other developmental anomalies and/or tumors, such as congenital hemihypertrophy, Beckwith-Wiedemann syndrome, congenital anomalies of the kidney and urinary tract syndrome, and Wilms tumor.[22]

MSK is usually a sporadic disorder, but familial clustering with autosomal dominant inheritance[23] and evidence for genetic alteration in the RET-GDNF axis suggest a genetic basis for MSK in at least a subset of patients.

Epidemiology

In the general population, the frequency of MSK may be underestimated because some affected individuals remain entirely asymptomatic. Up to 20% of patients with nephrolithiasis have at least a mild degree of MSK, but excretory urography in unselected patients indicates a disease frequency of approximately 1 in 5000 individuals.

Clinical Manifestations

MSK is asymptomatic unless complicated by nephrolithiasis, hematuria, or infection. Symptoms typically begin between the fourth and fifth decade of life, but adolescent presentations have been reported. Stones or granular debris in patients with MSK are composed of either pure apatite (calcium phosphate) or a mixture of apatite and calcium oxalate. Several factors appear to contribute to stone formation, including urinary stasis within the ectatic ducts, hypercalciuria, and hypocitraturia. Hyperparathyroidism also has been reported.

Hematuria, unrelated to either coexisting stones or infection, may be recurrent. The bleeding is usually asymptomatic, unless gross hematuria cause clot-related colic. UTI may occur in association with nephrolithiasis or as an independent event. In patients with stones, infections are more likely to occur in females than in males.

Decreased renal concentrating ability and impaired urinary acidification are common clinical features. In most patients, the acidification defect is not associated with overt systemic acidosis but bone mineralization defects are well described.[22]

Pathology

The pathologic changes are confined to the renal medullary and intrapapillary collecting ducts. Multiple spherical or oval cysts measuring 1 to 8 mm may be detected in one or more papillae. These cysts may be

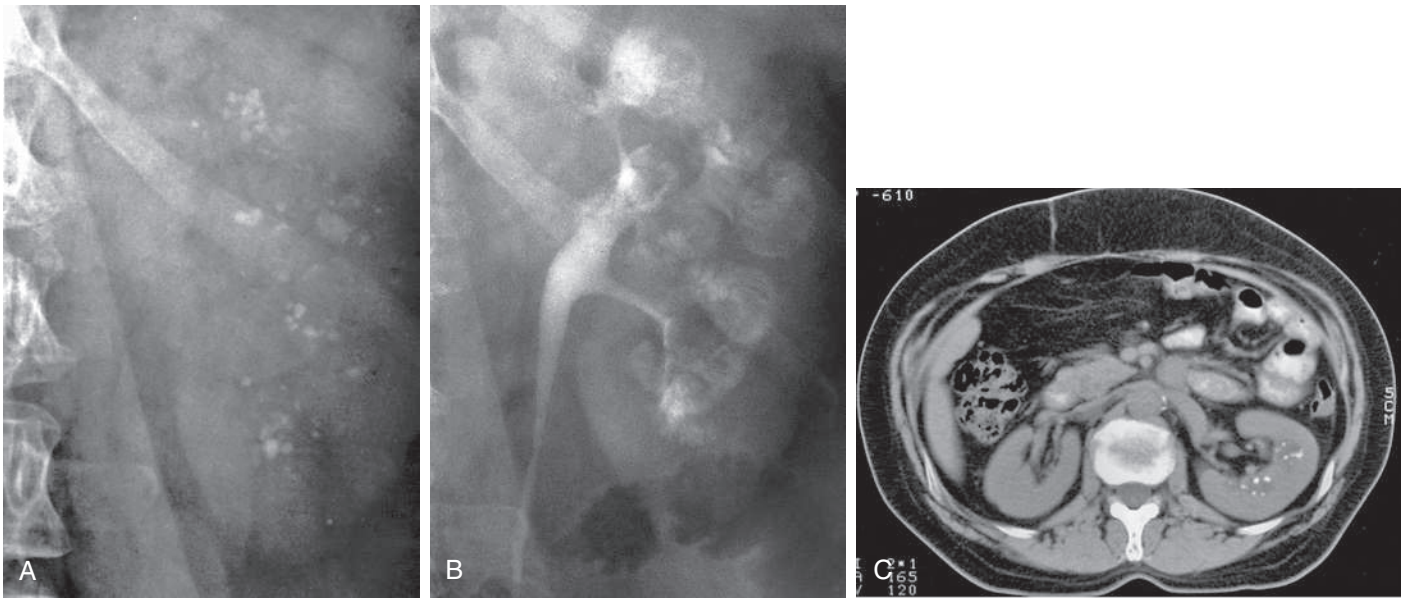

Fig. 45.5 Radiologic findings associated with medullary sponge kidney. (A) Initial film shows medullary nephrolithiases. (B) Ten-minute film from excretory urography shows clusters of rounded densities in the papillae among discrete linear opacities (paintbrush appearance). (C) Nonenhanced CT reveals densely echogenic foci in the medulla.

isolated or may communicate with the collecting system. The cysts are frequently bilateral and often contain spherical concretions composed of apatite. The affected pyramids and associated calyces are usually enlarged, and nephromegaly can result when many pyramids are involved. The renal cortex, medullary rays, calyces, and pelvis appear normal, unless complications (e.g., pyelonephritis or urinary tract obstruction) are superimposed.

Diagnosis

Abdominal plain radiographs often reveal radio-opaque concretions in the medulla (Fig. 45.5A). Historically, the diagnosis was established by excretory urography (see Fig. 45.5B). Retention of contrast media by the ectatic collecting ducts appears either as spherical cysts or more commonly as diffuse linear striations. The latter imparts a characteristic blush-like pattern to the papillae, the so-called bouquet of flowers or paintbrush appearance. Medullary nephrocalcinosis is a common but not invariant finding. Urography has been almost completely replaced by nonenhanced CT, which may help distinguish MSK from papillary necrosis or even ADPKD (see Fig. 45.5C).

Treatment

Asymptomatic patients with MSK require no therapy. Hematuria in the absence of stones or infection requires no intervention. If the tubular ectasia is unilateral and segmental, partial nephrectomy may alleviate recurrent nephrolithiasis and UTI. However, for the majority of patients who have bilateral disease, medical management is sufficient.

Hypercalcuria and hypocitrituria are the predominant factors contributing to MSK-related nephrolithiasis. The mainstays of treatment are potassium citrate and high fluid intake. Patients with persistent hypercalcuria and/or recurrent stone formers may benefit from thiazide diuretics. If thiazides are poorly tolerated or contraindicated, inorganic phosphate therapy may be useful. To avoid struvite stone formation, oral phosphates should *not* be used in patients with previous UTIs caused by urease-producing organisms. Patients who recurrently form and pass stones may require lithotripsy or surgical intervention (see Chapter 59).

UTIs should be treated with standard antibiotic regimens, and, for some patients, prolonged therapy may be warranted. Urease-producing organisms, such as coagulase-negative *Staphylococcus,* are particularly problematic as urinary pathogens in MSK. Positive urine cultures, even with relatively insignificant colony counts, must be vigorously pursued.

With proper management of the clinical complications, the long-term prognosis is excellent. Progression to renal impairment is unusual.

TUBEROUS SCLEROSIS COMPLEX

Definition

TSC is an autosomal dominant, tumor-suppressor gene syndrome in which benign focal malformations, called *hamartomas*, develop in multiple organ systems, including the kidneys, brain, heart, lungs, and skin.

Etiology and Pathogenesis

TSC results from inactivating mutations in one of two genes, *TSC1* on chromosome 9q32-q34 and *TSC2* on chromosome 16p13, adjacent to the *PKD1* gene. Large deletions involving both *PKD1* and *TSC2* results in the PKD1/TSC2 (infantile severe polycystic kidney disease with tuberous sclerosis [PKDTS]) contiguous gene deletion syndrome.

The focal development of hamartomas and the variability of disease expression even within families suggest that *TSC1* and *TSC2* function as tumor suppressor genes. The tumor suppressor gene paradigm proposes that two successive mutations are necessary to inactivate a target gene and cause tumor formation. The first mutation, inherited and therefore present in all cells, is necessary but not sufficient to produce tumors. A second mutation occurs after fertilization and is required to induce tumor transformation. The inactivating germ-line mutations identified in *TSC1* and *TSC2,* as well as the loss of heterozygosity detected in *TSC2*-associated and *TSC1*-associated hamartomas support the hypothesis that both *TSC1* and *TSC2* function as tumor suppressor genes.

The *TSC2* gene product tuberin interacts with hamartin, the product of the *TSC1* gene. The hamartin/tuberin (TSC1/TSC2) complex

BOX 45.1 Clinical Diagnostic Criteria for Tuberous Sclerosis Complex*

Major

- Facial angiofibromas or forehead plaque
- Nontraumatic ungual or periungual fibroma
- Hypomelanotic macules (>3)
- Shagreen patch (connective tissue nevus)
- Multiple retinal nodular hamartomas
- Cortical tuber(s)
- Subependymal nodule
- Subependymal giant cell astrocytoma
- Cardiac rhabdomyoma(s) (≥1)
- Lymphangioleiomyomatosis
- Renal angiomyolipoma

Minor

- Multiple, random dental pits
- Hamartomatous gastrointestinal or rectal polyps
- Bone cysts
- White matter radial migration lines
- Gingival fibromas
- Nonrenal hamartoma
- Retinal achromic patch
- "Confetti" skin lesions
- Multiple renal cysts

From reference 31.
*Two major features or one major feature with two minor features indicate definite TSC, one major feature and one minor feature indicate probable TSC, and one major feature or two minor features indicates possible TSC.

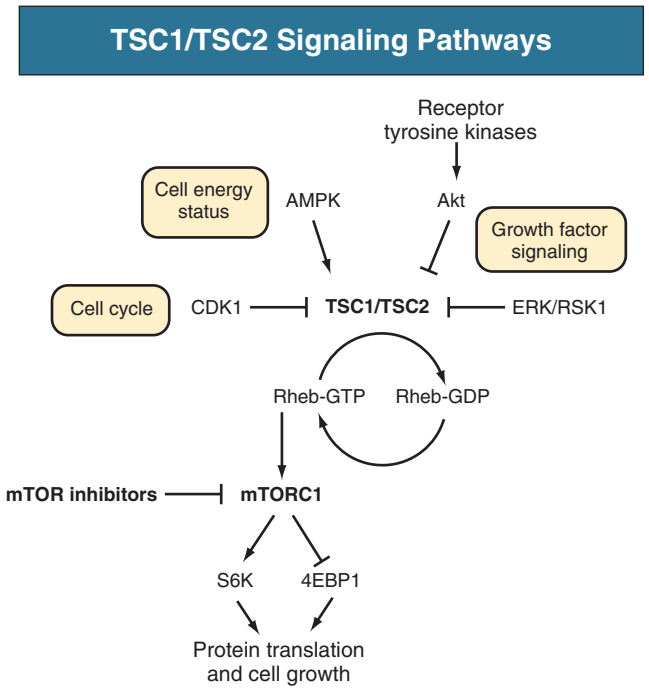

Fig. 45.6 The TSC1/TSC2 signaling pathways. Hamartin *(TSC1)* and tuberin *(TSC2)* integrate signals from extracellular growth factor binding (via *Akt* and *ERK/RSK1*), the intracellular energy status (via *AMPK*) and the cell cycle (via *CDK1*) to direct signaling pathways that regulate cellular proliferation, differentiation, and migration. Tuberin contains a guanosine triphosphatase (GTPase)-activating protein (GAP) domain in its carboxy terminus, and when it forms a complex with hamartin (TSC1/TSC2 complex) the small GTPase *Rheb* is converted from its active *GTP*-bound state to an inactive GDP-bound state. Rheb is an activator of the *mTORC1* kinase, which regulates a number of processes linked to protein synthesis and cell growth (via the ribosomal S6 kinases and the eukaryotic initiation factor 4E–binding protein (4E-BP1). mTORC1 is activated physiologically in response to growth factor signaling, which causes phosphorylation of tuberin, dissociation of the TSC1/TSC2 complex, and increased levels of Rheb-GTP. Inactivation of the TSC1/TSC2 complex through mutations in *TSC1* or *TSC2* leads to inappropriate activation of mTORC1. (From reference 24.)

functions in multiple cellular pathways, primarily by inhibiting the kinase activity of the mammalian target of rapamycin (mTOR), which functions in a protein complex (mTORC1) to regulate nutrient uptake, cell-cycle progression, cell growth, and protein translation[24] (Fig. 45.6). The *PKD1* gene product, polycystin1, plays a key role in regulating mTORC1 activity by complexing with tuberin and mTOR, thereby inhibiting the mTOR pathway.[25] In normal adult kidney, mTOR is inactive. With loss of function of either polycystin-1 or tuberin, mTOR activity is upregulated, contributing to dysregulated cell growth and cystogenesis. In addition, hamartin appears to function via TORC1-independent pathways to regulate the structural integrity of the primary cilium, suggesting that ciliary dysfunction is an additional mechanism in TSC pathogenesis.[26]

Epidemiology

TSC affects 1 in 6800 to 15,000 individuals.[27] The disease penetrance is quite variable. About 70% of patients with TSC are sporadic cases with no family history, and the disease apparently results from new mutational events. In sporadic cases, mutations in *TSC2* are approximately five times more common than mutations in *TSC1,* whereas the ratio is 1 : 1 in familial cases. *TSC1*-related disease is milder, apparently because of a reduced rate of "second hits."

Clinicopathologic Manifestations

The clinical features of *TSC1*- and *TSC2*-linked disease are similar, although *TSC2*-linked disease tends to be more severe. The most common clinical manifestations include seizures, intellectual disability and/or autism, skin lesions, interstitial lung disease, and tumors in the brain, retina, kidney, and heart. In affected individuals over 5 years of age, the most common skin lesions are facial angiofibromas (Fig. 45.7), hypomelanotic macules, and ungual fibromas.

Kidney involvement occurs frequently in TSC, with renal lesions that include angiomyolipomas (AMLs; 85%), cysts (30% to 47%), and renal cell carcinoma (RCC) (2% to 3%).[24,28] Other renal neoplasms, interstitial fibrosis with focal segmental glomerulosclerosis (FSGS), glomerular microhamartomas, and peripelvic and perirenal lymphangiomatous cysts also have been reported. Renal involvement in TSC often progresses insidiously, but can result in considerable morbidity, including retroperitoneal hemorrhage, renal impairment (~1%), and death. Renal complications are the most frequent cause of death in TSC.[24]

Renal Angiomyolipomas

AMLs are benign renal hamartomas composed of abnormal, thick-walled vessels and varying amounts of smooth muscle–like cells and adipose tissue (Fig. 45.8A and B). These are the most common renal lesions in patients with TSC, evident in approximately 80% of TSC patients by age 10 years.[24] Whereas solitary AMLs are found in the general population, particularly among older women, TSC-associated AMLs are multiple and bilateral, rarely occurring before 5 years of age,

but increasing in frequency and size with age.[24] They can become locally invasive, extending into the perirenal fat or more rarely, the collecting system, renal vein, and even the inferior vena cava and right atrium.

Clinical manifestations occur secondary to hemorrhage (intratumoral or retroperitoneal) or mass effects (abdominal or flank masses and tenderness, hypertension, renal impairment). Women tend to have more numerous and larger AML than men. Pregnancy appears to increase the risk for rupture and hemorrhage.

Renal Cystic Disease

Renal cysts occur less frequently than AML in patients with TSC. However, like AML, renal cysts tend to increase in size and number over time. The concurrence of cysts and AMLs, easily detected by CT, is strongly suggestive of TSC.

The cysts in TSC can develop in any nephron segment. When limited in number and size, TSC-related cysts are predominantly cortical. In some cases, glomerular cysts predominate.[17] The cystic lining epithelia appear to be unique to TSC, with large and acidophilic epithelia containing large hyperchromatic nuclei with occasional mitotic figures (see Fig. 45.8C). Associated papillary hyperplasia and adenomas are common.

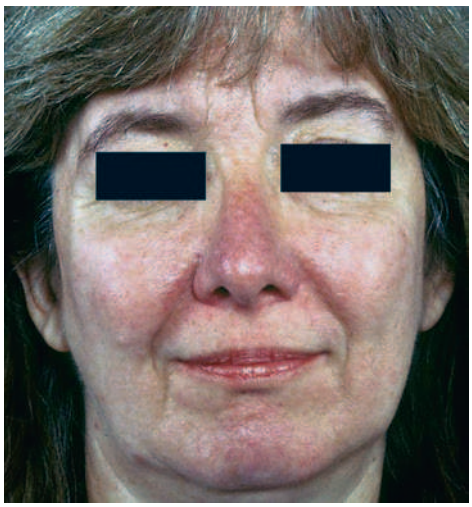

Fig. 45.7 Facial angiofibromas in tuberous sclerosis complex. The angiofibromas are small red bumps giving a facial rash in a butterfly distribution and on the chin.

A small subset of affected infants can present with massive renal cystic disease, severe hypertension, and a progressive decline in renal function with the onset of ESRD in the second or third decade of life. The majority of these patients have a contiguous germ-line deletion involving both the *TSC2* and *PKD1* genes, the PKDTS contiguous gene syndrome.[29] Early detection, strict BP control, and prompt therapy for the associated infantile spasms may favorably affect the overall prognosis.

Renal Neoplasms

Benign epithelial tumors, such as papillary adenomas and oncocytomas, are common in patients with TSC and can be multifocal. However, malignant transformation is rare, with a 2% to 3% lifetime risk for developing RCC. TSC-associated RCCs have a unique constellation of clinicopathologic features, including female predominance, younger age at diagnosis, association with AML, multiplicity, and slow progression.[30] Three distinct histopathologic patterns predominant, with papillary RCC being most common, followed by hybrid oncocytic/chromophobe tumor, and RCC with granular eosinophilic morphology. Although TSC-associated RCCs tend to have an indolent clinical course, the prognosis compared with sporadic RCC in the general population is unknown.

Diagnosis

TSC is a pleiotropic disease in which the size, number, and location of the lesions can be variable, even among affected individuals within the same family. Major and minor criteria have been developed to guide diagnosis (Box 45.2). Two major features or one major and two minor features are required to make the diagnosis of TSC. Imaging is the mainstay for diagnosis of TSC-associated renal lesions.[31] The presence of small cysts and fat-containing AMLs is strongly suggestive of TSC. Although the median age at presentation for both renal cysts and AML is 10 years, these lesions have been detected in infancy.[32]

Renal imaging is advised for monitoring disease progression in patients with TSC.[28] Ultrasound has historically been the preferred modality; it has high sensitivity in detecting the fat-rich AMLs and renal cysts, but is relatively insensitive for detecting fat-poor lesions. Current recommendations are to perform abdominal CT (Fig. 45.9) or magnetic resonance imaging (MRI) every 1 to 3 years for life to assess AML progression and renal cystic disease. On occasion, the distinction between an AML and RCC cannot be reliably established by imaging and biopsy is indicated.

TSC-associated renal cysts can radiologically mimic simple cysts and, when numerous, ADPKD. In the absence of AML, TSC-related renal

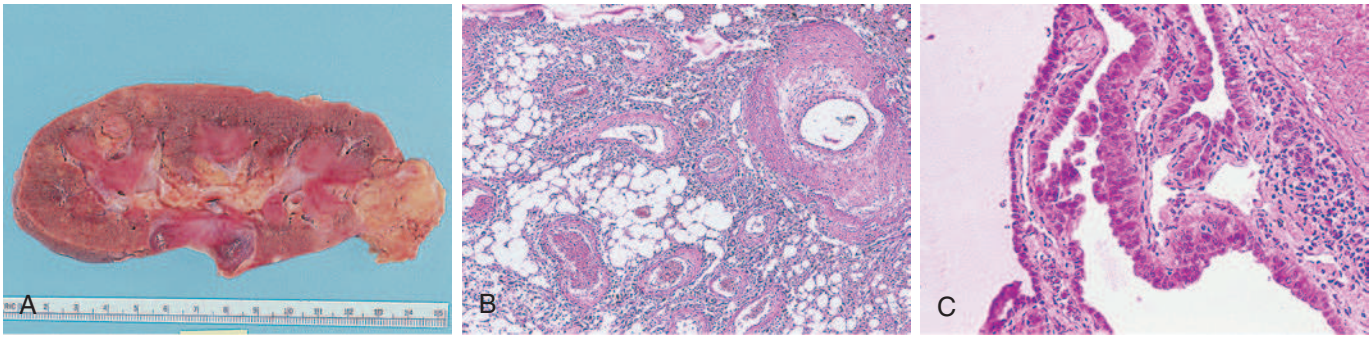

Fig. 45.8 Renal pathology in tuberous sclerosis complex (TSC). (A) Cut section shows multiple renal angiomyolipomas. (B) Light microscopy shows angiomyolipoma containing adipose tissue and spindle smooth muscle–like cells interspersed between abnormal vessels with thickened walls (HE stain, ×16). Fig. 45.9 Radiologic findings associated with tuberous sclerosis complex. Contrast-enhanced CT showing bilateral angiomyolipomas.

cystic disease is suggested by the limited number of cysts when compared with ADPKD and the absence of associated hepatic cysts. Although 10% of patients with TSC have hepatic AML, hepatic cysts are rare.

Gene-based diagnosis is currently available for *TSC1*- and *TSC2*-related disease, as well as to detect large-scale deletions associated with the PKDTS contiguous gene syndrome.

Treatment

Renal Angiomyolipomas

Renal AMLs are generally benign and require no treatment. Larger AMLs frequently develop micro- and macro-aneurysms, and the risk for serious hemorrhage correlates with aneurysms over 5-cm in diameter.[24] Therefore these large AMLs require preemptive treatment with either nephron-sparing surgery or embolization.[32] In addition to size and complications such as pain or hemorrhage, the inability to exclude an associated RCC should prompt intervention. When an associated malignancy cannot be excluded, nephron-sparing surgery, such as enucleation or partial nephrectomy is preferred.

The increased frequency and size of the AML in women and the reports of hemorrhagic complications during pregnancy suggest that female sex hormones may accelerate AML growth. Therefore it is prudent to caution women with multiple AMLs about the potential risks of pregnancy and estrogen administration.

Defective mTORC1 signaling is a central feature of TSC. Recent international TSC guidelines recommend mTOR inhibitors (rapalogs) as the first-line therapy for the treatment of asymptomatic, growing AMLs larger than 3 cm in diameter.[28] Sirolimus and everolimus are effective in reducing AML volume and/or postembolization response rates, with an acceptable safety profile, although they have a range of adverse events that must be borne in mind (see Chapter 101).[33]

Renal Cystic Disease

The mainstay of treatment of TSC-associated renal cystic disease is strict BP control. Surgical decompression of cystic kidneys has been suggested, but no significant beneficial effect has been established.

Renal Carcinoma

TSC-associated RCC should be suspected in enlarging, fat-poor lesions or when intratumoral calcifications are present and should be confirmed by biopsy. Because TSC-associated RCC are frequently bilateral, renal-sparing surgery should be performed whenever possible.

Renal Replacement Therapy

Chronic kidney disease, although rare in tuberous sclerosis, can occur by several different mechanisms, including AML-related parenchymal destruction, progressive renal cystic disease, interstitial fibrosis, and FSGS. A large French study reported TSC-associated ESRD to have an approximate prevalence of 0.7 cases per million. ESRD occurred in 1 per 100 patients with TSC and was more frequent in females (63%), with a mean age diagnosis of 29 years.[34] Both dialysis and renal transplantation are appropriate modes of renal replacement therapy. Given the risk for renal hemorrhage related to AML and malignant transformation, it may be advisable that patients with TSC and ESRD undergo bilateral nephrectomy before initiation of renal replacement therapy.

VON HIPPEL–LINDAU DISEASE

Definition

VHL disease is a dominantly transmitted, multisystem cancer predisposition syndrome associated with tumors of the eyes, cerebellum, spinal cord, adrenal glands, pancreas, and epididymis, as well as renal and pancreatic cysts.[35]

Etiology and Pathogenesis

VHL disease is a tumor suppressor disorder, with disease resulting from a germ-line mutation and a subsequent somatic mutation in the *VHL* gene. In approximately 80% of patients, VHL disease is familial, and disease in about 20% of cases results from de novo mutations. Moreover,

VHL mutations have been identified in both the germ-line of patients with VHL disease and in sporadic RCC, implying that *VHL* plays an important role in the pathogenesis of RCC.[36]

The VHL protein (pVHL) plays a critical role as a negative regulator of hypoxia-inducible factors.[37] In the normal physiologic state, pVHL functions in a multiprotein complex that directs a number of proteins, most notably the α subunits of the transcription factor, hypoxia-inducible factor (HIF-α), for destruction via the ubiquination pathway. In cells that lack pVHL, HIF-α subunits are stabilized and bind to HIF-β. The heterodimer then translocates to the nucleus, leading to overexpression of HIF-target genes, which encode proteins that regulate glucose uptake, metabolism, extracellular pH, erythropoiesis, angiogenesis (vascular endothelial growth factor [VEGF] and platelet-derived growth factor B [PDGFB]), and mitogenesis (transforming growth factor β [TGFβ]). This transcriptional dysregulation promotes the pathologic growth and survival of endothelial cells, pericytes, and stromal cells and ultimately their malignant transformation.[36,37]

Clinical Manifestations

VHL disease has an incidence of 1 in 36,000 live births and has been observed in all ethnic groups.[24,35] Biallelic *VHL* inactivation leads to increased risk for central nervous system (CNS) and retinal hemangioblastomas, RCC, pheochromocytomas, pancreatic islet cell tumors, endolymphatic sac tumors, and papillary cystadenomas of the broad ligament (females) and epididymis (males). In addition, cystic changes can occur in the kidney and pancreas.

VHL-associated disease appears to cluster in two complexes (Table 45.2). In the initial stratification, patients with VHL disease can be subclassified based on a low risk (type 1) or high risk (type 2) of developing pheochromocytoma. Type 1 disease is characterized by large deletions or truncations of the *VHL* gene, which cause complete inactivation of the gene and result in high levels of HIF activity. Type 2 disease primarily involves missense mutations and is associated with partial activity of pVHL. Type 2 can be further subdivided into three subtypes: type 2A, which has a low incidence of renal lesions; type 2B, which is associated with a high risk for RCC; and type 2C, which is associated only with pheochromocytoma and no other malignancies.[37]

RCCs are typically multiple and bilateral. Although RCC may manifest with hematuria or back pain, more often detection occurs as an incidental finding on unrelated imaging studies or during a screening protocol. The mean age of symptomatic presentation is 35 to 40 years, although patients have been diagnosed in adolescence. In VHL disease, men and women are equally affected with RCC, in contrast to the male predominance in sporadic RCC. VHL disease–associated RCC metastasizes to the lymph nodes, liver, lungs, and bones and accounts for about 50% of VHL disease–related deaths.

In VHL disease, renal cysts arise from tubular cells that have undergone somatic loss of the wild-type allele. Renal cysts occur in about 60% of patients and are commonly bilateral; deterioration of renal function as a result of cystic kidney disease has been reported but is unusual.

TABLE 45.2 Classification of von Hippel–Lindau Subtypes

Subtype	Tumor Manifestations
Type 1	Hemangioblastoma (CNS, retina), renal cell carcinoma, low risk for pheochromocytoma
Type 2A	Hemangioblastoma (CNS, retina), pheochromocytoma, low risk for renal cell carcinoma
Type 2B	Hemangioblastoma (CNS, retina), renal cell carcinoma, pheochromocytoma
Type 2C	Predominantly pheochromocytoma Very limited risk for hemangioblastoma and renal cell carcinoma

From reference 38.
CNS, Central nervous system.

Pathology

RCC is one of the most common tumors in VHL disease, with a lifetime risk of approximately 70% for patients with VHL disease.[35] VHL disease–associated RCCs are mostly of the clear cell type and usually bilateral and multifocal in distribution. Detailed microscopic examination of VHL disease–associated renal cystic lesions often reveals small foci of carcinoma. VHL disease–associated RCCs tend to have low-grade histology and a better 10-year survival rate than sporadic RCC. More advanced RCCs do metastasize, and metastatic disease is a major cause of death in patients with VHL disease.

Diagnosis

The minimum clinical criteria for the diagnosis of VHL disease in an at-risk individual include the presence of a single retinal or cerebellar hemangioblastoma, RCC, or pheochromocytoma.[35] Up to 50% of affected individuals with familial VHL disease may manifest only one feature of the syndrome. In presumed sporadic cases (20% of patients), the clinical diagnosis requires two tumors (such as two hemangioblastomas or a hemangioblastoma and a characteristic visceral tumor).

Molecular analysis of the *VHL* gene is indicated in patients with known or suspected VHL disease or in at-risk children from families with VHL, given that unsuspected, untreated tumors can cause significant morbidity.[36] Presymptomatic genotyping can be useful in determining the phenotypic classification of VHL disease and used to direct monitoring for a specific subset of tumors. In addition, genotyping can be useful in distinguishing whether a pheochromocytoma has occurred in the context of a VHL type 2 mutation, is found in multiple endocrine neoplasia (MEN) type 2, or is nonsyndromic.[38]

In patients with type 2 VHL disease, annual assessment of BP, measurement of urinary catecholamine metabolites, as well as abdominal ultrasound imaging should be initiated at the age of 2 years. Abdominal MRI and iodine-131 metaiodobenzyl-guanidine (MIBG) scans are indicated if abnormalities are detected. By the age of 16 years, all patients with VHL disease should have annual MRI scans of the abdomen. Ultrasound is a useful alternative imaging modality in pregnant women. Annual assessment should be lifelong. Early detection of renal disease and a multidisciplinary approach to follow-up can substantially improve survival.[35]

Differential Diagnosis

The differential diagnosis of VHL disease–associated renal lesions includes several conditions, most notably ADPKD and TSC (Table 45.3). As with VHL, ADPKD affects both sexes with a similar mean age at presentation. However in VHL disease, kidney involvement is characterized by a few bilateral cysts, RCC, normal kidney size, normal BP, and usually normal renal function. Renal cyst infection, a frequent finding in ADPKD, is uncommon in VHL disease, and RCC is an infrequent complication of ADPKD. Cysts in the liver are frequent in ADPKD and rare in VHL disease. Pancreatic cysts are rare in ADPKD, but can be numerous and scattered through the pancreas in VHL disease (Fig. 45.10A). The CNS in ADPKD is affected by arterial aneurysms, whereas hemangioblastomas are the predominant CNS manifestation in VHL disease (see Fig. 45.10B).

TSC should be considered in the differential diagnosis of multiple renal tumors. In both TSC and VHL disease, multiple renal cysts occur.

TABLE 45.3 Features of Renal Cystic Disease in Adults

Clinical Characteristics	Simple Cysts	ADPKD	MSK	VHL	TSC	Acquired Cystic Disease
Clinical onset (y)	>40	30-40	20-40	30-40	10-30	Chronic renal failure
Cysts	Single/multiple	Multiple	Multiple	Few, bilateral	Multiple	Multiple
Cyst infection	Uncommon	Common	Common	Uncommon	Uncommon	Uncommon
Tumors	No	Rare	No	RCC, often bilateral	Angiomyolipoma/RCC	Common
Blood pressure	Normal/ increased	Increased	Normal	Normal/increased	Normal/ increased	Normal/ increased
Renal function	Normal	Normal/ impaired	Normal	Normal	Normal/ impaired	Impaired/ESRD
Nephrolithiasis	No	Common	Common	No	No	No
Liver cysts	No	Common	No	Rare	No	No
Pancreas cysts	No	Few	No	Multiple	No	No
CNS involvement	No	Aneurysms	No	Hemangioblastomas	Seizures, intellectual disability	No
Skin lesions	No	No	No	No	See Fig. 45.9	No
Genetics						
Disease gene	No	*PKD1* *PKD2*	No	*VHL*	*TSC1* *TSC2*	No
Genetic testing*	No	Yes	No	Yes	Yes	No

*Genetic testing: Listed at the NIH Genetic Testing Registry (http://www.ncbi.nlm.nih.gov/gtr).
ADPKD, Autosomal dominant polycystic kidney disease; *CNS,* central nervous system; *ESRD,* end-stage renal disease; *MSK,* medullary sponge kidney; *RCC,* renal cell carcinoma; *TSC,* tuberous sclerosis complex; *VHL,* von Hippel–Lindau disease.

However, the TSC-associated renal tumor is usually an AML and extrarenal lesions readily distinguish VHL disease and TSC.

Treatment

Surgery continues to be the mainstay of treatment for RCC in patients with VHL disease. Optimal management requires surgical intervention before renal vein invasion and distant metastases occur because metastatic lesions respond poorly to chemotherapy and radiation. Nephron-sparing surgery is the procedure of choice when possible (see Chapter 59). Repeated surgical intervention may be required as tumors continue to develop. Laparoscopic surgery may have a role in the future management of these patients.

Bilateral nephrectomy and renal transplantation may be an acceptable alternative to repeated nephron-sparing surgery in patients with VHL disease–associated RCC. It remains to be determined whether post-transplant immunosuppression enhances the growth of the retinal and CNS hemangioblastomas and other lesions found in patients with VHL disease.

Drugs that inhibit the pVHL-HIF-VEGF pathway, such as the multiple tyrosine kinase inhibitors, sunitinib, sorafenib, and pazopanib, and the monoclonal anti-VEGF antibody bevacizumab, have a proven role for sporadic RCC and may be therapeutically useful in VHL-related hemangioblastomas and RCC.[37] A number of clinical trials are currently in progress (www.clinicaltrials.gov).

SIMPLE CYSTS

Introduction and Definition

Simple renal cysts are the most commonly acquired renal cystic lesion and occur twice as frequently in men as in women. Simple cysts are vusually unilateral and may be either solitary or multiple. They occur rarely in children but become increasingly common with age.[39] In a seminal ultrasound study, unilateral cysts were detected in 1.7% of patients 30 to 49 years of age, 11% of patients 50 to 70 years of age, and 22% to 30% of patients over age 70 years.[40] This age-related increase in cyst incidence has been corroborated by MRI studies.

Etiology and Pathogenesis

Simple renal cysts likely originate from the distal convoluted tubule or collecting ducts and may arise from renal tubular diverticula, but the pathogenic mechanisms are unknown. Focal tubular obstruction and renal parenchymal ischemia have both been suggested as etiologic processes. Less likely is the possibility that simple cysts arise from calyceal diverticuli, because simple cysts are often found in the renal cortex and their frequency increases with age.

Age, smoking, renal dysfunction, and hypertension[41] have been implicated as risk factors for simple cysts. However, these associations may be coincidental, given that the studies were largely retrospective, the cohorts had variable reasons for diagnostic referral, and the observations were not optimally controlled for patient age.[42]

Clinical Manifestations

Simple cysts are typically asymptomatic. However, increasing evidence supports a relationship between simple renal cysts and hypertension,[41] which may be associated with increased renalase levels.[43] In addition, red blood cell abnormalities (elevated red blood mass, hematocrit, and hemoglobin) are well described in patients simple renal cysts.[44] Patients also can present with hematuria, flank pain, evidence of infection, or obstruction of the collecting system. Clinical symptoms are more common with neoplasms than simple cysts, and should therefore prompt evaluation for cyst-associated malignancy.[42]

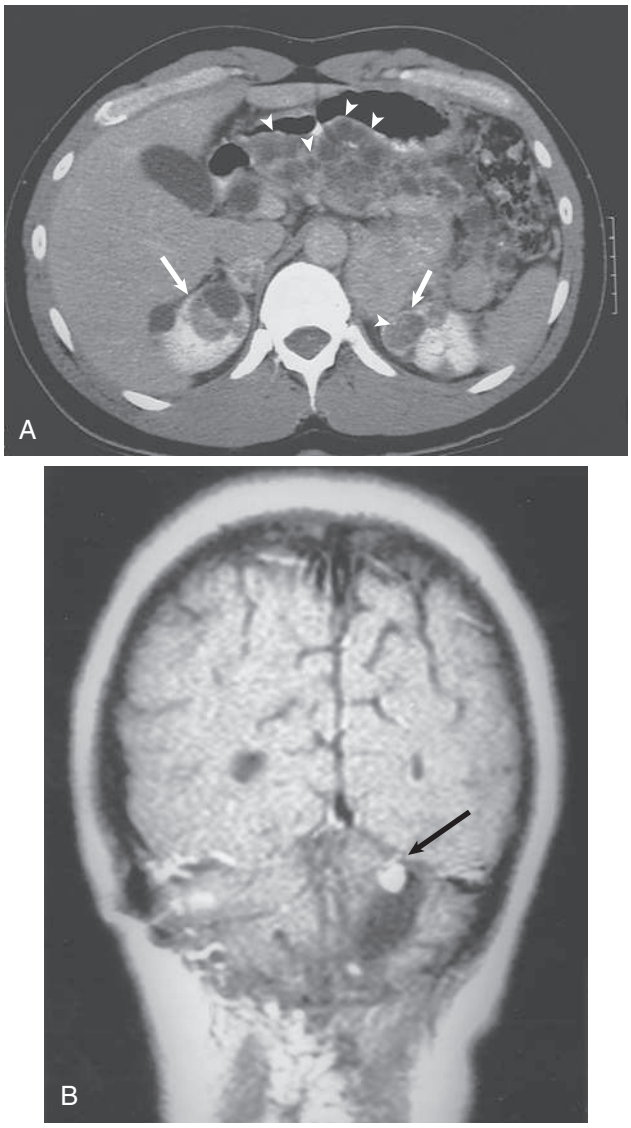

Fig. 45.10 Radiologic findings associated with von Hippel–Lindau syndrome. (A) Noncontrast CT shows massive cystic involvement of the pancreas *(arrowheads)* and bilateral renal cysts *(arrows).* (B) Contrast-enhanced MRI shows a right cerebellar hemangioblastoma with a small enhancing mass *(arrow).*

Pathology

Whether unilateral or bilateral, simple cysts are usually spherical and unilocular. They may be solitary or multiple. On average, simple cysts measure 0.5 to 1.0 cm diameter, but 3- to 4-cm cysts are not uncommon. Simple cysts can occur in the cortex, where they can protrude from the cortical surface (exophytic cysts), the corticomedullary junction, or the medulla. By definition, they do not communicate with the renal pelvis. The cyst walls are typically thin and transparent, lined with a single layer of flattened epithelium. Cyst fluid is essentially an ultrafiltrate of plasma. In the wake of infection, cyst walls can become thickened, fibrotic, and even calcified.

Diagnosis

Simple cysts are most often detected as incidental findings during abdominal imaging studies. On occasion, they are discovered during radiologic evaluation of palpable abdominal masses, pyelonephritis, or hematuria after abdominal trauma.

The critical clinical challenge is to distinguish single or multiple simple cysts from cysts associated with ADPKD, other cystic diseases, or RCC. This distinction usually can be made on the basis of patient age, family history, and renal imaging patterns (see Table 45.3).[42,45]

The ultrasound features of simple cysts include smooth walls, lack of septae, and lack of intracystic debris. If the ultrasound pattern is indeterminate, CT scanning should be performed. Benign cysts have homogeneous attenuation, no contrast enhancement, thin and smooth cyst walls, and no associated calcifications, unless prior infection has occurred.

A classification system for renal cysts based on their appearance and enhancement on CT, described by Israel and Bosniak[45] is widely used and informs management (see Table 59.5).

Treatment

Simple cysts associated with pain or renin-dependent hypertension can be managed with percutaneous aspiration under radiologic guidance and instillation of a sclerosing agent into the cyst cavity.[46] Laparoscopic or retroperitoneoscopic cyst unroofing (marsupialization) may be more appropriate for large cysts containing volumes in excess of 100 ml. Cyst infection with Enterobactericeae, staphylococci, and *Proteus* has been reported, and operative or percutaneous drainage is often required in addition to antibiotic treatment.

SOLITARY MULTILOCULAR CYSTS

Solitary multilocular cysts are generally benign neoplasms that arise from the metanephric blastema. These solitary cysts also have been designated multilocular cystic nephroma, benign cystic nephroma, and papillary cystadenoma. By definition, the cystic structures are unilateral, solitary, and multilocular. The cystic locules do not communicate with each other or with the renal pelvis. These locules are lined with a simple epithelium and the interlocular septa do not contain differentiated renal epithelia structures.

There is a spectrum of multilocular cysts; at one end is cystic nephroma (CN) and at the other end is cystic partially differentiated nephroblastoma (CPDN), in which the septa contain foci of blastemal cells. It is not clear whether a multilocular cyst represents a congenital abnormality in nephrogenesis, a hamartoma, a partially or completely differentiated Wilms tumor, or a benign variant of Wilms tumor.

There is a bimodal age distribution,[47] with approximately half the cases occurring in children younger than 4 years of age and half the cases detected in adults. The childhood cases (mostly CPDN) are usually found in boys, whereas multilocular cysts presenting in adulthood (mostly CN) occur more commonly in women. An abdominal or flank mass is the most common clinical feature, because these cysts are typically quite large and often replace an entire pole. Associated hematuria, calculi, urinary tract obstruction, and infection occur in rare instances. Diagnosis can be made either by ultrasound or CT (Fig. 45.11).

Almost all multilocular cysts are Bosniak class III (see Table 59.5) complex renal cysts suspicious for malignancy.[45] CPDN in children may contain blastema and incompletely differentiated metanephric tissue, but usually has a benign course. In adults, associated foci of RCC or sarcoma must be excluded. For both diagnostic accuracy and treatment, partial nephron-sparing surgery is usually required. The typical prognosis of solitary multilocular cysts is excellent.

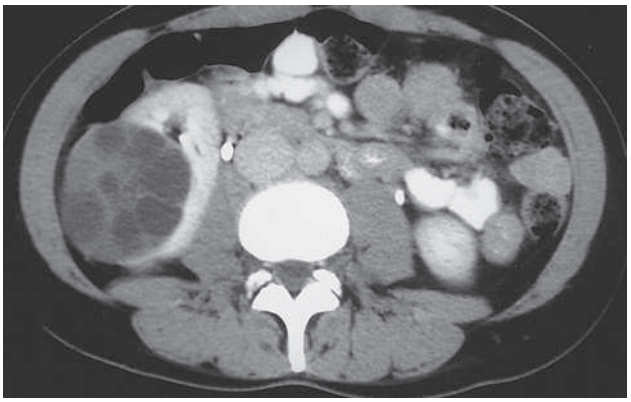

Fig. 45.11 Solitary multilocular cyst. Contrast-enhanced CT shows a solitary, septated, and well-circumscribed renal cystic lesion in the right kidney.

RENAL LYMPHANGIOMATOSIS

Renal lymphangiomatosis is a rare, generally benign disorder characterized by developmental malformation of renal lymphatic channels. Synonyms include hilar, pericalyceal, paracalyceal, peripelvic, or parapelvic lymphangiectasis.

The cystic phenotype is widely variable, and the underlying pathogenesis is unclear. Dilatation may involve a single lymphatic channel or multiple channels. The lymphangiectasis may be unilateral or bilateral, may be limited to the hilar region, or may extend into the renal parenchyma to the corticomedullary junction. On occasion, renal lymphangiomatosis may be very extensive and simulate either ADPKD or ARPKD.[48] The distinguishing features include cyst lining by lymphatic endothelium and cyst fluid containing lymphatic constituents such as albumin and lipid.

The characteristic ultrasound or CT findings include multiple, bilateral small peripelvic cysts that splay the renal hilum, as well as capsular cysts in the perirenal space, both separated by thin septations. Renal lymphangiomas are most often asymptomatic and require no treatment. However, the condition may be exacerbated by pregnancy, resulting in large perinephric lymph collections and ascites that can require percutaneous drainage.

GLOMERULOCYSTIC KIDNEY DISEASE

Glomerular cysts occur in three different clinical contexts: (1) isolated glomerulocystic kidney disease (GCKD); (2) glomerulocystic kidneys associated with heritable malformation syndromes, such as TSC, Meckel syndrome, ADTKD2, orofaciodigital syndrome type I, trisomies 9, 13, and 18, the short-rib polydactyly syndromes, and Zellweger cerebrohepatorenal syndrome; and (3) glomerular cystic changes in dysplastic kidneys.[17]

Isolated GCKD can occur as a sporadic condition, a familial disorder, or the infantile manifestation of ADPKD. Pathologically, the kidney architecture is normal, with no dysplastic elements in the cortex and no evidence of urinary tract obstruction. Cystic dilatation predominantly involves the Bowman space and the initial proximal tubule; it is defined as a two- or threefold dilatation of the Bowman space compared with the normal glomerular dimension. Glomerular cysts can be distributed from the subcapsular zone to the inner cortex. The typical ultrasound pattern in GCKD involves increased echogenicity of the renal cortex with minute cysts, smaller than those evident in ADPKD. Young infants with either familial or sporadic forms of GCKD also may have renal medullary dysplasia and biliary dysgenesis.[17]

Heritable GCKD is usually transmitted as an autosomal dominant trait often occurring as the infantile expression of ADPKD. In these infants, the kidneys are bilaterally enlarged and diffusely cystic. In non-ADPKD–associated GCKD families, the kidneys are typically normal in size, although on occasion enlarged kidneys are observed. Finally, several sporadic cases of nonsyndromal GCKD have been described, suggesting either spontaneous mutations or a recessively transmitted disorder.[17]

Familial hypoplastic GCKD (MIM 137920) appears to be a distinct form of GCKD in which the kidneys are smaller than normal and often associated with medullo-calyceal abnormalities. This multisystem disease is pleiotropic among affected family members with variable associations of hypoplastic GCKD, gynecologic abnormalities, maturity-onset diabetes of the young, type V (MODY5), and hypomagnesemia and results from mutations in HNF1B, the gene encoding hepatocyte nuclear factor 1-β.[49]

ACQUIRED CYSTIC DISEASE

Hypokalemic Cystic Disease

Renal cysts are often seen in association with chronic hypokalemia secondary to primary hyperaldosteronism or other renal potassium-wasting disorders. Nearly 50% of patients with idiopathic adrenal hyperplasia and 60% of patients with adrenal tumors are reported to have renal medullary cysts, which typically regress after adrenalectomy.

Hilar Cysts

Hilar cysts are spherical accumulations of clear, fat droplet–containing fluid within the renal sinus. These cystic structures are not lined by epithelia. They are most commonly seen in debilitated patients and may represent atrophy of the renal sinus fat.

Perinephric Pseudocysts

Perinephric pseudocysts are also unlined cavities. They typically occur under the renal capsule or in the perirenal fascia as a result of urine extravasation from traumatic or spontaneous rupture of a renal cyst, or as the posterior extension of a pancreatic pseudocyst. Surgical intervention is indicated for associated urinary tract obstruction. Otherwise, treatment is directed to the underlying cause.

Acquired Cystic Disease in Renal Failure

Acquired cystic disease is a significant complication of prolonged renal failure (see Table 45.3), occurring as the result of progressive structural end-stage kidney remodeling and may be associated with RCC. Acquired renal cystic disease is discussed further in Chapter 88.

SELF-ASSESSMENT QUESTIONS

1. Extrarenal complications of autosomal recessive polycystic kidney disease (ARPKD) can include which of the following?
   A. Congenital hepatic fibrosis
   B. Caroli syndrome
   C. Growth retardation
   D. Intracranial aneurysms
   E. All the above
2. Which renal cystic disease is distinguished by small, contracted kidneys?
   A. Autosomal recessive polycystic kidney disease (ARPKD)
   B. Nephronophthisis (NPHP)
   C. Medullary sponge kidney (MSK)
   D. Von Hippel–Lindau (VHL) disease
   E. None of the above
3. Which phenotypic feature most accurately distinguishes tuberous sclerosis complex (TSC) from von Hippel–Lindau disease?
   A. Systemic hypertension
   B. Renal cysts
   C. Renal angiomyolipomas
   D. Renal cell carcinoma
   E. Liver cysts
4. Gene-based testing is a clinically informative tool for which of the following disorders?
   A. ARPKD
   B. NPHP
   C. MSK
   D. VHL disease
   E. All the above
5. Medullary sponge kidney (MSK) is a single-gene disorder in a subset of patients.
   A. True
   B. False

Alport Syndrome and Other Familial Glomerular Syndromes

Michelle N. Rheault, Clifford E. Kashtan

ALPORT SYNDROME

Definition

Alport syndrome (AS) is a generalized, inherited disorder of basement membranes caused by mutations affecting specific proteins of the type IV (basement membrane) collagen family. The major features of AS are hematuria, progressive nephritis with proteinuria and declining renal function, sensorineural deafness, and ocular abnormalities. AS is a rare disease, affecting approximately 1 in 50,000 people and is seen in all ethnicities and races. AS accounts for approximately 0.5% of adults and 1.7% of children with end-stage renal disease (ESRD) in the United States.[1]

Etiology and Pathogenesis

Type IV Collagen

Type IV collagen is a major constituent of basement membranes. The type IV collagen family of proteins comprises six isomeric chains, designated α1(IV) to α6(IV). Each of these chains has a major collagenous domain of about 1400 residues containing the repetitive triplet sequence glycine (Gly)–X–Y, in which X and Y represent a variety of other amino acids; a C-terminal noncollagenous (NC1) domain of about 230 residues; and a noncollagenous N-terminal sequence of 15 to 20 residues.

Each type IV collagen molecule is a heterotrimer composed of three α chains. Formation of these heterotrimers is initiated by C-terminal NC1 domain interactions, accompanied by folding of the collagenous domains into triple helices. There are at least three types of type IV collagen heterotrimer: $\alpha1(IV)_2$–α2(IV), α3(IV)–α4(IV)–α5(IV), and $\alpha5(IV)_2$–α6(IV). Type IV collagen triple helices form open, nonfibrillar networks that associate with laminin assemblies through interactions mediated by nidogen to form basement membranes.

The six type IV collagen genes are arranged in pairs on three chromosomes (Fig. 46.1). The 5′ ends of each gene pair are adjacent to each other, separated by sequences of varying length that contain motifs involved in transcriptional regulation.[2]

In basement membranes there is a ubiquitous network comprising the α1(IV) and α2(IV) chains; and other networks, restricted in distribution, composed of α3(IV), α4(IV), and α5(IV) chains, or α5(IV) and α6(IV) chains. Glomerular basement membrane (GBM) contains separate α1–α2(IV) and α3–α4–α5(IV) networks, whereas epidermal basement membranes (EBMs) contain separate networks of α1–α2(IV) chains and α5–α6(IV) chains. The α3α4α5(IV) network is also expressed in the Bowman capsule and distal tubule in the kidney, alveolar basement membranes, and basement membranes of the testis, eye, and ear.[3] A network of α1, α2, α5, and α6(IV) chains has been described in smooth muscle basement membranes.[3] These various networks likely have different physical and functional characteristics and interact differently with other matrix components and adjacent cells. α1–α2(IV) chains are also found in mesangial matrix.

Genetics

There are three forms of AS: an X-linked form resulting from mutations at the *COL4A5* locus, primarily affecting the α5(IV) chain; an autosomal recessive form arising from mutations at the *COL4A3* locus or the *COL4A4* locus, affecting the α3(IV) and α4(IV) chains, respectively; and an autosomal dominant form from heterozygous mutations in *COL4A3* or *COL4A4* (Table 46.1). Approximately 80% of AS was previously thought to be inherited in an X-linked manner, with 15% autosomal recessive and 5% autosomal dominant inheritance patterns observed. With the advent of next-generation sequencing, it is clear that autosomal dominant Alport syndrome (ADAS) is more common than previously recognized, accounting for approximately 20% to 30% of affected families.[4]

X-Linked Alport syndrome. X-linked Alport syndrome (XLAS) is the predominant form of the disease. Several hundred *COL4A5* mutations have been described, mostly missense mutations, splice-site mutations, and deletions of fewer than 10 base pairs.[5,6] A common missense mutation involves replacement of a glycine residue in the collagenous domain of the α5(IV) chain by another amino acid. Such mutations are thought to interfere with the normal folding of the α5(IV) chain into triple helices with other α(IV) chains.

Untreated male patients with *COL4A5* mutations consistently progress to ESRD during the second or third decade of life, and most have deafness.[7] Genotype has a strong correlation with kidney disease progression in males with XLAS. In males with a large deletion, nonsense mutation, or a small mutation changing the mRNA reading frame, the risk for developing ESRD before age 30 is 90%. Splice-site mutations and missense mutations have a less severe renal phenotype with 70% and 50% reaching ESRD by age 30 years, respectively.[7] Women with XLAS have a wide variability in disease severity, and there is no genotype-phenotype correlation.[8] The severity of disease in a female heterozygous for a *COL4A5* mutation probably depends primarily on the relative activities of the mutant and normal X chromosomes in renal, cochlear, and ocular tissues due to X-inactivation.[9]

Autosomal recessive Alport syndrome. Autosomal recessive Alport syndrome (ARAS) arises from mutations affecting both alleles of *COL4A3* or *COL4A4*.[10] ARAS should be suspected when an individual with typical clinicopathologic features of the disease lacks a family history, especially when a young female has severe disease, such as deafness, nephrotic syndrome, or impaired renal function. However, sporadic cases of AS may represent *de novo* mutations at the *COL4A5* locus or a germ-line

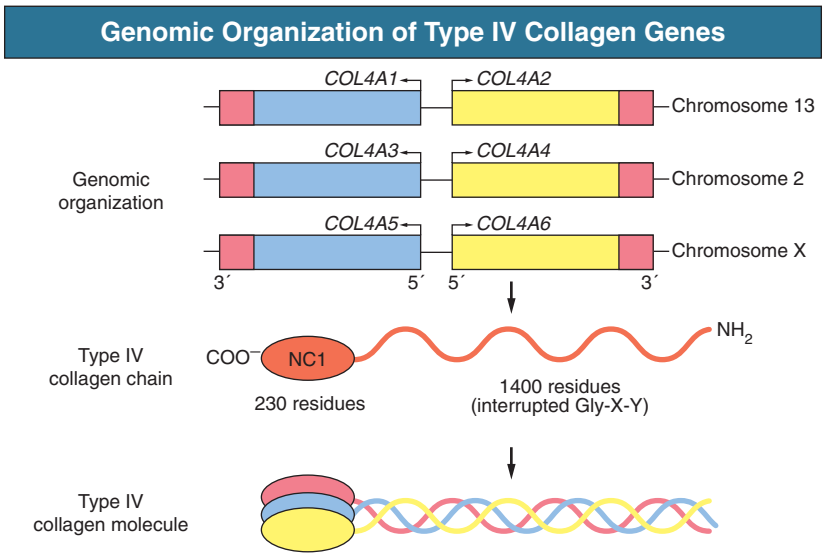

Fig. 46.1 Genomic organization of type IV collagen genes. Each type IV collagen chain is synthesized from one of the pairs of type IV collagen genes. Each type IV collagen molecule is a heterotrimer of three type IV collagen chains (see also Fig. 46.4).

TABLE 46.1 Molecular Genetics of Alport Syndrome

Inheritance	Affected Locus	Gene Product
X-linked (XLAS)	*COL4A5*	α5(IV)
X-linked + leiomyomatosis	*COL4A5* + *COL4A6*	α5(IV) + α6(IV)
Autosomal recessive (ARAS)	*COL4A3* *COL4A4*	α3(IV) α4(IV)
Autosomal dominant (ADAS)	*COL4A3* *COL4A4*	α3(IV) α4(IV)

COL4A5 mutation in the proband's mother. Most patients with ARAS develop ESRD and deafness before age 30 years, regardless of gender.[10]

Autosomal dominant Alport syndrome. Heterozygous mutations in *COL4A3* or *COL4A4* typically result in asymptomatic hematuria. In some families, however, these mutations also may be associated with progressive nephropathy, that is, ADAS. Patients with ADAS tend to have a slower course to ESRD than those with XLAS or ARAS.[11,12]

Type IV Collagen in Alport Basement Membranes

The GBMs and tubular basement membranes of males with XLAS usually fail to express the α3(IV), α4(IV), and α5(IV) chains but do express the α1(IV) and α2(IV) chains (Fig. 46.2). Women with XLAS frequently exhibit mosaic expression of the α3(IV), α4(IV), and α5(IV) chains in GBM, whereas expression of the α1(IV) and α2(IV) chains is preserved. Most males with XLAS show no EBM expression of α5(IV), whereas female heterozygotes frequently display mosaicism (Fig. 46.3). Lens capsules of some males with XLAS do not express the α3(IV), α4(IV), or α5(IV) chains, whereas expression of these chains appears normal in other patients.

In most patients with ARAS, GBM shows no expression of the α3(IV), α4(IV), or α5(IV) chains, but α5(IV) and α6(IV) are expressed in the Bowman capsule, distal thin basement membrane (TBM), and EBM (Fig. 46.4). Therefore XLAS and ARAS may be differentiated by immunohistochemical analysis. Basement membrane expression of type IV collagen α chains appears to be normal in patients with ADAS.

These observations indicate that a mutation affecting one of the chains involved in the α3–α4–α5(IV) network can prevent GBM expression not only of that chain but also of the other two chains as well; evidence suggests that this reflects post-translational events. Some mutant chains are unable to participate in the formation of trimers; as a result, the normal chains that are prevented from forming trimers undergo degradation. Other mutations may allow formation of abnormal trimers that are degraded before deposition in basement membranes can occur (Fig. 46.5).

Ultrastructural studies of Alport cochleae suggest that the hearing deficit may be attributable to a defect in adherence of the organ of Corti to the basilar membrane.[13]

Clinical Manifestations

Renal Defects

Hematuria is the cardinal finding of AS. Affected males have persistent microhematuria. Many also have episodic macrohematuria during upper respiratory tract infections, usually during the first two decades of life. Hematuria has been discovered in the first year of life in affected boys, in whom it is probably present from birth. Boys who are free of hematuria during the first 10 years of life are unlikely to be affected.

More than 90% of females with XLAS have persistent or intermittent microhematuria, but about 5% of obligate heterozygotes never manifest hematuria.[8] Hematuria is persistent in both males and females with ARAS. About 50% of carriers of *COL4A3* or *COL4A4* mutations have hematuria.

Proteinuria is usually absent early in life but develops eventually in all males with XLAS and in males and females with ARAS. Proteinuria increases progressively with age and may result in nephrotic syndrome. Proteinuria develops eventually in at least 75% of heterozygous females.[8] Hypertension also increases in incidence and severity with age and is more likely in affected males than affected females with XLAS, but there are no gender differences in the hypertension frequency in ARAS.

ESRD develops in all affected males with XLAS, at a rate determined primarily by the nature of the underlying *COL4A5* mutation.[7] Thus the rate of progression is fairly constant among affected males within a particular family, but there is significant interkindred variability.

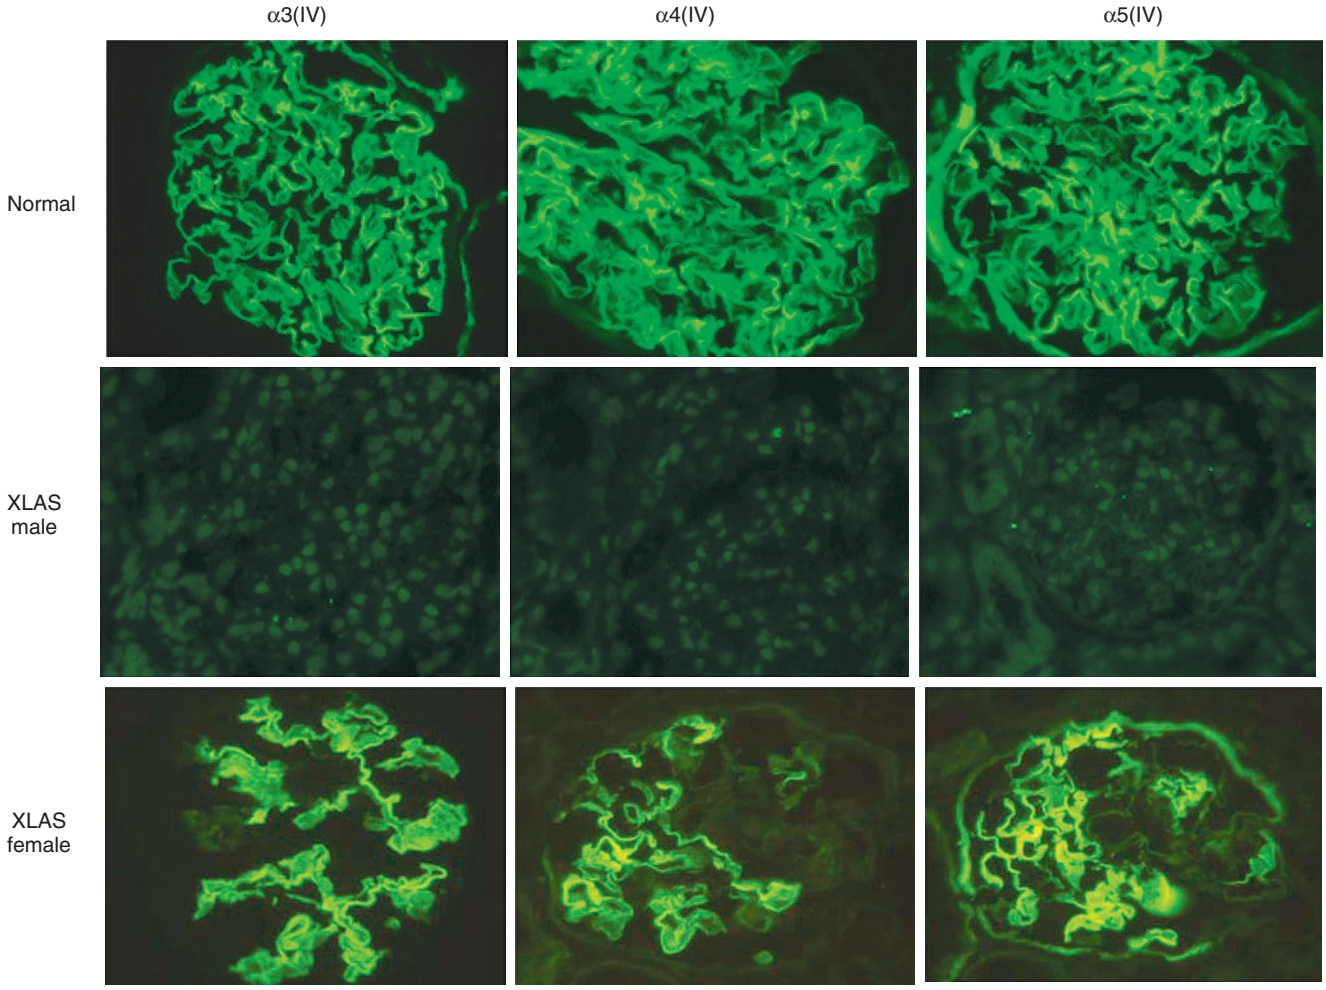

Fig. 46.2 Immunohistochemistry of glomerular basement membrane (GBM) in X-linked Alport syndrome (XLAS). In a normal individual *(top row),* GBM stains strongly for the α3(IV), α4(IV), and α5(IV) chains of type IV collagen. Staining of GBM of an affected male is negative for each of these chains *(middle row),* whereas an affected female shows mosaic immunoreactivity *(bottom row).*

Significant intrakindred variability in the rate of progression to ESRD has been reported in some families with missense *COL4A5* mutations.

Progression to ESRD in females with XLAS was considered an unusual event until a 2003 European study of several hundred females with XLAS found that 12% developed ESRD before age 40 (vs. 90% of males with XLAS), increasing to 30% by age 60 and 40% by 80.[8] A confirmatory European registry study showed a 15% prevalence of ESRD in heterozygous women.[14] The risk for ESRD is significantly increased in heterozygotes with proteinuria. The outcome of XLAS in females is presumed to depend on the relative activities of the normal and mutant X chromosomes, but other unknown factors also likely influence outcome.[9] Macrohematuria in childhood, nephrotic syndrome, and the finding of diffuse GBM thickening by electron microscopy (EM) are risk factors for chronic kidney disease (CKD) in affected females.[15] Sensorineural deafness and anterior lenticonus are also indicative of an unfavorable outcome in affected women. Both males and females with ARAS appear likely to progress to ESRD during the second or third decade of life.[10]

Cochlear Defects

Deafness is frequently but not universally associated with the Alport renal lesion, occurring in about 90% of males and 25% to 30% of females with XLAS.[7,8] In some families with Alport nephropathy and apparently normal hearing, deafness may occur late and may be very slowly progressive.

Hearing loss in AS is never congenital and usually becomes apparent by late childhood to early adolescence in boys with XLAS and in both boys and girls with ARAS. Hearing loss is present in 50% of males with XLAS by approximately age 15, 75% by age 25, and 90% by age 40.[7] Hearing loss is less common in females with XLAS, with 10% of XLAS affected by 40 years of age and about 20% by age 60.[8] Hearing loss is also common in ARAS with approximately 40% to 66% of individuals affected,[10] but less common in ADAS with only 2% to 13% affected.[11,12] Hearing impairment in members of families with AS is always accompanied by evidence of renal involvement. In its early stages, the hearing deficit is detectable only by audiometry, with bilateral reduction in sensitivity to tones in the range of 2000 to 8000 Hz. In affected males, the deficit extends progressively to other frequencies, including those of conversational speech.

Ocular Defects

Ocular defects occur in 30% to 40% of males with XLAS and in about 15% of XLAS females.[7,8] *Anterior lenticonus,* a cone-shaped distortion of the anterior surface of the lens, is virtually pathognomonic of AS, occurs in about 15% of males with XLAS, and is almost entirely restricted to AS families with progression to ESRD before age 30 years and

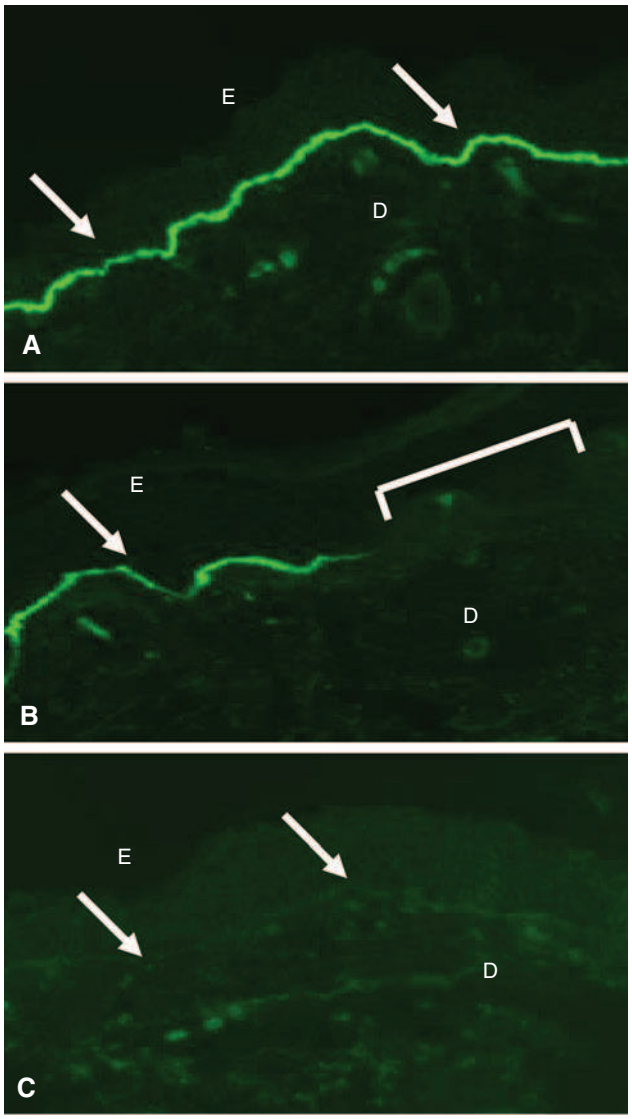

Fig. 46.3 Immunohistochemistry of epidermal basement membrane (EBM) in X-linked Alport syndrome. (A) In a normal male, EBM shows strong staining for α5(IV) at the dermoepidermal junction *(arrows)* between dermis *(D)* and epidermis *(E)*. (B) In an affected female, EBM shows mosaic staining *(arrow);* the *white bracket* identifies a length of EBM negative for α5(IV). (C) In affected males, staining of EBM *(arrows)* for α5(IV) is absent.

deafness.[7] Anterior lenticonus is absent at birth, usually appearing during the second to third decade of life after the onset of CKD and is bilateral in 75% of patients (Fig. 46.6A). The spectrum and frequencies of ocular lesions appear to be similar in XLAS and ARAS.[16] Ocular lesions are almost never observed in ADAS.[11,12]

Another common ocular manifestation of AS is a maculopathy, with whitish or yellowish flecks or granulations in a perimacular distribution. This is present in 50% to 60% of men with XLAS, in men and women with ARAS, and in approximately 15% of women with XLAS[16] (see Fig. 46.6B). The maculopathy does not appear to be associated with any visual abnormalities.

Corneal endothelial vesicles (posterior polymorphous dystrophy) have been observed in AS and may indicate defects in the Descemet membrane, the basement membrane underlying the corneal endothelium. Recurrent corneal erosion in AS has been attributed to alterations of the corneal EBM.

Leiomyomatosis

The association of AS with leiomyomatosis of the esophagus and tracheobronchial tree has been reported in about 30 families.[6] Affected females typically also have genital leiomyomas, with clitoral hypertrophy and variable involvement of the labia majora and uterus. Bilateral posterior subcapsular cataracts also occur frequently in affected individuals. Symptoms usually appear in late childhood and include dysphagia, postprandial vomiting, retrosternal or epigastric pain, recurrent bronchitis, dyspnea, cough, and stridor. This syndrome typically arises from a contiguous gene deletion on the X-chromosome involving exon 1 of *COL4A5,* the common promoter region that regulates gene expression of *COL4A5* and *COL4A6,* and the first 2 exons of the adjacent *COL4A6* gene.[17] The genotype-phenotype relationship in this disorder is uncertain because deletions in this region may occur without associated leiomyomas, and conversely some families with XLAS and leiomyomas do not have deletions involving the common promoter region and *COL4A6*.[18]

Hematologic Defects

An autosomal dominant syndrome of hereditary nephritis, deafness, and megathrombocytopenia called *Epstein syndrome* has been described in a small number of families. Families with Fechtner syndrome exhibit these features as well as leukocyte inclusions (May-Hegglin anomaly). Both Epstein and Fechtner syndrome arise from mutations in nonmuscle myosin heavy-chain IIA (*MYH9*).[19] Although in some patients ultrastructural changes in GBM resemble those of AS, basement membranes of these patients do not have abnormal expression of type IV collagen α chains. Therefore Epstein and Fechtner syndromes are best considered distinct forms of hereditary nephritis rather than variants of AS.

Arterial Abnormalities

Aneurysmal dilation of the thoracic and abdominal aorta and smaller arterial vessels has been described in a small number of males with AS.[20]

Renal Pathology

There are no pathognomonic lesions by light microscopy or immunofluorescence in AS. In affected males, biopsies obtained before 5 years of age typically show no light microscopy changes. Mesangial hypercellularity and matrix expansion are typically observed in older children and adolescents. Glomeruli of affected males eventually show focal segmental glomerulosclerosis (FSGS), and interstitial fibrosis and tubular atrophy are often found in affected boys older than 10 years.[21] Light microscopy findings in affected females correlate with proteinuria and kidney function; an affected female of any age who has isolated microhematuria is likely to have little or no abnormality by light microscopy. Indirect immunofluorescence of type IV collagen α-chain expression in renal or skin basement membranes can be diagnostic (see earlier discussion).

EM frequently reveals diagnostic abnormalities. In most patients with AS there is variable thickening, thinning, basket weaving, and lamellation of the GBM (Fig. 46.7). The thick segments measure up to 1200 nm in depth, usually have irregular outer and inner contours, and are found more frequently in males than in females. The lamina densa is transformed into a heterogeneous network of membranous strands, which enclose clear electron-lucent areas that may contain round granules of variable density measuring 20 to 90 nm in diameter. There are variable degrees of epithelial foot process fusion.

Not all Alport kindreds demonstrate these characteristic ultrastructural features. Thick, thin, normal, and nonspecifically altered GBMs have all been described. Affected young males, heterozygous females at any age, and, on occasion, affected adult males may have diffusely attenuated GBM measuring as little as 100 nm or less in thickness rather than

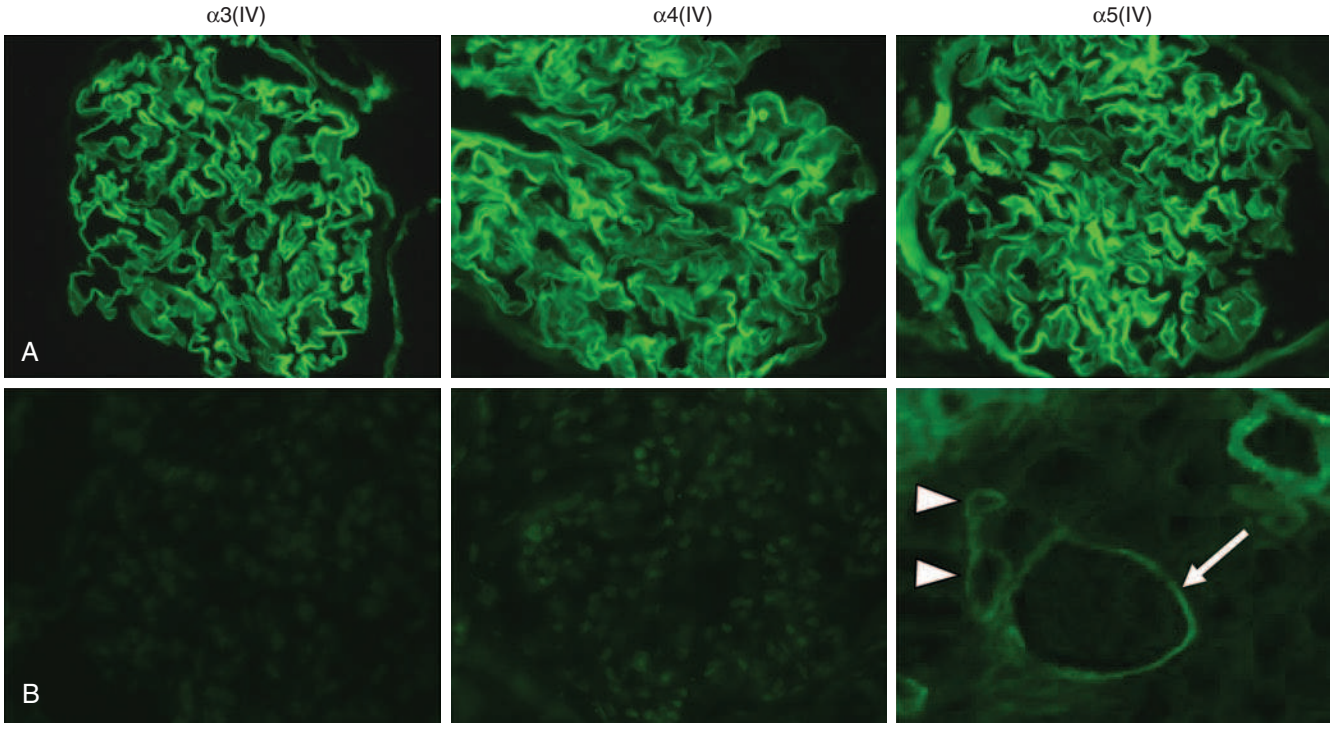

Fig. 46.4 Immunohistochemistry of kidney in patient with autosomal recessive Alport syndrome. (A) Normal glomerular basement membrane (GBM) and Bowman capsule staining for α3(IV), α4(IV), and α5(IV). (B) Patient shows no GBM staining, but α5(IV) is present in the Bowman capsule *(arrow)* and distal tubular basement membranes *(arrowheads)*.

the pathognomonic lesion. Although diffuse attenuation of GBM has been considered the hallmark of thin basement membrane nephropathy (TBMN), some patients with this abnormality are members of kindreds with a history of progression to renal failure. Therefore the significance of an ultrastructural finding of thin GBM must be considered in the context of the family history, basement membrane expression of type IV collagen α chains, and, if available, molecular genetic information. There are a number of families reported with features of hereditary FSGS with or without the classic AS basement membrane lesion associated with mutations in *COL4A3* or *COL4A4*.[22] These findings highlight the utility of detailed genetic evaluation to avoid misdiagnosis.

Diagnosis and Differential Diagnosis

Fig. 46.8 summarizes the evaluation of patients with hematuria and a positive family history. AS should be included in the initial differential diagnosis of patients with persistent microhematuria after excluding structural abnormalities of the kidneys or urinary tract (see Chapter 59). The presence on EM of diffuse thickening and multilamellation of the GBM predicts a progressive nephropathy, regardless of family history. However, in a patient with a negative family history, EM cannot differentiate de novo XLAS from ARAS. In some patients, the biopsy findings may be ambiguous, particularly in females and young patients of either gender. Furthermore, families with progressive nephritis and *COL4A5* mutations in association with GBM thinning have been described, indicating that the classic Alport GBM lesion is not present in all Alport kindreds.

If an undiagnosed patient has hematuria and multiple relatives with hematuria, who should undergo renal biopsy? The natural history of the AS renal lesion suggests that older, male individuals are more likely to exhibit diagnostic ultrastructural GBM abnormalities. In families with a firm diagnosis of AS established, evaluation of individuals with newly recognized hematuria can be limited to ultrasound of the kidneys and urinary tract to exclude coincidental tumor or structural anomalies of the urinary tract.

Absence of the α3, α4, and α5 chains of type IV collagen from GBM and distal TBM is unique to AS (Table 46.2). Expression of α5(IV) in the EBM detected by immunofluorescence may be informative, but apparently normal expression of type IV collagen α chains in basement membranes does not exclude the diagnosis of AS. Although mosaic expression of α5(IV) is diagnostic of the carrier state in heterozygous females, a normal result does not exclude heterozygosity. A female member of an Alport kindred who does not have hematuria still may be a carrier, but is less likely to exhibit detectable mosaicism than females with hematuria.

A firm histologic diagnosis of AS cannot always be established, or it may not be possible to determine the mode of transmission, despite careful evaluation of the pedigree and application of the full range of histologic methods. In these situations, genetic analysis may provide information essential for determining prognosis and guiding genetic counseling. Genetic analysis for AS is widely available in commercial and research laboratories.

Genetic analysis using conventional Sanger sequencing identifies 80% to 90% of males with *COL4A5* mutations. Next-generation sequencing allows for simultaneous evaluation of *COL4A3, COL4A4,* and *COL4A5*.[23] Identification of a specific genotype can provide some prognostic information about the risk for kidney disease progression and risk for associated hearing loss and eye findings in an individual patient.[7] Once a new diagnosis of AS is made, all potentially affected family members including females should be screened for hematuria to identify those who may be at risk for progressive kidney disease, and targeted mutation analysis can be offered if requested by at-risk individuals.[24]

Glomerular diseases that typically occur sporadically may on occasion be heritable and should be considered in the differential diagnosis.

Assembly of Type IV Collagen Heterotrimers in Health and in Alport Syndrome

(B) Glomerular capillary wall from a patient with Alport syndrome, at the same magnification. *CL,* Capillary lumen. Note the thickening of the glomerular basement membrane (GBM), the splitting of the lamina densa into multiple strands, and the marked irregularity of the epithelial aspect of the GBM in the patient with Alport syndrome.

These include IgA nephropathy, FSGS, membranous nephropathy, membranoproliferative glomerulonephritis, and C3 glomerulopathy.

Natural History

Microhematuria, the first and invariable renal manifestation of AS, probably reflects GBM thinning with focal ruptures because of defective expression of the α3–α4–α5(IV) network. In its early stages, AS is clinically and often histologically indistinguishable from TBMN, which typically has a benign outcome. GBM attenuation is therefore an insufficient explanation for the divergent natural histories of the two conditions. What factors initiate and drive the progression of Alport nephropathy to ESRD? Reduction in the quantity of α3(IV), α4(IV), and α5(IV) chains in GBM (as likely occurs in TBMN) probably has consequences different from complete loss of these chains, as occurs in most males with XLAS and most patients with ARAS. The normal transition from the $\alpha1(IV)_2$–$\alpha2(IV)_1$ network of nascent glomeruli to the α3(IV)– α4(IV)– α5(IV) network of mature glomeruli fails to occur in AS, and α1(IV) and α2(IV) chains accumulate in Alport glomeruli as the disease progresses.[25,26] Alport GBM also shows overexpression of other matrix proteins normally absent from GBM or present in scant quantities, including type V collagen, type VI collagen, laminin α2 chain, and fibronectin. These alterations in GBM composition are unique to AS.[25,27] Both glomerular endothelial cells and podocytes appear to contribute to the accumulation of these proteins in Alport GBM. Recently, mesangial filopodial invasion of the GBM with deposition of ectopic laminin chains was proposed as another mechanism of matrix accumulation.[28] Alterations in glomerular extracellular matrix are accompanied by changes in glomerular cell behavior, including expression of transforming growth factor β1, integrins, and matrix metalloproteinases. Activation of fibrogenic pathways in the renal interstitium presumably represents a downstream consequence of glomerular disease.

Treatment

Current clinical practice recommendations for delaying ESRD in patients with AS focus on the early introduction of renin-angiotensin system (RAS) blockade to suppress urinary protein excretion.[24,29] The use of RAS blockade is based on experimental and clinical evidence as well as practical considerations. Angiotensin-converting enzyme (ACE) inhibition lengthens survival in mice with ARAS, doubling survival when begun before the onset of proteinuria. ACE inhibition begun after the onset of proteinuria also improves survival in Alport mice, to a lesser degree. The effect of ramipril on survival was superior to that of candesartan in a murine comparison study.

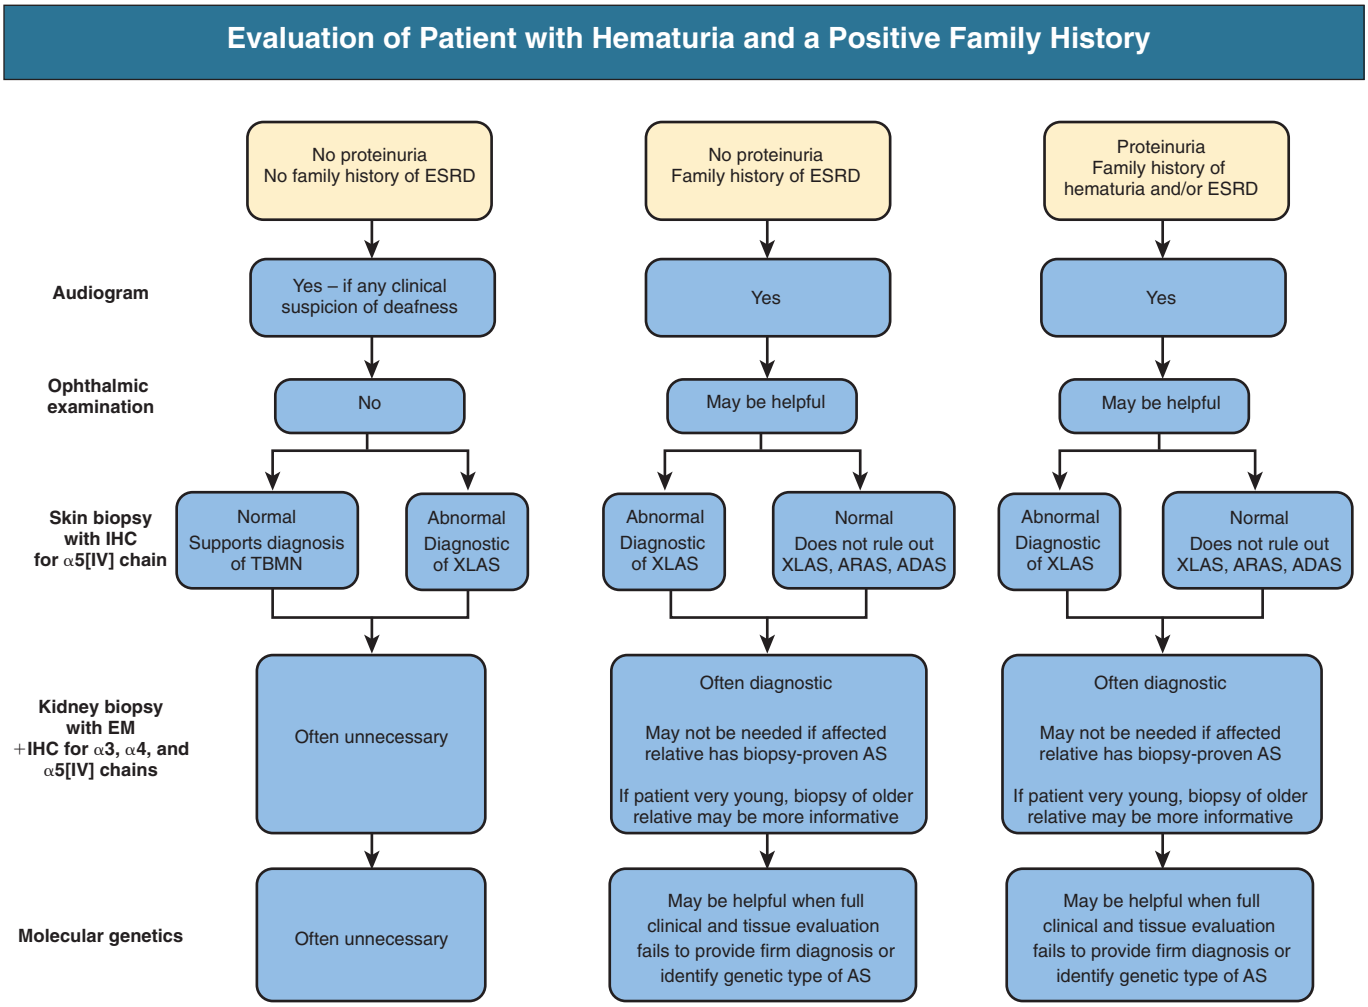

Fig. 46.8 Evaluation of patient with hematuria and positive family history. *ADAS,* Autosomal dominant Alport syndrome; *ARAS,* autosomal recessive Alport syndrome; *AS,* Alport syndrome; *EM,* electron microscopy; *ESRD,* end-stage renal disease; *IHC,* immunohistochemistry; *TBMN,* thin basement membrane nephropathy; *XLAS,* X-linked Alport syndrome.

Uncontrolled clinical studies in AS have shown that RAS blockade can reduce proteinuria. In a large multicenter, randomized, double-blind study comparing losartan with placebo or amlodipine in children with AS and proteinuria there was a significant reduction in proteinuria with losartan over 12 weeks.[30] A 3-year extension of this study showed comparable efficacy of enalapril and losartan in reducing proteinuria.[31] A retrospective review of treated Chinese children with AS similarly showed a decline in proteinuria with ACE inhibition that was sustained over 5 years of follow-up.[32]

Retrospective data from the European Alport Registry indicates that ACE inhibitor therapy initiated while glomerular filtration rate (GFR) is still normal delays ESRD by years.[33] This also has been shown in pairs of affected brothers discordant for ACE inhibitor therapy with a delay in ESRD of a median of 13 years in the earlier treated brother.[33] ACE inhibitors can be used safely in children with CKD, at doses that achieve suppression of urinary protein excretion.[34] RAS blockers are relatively inexpensive and widely available, so any child in the world with AS should be able to receive treatment.

Consensus recommendations for the management of AS children include (1) early screening for hematuria in at-risk children, (2) regular determination of urinary protein excretion on diagnosis, and (3) initiation of RAS blockade once overt proteinuria develops.[29] The goal of treatment is to reduce the ratio of urine protein to creatinine (uPCR) by 50% in children with a ratio of 0.2 to 1 mg/mg or to less than 0.5 mg/mg in those with uPCR greater than 2 mg/mg.[29] A randomized trial examining the effect of RAS blockade on the transitions from isolated hematuria to microalbuminuria to overt proteinuria is under way in Europe (EARLY PRO-TECT). Future clinical trials comparing RAS blockade to other therapies, alone or in combination, will be needed to identify the most effective approaches to delaying and preventing ESRD in patients with AS.

Transplantation

Renal transplantation is typically successful in patients with AS who reach ESRD with graft survival equivalent to that in patients with other diagnoses.[35] However, anti-GBM glomerulonephritis involving the renal allograft is a rare but dramatic manifestation of AS, occurring in 2% to 3% of male patients with AS who undergo transplantation and typically presents in the first year (see Chapter 24).

Are women who are heterozygous for *COL4A5* mutations suitable kidney donors? Clearly, those with proteinuria, hypertension, or reduced GFR should not donate, nor should women with hearing loss. A case

*In some Alport kindreds, staining of basement membranes for type IV collagen chains is entirely normal. Therefore a normal result does not exclude a diagnosis of X-linked Alport syndrome.
†Some heterozygous females have normal basement membrane immunoreactivity for type IV collagen chains. Therefore a normal result does not exclude the carrier state.

series of heterozygous donors showed new-onset hypertension, proteinuria, and decline in GFR after kidney donation in most women.[36] Given the recent finding that 30% to 40% of heterozygous women may eventually develop ESRD, the risk that a heterozygous donor will ultimately develop significant renal impairment must be higher than for the usual kidney donor. However, a common clinical scenario is a mother choosing to donate to her son with AS, and the choices of the whole family should be considered.

HEREDITARY ANGIOPATHY WITH NEPHROPATHY, ANEURYSMS, AND CRAMPS (HANAC SYNDROME)

An autosomal dominant hereditary angiopathy associated with nephropathy, aneurysms, and muscle cramps (HANAC syndrome) is caused by missense mutations in the *COL4A1* gene that allow for expression of an abnormal α1(IV) chain.[37] Renal findings in affected individuals include microhematuria and macrohematuria, mild renal impairment, and renal cysts. Retinal arteriolar tortuosity and retinal hemorrhage are common in affected individuals, as are intracranial aneurysms and leukoencephalopathy. Some affected individuals have elevated serum creatine kinase and muscle cramps.

Renal biopsy in affected individuals with hematuria shows no abnormalities of GBM structure or type IV collagen expression. However, basement membranes of the Bowman capsules, tubules, and interstitial capillaries exhibited irregular thickening, splitting into multiple layers and focal interruptions.

THIN BASEMENT MEMBRANE NEPHROPATHY

Definition

Isolated glomerular hematuria may occur as a familial or sporadic condition and is often associated with an excessively thin GBM on renal biopsy. The term *thin basement membrane nephropathy* (TBMN) is used to identify both familial and sporadic isolated hematuria associated with attenuated GBM. It is likely that several disorders that differ at the molecular level are associated with GBM thinning, and in some patients it is probably a normal variant.

Similar to AS, familial TBMN is an inherited GBM disorder manifested by chronic hematuria, but it differs clinically from AS in several important respects: (1) extrarenal abnormalities are rare; (2) proteinuria, hypertension, and progression to ESRD are unusual, seen in less than 10% of affected individuals, and extremely unusual before age 40; (3) gender differences in expression of TBMN are not apparent; and (4) transmission is autosomal dominant. TBMN and early AS may be difficult to differentiate histologically because diffuse GBM attenuation is characteristic of both. However, the GBM of patients with TBMN remains attenuated and does not undergo the progressive thickening and multilamellation that occurs in AS. Although TBMN is nonprogressive, careful evaluation and follow-up of individuals with TBMN is required to monitor for progressive kidney disease.

Etiology and Pathogenesis

Although TBMN is an autosomal dominant condition, a negative family history may not be reliable because patients are frequently unaware that they have relatives with hematuria. Familial TBMN has been localized to *COL4A3* or *COL4A4* in numerous kindreds,[38] and 50% or more heterozygotes have hematuria. However, linkage to *COL4A3* and *COL4A4* has been excluded in other families with isolated hematuria, indicating that TBMN is genetically heterogeneous.[39]

Immunohistologic studies of type IV collagen in GBM of patients with TBMN show no abnormalities in the distribution of any of the six α chains. Immunohistologic evaluation of GBM type IV collagen may therefore be useful in the differentiation of TBMN from AS.

Clinical Manifestations

TBMN is the most common cause of persistent microhematuria in children and adults and is common in the general population, with an

estimated prevalence of 1% to 2%.[40] Of patients referred to a nephrologist for evaluation of persistent hematuria, 20% to 25% will prove to have thin GBM on renal biopsy. Individuals with TBMN typically have persistent microhematuria that is first detected in childhood. In some patients, microhematuria is intermittent and may not be detected until adulthood. Episodic macrohematuria, often in association with upper respiratory infections, is not unusual. The hematuria of TBMN appears to be a lifelong condition.

Overt proteinuria and hypertension are unusual in TBMN but have been reported in up to 30% of adults. Some of these patients may have had AS, in which the predominant abnormality of GBM was attenuation rather than thickening and multilamellation. Other glomerular disorders, such as IgA nephropathy and FSGS, may occur concurrently with TBMN.

Pathology

Light and immunofluorescence microscopy are unremarkable in typical cases of TBMN. Most patients exhibit diffuse thinning of the whole GBM and of the lamina densa (Fig. 46.9). GBM width is age and gender dependent in normal individuals.[40] Both the lamina densa and the GBM increase rapidly in thickness between birth and 2 years of age, followed by gradual thickening into adulthood. GBM thickness in adult men (373 ± 42 nm) exceeds that in adult women (326 ± 45 nm). Each EM laboratory should establish a consistent technique for measuring GBM thickness and determine its own reference range for GBM width to make comparisons with published data meaningful. Typically, a value of 250 nm will accurately separate adults with normal GBM from those with TBMN. For children, the cut-off is in the range of 200 to 250 nm. Intraglomerular variability in GBM width is minimal in patients with TBMN.

Diagnosis and Differential Diagnosis

If the family history indicates autosomal dominant transmission of isolated hematuria without deafness or ocular abnormalities, if there is no family history of CKD, and if kidney and urinary tract imaging studies are normal, a presumptive diagnosis of TBMN often can be made without kidney biopsy (see Fig. 46.7). When family history is negative or unknown or there are coexisting features that are atypical for TBMN (e.g., proteinuria; deafness), renal biopsy may be very informative. Normal distribution of type IV collagen α chains in the kidney provides supportive but not conclusive evidence for a diagnosis of TBMN. Marked variability in GBM width within a glomerulus in a patient with persistent microhematuria should raise suspicion of AS, although focal lamina densa splitting has been described in TBMN. Genetic analysis may confirm a heterozygous mutation in *COL4A3* or *COL4A4*.

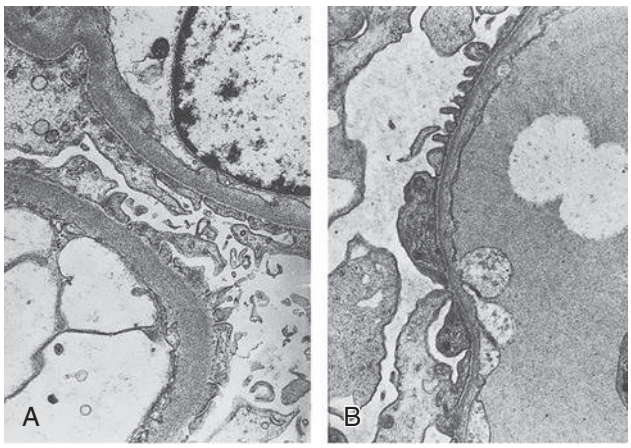

Fig. 46.9 Thin basement membrane nephropathy. Electron micrographs of renal biopsy specimens. (A) Normal glomerular capillary wall. (B) Thin basement membrane nephropathy at the same magnification. Note the diffuse and uniform attenuation of the glomerular basement membrane and the lamina densa. (From Warrell DA, Cox TM, Firth JD, Benz EJ Jr, eds. *Oxford Textbook of Medicine.* Oxford: Oxford University Press; 2003:322.)

Treatment

Patients with TBMN should be reassured but not lost to follow-up. The risk for chronic renal impairment is small (<5%) but real. Urinalysis and measurement of blood pressure and renal function are recommended every 1 to 2 years.

FABRY DISEASE (ANDERSON-FABRY DISEASE)

Definition

Fabry disease is caused by hereditary deficiency of the enzyme α-galactosidase A (α-Gal A), resulting in the intracellular accumulation of neutral glycosphingolipids with terminal α-linked galactosyl moieties (Fig. 46.10). Clinically, this leads to progressive CKD, pain crises, sweating abnormalities, vascular cutaneous lesions, and cardiac and eye abnormalities.

Etiology and Pathogenesis

More than 500 mutations causing Fabry disease have been identified in *GLA,* the gene for α-Gal A, which is located on the X chromosome. Most of the described mutations are associated with the classic Fabry phenotype, in which there is multisystem involvement. Certain missense mutations have been identified in patients with a mild phenotype limited to cardiac abnormalities.

Glycosphingolipids are normal constituents of the plasma membrane, the membranes of intracellular organelles, and circulate in association with apolipoproteins. The neutral glycosphingolipids that accumulate in Fabry disease are identical to those found in normal tissue. All tissues except red blood cells accumulate globotriaosylceramide (Gb3), with the highest concentrations found in the diseased kidney.

Clinical Manifestations and Pathology

Fabry disease is a multisystem disorder, with prominent and potentially devastating involvement of the kidneys, heart, and peripheral and central nervous systems. As expected for an X-linked disorder, severe clinical manifestations occur in hemizygous males, whereas heterozygous females have a variable but typically less severe course. In affected males, the initial features of the disease are seen in childhood and early adolescence

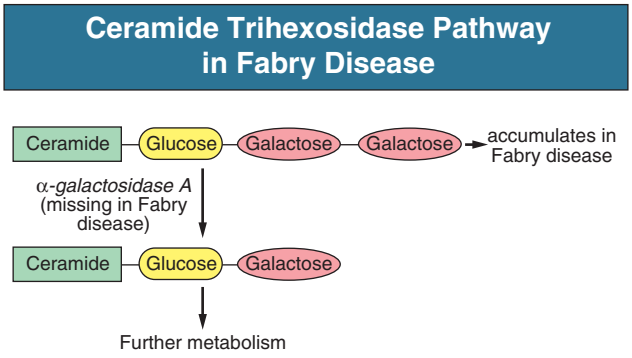

Fig. 46.10 Ceramide trihexosidase pathway in Fabry disease. α-Galactosidase A deficiency leads to tissue accumulation of trihexosylceramide.

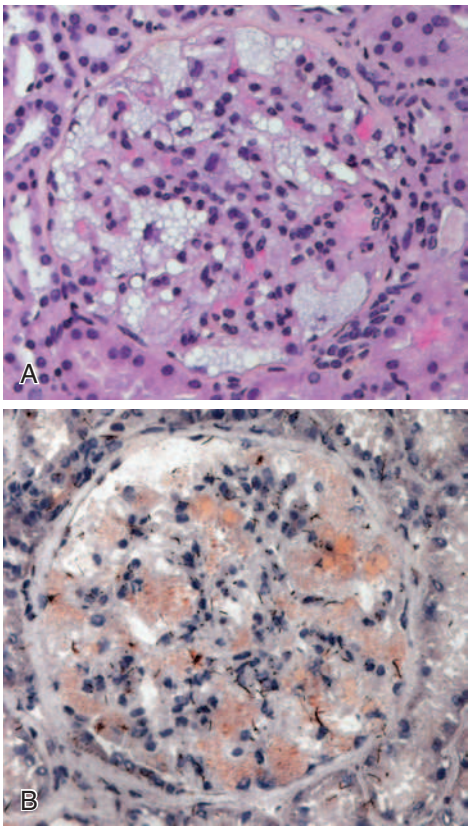

Fig. 46.11 Light microscopy of a renal biopsy specimen in Fabry disease. Glomerular epithelial cell glycosphingolipid deposition demonstrated by (A) vacuolation on hematoxylin-eosin staining (magnification ×20; (B) oil red O staining (×20). (Courtesy Dr. Paolo Menè and Dr. Antonella Stoppacciaro, University of Rome.)

and consist of paresthesias and pain in the hands and feet with episodic pain crises. The course of the disease is variable but usually leads to ESRD in the third to sixth decade. Myocardial or cerebral infarctions are typical terminal events. Severe Fabry disease in a female reflects extensive inactivation of the X chromosome carrying the normal α-Gal A allele.[41]

Renal Defects

Although the earliest manifestation of renal involvement is a concentrating defect, the nephropathy of Fabry disease typically manifests as mild to moderate proteinuria, sometimes with microhematuria, beginning in the third decade although proteinuria in childhood is reported. Nephrotic syndrome is unusual. Urinary oval fat bodies, with a Maltese cross configuration when viewed with a polarizing microscope, are a result of the large amounts of glycosphingolipid in the urine (see Chapter 4, Fig. 4.2B). Deterioration of renal function is gradual, with hypertension and ESRD developing by the fourth or fifth decade of life. Heterozygous women typically have mild renal involvement but up to 10% may develop ESRD.

Glomerular visceral epithelial cells are enlarged and packed with small, clear vacuoles that represent glycosphingolipid material (Fig. 46.11). Vacuoles also may be seen in parietal epithelial cells and the epithelial cells of the distal convoluted tubule and loop of Henle, but only rarely in mesangial cells, glomerular endothelial cells, or proximal tubular epithelial cells. There is progressive segmental and global glomerulosclerosis. Vacuoles are also observed in endothelial cells and smooth muscle cells of arterioles and arteries.

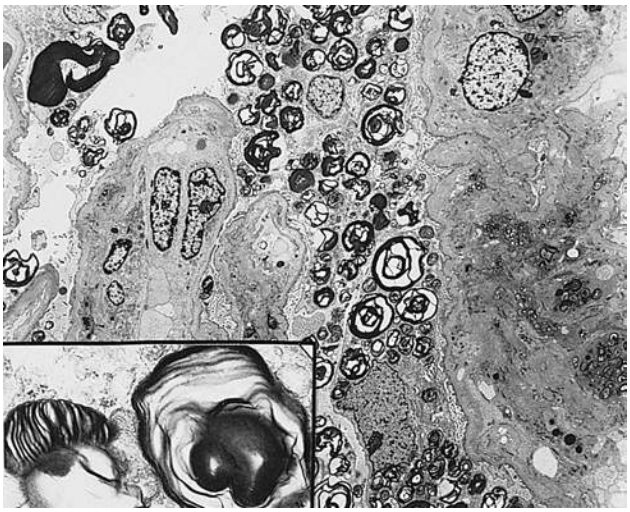

Fig. 46.12 Electron micrograph of a renal biopsy specimen in Fabry disease. Glycosphingolipid is deposited in cytoplasmic vacuoles in glomerular visceral epithelial cells. *Inset,* Cytoplasmic vacuoles contain electron-dense material in parallel arrays (zebra bodies) and in concentric whorls (myelin figures). (Courtesy Dr. J. Carlos Manivel.)

On EM, there are abundant inclusions within lysosomes, particularly within visceral epithelial cells (Fig. 46.12). The inclusions (myelin figures) are typically round, comprising concentric layers of dense material separated by clear spaces. The layers may be arranged in parallel (zebra bodies). Detachment of visceral epithelial cells from the underlying basement membrane may be observed. Inclusions are also observed in heterozygous females, although usually in smaller numbers than in affected males. Typical inclusions may be noted in excreted renal tubular cells.

The progression of Fabry nephropathy to ESRD probably reflects two parallel processes. Visceral epithelial cell dysfunction, which results in proteinuria, is followed by visceral epithelial cell detachment and necrosis, leading to capillary loop collapse and segmental sclerosis. Simultaneously, progressive impairment of arteriolar flow may develop as enlarging endothelial cells impinge on vascular lumina, resulting in ischemic glomerular damage.

Heart Defects

Glycosphingolipid accumulation in coronary artery endothelial cells and in the myocardium results in coronary artery narrowing, which may lead to angina, myocardial infarction, or congestive heart failure. Left ventricular hypertrophy (LVH) may be an early finding.[42] Arrhythmias resulting from infiltration of the conduction system and valvular lesions also may occur. Certain missense mutations affecting α-Gal A may present as isolated LVH.

Nervous System

Autonomic dysfunction is a prominent feature of Fabry disease, typically manifested by hypohidrosis, acral paresthesias and pain, and altered intestinal motility. Cerebrovascular symptoms (secondary to narrowing of the vascular lumen from accumulation of glycosphingolipid in vascular endothelial cells) tend to appear during the fourth decade and include hemiparesis, vertigo, diplopia, dysarthria, nystagmus, nausea and vomiting, headache, ataxia, and memory loss. The vertebrobasilar circulation is preferentially involved. Symptoms are often recurrent. Life-threatening intracerebral hemorrhage and infarction are not unusual. Dementia arising from glycosphingolipid accumulation in small cerebral blood vessels also has been described.

Fig. 46.13 Angiokeratoma in Fabry disease. Note the multiple periumbilical angiokeratomas. (Courtesy Dr. S. Waldek.)

Skin

Angiokeratomas usually appear during the second decade of life and can be the earliest presentation of Fabry disease, presenting as dark-red macules or papules of variable size (Fig. 46.13), originally known as *angiokeratoma corporis diffusum*. Typical locations include the lower trunk, buttocks, hips, genitalia, and upper thighs. The number of lesions varies from none up to 40 and increase in size and number.[43] On histologic examination, angiokeratomas consist of dilated small veins in the upper dermis, covered by hyperkeratotic epidermis. Telangiectasias may be noted, especially behind the ears.

Eyes

Characteristic corneal opacities are common in both men and women with Fabry disease, present in approximately 75% of affected men and women.[44] These lesions, termed *verticillata,* are identified by slit-lamp examination and are whorls of whitish discoloration that radiate from the center of the cornea. Cataracts (23% of males and 10% of females) and dilated conjunctival or retinal vessels may be observed.[44]

Lungs

Dyspnea and cough are common in men with Fabry disease, often with obstructive features on spirometry. This may be a consequence of fixed narrowing of the airways caused by glycosphingolipid accumulation.

Diagnosis

Diagnosis of affected males usually can be made clinically, with the additional information from slit-lamp eye examination to identify corneal opacities. The diagnosis should be confirmed by demonstrating decreased (<15%) or absent α-Gal A activity in serum, leukocytes, cultured skin fibroblasts, or tissue. Atypical variants may have enzyme activity up to 35% of normal. Heterozygous females may have very low (<15%) α-Gal A activity similar to that in males or may have more normal levels, making measurement of enzyme activity an insensitive way of diagnosing carriers. If enzyme levels are equivocal, alternative approaches to diagnosis include careful slit-lamp eye examination, measurement of urinary ceramide digalactoside and trihexoside, and genetic testing. Current information on laboratories offering sequencing of the α-Gal gene can be obtained at https://www.ncbi.nlm.nih.gov/gtr/conditions/C0002986/. Identification of carriers is particularly relevant when family members are being considered as living kidney donors.

Fabry disease should be considered in patients with unexplained ESRD,[45] especially if LVH is present or there is a history of stroke or nondiabetic paresthesia.

Treatment

The introduction of enzyme replacement therapy with recombinant human α-Gal A (agalsidase) has transformed the treatment of Fabry disease. Randomized clinical trials showed that agalsidase administration for 5 to 6 months resulted in reduced plasma and urine Gb3; amelioration of neuropathic pain; enhanced quality of life; clearing of Gb3 deposits from kidney, heart, and skin; and improved cerebral blood flow.[46] A multicenter longitudinal study showed that agalsidase stabilized renal function in patients with mild to moderate renal impairment at baseline and reduced left ventricular mass in those with LVH at baseline over 1 to 2 years of treatment. However, the impact of enzyme replacement therapy on long-term renal outcome is still unclear. Addition of RAS blockade to enzyme replacement can result in sustained reductions in proteinuria. In patients with ESRD, agalsidase may be infused during hemodialysis because there is little clearance of the enzyme by hemodialysis. Agalsidase therapy has been recommended for all affected males and symptomatic carrier females, but the drug is prohibitively expensive in many parts of the world.[47,48] An alternative treatment approach based on chemical "chaperones" is under investigation; however, a recent study did not show a significant treatment effect.

Renal transplantation is an effective treatment for advanced Fabry nephropathy but does not ameliorate the extrarenal manifestations. Transplanted kidneys from deceased donors or unaffected living donors may develop glycosphingolipid inclusions, but this usually is not clinically significant. Fabry heterozygotes should not become kidney donors. Coronary artery and cerebrovascular disease are the major causes of mortality in patients with Fabry disease who have undergone renal transplantation. Renal allograft recipients with Fabry disease are candidates for agalsidase treatment.

Fabry Disease in Childhood

Often it is not appreciated that the signs and symptoms of Fabry disease, particularly pain crises, acroparesthesias, angiokeratomas, and corneal opacities, typically have their onset in childhood, and thus the diagnosis is frequently delayed until well into adult life.[48] Symptomatic children with Fabry disease are potential candidates for agalsidase therapy.[48]

NAIL-PATELLA SYNDROME

Definition

Nail-patella syndrome (NPS) is an uncommon autosomal dominant condition characterized by hypoplasia or absence of the patellae, dystrophic nails, dysplasia of the elbows and iliac horns, and renal disease.

Etiology and Pathogenesis

NPS is caused by mutations in the LIM homeodomain transcription factor *LMX1B,* including missense, splicing, insertion or deletion, and nonsense alterations. In vitro studies of the transcriptional effects of mixing wild-type and mutant *LMX1B* suggest that NPS results from haploinsufficiency of *LMX1B,* rather than a dominant-negative effect. Although *LMX1B* appears to be important for normal limb and kidney development, the precise mechanisms for the renal effects of *LMX1B* mutations remain under investigation.

Clinical Manifestations

Renal Defects

Clinically apparent renal disease occurs in fewer than half of NPS patients. The nephropathy is usually benign, with an approximately 3% to 5% risk for progression to ESRD.[49,50] The clinical signs of NPS nephropathy appear in adolescence or young adulthood and typically include microhematuria and mild proteinuria, although some patients develop

nephrotic syndrome and mild hypertension. The severity of the renal manifestations may differ substantially in related individuals.

Skeletal Defects

The patellae are absent or hypoplastic in more than 90% of patients with NPS, which may be associated with knee joint effusions and osteoarthritis (Fig. 46.14).[49,50] In about 80% of patients, osseous processes project posteriorly from the iliac wings (iliac horns), which is pathognomonic (Fig. 46.15). Anomalies of the elbows include aplasia, hypoplasia, and posterior processes at the distal end of the humeri.

Nails

Nail abnormalities occur in about 98% of patients and are typically bilateral and symmetric. Fingernails are affected more often than toenails. The nails may be absent or dystrophic with discoloration, koilonychia, longitudinal ridges, or triangular lunulae.[50]

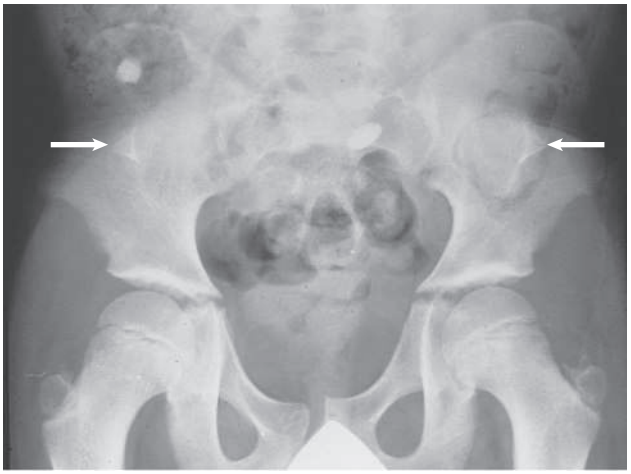

Fig. 46.15 Nail-patella syndrome. Iliac horns *(arrows)*. (Courtesy Dr. R. Vernier.)

Renal Pathology

Light microscopy findings in NPS are nonspecific and may demonstrate FSGS, mild mesangial hypercellularity, or no changes, in which case EM is required to make the diagnosis. EM shows multiple irregular lucencies of the GBM, giving it a moth-eaten appearance (Fig. 46.16). Such lucencies also may be observed in the mesangium. These lucent areas sometimes contain cross-banded collagen fibrils, which are more easily observed after staining with phosphotungstic acid (Fig. 46.17).

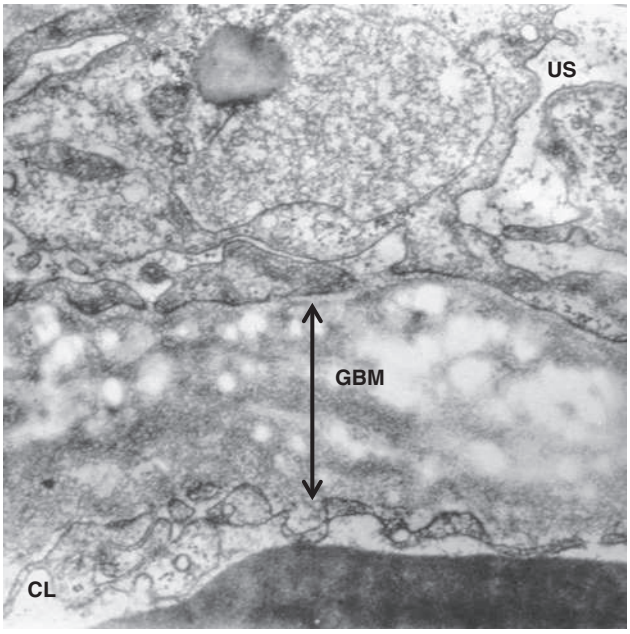

Fig. 46.16 Electron micrograph of renal biopsy specimen in nail-patella syndrome. The glomerular basement membrane appears moth-eaten on routine staining. *CL,* Capillary lumen; *US,* urinary space. (Courtesy Dr. R. Vernier.)

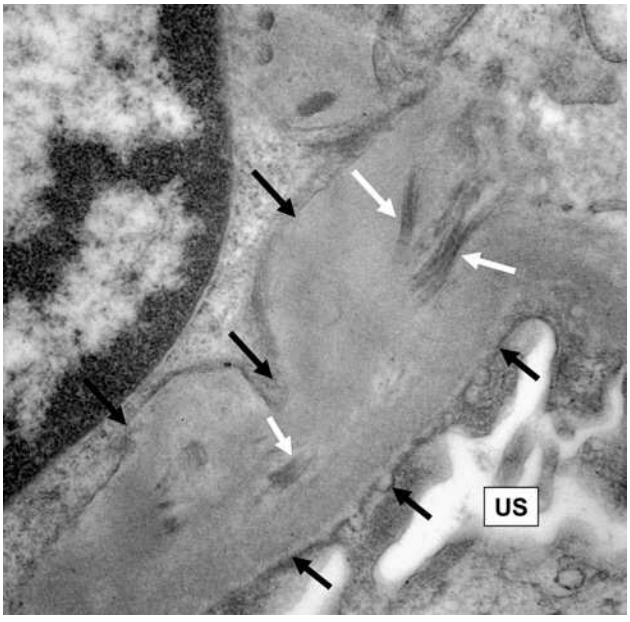

Fig. 46.17 Electron micrograph of renal biopsy specimen in nail-patella syndrome. *Black arrows* show margins of irregular glomerular basement membrane. Staining with phosphotungstic acid reveals fibrillar collagen *(white arrows)*. *US,* Urinary space.

The fibrils, which are type III collagen, tend to be arranged in clusters, and the surrounding GBM is often thickened. This may be observed without clinically evident renal disease, but fibrils have not been found in extraglomerular basement membranes. Cross-banded fibrils of type III collagen have been seen in GBM of patients with glomerular disease who lack nail or skeletal abnormalities, sometimes as a familial condition with autosomal recessive inheritance (collagen III glomerulopathy; see Chapter 28). It is unclear whether there is a pathogenic relationship between collagen type III glomerulopathy and NPS.

Treatment

No specific therapy is available for the nephropathy of NPS. There has been no reported recurrence in transplanted kidneys. Because NPS is an autosomal dominant disorder, careful evaluation of potential living related kidney donors for features of NPS is essential.

SELF-ASSESSMENT QUESTIONS

1. You are seeing a 15-year-old boy with Alport syndrome. What statement about his parents is *most* likely to be true?
   A. His father has Alport syndrome.
   B. His mother has Alport syndrome.
   C. Both parents are carriers of Alport syndrome.
   D. Neither parent has Alport syndrome.
   E. None of the above
2. Which of the following ocular abnormalities have been described in patients with Alport syndrome?
   A. Anterior lenticonus
   B. Recurrent corneal erosions
   C. Perimacular flecks
   D. Posterior polymorphous dystrophy
   E. All of the above
3. Which of the following statements about hearing loss in Alport syndrome is true?
   A. Alport syndrome may be picked up by neonatal hearing screening.
   B. In males with Alport syndrome, hearing loss is usually undetectable by audiometry until adulthood.
   C. Hearing loss in Alport syndrome initially targets high frequencies above the range of conversational speech.
   D. The hearing loss of Alport syndrome is conductive.
   E. Hearing loss in Alport syndrome is typically unilateral.

Inherited Disorders of Sodium and Water Handling

Detlef Bockenhauer

Every 24 hours, glomerular filtration yields about 150 liters of water, and 21,000 mmol of sodium (Na^+) in a healthy individual, yet only minute fractions of these quantities are excreted eventually in the urine. The precise amount excreted is tightly regulated to maintain homeostasis. Many different tubular transporters are involved in this homoeostatic process and are either directly or indirectly dependent on the electrochemical gradient for Na^+ generated by the Na^+,K^+-ATPase. In this way, Na^+ reabsorption is central not only for volume, but also for acid-base and electrolyte homeostasis. This molecular integration of homeostatic processes is reflected in the clinical picture; whereas disorders of water transport primarily cause a disturbance of serum Na^+ concentration, disorders of Na^+ transport generate specific patterns of clinical signs and symptoms related to blood pressure (BP) and electrolyte and acid-base disturbances, which help establish the underlying diagnosis.

PHYSIOLOGY OF SODIUM AND WATER REABSORPTION

Sodium Transporters and the Corresponding Inherited Disorders

In all tubular epithelial cells, a basolateral energy-requiring Na^+,K^+-ATPase ensures that intracellular Na^+ is kept at low levels and K^+ is high. Coupled with apical K^+, which travels down its concentration gradient to establish a lumen-positive electrical potential, an electrochemical gradient for Na^+ is created across the apical cell membrane, which drives Na^+ uptake from the tubular lumen into the cell via dedicated transporters and channels. Transport across the basolateral membrane to complete Na^+ reabsorption is facilitated by the Na^+,K^+-ATPase in all segments. Na^+ transport in each segment is inhibited by specific diuretics, so insight into the clinical picture of inherited disorders of Na^+ transport is gained by considering the effects of the corresponding diuretic. An overview of the transport process is given in Fig. 47.1.

In the proximal tubule (PT), an apical Na^+-hydrogen (H^+) exchange protein (NHE3) facilitates most of the Na^+ reabsorption. Because of this connection with H^+ excretion, this transport process is indirectly blocked by carbonic anhydrase inhibitors, such as acetazolamide. So far, no inherited disorder of isolated Na^+ in the PT has been reported. Instead, impaired sodium reabsorption in the PT typically occurs in the context of general PT dysfunction, which underlies renal Fanconi syndrome (see Chapter 48).

In the thick ascending limb (TAL), the Na^+-K^+-$2Cl^-$ cotransporter (NKCC2) can be blocked by loop diuretics such as furosemide. The corresponding inherited disorder is Bartter syndrome, in which the function of this transporter is either directly or indirectly impaired. Thus Bartter syndrome can be conceptualized as "inherited furosemide."

In the distal convoluted tubule (DCT), Na^+ is reabsorbed by the Na^+-Cl^- cotransporter (NCCT), which is inhibited by thiazides. Disorders involving this transporter include Gitelman syndrome, caused by inherited loss of function of this transporter. Gitelman syndrome can therefore be conceptualized as "inherited thiazide." The mirror image of Gitelman syndrome is pseudohypoaldosteronism type 2 (PHA2), or Gordon syndrome, in which the underlying genetic causes lead to an overactivity of NCCT.

In the collecting duct (CD), Na^+ reabsorption is facilitated by the epithelial sodium channel (ENaC) (Fig. 47.1). Amiloride and triamterene specifically block ENaC. Several inherited disorders affect transport through this channel. Inherited loss of function of ENaC is called *PHA type 1*. Because ENaC is highly regulated by the mineralocorticoid receptor (MR), there are several other disorders that affect ENaC function through dysregulation of the MR. These and other disorders that affect Na^+ transport (Table 47.1) are discussed in the following section.

Water Reabsorption

In the PT, water follows sodium chloride (NaCl, salt) passively through aquaporins, the constitutively open water transport proteins in apical and basolateral tubular cell membranes. In this way Na^+ transport is directly linked to unregulated water reabsorption. The TAL and CD are the segments critical for regulated water reabsorption. The TAL is water impermeable and thus also called the *diluting segment*, because salt transport via NKCC2 dilutes the tubular fluid. This helps establish the interstitial concentration gradient, which drives water reabsorption in the arginine vasopressin (AVP) sensitive parts of the nephron, the late DCT and CD. In this way, sodium transport is linked to regulated water reabsorption. Consequently, patients with Bartter syndrome have impaired urinary concentrating ability, which helps explain the polyuria associated with this disorder.

Final control over water reabsorption is exerted in the CD and regulated by AVP. In the absence of AVP, the apical membranes of the epithelial cells in the CD are water impermeable, resulting in water diuresis (Fig. 47.2). Binding of AVP to the AVPR2 receptor in the CD initiates a signaling cascade that results in the insertion of the water channel aquaporin 2 (AQP2) into the apical membrane, allowing water to pass through the epithelial cell layer, following the interstitial concentration gradient, resulting in antidiuresis. Inherited disorders affecting the function of AVPR2 or AQP2 cause either nephrogenic diabetes insipidus

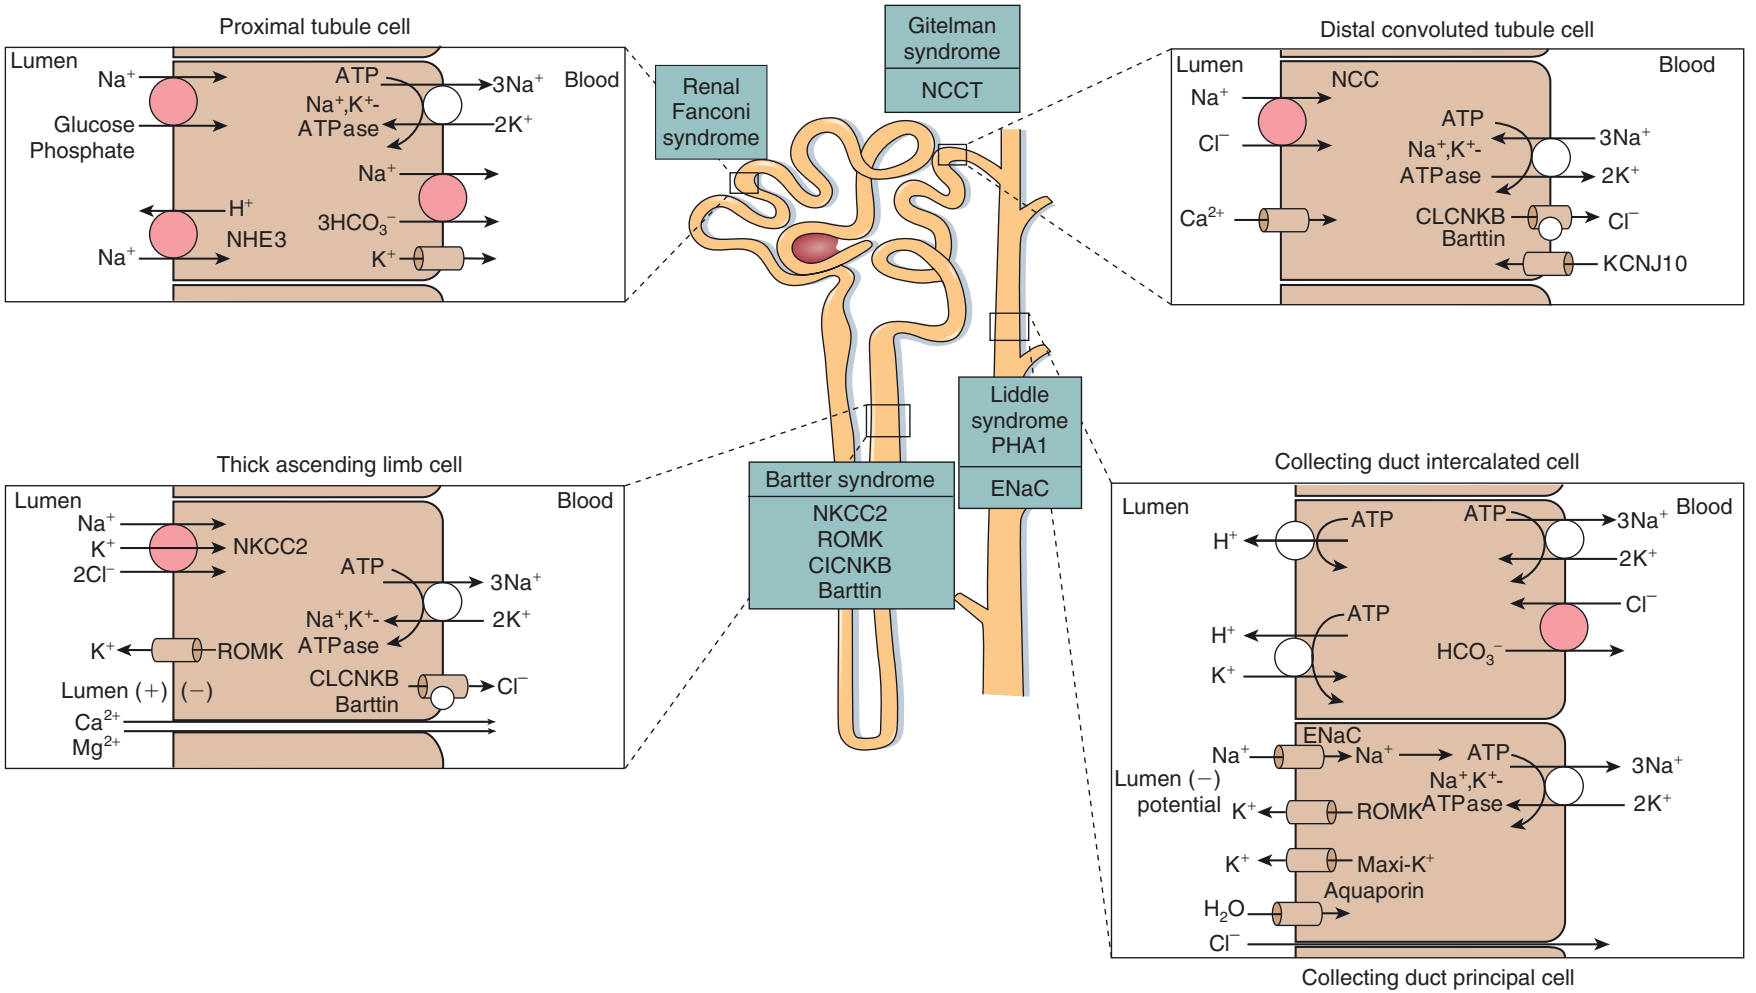

Fig. 47.1 The molecular basis of salt handling along the nephron. The physiological mechanisms of salt handling along the nephron are discussed in more detail in Chapter 2. **Salt transport in the thick ascending limb (TAL) of the loop of Henle.** 0% to 20% of filtered Na is reabsorbed here. The furosemide-sensitive cotransporter Na-K-2Cl-ATPase (NKCC2, mutations of which cause Bartter syndrome type 1 (BS1)) provides Na^+ entry into the epithelial cell. Apical K^+ recycling through the ROMK channel (the cause of BS2) ensures the efficient functioning of NKCC2, establishing a lumen-positive transepithelial voltage that drives paracellular cation reabsorption. Chloride exits through basolateral Cl^- channels, predominantly CLCNKB (the cause of BS3). The β-subunit (barttin, cause of BS4) is necessary for normal functioning of CLCNKB. **Salt transport in the distal convoluted tubule.** 5-10% of filtered Na^+ is reabsorbed here via the thiazide-sensitive Na^+-Cl^- cotransporter (NCCT, the cause of Gitelman syndrome) on the apical side. CLCNKB is expressed here as well as in TAL; therefore mutations in this channel cause BS3 (a TAL disorder), but can phenocopy Gitelman syndrome (a DCT disorder). **Salt transport in principal cell of the collecting duct.** 2-5% of filtered Na^+ is reabsorbed here via the amiloride-sensitive epithelial Na^+ channel (ENaC). Loss-of-function mutations in ENaC cause pseudohypoaldosteronism type 1 (PHA1), gain-of-function mutations cause Liddle syndrome. Na^+ uptake is indirectly coupled to K^+ (through ROMK) and H^+ secretion (through H^+-ATPase in the neighboring intercalated cell). Aldosterone activates the mineralocorticoid receptor, increasing activity of ENaC and Na^+,K^+-ATPase, enhancing Na^+ reabsorption and K^+ and H^+ secretion, resulting in hypokalemic alkalosis. Cortisol is also a ligand for the mineralocorticoid receptor but is normally removed by oxidation by 11β-hydroxysteroid dehydrogenase to cortisone. (With permission from Hoenig MP, Zeidel ML. Homeostasis, the milieu interieur, and the wisdom of the nephron. *Clin J Am Soc Nephrol* 2014;9[7]:1272-1281.)

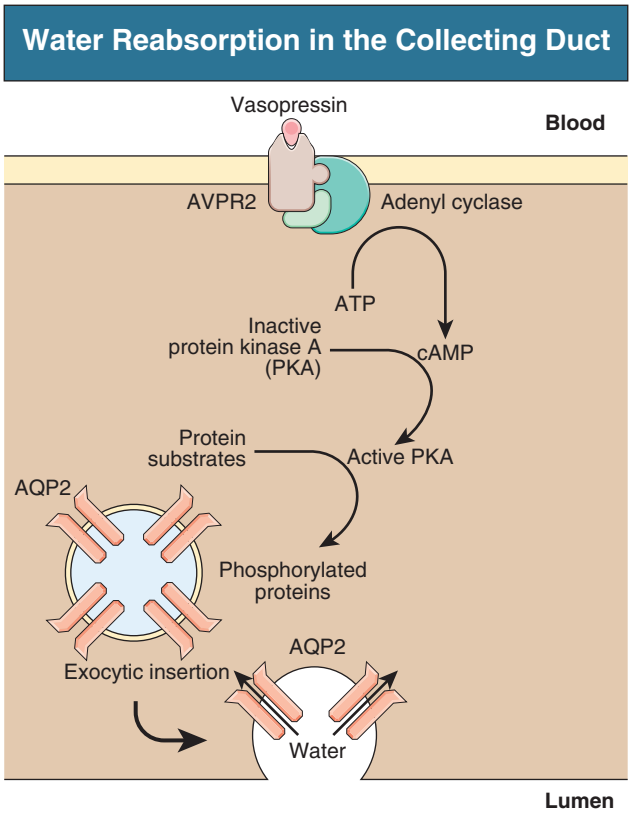

Fig. 47.2 Water reabsorption in the collecting duct. Activation of the basolateral arginine vasopressin type 2 receptor *(AVPR2)* initiates the signaling cascade that ultimately results in insertion of the aquaporin 2 *(AQP2)* water channel in the apical membrane, making it water permeable and thus allowing water reabsorption and urinary concentration. Loss-of-function mutations in AVPR2 cause X-linked nephrogenic diabetes insipidus, whereas gain-of-function mutations cause nephrogenic syndrome of inappropriate antidiuresis. Loss-of-function mutations in AQP2 are the cause of autosomal nephrogenic diabetes insipidus. *ATP,* Adenosine triphosphate; *cAMP,* cyclic adenosine monophosphate.

(NDI) through loss of function or nephrogenic syndrome of inappropriate antidiuresis (NSIAD) through gain of function.

DISORDERS OF SODIUM HANDLING

Based on the biochemical phenotype, four main categories can be distinguished. The causes are summarized in Fig. 47.3. Their diagnostic evaluation and management are summarized in Figs. 47.4 and 47.5.

1. Hypokalemic alkalosis and low-normal BP (Bartter syndrome, Gitelman syndrome, EAST syndrome)
2. Hypokalemic alkalosis and high BP (Liddle syndrome, apparent mineralocorticoid excess, glucocorticoid-remediable hyperaldosteronism, adrenal 17α-hydroxylase deficiency, adrenal 11β-hydroxylase deficiency)
3. Hyperkalemic acidosis and low-normal BP (PHA1, adrenal 21-hydroxylase deficiency, adrenal aldosterone synthase deficiency)
4. Hyperkalemic acidosis and high BP (Gordon syndrome)

Some of the disorders are caused by mutated renal transport proteins (e.g., Gitelman syndrome) or associated regulatory proteins (e.g., Gordon syndrome). In others, the genetic defect resides in the adrenals and the changes in adrenal mineralocorticoids and glucocorticoids create the renal phenotype. All the inherited disorders are rare with estimated incidences of around 1 in 100.000.

CONDITIONS WITH HYPOKALEMIA, METABOLIC ALKALOSIS, AND LOW-NORMAL BLOOD PRESSURE

Bartter Syndrome

Bartter syndrome is a genetically heterogeneous autosomal recessive disorder of salt reabsorption in the TAL.[1]

Pathogenesis

Currently four causative genes have been associated with Bartter syndrome: *NKCC2* for Bartter syndrome type 1 (BS1), *ROMK* (renal outer medullary potassium) for type 2 (BS2), *ClCKNB*, type 3 (BS3), and *BSND* for type 4 (BS4) (see Table 47.1 and Fig. 47.1). In addition, another disorder, familial hypocalcemic hypercalciuria, caused by activating mutations in *CaSR*, encoding the calcium-sensing receptor, can cause Bartter-like electrolyte abnormalities and is thus sometimes referred to as *Bartter type 5*,[2] but will not be discussed here. Although all the genetic defects directly or indirectly impair salt reabsorption through NKCC2, differences between the various forms of Bartter syndrome typically allow correct classification on clinical grounds. A first discriminator is the urine calcium excretion. TAL is an important segment for calcium reabsorption, which occurs passively through paracellular pathways, lined by claudins.[3] The driving force for this is generated by the combined action of NKCC2 and ROMK. Whereas transport via NKCC2 is electroneutral, potassium is recycled back into the tubular lumen via ROMK, establishing a lumen positive transepithelial potential. Consequently, calcium reabsorption in the TAL is impaired in BS1 and BS2, leading to hypercalciuria and nephrocalcinosis, whereas it is typically unaffected in BS3 and BS4. CLCKNB is also expressed in the DCT, so symptoms of BS3 can overlap with Gitelman syndrome. Hypomagnesemia is thus a common feature. Finally, Barttin is also critical for inner ear function, so affected patients have sensorineural deafness in addition to Bartter syndrome.

The initial step of tubuloglomerular feedback (TGF) occurs in the macula densa, which is part of the TAL; reduced Cl^- absorption in the macula densa initiates a signaling cascade that includes enhanced prostaglandin E2 (PGE2) production with consequent activation of renin and aldosterone.[4] Because Cl^- absorption is impaired in Bartter syndrome, these patients have impaired TGF with elevated levels of PGE2, renin, and aldosterone, and it is the latter that mediates the typical electrolyte profile of hypokalemic metabolic alkalosis.[5]

Clinical Manifestations

Bartter syndrome from mutations in NKCC2, ROMK, or Barttin usually has earlier onset than that caused by mutations of CLC-Kb, mostly during pregnancy (*antenatal* Bartter syndrome).[6,7] In contrast, the later onset form is often called *classic* Bartter syndrome, reflecting the phenotype originally described by Bartter and colleagues.[8]

The clinical features of antenatal Bartter syndrome include polyuria, hypokalemic metabolic alkalosis, and high urinary chloride excretion in a newborn with vomiting and failure to thrive and a history of polyhydramnios and premature delivery. A prenatal diagnosis of Bartter syndrome may be made by demonstration of high Cl^- concentrations in amniotic fluid, if genetic testing is not informative. BS2, secondary to ROMK mutations, can have a different phenotype in the first days of life, because ROMK is not only involved in salt reabsorption in the TAL, but also mediates potassium secretion in the CD. Consequently, patients with BS2 often present initially with hyperkalemia and hyponatremia, leading to an erroneous diagnosis of PHA1.[9] Over the course of the first few days to weeks, serum potassium levels decrease, presumably as a result of the expression of other potassium channels in the

TABLE 47.1 Inherited Single-Gene Defects of Sodium and Water Handling

CD that compensate for the loss of ROMK function. Hypercalciuria and nephrocalcinosis are typical features of BS1 and BS2.[3]

Classic Bartter syndrome is typically associated with mutations in *CLCNKB* (BS3). These patients present mostly in the first decade of life with vomiting, polyuria, recurrent episodes of dehydration, and hypokalemic metabolic alkalosis. Electrolyte abnormalities are typically more severe than in antenatal Bartter syndrome.[6,7] Moreover, hypomagnesemia with renal Mg^{2+} wasting is common. This also may explain why some patients with BS3 can phenotypically mimic Gitelman syndrome.[10]

BS4 is characterized also by sensorineural deafness. Clinically, it manifests as a severe form of BS3, sometimes with extreme electrolyte abnormalities.[5] Presumably, in BS3, the closely related chloride channel CLC-Ka can compensate for the loss of CLC-Kb function in the inner ear and to some degree in the kidney. However, both channels require Barttin as a subunit, so that loss-of-function mutations in Barttin are functionally equivalent to loss of both chloride channels.[11] Patients with BS4 typically experience progressive chronic kidney disease, although a milder phenotype has been reported, presumably due to mutations with residual Barttin function.[12]

Diagnosis and Differential Diagnosis

The key features of Bartter syndrome are hypokalemic, hypochloremic alkalosis with evidence of renal Cl^- and K^+ wasting and low or normal BP. In syndromes of chronic severe hypokalemia with metabolic alkalosis, the differential diagnosis is facilitated by evaluating the BP and urinary chloride concentration.

Hypertension in the context of hypokalemic alkalosis indicates a primary activation of salt reabsorption in the CD, such as from pathologic activation of the MR (e.g., hyperaldosteronism) or the sodium channel ENaC. Bartter syndrome, however, is associated with a normal or low-normal BP. The clinical picture can be mimicked by extrarenal loss of sodium, for example, in diarrhea, vomiting, or burns and is characterized by very low Cl^- excretion in the urine, (FECl <0.5%). Congenital chloride diarrhea can be misdiagnosed as BS because the biochemical picture in the blood is identical and the large and often clear-appearing stool volume is misinterpreted as urine, especially in female babies in diapers.[13]

Analysis of urinary Ca^{2+} excretion can help distinguish between the various forms of BS and Gitelman syndrome (Table 47.2). Genotyping is recommended to confirm the final diagnosis.

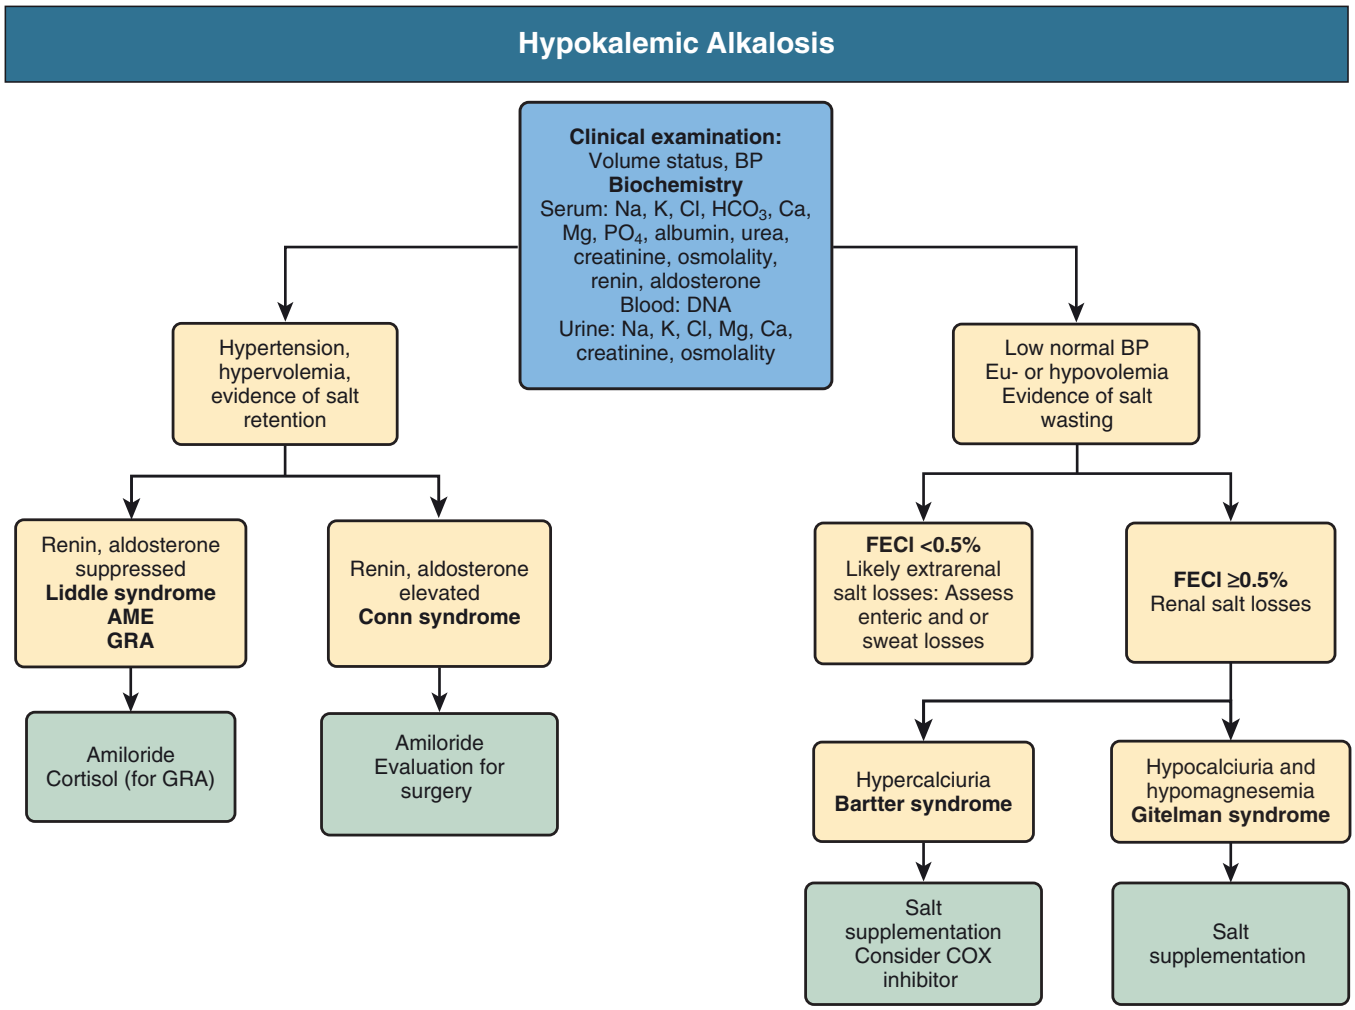

Fig. 47.4 Diagnostic and management algorithm for inherited conditions causing hypokalemic alkalosis. *AME,* Apparent mineralocorticoid excess; *BP,* blood pressure; *COX,* cyclooxygenase; *GRA,* glucocorticoid-remediable aldosteronism; *FECl,* fractional excretion of chloride.

Treatment

Patients with neonatal Bartter syndrome have marked fluid and electrolyte disturbances that need to be corrected carefully. Saline infusion may be required in the neonatal period. Potassium chloride supplementation is commonly provided. Addition of spironolactone or amiloride improves hypokalemia and alkalosis but worsens salt wasting and thus increases the risk for hypovolemic shock. If used, sufficient salt supplementation is critical.[5]

A key problem in renal wasting disorders is that supplementation initially results in increased urinary losses. After supplementation, serum levels transiently rise, leading to an increased concentration in the glomerular filtrate with consequent loss in the urine and decreasing serum levels. Monitoring the efficacy of supplementation thus depends strongly on the timing of the blood sample. Although cardiac arrhythmias may occur with marked hypokalemia,[14] the dramatic swings in serum potassium associated with large doses of intermittent supplementation may be more harmful than consistent levels below the normal range. Moreover, large doses of supplementation may cause gastrointestinal disturbances, such as ulcers and diarrhea, that can worsen the electrolyte profile. Thus smaller but more frequent administration of electrolyte supplements may be better tolerated and safer.

A key component of treatment, especially for antenatal BS, is prostaglandin synthesis inhibition through cyclooxygenase (COX) inhibitors, such as indomethacin (1 to 3 mg/kg/24 h). Selective COX-2 inhibitors may provide similar efficacy but with less potential toxicity.[15] COX inhibitors act by interfering with the pathologic TGF in BS and by decreasing delivery of Na^+ and Cl^- to the distal nephron.[5] Treatment results in reduction of polyuria and polydipsia, improved growth and activity, and better control of plasma electrolytes. Serum levels of renin and aldosterone often decrease to the normal range.

Outcome

Dramatic complications, such as intracranial hemorrhage and bronchopulmonary dysplasia, are typically seen in patients with antenatal BS and are a consequence of extreme prematurity. There is a spectrum of severity; the electrolyte and acid-base imbalance itself can be severe, with complications such as arrhythmias, paralysis, rhabdomyolysis, and apnea, yet others may have few symptoms, and disease in some patients is diagnosed incidentally later in life when a blood test is obtained for an unrelated reason. Importantly, even patients with more severe electrolyte imbalance usually improve clinically with appropriate therapy. Progressive chronic kidney disease can be a complication of prematurity, but also can be seen in patients with BS3 born at term and is common in BS4. The reasons for this are unclear.

Gitelman Syndrome

Gitelman syndrome is an autosomal recessive condition with a prevalence of estimated at approximately 1 in 40,000 in White populations, making it arguably the most frequently inherited tubulopathy.[16]

Pathogenesis

The similarity between the features of Gitelman syndrome and those caused by thiazide administration originally suggested that the defect might be in the distal convoluted tubule, which was confirmed when the condition was shown to be due to inactivating mutations in *SLC12A3*, the gene encoding the thiazide-sensitive transporter NCCT (see Fig. 47.1).[17] Loss of NCCT function results in Na^+ and Cl^- wasting from this segment, leading to hypovolemia with secondary activation of the renin-aldosterone system. As in Bartter syndrome, the resulting increase in Na^+ reabsorption in the CD is counterbalanced by K^+ and H^+ excretion, causing hypokalemic alkalosis.

The hypocalciuria may be caused by enhanced proximal tubular calcium reabsorption, secondary to plasma volume contraction.[18] The renal magnesium wasting is caused by downregulation of the epithelial magnesium channel TRPM6 in the distal convoluted tubules.

Clinical Manifestations and Diagnosis

The severity of symptoms varies widely. More severely affected patients report a decreased quality of life with generalized muscle weakness, inability to work for extended periods, salt craving, and polyuria.[19] Cardiac disturbances, muscle cramps, and tetany are only exceptionally present. Chondrocalcinosis and sclerochoroidal calcifications can occur later in life.[16] Laboratory evaluation shows hypokalemic hypochloremic metabolic alkalosis with hypocalciuria and hypomagnesemia with elevated

TABLE 47.3 Features of Liddle Syndrome, Apparent Mineralocorticoid Excess, and Glucocorticoid-Remediable Aldosteronism

Feature	Liddle Syndrome	AME	GRA
Inheritance	Autosomal dominant	Autosomal recessive	Autosomal dominant
Chief features	Significant hypertension, polyuria, growth retardation	Low birth weight, early-onset hypertension, polyuria, growth retardation	Significant hypertension, hemorrhagic stroke
Plasma aldosterone	Reduced	Reduced	Elevated
Plasma renin activity	Reduced	Reduced	Reduced
Urinary mineralocorticoid metabolites	Normal	Elevated ratios of THF + allo-THF to THE; free cortisol to cortisone	Elevated cortisol C-18 oxidation products
Response of the Hypertension to:			
Glucocorticoids	No	Satisfactory	Satisfactory
Triamterene	Satisfactory	Satisfactory	Satisfactory
Spironolactone	No	Satisfactory	Satisfactory

These syndromes are all characterized by hypokalemia, metabolic alkalosis, and hypertension.
AME, Apparent mineralocorticoid excess; *GRA,* glucocorticoid-remediable aldosteronism; *THE,* tetrahydrocortisone; *THF,* tetrahydrocortisol.

urinary Cl^-, K^+ and Mg^{2+} excretion. BP will usually be in the low-normal range. The differential diagnosis includes Bartter syndrome, especially BS3, HNF1B-related disease, and EAST syndrome, as well as acquired disorders, such as thiazide abuse and Sjögren syndrome.[16] Genotyping should be performed to confirm the diagnosis.

Treatment

Gitelman syndrome is primarily a salt-wasting disorder, and treatment consists of a liberal salt intake, if not pharmacologic supplementation. K^+ and Mg^{2+} supplements are usually given to improve muscle weakness or cramps. However, dosing may be limited by diarrhea and abdominal discomfort, and values in the normal range are typically not achieved. In exceptional cases of severe symptoms, parenteral Mg^{2+} has been infused. COX inhibitors are usually not helpful. K^+-sparing diuretics may improve the biochemistry but compound the salt wasting and should be used carefully.

The long-term prognosis for cardiac and renal function as well as for general health is good, although some patients do complain about markedly impaired quality of life. There is no clear association between severity of the electrolyte imbalance and symptoms, which complicates adjustment of treatment.

EAST Syndrome

EAST (also called SESAMe) syndrome is characterized by the cardinal manifestation of *e*pilepsy, *a*taxia, *s*ensorineural deafness and *t*ubulopathy.[20,21] It is due to mutations in the basolateral K-channel KCNJ10. The tubulopathy is identical to Gitelman syndrome. Treatment is symptomatic.

CONDITIONS WITH HYPOKALEMIA, METABOLIC ALKALOSIS, AND HYPERTENSION

Conditions with hypokalemia, metabolic alkalosis, and hypertension are caused by primary activation of the MR or its downstream effector, the epithelial Na^+ channel ENaC.

Liddle Syndrome

Liddle syndrome is an autosomal dominant disorder caused by gain-of-function mutations in ENaC.[22] Consequently, the enhanced Na^+ reabsorption through ENaC is independent of MR activation and renin and aldosterone levels are suppressed, and there is no response to MR blockers, such as spironolactone or eplerenone. However, triamterene and amiloride, which are blockers of ENaC, correct hypertension, renal K^+ loss, and hypokalemia.[23]

Pathogenesis

Liddle syndrome is caused by mutations of the β (SCNN1B) or γ (SCNN1G) subunit of ENaC. The majority of patients carry a mutation that impairs retrieval of the channel from the membrane, leading to enhanced ENaC activity.[24]

Clinical Manifestations and Diagnosis

Liddle syndrome is a rare disorder of hypertension that typically presents in teenage children with hypokalemic metabolic alkalosis and low blood levels of renin and aldosterone. However, onset as early as the newborn period has been described.

This condition is easily distinguished from primary hyperaldosteronism or renal artery stenosis by the finding of low renin and aldosterone levels. Other conditions with similar phenotype include apparent mineralocorticoid excess, and glucocorticoid-remediable aldosteronism (Table 47.3), as well as 11β-hydroxylase (steroid 11β-monooxygenase) or 17α-hydroxylase (steroid 17α-monooxygenase) deficiency and can be separated by urinary steroid profiles and genetic testing. An activating mutation of the MR with exacerbation of hypertension in pregnancy has also been reported and should be differentiated.[25]

Treatment

Therapy consists of ENaC blockade with triamterene or amiloride, which usually normalizes the BP and K^+ levels. Because the pathogenetic disorder is not correctable with age, lifelong therapy is required. Some patients require additional antihypertensives, presumably because of fixed microvascular injury caused by the hypertension. Among those who develop end-stage renal disease from uncontrolled hypertension, there is no recurrence of the disease after transplantation because the graft does not contain the genetic alteration.

Apparent Mineralocorticoid Excess

Pathogenesis

Apparent mineralocorticoid excess (AME) is an autosomal recessive condition resulting from deficiency of the type II (renal and placental) isoform of the enzyme 11β-hydroxysteroid dehydrogenase. Clinical features of AME are similar to those of Liddle syndrome, but symptoms typically present earlier (in infancy) and more severely.

Normally, aldosterone is the principal ligand for the MR and in this way increases synthesis of various proteins, chiefly Na^+,K^+-ATPase on the basolateral surface and ENaC on the apical surface. These proteins facilitate the increased Na^+ reabsorption and K^+ secretion in the aldosterone-sensitive distal nephron (see Fig. 47.1). MR is not specific for aldosterone, but can also bind cortisol, which circulates in blood at roughly 1000-fold higher concentration than aldosterone. To provide specificity, the MR is protected by the activity of the 11β-hydroxysteroid dehydrogenase type 2 (HSD11B2), which is highly expressed in the distal nephron and metabolizes cortisol to cortisone, which lacks MR binding ability.

Loss-of-function mutations in HSD11B2 thus cause AME by allowing nonspecific activation of MR by cortisol.[26] Carbenoxolone and glycyrrhizic acid (found in licorice compounds) are potent inhibitors of this enzyme, so licorice consumption can lead to an acquired form of AME. HSD11B2 is also expressed in the placenta, likely explaining the intrauterine growth restriction typically seen in patients with AME.

Clinical Manifestations and Diagnosis

Apparent mineralocorticoid excess is characterized by early onset of severe hypertension in childhood, hypokalemia, metabolic alkalosis, with suppressed plasma levels of renin and aldosterone, and increased metabolites of cortisol in the urine. A history of low birth weight and subsequent failure to thrive is typical.[27] Untreated, stroke and other complications of severe hypertension are seen even during childhood. Milder clinical manifestations can be seen with mutations that retain some functionality of the enzyme. Polyuria resulting from a urinary concentrating defect is another typical feature and likely linked to the electrolyte abnormalities in blood and urine because it improves after treatment of AME.[28]

The diagnosis of AME should be prompted by the electrolyte profile and early-onset hypertension with suppressed renin and aldosterone levels. A urinary steroid profile is diagnostic by showing elevated urinary levels of hydrogenated metabolites of cortisol (tetrahydrocortisol plus allotetrahydrocortisol) compared with cortisone (tetrahydrocortisone). The ratio of urinary free cortisol to cortisone is also increased. Genetic testing confirms the diagnosis.

Treatment

Blockers of MR (e.g., spironolactone or eplerenone) or its main effector ENaC (e.g., amiloride or triamterene) provide specific treatment. However, because MR blockers are competitive antagonists and in AME compete against the 1000-fold higher cortisol concentrations (compared with aldosterone), large doses are needed and ENaC blockers (or a combination of both) are usually more effective in clinical practice.

Glucocorticoid-Remediable Aldosteronism

Glucocorticoid-remediable aldosteronism (GRA) is an autosomal dominant condition. Patients present with features typical of primary hyperaldosteronism: hypertension, suppressed plasma renin activity, and hypokalemia. Unlike primary hyperaldosteronism (secondary to aldosterone-producing adrenal adenoma), hypersecretion of aldosterone in GRA can be reversed by the administration of corticosteroids. Affected individuals have early-onset hypertension. There is a high prevalence of hemorrhagic stroke, largely from ruptured intracranial aneurysms.

Pathogenesis

Patients with GRA have adrenocorticotropic hormone (ACTH)-sensitive aldosterone production occurring in the zona fasciculata of the adrenal gland, which is normally responsible only for cortisol synthesis. The two isoenzymes of 11β-hydroxylase involved in the biosynthesis of aldosterone and cortisol are steroid 11β-hydroxylase (CYP11B1) and aldosterone synthase (CYP11B2), respectively. The genes for these isoenzymes are located close to each other on the long arm of chromosome 8. Unequal meiotic crossovers may produce hybrid genes by fusion of the promoter end of *CYP11B1* with the coding sequence of *CYP11B2,* so that *CYP11B2* encoding aldosterone synthase is inappropriately regulated by ACTH.[29]

Diagnosis

Patients with GRA are often misdiagnosed as having primary hypertension. Hypertensive patients with early-onset hypertension, early cerebral hemorrhage (<40 years), hypokalemia before or after diuretic therapy, and refractoriness to standard antihypertensive medication are candidates for GRA testing, especially in the presence of a family history of hypertension or early death. Similar to other genetic forms of hypertension (Liddle syndrome, AME, Gordon syndrome), plasma renin activity is low. Aldosterone levels are normal to high and do not change with posture but are suppressed by dexamethasone.

A urinary steroid profile will show the biochemical hallmark of GRA increased levels of the so-called hybrid steroids (18-hydroxycortisol and 18-oxocortisol). Genetic testing confirms the diagnosis.

Treatment

Treatment with low-dose corticosteroid is effective in patients with GRA because it suppresses ACTH and thus the aberrant ACTH-mediated aldosterone production in the zona fasciculata. Typically, dexamethasone 0.125 to 0.25 mg or prednisolone 2.5 to 5 mg is administered at bedtime. Therapeutic goals are normotension and normalization of biochemical markers (urinary 18-oxosteroid, serum aldosterone). MR antagonists (spironolactone, eplerenone) and ENaC antagonists are also useful treatments.

The contrasting features of Liddle syndrome, AME, and GRA are summarized in Table 47.3.

Adrenal Enzymatic Disorders

Inherited deficiency of 11β- or 17α-hydroxylase also causes mineralocorticoid excess with hypertension and hypokalemic metabolic alkalosis. These disorders are not discussed here. Hypertension is caused by excessive mineralocorticoid production. Again, a urinary steroid profile helps establish the diagnosis, which can be confirmed by genetic testing.

CONDITIONS WITH HYPONATREMIA, HYPERKALEMIA, METABOLIC ACIDOSIS, AND NORMAL/LOW BLOOD PRESSURE

Conditions with hyponatremia, hyperkalemia, metabolic acidosis, and low-normal BP have features of mineralocorticoid deficiency either because of a synthetic defect or because of end-organ resistance.

Pseudohypoaldosteronism

Pseudohypoaldosteronism (PHA) is a state of renal tubular unresponsiveness to the action of aldosterone. Symptoms start in infancy with marked salt wasting and failure to thrive.

PHA1 exists in an autosomal dominant (adPHA1) and an autosomal recessive form (arPHA1). The adPHA1 is due to inactivating mutations in the MR *(NR3C2)*.[30] In contrast, arPHA1 is due to inactivating mutations of the α, β, or γ subunits of ENaC.[31]

Diagnosis

PHA1 presents typically in the first few days of life with weight loss, hypovolemia, and poor feeding. The typical electrolyte profile shows

mild to moderate hyponatremia, often severe (arPHA1) hyperkalemia, and metabolic acidosis. Urinary Na^+ is high, with virtually absent K^+ excretion. Occasionally, patients with BS2 can present similarly (see "Bartter Syndrome"). PHA1 can be distinguished from aldosterone deficiency states, such as congenital adrenal hyperplasia, by the massively elevated aldosterone levels in blood. The diagnosis can be confirmed by genetic testing. An acquired form of PHA1 can be seen with urinary tract obstruction and/or pyelonephritis.

Clinical Features

The clinical manifestations are dominated by the electrolyte abnormalities and hypovolemia, which if untreated can lead to circulatory shock. ENaC is also expressed in the skin and lungs, where it mediates salt reabsorption. Consequently, patients with arPHA1 have increased sweat Na^+ concentration and can develop a miliary rash from blockage of the sweat glands. In addition, patients can have cystic fibrosis–like lung disease secondary to viscous high-salt containing bronchial secretions.

Treatment

Initial treatment consists of volume resuscitation with 0.9% saline. Without treatment, PHA1, especially arPHA1, can be lethal. Maintenance treatment consists of NaCl and $NaHCO_3$ supplementation adjusted to maintain euvolemia, normonatremia, and acid-base homoeostasis. In arPHA1, Na^+ exchange resins can help stabilize patients by providing a steady source of Na^+ and an alternative means for K^+ excretion. Patients with adPHA1 typically improve spontaneously over the first few months of life and maintain normal serum electrolytes without supplementation, although may have increased renin-aldosterone levels.[32]

Aldosterone Biosynthetic Defects

Patients with defects in aldosterone biosynthesis show salt wasting with hyponatremia, hyperkalemia, hypovolemia, and elevated plasma renin activity, yet obviously low or absent aldosterone levels. These conditions are not discussed here.

A CONDITION WITH HYPERKALEMIA, METABOLIC ACIDOSIS, AND HYPERTENSION

Pseudohypoaldosteronism Type 2 (Gordon Syndrome)

The clinical mirror image of Gitelman syndrome, Gordon syndrome is an autosomal dominant condition characterized by hypertension, hyperkalemia, and mild hyperchloremic metabolic acidosis.

Pathogenesis

Initially, two genes were identified as responsible for PHA2.[33] These genes encode two members of the with-no-lysine kinase family: WNK1 and WNK4, both expressed in the convoluted tubule and the CDs. WNK4 acts as a negative regulator of thiazide-sensitive NCCT function reducing cell surface expression of NCCT. WNK4 also downregulates ROMK and epithelial chloride flux. Mutations in *WNK4* are missense and cause loss of function, so that WNK4 loses its ability to suppress NCCT and ROMK, leading to Na^+ and K^+ retention. WNK1 prevents WNK4 from interacting with NCCT. Mutations in *WNK1* are intronic deletions that increase WNK1 expression. Subsequently, two further causative genes were identified: *CUL3 and KLHL3.*[34] Their encoded proteins form a ubiquitin-ligase complex that regulates WNK1 and 4 abundance. Mutations in KLHL3 also can be autosomal recessive. Moreover, mutations in CUL3 are frequently *de novo*, so the absence of a family history does not exclude the diagnosis. An acquired form of PHA2 may occur as a side effect of calcineurin inhibitors, especially tacrolimus, which affect WNK activity.[35]

Clinical Manifestations and Diagnosis

Hyperkalemia may be present from birth, but as in GRA, hypertension may not be manifested until later in life. Patients show hyperchloremic metabolic acidosis; plasma renin and aldosterone are reduced to variable degrees. Patients with CUL3 mutations appear to be phenotypically more seriously affected with higher serum K^+ levels, more pronounced acidosis and hypertension and consequently younger age at diagnosis.[34] In addition, most patients with CUL3 mutations have failure to thrive and growth impairment.

Treatment

Thiazides are able to completely correct the clinical and biochemical features of Gordon syndrome. Establishing the diagnosis is thus critical for targeted and effective treatment.

INHERITED DISORDERS OF WATER HANDLING

Congenital Nephrogenic Diabetes Insipidus

Congenital nephrogenic diabetes insipidus (NDI) is a rare polyuric disorder characterized by the failure to concentrate urine despite elevated levels of vasopressin. Congenital NDI is caused by mutations in key proteins controlling water reabsorption in the CD. Acquired DI is much more common, and its diagnosis and management are discussed in Chapter 8.

Pathogenesis

More than 90% of patients have X-linked recessive NDI with mutations in *AVPR2,* the gene for the arginine vasopressin type 2 receptor (AVPR2). Consequently, most patients are male, although female carriers can have a urinary concentrating defect of variable severity, presumably resulting from non-random X-inactivation.[36] AVPR2 is expressed predominantly in the kidney, where it mediates urinary concentration, but to some degree also in the vasculature, where it mediates vasodilatation and release of von Willebrand factor.[37] In less than 10% of the families, congenital NDI has an autosomal recessive inheritance with mutations in *AQP2,* the gene encoding the water channel AQP2, the final effector protein in the vasopressin-initiated signaling cascade. A rare autosomal dominant form of NDI, resulting from dominant negative mutation in *AQP2,* has also been reported. Some inherited diseases, such as Bartter syndrome and AME also can be associated with so-called secondary inherited NDI.[38] The cause of the AQP2 deficiency in these disorders is unclear, but likely related to blood and/or urinary electrolyte abnormalities.

Clinical Features

Manifestations of congenital NDI typically appear within the first weeks to months of life. NDI does not cause polyhydramnios because the osmotic load is cleared by the placenta. Clinical features at presentation are polyuria and failure to thrive, as well as a history of vigorous sucking followed by vomiting.[36] Unrecognized and untreated, the baby can experience repeated episodes of hypernatremic dehydration, with delayed development and cognitive impairment as possible consequences. Cranial computed tomography may occasionally show dystrophic calcification in the basal ganglia and the cerebral cortex in such untreated patients.

Behavioral abnormalities in the form of attention-deficit hyperactivity disorder and impaired school performance are commonly reported and may be secondary to preoccupation with drinking and voiding. An adult with congenital NDI usually drinks and voids about 10 to 12 l/day. Urinary tract dilatation can be seen, especially if there are voiding abnormalities.

Some mutations in either AVPR2 or AQP2 may retain partial functionality of the protein, leading to a phenotype of partial NDI, in which urinary concentration is possible but subnormal. Clinical symptoms

are consequently milder, and the disease may remain undiagnosed throughout life.[39]

Diagnosis

The initial diagnosis of DI rests on the combination of an inappropriately dilute urine in the context of hypernatremic dehydration. Thus simple blood and urine chemistries easily establish the diagnosis, yet most parents of affected infants report repeated visits to hospital because of vomiting when they were sent home and reassured as the assessing medical personnel mistakenly considered the large urine output as inconsistent with severe dehydration, rather than as an important clue to DI. Once the diagnosis of DI has been established, the nephrogenic form can then be proven by the absence of a response in urinary concentration after administration of desamino-8-D-arginine vasopressin (DDAVP), a vasopressin analogue with high specificity for AVPR2. A complication of the DDAVP test is acute hyponatremia in those patients who respond to the drug, yet keep on drinking. The risk for this is low because most patients will simply stop drinking with normalization of serum osmolality, but patients with habitual polydipsia and infants hungry for milk are at risk. Limiting the volume of fluid intake equal to the volume of urine produced during the test is key to avoidance of this complication. Administering DDAVP 0.3 mcg/kg intravenously has the advantage of the shortest observation period (2 hours) combined with certainty of administration. It also allows the distinction between X-linked and autosomal NDI; as patients with autosomal NDI still express AVPR2, they will show the vascular effects in the form of a small drop in BP, an increase in heart rate and release of von Willebrand factor, whereas these changes are absent in patients with AVPR2 mutations. Serum levels of DDAVP with other modes of administration are not sufficient to appreciate these changes.[37] A normal renal response to DDAVP is an increase in urine osmolality to greater than 800 mOsm/kg, whereas patients with NDI show no response and urine osmolality remains below 200 mOsm/kg. An intermediate response may represent partial NDI or simply a washout of the medullary concentration gradient. The latter can be confirmed by achieving a urine osmolality of greater than 800 mOsm/kg after repeated administration of DDAVP. As normal urinary concentrating ability develops only during the first year of life, a response less than 800 (but >300) mOsm/kg may be normal in infants.

Differential Diagnosis

Patients with central DI or habitual polydipsia can be distinguished by a normal response to DDAVP. Patients with secondary inherited NDI typically have other electrolyte abnormalities, such as hypokalemia and hypercalciuria, in addition to other features typical for the primary diagnosis, such as polyhydramnios in Bartter syndrome and hypertension in AME. Onset of polyuria later in childhood or adulthood argues for acquired forms of NDI. Patients with partial NDI represent a diagnostic challenge. Further blood tests and a renal ultrasound can help exclude underlying structural or parenchymal renal disease, such as nephronophthisis or tubulointerstitial or cystic kidney disease. Genetic testing can help confirm the diagnosis.

Treatment

Management of NDI concentrates on reducing polyuria, avoiding episodes of dehydration, and providing sufficient calories to allow normal physical growth and development. A key determinant of overall urine output is the osmotic load, which mainly derives from protein and salt intake. The higher the osmotic load, the more water is required to excrete it. Involvement of a dietician is key (especially in infancy) to minimize osmotic load while ensuring that protein and caloric intake meets the recommended daily intake. A goal of 15 mOsm/kg is typically achievable; consequently, a patient with an average urine osmolality of 100 mOsm/kg would need 150 ml/kg/day to excrete this load.

Thiazide diuretics (e.g., hydrochlorothiazide 1 to 2 mg/kg every 12 hours) are effective in reducing urine output when combined with reduction of salt intake. Thiazides inhibit salt reabsorption in distal convoluted tubules, which leads to mild volume depletion. Hypovolemia stimulates fluid reabsorption in the PTs, thereby diminishing water delivery to the CDs. Combination therapy with amiloride 0.1 to 0.2 mg/kg every 8 to 12 hours, helps control the potential hypokalemia from thiazide treatment and may enhance the antipolyuric effect.

COX inhibitors are typically the most effective drugs in reducing urine volume, at least during infancy, probably by enhancing proximal sodium reabsorption. Indomethacin 1 to 2 mg/kg/day is used most often but may reduce GFR and cause gastrointestinal side effects. Selective COX2 inhibitors, such as celecoxib might be preferable, but their use in NDI has so far not been reported.

Nephrogenic Syndrome of Inappropriate Antidiuresis

NSIAD represents the mirror image to NDI and this clinically is the inherited equivalent to the syndrome of inappropriate antidiuresis (SIADH) (see Chapter 8).

Pathogenesis

NSIAD is due to gain-of-function mutations in AVPR2, leading to constitutive activation of the urinary concentrating mechanism in the CD, irrespective of serum osmolality.[40] The inheritance is X-linked dominant, although males are typically more severely affected.[41]

Clinical Features, Diagnosis, and Treatment

NSIAD is characterized by an inappropriately concentrated urine (>100 mOsm/kg) in the context of hyponatremia and hypoosmolality. In contrast to SIADH, vasopressin levels are suppressed. Genetic testing will confirm the diagnosis. Severely affected patients (typically males) may have recurrent episodes of severe symptomatic hyponatremia, whereas others may have no apparent symptoms. Avoidance of fluid intake, mediated by low serum osmolality, constitutes simple and intuitive treatment and may explain the absence of symptoms in some patients.[39] Fluid restriction is difficult in infancy as fluid and caloric intake is coupled. Increasing the osmotic load (e.g., by urea supplementation) may help symptomatic patients. AVPR2 antagonists (aquaretics) are typically not helpful because there is no vasopressin excess.

SELF-ASSESSMENT QUESTIONS

1. Which of the following conditions is characteristically associated with hypocalciuria?
   A. Bartter syndrome
   B. Liddle syndrome
   C. Gitelman syndrome
   D. Gordon syndrome
2. The treatment of Bartter syndrome may include which of the following? (More than one answer may be correct.)
   A. Amiloride
   B. Prostaglandin synthesis inhibitors
   C. KCl supplementation
   D. NaCl supplementation
   E. All are correct
3. Which of the following is a sign of hypokalemic, hypochloremic metabolic alkalosis?
   A. Aldosterone deficiency
   B. Enhanced Na^+ transport through the epithelial Na^+ channel ENaC in the collecting duct
   C. Pseudohypoaldosteronism type 1
   D. Pseudohypoaldosteronism type 2
4. Which of the following is the best suited maintenance fluid solution in patients with nephrogenic diabetes insipidus needing intravenous fluids?
   A. 0.9% saline
   B. Hartman solution
   C. 5% Dextrose in water
   D. 0.45% saline

Fanconi Syndrome and Other Proximal Tubule Disorders

John W. Foreman

The proximal tubule reabsorbs the majority of several key solutes, including glucose, amino acids, bicarbonate, and phosphate. This chapter describes a number of disorders, mainly heritable, that affect proximal tubule reabsorption. Chapters 10 and 12 discuss familial forms of hyperphosphaturia and renal tubular acidosis (RTA), respectively.

Most nonelectrolyte solutes are reabsorbed in the proximal tubule through specific transport proteins that cotransport them in conjunction with sodium (Fig. 48.1). The driving force for this solute transport is the electrochemical gradient for sodium entry maintained by the enzyme Na^+,K^+-ATPase. Most disorders of isolated solute reabsorption are related to defects in specific transport proteins, whereas disorders affecting multiple solutes, such as Fanconi syndrome, are probably secondary to defects in energy generation, Na^+,K^+-ATPase activity, or dysfunction of cellular organelles involved with membrane protein recycling.

FANCONI SYNDROME

Definition

In the 1930s de Toni, Debré, and coworkers and Fanconi independently described several children with the combination of renal rickets, glycosuria, and hypophosphatemia. Fanconi syndrome now refers to a global dysfunction of the proximal tubule leading to excessive urinary excretion of amino acids, glucose, phosphate, bicarbonate, uric acid, and other solutes handled by this nephron segment. These losses lead to the clinical problems of acidosis, dehydration, electrolyte imbalance, rickets, osteomalacia, and growth failure. Numerous inherited or acquired disorders are associated with Fanconi syndrome (Box 48.1).

Etiology and Pathogenesis

The sequence of events leading to Fanconi syndrome is incompletely defined and probably varies with each cause. Possible mechanisms include widespread abnormality of most or all of the proximal tubule carriers, such as a defect in sodium binding to the carrier or insertion of the carrier into the brush border membrane, "leaky" brush border membrane or tight junction, inhibited or abnormal Na^+,K^+-ATPase pump, or impaired mitochondrial energy generation (see Fig. 48.1). An abnormality in energy generation has been implicated in multiple disorders, including hereditary fructose intolerance, galactosemia, mitochondrial cytopathies, and heavy metal poisoning, as well as in several experimental models of Fanconi syndrome. Abnormal subcellular organelle function, such as the lysosome in cystinosis or the megalin-cubilin endocytic pathway in Dent disease, is also a cause of Fanconi syndrome (Fig. 48.2).

In adults, the most common causes of persistent Fanconi syndrome are an endogenous or exogenous toxin such as a heavy metal, a medication, or dysproteinemia. In children, the most common persistent cause is an inborn error of metabolism, such as cystinosis. Specific causes of Fanconi syndrome are discussed after a general description of the clinical manifestations and treatment of the syndrome.

Clinical Manifestations

Fanconi syndrome gives rise to a number of clinical abnormalities (Box 48.2).

Aminoaciduria

Aminoaciduria is a cardinal feature of Fanconi syndrome. Virtually every amino acid is found in excess in the urine, thus the term *generalized aminoaciduria.* However, there are no clinical consequences because the losses are trivial (0.5 to 1 g/day) in relation to dietary intake.

Glycosuria

Glycosuria in the absence of hyperglycemia secondary to proximal tubule dysfunction is another of the cardinal features of Fanconi syndrome and results from impaired tubular reabsorption of glucose. It is often one of the first diagnostic clues (Fig. 48.3). As with aminoaciduria, glycosuria rarely causes symptoms such as weight loss or hypoglycemia.

Hypophosphatemia

Hypophosphatemia from impaired phosphate reabsorption is common in Fanconi syndrome. Tubular phosphate handling can be assessed by measuring the tubular reabsorption of phosphate (TRP) which is normally greater than 80% by the following equation:

$$TRP = 1 - (U_p \times P_c / U_c \times P_p) \times 100\%$$

where U_p, P_p, U_c, and P_c are the urinary and serum phosphate and creatinine concentrations, respectively. Subtle changes in phosphate reabsorption can be assessed by measuring the maximum phosphate reabsorption in relation to the glomerular filtration rate (TmP/GFR) on fasting urine and blood samples, as shown in Fig. 10.15. Elevated parathyroid hormone (PTH) and low vitamin D levels also may play a role in the phosphaturia of Fanconi syndrome, although these hormonal abnormalities are not always present. A few patients have impaired conversion of 25-hydroxyvitamin D to 1,25-hydroxyvitamin D; metabolic acidosis, another feature of Fanconi syndrome, also may impair this conversion. Another mechanism for the hypophosphatemia is impairment of the megalin-dependent reabsorption and degradation of filtered PTH.[1] Unabsorbed PTH then binds to receptors in more distal portions of the proximal tubule, leading to increased endocytosis of apical phosphate transporters and increased phosphaturia. The hypophosphatemia, especially if accompanied by hyperparathyroidism and

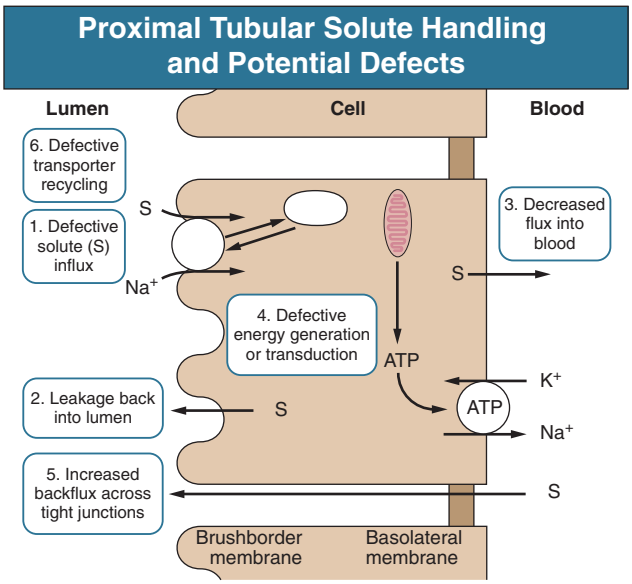

Fig. 48.1 Defects and potential defects in proximal tubular solute handling. Solute uptake by the brush border membrane from the lumen is coupled to Na^+ influx. The favorable electrochemical driving force for luminal Na^+ is maintained by the Na^+,K^+-ATPase pump. Transported solute is then either used by the cell or returned to the blood across the basolateral membrane. Fanconi syndrome could arise because of a defect in one of six areas as shown. *ATP,* Adenosine triphosphate.

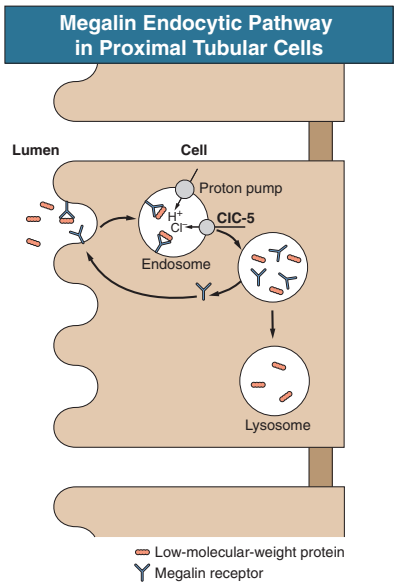

Fig. 48.2 Megalin -cubilin endocytic pathway in proximal tubular cells. Low-molecular-weight proteins in the luminal fluid bind to the megalin-cubilin complex and are endocytosed. The recycling of megalin and further catabolism of these proteins depend on acidification of the vesicle by a proton pump. The *ClC-5* chloride channel provides an electrical shunt for efficient functioning of the proton pump. This endocytosis pathway plays a role in membrane transporter recycling, and disruption of this pathway interferes with absorption of other luminal solutes.

BOX 48.1 Causes of Fanconi Syndrome

Inherited Causes

- Cystinosis
- Galactosemia
- Hereditary fructose intolerance
- Tyrosinemia
- Wilson disease
- Lowe syndrome
- Dent disease
- Glycogenosis
- Mitochondrial cytopathies
- Idiopathic

Acquired Causes*

- Drugs: *Cisplatin, ifosfamide, tenofovir, cidofovir, adefovir,* didanosine, gentamicin, azathioprine, valproic acid (sodium valproate), suramin, streptozocin (streptozotocin), ranitidine
- Dysproteinemias: *Multiple myeloma, Sjögren syndrome, light-chain proteinuria, amyloidosis*
- Heavy metal poisoning: Lead, cadmium
- Other poisonings: Chinese herbal medicine, glue sniffing
- Other: Nephrotic syndrome, renal transplantation, acute tubular necrosis

*Italics indicates more common causes.

BOX 48.2 Features of Fanconi Syndrome

Metabolic Abnormalities

- Glycosuria
- Hyperaminoaciduria
- Hypophosphatemia
- Acidosis
- Hypokalemia
- Hypouricemia
- Hypocarnitinemia

Clinical Features

- Rickets, osteomalacia
- Growth retardation
- Polyuria
- Dehydration
- Proteinuria

low 1,25-hydroxyvitamin D levels, often leads to significant bone disease, manifesting with pain, fractures, rickets, or growth failure.

Natriuresis and Kaliuresis

Natriuresis and kaliuresis are common in Fanconi syndrome and can give rise to significant and even life-threatening problems. The decreased proximal reabsorption of sodium leads to increased potassium excretion secondary to increased distal delivery of sodium and activation of the renin-aldosterone system from hypovolemia. In some cases, sodium and potassium losses are so great that metabolic alkalosis results, simulating Bartter syndrome despite the lowered bicarbonate threshold.

Hyperchloremic Metabolic Acidosis

Hyperchloremic metabolic acidosis, another feature of Fanconi syndrome, is a result of impaired bicarbonate reabsorption by the proximal tubule (proximal or type 2 RTA; see Chapter 12). This impaired reabsorption can lead to the loss of more than 30% of the normal filtered load of bicarbonate. As the serum bicarbonate concentration ($[HCO_3^-]$) falls, the filtered load falls, and excretion drops such that the serum $[HCO_3^-]$ usually remains between 12 and 18 mmol/l. On occasion, there is an associated defect in distal acidification, usually in association with long-standing hypokalemia or nephrocalcinosis. Ammoniagenesis is usually normal or increased because of the hypokalemia and acidosis, unless there is an associated impairment in GFR.

Polyuria and Polydipsia

Polyuria, polydipsia, and frequent bouts of severe dehydration are common symptoms in young patients with Fanconi syndrome. The polyuria is mainly related to the osmotic diuresis from the excessive

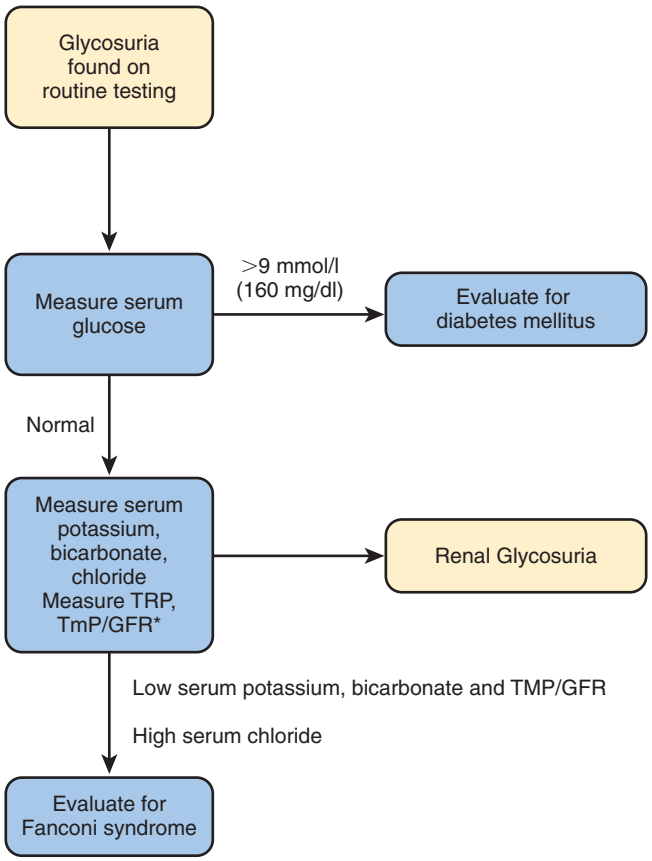

Fig. 48.3 Evaluation of glycosuria. *GFR,* Glomerular filtration rate; *TmP,* tubular maximum reabsorptive capacity; *TRP,* tubular reabsorption of phosphate.

urinary solute losses; but some patients have an associated concentrating defect, especially those with prolonged hypokalemia.

Growth Retardation

Growth retardation in children with Fanconi syndrome is multifactorial. Hypophosphatemia, disordered vitamin D metabolism, and acidosis contribute to growth failure, as do chronic hypokalemia and extracellular volume contraction. Glycosuria and aminoaciduria probably do not play a role. However, even with correction of all these metabolic abnormalities, most patients fail to grow, especially those with cystinosis.

Hypouricemia

Hypouricemia, caused by impairment in renal handling of uric acid, is often present in Fanconi syndrome, especially in adults. Urolithiasis from the uricosuria only rarely has been reported, probably because the urine flow and pH are increased, inhibiting uric acid crystallization.

Proteinuria

Proteinuria is usually minimal, except when Fanconi syndrome develops in association with the nephrotic syndrome. Typically, only low-molecular-weight proteins (<30,000 d) are excreted, such as vitamin D and A binding proteins, enzymes, immunoglobulin light chains, and hormones.

Treatment of Fanconi Syndrome

Therapy should be directed at the underlying causes of Fanconi syndrome when possible (see later discussion). This includes avoidance of the offending nutrient in galactosemia, hereditary fructose intolerance, or tyrosinemia; penicillamine or other copper chelators for treatment of Wilson disease; or chelation therapy for treatment of heavy metal intoxication. In these patients, resolution of Fanconi syndrome usually is complete.

In all patients with Fanconi syndrome, therapy is also directed at the biochemical abnormalities secondary to the renal solute losses and the bone disease often present in these patients. The proximal RTA (type 2 RTA) usually requires large doses of alkali for correction. Some patients benefit from hydrochlorothiazide to minimize the volume expansion associated with these large doses of alkali. Potassium supplementation usually is also needed, especially if there is significant RTA. If given in combination with a metabolizable anion, such as potassium citrate, lactate, or acetate, these supplements will correct not only the hypokalemia but also the acidosis. A few patients will require sodium supplementation along with potassium, and even fewer will require sodium chloride supplementation (especially those who have alkalosis as a result of volume contraction from large urinary NaCl losses). Magnesium supplementation may be required. Adequate fluid intake is essential. Correction of hypokalemia and its effect on the concentrating ability of the distal tubule may lessen the polyuria.

Bone disease is multifactorial, including urinary loss of vitamin D binding protein and vitamin D, decreased synthesis of calcitriol in some patients, hypercalciuria, chronic acidosis, and hypophosphatemia, which is the major factor. Hypophosphatemia should be treated with 1 to 3 g/day of oral phosphate with the goal of normalizing serum phosphate levels. Many patients with Fanconi syndrome will require supplemental vitamin D for adequate treatment of the rickets and osteomalacia. It is unclear whether standard vitamin D (calciferol [ergocalciferol]) or a vitamin D metabolite is better for supplementation, but most clinicians use a vitamin D metabolite, such as 1,25-dihydroxycholecalciferol (calcitriol). These metabolites obviate the concern of inadequate vitamin D hydroxylation by the proximal tubule mitochondria and reduce the risk for prolonged hypercalcemia because of their shorter half-life. Vitamin D therapy will also improve the hypophosphatemia and lessen the risk for hyperparathyroidism. Supplemental calcium is indicated in those with hypocalcemia after supplemental vitamin D is started. Hyperaminoaciduria, glycosuria, proteinuria, and hyperuricosuria usually do not lead to clinical difficulties and do not require specific treatment. Carnitine supplementation, to compensate for the urinary losses, may improve muscle function and lipid profiles, but the evidence is inconsistent.

INHERITED CAUSES OF FANCONI SYNDROME

Cystinosis

Definition

Cystinosis, or cystine storage disease, is characterized biochemically by excessive intracellular storage, particularly in lysosomes, of the amino acid cystine.[2] Three different types of cystinosis can be distinguished based on clinical course, age at onset, and intracellular cystine content. Benign or adult cystinosis is associated with cystine crystals in the cornea and bone marrow only, as well as the mildest elevation in intracellular cystine levels; no renal disease occurs. Infantile or nephropathic cystinosis is the most common form of cystinosis and is associated with the highest intracellular levels of cystine and the earliest onset of renal disease. In the intermediate or adolescent form, intracellular cystine levels are between those of the infantile and adult forms, with later onset of renal disease.

Etiology and Pathogenesis

Nephropathic cystinosis is transmitted as an autosomal recessive trait localized to the short arm of chromosome 17, with an estimated

incidence of 1 in 200,000 live births. The *CTNS* gene codes for a lysosomal membrane protein, cystinosin, that mediates the transport of cystine from the lysosome.[3] The benign and intermediate forms of cystinosis are also associated with *CTNS* mutations but still have some functional transport protein, leading to lower intracellular cystine levels and slower onset of renal disease in the intermediate form and no renal disease in the benign form. Recently, cystinosin has been shown to play a role in other cellular processes besides lysosomal cystine transport, which may explain the persistence of the Fanconi syndrome in spite of cystine depletion.[4]

Clinical Manifestations

The first clinical symptoms and signs in nephropathic cystinosis are those of Fanconi syndrome and usually appear in the second half of the first year of life. Subtle abnormalities of tubular function can be demonstrated earlier in families with index cases, but there always is a delay between birth and the first symptoms. Rickets is common after the first year of life, along with growth failure. The growth failure occurs before the GFR declines and despite correction of electrolyte and mineral deficiencies. The GFR invariably declines and end-stage renal disease (ESRD) occurs by late childhood.

Nephrocalcinosis is relatively common, and a few patients have renal calculi. Photophobia is another common symptom that occurs by 3 years of age and is progressive. Older patients with cystinosis may develop visual impairment and blindness. Children with cystinosis usually have a fair complexion and blond hair, but dark hair has been observed in some. Cystinosis has been observed in other ethnic groups but is less common than in Whites.

The diagnosis is based on the demonstration of elevated intracellular levels of cystine, usually in white blood cells or skin fibroblasts. Patients with nephropathic and intermediate cystinosis have intracellular cystine levels that exceed 2 nmol half-cystine per mg protein (normal <0.2 nmol half-cystine per mg protein). Heterozygotes for cystinosis have levels that range from 0.2 to 1 nmol half-cystine/mg protein. A slit-lamp demonstration of corneal crystals strongly suggests the diagnosis[2] (Fig. 48.4). A prenatal diagnosis can be made with amniocytes or chorionic villi.

Common late complications of cystinosis include hypothyroidism, splenomegaly and hepatomegaly, decreased visual acuity, swallowing difficulties, pulmonary insufficiency, and corneal ulcerations.[5] Less frequently, older patients have developed insulin-dependent diabetes mellitus, myopathy, and progressive neurologic disorders. Decreased brain cortex also has been noted on imaging in some patients. Older patients may develop vascular calcification, especially of the coronary arteries, which can lead to myocardial ischemia.

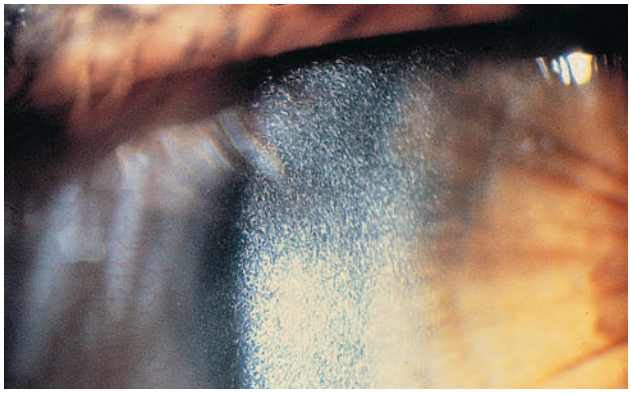

Fig. 48.4 Corneal opacities in cystinosis. Tinsel-like refractile opacities in the cornea of a patient with cystinosis under slit-lamp examination. (From reference 39.)

Renal Pathology

The morphologic features of the kidney in cystinosis vary with the stage. Early in the disease, cystine crystals are present in tubular epithelial cells, interstitial cells, and rarely glomerular epithelial cells[6,7] (Fig. 48.5A). A swan-neck deformity or thinning of the first part of the proximal tubule is an early finding but is not unique to cystinosis. Later, there is pronounced tubular atrophy, interstitial fibrosis, and abundant crystal deposition with giant cell formation of the glomerular visceral epithelium, segmental sclerosis, and eventual glomerular obsolescence. Electron microscopy (EM) demonstrates intracellular crystalline inclusions consistent with cystine (see Fig. 48.5B). Peculiar "dark cells," unique to the cystinotic kidney, also have been observed. These are mostly macrophages and some podocytes and are probably dark because of a reaction of cystine with osmium tetroxide.

Treatment

Nonspecific therapy for infantile cystinosis consists of vitamin D therapy and replacement of the urinary electrolyte losses, followed, in due course, by the management of the progressive renal failure (Table 48.1). Cysteamine therapy can lower tissue cystine levels and slow the decline in GFR, especially in children with a normal serum creatinine

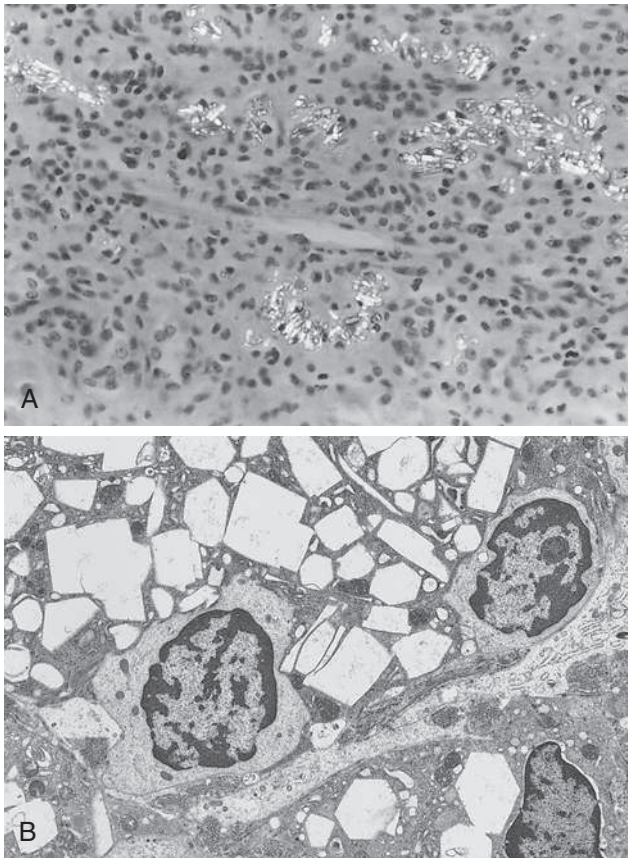

Fig. 48.5 Cystine crystals in the kidney in cystinosis. (A) Crystals are seen in photomicrograph of alcohol-fixed nephrectomy specimen, taken through incompletely crossed polarizing filters. Birefringent crystals are evident in tubular epithelial cells and free in the interstitium. (B) Electron micrograph of a renal biopsy specimen shows hexagonal, rectangular, and needle-shaped crystals in macrophages within the interstitium. (Original magnification ×3000.) (*A* from reference 6; *B* from reference 7.)

concentration treated before 2 years of age[8] (Fig. 48.6). Cysteamine therapy also improves linear growth but not Fanconi syndrome. The most common problems associated with cysteamine therapy are nausea, vomiting, and a foul odor and taste. Treatment should begin with a low dose of cysteamine soon after the diagnosis is made, increased during 4 to 6 weeks to 60 to 90 mg/kg/day in four divided doses as close to every 6 hours as possible. Slowly increasing the dose minimizes the risk for neutropenia, rash, and arthritis. Leukocyte cystine levels should be checked every 3 to 4 months to monitor effectiveness and compliance, with the goal of achieving and maintaining a cystine level below 2.0 and preferably below 1.0 nmol half-cystine/mg protein. A long-acting formulation of cysteamine is available that allows twice-daily dosing. This formulation is equally effective and may aid compliance, but is significantly more expensive than the standard formulation of cysteamine. A 50-mM solution of cysteamine applied topically onto the eye has proved useful in depleting the cornea of cystine crystals, but it requires administration 6 to 12 times a day to be effective.

Treatment of ESRD in these children poses no greater problems than in other children. Successful renal transplantation reverses the renal failure and Fanconi syndrome but does not appear to improve the extrarenal manifestations of cystinosis. Cysteamine therapy should be continued after transplantation. Cystine does not accumulate in the transplanted kidney, except in infiltrating immunocytes.

TABLE 48.1 Treatment of Cystinosis

Problem	Therapy
Removal of lysosomal cystine	Cysteamine, 0.325 g/m^2 q6h Delayed-release cysteamine, 0.65 g/m^2 q12h Goal: Maintain leukocyte cystine level <1 nmol half-cystine*/mg protein
Correction of Tubulopathy	
Dehydration	2-6 l/day fluid
Acidosis	2-15 mmol/kg/day K^+ citrate
Hypophosphatemia	1-4 g/day K^+ phosphate
Rickets	0.25-1 mcg/day calcitriol
Adjunct therapies	NaCl, carnitine, indomethacin, hydrochlorothiazide
Later Therapies	
Growth failure	Growth hormone
Hypothyroidism	Thyroxine
Renal failure	Renal replacement therapy, ideally renal transplantation

*By convention, units are half-cystine because the cystine originally was converted to two cysteine molecules, or "broken in half," before measurement.

Galactosemia

Etiology and Pathogenesis

Galactosemia is an autosomal recessive disorder of galactose metabolism. It is most often the result of deficient activity of the enzyme galactose-1-phosphate uridyltransferase, the incidence of which is 1 in 62,000 live births.[9] Deficiency of this enzyme leads to the intracellular accumulation of galactose-1-phosphate, with damage to the liver, proximal renal tubule, ovary, brain, and lens. A less frequent cause of galactosemia is a deficiency of galactose kinase, which forms galactose-1-phosphate from galactose. Cataracts are the only manifestation of this form of galactosemia.

The pathogenesis of the symptoms of galactosemia is not clear. Accumulation of galactose-1-phosphate subsequent to the ingestion of galactose can inhibit pathways for carbohydrate metabolism, and its level correlates somewhat with clinical symptoms. Defective galactosylation of proteins also has been postulated. Proposed as a pathogenetic mechanism, formation of galactitol from galactose by aldose reductase is probably responsible for the cataract formation.

Clinical Manifestations

Affected infants ingesting milk containing lactose (the most common source of galactose in the diet) rapidly develop vomiting, diarrhea, and failure to thrive. Jaundice from unconjugated hyperbilirubinemia is common, along with severe hemolysis. Continued intake of galactose leads to hepatomegaly and cirrhosis. Cataracts appear within days after birth, although at first they often are detectable only with a slit lamp. Cognitive dysfunction or developmental delay may develop within a few months. Fulminant *Escherichia coli* sepsis has been described, possibly a consequence of inhibited leukocyte bactericidal activity.

In addition to these clinical findings, galactose intake leads within days to hyperaminoaciduria and albuminuria. Increased urine sugar excretion is principally a result of galactosuria and not glycosuria. There seems to be little or no impairment in glucose handling by the proximal tubule. Galactosemia should be suspected whenever there is a urinary reducing substance that does not react in a glucose oxidase test. The diagnosis can be confirmed by demonstration of deficient transferase activity in red blood cells, fibroblasts, leukocytes, or hepatocytes. Most infants with galactosemia are found through newborn metabolic screening.

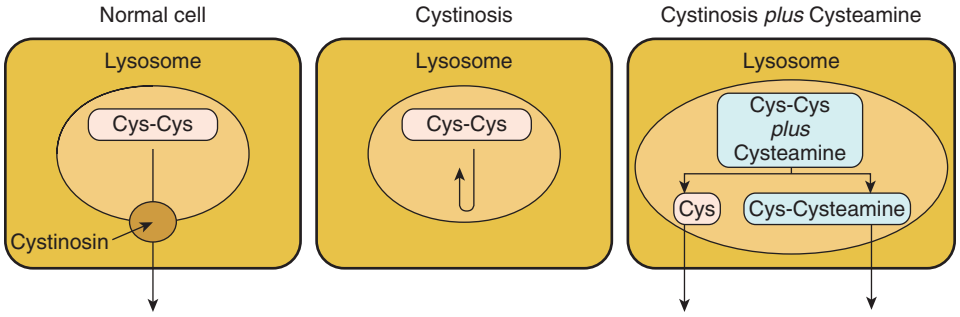

Fig. 48.6 Effect of cysteamine on lysosomal cystine. In cystinosis, the transporter (cystinosin) for cystine *(Cys-Cys)* egress from the lysosome is defective and cysteine accumulates. Cysteamine can easily enter the lysosome and combine with cystine, forming cysteine *(Cys)* and the mixed disulfide cysteamine-cysteine. Both these compounds can exit the lysosome through a transporter other than the cystine carrier.

Treatment

Galactosemia is treated by elimination of galactose from the diet. Acute symptoms and signs resolve in a few days. Cataracts will also regress to some extent. Even with early elimination of galactose, developmental delay, speech impairment, ovarian dysfunction, and growth retardation are common. Profound intellectual deficits are rare even in infants treated late.

Hereditary Fructose Intolerance

Etiology and Pathogenesis

Hereditary fructose intolerance is another disorder of carbohydrate metabolism associated with Fanconi syndrome.[10] Fructose intolerance is inherited as an autosomal recessive trait, with an estimated incidence of 1 in 20,000 live births. It is caused by a deficiency of the B isoform of the enzyme fructose-1-phosphate aldolase, which cleaves fructose-1-phosphate into D-glyceraldehyde and dihydroxyacetone phosphate. Deficient activity of aldolase B leads to tissue accumulation of fructose-1-phosphate and reduced levels of adenosine triphosphate (ATP). Experimentally, mice with aldolase B deficiency can be rescued by blocking fructokinase, which prevents the accumulation of fructose-1-phosphate and maintains ATP.

Clinical Manifestations

Symptoms of hereditary fructose intolerance appear at weaning when fruit, vegetables, and sweetened cereals that contain fructose, sucrose, or sorbitol (the latter is converted to fructose in the body) are introduced. Affected children experience nausea, vomiting, and symptoms of hypoglycemia shortly after ingestion of fructose, sucrose, or sorbitol. These symptoms may progress to seizures, coma, and even death, depending on the amount consumed. When they are exposed to fructose, infants may have a catastrophic illness, with severe dehydration, shock, acute liver impairment, bleeding, and acute kidney injury (AKI). Concomitant serum biochemical findings after fructose ingestion are decreased glucose, phosphate, and bicarbonate and increased uric acid and lactic acid. Chronic exposure to fructose leads to failure to thrive, hepatomegaly and fatty liver, jaundice, hepatic cirrhosis, Fanconi syndrome, and nephrocalcinosis. Children with hereditary fructose intolerance quickly develop an aversion to sweets.

Diagnosis

The diagnosis should be suspected when symptoms develop after the ingestion of fructose. This can be confirmed by assaying the activity of fructose-1-phosphate aldolase in a liver biopsy specimen and increasingly by genetic testing using leukocytes.

Treatment

Treatment of hereditary fructose intolerance involves strict avoidance of foods containing fructose and sucrose, but because most patients develop a strong aversion to such foods, this is usually easy. The greatest risk occurs during infancy, before those affected learn to avoid fructose.

Glycogenosis

Most patients with glycogen storage disease and Fanconi syndrome have an autosomal recessive disorder characterized by heavy glycosuria and increased glycogen storage in the liver and kidney, known as the *Fanconi-Bickel syndrome*, or *glucose-losing syndrome,* because the glucose losses can be massive.[11] The defect is deficient activity of the sugar transporter GLUT2 (Fig. 48.7). GLUT2 facilitates sugar exit from the basolateral side of the proximal tubule and intestinal cell and sugar entry and exit from the hepatocyte and pancreatic β cell. A few

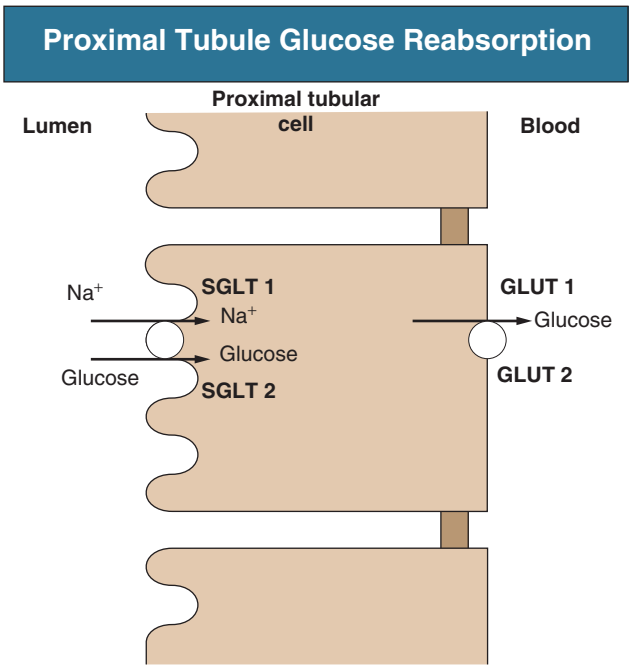

Fig. 48.7 Proximal tubule glucose reabsorption. Glucose enters the proximal tubule cell coupled to Na^+ reabsorption from the lumen through a high-capacity, low-affinity transporter *(SGLT2)* in the early proximal tubule and a low-capacity, high-affinity transporter *(SGLT1)* in the late proximal tubule. Glucose exits the cell through the transporters *GLUT1* and *GLUT2* located in the late and early proximal tubule, respectively.

patients with type I glycogen storage disease have mild Fanconi syndrome but not Fanconi-Bickel syndrome. The therapy for this disorder is directed at the renal solute losses, treatment of rickets (which can be severe), and frequent feeding to prevent ketosis. Uncooked cornstarch has been shown to lessen the hypoglycemia and to improve growth.

Tyrosinemia

Definition

Hereditary tyrosinemia type I, also known as *hepatorenal tyrosinemia,* is a defect of tyrosine metabolism affecting the liver, kidneys, and peripheral nerves.[12]

Etiology and Pathogenesis

The cause of hereditary tyrosinemia type I is a deficiency of fumarylacetoacetate hydrolase (FAH) activity; it is an autosomal recessive disorder. Decreased or absent FAH activity leads to accumulation of maleylacetoacetate (MAA) and fumarylacetoacetate (FAA) in affected tissues. These compounds can react with free sulfydryl groups, reduce intracellular levels of glutathione, and act as alkylating agents. MAA and FAA are not detectable in plasma or urine but are converted to succinylacetoacetate and succinylacetone. Succinylacetone is structurally similar to maleic acid, a compound that causes Fanconi syndrome experimentally in rats and may be the cause of Fanconi syndrome in humans affected with tyrosinemia.

Clinical Manifestations

The liver is the major organ affected, evident as early as the first month of life. Such infants usually have severe disease and die in the first year. All children with tyrosinemia will eventually develop macronodular cirrhosis, and many develop hepatocellular carcinoma. Acute, painful

peripheral neuropathy and autonomic dysfunction also can occur. Proximal renal tubular dysfunction is evident in all patients with tyrosinemia, especially those presenting after infancy. Nephromegaly is very common, and nephrocalcinosis may be seen. Glomerulosclerosis and impaired GFR may be seen with time.

Diagnosis

The diagnosis should be suspected with elevated plasma tyrosine and methionine levels together with their *p*-hydroxy metabolites. The presence of succinylacetone in blood or urine is diagnostic of hereditary tyrosinemia type I.

Treatment

The institution of a diet low in phenylalanine and tyrosine dramatically improves the renal tubular dysfunction. Nitisinone, which inhibits the formation of MAA and FAA, dramatically improves the renal and hepatic dysfunction.[12] Liver transplantation has been successfully used to treat patients with severe liver failure and prevent the development of hepatocellular carcinoma. Liver transplantation leads to rapid correction of Fanconi syndrome.

Wilson Disease

Definition

Wilson disease is an inherited disorder of copper metabolism that affects numerous organ systems.[13,14] It has an overall incidence of 1 in 30,000 live births. About 40% of patients present with liver disease, 40% with extrapyramidal symptoms, and 20% with psychiatric or behavioral abnormalities.

Etiology and Pathogenesis

Wilson disease is caused by a defect in the P-type copper–transporting adenosine triphosphatase ATP7B, which is highly expressed in the liver, kidney, and placenta. It impairs biliary copper excretion and the incorporation of copper into ceruloplasmin. These abnormalities cause excessive intracellular accumulation of copper in the liver, with subsequent overflow into other tissues, such as brain, cornea, and renal proximal tubule.

Clinical Manifestations

Patients typically present with chronic liver disease, often with relatively high serum bilirubin relative to alkaline phosphatase (bilirubin [mg/dl]/alkaline phosphatase >4). Excessive storage of copper in the kidney leads to renal tubular dysfunction in most patients and full-blown Fanconi syndrome in some. Hematuria also has been noted. Renal plasma flow and GFR decrease as the disease progresses, but death from extrarenal causes occurs before the onset of renal failure. Fanconi syndrome usually appears before the onset of hepatic failure. Hypercalciuria with development of renal stones and nephrocalcinosis also have been reported. Besides proximal tubular dysfunction, abnormalities in distal tubular function, decreased concentrating ability, and distal RTA (type 1 RTA) also have been observed. Neurologic abnormalities, such as dysarthria and gait disturbances, may be the presenting symptom in young adults with Wilson disease. Kayser-Fleischer rings, dense brown copper deposits around the iris, may be visible but typically can be seen only with a slit lamp.

Renal Pathology

Histologic examination of the kidney in untreated Wilson disease shows either no alteration on light microscopy or only some flattened proximal tubular cells without recognizable brush borders. EM shows loss of the brush border, disruption of the apical tubular network, electron-dense bodies probably representing metalloproteins in the subapical region of tubule cell cytoplasm, and cavitation of the mitochondria with disruption of the normal cristae pattern. Rubeanic acid staining shows intracytoplasmic copper granules. The copper content of kidney tissue is greatly elevated.

Diagnosis

The diagnosis of Wilson disease should be suspected in children and young adults with unexplained neurologic disease, chronic active hepatitis, acute hemolytic crisis, behavioral or psychiatric disturbances, or the appearance of Fanconi syndrome. In such patients, the presence of Kayser-Fleischer rings is an important clue in making the diagnosis. Serum ceruloplasmin levels are decreased in 96% of patients with Wilson disease. A greatly increased urinary copper level is also useful in making the diagnosis, especially if it increases significantly with D-penicillamine. Liver copper levels are increased in untreated patients. Mutational analysis is also available.

Treatment

Treatment with penicillamine 1 to 1.5 g/day reverses the renal dysfunction and potentially the hepatic and neurologic disease, depending on the degree of damage before the onset of therapy. Recovery, however, is quite slow. Trientine also can chelate copper and is indicated in patients who cannot tolerate penicillamine. Tetrathiomolybdate is a potent agent in removing copper from the body and has been used in some patients with neurologic disease to prevent the immediate worsening of symptoms that can occur with penicillamine. Zinc salts, which induce intestinal metallothionein and blockade of intestinal absorption of copper, are useful in maintenance therapy. Liver transplantation has been successful in some patients but should be reserved for those with liver failure.

Lowe Syndrome

Lowe syndrome (oculocerebrorenal syndrome) is characterized by congenital cataracts and glaucoma, severe developmental delay, hypotonia with diminished to absent reflexes, and renal abnormalities.[15,16] Fanconi syndrome is followed by progressive renal impairment. ESRD usually does not occur until the third to fourth decade of life.

Lowe syndrome is transmitted as an X-linked recessive trait. Despite this inheritance pattern, Lowe syndrome has occurred in a few females. The defective gene codes for phosphatidyl inositol 4,5-bisphosphate 5-phosphatase, *OCRL1*, involved with cell trafficking and signaling.

Light microscopy of the kidney is normal early in the disorder, with endothelial cell swelling and thickening and splitting of the glomerular basement membrane seen by EM. In the proximal tubule cells, there is shortening of the brush border and enlargement of the mitochondria, with distortion and loss of the cristae. Only symptomatic treatment is available.

Dent Disease

Definition

Dent disease is an X-linked recessive disorder characterized by low-molecular-weight proteinuria, hypercalciuria, nephrolithiasis, nephrocalcinosis, and rickets.[17,18] Affected males often have aminoaciduria, phosphaturia, and glycosuria. Renal failure is common and may occur by late childhood. Hemizygous females usually have only proteinuria and mild hypercalciuria. X-linked recessive nephrolithiasis and X-linked recessive hypophosphatemic rickets have similar features, and most have a defect in the renal ClC-5 chloride channel. Dent disease type 2 is a clinically similar disease affecting males, but there is a mutation in the same gene that causes Lowe syndrome, although patients with Dent type 2 do not have the brain or eye involvement seen in Lowe syndrome.[17]

Etiology and Pathogenesis

Most of these disorders are caused by a mutation in the *CLCN5* gene leading to inactive ClC-5 chloride channel function (see Fig. 48.2). The ClC-5 chloride channel spans the membrane of preendocytic vesicles just below the brush border of the proximal tubule. This channel plays a role in the acidification of these vesicles by a proton pump. Lack of this Cl^- channel interferes with protein reabsorption from the tubule through the megalin-cubilin receptor system and cell surface receptor recycling, which may explain the phosphaturia, glycosuria, and aminoaciduria.

The defective *OCRL1* in patients with Dent disease type 2 interferes with normal cell protein trafficking. The renal disease is similar to that seen in type 1 Dent disease. Although patients do not have the eye and brain disease seen in patients with Lowe, a few patients with Dent type 2 have a mild intellectual deficit, hypotonia, and subclinical cataracts.

Filtered PTH is also reabsorbed by the megalin-cubilin system for degradation in the lysosome. Decreased PTH reabsorption allows increased binding to luminal PTH receptors and increased endocytosis of luminal phosphate transporters, leading to increased phosphaturia.[1]

Mitochondrial Cytopathies

Definition

Mitochondrial cytopathies are a diverse group of diseases with abnormalities in mitochondrial DNA that lead to mitochondrial dysfunction in various tissues.[19]

Clinical Manifestations

Most of the mitochondrial cytopathies manifest with neurologic disorders such as myopathy, myoclonus, ataxia, seizures, external ophthalmoplegia, stroke-like episodes, and optic neuropathy. Other manifestations include retinitis pigmentosa, diabetes mellitus, exocrine pancreatic insufficiency, sideroblastic anemia, sensorineural hearing loss, pseudoobstruction of the colon, hepatic disease, cardiac conduction disorders, and cardiomyopathy.

The most common renal manifestation associated with mitochondrial cytopathies is Fanconi syndrome, although a number of patients have been described with focal segmental glomerulosclerosis (FSGS) and corticosteroid-resistant nephrotic syndrome. All the patients with renal abnormalities have had extrarenal disorders, mainly neurologic disease. Most patients present in the first months of life and die soon afterward.

Diagnosis

A clue to mitochondrial cytopathies is elevated serum or cerebrospinal fluid lactate levels, especially in association with an altered lactate-to-pyruvate ratio, suggesting a defect in mitochondrial respiration. The presence of "ragged red fibers," a manifestation of abnormal mitochondria, in a muscle biopsy specimen is another clue, especially with large abnormal mitochondria on EM of muscle tissue.

Treatment

There is little to offer these patients in terms of definitive therapy. Low mitochondrial enzyme complex III activity can be treated with menadione or ubidecarenone. Deficient mitochondrial enzyme complex I activity may be treated with riboflavin and ubidecarenone. Ascorbic acid has been used to minimize oxygen free radical injury. High-lipid, low-carbohydrate diet has been tried in cytochrome c oxidase deficiency.

Idiopathic Fanconi Syndrome

A number of patients develop the complete Fanconi syndrome in the absence of any known cause. Traditionally called *adult* Fanconi syndrome because it was thought that only adults were affected, it is now clear that children may be affected, and a more proper designation is *idiopathic* Fanconi syndrome. Not all the features of Fanconi syndrome may be present when the patient is first seen, but do appear with time. Idiopathic Fanconi syndrome can be inherited in an autosomal dominant, autosomal recessive, or even X-linked pattern. However, most cases occur sporadically, with no evidence of genetic transmission. The prognosis is variable, and some patients develop ESRD 10 to 30 years after onset of symptoms. A few patients have undergone renal transplantation; in some, Fanconi syndrome has recurred in the allograft without evidence of rejection, suggesting an extrarenal cause of the idiopathic form.

Renal morphologic descriptions of such cases are scanty. In some reports, no abnormalities were found, and, in others, tubular atrophy with interstitial fibrosis was interspersed with areas of tubular dilation. Greatly dilated proximal tubules with swollen epithelium and grossly enlarged mitochondria with displaced cristae also have been noted.

ACQUIRED CAUSES OF FANCONI SYNDROME

Numerous substances can injure the proximal renal tubule. Injury can range from an incomplete Fanconi syndrome to acute tubular necrosis (ATN) or ESRD. The extent of the tubular damage varies depending on the type of toxin, amount ingested, and host. A careful history of possible toxin exposure and recent medications is important in patients with tubular dysfunction. Box 48.1 lists the more common causes of acquired Fanconi syndrome.

Heavy Metal Intoxication

A major cause of proximal tubular dysfunction is acute heavy metal intoxication, principally lead and cadmium. In lead poisoning, the renal tubular dysfunction, mainly aminoaciduria and mild glycosuria and phosphaturia, is usually overshadowed by the development of chronic kidney disease and involvement of other organs, especially the central nervous system.[20] Fanconi syndrome associated with cadmium poisoning is associated with severe bone pain, giving rise to the name itai-itai ("ouch-ouch") disease for its occurrence in Japanese patients affected by industrial contamination of the soil.[21]

Tetracycline

Outdated tetracycline causes reversible Fanconi syndrome even in therapeutic doses. Recovery is rapid when the degraded drug is stopped. The compound responsible for the tubule dysfunction is anhydro-4-tetracycline, formed from tetracycline by heat, moisture, and low pH.

Cancer Chemotherapy Agents

A number of cancer chemotherapy agents have been associated with Fanconi syndrome and renal tubular dysfunction, especially cisplatin and ifosfamide. Carboplatin has been associated with reduced GFR and magnesium wasting but not Fanconi syndrome. The nephrotoxicity of both cisplatin and ifosfamide is dose dependent and often irreversible. Besides the usual manifestations of Fanconi syndrome, cisplatin toxicity is characterized by hypomagnesemia, caused by hypermagnesuria, which can be extremely severe, persistent, and difficult to treat.[22,23] Ifosfamide is more often associated with hypophosphatemic rickets.[22] Chloroacetaldehyde, a metabolite of ifosfamide, appears experimentally to cause Fanconi syndrome. Both ifosfamide and cisplatin can cause an irreversible reduction in GFR.

Other Drugs and Toxins

Exposure to a wide range of toxins may give rise to Fanconi syndrome, often in association with a reduced GFR, including 6-mercaptopurine, toluene (glue sniffing), and Chinese herbal medicines containing *Aristolochia* spp.[24] In addition, anecdotal reports have associated Fanconi syndrome with valproic acid (valproate), suramin, gentamicin, and

ranitidine. Antiviral medications, especially antiretroviral agents such as tenofovir, are an increasingly common cause of Fanconi syndrome.[25]

Dysproteinemias

Dysproteinemia[26] from multiple myeloma, light-chain proteinuria,[27] Sjögren syndrome, and amyloidosis is sometimes associated with Fanconi syndrome, which appears to be correlated with urinary free light chains that can cause proximal tubule dysfunction through intracellular crystallization or lysosomal dysfunction.[28]

Glomerular Disease

Nephrotic syndrome has been rarely associated with Fanconi syndrome. Most of these patients have FSGS, and the occurrence of Fanconi syndrome heralds a poor prognosis.

After Acute Kidney Injury

Tubular dysfunction can occur transiently during recovery from AKI from any cause, regardless of whether a known tubular toxin was originally implicated.

After Renal Transplantation

Fanconi syndrome has appeared rarely after renal transplantation. The pathogenesis probably is multifactorial, including sequelae of ATN, rejection, nephrotoxic drugs, ischemia from renal artery stenosis, and residual hyperparathyroidism.

FAMILIAL GLUCOSE-GALACTOSE MALABSORPTION AND HEREDITARY RENAL GLYCOSURIA

Definition

Renal glycosuria refers to the appearance of readily detectable glucose in the urine when the serum glucose concentration is in a normal range (see Fig. 48.3). When the serum glucose concentration is in a physiologic range, virtually all the filtered glucose is reabsorbed in the proximal tubule.[29] Filtered glucose enters the proximal tubule through two specific carriers (SGLT1 and SGLT2) coupled to sodium and exits the cell through the sugar transporters GLUT1 and GLUT2 (see Fig. 48.7). However, when the serum level exceeds the physiologic range, the filtered load exceeds the capacity of these carriers, and glucose begins to appear in the urine; this is termed the *renal threshold.*

Etiology and Pathogenesis

Familial glucose-galactose malabsorption is a rare autosomal disorder caused by mutations in the gene coding for the brush border sodium-glucose cotransporter SGLT1, which is found in the intestinal cell and the S_3 segment of the proximal renal tubule cell. The disorder is characterized by the neonatal onset of life-threatening diarrhea from the intestinal malabsorption of glucose and galactose, which resolves rapidly with the removal of glucose and galactose and its dipeptide, lactose, from the diet. These patients frequently also have mild renal glycosuria.

Familial renal glycosuria occurs with an incidence of 1 in 20,000 live births and can be inherited as a heterozygous, homozygous, or mixed heterozygous trait.[29] This disorder is caused by mutations in the *SLC5A2* gene that codes for the SGLT2 glucose transporter found in the early portion of the proximal tubule. Inhibitors of SGLT2, which mimic this genetic defect, have been used recently in type 2 diabetes to lower hyperglycemia without causing weight gain or aggravating hyperinsulinism.

In the past, renal glycosuria was divided into three types based on the reabsorption patterns observed during glucose infusion studies, but this typing system has been questioned because clearance data suggest patients with renal glycosuria have rates of glucose reabsorption that vary from virtually no reabsorption to near-normal rates, rather than three distinct types, reflecting different mutations in the *SLC5A2* gene and differing amounts of functional protein.

Natural History

Patients with familial glucose-galactose malabsorption appear to grow and develop normally with removal of the offending sugars from the diet. The clinical course of hereditary renal glycosuria is benign, except for a few patients with polyuria and salt wasting, and it is not a precursor to diabetes mellitus. Patients need to be aware of the condition in order not to receive unnecessary diagnostic investigations or even treatment for presumed diabetes mellitus.

AMINOACIDURIAS

As with glucose, amino acids are almost completely reabsorbed in the proximal tubule by a series of specific carriers. Studies have described a number of inherited disorders resulting in the incomplete reabsorption of a specific amino acid or a group of amino acids[30,31] (Table 48.2). Most do not result in kidney disease.

Cystinuria

Definition

Cystinuria is characterized by the excessive urinary excretion of cystine and the dibasic amino acids ornithine, lysine, and arginine and accounts for about 1% to 2% of all kidney stones and 6% to 8% of pediatric kidney stones.[32]

Etiology and Pathogenesis

These four amino acids share a transport system on the brush border membrane of the proximal tubule. Because of the relative insolubility of cystine when its urine concentration exceeds 250 mg/l (1 mmol/l), patients with cystinuria have recurrent renal calculi.

Cystinuria is an autosomal recessive trait with a disease incidence of 1 in 15,000 births.[33] Early studies suggested there were three genetic types on the basis of in vitro studies of intestinal transport and amino acid excretion in heterozygotes. More recently, two genes (*SLC3A1* coding for the protein rBAT and *SLC7A9* for the protein $b^{0,+}$AT) have been identified that are defective in cystinuria. *SLC3A1* heterozygotes have normal excretion rates for cystine. *SLC7A9* heterozygotes have cystine excretion rates that range from normal to almost that of homozygous patients. Based on these data, a newer classification proposed type A for mutations in both *SLC3A1* genes and type B for mutations in *SLC7A9*.[33] Type AB is compound heterozygote. Type A accounts for 38% of cystinuria patients, type B for 47%, and type AB for 14%.

TABLE 48.2 Inherited Aminoacidurias

Disease	Clinical Findings	Urine Amino Acids
Cystinuria	Urolithiasis	Cystine, lysine, ornithine, arginine
Hartnup disease	Rash, neurologic disease	Neutral amino acids
Iminoglycinuria	None	Proline, hydroxyproline glycine
Lysinuric protein intolerance	Hyperammonemia, vomiting, diarrhea	Dibasic amino acids

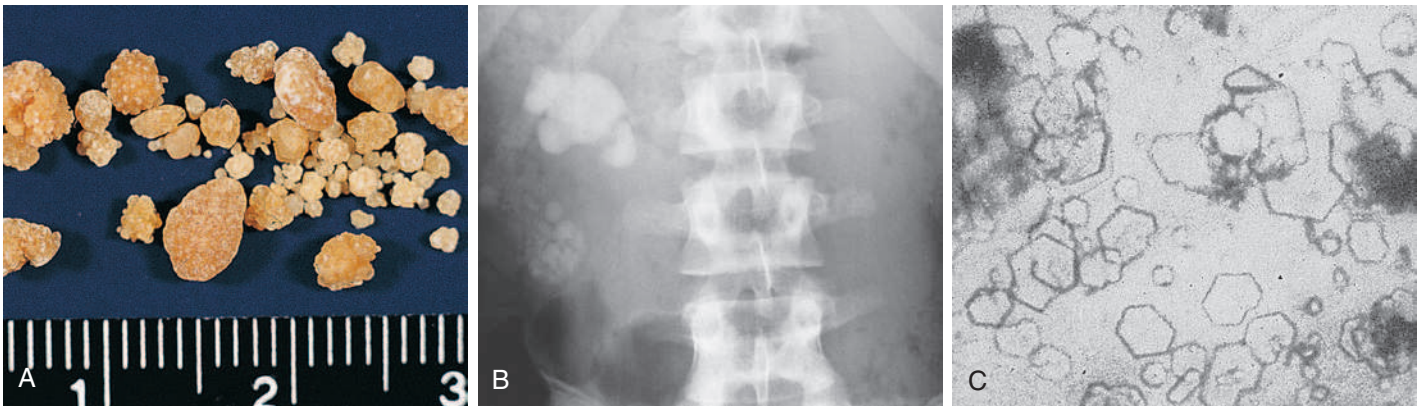

Fig. 48.8 Cystinuria. (A) Rough and smooth cystine calculi. (B) Plain radiograph of a cystine calculus in the right renal pelvis and further multiple parenchymal calculi. (C) Urine microscopy showing characteristic flat hexagonal crystals (see also Fig. 4.4G).

Clinical Manifestations

Cystine stones (calculi) are typically yellow-brown (Fig. 48.8A) and radiopaque (see Fig. 48.8B). Cystine crystals appear as microscopic, flat hexagons in the urine (see Fig. 48.8C), and this is a clue to the diagnosis.

Diagnosis

Patients can be screened for cystinuria with the cyanide-nitroprusside test, but type B heterozygotes also may give a positive result. The definitive test is to quantify cystine and dibasic amino acid excretion in a 24-hour urine specimen. Homozygotes excrete more than 118 mmol cystine per mmol creatinine (250 mg/g creatinine).

Treatment

The aim of therapy in cystinuria is to lower the urine cystine concentration to below 300 mg/l (1.25 mmol/l). The first step is to increase fluid intake. However, because most patients with cystinuria excrete 0.5 to 1 g/day of cystine, a urine output of 2 to 4 l/day is needed to achieve this goal. Cystine solubility increases in alkaline urine, but the urine pH must be above 7 to 7.5 to be effective. In patients with recurrent stone disease, thiols such as penicillamine and tiopronin, are extremely useful through the formation of a more soluble, mixed disulfide of the thiol and cysteine from cystine. Tiopronin is the most commonly prescribed thiol because it has fewer side effects than penicillamine and is started at a low dose (100 mg bid) and slowly increased (maximum 1200 mg/day) to a to achieve a urine cystine concentration below 300 mg/l in conjunction with a high fluid intake. Penicillamine is also effective and the dose should be slowly increased to minimize side effects. Captopril can be useful (an effect resulting from its thiol structure, not its angiotensin-converting enzyme inhibitor effect), but the dose range (75 to 150 mg/day) may be limited by its hypotensive effects.

HEREDITARY DEFECTS IN URIC ACID HANDLING

Hereditary Renal Hypouricemia

Hereditary renal hypouricemia is a rare autosomal recessive disorder characterized by very low serum uric acid levels (<2.5 mg/dl; [<150 µmol/l] in adult men and <2.1 mg/dl [<124 µmol/l] in adult women) and increased uric acid clearance, ranging from 30% to 150% of the filtered load.[34] In the normal kidney, uric acid is both reabsorbed and secreted in the proximal tubule by two different uric acid–anion exchange transporters and a voltage-sensitive pathway. In some patients, the defect is in the gene *SLC22A12* that codes for the protein URAT1; other patients have been found to have mutations in *SLC2A9 (GLUT9)*. Most patients do not have symptoms, and hypouricemia is found incidentally when a low serum uric acid concentration is noted during routine serum chemistry evaluation. About one fourth of patients with renal hypouricemia have had renal stones, but only one third of these were uric acid stones. There also may be hypercalciuria, and a few patients have had exercise-induced AKI, thought to be caused by acute tubular injury by passage of uric acid "gravel" in association with volume depletion and reduced urine pH. Most patients require no treatment, but if forming uric acid stones, they should maintain a high fluid intake. Urine alkalinization and allopurinol can be used for patients with persistent uric acid stones.

Familial Juvenile Hyperuricemic Nephropathy, Medullary Cystic Kidney Disease Type 2, and Uromodulin Mutations

Familial juvenile hyperuricemic nephropathy (FJHN) and medullary cystic kidney disease type 2 (MCKD2) are rare autosomal dominant conditions characterized by hyperuricemia, early-onset gout, and tubulointerstitial nephropathy.[35] Most patients with either FJHN or MCKD2 have a defect in the gene *UMOD,* on chromosome 16p12, coding for the Tamm-Horsfall/uromodulin protein, which is synthesized in the epithelial cells of the thick ascending limb (TAL) of the loop of Henle. The defective protein is retained in the endoplasmic reticulum and probably leads to inflammation, interstitial fibrosis, and functional abnormalities of the TAL. The defective protein also causes decreased salt and water reabsorption because *UMOD* plays a role in regulating the sodium-potassium-chloride transporter[36] and the rat outer medullary potassium channel.[37] The decreased salt and water reabsorption leads to increased proximal salt reabsorption and secondarily of uric acid, leading to hyperuricemia.

Diagnosis is suggested by a fractional excretion of uric acid of less than 5% (normal, 10% to 15%). Definitive diagnosis can be made by genetic testing of the *UMOD* gene. Controversy exists as to whether lowering of serum uric acid slows the progression of CKD; the studies reporting benefit have usually involved starting a xanthine oxidase inhibitor early in the disease.

More recently from genome-wide association studies, variants in the *UMOD* gene have been identified as risk factors for chronic kidney disease and hypertension.[38] The variants are common and are in the noncoding regions of the *UMOD* gene and lead to an increase in functional UMOD protein in contrast to FJHN/MCKD2.

SELF-ASSESSMENT QUESTIONS

A 3-year-old boy presents with failure to thrive and photophobia. His urine contains glucose and +1 protein with a pH of 5.5. Serum chemistries are:
Na^+ 135 mmol/l
K^+ 2.5 mmol/l
Cl^- 111 mmol/l
HCO_3^- 15 mmol/l
Glucose 91 mg/dl (5 mmol/l)
Phosphorus 2.5 mg/dl (0.8 mmol/l) (normal for age 4.5-5.5 mg/dl)
Creatinine 0.4 mg/dl (35 µmol/l)

1. Slit-lamp examination of his eyes shows tinsel-like refractile opacities in his cornea. What is the most likely diagnosis?
   A. Lowe syndrome
   B. Cystinosis
   C. Tyrosinemia
   D. Hereditary fructose intolerance
   E. Galactosemia
2. Cystinuria is associated with which amino acids in the urine besides cystine?
   A. Arginine, lysine, ornithine
   B. Arginine, lysine, histidine
   C. Lysine, ornithine, histidine
   D. Ornithine, glycine, alanine
   E. Ornithine, glycine, serine
3. What is the most common cause of Fanconi syndrome in adults?
   A. Multiple myeloma
   B. Medications
   C. Nephrotic syndrome
   D. Cystinosis
   E. Cadmium
4. The defect in familial glycosuria is an abnormality in which transporter?
   A. GLUT1
   B. ClC-5
   C. Na^+-K^+-$2Cl^-$
   D. Na^+/H^+
   E. SLGT2
5. Most patients with Dent disease have a mutation in which transporter?
   A. Na^+-K^+-$2Cl^-$
   B. GLUT2
   C. Na^+/H^+
   D. ClC-5
   E. Na^+-Cl^-

Sickle Cell Diseases and the Kidney

Claire C. Sharpe, Fatiu A. Arogundade

SICKLE CELL DISEASE

Epidemiology

Sickle cell disease (SCD) is an autosomal recessive inherited disorder that predominantly affects persons of African, Mediterranean, Indian, and Middle Eastern descent but was first recognized in West Africa. The high prevalence of SCD in this region probably represents a survival benefit because the presence of the sickle cell gene protects against malaria. SCD is now a worldwide health problem because the carrier state has spread throughout Africa, around the Mediterranean, and to the Middle East and India, as well as to the Caribbean, North America, and Northern Europe. The prevalence of the sickle cell gene is about 8% in African Americans and about 25% in adult Nigerians. Of babies born with SCD, 25% worldwide are born outside of sub-Saharan Africa.[1-3]

Genetics

The sickle hemoglobin (Hb) mutation (hemoglobin S, or HbS) results in the replacement of the normal glutamine by valine in the sixth position of the β-globin subunit, thereby changing the configuration of the Hb tetramer molecule in the homozygous person from $\alpha 2\beta 2$ to $\alpha 2\beta^{S}2$. SCD occurs in those homozygous for HbS (commonly referred to as *sickle cell anemia*,) or in heterozygotes when HbS coexists with another abnormal or missing β-chain (e.g., HbC ($\alpha 2\beta^{S}\beta^{C}$) or HbSβ thalassemia ($\alpha 2\beta S$). Sickle cell trait occurs in those heterozygous for HbS when the other Hb molecule is normal (HbAS ($\alpha 2\beta^{A}\beta^{S}$).

Restriction enzyme techniques have identified several HbS haplotypes—mutations of the HbS molecule that have probably arisen independently of each other. There are four major types in Africa—the Benin, Senegal, Cameroon, and Bantu (or Central African Republic)—and one Asian haplotype. Variations in these haplotypes determine disease severity; for example, the Senegalese haplotype is associated with a higher fetal Hb (HbF) concentration (a key driver of disease severity) and has a better prognosis than others. In a sample population of Nigerians, Benin haplotype was detected in 92%. Gender also influences disease severity; female HbSS patients with Benin haplotype have a higher HbF level than male patients.[4,5]

Pathophysiology

The driving pathophysiologic factor is HbS polymerization. During cellular or tissue hypoxia, dehydration, or oxidative stress, the mutated β-globin chains of the HbS molecule tend to crystallize to a polymer nucleus. Polymerization disrupts the architecture and changes the shape of the red blood cell (RBC) to a characteristic crescent or sickle, which increases its rigidity (Fig. 49.1). Polymerization is dynamic and depends on local oxygen tension. It is also promoted by acidosis (which decreases the affinity of HbS for oxygen) and hyperosmolarity (which increases RBC Hb concentration). As a consequence of repeated polymerization cycles, sickle RBCs exhibit abnormally high adhesion to activated endothelium, owing to acquired membrane changes and retained adhesion receptors on reticulocytes, especially the stress reticulocytes. This increases microvascular transit time, thereby stimulating further sickling. This results in premature destruction (hemolysis) of the RBCs and frequent, widespread vaso-occlusive episodes with subsequent acute and chronic organ damage.

The tendency of HbS to polymerize is influenced by the presence or absence of HbF, which contains γ-Hb chains in place of β-Hb ($\alpha 2\gamma 2$). In RBCs that contain HbF (known as F cells) the presence of HbF dilutes the concentration of HbS, thus increasing the threshold at which polymerization occurs. In addition, both HbF and its mixed hybrid tetramer ($\alpha 2\beta^{S}\gamma$) cannot enter the deoxy sickle Hb polymer phase, further limiting the degree of polymerization that can occur within a cell.[6] The main determinant of disease severity, therefore, is the rate and extent of HbS polymerization, which drives the two major pathophysiologic processes: vaso-occlusion with ischemia-reperfusion injury and hemolytic anemia (Fig. 49.2).[7]

Vaso-occlusion occurs in all patients, often triggered by inflammation, and is typically found in clinical states of infection, hypoxia, hypovolemia, hypothermia, acidosis, and hyperosmolality. Vaso-occlusion is probably caused by dynamic endothelial-leukocyte-RBC adhesive interactions in the postcapillary venules and precapillary obstruction by rigid, deformed RBCs. Episodic microvascular occlusion and ischemia can be interrupted by restoration of blood flow and reperfusion, which further promote inflammatory stress and tissue injury. In addition, hemolysis contributes to the development of progressive vasculopathy, characterized by endothelial dysfunction and proliferative changes in the intima and smooth muscle of blood vessels. An important role is ascribed to free Hb, which inactivates nitric oxide and generates reactive oxygen species. These separate pathologic processes have been used to explain the distinct subphenotypes of clinical complications of SCD whereby some patients present with frequent vaso-occlusive crises, acute chest syndrome (ACS), and osteonecrosis, and others have more severe anemia, recurrent leg ulceration, pulmonary hypertension, priapism, and chronic kidney disease (CKD).[8,9]

Natural History and Clinical Manifestations

SCD is a highly variable condition, though life expectancy is reduced in all subjects, especially in those with symptomatic disease. Although few data are available, median survival in some parts of sub-Saharan Africa may be as low as 5 years whereas it is 45 to 55 years in the United States and Jamaica.[5,10] The clinical manifestations of SCD are individualized and age dependent (Fig. 49.3).[11] Newborn babies are

asymptomatic for the first couple of months of life because fetal Hb predominates at this age. However, as γ-chains are rapidly replaced through β-chain synthesis, symptoms, often potentially life-threatening, begin to occur, including dactylitis, ACS, overwhelming sepsis, and acute splenic sequestration. Stroke is also a feature of early childhood, with the median age of onset of 6 years and an incidence of 8% by aged 14, rising to 11% by the age of 20. However, this has been largely mitigated in developed countries by screening at-risk children with transcranial Doppler (looking for increased blood flow velocity, which is suggestive of arterial stenosis) and the use of chronic transfusion for both primary and secondary prevention.[12] Human parvovirus B19 infection can lead to a severe and sudden fall in Hb in children and adolescents with SCD because the virus destroys red cell precursors for 8 to 10 days, which results in severe anemia. After the age of 5 years, when

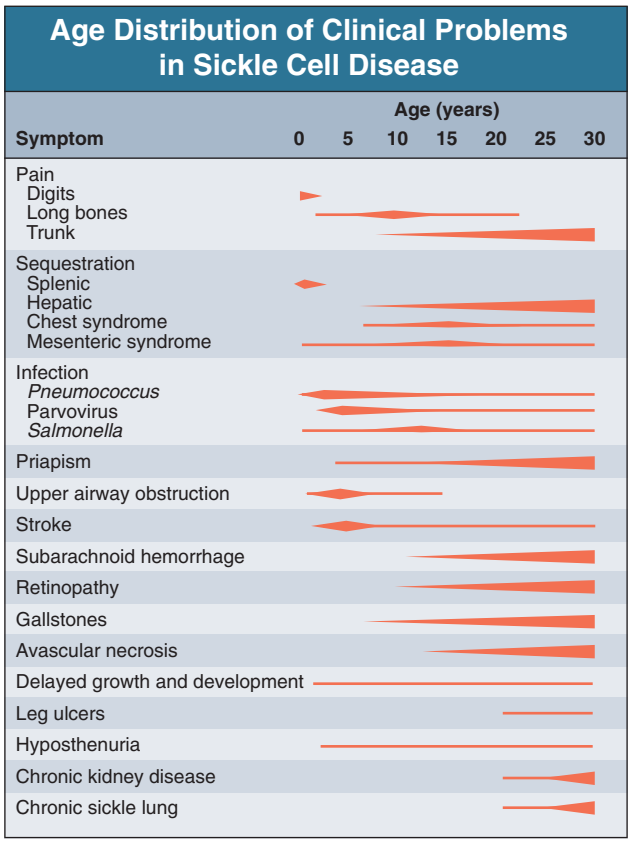

Fig. 49.3 Age distribution of clinical problems in sickle cell disease. (Modified from reference 11.)

active bone marrow is withdrawn from the small bones, dactylitis is replaced by the classic painful vaso-occlusive crisis (VOC), which increases in frequency with increasing age. In addition, adolescence is associated with nocturnal enuresis, avascular necrosis of the hip, leg ulcerations, delayed puberty, and priapism. Over the age of 25 to 30 years, the frequency of VOC tends to reduce and is replaced with signs and symptoms of chronic organ damage, including heart failure, pulmonary hypertension, sickle hepatopathy, and sickle cell nephropathy.[5] In younger patients, the primary cause of death is usually infection, whereas in older patients, the primary cause of death is commonly irreversible organ damage (Fig. 49.4).[13]

SICKLE CELL NEPHROPATHY

Sickle cell nephropathy (SCN) develops slowly, starting in the very young with glomerular hyperfiltration, leading to microalbuminuria in late childhood or early adulthood. Although many patients do not progress further, a number develop proteinuria and progressive CKD. These patients are at increased risk for acute kidney injury (AKI) complicating VOC or other interim illnesses; events that often precipitate a further decline in their baseline renal function. The prevalence of microalbuminuria is approximately 60% in those over 45 years, but only 4% to 12% of patients with SCD develop end-stage renal disease (ESRD), though this figure may increase as the patient cohort ages.[13,14] In keeping with this, in 2008, advanced CKD was reported in 24% of patients with SCD who had survived to 60 years of age or more and was the cause of death in 45%.[15]

In general, SCN is more prevalent and more severe in those with HbSS- and HbSβ^0-thalassemia than in those with milder forms of SCD such as HbSC.[10,16]

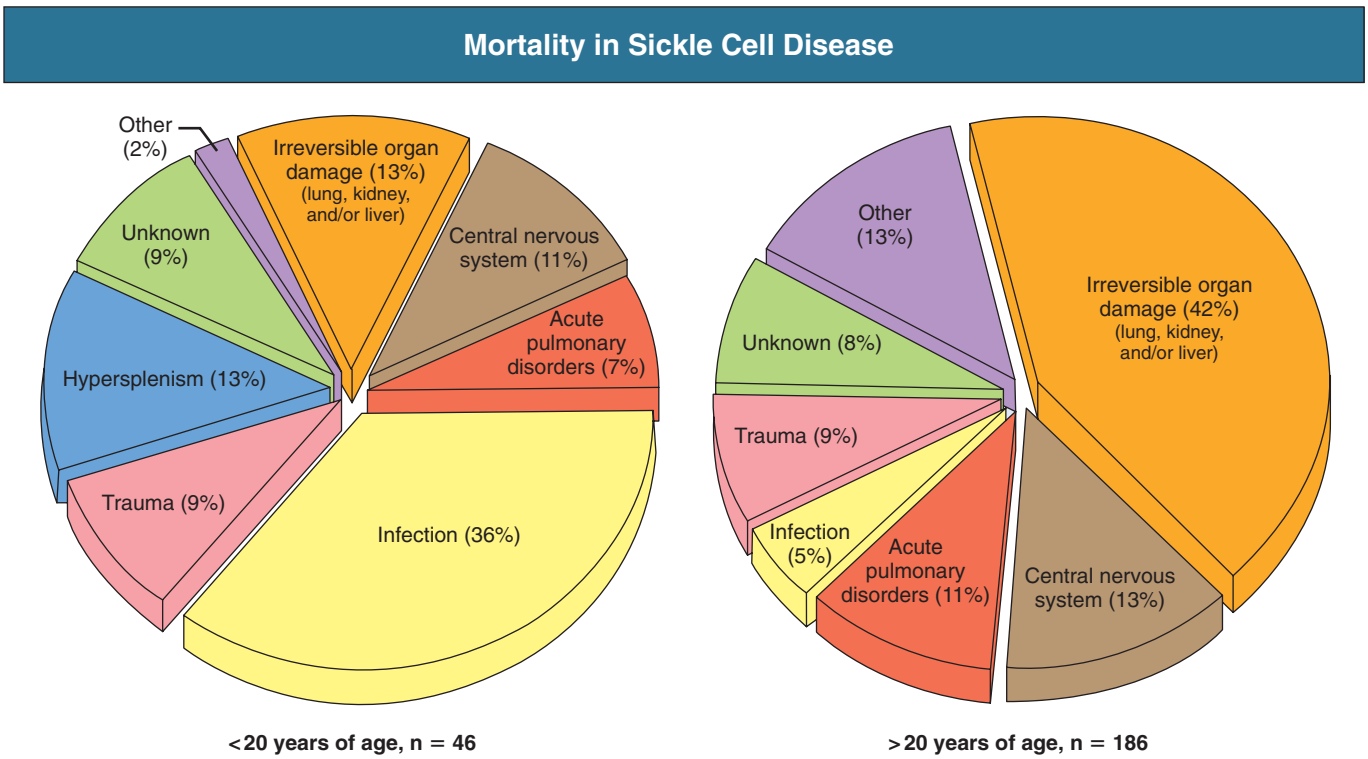

Fig. 49.4 Mortality in sickle cell disease. Causes of death among 232 HbSS patients, comparing patients younger than 20 years (46 died) with patients older than 20 years (186 died). The infection category includes both bacterial and viral diseases. (Modified from reference 13.)

Genetic Modifiers of Risk for Developing Sickle Cell Nephropathy

Other genetic modifiers are also associated with disease severity and risk for developing SCN, often through their influence on HbF levels. A polymorphism in the *BCL11A* gene (a fetal Hb silencing factor) leads to higher HbF levels, reduced hemolysis, and amelioration of SCD-related complications. Co-inheritance of α-thalassemia and SCD is found in approximately one third of patients and is associated with reduced hemolysis and protection from albuminuria. Over the past decade, genetic risk factors for CKD have been identified in the African American population, the most important of which are haplotypes of the *APOL1* gene. These are associated with increased risk for hemolysis and, when combined with genotypes for α-thalassemia and BCL11A, can be used to stratify risk for progressive CKD in SCD patients.[17] Using estimated glomerular filtration rate (eGFR) as a marker of renal function, the transforming growth factor-β/bone morphogenic protein (TGF-β/BMP) pathway[18] has been implicated as a cause of progressive kidney function loss in SCN.

Pathophysiology of Sickle Cell Nephropathy

The pathogenesis of SCN is directly related to the blood supply of the kidney and its circulation. In health the kidneys receive approximately 25% of the cardiac output to achieve effective filtration of the plasma at a rate of approximately 100 ml/min/1.73 m^2, despite representing less than 1% of total body weight. As a consequence, the cortex of the kidney is at risk for receiving excess oxygen, which is mitigated by shunting of oxygen from the afferent arteriole to the efferent arteriole. The vessels (vasa recta) that supply the medulla of the kidney branch off early from the efferent arteriole taking only a fraction of the total renal blood flow (RBF) with them. Much of the blood that enters the renal cortex is therefore delivered back to the venous circulation without entering the medulla at all. The maintenance of the relatively sluggish but intricate medullary blood flow is critical to maintaining the corticomedullary interstitial solute gradient generated by the countercurrent multiplier system of the loop of Henle, which drives water and solute reabsorption and allows for effective urinary concentration.[19] The resulting hypoxia (partial pressure of oxygen 10 to 35 mm Hg), acidosis, and hyperosmolarity of the inner medulla make it an ideal environment for the polymerization of deoxygenated HbS and subsequent sickling of erythrocytes. Over time, repeated cycles of sickling and sludging cause microinfarcts and ischemic injury leading to the chronic microvascular disease that is apparent in established SCN (Fig. 49.5).[20] Local activation of hypoxia inducible factor 1α (HIF1α) upregulates the expression of endothelin-1 which, in the presence of reduced nitric oxide, leads to an increase in reactive oxygen species and vasoconstriction, thus feeding into a cycle of chronic medullary hypoxia (Fig. 49.6).[21]

Despite reduced circulation in the renal medulla, total RBF and GFR are paradoxically increased. The subsequent hyperfiltration eventually results in proteinuria and glomerulosclerosis, which together with tubulointerstitial fibrosis marks the onset of progressive CKD.[22] Although in part the result of the increased cardiac output seen in patients with SCD, this increase in RBF cannot be completely explained by anemia or increased plasma volume, as it is not reversed by correction of the anemia with transfusion. One explanation involves the hemoxygenase-carbon monoxide system. Heme oxygenase-1 (HO-1) is upregulated in injured kidneys (and other tissues) in response to ongoing hemolysis in SCD. HO-1 is responsible for the conversion of heme to biliverdin with the subsequent release of carbon monoxide. Both biliverdin and carbon monoxide at these levels are potent antioxidants, and the carbon monoxide acts locally as a vasorelaxant, thus increasing both RBF and GFR.[23] This provides a possible link between the degree of hemolysis experienced by a patient and the likelihood of developing proteinuria.

The endothelial dysfunction and vasculopathic state of SCD described earlier is also pivotal to the development of SCN. Cross-talk between glomerular endothelial cells and podocytes is important to maintain healthy glomerular function; when the endothelium is dysfunctional this could lead to podocyte injury and the development of glomerular lesions and proteinuria. FMS-like tyrosine kinase 1 is a receptor for

vascular endothelial growth factor (VEGF), and increased levels of the soluble form (sFlt-1) have been associated with endothelial dysfunction in pre-eclampsia. Serum levels of sFLT-1 are raised in SCD and so may play a role in the development of proteinuria.[23]

CLINICAL MANIFESTATIONS OF SICKLE CELL NEPHROPATHY

Glomerular Abnormalities

Hyperfiltration

Glomerular hypertrophy is ubiquitous in SCD and has been reported in children as young as 1 to 3 years of age (Fig. 49.7).[24] Increased renal growth is observed from infancy in children with SCD and accompanies the early rise in GFR.[25,26] GFR continues to rise throughout childhood and early adulthood, often exceeding 200 ml/min/1.73 m^2. However, in contrast to diabetic nephropathy, this hyperfiltration is not associated with an increase in systemic blood pressure (BP), because patients with SCD tend to have reduced systemic vascular resistance and hence lower mean arterial pressure when compared with age and ethnicity-matched controls.[23,27]

Microalbuminuria and Proteinuria

The appearance of albumin in the urine at levels above those detected in normal individuals occurs after a period of prolonged hyperfiltration and is apparent in some patients from late childhood. Unlike hyperfiltration, the prevalence of microalbuminuria continues to increase with age, reaching more than 60% of all patients with HbSS SCD over the age of 45 years.[14,28] In some patients, microalbuminuria can develop

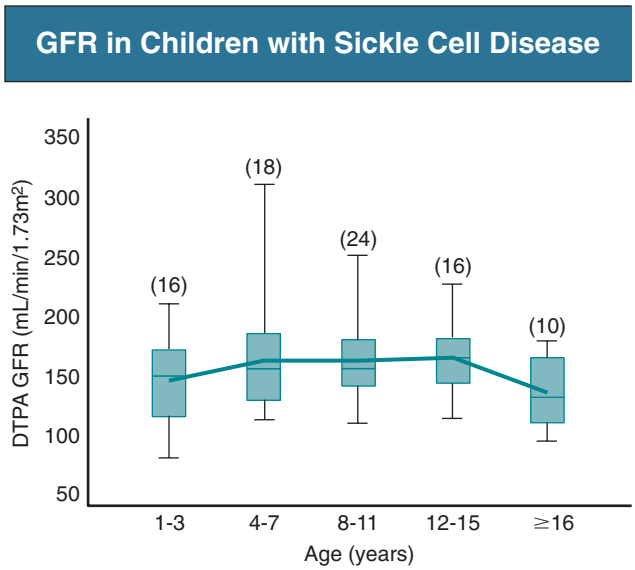

Fig. 49.7 Diethylenetriaminepentaacetic acid (DTPA) glomerular filtration rates in children with sickle cell disease. (From reference 24.)

into frank proteinuria (ratio of urine protein to creatinine ratio [uPCR] >50 mg/mmol), occasionally reaching the nephrotic range (>3.5 g/24 h), which is associated with increased mortality.[16] Nephrotic syndrome, although uncommon (~4% of all those with proteinuria) is associated with a very poor renal prognosis. One rare recognized cause of sudden

onset of nephrotic syndrome in patients with SCD is recent infection with human parvovirus B19 (HPV B19). Although widespread in the community, this usually benign infection becomes significant in patients with SCD because it causes acute but self-limiting red cell aplasia. In combination with severe hemolysis, this leads to life-threatening anemia requiring supportive transfusion. Several reports have described patients in whom infection was followed by acute nephrotic syndrome within 2 to 3 months. In cases in which biopsy has been performed early, the collapsing variant of focal segmental glomerulosclerosis (FSGS) has been found (with or without evidence of direct HPV B19 infection). Although the acute features of the nephrotic syndrome are self-limiting, the sequelae of the condition are worsening glomerulosclerosis, tubulointerstitial fibrosis, and progressive renal dysfunction.[29]

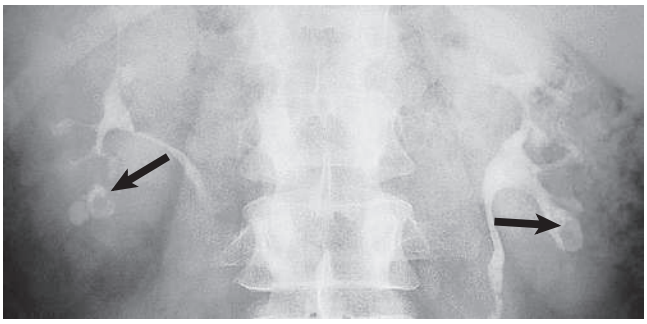

Fig. 49.8 Papillary necrosis in sickle cell disease. Intravenous urography shows abnormal calyces with filling defects *(arrows)*.

Tubular Abnormalities

Hyposthenuria

Hyposthenuria (the excretion of urine of low specific gravity secondary to inability of the kidney to concentrate the urine) is almost universal in people with SCD, who can rarely achieve a urine osmolality above 450 mOsm/kg, even under water-deprived conditions, and also occurs in older people with sickle cell trait. It often leads to enuresis in children and can cause marked dehydration. It is primarily caused by sickling in the vasa recta, leading to microthrombi, infarction, and collateral formation of blood vessels. As a consequence there is a defect in the countercurrent exchange mechanism resulting in insufficient trapping of solute in the inner medulla leading to abnormalities in renal water conservation.[20] In addition, the increased delivery of salt and water in the tubular filtrate secondary to the high GFR and the intermittent hypoxia caused by sickling in the microvasculature, lead to local endothelin-1 (ET-1) release. ET-1 is not only a potent vasoconstrictor but also has marked natriuretic and diuretic properties through stimulation of ET type b receptors in the renal collecting ducts, leading to increased salt and water loss.[30] Although hyposthenuria is reversible by blood transfusion until the age of 10 years, after this age it becomes irreversible and is associated with a permanently damaged microvasculature and increased urine output, leading to a tendency to dehydration.[20,31]

Increased Proximal Tubular Function

The increase in sodium and water loss from the nephron leads to a reactive increase in sodium and water reabsorption by the proximal tubule secondary to tubuloglomerular feedback. This reabsorption of sodium is the driving force for the reabsorption of other solutes such as phosphate and β2-microglobulin, and hence many patients have hyperphosphatemia. There is also an increase in proximal tubular secretion of other solutes, such as creatinine and uric acid. Despite this, serum levels of uric acid are often raised as a result of severe hemolysis and may result in episodes of acute gout. In contrast, up to 30% of the total creatinine excretion can arise from tubular secretion resulting in low serum creatinine levels and over-estimation of renal function when creatinine-based formulas for GFR are used.[32] Increased sodium reabsorption requires increased oxygen consumption and hypermetabolism of the renal tubules; a phenomenon that may exacerbate renal hypoxia in SCD.[23]

Acidification Defect

A retrospective study in 2014 of 411 homozygous SCD patients with eGFR greater than 60 ml/min/1.73 m^2 revealed that 42% had partial metabolic acidosis as assessed by serum levels of carbon dioxide (52% of women, 27% of men), apparently because of a lack of ammonia buffering capacity rather than a defect in the distal tubule. Although serum potassium levels were not linked to acidosis in this study, hyperkalemia is a common phenomenon in patients with SCD and has been attributed by others to hyperchloremic metabolic acidosis linked to type IV renal tubular acidosis or resistance of the distal tubule to aldosterone.[23]

Hematuria, Papillary Necrosis, and Renal Medullary Carcinoma

Hematuria is common in patients with SCD and sickle cell trait. It can range from painless microhematuria, through visible and painless, to visible and painful. It is usually self-limiting but occasionally can be severe enough to require transfusion. Microinfarcts, capillary congestion, and rupture are often the cause, but occasionally, complete occlusion of the vasa recta can lead to renal papillary necrosis with sloughing of the ischemic papilla, severe hemorrhage, and obstruction, which may be complicated by superimposed infection and painful clot colic (Fig. 49.8).[18] The left-sided predominance of hematuria has been attributed to the so-called nutcracker phenomenon, with compression of the left renal vein between the aorta and the superior mesenteric artery, increasing the pressure in the renal vein. This may contribute to the development of hematuria in in patients with SCD, because the increased renal vein pressure could worsen anoxia in the renal medulla, increasing the likelihood of sickling in the left kidney.

Renal medullary carcinoma is an aggressive form of renal cell carcinoma that uniquely affects patients with sickle cell hemoglobinopathies, particularly sickle cell trait or HbSC, especially in teenagers and young adults. Chronic medullary hypoxia is thought to contribute to its pathogenesis. The tumors are resistant to chemotherapy and tend to be metastatic at diagnosis, with a reported postsurgical mean survival of only 15 weeks. It is not yet clear whether regular evaluation for renal medullary carcinoma in young patients with SCD or trait could result in an early diagnosis and a better survival. Gross hematuria, flank pain, and weight loss are ominous signs of malignancy, particularly in young patients with sickle cell trait. The tumor is typically located deep in the parenchyma, unlike Wilms tumor or renal cell carcinoma. Immunohistochemical analysis for epithelial cell markers (e.g., CAM 5.5), epithelial membrane antigen, and cytokeratin may assist in diagnosis.[22,33]

URINARY TRACT INFECTIONS

Patients with SCD have an increased susceptibility to bacterial infections; even low-grade bacteremia with a common organism may be fatal. In addition to the impaired immunity resulting from autosplenectomy, there is opsonic antibody deficiency, which predisposes to bacterial infections. Bacteriuria was found to be present in 26% of children with SCD presenting with fever in Nigeria, and urinary tract infection complicated pregnancy in 12% of mothers with SCD in a large UK cohort.[34,35]

Pyelonephritis and urosepsis, as with any infection, may precipitate a sickle cell crisis. The most common organisms isolated include *Escherichia coli, Klebsiella* spp., and other gram-negative Enterobacteriaceae.

CLINICAL SYNDROMES OF RENAL IMPAIRMENT

Acute Kidney Injury

Although much is known about CKD, there is little in the literature about AKI in patients with SCD. It is reported as a complicating factor in 2% to 8% of hospital admissions with painful VOC or ACS. The severity of the AKI appears to be directly related to the severity of the acute sickling crisis.[36,37] Other causes of AKI are rhabdomyolysis, sepsis, and drug nephrotoxicity. Less common causes of acute renal dysfunction are renal vein thrombosis and hepatorenal syndrome (caused by SCD related hepatic failure). Volume depletion due to inability to concentrate urine makes patients more susceptible to AKI. Although most patients recover, repeated episodes of AKI increase the risk for CKD. After severe episodes, renal function on recovery is often lower than before the acute event.[3,38] In addition, patients with underlying CKD are more prone to AKI, making this a vicious cycle in patients with frequent hospital admissions.

Progressive Chronic Kidney Disease

Progressive loss of renal function in SCN is an increasingly large problem as life expectancy increases. Similarly to diabetic nephropathy, patients with SCN progress through stages of tubular dysfunction and hyperfiltration, through microalbuminuria to heavy proteinuria, and eventually loss of GFR. Over time, single-nephron GFR increases as other nephrons are lost, resulting in worsening damage to the glomeruli (manifest by FSGS), increasing proteinuria, and subsequent interstitial fibrosis and tubular atrophy. Although hypertension is less common in patients with SCD than in an age- and ethnicity-matched cohort, when it is present it has a marked impact on the rate of progression of CKD.[39] Predictors of CKD are hypertension, proteinuria, nephrotic syndrome, hematuria, increasingly severe anemia, and inheritance of the Bantu, or Central African Republic, β-globin gene cluster haplotype. In our series, younger age at diagnosis and higher duration of SCD were found to strongly predict the development of nephropathy.[40,41]

As renal function declines, the ability of the kidney to synthesize erythropoietin (EPO) also declines. Chronic anemia and tissue hypoxia are strong drivers for EPO synthesis, and patients with SCD with normal kidney function often have EPO levels well above the normal range. However, when the GFR falls below approximately 60 ml/min, their ability to produce sufficient endogenous EPO also begins to decline, resulting in worsening anemia. In patients who develop progressive renal dysfunction secondary to SCN, the rate of decline can be quite rapid once the GFR falls below 40 ml/min/1.73 m^2, and so timely preparation for renal replacement therapy (RRT) is very important. Many patients who have suffered frequent vaso-occlusive crises and admissions to hospital often have very poor peripheral veins and so need expert surgical input when planning for dialysis access.

INVESTIGATION AND MANAGEMENT OF SICKLE CELL NEPHROPATHY

Serum cystatin C is promising as a more accurate marker of renal function than creatinine in adults and children with SCD and may detect decline in GFR earlier.[18] However, it has yet to be fully validated against gold standard measures that calculate true GFR, so at present creatinine and creatinine-based equations, which estimate GFR, should continue to be used in patients with SCD. It is therefore the pattern and rate of change of either serum creatinine or eGFR that should be considered rather than the absolute value, bearing in mind that relatively modest changes in creatinine at higher levels of GFR can represent significant decline in renal function. Renal function should be monitored at least annually. Creatinine levels are often low in people with SCD secondary to reduced muscle bulk, hyperfiltration, and increased proximal tubular secretion, resulting in a high eGFR. Increased rate of change of creatinine may therefore indicate declining renal function before the value moves out of the normal range. Anyone with an eGFR that is declining at more than 5 ml/min/year or an absolute value less than 60 ml/min should be identified and referred to a nephrologist (Fig. 49.9). Rigorous BP control is recommended, as for other causes of CKD.[39] A BP of 140/90 is permissible for patients with a negative dipstick result or those with an ACR less than 3.5 mg/mmol, but a target of 130/80 should be used for those with an ACR greater than 3.5 mg/mmol.[42] Urinary tract infections should be promptly treated with appropriate antibiotics. Glucose-6-phosphate dehydrogenase deficiency (G6PD deficiency), which may precipitate intravascular hemolysis, should be excluded because some antibiotics, including sulfonamides and nitrofurantoin, precipitate hemolysis by antagonizing folate synthesis. Long-term use of nonsteroidal antiinflammatory drugs should be avoided in patients with an eGFR less than 60 ml/min; if unavoidable, regular monitoring of renal function is recommended.[43]

The population at risk for developing SCN is also at risk for other diseases that affect the kidneys, including lupus nephritis, various forms of glomerulonephritis, blood-borne viruses, renal carcinoma, myeloma, and renal stones. This differential should be considered when investigating a patient with SCD and new-onset proteinuria or hematuria. Although it is common practice not to investigate patients with microalbuminuria (ACR >3.5 mg/mmol), patients with urinary protein to creatinine ratio (uPCR) greater than 50 mg/mmol should be evaluated for other causes of CKD (Fig. 49.9); if any of these investigations are abnormal, or the patient's signs and symptoms do not conform to those expected within the natural history of SCN as described previously, they should be referred for further renal or urologic evaluation. In particular, patients with sudden onset of heavy proteinuria, with or without nephrotic syndrome, warrant renal biopsy to look for causes other than SCN. There is no pathognomonic lesion that defines SCN. Glomerular hypertrophy with distended capillaries is universally found but is not confined to those who have developed microalbuminuria or proteinuria. FSGS is the most common lesion associated with proteinuria, but is not specific to SCN (Fig. 49.10). Other lesions that have been reported on renal biopsy in SCD include thrombotic microangiopathy and membranoproliferative glomerulonephritis, neither exclusive to SCN. The only characteristic interstitial lesion is abundant hemosiderin granules in proximal tubular epithelial cells.[44] Renal iron deposition also has been noted on magnetic resonance scans in patients with SCD but appears not to be related to liver iron concentration, a marker of total body iron load. Renal iron does appear to be correlated with markers of hemolysis but has not been shown to be associated with renal dysfunction or degree of albuminuria.[45]

Inhibition of the Renin-Angiotensin System

Only one small randomized, controlled trial evaluated angiotensin-converting enzyme (ACE) inhibition in patients with SCD and proteinuria; a more recent systematic review concluded that available evidence was insufficient to offer recommendations on treatment.[46] However, based on the evidence available for other causes of proteinuric renal disease, it is recognized practice to use ACE inhibitors or angiotensin receptor blockers (ARBs) in the treatment of SCN when the uPCR is greater than 50 to 100 mg/mmol. These drugs must be introduced cautiously because many patients have a low or normal BP, and so moderate doses can cause postural hypotension, which can be

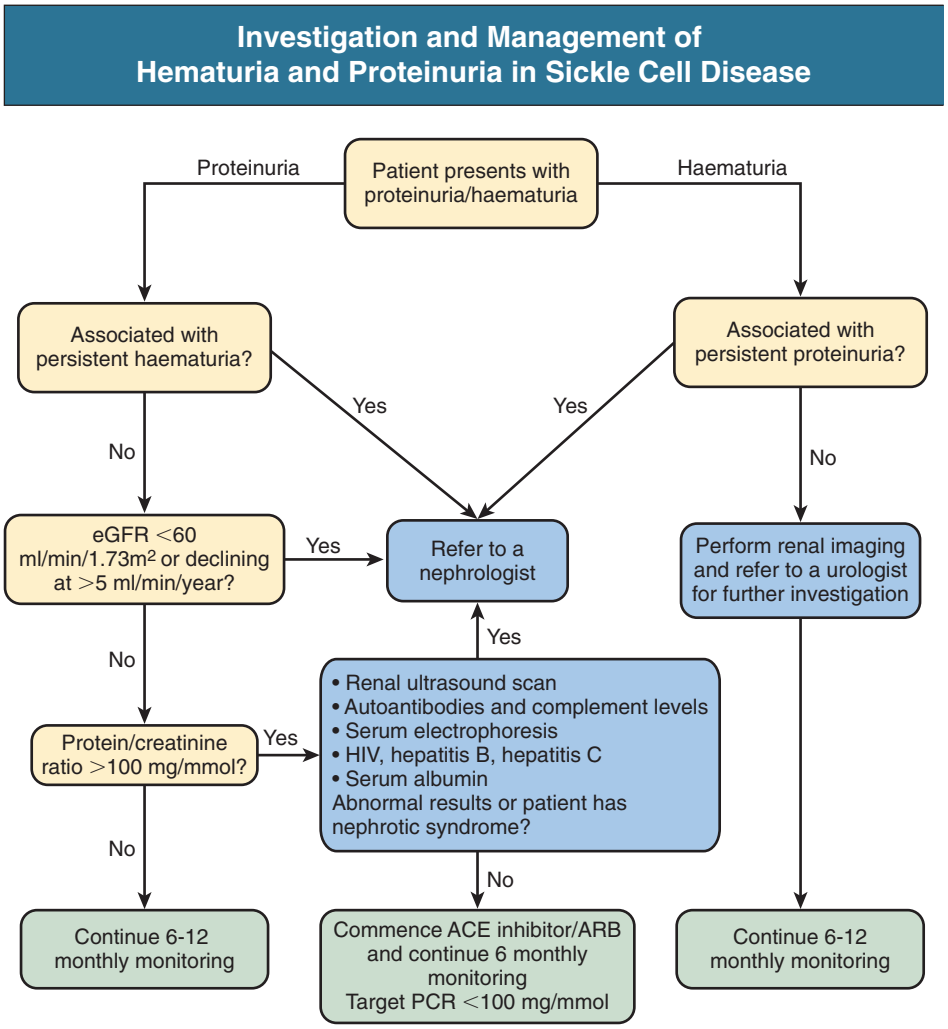

Fig. 49.9 Investigation and management of hematuria/proteinuria in patients with sickle cell disease.

partially circumvented by taking the medication at bedtime. Patients have reported that this has the benefit of reducing nocturnal urinary frequency, presumably as a direct result of a functional drop in GFR. Patients with SCN are prone to hyperkalemia, which can be exacerbated by ACE inhibitor and ARB treatment and is often the dose-limiting factor. It is also particularly important to inform patients and other caregivers that ACE inhibitors and ARB should be temporarily stopped during acute illnesses associated with dehydration to mitigate the risk for AKI.[3]

Hydroxycarbamide and Blood Transfusion

Oral hydroxycarbamide (HC; also known as hydroxyurea) is the only licensed drug for the management of SCD. Although it has pleotropic effects, it primarily acts to increase levels of fetal Hb that serve to dilute the levels of HbS and reduce risk for polymerization. There are, however, no RCTs of HC in the management or progression of SCN in adults and only one in infants, which showed no impact on hyperfiltration, though urinary concentrating ability was improved.[47] A number of observational trials of HC in older children and adults have shown both a reduction in hyperfiltration and albuminuria.[3] Hydroxycarbamide therefore should be considered for patients with microalbuminuria/proteinuria or abnormal renal function alongside treatment with an ACE inhibitor or ARB (or in those intolerant of this treatment).

There is little evidence for the benefits of long-term RBC transfusions on prevention of renal complications of SCD. A retrospective analysis of 120 children with sickle hemoglobinopathies concluded that chronic transfusion protected against the onset of microalbuminuria when commenced before the age of 9 years. Two studies, however, found that chronic transfusion made no difference to onset of proteinuria

and prolonged courses of transfusion therapy can lead to iron overload, which is particularly difficult to treat in patients with CKD.[3]

Erythropoiesis-Stimulating Agents

ESAs can be useful, particularly in combination with HC in patients who are intolerant of HC alone because of reticulocytopenia. They should be commenced when the Hb has fallen by approximately 10% to 15% from the normal baseline at steady state, though patients with CKD stages 3 to 4 often require very high doses of ESAs to have an impact on Hb levels. Although Hb targets should be lower than in the general population with CKD (80 to 100 g/dl) because of the increased risk for triggering vaso-occlusive crises, they are rarely achieved and most patients become transfusion dependent by the time they reach ESRD. However, it is often still beneficial to continue ESA therapy after the commencement of RRT because this can prolong the interval between RBC transfusion and minimize the risks for iron overload.[3] It is important to ensure that adequate iron stores are maintained to achieve maximum erythropoiesis. Intestinal losses of iron resulting from subclinical bleeding are significant in advanced CKD and absorption of oral iron is reduced. Intravenous iron supplementation may be necessary therefore in patients deficient in iron, on ESAs, and not receiving iron through regular transfusions.

Hemopoietic Stem Cell Transplantation

Hemopoietic stem cell transplantation (HSCT) is potentially curative but has largely been limited to children with severe cerebrovascular complications, ACS, or frequent VOC not responding to HC therapy. The few reports of HSCT in adults with SCN have mixed renal outcomes.[3]

RENAL REPLACEMENT THERAPY

Dialysis

Outcome data for patients with SCD on dialysis are few, but one report from the United States showed that the average age of those reaching ESRD was very young (23.1 years in patients with HbSS) and the mean time to death after was only 4 years despite regular hemodialysis.[41] Similar findings were reported in patients in Saudi Arabia; those with SCD suffered more infectious complications, lived on average for only 27 months after commencing RRT, and were significantly younger when they died (31 vs. 47.8 years) compared with patients with ESRD of other causes.[48] An examination of the U.S. Renal Data System of all patients who commenced RRT between 1992 and 1997 revealed that, not only was SCN an independent risk factor for death, but patients with SCD were much less likely to receive a kidney transplant.[49] More recently, a 5-year study of patients with SCD receiving hemodialysis in France reported that patients with SCD were much more likely to die over a 5-year period compared with a hemodialysis population with ESRD from other causes (46.3% vs. 6.4%) and were much less likely to receive a kidney transplant (26% vs. 53.5%).[50] Infectious complications and thrombosis of dialysis access was a common complication in the group with SCD.

Transplantation

Although there may be many obstacles in the path to kidney transplantation, it is probably the modality that offers the best outcome for patients with SCD requiring RRT.[51] SCN ceases to be an independent risk factor for death after transplantation. A study of the U.S. Renal Data System identified 82 patients who had received a renal transplant for SCN. The 1-year acute rejection rate and graft survival were not significantly different in these patients compared with ethnically matched controls who received grafts for other causes of renal failure, though the 3-year graft survival was lower (48% vs. 60%).[52] Although long-term graft and patient survival are not quite as good as for patients with other causes of ESRD, the prognosis for individuals with SCN is far better after transplantation with a projected 7-year survival of 67% (vs. 83% for other African Americans) when compared with a 10-year survival of only 14% for those who remain on dialysis.[22] Although outcomes after transplantation in SCD have improved over the last 20 years and the results are comparable to those in patient groups without SCD, it is not without complications. Delayed graft function and graft loss are more common than in other patient groups, and the recurrence of frequent VOC after transplantation as the Hb rises is problematic. Treatment with regular exchange transfusion aimed at keeping the HbS level below 30% may help reduce the risk for these complications.[3]

SICKLE CELL TRAIT AND CHRONIC KIDNEY DISEASE

In patients with heterozygous sickle cell trait, approximately 40% of their RBC Hb is HbS and the rest is normal HbA. In general these patients have normal Hb levels and do not have symptoms of hemolysis or vaso-occlusion. However, there have been reports of catastrophic vaso-occlusive crises and sudden death in young people with sickle cell trait under extreme adverse conditions such as excessive exercise or exposure to severe hypoxia. In addition, renal medullary carcinoma is more common in patients with SCT than SCD, though the reasons for this are unclear. Non-malignant microhematuria and macrohematuria are reported more frequently in patients with sickle cell trait than in the general population, and older patients exhibit a loss of urinary concentrating ability. Patients who co-inherit sickle cell trait and adult polycystic kidney disease (APKD) have a more rapid decline to ESRD than family members with APKD who do not carry an HbS gene. Whether having sickle cell trait alone is a risk factor for progressive CKD has been debated, but a recent study in the United States using data from five large prospective studies of African Americans concluded that patients with SCT had an odds ratio (OR) of developing incident CKD of 1.76, an OR of experiencing a decline in renal function of 1.32, and an OR of having albuminuria of 1.86 compared with noncarriers.[23,53,54]

SELF-ASSESSMENT QUESTIONS

1. Hyperfiltration is an early sign of sickle cell nephropathy and can be detected from:
   - **A.** Infancy
   - **B.** Teenage years
   - **C.** Early adulthood
   - **D.** After the fourth decade of life
2. Albuminuria is more common in patients with:
   - **A.** HbSS disease than HbSbeta thalassemia
   - **B.** Sickle cell disease (SCD) and α-thalassemia than SCD alone
   - **C.** HbSS disease than HbSC disease
   - **D.** SCD but low levels of hemolysis
3. Inhibitors of the renin-angiotensin system:
   - **A.** Always should be avoided in patients with SCD because of the risk for hyperkalemia
   - **B.** Have been demonstrated to be effective in SCN in a large randomized, controlled trial
   - **C.** Should be stopped during acute sickle crisis
   - **D.** Always should be taken in the morning

50

Congenital Anomalies of the Kidney and Urinary Tract

John O. Connolly, Melanie M. Y. Chan, Guy H. Neild

Congenital anomalies of the kidney and urinary tract (CAKUT) are a group of phenotypically diverse structural malformations characterized by defects in renal and urinary tract development. Nearly half of children who develop end-stage renal disease (ESRD) have asymmetric, irregularly shaped kidneys,[1,2] often referred to as *bilateral renal scarring* and frequently associated with lower urinary tract anomalies, including vesicoureteral reflux (VUR). These cases were previously described as reflux nephropathy or chronic pyelonephritis; but with advances in genetics and developmental biology, it is becoming clear that many are the result of primary renal malformations (renal dysplasia) often associated with congenital malformations of the ureter, bladder, and urethra. This is a change from the view that renal scarring and damage are secondary to the outflow problem and ureteral reflux. Although it is still a matter of some debate, the concept of acquired renal scarring is often wrong, and the British Association for Pediatric Nephrology now suggests that clinical distinction between reflux nephropathy and renal dysplasia is unnecessary.[1]

CLINICAL PRINCIPLES

Congenital renal tract abnormalities may present in one of the following five settings:

1. Antenatal diagnosis by fetal ultrasound screening
2. Failure to thrive in an infant or young child
3. Investigation of urinary tract infection (UTI)
4. An incidental finding in a child or adult
5. An adult with abnormal urinalysis, stones, hypertension, or renal impairment

The identification of these problems always poses the following questions:

- What is the cause?
- What is the natural history?
- Is surgical intervention required?

Such patients fall into two broad groups. First, there is a group of patients who appear to have normal bladders without outflow obstruction and normal caliber ureters when not micturating, described as having either primary VUR or primary renal dysplasia. Second, there is a group with some form of bladder outflow dysfunction that causes secondary VUR and dilated upper urinary tracts, the most common cause of which is posterior urethral valves in males.

As predicted by the Brenner hypothesis,[3] small asymmetric kidneys with reduced glomerular filtration rate (GFR) develop all the features of glomerular hyperfiltration, with the onset of progressive renal failure signaled by increasing proteinuria. This now can be significantly modified by treatment with renin-angiotensin system (RAS) blockade.[4] The details of antenatal and pediatric management of these patients are beyond the scope of this chapter, which focuses on management in adolescence and adult life.

DEVELOPMENT OF THE KIDNEY AND URINARY TRACT

The kidneys and urinary tract develop simultaneously from the cloaca and intermediate mesoderm (Fig. 50.1).[5-7] Kidney development can be divided into three phases; the pronephros, mesonephros, and metanephros. The pronephros develops 22 days after conception and forms a transient, rudimentary, and nonfunctioning system that degrades by day 28. It elongates caudally to meet the cloaca by day 26, becoming the mesonephric (Wolffian) duct, which ultimately contributes to the formation of the urinary bladder and male genital system (epididymis and caudal vas deferens). Functioning mesonephric tubules develop from the intermediate mesoderm and start to excrete urine, although most of these subsequently degenerate. By the 5th week of fetal life the ureteral bud branches from the caudal part of the mesonephric duct into the metanephric mesenchyme to become the metanephros, the precursor to the adult kidney (see Fig. 50.1A). This process is mediated by the GDNF/c-RET/Wnt-11 signaling pathway, disruptions of which can result in varying phenotypes, including renal agenesis. Reciprocal induction between the ureteral bud and the metanephric mesenchyme results in branching morphogenesis and elongation of the ureteral bud to form the collecting system and mesenchymal epithelial transformation of the metanephric mesenchyme to generate primitive nephrons (see Fig. 50.1B to D). The metanephros starts to function 6 to 10 weeks after fertilization, with nephrogenesis complete by 36 weeks. Sixty percent of nephrons are formed in the last trimester, which has important clinical implications for preterm and low-birth-weight infants, who have increased long-term risk for chronic kidney disease (CKD).[8] The extent to which reduced nephron number contributes to this increased risk relative to exposure to nephrotoxic insults and acute kidney injury as a neonate is not yet understood.

The lower urinary tract is formed from the endodermal cloaca, which is divided by the urorectal septum into ventral and dorsal parts that develop into the urogenital sinus and rectum, respectively (see Fig. 50.1E). The urogenital sinus gives rise to the early bladder, the urethra and vestibule of the vagina in females, and the posterior urethra in males. Growth of the anterior abdominal wall between the allantois and the urogenital membrane is accompanied by an increase in size and capacity of this bladder precursor. The allantois remains attached to the apex of the fetal bladder and extends into the umbilical root, although it loses its patency and persists as the urachal remnant, the

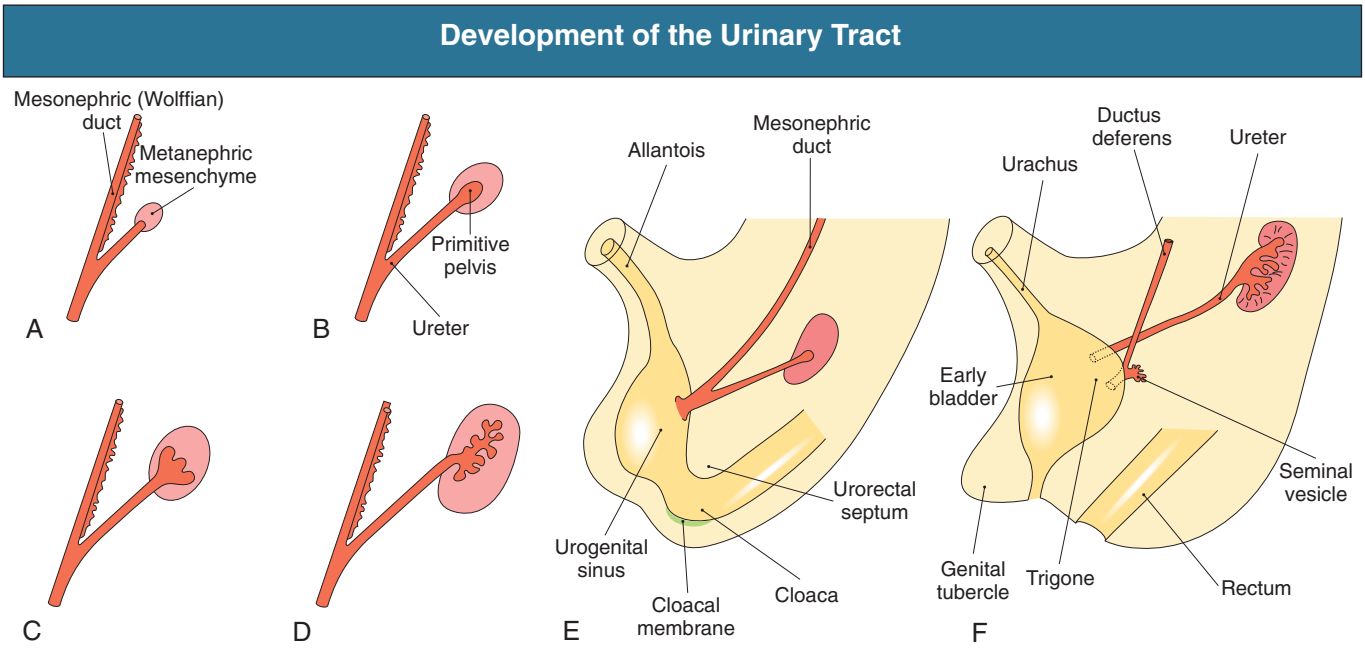

Fig. 50.1 Development of the urinary tract. Growth and development of the ureter, pelvis, and calyces are shown in parts (A) to (D). (A) The metanephric kidneys first become detectable as small areas in the mesoderm close to the aorta. The primitive epithelial ureter buds off from the mesonephric duct and makes contact with the metanephric mesenchyme. (B) Under the influence of signals from the ureter, the mesenchyme condenses and proliferates around the ureteral tip, with simultaneous elongation and branching of the ureteral tip. (C and D) A primitive pelvis appears, then branches to form the divisions of the calyces. The branching process continues, with the epithelial system eventually differentiating into the nephrons of the renal parenchyma. As the fetus grows, the kidney ascends because of the continuous rostral growth. (E) Growth and development of the cloaca during weeks 5 to 6 of gestation. (F) Growth and development of the urogenital sinus into bladder and outflow tract during weeks 8 to 9.

median umbilical ligament, which connects the bladder to the umbilicus (see Fig. 50.1F). By the seventh week, there is a separate opening of the distal mesonephric duct into the bladder at what will become the vesicoureteral opening and the area known as the *trigone*. At the same time the paramesonephric (müllerian) ducts start to regress in males and fuse in females to become the uterovaginal cord, which opens into the urogenital sinus and will go on to develop into the vagina.

PATHOGENESIS

Familial clustering, monogenic syndromes associated with urinary tract malformations, and animal models suggest a strong genetic basis for CAKUT. Ultrasound screening of asymptomatic first-degree relatives of patients with CAKUT reveals structural urinary tract malformations in up to 23%.[9] Developmental mouse models, candidate gene studies, genome-wide linkage analyses, targeted next-generation sequencing, and copy number variation analyses have all contributed to our current understanding of the genetic causes of CAKUT, with over 40 monogenic CAKUT-causing genes identified. However, the genotype-phenotype heterogeneity and incomplete penetrance seen in this disorder means that a genetic cause has been identified in less than 20% of patients.[10] Environmental and epigenetic factors are also thought to contribute to the pathogenesis of CAKUT. Pregestational maternal diabetes mellitus has been associated with an increased risk for kidney and urinary tract anomalies, with hyperglycemia shown to adversely affect nephron number in animal models.[10]

Renal development is tightly regulated by the expression of transcription factors, growth factors, and adhesion molecules.[6] Pathogenic variants of in genes encoding all classes of these molecules, affecting different stages of nephrogenesis, have been identified in patients with CAKUT (Table 50.1). Variants in the transcription factors *HNF1B* (hepatocyte nuclear factor 1B) and *PAX2* (paired box gene 2) are estimated to explain approximately 15% of CAKUT (both syndromic and isolated) and are associated with cystic kidneys and renal hypodysplasia, respectively.

- HNF1B mediates the development of the kidneys, liver, pancreas, and urinary tract. Heterozygous variants can result in renal cysts and diabetes syndrome[11] but have also been identified in a wide range of isolated CAKUT phenotypes, including renal hypodysplasia, cystic kidneys, single and horseshoe kidneys, and malformations of the collecting system.[12] *HNF1B* mutations are also associated with extrarenal phenotypes (mature-onset diabetes of the young [MODY] type 5, pancreatic hypoplasia, genital malformations, hyperuricemia, and hypomagnesemia), highlighting the utility of a molecular diagnosis in guiding screening for possible nonrenal associations.
- *PAX2* is expressed in the metanephros, in cell lineages forming nephrons, and in those destined to differentiate into the ureter, renal pelvis, and branching collecting duct system. *PAX2* homozygous mutant mice are born without kidneys, ureters, or genital tracts, suggesting its role in multiple steps of urogenital development.[13] Heterozygous variants in *PAX2* were first discovered in patients with renal-coloboma syndrome presenting with renal hypodysplasia, optic nerve abnormalities, and hearing loss, but variants have now been

identified in a wide range of phenotypes, including VUR and multicystic dysplastic kidney (MCDK).[14]

- Normal development of the lower urinary tract requires urinary tract epithelial differentiation, formation of smooth muscle and neuromuscular differentiation to initiate peristalsis of urine from the fetal kidney to the bladder.[15] *UPK3A* is expressed in embryonic urothelial cells and believed to be important for urinary tract epithelial differentiation. Although *Upk3a*-null mice develop VUR,[16] variants in *UPK3A* have yet to be confirmed as pathogenic in CAKUT. Similarly, mice lacking the transcription factor Teashirt 3 *(Tshz3)* fail to develop normal smooth muscle in the ureter and have congenital hydronephrosis without anatomic obstruction[17]; however, no pathogenic variants have yet been identified in humans. Autosomal recessive mutations in heparanase 2 *(HPSE2)* have been detected in patients with urofacial syndrome, a congenital disease characterized by grimacing and incomplete bladder emptying, but have yet to be otherwise implicated in congenital bladder obstruction.[18]

Administration of angiotensin-converting enzyme (ACE) inhibitors during pregnancy in humans can cause hypotension and anuria in the baby with histologic features of renal tubular dysplasia. This phenotype is also seen in patients with recessive mutations in the genes renin *(REN),* angiotensinogen *(AGT), ACE* and angiotensin II receptor type 1 *(AGTR1),*[19] emphasizing the importance of the RAS in maintaining an adequate systemic blood pressure (BP) and renal blood flow for normal fetal kidney development.

EPIDEMIOLOGY

CAKUT accounts for 20% to 30% of all developmental anomalies identified in the antenatal period and has a prevalence of 3 to 6 per 1000 births.[10] It usually occurs in isolation; however, 30% are associated with nonrenal abnormalities and have been described in over 200 different syndromes, including Fraser syndrome, Kallman syndrome, and branchio-oto-renal syndrome. CAKUT accounts for 40% to 50% of children with CKD and is the leading cause of ESRD in children, accounting for 42% of those requiring renal replacement therapy (RRT).[10] CAKUT also contributes significantly to the burden of renal disease in adults accounting for 4.3% of patients with ESRD, with an estimated median age for initiation of RRT of 31 years.[10] Individuals with reduced nephron mass secondary to a solitary functioning kidney appear to have a worse renal prognosis; evidence of renal injury (defined as hypertension, albuminuria, or use of renoprotective medications) is seen in up to a third of children at a mean age of 10 years, and observational data suggest that 20% to 50% of patients with a congenital solitary kidney require RRT by the age of 30.[20]

RENAL MALFORMATIONS

Congenitally abnormal kidneys may be large or small, cystic or irregular in outline, and absent or misplaced. These conditions were traditionally discussed based on findings on intravenous urography (IVU), but are now primarily investigated with computed tomography (CT), magnetic resonance imaging, and nuclear medicine imaging.

Large Kidneys

Enlarged kidneys resulting from congenital problems are usually hydronephrotic or cystic. Wilms tumor also must be considered. The differential diagnosis in adults of enlarged kidneys, both congenital and acquired, is shown in Chapter 5 (see Fig. 5.1), and the differential diagnosis of cystic kidney disease is discussed further in Chapters 44 and 45.

Irregular Kidneys

Irregularity of the renal outline may result from fetal lobulation or a "dromedary hump," neither of which has any functional implications. Much more important is the diagnosis of renal dysplasia.

Renal Dysplasia

Table 50.2 presents the range of dysplastic and other malformations of the kidney. Abnormalities of the ureter, bladder, and urethra are often associated with renal dysplasia. All types of renal dysplasia can also occur as isolated developmental anomalies. Renal dysplasia, although typically producing small, irregular kidneys, may be cystic or multicystic renal dysplasia.

Renal Hypoplasia (Oligomeganephronia)

Renal hypoplasia is defined as a congenitally small kidney (two standard deviations below the expected mean) that lacks evidence of either parenchymal maldifferentiation (renal dysplasia) or acquired disease sufficient to explain the reduced size. The term is often used loosely, and includes small kidneys with a normal number of nephrons as well as oligomeganephronia. This is a type of renal hypoplasia resulting from a congenital reduction in the number of nephrons. It results from arrested development of the metanephric blastema at 14 to 20 weeks of gestation with subsequent hypertrophy of glomeruli and tubules in the kidney. The hypertrophy and hyperfiltration result in progressive nephron injury and sclerosis later in life. Oligomeganephronia is recognized on renal biopsy by the large size of the glomeruli and tubules and the small number of glomeruli seen despite a good core of renal cortex.

TABLE 50.2 Definitions of Renal Dysplasia and Malformations

Term	Characteristics
Renal agenesis	Absence of the kidney or an identifiable metanephric structure.
Renal aplasia	Severe dysplasia with extremely small kidney, sometimes identifiable only by histologic examination.
Renal dysplasia	Abnormal differentiation of renal parenchyma with development of abnormal structures, including primitive ducts surrounded by collars of connective tissue, metaplastic cartilage, variety of nonspecific malformations such as preglomeruli of fetal type, and reduced branching of collecting ducts with cystic dilations and primitive tubules. Dysplastic kidneys often contain cysts.
Renal hypoplasia	Significantly reduced renal mass with either normal or reduced (oligomeganephronia) nephron number without evidence of maldevelopment of parenchyma.
Renal hypodysplasia	Reduced renal mass and nephron number with dysplastic features. Previously thought to be secondary to scarring from reflux or reflux nephropathy, but now increasingly considered to be primary dysplasia with associated reflux.
Renal multicystic dysplasia	Severe cystic dysplasia with extremely enlarged kidney full of cystic structures; occurs as an isolated renal lesion in response to ureteral atresia and urethral obstruction; 10% of patients have a family history.

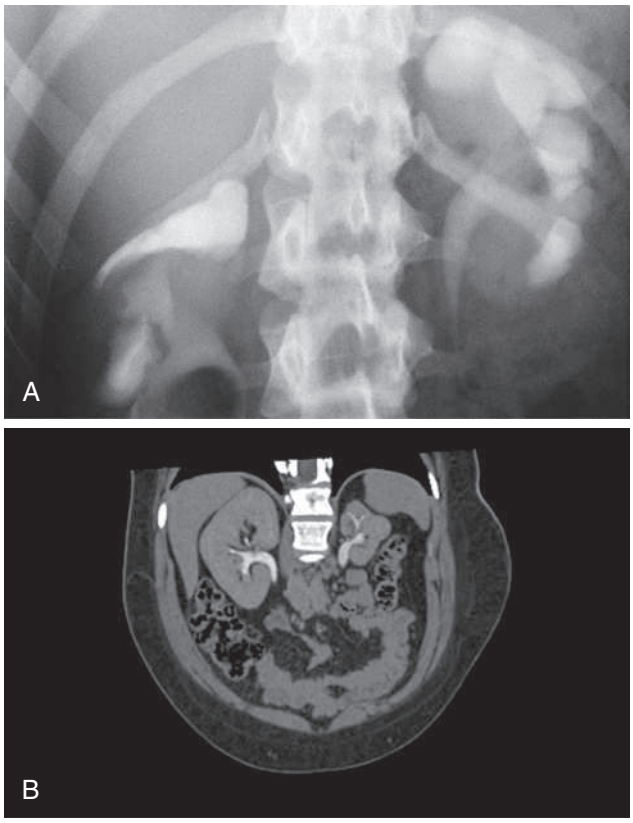

Fig. 50.2 Renal dysplasia. (A) Intravenous urogram (IVU) shows gross bilateral scarring in a 20-year-old woman who has been assessed since the age of 2 years. Progressive scarring has been observed in the absence of urinary tract infections and obstruction. This probably represents primary renal dysplasia. (B) Computed tomography IVU shows gross scarring of right kidney. (Courtesy Dr. A. Kirkham, University College Hospitals, London.)

Differential Diagnosis of Scarred Kidneys

Renal hypodysplasia versus reflux. Progressive scarring and renal failure were once considered to be caused by chronic parenchymal infection (so-called chronic pyelonephritis) and were regarded as a consequence of VUR. The 1980s, however, saw a retreat from the paradigm of the primary role of infection, and emphasis was placed on scarring as a result of reflux and the progressive nature of the glomerular lesion associated with glomerular hypertension (or hyperfiltration), so-called reflux nephropathy (see Chapter 61).[3] Current thinking is that scarring often follows from renal dysplasia, and that the reflux is a secondary or incidental feature (Fig. 50.2). Thus irregular kidneys with normal-caliber ureters are more likely to be caused by primary dysplasia, and no evidence of VUR may be seen.

Renal scarring in adults. A practical clinical problem is the differential diagnosis of scarred, asymmetric kidneys. With older patients, the differential diagnosis of scarred or "lumpy, bumpy" kidneys widens. Sometimes attributed to other diagnoses, including analgesic nephropathy, this appearance is now often designated reflux nephropathy. In older patients, multiple scarring from atheromatous arterial disease and embolization of the kidney is an increasingly important cause of renal failure. The diagnosis has historically been made by the radiologic features on IVU, but CT and magnetic resonance (MR) urography are now the gold standard, with scarring best demonstrated by technetium 99m–labeled dimercaptosuccinic acid (^{99m}Tc-DMSA) scintigraphy.

Absent Kidneys

Unilateral Renal Agenesis

Complete absence of one kidney occurs in 1 in 500 to 1000 births. It can be familial and is referred to as *hereditary renal aplasia* by pediatricians. It is an autosomal dominant trait with incomplete penetrance and variable expression and can be associated with bilateral renal agenesis or severe dysplasia. Pathogenic variants in the genes *RET, BMP4, ITGA8, FRAS1,* and *FREM2* have been identified.[10]

Typically, there is no ureter, and the ipsilateral half of the bladder trigone is missing. The remaining kidney is usually hypertrophic, but it may be ectopic, malrotated, or hydronephrotic with a megaureter. The more severe the dysplasia of the remaining kidney, the earlier is the presentation. The ipsilateral testis and seminal tract are usually absent, and in 10% of cases, the adrenal gland is also missing. Girls can have an absent fallopian tube or ovary or malformation of the vagina or uterus. Other associations include imperforate anus and malformations of the vertebrae and cardiovascular system. Agenesis could result from failure in formation of the metanephros or the ureteral bud; however, in association with cloacal abnormalities, the ureteral bud is more likely.

Normality of the single kidney should be confirmed by ^{99m}Tc-DMSA scintigraphy, normal isotopic GFR, and absence of proteinuria. If the remaining kidney is abnormal or GFR is less than 30 ml/min, lifelong follow-up is necessary. Ultrasound of the kidneys is recommended in all first-degree relatives of individuals with unilateral or bilateral renal agenesis.

Bilateral Renal Agenesis

Bilateral renal agenesis is lethal. It is associated with pulmonary hypoplasia and a characteristic facial appearance (Potter facies) caused by

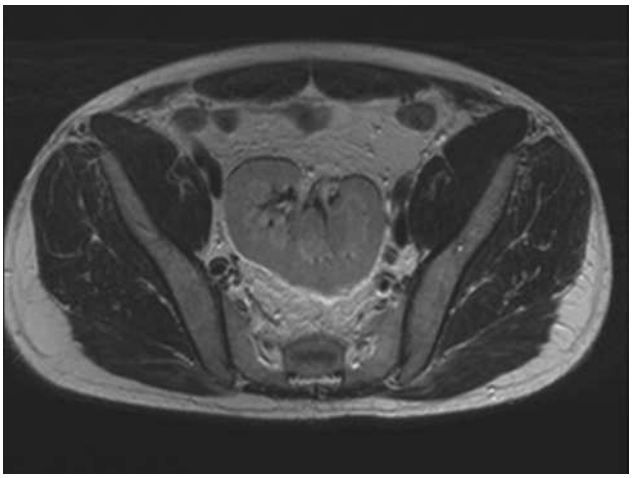

Fig. 50.3 Single pelvic kidney. MR scan, transverse section, shows single midline pelvic kidney. (Courtesy Dr. A. Kirkham, University College Hospitals, London.)

intrauterine compression, which is a consequence of oligohydramnios. The prevalence is about 1 in 10,000 births, with risk for occurrence in siblings of about 3%, unless there is a family history of agenesis, in which risk rises to 15% to 20%.

Misplaced Kidneys

Renal Ectopia, Malrotation, and Crossed Fused Kidneys

The starting position of the fetal kidney is deep in the pelvis. Kidneys that fail to ascend properly and therefore remain lower than usual occur in 1 in 800 births (Fig. 50.3). During development and ascent of the kidney, the renal pelvis comes to face more medially. The most common anomaly is for the pelvis to face forward. The more ectopic the kidney, the more severe is the rotation and more abnormal the appearance. In more than 90% of ectopia, there is fusion of both kidneys. This is best visualized on CT or MR urography (Fig. 50.4). Symptoms and complications, if any, are caused by associated reflux or pelviureteral junction (PUJ) obstruction.

Horseshoe Kidney

If both kidneys are low, they may join at the lower pole and are usually drained by two ureters (Fig. 50.5). The kidneys lie lower than normal, and further ascent is prevented by the root of the inferior mesenteric artery. Horseshoe kidney occurs in 1 in 400 to 1800 births and is more common in males (2:1). Patients present, if at all, with complications of reflux, obstruction, or stone formation.

Calyceal Abnormalities

Hydrocalyx and Hydrocalycosis

Dilated calyces are usually caused by obstruction. Focal dilation also can be caused by congenital infundibular stenosis, extrinsic compression from vessel or tumor, stones, or tuberculosis. If obstruction is excluded, the appearance is likely to be a congenital abnormality and can be an incidental finding. Moreover, if the GFR is normal and the divided function of the kidneys is 50:50, surgery to improve the anatomy should not be attempted.

Megacalycosis

In megacalycosis, there is bizarre dysplasia of the calyceal system with an increase in the number of calyces. There is no obstruction, and the cause is malformation of renal papillae. Megacalycosis is congenital, usually unilateral, and an incidental finding. It is much more common

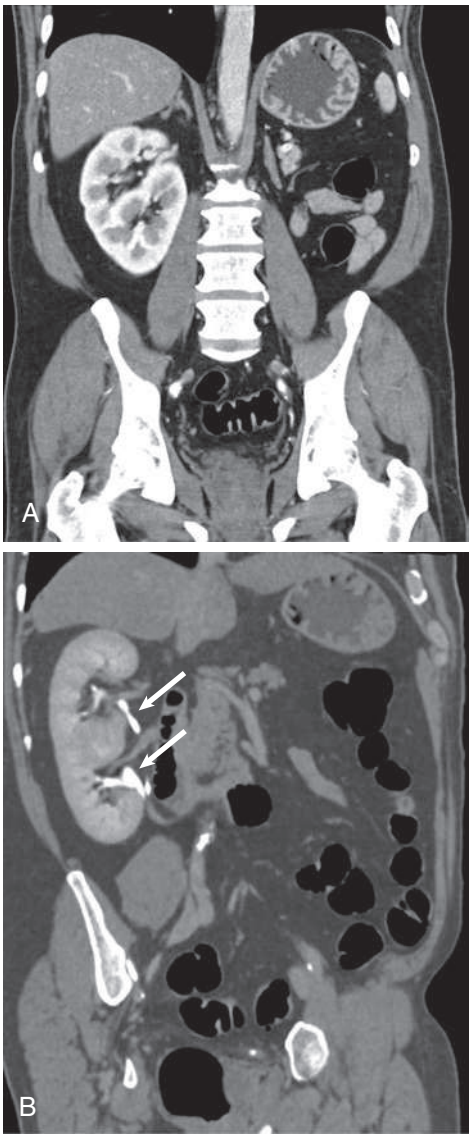

Fig. 50.4 Crossed fused ectopia. (A) MR scan shows fused kidneys on right. (B) There are two ureters *(arrows)*. (Courtesy Dr. A. Kirkham, University College Hospitals, London.)

in males (6:1) and has been described only in Caucasians. Bilateral disease is confined to males, and segmental, unilateral disease to females, which suggests an X-linked partially recessive gene with reduced penetrance in females. There may be an associated ipsilateral segmental megaureter, usually affecting the distal third.

Calyceal Diverticulum (Calyceal Cyst)

A calyceal diverticulum is a cavity peripheral to a minor calyx that is not a closed cyst but rather is connected to the calyx by a narrow channel (Fig. 50.6). It is usually an incidental finding and may manifest with symptoms relating to stones or infection within the cavity.

Bardet-Biedl Syndrome

Multiple calyceal clubbing and calyceal diverticula are the characteristic features of the renal dysplasia seen in Bardet-Biedl syndrome (formerly known as *Laurence-Moon-Biedl syndrome*). This autosomal recessive condition is characterized by retinitis pigmentosa, dysmorphic extremities (sometimes with polydactyly), obesity, and hypogonadism. Calyceal

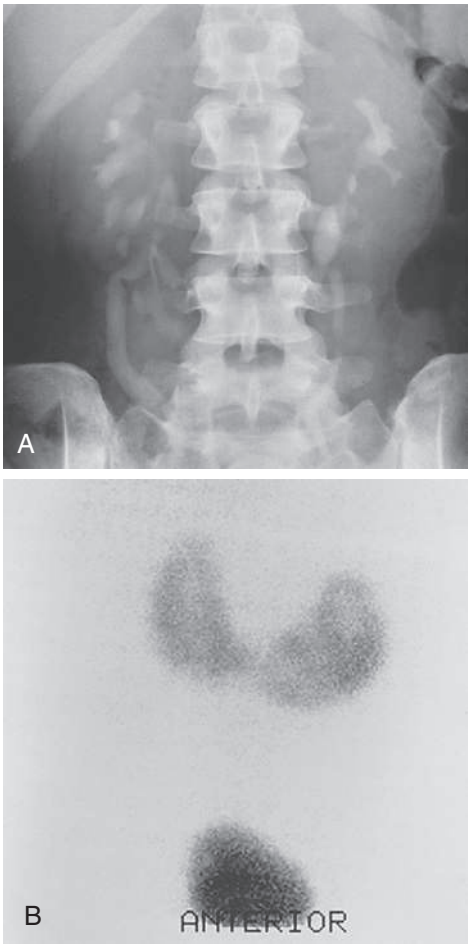

Fig. 50.5 Horseshoe kidney. (A) IVU soon after pregnancy in a 25-year-old woman shows not only the horseshoe kidney joining in the midline but also dilated ureters as a transient effect of pregnancy. (B) Dimercaptosuccinate scan shows a horseshoe kidney.

malformation is associated with parenchymal dysplasia; renal failure in early adult life is common. It has now been shown that Bardet-Biedl syndrome is caused by a defect of the basal body of ciliated cells,[21] and mutations in 20 genes coding for different proteins located in the basal body and cilia of the cell have been reported, making the syndrome an archetypal ciliopathy.

Pelviureteral Junction Obstruction

In children, PUJ obstruction is one of the most frequent causes of obstructive uropathy. The condition is usually congenital but can have an acquired mechanical basis caused by stenosis or external compression from adhesions, aberrant lower pole vessels, or kinking of the most proximal ureter. Associated abnormalities are common, and up to 50% of infants have another urologic abnormality, such as contralateral PUJ obstruction, contralateral renal dysplastic and multicystic kidney, minor degrees of VUR, and contralateral renal agenesis.

Older children can present with an abdominal mass or with flank pain, hematuria secondary to mild trauma, or UTI. Hypertension is unusual but can occur temporarily after surgical correction.

Diagnostic procedures need to differentiate between significant obstruction that requires surgical correction and congenital ectasia of the renal pelvis, in which case surgery is not indicated (Fig. 50.7). Indications for surgical intervention include impairment of renal function, pyelonephritis, renal stones, and pain. Kidneys with good function can

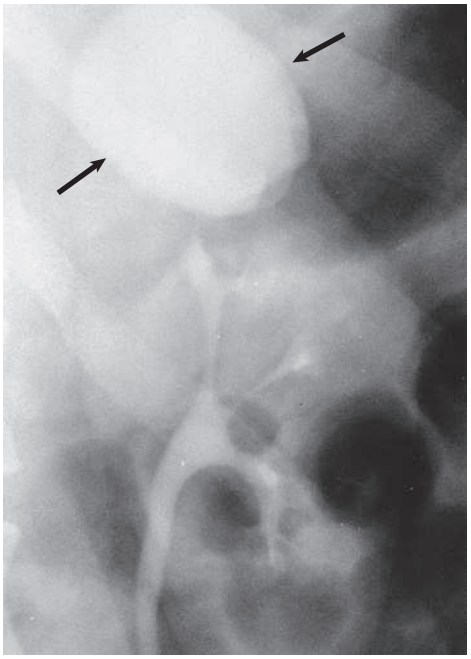

Fig. 50.6 Calyceal cyst. IVU shows an upper pole calyceal cyst filled with contrast *(arrows)*. Plain abdominal radiograph showed a group of stones in the floor of the cyst.

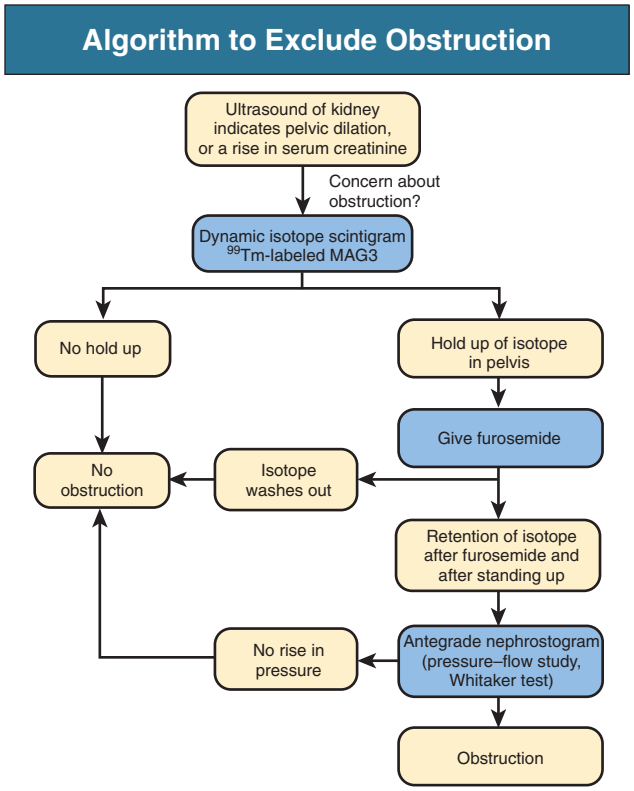

Fig. 50.7 Algorithm to exclude pelviureteral junction (PUJ) obstruction. Diagnostic path used to differentiate between significant PUJ obstruction and congenital ectasia of renal pelvis. *MAG3,* Mercaptoacetyltriglycine.

generally be left alone, and surgery is indicated only when function is clearly deteriorating.[22]

Gonadal Dysgenesis

The problems of intersex, gender identity, and micropenis are beyond the scope of this chapter and rarely encountered in adult practice. Patients will be met, however, with ESRD who are phenotypically female but are genotype XY and have mutations of *WT1* (Denys-Drash and Frasier syndromes). They have gonadal dysgenesis and must have their streak ovaries removed; otherwise, gonadoblastomas will develop.

URETERAL ABNORMALITIES

Duplex Ureters

Duplication of the ureter and the renal pelvis is a common anomaly, with an incidence of about 1 in 150 births; unilateral duplication is six times more frequent than bilateral. It is more common in girls. If duplication has been detected in a patient, the likelihood of another sibling with duplication rises to 1 in 8.

Pathogenesis

If the ureteral bud bifurcates after its origin from the mesonephric duct but arises at a normal site, an incomplete ureteral duplication with a Y ureter will develop.[7] Complete ureteral duplication occurs if there are two ureteral buds, one in the normal location and the other in a low position. The normal bud ends in a correct site on the trigone in the bladder and is nonrefluxing. The lower bud, representing the ureter of the lower pole of the kidney, ends in the bladder as a lateral orifice with a short submucosal tunnel. The lower pole ureter is therefore often associated with VUR, and scarring of the lower pole can result.

If there are two ureteral buds, one with a normal location and one with a high position, the upper ureter is incorporated into the developing bladder, ending more distally and medial to the normal one. Thus the upper pole ureter ends ectopically, and because of obstruction or dysplasia, there is often severe scarring of the upper pole moiety.

Clinical Manifestations

In most adult patients, ureteral reduplication is asymptomatic and causes no long-term problems. Children with ureteral duplication often have VUR. The spontaneous disappearance of reflux is less common in duplex ureters than in patients with a single ureter.[23] Duplex ureters are best diagnosed by CT urogram. PUJ obstruction of the ureter draining the lower pole of the kidney can occur.

Associated conditions, such as ectopic ureters and ureterocele (see later discussion), usually cause problems in early life and therefore have been addressed by adolescence. Upper pole scarring is associated with an ectopic ureter and lower pole scarring with VUR (Fig. 50.8A).

Ectopic Ureters

Ectopic ureters are almost always associated with ureteral reduplication, and 10% are bilateral. There is a female-to-male ratio of 7:1. The ectopic ureter comes from the upper pole and inserts into the bladder more distally and toward the bladder neck or opens into the upper urethra. In females, the ureter may end in the urethra, vagina, or vulva, and patients present with incontinence, UTIs, or a persistent vaginal discharge, particularly if the external sphincter is damaged, as during labor.

Ectopic ureters are rare in males and manifest as UTI. Usually, there is a single ureter associated with a dysplastic kidney, which ends in the posterior urethra, ejaculatory duct, seminal vesicle, or vas. Males are usually continent because the ureter is proximal to the external sphincter.

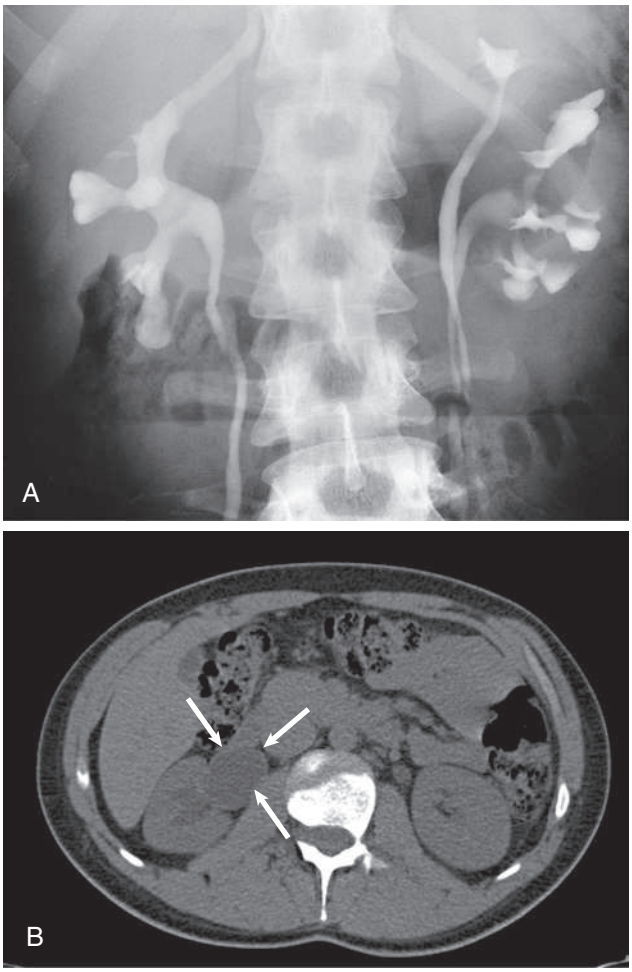

Fig. 50.8 Duplex kidney. (A) IVU shows a duplex left kidney. The lower pole is scarred and shows evidence of reflux damage. The two ureters enter the bladder separately, with the lower pole ureter in the abnormal location. The right kidney also shows features of reflux, with clubbing of the calyces and some scarring. (B) CT scan shows an isolated right-sided megaureter *(arrows)*.

Ectopic ureters are best visualized by CT or MR urography. A voiding cystourethrogram shows reflux into the lower pole of the kidney in 50% of patients.

Ureterocele

Ureteroceles are cystic dilations of the terminal segments of the ureter and are caused by maldevelopment of the caudal ureter. Ureteroceles affect females more than males (4:1) and almost exclusively affect Caucasians, and 10% are bilateral. Ectopic ureters and ureters with ureteroceles frequently (80%) drain the upper pole and are often associated with dysplastic or nonfunctional renal tissue. These usually present in childhood with infection; when large, they can obstruct the bladder neck or even the contralateral ureter. In adults, ureteroceles typically manifest with stones in the lower ureter.

The treatment of simple ureteroceles is surgical excision with reimplantation of the ureter or endoscopic puncture if they subtend a well-functioning moiety. There are usually no medical sequelae.

Megaureter

Isolated dilation of the ureter does not necessarily imply obstruction. There are three broad groups of conditions with widely dilated ureters, as follows:

1. *Obstruction of the ureter itself.* This may be intrinsic (e.g., stone) or extrinsic (e.g., retroperitoneal fibrosis); it is not associated with reflux.
2. *Bladder outflow obstruction, with secondary ureteral obstruction.* Examples include a neuropathic bladder and posterior urethral valves; this may or may not be associated with reflux.
3. *A dilated but nonobstructed ureter.* This often occurs without reflux, and there can be normal renal function; this may be caused by an adynamic segment of the lower ureter (see Fig. 50.8B).

Pathogenesis

In the normal ureter, there is a characteristic helical orientation of muscle fibers. When the megaureter is secondary to bladder outflow obstruction, there is muscle hyperplasia and hypertrophy of the ureteral wall. In megaureters with no apparent cause, a variety of abnormalities of muscle orientation are described or there may be absence of muscle fibers at the proximal end of the undilated segment.

Electron microscopy shows an increase in collagen between the muscle bundles at the level of the obstructing segment. Obstruction appears to be caused by a failure of peristalsis through the distal ureteral segment.

Clinical Manifestations

Most cases of megaureter associated with obstruction present in childhood with severe infections, often complicated by septicemia. These patients have a high incidence of other congenital abnormalities. In less severe cases or with no obstruction, patients can present with abdominal pain, loin pain, hematuria, and UTI. Renal stones can form easily in the dilated systems. The exclusion of obstruction is often established only by an antegrade pressure-flow study (Whitaker test), in which a nephrostomy is placed in the renal pelvis and contrast material infused at 10 ml/min.[24]

Treatment

A definitive diagnosis must be made on whether an obstruction exists (see Fig. 50.7). The current view is that patients with asymptomatic nonobstructed disease should be managed conservatively, and most do well with this approach.

BLADDER AND OUTFLOW DISORDERS

Prune-Belly Syndrome

Prune-belly syndrome occurs in males and consists of absence of the muscles of the anterior abdominal wall, bizarre malformations of the urinary tract with gross dilation of the bladder and ureters, and bilateral undescended testes.[18,25,26] When the disorder is diagnosed early, renal outcome is related to the degree of renal dysplasia. There are incomplete forms of prune-belly syndrome (pseudo-prune). Rarely, a similar megacystis or megaureter may be seen in a male or female patient.

Pathogenesis

The incidence of prune-belly syndrome varies from 1 in 35,000 to 1 in 50,000 live births. Some familial cases have been reported demonstrating autosomal recessive inheritance; a mutation in *CHRM3*, a muscarinic acetylcholine receptor involved with parasympathetic-mediated detrusor contraction, has been identified in one family with prune-belly–like syndrome (pseudo-prune).[27] There is also evidence for a primary, localized arrest of mesenchymal development, supported by the lack of prostatic differentiation; the epithelial element in the prostate is absent or hypoplastic. Ultrastructure studies of the ureter show massive replacement of smooth muscle with fibrous and collagen tissue and the absence of nerve plexuses. An almost identical syndrome can result from fetal urethral obstruction, including urethral atresia.

Fig. 50.9 Prune-belly syndrome. Note the lax abdominal musculature leading to a pot-bellied appearance. There is also marked thoracic cage deformity. (Courtesy Prof. C. R. J. Woodhouse, University College Hospital, London.)

Clinical Manifestations

The prognosis depends on the degree of renal dysplasia and injury. Three prune-belly groups can be distinguished. In group I (20%), complete urethral obstruction causes stillbirth or neonatal death. In group II (20%), acute, early presentation requires diversion and reconstruction. In group III (60%), good health and renal function continue despite urologic appearances.

There is complete absence or incomplete formation of the rectus abdominis and other muscles, which leads to the wrinkled abdominal wall of the prune infant (Fig. 50.9C). This gives way to a fairly smooth "pot belly" in later life (Fig. 50.10). Reconstructive surgery is not normally required. The patients grow up physically active and strong but cannot sit up directly from a supine position. Abnormalities of the thoracic cage, such as pectus excavatum, are common.

Although true outflow obstruction may be present, the gross and irregular dilation of the urinary tract characteristic of prune-belly syndrome is primarily caused by a developmental defect with a variable degree of smooth muscle aplasia leading to aperistaltic ureters (see Fig. 50.9A and B). Urodynamic studies are often difficult to interpret because of gross VUR, but typically there is a low-pressure bladder. With late manifestation, some patients have detrusor instability.

Differential Diagnosis

In severe cases of megacystis or megaureter with gross impairment of renal function (often with dysplastic kidneys), the differential diagnosis of prune-belly syndrome includes posterior urethral valves, renal dysplasia with or without multiple congenital defects, neuropathic bladder, and nephrogenic diabetes insipidus.

Natural History

Once any outflow obstruction is addressed, usually in infancy, the renal function should remain stable despite the frightening radiologic appearances. In prune-belly patients observed in our unit for up to 40 years,

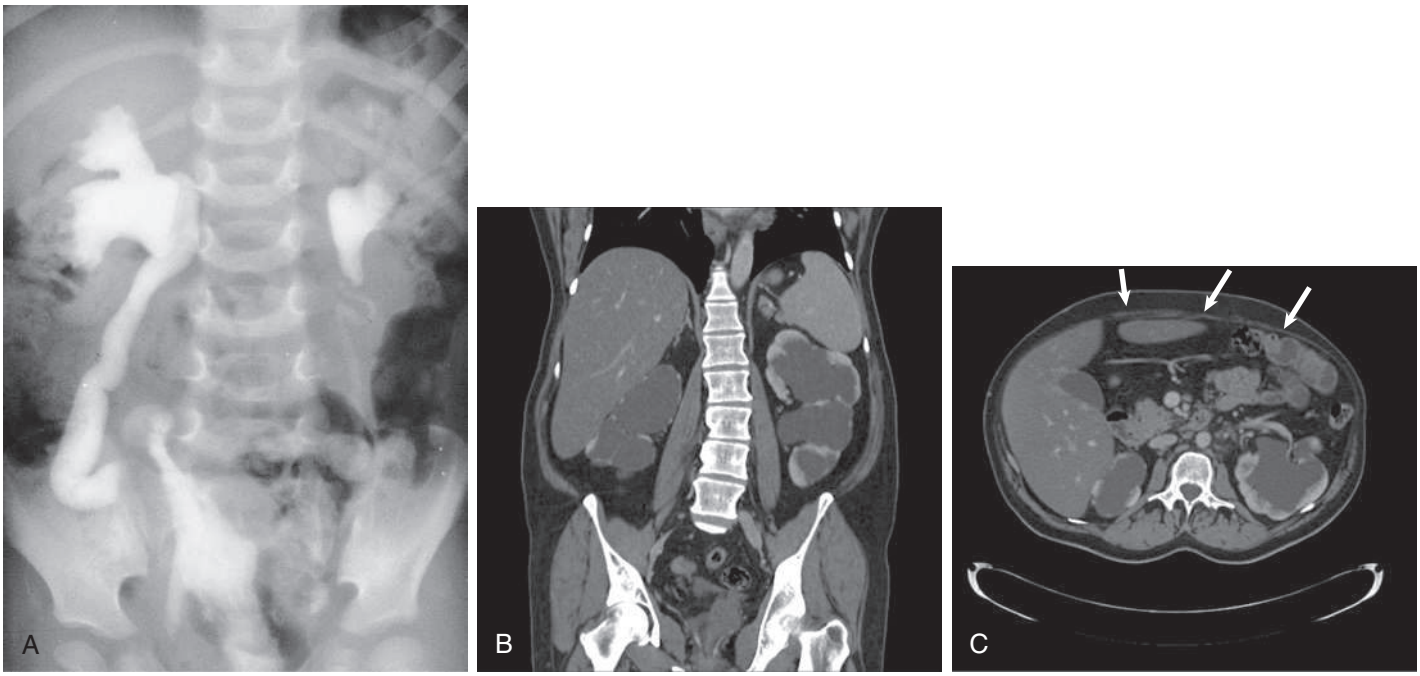

Fig. 50.10 Prune-belly syndrome. (A) Typical IVU appearance of a patient with prune-belly syndrome and good renal function. Often, the ureters are extremely dilated and tortuous. (B) CT urogram showing gross bilateral hydronephrosis. (C) Absence of anterior abdominal wall musculature *(arrows)*.

renal deterioration and hypertension have been rare. In the small number who have progressed, recurrent infection, hypertension, and proteinuria have been warning signs of impending trouble. Renal scarring should be assessed by isotopic DMSA scintigraphy and renal function followed by serial isotopic GFR measurements. Lifelong attention to BP, UTIs, and stones is necessary.

Treatment

In all children with prune-belly syndrome, even with good renal function, a careful search for obstruction should begin with the urethra and work up to the PUJ. Often, however, no obstruction is found, and no surgery is required. In many other patients, the floppy bladder is not anatomically obstructed, but bladder emptying is improved by urethrotomy ("functional obstruction"). In infancy, there is debate about the need for reconstructive surgery. Certainly, a group of patients born with severely compromised renal function do require reconstruction after stabilization by early diversion.

The current view is that the testes should be brought down to the scrotum in infancy in the hope that earlier surgery will produce proper germ cell development and thus preserve fertility. Although men with prune-belly syndrome have azoospermia, and are by definition infertile, there are case reports of successful paternity using intracytoplasmic sperm injection.

Bladder Exstrophy (Ectopia Vesicae)

Classic exstrophy is the failure of the anterior abdominal wall and bladder to close. However, these defects range from epispadias of an otherwise normal penis to major cloacal abnormalities (Fig. 50.11). The condition occurs in 1 in 10,000 to 50,000 births. The male-to-female ratio is 2:1.

Pathogenesis

Failure of growth of the lower abdominal wall between the allantois and the urogenital membrane coupled with breakdown of the urogenital membrane leaves a small, open bladder plate, a low-placed umbilical

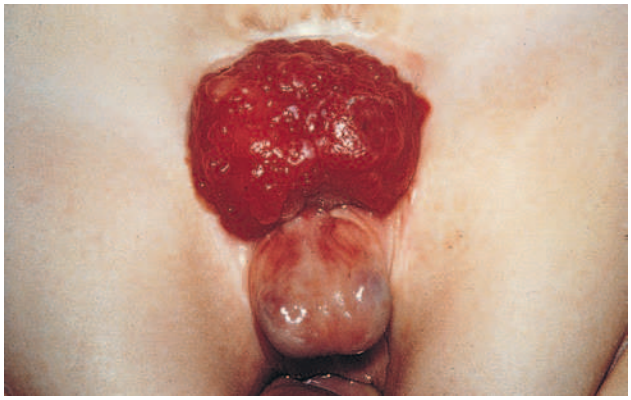

Fig. 50.11 Bladder exstrophy. The entire length of the penis is also open (epispadias). (Courtesy Prof. C. R. J. Woodhouse, University College Hospital, London.)

root, and diastasis of the pubic bones (Fig. 50.12B). The genital tubercle is probably placed lower in these patients, and the cloacal membrane ruptures above it, leading to a penis with an open dorsal surface that is continuous with the bladder plate. A midline closure defect causes a failure of fusion of the lower anterior abdominal wall, including the symphysis pubis, lower urinary tract, and external genitalia. Reports of familial clustering and twin studies suggest an as yet undetermined genetic basis for the disorder.

Clinical Manifestations

In severe cases, the bladder mucosa lies exposed on the lower abdominal wall, with the bladder neck and urethra laid open. The prostate and testes are normal. Most patients have normal kidneys at birth, although many reports do not record the state of the kidneys at birth. In one series, 33% had dilated ureters at presentation, but IVU was usually normal after diversion. In another series, however, one third of patients

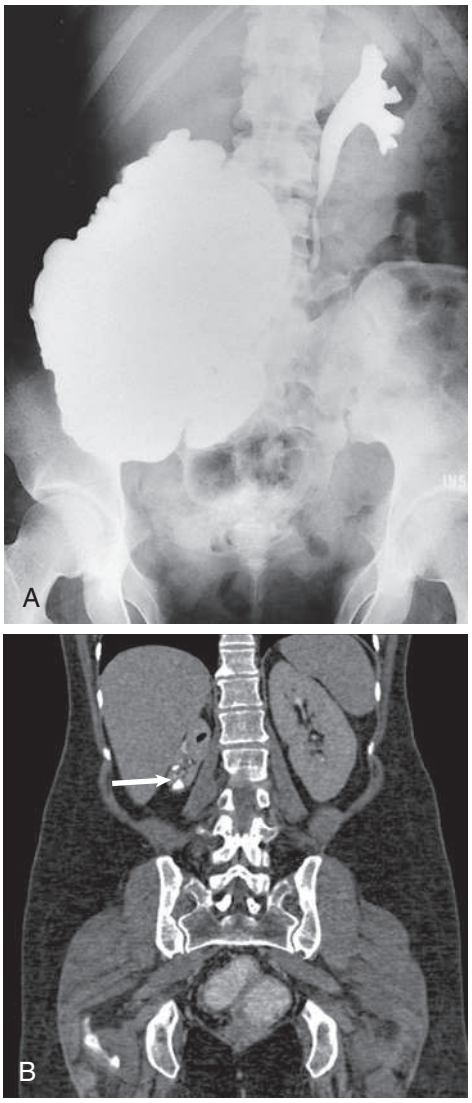

Fig. 50.12 Cystography in bladder exstrophy. (A) A 26-year-old woman with bladder exstrophy who has a continent Mitrofanoff system (see Fig. 52.18) with use of the colon to create a reservoir. There is reflux into the left kidney. Reflux also occurs into the right kidney, but the kidney is obscured by the full reservoir. Glomerular filtration rate is 130 ml/min. (B) MR scan of a patient with bladder exstrophy shows scarred, small left kidney with several renal calculi *(arrow)*. Note widely splayed symphysis pubis.

were said to have "unilateral renal agenesis."[28] Renal function may be preserved after the diversion, although reflux is common (see Fig. 50.12A).

Other congenital abnormalities are only rarely present. More severe cloacal abnormalities are associated with imperforate anus and high or low rectal atresia.

Natural History

Long-term renal outcome depends on the bladder. In a study with 12-year follow-up, the kidneys survive much better with a well-functioning bladder; 13% of those with a good bladder had significant renal damage compared with 82% with ileal conduits, 22% with non-refluxing colonic conduits, and 33% with ureterosigmoidostomy.[29] Currently, the bladder is most commonly augmented (enterocystoplasty, ileocystoplasty, caecocystoplasty) or replaced by bowel (intestinal reservoir). In a study of 53 such patients monitored more than 10 years, renal function deteriorated (GFR decrease ≥20%) in only 10 patients.[30]

TABLE 50.3 Causes of Neuropathic Bladder

Site of Lesion	Causes
Cerebral	Cerebrovascular accident, cerebral palsy, encephalopathy, trauma, Parkinson disease, dementia
Spinal	Isolated (no other neurologic features), trauma, multiple sclerosis, compression, spina bifida, spinal dysraphism, tethered cord, sacral agenesis, sacral teratoma
Peripheral nerve	Pelvic surgery, diabetes

Treatment

When the infant is born, the three urologic treatment goals are to close the abdominal wall, establish urinary continence to preserve renal function, and reconstruct cosmetically acceptable genitalia. The aim of initial surgery is to convert the defect to a complete epispadias (Fig. 50.13). At 4 years of age, reconstruction of the bladder neck and correction of the epispadias can be performed. If the bladder is small, intestinal augmentation is required. Patients may be able to void, but many have to use catheters. Incontinence may be a long-term problem.

Neuropathic Bladder

In childhood, the most common cause of a neuropathic bladder is myelomeningocele, although with antenatal diagnosis and termination of affected pregnancies, it is becoming less common. A neuropathic bladder also may be seen without associated neurologic or other obvious causes (Table 50.3). The principal consequences are incontinence, infection, and reflux with upper tract dilation and subsequent renal failure. Early urodynamic assessment is essential (Fig. 50.14). Three different patterns of bladder behavior are seen: contractile, intermediate, and acontractile.

Contractile Behavior

An overactive detrusor (hyperreflexia) can produce some bladder emptying (incontinence). Unfortunately, 95% of patients have sphincter

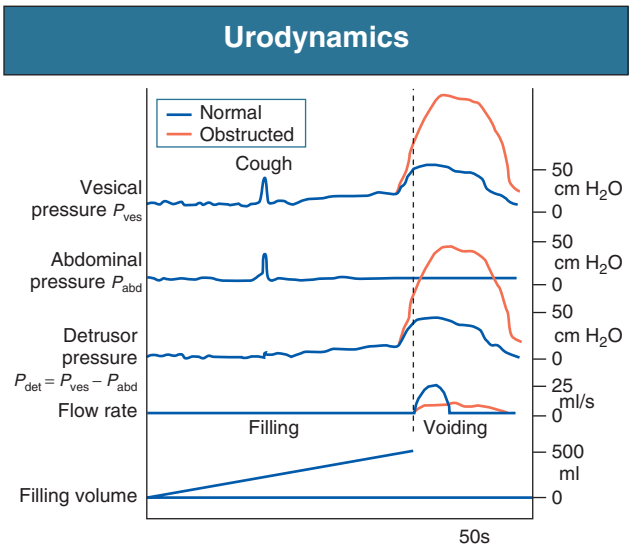

Fig. 50.14 Urodynamic assessment by cystometrography. The vesical pressure is measured simultaneously with the abdominal pressure through the rectum; the detrusor pressure is the difference. A cough is used as a marker to show that the system is working. During filling, the first desire to void is normally at a detrusor pressure of less than 10 cm H_2O. This point is noted. The voiding pressure should normally be less than 40 cm H_2O (and is lower in women). Detrusor instability is an unstable (spontaneous) contraction occurring with a detrusor pressure above 15 cm H_2O. Higher pressure can cause incontinence. In combination with radiologic imaging (videocystometrography), the following are recorded: bladder neck, closed or open; bladder pressure, end filling; voiding detrusor pressure; bladder stability; compliance; flow rate, maximum; sensation, first; volume, voided and residual. (Courtesy Prof. M. Craggs, University College London.)

dyssynergia (inability to relax the urethral sphincter), which results in no relaxation and incomplete emptying of the bladder. Patients with incomplete lesions may have some control of the distal sphincter and normal anal and sacral reflexes. Ironically, although this latter group has the least neurologic deficit, they have the worst bladder situation, generating high pressures and great risk for renal injury. The bladder becomes progressively hypertrophic, fibrotic, and poorly compliant. Botulinum toxin A can be injected into the bladder wall to improve compliance and reduce bladder pressure; it is increasingly being used in children with neuropathic bladders to delay or avoid the need for augmentation cystoplasty.

Intermediate Behavior

These patients have some detrusor activity, but not sufficient to empty the bladder. These intermediate bladders are poorly compliant, and patients have no voluntary control of their sphincters. Any rise in bladder pressure tends to cause incontinence, or the high intravesical pressures lead to renal injury.

Acontractile Behavior

About 25% of patients have no detrusor activity, and the bladder overflows when it is sufficiently full. This acontractile bladder is not usually associated with renal failure.

Myelodysplasia

Myelodysplasia refers to a group of neural tube anomalies that primarily affect the lumbar and sacral segment of the spinal cord and are the most common cause of neurogenic bladder dysfunction in children. *Spina bifida* reflects defective fusion of the posterior vertebral arches. *Meningocele* implies that the meninges extend beyond the confines of the vertebral canal with no neural elements contained inside. A *myelomeningocele* has neural tissue protruding with the meningocele. *Spinal dysraphism* (symptomatic spina bifida occulta) defines a group of structural anomalies of the caudal end of the spinal cord that do not result in an open vertebral canal but are associated with incomplete fusion of the posterior vertebral arches.

Sacral agenesis is a rare anomaly in which part or all of two or more vertebral bodies is absent. It occurs early in fetal development when there is failure of ossification of the lowest vertebral segments. The only known teratogen is insulin. Sacral agenesis occurs in 1% of children born to insulin-dependent mothers. Partial sacral agenesis can be associated with an anterior meningocele.

Pathogenesis

The neural tube normally forms as the neural folds close over and fuse, starting in the cervical region and progressing caudally. It is believed that the embryologic defect is an incomplete tubularization of the neural tube, with inadequate mesodermal invagination and subsequent arrest of vertebral arch formation.

The incidence of myelodysplasia varies from 1 to 5 in 1000 live births, but there are wide geographical variations. Monozygotic twins are often discordant for spina bifida, but siblings are at increased risk (1:10 to 1:20) and children of affected parents have a 4% chance of having a similarly affected child. Myelomeningocele accounts for more than 90% of myelodysplastic infants. Folic acid supplements taken during the first trimester reduce the incidence of myelodysplasia by 52%.

Clinical Manifestations

All causes of tethered cord can produce a variable neurologic deficit. During development, some children experience progressive neurologic disturbance with bladder dysfunction, bowel dysfunction, scoliosis, and a syndrome of pes cavus and limb growth failure.

Bladder dysfunction. Neuropathic bladder can be an isolated problem with abnormal urodynamic studies but a normal neurologic examination.

Bowel dysfunction. Bowel dysfunction is often present and needs to be treated accordingly. There may be severe constipation and overflow incontinence. The antegrade continent enterostomy procedure has been developed to improve management. The appendix is brought out to the abdominal surface, and thus the colon can be irrigated antegrade with saline.

Cognitive impairment. Patients with myelomeningocele may have some intellectual impairment, especially those who have required ventriculoperitoneal shunting for associated hydrocephalus. Manual dexterity also may be affected. These are crucial issues in long-term management.

Natural History

About 14% of patients have renal complications at birth and are at high risk in the next few years. Ultimately, about 50% will develop upper tract problems, although these can take up to 30 years to occur (Fig. 50.15). In one prospective study, renal outcome could be predicted by the urodynamic findings, with worst outcomes related to increased bladder wall thickness, degree of reflux, urethral pressures above 70 cm H_2O, and reduced bladder capacity. VUR occurs in 3% to 5% of newborns with detrusor hypertonicity or dyssynergia. Without treatment, this increases to 30% to 40% by age 5 years.[31]

Treatment

The management of the bladder depends on the urodynamic findings. In the 1970s, clean intermittent self-catheterization (CISC) was

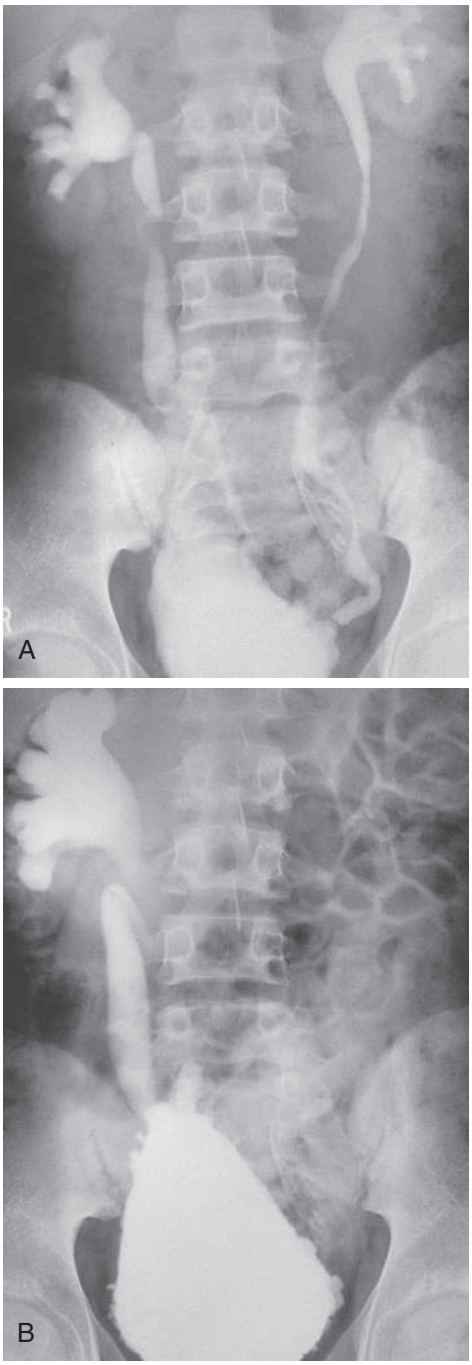

Fig. 50.15 Sacral spina bifida with neuropathic bladder. (A) IVU shows evidence of a previous hydronephrosis and subsequent scarring of the right kidney. The architecture of the left kidney is well preserved. (B) Micturating cystogram. The typical tapering, hypertrophied, trabeculated bladder gives the characteristic fir (pine) cone appearance. Note the gross reflux on the right side. This is probably helping to protect the left kidney by acting as a "pop-off" mechanism. This is analogous to the protection that can occur in boys with posterior urethral valves.

introduced,[32] but before that time, urinary diversion was the usual treatment. Currently, when reflux and hydroureter are present, the management is principally with CISC and antimuscarinic drugs that increase bladder compliance. With persisting symptoms related to bladder storage or hyperreflexia, bladder wall injection with botulinum toxin type A1 is offered. In the presence of deteriorating renal function or intractable symptoms, continent bladder augmentation or sometimes ileal conduit is required.[33]

Bladder Neck Obstruction

Congenital bladder neck obstruction is rare and is usually caused by a neuropathic bladder, posterior urethral valves, or an ectopic ureterocele.

Posterior Urethral Valves

Posterior urethral valves are the most common cause of severe subvesical obstruction in the male infant (but account for only 10% of neonatal hydronephrosis). As a result, bilateral hydronephrosis and megaureter occur. Obstruction is caused by a diaphragm that extends from the floor to the roof of the urethra at the apex of the prostate. Valves appear as mucosal folds in the posterior urethra below the verumontanum. There is dilation of the proximal urethra and bladder wall hypertrophy and trabeculation. Above the valves, the prostatic urethra dilates, undermining the bladder neck. The valves obstruct flow only in one direction, and therefore a catheter can be passed without difficulty.

Pathogenesis

The urethra develops in two parts: differentiation of the urogenital sinus part (posterior urethra) and tubularization of the urethral plate (anterior urethra). Early obstruction during renal development can result in severe renal dysplasia.

Clinical Manifestations

Most cases of posterior urethral valves are now detected antenatally on ultrasound as evidenced by bilateral hydronephrosis, dilated bladder, posterior urethra (keyhole sign), and, in severe cases, oligohydramnios. Infants present with a palpably distended bladder and enlarged kidneys, abnormal urine stream, or failure to thrive as a result of renal failure. At diagnosis, 30% to 52% of children also have VUR. Children with less severe disease present with poor stream, hematuria, incontinence, acute UTI, or renal failure. However, late presentation is also associated with worse outcome.[34]

Three abnormal features can help protect the kidney, reducing the high pressures generated during voiding: massive unilateral reflux, usually with ipsilateral renal dysplasia (thereby protecting the other kidney); large bladder diverticulum; and urinary extravasation, often with urinary ascites. These protective mechanisms are referred to as *pop-off mechanisms*[35] (see Fig. 50.15B). Ultrasound can show the bladder thickening, dilated system, and dilation of the posterior urethra. A specific diagnosis should be documented by videocystometrography (see Urodynamics).

Natural History

In the 1960s, 25% of children with posterior urethral valves died within the first 12 months, and 25% died later in childhood, including "renal death" (i.e., ESRD). By the late 1990s, early mortality was less than 5%, and after 15 years of follow-up, only 15% to 20% of patients had reached ESRD.[36]

The bladder may become stretched, resulting in poor emptying, or unstable, leading to poor compliance, unsuppressed detrusor contractions, and high storage pressure. Both situations are exaggerated by progressive polyuria. Such patients may have a daily urine volume of 5 liters. Urodynamic follow-up studies suggest that instability decreases with time; bladder capacity increases, but there are unsustained voiding contractions. The prognosis correlates with the nadir serum creatinine value once obstruction has been relieved. Despite adequate early treatment, CKD caused by renal dysplasia develops in many children.[33,37]

Treatment

All children have had transurethral resection of their valves in infancy. Bladder diversion should be avoided. Bladder instability and poor bladder

compliance must be treated, regardless of whether symptoms result. Boys with substantial residual volumes can be managed by CISC, but compliance is often poor because of urethral discomfort or because previous urethral surgery has made the passage of catheters difficult. Compliance is a particular problem with adolescents who are continent and for whom renal failure is too abstract a concept. Continence often improves spontaneously at puberty but can be helped by imipramine. Deterioration in renal function will require further examination of urine flow rate and exclusion of urethral stricture.

Urethral Diverticulum

Urethral diverticulum usually occurs in boys and is rare. It may manifest with UTI, obstruction, or stones. The two types are anterior and posterior. The anterior type can be associated with anterior urethral valves and obstruction.

Other Congenital Causes of Bladder Outflow Obstruction

Urofacial Syndrome

Urofacial syndrome, or Ochoa syndrome, is a rare autosomal recessive disease characterized by facial grimacing when attempting to smile and failure of the urinary bladder to void completely, despite a lack of anatomic bladder outflow obstruction or overt neurologic damage. Patients present with enuresis and UTI and all the features of a neuropathic bladder together with dilated upper tracts. They are at risk for renal failure. Mutations of heparanase-2 *(HPSE2)* and leucine-rich repeats and immunoglobulin-like domains 2 *(LRIG2)* have been reported in urofacial syndrome, and the proteins they encode are expressed in the fetal bladder. It is proposed that they play an important role in the neural control of bladder function.[38] Urofacial syndrome is part of a spectrum of congenital bladder disorders that include non-neurogenic neurogenic bladder or Hinman syndrome.

GENERAL MANAGEMENT OF CONGENITAL RENAL TRACT ABNORMALITIES

The principles of management of congenital tract abnormalities are shown in Box 50.1. The most important part of the management is ensuring that the patient, family, and primary care physician know what can and must be done. First, they must understand the necessity of long-term follow-up at least annually. ESRD often occurs when a patient is lost to follow-up, often manifesting later with accelerated hypertension and rapid loss of renal function.

BOX 50.1 General Principles of Management of Congenital Renal Tract Abnormalities

- Educate and explain to encourage compliance
- Review urologic status
- Find cause of urinary tract obstruction and treat
- Control blood pressure
- Monitor renal function and proteinuria
- Treat acidosis
- Prevent bone disease
- Check for stones
- Institute clean intermittent self-catheterization for chronic urinary retention
- Maintain bladder storage pressure below 40 cm H_2O
- Maintain bladder volume below 400 ml

Clinical Evaluation

By the time the adolescent attends an adult clinic, it is assumed that the urinary tract is not obstructed and that further surgery is not required. Nevertheless, it is the responsibility of the nephrologists and urologists who care for these young people to review this aspect periodically.

Symptomatic UTI is common and must be treated promptly. Increase in frequency or severity of infections must lead to investigations to find the cause.[39] The BP must be monitored regularly and kept normal. Finally, renal function must be monitored, proteinuria assessed, and the cause of any deterioration identified. As in any renal condition, the remnant kidney function may decline inexorably, which is associated with increasing proteinuria and hypertension. As with other renal conditions, kidney function is usually stable when proteinuria is minimal or absent. Deterioration in the absence of proteinuria must alert the physician to the likelihood of obstruction or the adverse effect of a nephrotoxic drug.

The routine investigations performed to document the current situation act as a reference point for the future (Table 50.4). If the bladder empties completely with an adequate flow rate (15 ml/s), no problems should arise. If there is any doubt about the condition of the bladder, urodynamic investigations are necessary. If the clinical situation changes, further investigations are required. An increase in UTIs might suggest a stone or increase in residual urine. With an unexpected decline in renal function, obstruction again must be excluded.

The patient should keep a 24-hour urine volume diary every 6 to 12 months, recording the time of voiding and volume passed. It is best to ask patients to do this on 2 consecutive days, to determine the maximum bladder capacity and the total 24-hour urine volume. This should be done before urodynamic investigations, because results can be misleading if the bladder is not filled to capacity.

TABLE 50.4 Monitoring Patients With Congenital Renal Tract Abnormalities

Routine Investigations for Assessment of Clinical Status

Baseline Measurements	Reason for Test
Radiology	
CT KUB	Exclude stones
Ultrasound	
Ultrasound of kidneys	Baseline
Ultrasound of bladder after micturition	Assess residual volume
Urine flow rate	Ensure adequacy
Scintigraphy	
Glomerular filtration rate: ^{51}Cr-labeled EDTA	Baseline
Dynamic isotope scan: ^{99}Tc-labeled MAG3 or DTPA	Assess outflow obstruction/holdup
Static isotope scan: ^{99}Tc-labeled DMSA	Assess scarring and divided function
Biochemistry	
Urine protein-creatinine ratio	Baseline

^{51}*Cr,* Chromium-51; *CT,* computed tomography; *DMSA,* dimercaptosuccinic acid; *DTPA,* diethylenetriaminepentaacetic acid; *EDTA,* ethylenediaminetetraacetic acid; *KUB,* kidney, ureter, bladder; *MAG3,* mercaptoacetyltriglycine; ^{99}*Tc,* technetium-99.

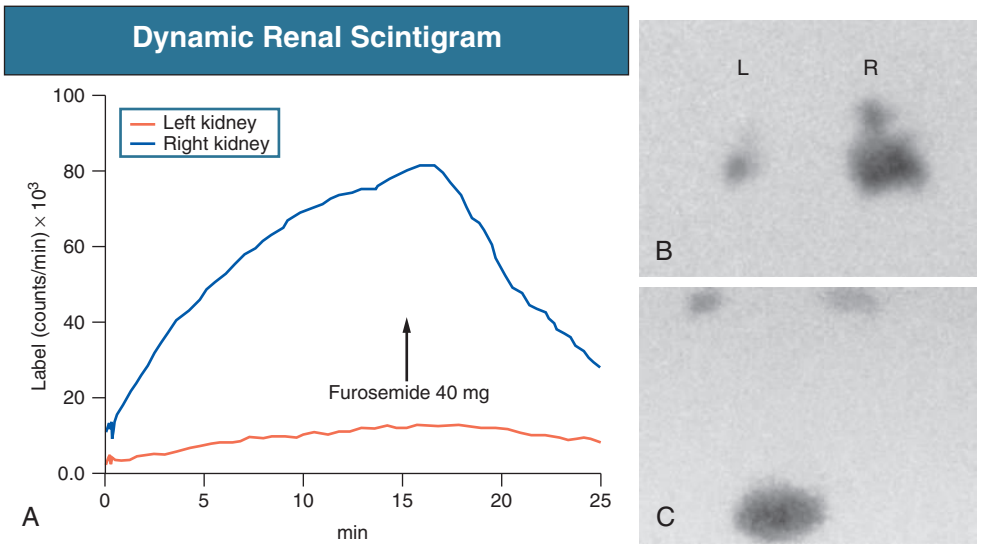

Fig. 50.16 Dynamic ^{99m}Tc-labeled MAG3 renal scintigram. (A) Time-activity curve showing accumulation of isotope in right kidney that washes out after furosemide, thus excluding significant obstruction. (B and C) Images from the same study showing holdup of isotope in dilated right *(R)* renal pelvis (B) that washes out into the bladder after furosemide (C), excluding significant obstruction.

Exclude Obstruction

Obstruction must always be excluded if there is a change in renal function. The possibility of obstruction may be raised by a routine ultrasound (see Fig. 50.7) and should be pursued with mercaptoacetyltriglycine (MAG3) scintigraphy to exclude obstruction (Fig. 50.16).

In patients with conduits, obstruction can be excluded by infusion of contrast material into the loop (loopogram) and demonstration of reflux up the ureter.

Rarely, in patients with large bladders or in transplant recipients, the kidney may become obstructed when the bladder reaches a certain volume. This can be investigated by filling the bladder by a catheter and performing ^{99m}Tc-labeled MAG3 scintigraphy, initially with the bladder full. If there is no excretion, the bladder volume can be reduced in 100-ml increments until there is flow down the ureter (Fig. 50.17).

Urodynamics

Any urodynamic investigation should start with a free urine flow rate. Provided the flow rate is normal and the bladder empties completely (leaving no residual volume on postmicturition ultrasound), it can be assumed that there is no significant bladder outflow obstruction.

Complete investigation of abnormalities of bladder and urethral function requires synchronous recordings of intravesical and intrarectal pressures taken during bladder filling and emptying (see Fig. 50.14). Combined with radiologic imaging, the study is known as *videocystometrography* (VCMG).

Surgical Correction of the Urinary Tract

A normal bladder acts as a low-pressure, good-volume urine reservoir that is continent, is sterile, and empties freely and completely. Any other form of urine reservoir aims to recreate such an environment. When this is not achieved in either a natural or a reconstructed bladder, complications such as sepsis and renal dysfunction can occur.

A variety of conduits and continent reservoirs have been developed to replace unusable bladders. Ileal conduit diversion has been most widely used for native kidneys, although deterioration in renal function frequently results from long-term complications, including urosepsis, renal calculi, and most often stenosis, leading to obstruction or reflux with ureteral dilation. There is an overall complication rate of 45%, but with a high index of suspicion and an aggressive diagnostic and therapeutic approach, many of these problems can be detected and treated early, with resultant good long-term function of native kidneys. Similar results may be obtained when renal transplantation is performed in these patients.[40] Other forms of urinary diversion that are continent and therefore more socially acceptable to patients are now widely used in general urologic practice and are being encountered in renal transplantation (Fig. 50.12A). These forms include augmented bladders draining through the urethra and augmented or intestinal bladders draining through continent stomas.

COMPLICATIONS

Urinary Tract Infections

Symptomatic UTIs are common.[39] Risk factors include stagnation of urine, stones, foreign bodies (stents, catheters), previous infections, and renal scarring. UTIs must be treated promptly after a urine culture specimen (midstream or catheter specimen) has been taken. Recurrent UTIs, particularly after a period of stability, must lead to further investigations to exclude stones or obstruction, including CT kidney, ureter, bladder (KUB), renal ultrasound, and postmicturition bladder ultrasound.

Asymptomatic UTIs often do not require treatment (except during pregnancy). For patients with urinary diversions, it is important to obtain a catheter specimen of urine because urine taken from a bag is invariably infected.

It is sometimes appropriate to give prophylactic antibiotics, such as trimethoprim or nitrofurantoin, to eradicate infection. Many patients think cranberry juice helps them; it reduces the incidence of *Escherichia coli* infection but will not treat a symptomatic infection. Nitrofurantoin should be avoided if GFR is below 50 ml/min, because it is renally excreted and toxic in renal failure. Quinolones should not be used for prophylaxis, if possible, because of the risk for inducing resistance. When foreign bodies such as stones remain, attempts to sterilize the urinary tract are unlikely to be successful.

If prophylactic antibiotics are no longer effective at preventing infection, it is advisable to stop all antibiotics and give the patient a supply of antibiotics to treat symptoms arising at home.

Single Kidney Obstruction by Full Bladder

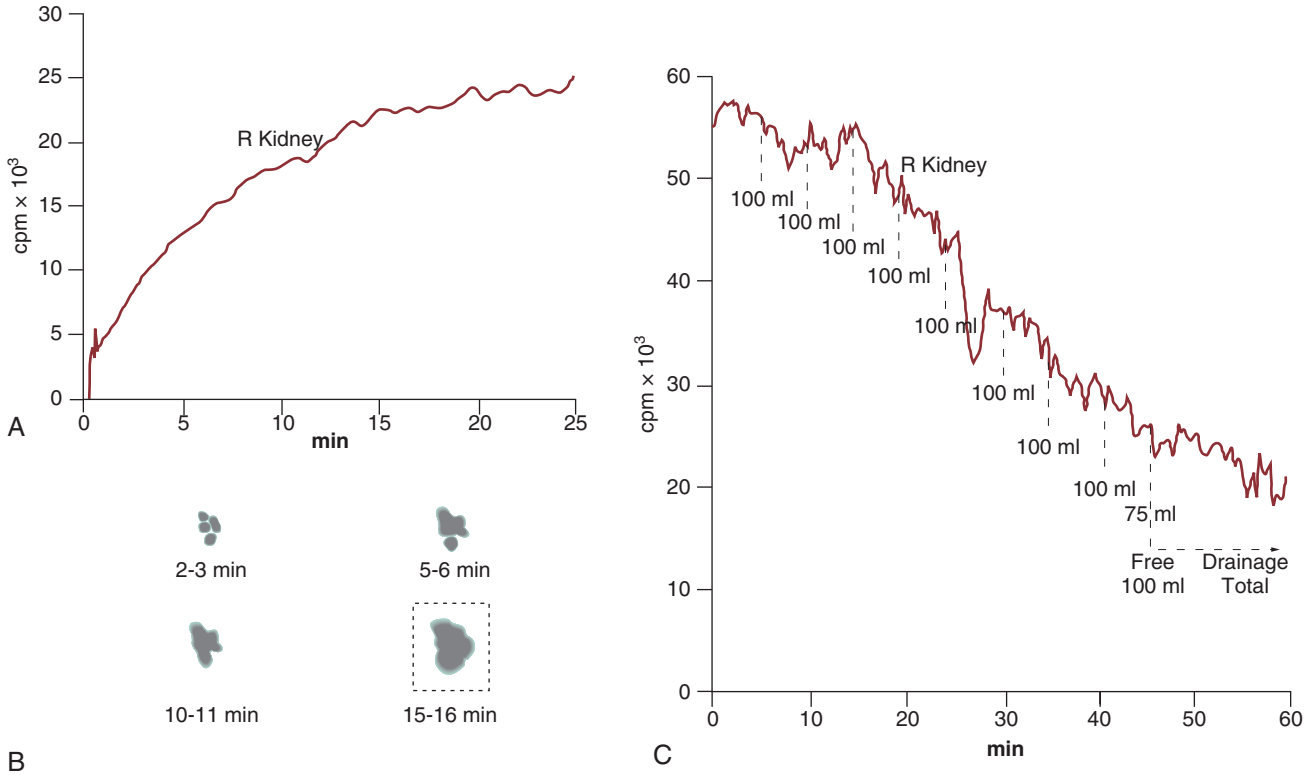

Fig. 50.17 Dynamic isotope scan (MAG3) starting with bladder full in a patient with a solitary right kidney. (A) Rising curve of tracer accumulating in kidney and showing no excretion. *cpm,* Counts per minute. (B) Accumulation of isotope in hydronephrotic pelvis without excretion to bladder. (C) The 100-ml increments of fluid removed from bladder result in eventual free drainage of the kidney.

Glomerular Hyperfiltration

If renal function is declining with proteinuria and hypertension, glomerular hyperfiltration is likely, although all other causes of renal dysfunction must be excluded. Patients should be treated with RAS blockade with ACE inhibitors or angiotensin receptor blockers (ARBs).[4]

Proteinuria and Progressive Renal Failure

Can progression to ESRD be predicted, and does treatment with ACE inhibitors delay or prevent this?[4] We investigated this in a retrospective review of patients with scarred irregular kidneys caused by primary renal dysplasia or abnormal bladder function. All patients had at least 5 years of follow-up, and when ACE inhibitors were started, estimated GFR (eGFR) was below 60 ml/min/1.73 m^2 (mean, 41 ml/min), with mean proteinuria of 1.7 g/24 h. ESRD developed in 46% of patients but in none with proteinuria less than 0.5 g/24 h and in only 2 of 18 patients with eGFR above 50 ml/min. The renal outcome of the two groups was similar whether there was primary renal dysplasia or abnormal bladder function. There was a watershed GFR of 40 to 50 ml/min, above which ACE inhibitor treatment improved renal outcome.[4] The similar outcome of the two groups indicates that progressive renal failure in young men born with abnormal bladders is caused by intrinsic renal pathophysiologic processes, in contrast to the view that it is a result of poor bladder function.

Hypertension

Hypertension is common in the presence of scarred kidneys, but it is usually controlled easily with one or two drugs. Patients in whom CKD is secondary to obstruction tend to have volume contraction and therefore often have normal BP or only mild hypertension. ACE inhibitors or ARBs are preferred for patients with proteinuria and progressive renal failure. Diuretics should not be used if the patient is volume-contracted.

Stones

Stones that form in the presence of infected urine are typically magnesium ammonium phosphate (struvite) or calcium phosphate (hydroxyl apatite, carbonate apatite, calcium hydrogen phosphate [brushite], tricalcium phosphate [whitlockite]). These salts are poorly soluble in alkaline urine. In 90% of patients, the infecting organism is *Proteus* spp.,[41] but other urea-splitting organisms (including some staphylococci and *Pseudomonas* spp.) also generate ammonia.

Stones, usually calcium phosphate, are common in conduits because of the alkaline environment and occur in 5% to 30% of ileal conduits. Stones must be suspected if UTIs recur or become more frequent, if renal function suddenly deteriorates, or if there is an unexplained sterile pyuria.

Tubular Dysfunction

Patients whose renal failure is secondary to obstruction have significant tubular injury. This may cause problems, in particular with urinary concentration, acidification, and sodium reabsorption.

Polyuria

Nocturia is one of the most significant symptoms in the assessment of patients in whom obstruction or tubular dysfunction is suspected. Overfilling of the bladder or reservoir is an important cause of intermittent upper tract obstruction and deteriorating function. The 24-hour urine volume diary is a simple way to assess this.

Salt Depletion

Patients with tubular damage may have a salt-losing tendency. Patients typically have a cool periphery and constricted hand veins with no peripheral edema. Increasing salt intake can relieve cramps, improve renal function, and reduce hyperuricemia, but at the cost of increasing BP. With patients who are salt depleted, it is important to give sodium chloride because it is the chloride anion that is deficient and responsible for the reduction in circulating volume.

Acidosis

There is often a metabolic acidosis disproportionate to the degree of renal impairment. This is secondary both to a proximal tubular failure of bicarbonate reabsorption and a distal tubular failure to secrete hydrogen ions. It is our practice to give sufficient sodium bicarbonate to correct the serum bicarbonate into the normal range.

Bone Disease

In addition to the typical bone disease of progressive CKD, acidosis contributes significantly to osteomalacia. Growing children are particularly vulnerable to osteomalacia, and great care must be taken to correct acidosis and actively manage bone disease.

Urinary Diversions

Ureterosigmoidostomy

Fortunately, it is now rare to meet a patient who has a ureterosigmoidostomy, which was widely used as a technique for urinary diversion until the 1970s. The ureters were anastomosed directly into the sigmoid colon with no disruption of bowel continuity. This technique was most often used in patients with bladder exstrophy. Although patients start with normal renal function, there is frequently deterioration in function. In one series of 25 patients, significant renal damage occurred in 50%. Stones, infection, and ureteral strictures are common, and patients remain at risk for colonic carcinoma, with a 10% incidence of carcinoma at 20-year follow-up. However, this diversion is probably best known for the hyperchloremic, hypokalemic acidosis that occurs. Once the urine is in contact with the colonic mucosa, the urinary sodium exchanges for potassium and the chloride for bicarbonate, and large quantities of ammonium ions are produced by the action of the fecal bacteria on urinary ammonia. Ammonium ions are absorbed both with chloride and in exchange for sodium. The severe acidosis is caused by ammonium ion retention and stool loss of bicarbonate. Patients are managed with large doses of oral sodium bicarbonate, which is titrated to keep plasma bicarbonate in the normal range (>22 mmol/l).

Ileal Conduits

Unlike the sigmoidostomy, in which urine enters a reservoir, the ileal conduit is free flowing, with rapid urinary transit and no reservoir. Therefore metabolic complications are much less common, although again the bowel can exchange sodium and chloride for potassium and bicarbonate.[42,43] A number of other complications of ileal and colonic conduits can lead to progressive loss of renal function (Box 50.2).

BOX 50.2 Long-Term Complications of Urinary Diversion

- Pyelonephritis and scarring
- Calculi
- Obstruction
- Strictures
- Bladder mucus causing obstruction
- Cancer at intestinal-ureteral anastomosis
- Hyperchloremic acidosis
- Delayed linear growth in children
- Effects of intestinal loss from gastrointestinal tract (e.g., vitamin B_{12} deficiency)
- Complications related to abnormal pelvic anatomy (e.g., in pregnancy)
- Psychological and body image problems

Enterocystoplasty and Intestinal Urinary Reservoirs

In 53 patients with bladder exstrophy monitored more than 10 years with serial isotopic GFRs, renal function deteriorated (GFR decrease ≥20%) in only 10 (~20%).[30] Loss of function was caused principally by chronic urinary retention with or without infection in poorly compliant patients who did not catheterize regularly. Patients also must be checked regularly to ensure that anastomotic stenoses and high-pressure reservoirs do not occur. Stones are common and occur in up to 52% of patients.[44]

END-STAGE RENAL DISEASE AND TRANSPLANTATION

This group of patients presents two important problems if they develop ESRD. First, because of multiple abdominal surgeries, continuous ambulatory peritoneal dialysis (CAPD) is often impossible, although if there is any doubt and the patient is interested, CAPD should be attempted. Second, the bladder and urinary reservoir must be suitable for renal transplantation. If a bladder has just destroyed two good native kidneys, it is likely to do the same to a transplant kidney. Most patients will be maintained on hemodialysis, but it is frequently difficult to establish a good arteriovenous fistula because of chronic hypovolemia and vasoconstriction. Patients receiving dialysis often continue to pass 1 liter or more of urine per 24 hours, and they also remain at risk for serious UTI and pyelonephritis.

Pretransplantation Assessment

Transplantation into the abnormal lower urinary tract requires careful evaluation and follow-up. Thorough preoperative assessment of bladder function is essential (Fig. 50.18). Patients considered to have normal bladders require at least postmicturition bladder ultrasound and urinary flow rate.

All patients with abnormal bladders or reservoir must have a full videocystometrogram to ensure that the bladder reservoir is large and adequately compliant. If the bladder is small or has not been used for some time, bladder cycling, which involves periodically filling and distending the bladder through a suprapubic catheter, may be required. A urodynamic study before transplantation indicated that poor bladder function, as shown by small bladder volumes, is a predictor of graft loss even in patients with previously normal bladder function.[45]

Intermittent self-catheterization is safe and effective for a patient with a poor flow rate who fails to empty the bladder. This, however, is possible only with a normal urethra and a cooperative patient. When

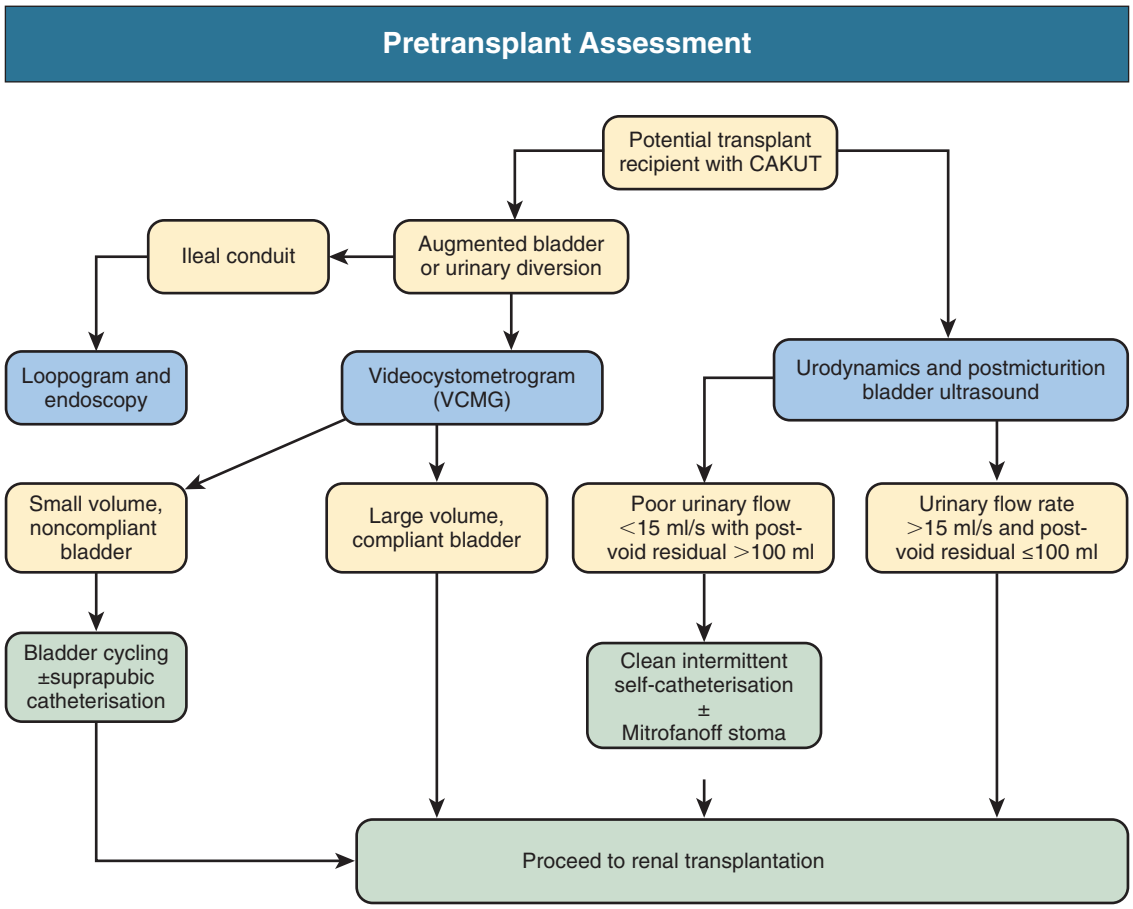

Fig. 50.18 Pretransplant assessment of patients with an abnormal lower urinary tract.

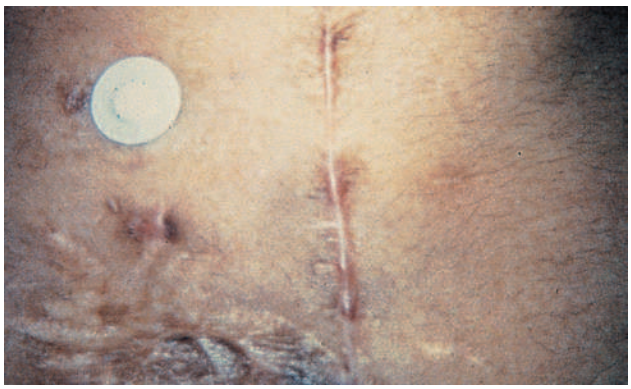

Fig. 50.19 **Mitrofanoff stoma.** This patient was born with bladder exstrophy and has had a successful renal transplant for 22 years. Her kidney is plumbed into a colonic reservoir, and she catheterizes herself through a continent Mitrofanoff stoma, which is covered by a small plaster in the photograph.

this is not practical, we attempt to establish suprapubic drainage through a continence stoma, such as a Mitrofanoff stoma (Fig. 50.19). If a conduit is to be used, a loopogram and endoscopy must ensure it is in good condition. We do not remove native kidneys unless they are causing recurrent UTI.

Transplant Outcome

In an 18-year experience, we performed transplantation in 65 patients with abnormal bladders, with a total of 72 renal transplants.[46] In 52 cases the ureters were transplanted into unaugmented bladders; in 20 cases, there was some form of augmentation or diversion. Results were compared with 59 transplants in 55 patients who had renal failure from renal dysplasia and whose bladder function was considered normal. There was no difference in actuarial graft survival in the two groups at 10 years (abnormal bladders, 66%; normal bladders, 61%), although longer follow-up showed an advantage for normal bladders, with a kidney half-life of 29 to 33 years compared with 15 years for the abnormal bladders. UTIs were relatively common in all patients but produced problems only in patients with abnormal bladders.

Management

A double-J ureteral stent should be placed routinely at the time of transplant surgery. Adequacy of urinary drainage must be assessed frequently, even when graft function seems to be good. Two months after transplantation, when the ureteral stent has been removed, we recommend performing a baseline postmicturition ultrasound of the transplant kidney and bladder, in addition to a dynamic ^{99m}Tc-MAG3 scintigraphy scan in patients with abnormal bladders.

Ultrasound and ^{99m}Tc-MAG3 scintigraphy are then repeated when clinically indicated. The protein-to-creatinine ratio is measured on a random urine sample at every outpatient visit. If there is renal dysfunction, imaging tests are repeated, and if there is a change from baseline, renal biopsy is performed to exclude an immunologic cause of graft dysfunction. If there is a documented deterioration in renal function in the absence of rejection or calcineurin inhibitor toxicity, the DMSA scan is repeated (to see whether new scarring has occurred) and the bladder reassessed urodynamically.[47]

Complications

UTIs must be detected and treated early, and recurrent UTIs may require long courses of antibiotics or even removal of the native tracts. Symptomatic UTIs are common in the first 3 months after transplantation (63%); fever and systemic symptoms occur in 39% of patients with normal bladders and 59% with abnormal bladders. UTI directly contributes to graft loss in patients with abnormal bladders but causes no consequences in those with normal bladders.[39] Prophylactic administration of antibiotics for the first 6 months reduces significantly the subsequent incidence of UTI. When UTIs recur, a cause must be sought with ultrasound of the kidneys and bladder. A CT KUB can be done to look for stones in native or transplant kidneys and the bladder or urinary diversion. If there is a residual volume after double micturition, the patient must be instructed to perform CISC. With these measures, good results are obtained.

SELF-ASSESSMENT QUESTIONS

1. Which statement about unilateral renal agenesis is *false*?
   - **A.** It occurs in 1 in 10,000 births.
   - **B.** Typically, there is no ureter.
   - **C.** The fallopian tube may be absent in girls.
   - **D.** Renal ultrasound is recommended in first-degree relatives.
   - **E.** It can be part of a syndrome.
2. Which statement about prune-belly syndrome is *false*?
   - **A.** It usually occurs in males only.
   - **B.** The muscles of the anterior abdominal wall are absent.
   - **C.** Gross dilation of the bladder occurs, with normal ureters.
   - **D.** Males have bilateral undescended testes.
   - **E.** Patients are usually infertile.
3. Ureterosigmoidostomy may lead to all the following *except:*
   - **A.** Hyperchloremia
   - **B.** Hyperkalemia
   - **C.** Acidosis
   - **D.** Ammonium ion retention
   - **E.** Colonic carcinoma
4. Which of the following statements about posterior urethral valves is *false*?
   - **A.** They are usually detected antenatally.
   - **B.** Patients require urethral surgery.
   - **C.** Progressive renal failure is associated with proteinuria.
   - **D.** Posterior urethral valves may be confused with urofacial (Ochoa) syndrome.
   - **E.** Posterior urethral valves occur in males and females.
5. Which of the following statements about UTI in an augmented bladder is *false*?
   - **A.** The patient with UTI does not require treatment when asymptomatic.
   - **B.** UTI often causes calcium oxalate stones.
   - **C.** Recurrent UTIs should be investigated with ultrasound, including assessment of postvoid residual volume.
   - **D.** UTI may indicate poor bladder emptying.

51

Urinary Tract Infections in Adults

Thomas Hooton

DEFINITION

Urinary tract infection (UTI) in adults can be categorized into five groups: women with acute uncomplicated cystitis, women with recurrent cystitis, women with acute uncomplicated pyelonephritis, complicated UTI, and asymptomatic bacteriuria (Box 51.1).[1] Chapter 42 discusses UTI in pregnancy, and Chapter 61 describes vesicoureteral reflux (VUR) in children.

Complicated UTI is defined as UTI that increases the risk for serious complications or treatment failure. Patients with various conditions, such as those presented in Box 51.1, are at increased risk for complicated UTI. Complicated UTIs may require different pretreatment and posttreatment evaluation and type and duration of antimicrobial treatment than for uncomplicated UTI. On occasion, complicated UTIs are diagnosed only after a patient has a poor response to treatment.

EPIDEMIOLOGY

Acute uncomplicated UTIs are extremely common, with several million episodes of acute cystitis and at least 250,000 episodes of acute pyelonephritis occurring annually in the United States. The incidence of cystitis in sexually active young women is about 0.5 per 1 person-year.[2] Acute uncomplicated cystitis may recur in 27% to 44% of healthy women, even though they have a normal urinary tract.[3] The incidence of pyelonephritis in young women is about 3 per 1000 person-years.[4] The self-reported incidence of symptomatic UTI in postmenopausal women is about 10% per year.[5] The incidence of symptomatic UTI in adult men younger than 50 years is much lower than in women, ranging from 5 to 8 per 10,000 men annually.

Complicated UTIs occur in a wide range of settings (see Box 51.1). Nosocomial UTIs are a common type of complicated UTI and occur in 5% of admissions in the university tertiary care hospital setting; catheter-associated infections account for most of the infections. Catheter-associated bacteriuria is the most common source of gram-negative bacteremia in hospitalized patients.[6]

Asymptomatic bacteriuria is defined as the presence of two separate consecutive clean-voided urine specimens, both with 10^5 or more colony-forming units per milliliter (cfu/ml) of the same uropathogen in the absence of symptoms referable to the urinary tract.[7] Asymptomatic bacteriuria is found in about 5% of young adult women,[8] but rarely in men younger than 50. The prevalence increases up to 16% of ambulatory women and 19% of ambulatory men older than 70 and up to 50% of elderly women and 40% of elderly men who are institutionalized.[7] Asymptomatic bacteriuria may be persistent or transient and recurrent, and many patients have had previous symptomatic infection or develop symptomatic UTI soon after having asymptomatic bacteriuria. Asymptomatic bacteriuria is generally benign, although it may lead to serious complications in some clinical settings.

PATHOGENESIS

Uncomplicated Infection

Most uncomplicated UTIs in healthy women result when uropathogens (typically *Escherichia coli*) present in the rectal flora enter the bladder through the urethra after an interim phase of periurethral and distal urethral colonization. Colonizing uropathogens also may come from a sex partner's vagina, rectum, or penis. Hematogenous seeding of the urinary tract by potential uropathogens such as *Staphylococcus aureus* is the source of some UTIs, but this is more likely to occur in the setting of persistent bloodstream infection or urinary tract obstruction.

Many host behavioral, genetic, and biologic factors predispose healthy young women to uncomplicated UTI (Table 51.1).[2,9] Factors protecting individuals from UTI include the host's immune response; maintenance of normal vaginal flora, which protects against colonization with uropathogens; and removal of bladder bacteriuria by micturition.[10] Uropathogenic *E. coli,* the predominant pathogens in uncomplicated UTI, are a specific subset of extraintestinal pathogenic *E. coli* that have the potential for enhanced virulence[11] (see Table 51.1). P-fimbriated strains of *E. coli* are associated with acute uncomplicated pyelonephritis, and their adherence properties may stimulate epithelial and other cells to produce pro-inflammatory factors that stimulate the inflammatory response.[12] Other virulence determinants include adherence factors (type 1, S, and Dr fimbriae), toxins (hemolysin), immune evasion, iron acquisition (aerobactin), flagella, and serum resistance.[11,13] Bacterial virulence determinants associated with cystitis and asymptomatic bacteriuria have been less well characterized. Triggers for development of urinary symptoms are not entirely clear.

Factors affecting the large difference in UTI prevalence between men and women include the greater distance between the anus and the urethral meatus, the drier environment surrounding the male urethra, and the greater length of the male urethra. Risk factors associated with UTIs in healthy men include intercourse with an infected female partner, anal intercourse, and lack of circumcision, although these factors often are not present in men with UTI. Most uropathogenic strains infecting young men are highly virulent, suggesting that the urinary tract in healthy men is relatively resistant to infection.

TABLE 51.1 Factors Modulating Risk for Acute Uncomplicated Urinary Tract Infections in Women

Host Determinants	Uropathogen Determinants
Behavioral: Sexual intercourse, use of spermicidal products, recent antimicrobial use, suboptimal voiding habits	*Escherichia coli* virulence determinants: P, S, Dr, and type 1 fimbriae; hemolysin; aerobactin; serum resistance
Genetic: Innate and adaptive immune response, enhanced epithelial cell adherence, antibacterial factors in urine and bladder mucosa, nonsecretor of ABO blood group antigens, P1 blood group phenotype, reduced *CXCR1* expression, previous history of recurrent cystitis	
Biologic: Estrogen deficiency in postmenopausal women, glycosuria (including from SGLT-1 inhibitors)	

TABLE 51.2 Bacterial Etiology of Urinary Tract Infections

	URINARY TRACT INFECTION (%)	
Organisms	**Uncomplicated**	**Complicated**
Gram-Negative Organisms		
Escherichia coli	70-95	21-54
Proteus mirabilis	1-2	1-10
Klebsiella spp.	1-2	2-17
Citrobacter spp.	<1	5
Enterobacter spp.	<1	2-10
Pseudomonas aeruginosa	<1	2-19
Other	<1	6-20
Gram-Positive Organisms		
Coagulase-negative staphylococci (*Staphylococcus saprophyticus*)	5-20 or more	1-4
Enterococci	1-2	1-23
Group B streptococci	<1	1-4
Staphylococcus aureus	<1	1-2
Other	<1	2

(Data for complicating factors from Nicolle LE. A practical guide to the management of complicated urinary tract infection. *Drugs.* 1997;53:583-592.)

BOX 51.1 Categories of Urinary Tract Infection in Adults

- Acute uncomplicated cystitis in healthy women
- Recurrent acute uncomplicated cystitis in healthy women
- Acute uncomplicated pyelonephritis in healthy women
- Complicated urinary tract infection*
  - Male sex
  - Pregnancy
  - Poorly controlled diabetes mellitus
  - Obstruction or other structural factor: Urolithiasis, malignancies, ureteral and urethral strictures, bladder diverticula, renal cysts, fistulas, ileal conduits, other urinary diversions
  - Functional abnormality: Neurogenic bladder, vesicoureteral reflux
  - Foreign bodies: Indwelling catheter, ureteral stent, nephrostomy tube
  - Other conditions: Renal failure, renal transplantation, immunosuppression, multidrug-resistant uropathogens, health care–associated (includes hospital-acquired/LTCF-acquired) infection, prostatitis-related infection, upper tract infection in an adult other than a healthy woman, other functional or anatomic abnormality of urinary tract)
- Asymptomatic bacteriuria

(Data for complicating factors from Nicolle LE. A pactical guide to the management of complicated urinary tract infection. *Drugs.* 1997;53:583-592.)
*This is a selected list of complicating factors. Some factors complicate urinary tract infections through several mechanisms.

Complicated Infection

The initial steps leading to uncomplicated UTI discussed earlier probably also occur in most individuals who develop a complicated UTI. Factors that predispose individuals to complicated UTI generally do so by causing obstruction or stasis of urine flow, facilitating entry of uropathogens into the urinary tract by bypassing normal host defense mechanisms, providing a nidus for infection that is not readily treatable with antimicrobials, or compromising the host immune system (see Box 51.1).[1] UTIs are more likely to become complicated in the setting of impaired host defense, as occurs with indwelling catheter use, VUR, obstruction, neutropenia, and immune deficiencies. Diabetes mellitus is associated with several syndromes of complicated UTI, including renal and perirenal abscess, emphysematous pyelonephritis and cystitis, papillary necrosis, and xanthogranulomatous pyelonephritis.[14] Uropathogen virulence determinants are less important in the pathogenesis of complicated UTIs compared with uncomplicated UTIs. However, infection with multidrug-resistant uropathogens is more likely with complicated UTI.

ETIOLOGIC AGENTS

Uncomplicated upper and lower UTI are most often caused by *E. coli,* present in 70% to 95%, and *Staphylococcus saprophyticus,* present in 5% to more than 20%. Other organisms are less common (Table 51.2).[1] *S. saprophyticus* only rarely causes acute pyelonephritis.[15] Among otherwise healthy nonpregnant women, the isolation of lactobacilli, enterococci, group B streptococci, and coagulase-negative staphylococci other than *S. saprophyticus* most often represents contamination of the urine specimen[16] unless found in voided midstream urine in high counts and pure growth in symptomatic women.

A broader range of bacteria can cause complicated UTI, and many are resistant to broad-spectrum antimicrobial agents. Although *E. coli* is the most common, *Citrobacter* spp., *Enterobacter* spp., *Pseudomonas aeruginosa,* enterococci, and *S. aureus* account for a relatively higher proportion of cases compared with uncomplicated UTIs (see Table 51.2).[1] The proportion of infections caused by fungi, especially *Candida* spp., is increasing (see Chapter 53). Patients with chronic conditions, such as spinal cord injury and neurogenic bladder, are more likely to have polymicrobial and multidrug-resistant infections.

CLINICAL SYNDROMES

Acute Uncomplicated Cystitis in Young Women

Women with acute uncomplicated cystitis generally present with acute onset of dysuria, frequency, urgency, or suprapubic pain. Acute dysuria in a sexually active young woman is usually caused by acute cystitis; acute urethritis from *Chlamydia trachomatis, Neisseria gonorrhoeae,* or herpes simplex virus infections; or vaginitis caused by *Candida* spp. or *Trichomonas vaginalis*.[6] These three entities usually can be distinguished by the history, physical examination, and simple laboratory tests. Pyuria is present in almost all women with acute cystitis as well as in most women with urethritis caused by *N. gonorrhoeae* or *C. trachomatis,* and its absence strongly suggests an alternative diagnosis. Hematuria (microscopic or gross) is common in women with UTI but not in women with urethritis or vaginitis.

Definitive diagnosis of UTI requires the presence of significant bacteriuria, the traditional standard for which is 10^5 or more uropathogens per milliliter of voided midstream urine. Studies have shown, however, that up to half of women with cystitis have lower colony counts, which are missed with use of the traditional definition.[17,18] The Infectious Diseases Society of America (IDSA) consensus definition of cystitis is 10^3 cfu/ml or more uropathogens.[19] Urine cultures are generally not indicated in women with uncomplicated cystitis, because the patient's history has been shown to be highly reliable in establishing the diagnosis,[20] the causative organisms are predictable, and the culture results usually become available only after therapeutic decisions have been made.

E. coli in uncomplicated UTI is often resistant to sulfonamides and amoxicillin, and increasing resistance is also being observed for trimethoprim, TMP-SMX, and cotrimoxazole in outpatient urinary strains in the United States, Canada, and Europe.[21-23] In the United States, cotrimoxazole resistance rates among *E. coli* strains causing uncomplicated UTI range from 15% to 42% in different regions,[21] with a similar range among European countries and Brazil.[22] Many drug-resistant *E. coli* organisms are clonal and have been hypothesized to enter new environments by contaminated products ingested by community residents.[24] The prevalence of *E. coli* resistance to nitrofurantoin is generally less than 5%, although nitrofurantoin is inactive against *Proteus* spp. and some *Enterobacter* and *Klebsiella* spp. Fluoroquinolones remain active against most *E. coli* strains causing uncomplicated cystitis, although resistance is increasing in many areas of the world.[21,22] In a recent antimicrobial susceptibility study of more than 12 million *E. coli* isolates from U.S. outpatients, fluoroquinolone resistance increased from 3% to 17% over 10 years.[25] In addition, infections caused by extended-spectrum β-lactamase (ESBL)-producing strains are increasing in number, even in the setting of uncomplicated UTI.

Recommended management of acute uncomplicated cystitis is summarized in Fig. 51.1 and Table 51.3. Updated IDSA guidelines emphasize the importance of considering ecologic adverse effects of antimicrobial agents (i.e., selection for colonization or infection with multidrug-resistant organisms—so-called collateral damage) when selecting a treatment regimen.[26] Short-course regimens are recommended as first-line treatment for acute uncomplicated cystitis because of comparable efficacy, better compliance, lower cost, and fewer adverse effects than with longer regimens.[27] Given the benign nature of uncomplicated cystitis along with its high frequency, the IDSA guidelines give equal weight to the risk for ecologic adverse effects and drug effectiveness in the recommendations.

Nitrofurantoin is well tolerated and has good efficacy when given twice daily for 5 days, and it has a low propensity for ecologic adverse effects.[28] Despite concern about the high prevalence of resistance to TMP-SMX, this combination remains very effective and is inexpensive and well tolerated. Fosfomycin is also considered a first-line regimen because of its low propensity for ecologic adverse effects, even though it appears to be clinically inferior to TMP-SMX and fluoroquinolones.[26]

TABLE 51.3 Oral Antimicrobial Agents for Acute Uncomplicated Cystitis

Drug	Dose (mg)	Interval*	Comment
Nitrofurantoin			Less active against *Proteus* spp.
Monohydrate/macrocrystals	100	q12h	
Macrocrystals	50	q6h	
Trimethoprim-sulfamethoxazole (TMP-SMX)	160/800	q12h	If used in pregnancy (not approved use), avoid in first trimester.
Trimethoprim	100	q12h	If used in pregnancy (not approved use), avoid in first trimester.
Fosfomycin	3000	Single dose	Less effective than fluoroquinolone or TMP-SMX.
Pivmecillinam	400	q12h	Availability limited to some European countries; not available for use in North America. Associated with minimal resistance and propensity for collateral damage, but efficacy rates are lower than other agents.
Cefpodoxime proxetil	100	q12h	Comparable to TMP-SMX, inferior to ciprofloxacin in 3-day regimen[35]
Amoxicillin-clavulanate	500/125	q12h	Inferior to ciprofloxacin in 3-day regimen[34]
Amoxicillin	500	q12h	Used only when causative pathogen is known to be susceptible or for empiric treatment of mild cystitis in pregnancy
Fluoroquinolones			
Ciprofloxacin	250	q12h	Avoid fluoroquinolones if possible in pregnancy, nursing mothers, or persons younger than 18 years old. Although highly effective, should be considered second-line treatment to preserve their usefulness for other infections. Moreover, in the United States, the FDA has stated that the risks of systemic fluoroquinolone antibacterial drugs outweigh their benefits for uncomplicated cystitis.
Ciprofloxacin extended release	500	q24h	
Levofloxacin	250	q24h	
Ofloxacin	200	q12h	

*Duration of therapy depends on the clinical setting (see text and Fig. 51.1); *q6h, q12h, q24h,* every 6, 12, or 24 hours.
FDA, U.S. Food and Drug Administration.

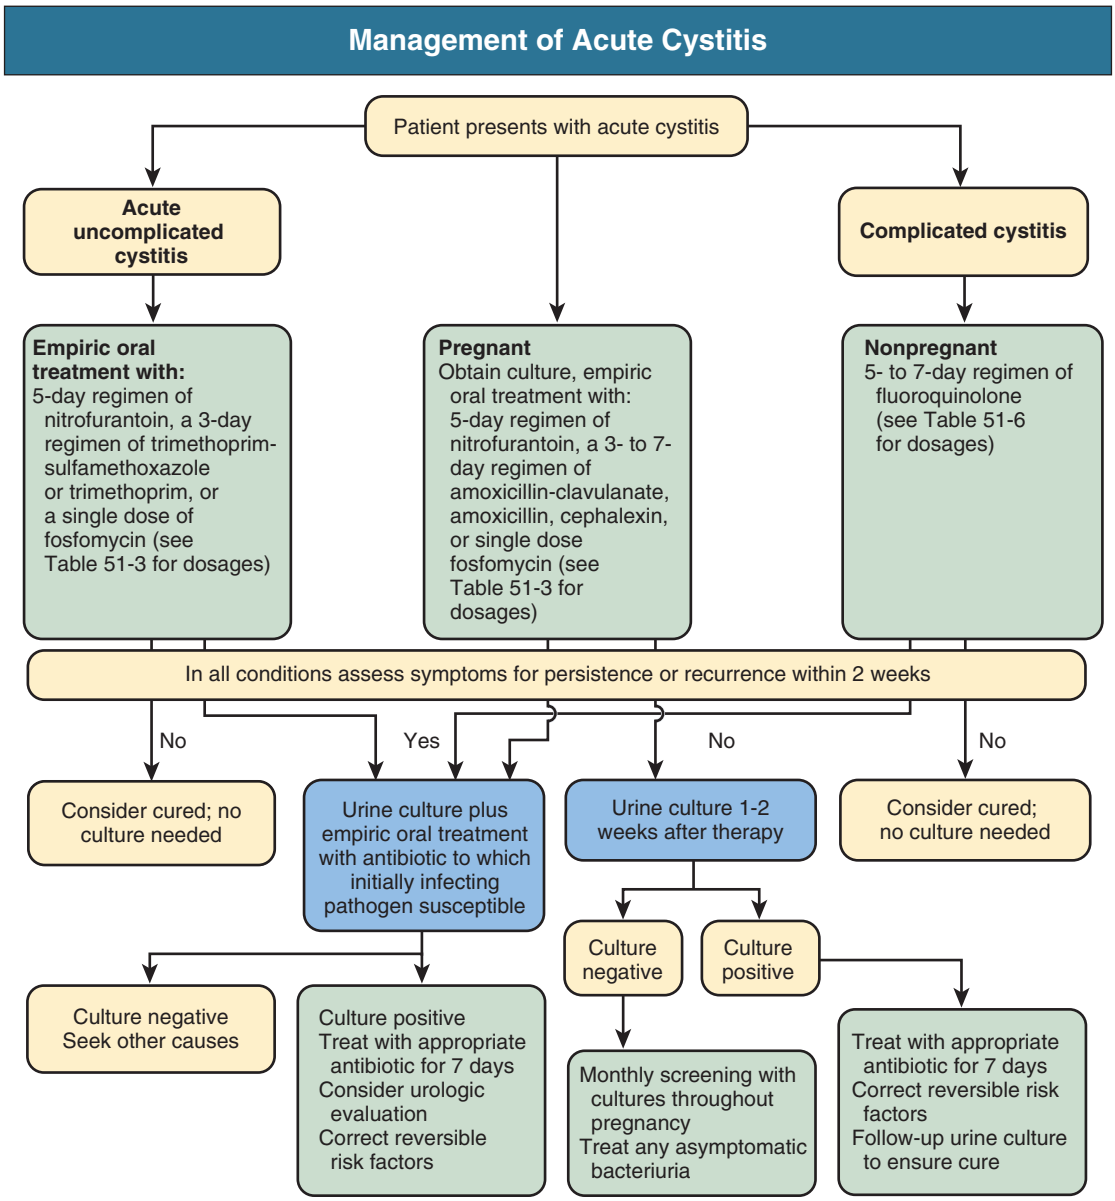

Fig. 51.1 Algorithm for management of acute cystitis.

Moreover, both nitrofurantoin and fosfomycin appear to have a role as therapeutic agents effective against ESBL *E. coli* UTIs.[29,30] Pivmecillinam, an extended gram-negative spectrum penicillin used only for treatment of UTI, is an appropriate choice for therapy in regions where it is available (availability limited to some European countries; not licensed and/or available for use in North America), because of minimal resistance and propensity for collateral damage, but efficacy rates are notably lower than with other recommended agents.[26] Pivmecillinam also may have a role in the treatment of ESBL-producing uropathogens.[32] The choice of an antimicrobial agent should be individualized based on the patient's allergy and compliance history, local practice patterns, prevalence of resistance in the local community (if known), availability, cost, and how comfortable the patient and provider are with increased risk for treatment failure associated with the use of an antimicrobial agent that may cause less collateral damage but is less effective than another drug.[26] If a first-line antimicrobial agent is not a good choice because of one or more of these factors, fluoroquinolones or β-lactams are reasonable alternatives, although it is preferable to minimize their use because of concerns about ecologic adverse effects.[26] Thus, although fluoroquinolones (3-day duration) are highly effective in the treatment of cystitis, many experts recommend that they be considered as second-line therapy for uncomplicated cystitis, to help preserve their usefulness in the treatment of other infections.[26] Moreover, in the United States, the Food and Drug Administration (FDA) has stated that the risks of systemic fluoroquinolone antibacterial drugs outweigh their benefits for uncomplicated cystitis.[31] In general, β-lactam antibiotics have been inferior to TMP-SMX or fluoroquinolones in regimens of the same duration.[36]

Although broad-spectrum oral β-lactams (e.g., cefixime, cefpodoxime, cefprozil, cefaclor, amoxicillin-clavulanate) demonstrate in vitro activity against most uropathogens causing uncomplicated cystitis, clinical data are sparse. Recent trials demonstrated that cure rates with 3-day regimens of amoxicillin-clavulanate[34] or cefpodoxime proxetil[35] were lower than a 3-day regimen of ciprofloxacin. Moreover, there are concerns about the possibility of ecologic adverse effects with oral broad-spectrum cephalosporins, as has been observed with parenteral cephalosporins,

although again few data exist. Routine post-treatment cultures in women are not indicated unless the patient is symptomatic. If the patient remains symptomatic and has documented persistent infection, a longer course of therapy based on sensitivities, usually with a fluoroquinolone, should be used. The benefit of detecting and treating asymptomatic bacteriuria in healthy women has been demonstrated only in pregnancy and before urologic instrumentation or surgery.[7,37]

Recurrent Acute Uncomplicated Cystitis in Women

Much recurrent cystitis in healthy women is caused by persistence of the initially infecting strain in the fecal flora.[38] Experimental studies in mice also suggest that some same-strain recurrent UTIs may be caused by a latent reservoir of uropathogens in the bladder epithelium that persist after the initial UTI,[39] and indirect evidence indicates that this may occur in humans.[40] If the recurrence is within 1 or 2 weeks of treatment, an antimicrobial-resistant uropathogen should be considered, and a urine culture should be performed followed by treatment with an alternative regimen. It is reasonable to treat later recurrences the same as the original infection, although if the recurrence is within 6 months, one should consider a first-line drug other than the one used originally, especially if TMP-SMX was used, because of the likelihood of resistance.[16]

The goal of long-term management of recurrent cystitis should be to improve the quality of life while minimizing antimicrobial exposure.[16] Women with recurrent cystitis may benefit from behavioral modification (Fig. 51.2), such as avoiding spermicides, increasing fluid intake, and ensuring postcoital micturition, although the benefit of these practices has not been proven. Data on efficacy are sparse, but targeting the adherence mechanism of *Enterobacteriacea* with D-mannose powder is another antimicrobial-sparing modality used by some women to prevent UTI.[41] Although cranberry products are widely used by women as a preventive for recurrent UTI, randomized, placebo-controlled trials (RCTs) have shown no benefit from cranberry juice.[42] Women who do not want to try or who obtain no benefit from the preceding approaches should be offered antimicrobial prophylaxis.

Antimicrobial prophylaxis has been shown to reduce the risk for recurrent cystitis by approximately 95% (Table 51.4; see also Fig. 51.2).[43] Prophylaxis should be considered for women who experience three or more infections during a 12-month period or whenever the woman thinks her life is being adversely affected by frequent recurrences. Several approaches have been used, including continuous prophylaxis, postcoital prophylaxis, and intermittent self-treatment (which is really an early treatment method).[16] In postmenopausal women with recurrent UTI, intravaginal estradiol is effective, presumably by normalizing the vaginal flora, which reduces the risk for coliform colonization of the vagina.[38] This approach offers an alternative to antimicrobial strategies (see Fig. 51.2).

Many promising antimicrobial-sparing approaches are being developed to specifically target virulence pathways, which might prevent uropathogens from causing disease, without altering the gut commensal microbiota. Antivirulence therapeutics target processes that are critical for UTI pathogenesis but are not required for the essential processes of growth and cell division (targets of conventional antimicrobials).[13]

Acute Uncomplicated Pyelonephritis in Women

Acute pyelonephritis is suggested by fever (temperature ≥38° C), chills, flank pain, nausea and vomiting, and costovertebral angle tenderness. Cystitis symptoms are variably present. Symptoms may vary from a mild illness to a sepsis syndrome with or without shock and renal failure. Pyuria is almost always present, but leukocyte casts, specific for UTI, are infrequently seen. Gram stain of the urine sediment may aid in differentiating gram-positive and gram-negative infections, which can influence empiric therapy. A urine culture, which should be performed in all women with acute pyelonephritis, will have 10^4 cfu/ml or more of uropathogens in up to 95% of patients.[19]

On pathologic examination, the kidney shows a focal inflammatory reaction with neutrophil and monocyte infiltrates, tubular damage, and interstitial edema (Fig. 51.3). Although imaging studies are generally not performed, the infected kidney is often enlarged, and contrast-enhanced computed tomography (CT) shows decreased opacification of the affected parenchyma, typically in patchy, wedge-shaped, or linear patterns (Fig. 51.4).

The availability of effective oral antimicrobials, especially the fluoroquinolones, allows initial oral therapy in appropriate patients or, in those requiring parenteral therapy, the timely conversion from

TABLE 51.4 Antimicrobial Prophylaxis Regimens for Women With Recurrent Acute Uncomplicated Cystitis*

Drug	Dose (mg)	Frequency
Continuous Prophylaxis		
Nitrofurantoin	50 or 100	Daily
TMP-SMX	40/200	Daily
TMP-SMX	40/200	Three times weekly
Trimethoprim	100	Daily
Cefaclor	250	Daily
Cefalexin (cephalexin)	125 or 250	Daily
Norfloxacin*	200	Other fluoroquinolones are likely to be as effective.†
Postcoital Prophylaxis		
Nitrofurantoin	50 or 100	Single dose
TMP-SMX	40/200	Single dose
TMP-SMX	80/400	Single dose
Cefalexin	250	Single dose
Ciprofloxacin*	125	Single dose
Norfloxacin*	200	Single dose
Ofloxacin*	100	Single dose

*See text and Fig. 51.2 for management strategy.
†Women should be cautioned about pregnancy when fluoroquinolones are being used. Fluoroquinolones are highly effective but not recommended, especially given the recent FDA warning that the risks of systemic fluoroquinolone antibacterial drugs outweigh their benefits for uncomplicated cystitis.

TABLE 51.5 Parenteral Regimens for Acute Uncomplicated Pyelonephritis and Complicated Urinary Tract Infection*

Drug	Dose (mg)	Interval
Ceftriaxone	1000-2000	q24h
Cefepime	1000-2000	q12h
Fluoroquinolones†		
Ciprofloxacin	200-400	q12h
Levofloxacin	250-750	q24h
Gentamicin† (± ampicillin)	3-5 mg/kg body weight 1 mg/kg body weight	q24h q8h
Ampicillin (+ gentamicin†)	1000	q6h
Trimethoprim-sulfamethoxazole†	160/800	q12h
Aztreonam	1000	q8-12h
Piperacillin-tazobactam	3375	q6-8h
Imipenem-cilastatin†,‡	250-500	q6-8h
Meropenem‡	500	q8h
Ertapenem‡	1000	q24h
Ceftolozane/tazobactam	1500	q8h
Ceftazidime/avibactam	2500	q8h
Vancomycin§	1000	q12h

*Duration depends on clinical setting (see text and Fig. 51.5).
†Avoid, if possible, in pregnancy.
‡Recommended if ESBL Enterobacteriacea is suspected or known. Ertapenem is not indicated for suspected or known *Pseudomonas* infection.
§Recommended if methicillin-resistant *Staphylococcus aureus* (MRSA) is suspected or known.

intravenous to oral therapy and reduced need for hospitalization. Indications for hospital admission include inability to maintain oral hydration or to take medications; uncertain social situation or concern about compliance; uncertainty about the diagnosis; and severe illness with high fevers, severe pain, and marked debility. Outpatient therapy is safe and effective for select patients who can be stabilized with parenteral fluids and antibiotics in an urgent care facility and sent home with oral antibiotics under close supervision. In one population-based study of acute pyelonephritis in adult women, only 7% were hospitalized.[4]

The management strategy for acute uncomplicated pyelonephritis is shown in Fig. 51.5. Many effective parenteral (Table 51.5) and oral (Table 51.6) regimens are available for patients with acute uncomplicated pyelonephritis. For outpatients, an oral fluoroquinolone should be used for initial empiric treatment of infection caused by gram-negative bacilli.[26,33] TMP-SMX or other agents can be used if the infecting strain is known to be susceptible. If enterococci are suspected from the Gram

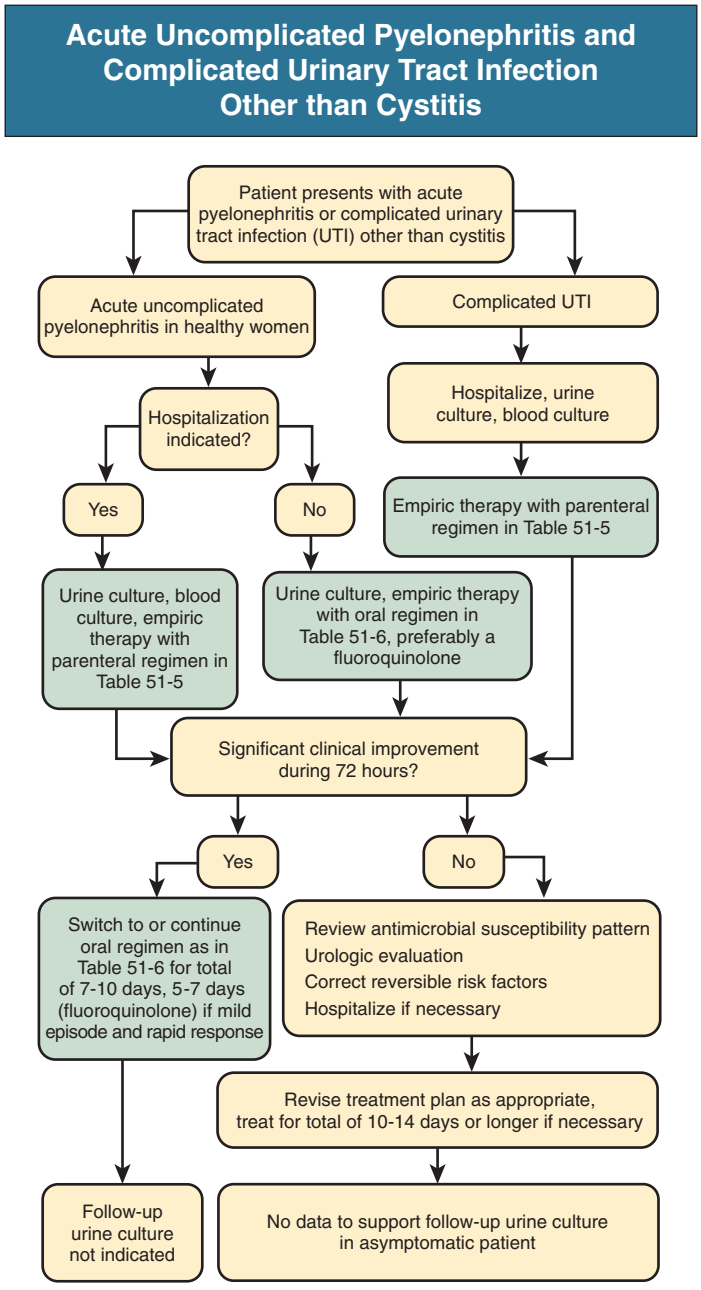

Fig. 51.5 Management algorithm for acute uncomplicated pyelonephritis and complicated urinary tract infection other than cystitis.

stain, amoxicillin should be added to the treatment regimen until the causative organism is identified. Second- and third-generation cephalosporins also appear effective, although published data are sparse. Nitrofurantoin, fosfomycin, and pivmecillinam are not approved or recommended for the treatment of pyelonephritis. When antimicrobial resistance or intolerance of oral medications is a concern, one or more doses of a broad-spectrum parenteral antimicrobial is recommended until in vitro activity can be ensured.[26]

For hospitalized patients without evidence of gram-positive infection, ceftriaxone is effective and inexpensive. If enterococci are suspected based on the Gram stain, ampicillin plus gentamicin, ampicillin-sulbactam, and piperacillin-tazobactam are reasonable empiric choices. TMP-SMX should not be used alone for empiric therapy for pyelonephritis in areas with a high prevalence of resistance to this combination. Patients with acute uncomplicated pyelonephritis often can be switched to oral therapy after 24 to 48 hours, although longer durations of parenteral therapy are occasionally indicated in patients with continued high fever, severe flank pain, or persistent nausea and vomiting.

Treatment of acute uncomplicated pyelonephritis can be limited to 5 to 7 days for patients who have a rapid resolution of fever and symptoms soon after initiation of treatment. However, β-lactam regimens shorter than 14 days have been associated with unacceptably high failure rates in some studies.[33] One study demonstrated superiority of a 7-day ciprofloxacin regimen over a 14-day TMP-SMX regimen, with the difference accounted for entirely by the higher rate of resistance of the uropathogens to TMP-SMX.[15]

A recent study of patients with acute pyelonephritis presenting to emergency departments in the United States demonstrated that antimicrobial resistance prevalence (fluoroquinolone-resistant and ESBL-producing strains) is increasing and that such patients are often treated with empiric antimicrobial drugs that are inactive against the causative strains.[44] The authors conclude that in areas with high fluoroquinolone resistance rates, where ESBL-producing *Enterobacteriaceae* infections have emerged, or among persons with antimicrobial drug resistance risk factors, clinicians should consider empiric treatment with a carbapenem or another agent found to be active against these resistant strains.

Routine post-treatment urine cultures in asymptomatic patients are not cost-effective, but cultures should be performed if symptoms persist or recur. Recurrent infections are treated with a 7- to 14-day course of an antibiotic to which the organism is susceptible. Symptomatic patients who have persistent infection with the same strain as the initial infecting strain warrant at least 10 to 14 days of therapy with a different antibiotic, and complicating factors should be looked for and corrected if found.

Complicated Infections

Patients with complicated UTI may present with classic signs of cystitis and pyelonephritis but also may have vague or nonspecific symptoms, such as fatigue, irritability, nausea, headache, and abdominal or back pain. Acute cystitis in healthy individuals other than young women is more likely to involve occult renal or prostatic infection and may respond poorly to short-course therapy. Noninvasive tools to localize infections to the kidney or prostate are lacking, so clinical estimation of risk in a given patient is imprecise. Some patients, such as those who are diabetic or pregnant, warrant special attention because of the serious complications that can occur if treatment is inadequate. Urethritis must be excluded in dysuric sexually active men by a urethral Gram stain or a first-voided urine specimen wet-mount evaluation for urethral leukocytosis. Complicated UTI, as with uncomplicated infection, is generally associated with pyuria and bacteriuria, although these may be absent if the infection does not communicate with the collecting system.

Urine culture should always be performed in patients with suspected complicated UTI. The IDSA consensus definition of complicated UTI is 10^5 cfu/ml or more in the urine of women and 10^4 cfu/ml or more in men,[19] but lower counts in symptomatic persons, as demonstrated in patients with uncomplicated UTI, may well represent significant bacteriuria. This is especially true when the specimen is collected from a urinary catheter. Thus it is reasonable to use a colony count threshold of 10^3 cfu/ml of uropathogens to diagnose complicated UTI.

The wide variety of underlying conditions (see Box 51.1), diverse bacterial agents (see Table 51.2), and paucity of RCTs make generalizations about antimicrobial therapy difficult. Figs. 51.1 and 51.5 outline the management strategy for complicated cystitis and other complicated UTIs, respectively.

Correction of any underlying anatomic, functional, or metabolic defect must be attempted, because antibiotics alone may not be successful.[1]

TABLE 51.6 Oral Regimens for Acute Uncomplicated Pyelonephritis and Complicated Urinary Tract Infection*,†

Drug	Dose (mg)	Interval	Comment
Fluoroquinolones			Preferred for empiric treatment; avoid if possible in pregnancy, nursing mothers, or persons younger than 18 years of age.
Ciprofloxacin	500	q12h	
Ciprofloxacin extended release	1000	q24h	
Levofloxacin	250-750	q24h	
Trimethoprim-sulfamethoxazole	160/800	q12h	Use only when the causative pathogen is known to be susceptible. If used in pregnancy (not approved use), avoid in first trimester.
Cefpodoxime proxetil	200	q12h	Data are sparse; use only when the causative pathogen is known to be susceptible.
Amoxicillin-clavulanate	500/125 to 875/125	q12h	Use only when the causative pathogen is known to be susceptible or in addition to a broad-spectrum agent when empiric coverage against enterococci is desirable.

*A long-acting parenteral antibiotic should be given concomitantly if there are concerns about drug resistance.
†Duration depends on clinical setting (see text and Fig. 51.5).

For empiric therapy in patients with mild to moderate illness who can be treated with oral medication, the fluoroquinolones provide the broadest spectrum of antimicrobial activity, cover most expected pathogens, and achieve high levels in the urine and urinary tract tissue. An exception is moxifloxacin, which may not achieve sufficient concentrations in urine to be effective for complicated UTI. If the infecting pathogen is known to be susceptible, TMP-SMX or other agents are reasonable therapeutic choices. Nitrofurantoin and fosfomycin should be avoided except for cystitis in pregnancy, in which duration of treatment is 5 days or single-dose, respectively.

For initial treatment in more seriously ill, hospitalized patients, several parenteral antimicrobial agents are available (see Table 51.5). The broader spectrum agents shown in Table 51.5 are preferable for health care–associated infections. *S. aureus* is more common in complicated UTIs, and, if suspected, the therapeutic regimen should have activity against *S. aureus.* Studies show that a high proportion of *S. aureus* isolates, even in the community, are methicillin resistant (MRSA), so vancomycin should be included in the empiric treatment regimen if *S. aureus* is suspected. Potential concerns that must be considered in the management of complicated UTI include the increasing prevalence of resistance to fluoroquinolones in institutional settings and the frequency of enterococcal infections.

The antimicrobial regimen can be modified when the infecting strain has been identified and antimicrobial susceptibilities are known. Patients receiving parenteral therapy can be switched to oral treatment after clinical improvement. Few studies evaluate duration of treatment in populations with complicated UTIs. However, it is desirable to limit the duration of treatment, especially for milder infections, to reduce the selection pressure for drug-resistant flora. In one study, clinical and microbiologic success rates after treatment were almost identical in patients with acute pyelonephritis or complicated UTI treated with a 5-day course of levofloxacin or a 10-day course of ciprofloxacin.[45] These data suggest that a 5- to 10-day regimen is reasonable for most patients with complicated UTI, depending on their severity of illness and clinical response; shorter regimens, such as a 5-day regimen of a urinary fluoroquinolone, are likely to be sufficient in patients who are less severely ill, are infected with uropathogens susceptible to the antibiotic used, and have a rapid response to treatment. A recent large retrospective study of male veterans with UTI found no difference in recurrence rates with 7 days of treatment versus longer, with a trend toward more *Clostridium difficile* infections in those treated longer.[46] At least 10 to 14 days of therapy is recommended in patients who have a delayed response.

Routine post-treatment cultures are not indicated unless the patient is symptomatic, except in pregnant women (see Fig. 51.1). In men, early recurrence of UTI with the same species suggests a prostatic source of infection and warrants a 4- to 6-week regimen of either a fluoroquinolone (preferable) or TMP-SMX, depending on the antimicrobial susceptibility of the infecting strain.

Chronic Kidney Disease. Because of the wide variety of underlying diseases and comorbidities, prior instrumentation of the urinary tract, and differences in age and gender, the incidence of UTI in patients with chronic kidney disease (CKD) is not known.[47] Moreover, there are few data on urine concentrations of antimicrobials used for the treatment of UTI in patients with CKD.[48] Studies in animals suggest that (1) urine drug concentrations are necessary to sterilize urine, (2) effective tissue concentrations are necessary to treat pyelonephritis, and (3) serum concentrations of antimicrobials are correlated with the drug concentrations in renal tissue. Thus, for patients with CKD who have a therapeutic serum drug level and adequate perfusion of the renal parenchyma, the delivery of therapeutic concentrations of both the parenchyma and the urine should be adequate, but some oral agents for cystitis may not deliver adequate concentrations to the urine.[48] For patients with a low glomerular filtration rate (GFR) and pyelonephritis or cystitis, the agents listed in Tables 51.5 and 51.6 for pyelonephritis and complicated cystitis should be adequate to treat these infections if the organism is susceptible.[48]

As noted previously, however, β-lactams are not as effective as fluoroquinolones, even in patients with normal renal function.[33] For oral treatment, renal function (estimated GFR) adjusted doses of ciprofloxacin or levofloxacin, but not moxifloxacin, are recommended. Nitrofurantoin and sulfamethoxazole are not recommended in patients with reduced creatinine clearance, although trimethoprim concentrations appear to be adequate.[47] Likewise, according to the package insert, renal impairment significantly decreases the excretion of fosfomycin, which also should not be used in such patients.

Catheter-Associated Infections. Approximately 15% to 25% of patients in general hospitals have a urethral catheter inserted at some time during their stay, and approximately 5% to 10% of long-term care facility residents are managed with urethral catheterization, in some cases for years. The incidence of bacteriuria associated with indwelling catheters is 3% to 10% per day of catheterization, and the duration of catheterization is the most important risk factor for the development of catheter-associated bacteriuria.

Catheter-associated bacteriuria is the most common source of gram-negative bacteremia in hospitalized patients. Complications of long-term catheterization (≥30 days) include almost universal bacteriuria, often with multiple antibiotic-resistant flora, and (in addition to cystitis, pyelonephritis, and bacteremia, as seen with short-term catheterization) frequent febrile episodes, catheter obstruction, stone formation associated with urease-producing uropathogens, and local genitourinary infections. Other rare complications include fistula formation and bladder cancer. An increase in mortality risk has been reported with catheter-associated bacteriuria, but it is difficult to distinguish the role of the catheter because most deaths occur in patients who have severe underlying disease.

Most episodes of catheter-associated bacteriuria are asymptomatic and do not require routine screening or treatment because treatment does not reduce the complications of bacteriuria and can lead to antimicrobial resistance.[7] Moreover, the presence or absence of pyuria does not differentiate symptomatic from asymptomatic urinary infection.[7] Symptomatic UTIs, often caused by many multidrug-resistant uropathogens, warrant broad-spectrum therapy, as described previously. In a symptomatic catheterized patient, a urine culture specimen should be obtained from a freshly placed catheter if the catheter has been in place for a few days, because the catheter biofilm may result in spurious culture results. Moreover, clinical outcomes are improved if the catheter is replaced at the time of antimicrobial therapy.[49] Seven days is the recommended duration of antimicrobial treatment for patients who have prompt resolution of symptoms, and 10 to 14 days if response is delayed.[50]

Preventive measures are indicated to reduce the morbidity, mortality, and costs of catheter-associated infection. Effective strategies include avoidance of a catheter when possible and, when the catheter is necessary, sterile insertion, prompt removal, and strict adherence to a closed collecting system.[6,50] Bundling of preventive steps may be useful.[51,52] Meta-analyses have shown that rates of catheter-associated bacteriuria, at least in patients catheterized for less than 2 weeks, are higher in patients with an indwelling urethral catheter than in those with intermittent or suprapubic catheterization.[53] Likewise, condom catheterization is preferable to indwelling urethral catheterization in appropriately selected men.[54] Although highly effective in reducing catheter-associated UTI rates, prophylactic systemic antimicrobial agents are generally not recommended for routine use because of concerns about selection for antimicrobial resistance. Antimicrobial-coated catheters appear to be effective in reducing catheter-associated bacteriuria in patients catheterized for less than 2 weeks, but these have not been shown to be effective in reducing symptomatic infection.

Spinal Cord Injury. Spinal cord injury alters the dynamics of voiding and often requires the use of bladder drainage with catheters. The diagnosis of UTI in patients with spinal cord injuries is often problematic and is based on the combination of symptoms and signs (which are often nonspecific), pyuria, and significant bacteriuria. Uropathogens are usually present in quantities of 10^5 cfu/ml or more. Fluoroquinolones are the empiric oral agents of choice in patients with mild to moderate infection, although many uropathogens, even in the outpatient setting, are resistant to this class of antibiotic, and parenteral antibiotics may be needed.

Treatment of asymptomatic bacteriuria in patients with spinal cord injuries is not of proven benefit and increases the risk for infection with antimicrobial-resistant uropathogens.[7,55] Likewise, antibiotic prophylaxis is generally not recommended, although it may be considered for select outpatients with frequent symptomatic UTIs for whom there are no correctible risk factors. Recent studies have shown that use of a hydrophilic-coated catheter for intermittent catheterization is associated with a reduction in the incidence of symptomatic UTI in patients with spinal cord injury.[56]

Prostatitis. Prostatitis occurs in up to 25% of men during their lifetime, but it is caused by acute or chronic bacterial infection in a minority.[57] The most common organisms causing bacterial prostatitis are gram-negative bacilli, including *E. coli, Proteus* spp., *Klebsiella* spp., *P. aeruginosa,* and, less frequently, enterococci and *S. aureus*. The pathogenesis of prostatitis is believed to be related to reflux of infected urine from the urethra into the prostatic ducts. Prostatic calculi, commonly found in adult men, may provide a nidus for bacteria and protection from antibacterial agents.

Acute bacterial prostatitis is rare. Patients present with dysuria, frequency, urgency, obstructive voiding symptoms, fever, chills, and myalgias. The prostate is tender and swollen. Prostatic massage, as a diagnostic test, is contraindicated in men in whom the diagnosis of acute prostatitis is being considered because of the risk for precipitating bacteremia. The patient will usually have pyuria and a positive urine culture. Patients who are severely ill require hospitalization and parenteral antibiotics, but many patients can be treated in the outpatient setting with oral fluoroquinolones. The recommended duration of treatment is 14 to 30 days.[57] Rarely, abscess formation may occur.

Chronic bacterial prostatitis is characterized by recurrent UTIs with the same uropathogen with intervening asymptomatic periods. The prostate typically is normal to palpation during asymptomatic periods. Chronic bacterial prostatitis is characterized microscopically by the presence of 10 or more leukocytes per high-power field in expressed prostatic secretions or postmassage voided urine in the absence of significant pyuria in first-voided and midstream urine specimens, as well as a uropathogen colony count at least 10-fold higher in the expressed prostatic secretions or postmassage voided urine compared with the first-voided midstream urine. In addition, macrophage-laden fat droplets (oval fat bodies) are usually prominent in the prostatic secretions. These tests, however, are infrequently performed by urologists. Cure rates, which historically have been low, are 60% to 80% with the fluoroquinolones, which are the antibiotics of choice. The optimal duration of treatment is unknown, but 4 to 6 weeks is recommended by some authorities,[57] whereas others recommend up to 3 months. Some patients require long-term, low-dose suppressive therapy to prevent symptomatic UTIs. Surgical intervention is only rarely considered and is associated with high morbidity.

Renal Abscess. Renal cortical and corticomedullary abscesses and perirenal abscesses occur in 1 to 10 per 10,000 hospital admissions.[58] Patients usually present with fever, chills, back or abdominal pain, and costovertebral angle tenderness, but they may have no urinary symptoms or findings if the abscess does not communicate with the collecting system, as often occurs with a cortical abscess. Bacteremia may be primary (cortical abscess) or secondary (corticomedullary or perirenal). The clinical presentation may be insidious and nonspecific, especially with perirenal abscess, and the diagnosis may not be made until admission to a hospital or at autopsy. CT is recommended to establish the diagnosis and location of a renal or perirenal abscess (Fig. 51.6). Empiric antibiotic therapy should be broad and cover *S. aureus* and other uropathogens causing complicated UTI (see Fig. 51.5 and Table 51.5) and modified once urine culture results are known.

A *renal cortical abscess* (renal carbuncle) is usually caused by *S. aureus,* which reaches the kidney by hematogenous spread. Treatment with antibiotics is usually effective, and drainage is not required unless the patient is slow to respond. A *renal corticomedullary abscess,* in contrast, usually results from ascending UTI in association with an underlying urinary tract abnormality, such as obstructive uropathy or VUR,

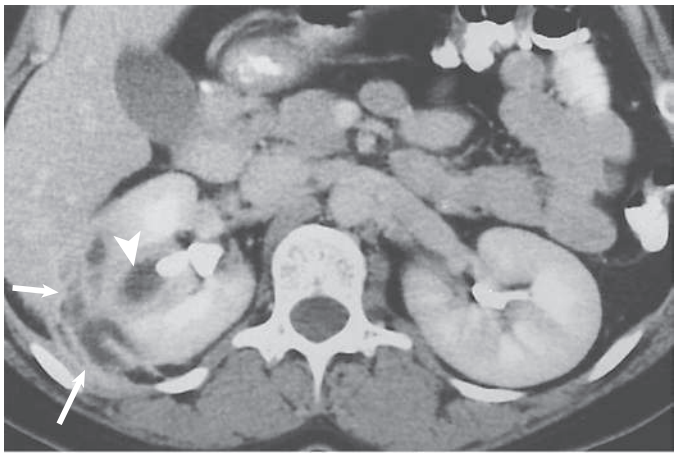

Fig. 51.6 Renal abscess. Contrast-enhanced CT scan shows an abscess in the medulla of the kidney *(arrowhead)* with penetration and extension into the perinephric space *(arrows)*. (Courtesy L. Towner.)

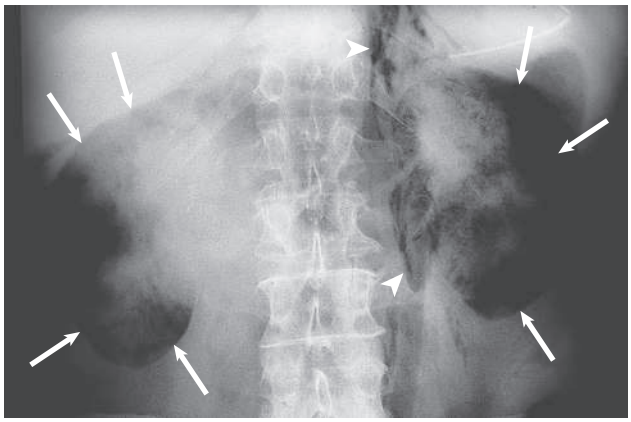

Fig. 51.7 Emphysematous pyelonephritis. A plain radiograph in this febrile patient with diabetes revealed diffuse gas formation throughout both kidneys *(outlined by arrows)* and gas dissecting in the left retroperitoneal space *(arrowheads)*. (Courtesy W. Bush, University of Washington, Seattle.)

and is usually caused by common uropathogenic species such as *E. coli* and other gram-negative bacilli. Such abscesses may extend deep into the renal parenchyma, perforate the renal capsule, and form a perirenal abscess. Treatment with antimicrobial agents without drainage may be effective if the abscess is small and if the underlying urinary tract abnormality can be corrected. Aspiration of the abscess may be necessary in some patients, and nephrectomy may occasionally be required in patients with diffuse renal involvement or with severe sepsis. Perirenal abscesses usually occur in the setting of obstruction or other complicating factors (see Box 51.1) and result from ruptured intrarenal abscesses, hematogenous spread, or spread from a contiguous infection. Causative uropathogens are those usually found in complicated UTIs (see Table 51.2), including *S. aureus* and enterococci; polymicrobial infections are common. Anaerobes or *Mycobacterium tuberculosis* may be causative (see Chapter 52). A previously high mortality rate has been lowered with earlier diagnosis and therapy. In contrast to the other types of renal abscesses, drainage of pus is the cornerstone of therapy and nephrectomy may be indicated.

Papillary Necrosis. More than half of patients who develop papillary necrosis have diabetes, almost always in conjunction with a UTI, but the condition also complicates sickle cell disease, analgesic abuse, and obstruction. Renal papillae are vulnerable to ischemia because of the sluggish blood flow in the vasa recta, and relatively modest ischemic insults may cause papillary necrosis. The clinical features are those typical of pyelonephritis. In addition, passage of sloughed papillae into the ureter may cause renal colic, renal impairment or failure, or obstruction with severe urosepsis. Papillary necrosis in the setting of pyelonephritis is associated with pyuria and a positive urine culture. Causative uropathogens are those typical of complicated UTI. CT is the preferred diagnostic procedure. Radiologic findings include an irregular papillary tip; dilated calyceal fornix; extension of contrast material into the parenchyma; and a separated crescent-shaped papilla surrounded by contrast, called the *ring sign* (see Fig. 49.8) Broad-spectrum antibiotics are indicated. Papillae obstructing the ureter may require removal with a cystoscopic ureteral basket or relief of obstruction by insertion of a ureteral stent.

Emphysematous Pyelonephritis. Emphysematous pyelonephritis is a fulminant, necrotizing, life-threatening variant of acute pyelonephritis caused by gas-forming organisms, including *E. coli, Klebsiella pneumoniae, P. aeruginosa,* and *Proteus mirabilis*.[59] Up to 90% of cases occur in diabetic patients, and obstruction may be present. Symptoms are suggestive of pyelonephritis, and there may be a flank mass. Dehydration and ketoacidosis are common. Pyuria and a positive urine culture are usually present. Gas is usually detected by a plain abdominal radiograph or ultrasound (Fig. 51.7). CT is the diagnostic modality of choice, however, because it can localize the gas better than ultrasound. Accurate localization of gas is important because gas also may form in an infected obstructed collecting system or renal abscess; although serious, these conditions do not carry the same poor prognosis and are managed differently. Parenteral broad-spectrum antibiotics and percutaneous catheter drainage with relief of obstruction may be adequate for less severely ill patients, but nephrectomy is warranted for those who are more severely ill and those less severely ill who do not respond to the preceding steps. Medical treatment is associated with mortality of 60% to 80%, which is lowered to 20% or less with surgical intervention (e.g., nephrectomy, percutaneous drainage).

Renal Malacoplakia. Malacoplakia is a chronic granulomatous disorder of unknown etiology involving the genitourinary, gastrointestinal, skin, and pulmonary systems.[60] It is characterized by an unusual inflammatory reaction to a variety of infections and is manifested by the accumulation of macrophages containing calcified bacterial debris called *Michaelis-Gutmann bodies* (Fig. 51.8). The underlying disorder appears to be a monocyte-macrophage bactericidal defect. The diagnosis is made by histologic examination of involved tissue. Genitourinary malacoplakia, most often involving the bladder, is usually associated with gram-negative UTI. Patients with renal malacoplakia generally have fever, flank pain, pyuria and hematuria, bacteriuria, and, if both kidneys are involved, impaired renal function. CT usually shows enlarged kidneys with areas of poor enhancement, and the condition may be indistinguishable from other infectious or neoplastic lesions. On occasion, the malacoplakia may extend through the renal capsule into the perinephric space, simulating a renal carcinoma (see Fig. 51.8). Treatment consists of therapy with a broad-spectrum antimicrobial, attempted correction of any underlying complicating conditions, and improvement of renal function. Nephrectomy is recommended for advanced unilateral disease. When the disease is bilateral or occurs in a transplanted kidney, the patient's prognosis is very poor.

Xanthogranulomatous Pyelonephritis. Xanthogranulomatous pyelonephritis is a poorly understood, uncommon but severe chronic destructive

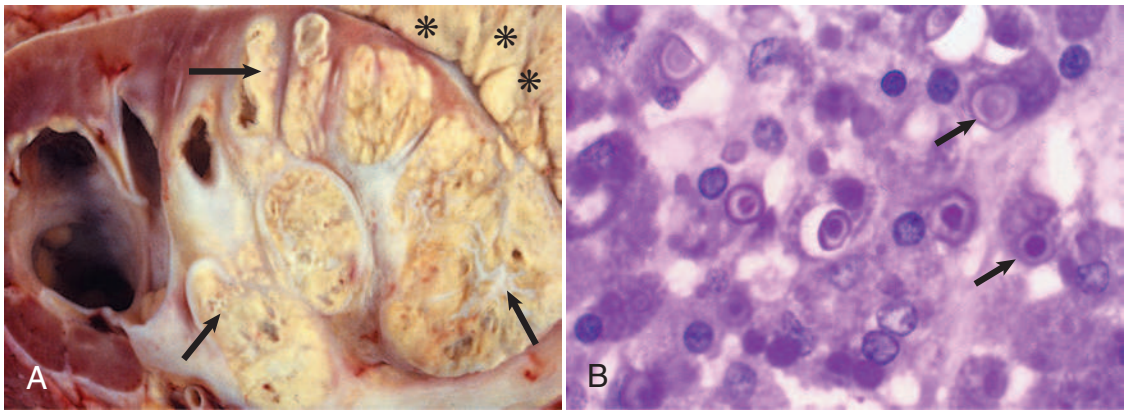

Fig. 51.8 Renal malacoplakia. (A) Malacoplakia involving most of the kidney *(arrows)* with extension through the capsule *(asterisks)*. A small portion of normal kidney is present associated with hydronephrosis secondary to obstruction by the malacoplakia. (B) The kidney tissue shows many macrophages containing intracytoplasmic inclusions (*arrows* identify two particularly well-demarcated macrophages with Michaelis-Gutmann bodies). (Courtesy L. Truong, Baylor College of Medicine, Houston, Tex, and N. Sheerin, Guy's Hospital, London.)

granulomatous inflammation of renal parenchyma associated with obstruction and infection of the urinary tract.[61] The renal parenchyma is replaced with a diffuse or segmental cellular infiltrate of foam cells, which are lipid-laden macrophages. The process also may extend beyond the renal capsule to the retroperitoneum. Its pathogenesis appears to be multifactorial, with infection complicating obstruction and leading to ischemia, tissue destruction, and accumulation of lipid deposits. Patients with xanthogranulomatous pyelonephritis are characteristically middle-aged women and have chronic symptoms such as flank pain, fever, chills, and malaise. Flank tenderness, a palpable mass, and irritative voiding symptoms are common. The urine culture is usually positive with *E. coli*, other gram-negative bacilli, or *S. aureus*. CT generally shows an enlarged nonfunctioning kidney, often the presence of calculi and low-density masses (xanthomatous tissue), and in some cases, involvement of adjacent structures (Fig. 51.9). It may be difficult to distinguish from neoplastic disease. Broad-spectrum antimicrobials are indicated, but total or partial nephrectomy is usually necessary for cure.

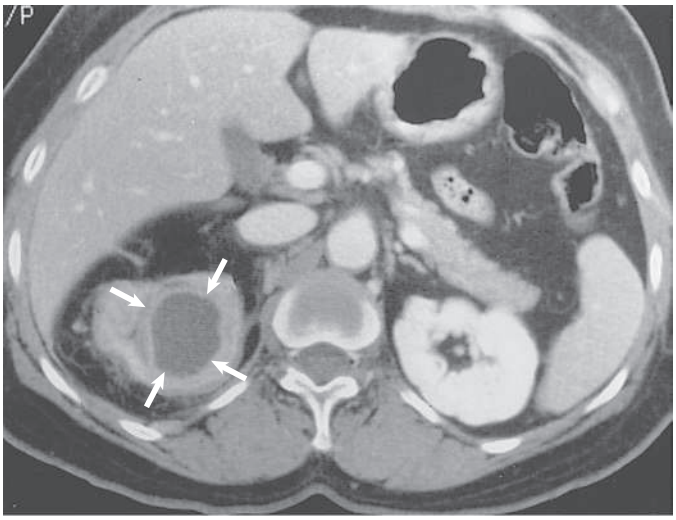

Fig. 51.9 Xanthogranulomatous pyelonephritis. Contrast-enhanced CT scan with the inflammatory mass outlined by *arrows*. Pathologic diagnosis confirmed xanthogranulomatous pyelonephritis. (Courtesy W. Bush, University of Washington, Seattle, Wash.)

Asymptomatic Bacteriuria

Asymptomatic bacteriuria is common and generally benign.[7,37] Pyuria is often present, especially in elderly people, and is a predictor for subsequent symptomatic UTI in some groups. Causative uropathogens are the same as those causing UTIs in the same population. Screening for and treatment of asymptomatic bacteriuria is generally not warranted.[7] In young women with recurrent UTI, asymptomatic bacteriuria may be protective against symptomatic recurrence and treatment may increase the risk for such recurrences.[62] However, patients at high risk for serious complications warrant a more aggressive approach to diagnosis and treatment, including pregnant women and patients undergoing urologic surgery. Current management strategies in patients with a renal transplant, including long-term antimicrobial prophylaxis, help prevent both asymptomatic bacteriuria and symptomatic UTI. It is not clear, however, whether screening for or treatment of asymptomatic bacteriuria in such patients is worthwhile.[7] Some authorities advise treatment of asymptomatic bacteriuria found in patients with anatomic or functional abnormalities of the urinary tract, diabetic patients, and patients with urea-splitting bacteria (e.g., *P. mirabilis, Klebsiella* spp.).[37] Evidence-based guidelines for screening and treatment of asymptomatic bacteriuria in these populations are needed.

Asymptomatic bacteriuria in catheterized patients in hospitals and long-term care facilities, although thought to be generally benign, represents a large reservoir of antimicrobial-resistant urinary pathogens that increases the risk for cross-infection among catheterized patients and results in frequent inappropriate antimicrobial use.[50]

IMAGING OF THE URINARY TRACT

Urologic consultation and evaluation of the urinary tract should be considered in patients who present with symptoms or signs of obstruction, urolithiasis, flank mass, or urosepsis. Similarly, such an evaluation should be considered for those patients with presumptive uncomplicated or complicated UTI who have *not* had a satisfactory clinical response after 72 hours of treatment, to exclude complicating factors. A renal ultrasound can detect the size and contour of the kidneys and bladder, the presence of a renal mass or abscess, certain renal and ureteral calculi, hydronephrosis suggestive of obstructive uropathy, and elevated postvoid residual urine.[63] A plain abdominal radiograph (kidneys, ureters, bladder [KUB]) can identify radiopaque calculi along the genitourinary tract, especially proximal and distal ureteral stones that can be missed on

ultrasound. However, renal ultrasound and KUB are less sensitive than CT for detection of many conditions in patients with complicated UTI. Thus any finding suggesting mass or complex fluid collection should prompt follow-up imaging with CT. CT offers fine anatomic detail and is thus the superior study for evaluation of focal inflammation, renal or perirenal abscess and masses, and both radio-opaque and radiolucent stones. However, CT also carries the greatest risk profile, exposing the patient to both intravenous contrast and ionizing radiation.[63] Non–contrast-enhanced spiral CT is a rapid, safe, and sensitive method for evaluating patients with suspected renal stones. Radionuclide imaging procedures have no role in the evaluation of adults with UTI, although they are very useful in children with pyelonephritis (see Chapter 61).

Excretory urography and cystoscopy in women with recurrent cystitis rarely demonstrate abnormalities or alter management[3] and therefore are not recommended. Likewise, imaging studies in young women with acute pyelonephritis are also generally not cost-effective and have a low diagnostic yield, although it is reasonable to obtain such studies after two episodes of pyelonephritis or if any complicating factor is present (see Box 51.1). Imaging studies and cystoscopy are probably unnecessary in a man who has had a single UTI with no obvious complicating factors and whose infection responds promptly to treatment.

SELF-ASSESSMENT QUESTIONS

1. Which of the following antimicrobials is *not* recommended for first-line use for uncomplicated cystitis by the Infectious Disease Society of America treatment guidelines?
   A. Fosfomycin
   B. Ciprofloxacin
   C. Cotrimoxazole
   D. Nitrofurantoin
2. What approach has not been shown to be effective in the management of recurrent cystitis in women?
   A. Postcoital antimicrobial prophylaxis
   B. Daily antimicrobial prophylaxis
   C. Intermittent self-treatment
   D. Periodic screening and treatment of asymptomatic bacteriuria
3. Which of the following antimicrobials should be *avoided* in the treatment of prostatitis?
   A. Ciprofloxacin
   B. Nitrofurantoin
   C. Levofloxacin
   D. Trimethoprim-sulfamethoxazole
4. In which of the following conditions is screening for and treatment of asymptomatic bacteriuria indicated?
   A. Elderly men and women
   B. Catheterized men and women
   C. Pregnant women and patients undergoing urologic instrumentation
   D. After treatment for acute pyelonephritis

Tuberculosis of the Urinary Tract

R. Kasi Visweswaran, K. P. Jayakumar

DEFINITION

Tuberculosis (TB) is a major global health problem. According to a recent report by the World Health Organization (WHO), there were nearly 9.6 million new cases in 2014, with 1.1 million deaths among HIV-negative and 0.39 million deaths among HIV-positive individuals attributed to TB.[1] Between 1999 and 2020, there will be an estimated 1 billion new cases of TB if control measures are not improved. In developed countries, TB commonly affects older individuals and immigrants from countries with high prevalence. The incidence of TB is 100 times greater in HIV-infected individuals, and TB is the most common fatal opportunistic infection in people with HIV.[2] TB also is more common in patients with chronic kidney disease (CKD) than those with normal kidney function, especially when associated with anatomic abnormalities or immunosuppression. In some endemic areas, TB has been reported to occur in up to 8.7% of patients on hemodialysis, 12.3% of renal allograft recipients,[3] and 9.3% of children with nephrotic syndrome.[4]

Genitourinary TB constitutes 9% of extrapulmonary TB. In HIV-negative patients[5] it is almost always secondary to a symptomatic or asymptomatic primary lesion in the lung. Renal involvement also may occur as a complication of miliary TB.

The incidence of multidrug-resistant (MDR TB) and extensively drug-resistant TB (XDR TB) is increasing. According to WHO estimates, there were 480,000 new cases of MDR TB worldwide and 190,000 deaths in 2014[1] and 9% of people with MDR TB also have XDR TB.

ETIOLOGY

The tubercle bacillus is a nonmotile, nonsporing, strictly aerobic straight or slightly curved rod-like bacillus that is weakly gram-positive and acid and alcohol-fast (Fig. 52.1). The cell wall has high concentration of waxy lipids (mainly mycolic acids) that make the organism resistant to acids, alkalis, antibiotics, osmotic agents, and intracellular events. The core of the cell wall is composed of peptidoglycan that is linked to galactofuran and arabinofuran, which is further linked to mycolic acid. The mycolyl transferase and lipoarabinomannan (LAM) is called antigen 85 of mycolic acid.[6] The most superficial layer consists of glycolipids and polypeptides (Fig. 52.2). The polypeptides are isolated and purified to make the skin testing antigen purified protein derivative. The following characteristics and composition of the lipid shell wall of mycobacteria have enabled their survival in the Earth for thousands of years and under adverse conditions (Table 52.1).

Whereas most TB, including genitourinary TB, is caused by *Mycobacterium tuberculosis,*[7] other mycobacteria may rarely cause clinical disease, especially in immunocompromised hosts. These include *M. avium-intracellulare*, *M. kansasii, M. bovis, M. fortuitum,* and *M. szulgai*. *M. chelonei abscessus* belong to the group of "rapid growers" among the atypical mycobacteria and cause abscesses after injection or percutaneous procedures, especially in patients with diabetes.[8]

PATHOGENESIS

The clinical and pathologic manifestations of TB depend on the virulence of the organism and the effectiveness of the host response. The host response may lead to complete containment of infection or result in an illness of varying severity.[9] Between-strain differences also may determine whether an infected person develops primary TB, reactivation TB, or a chronic asymptomatic infection. A low serum level of 25-hydroxyvitamin D also may compromise cell-mediated immunity and increase the risk for activation of latent TB.[10]

When an infected droplet with the size of 1 to 5 μm is deposited in the respiratory tract, tonsillar fossa, or gastrointestinal tract, a primary focus develops with the formation of a nonspecific, asymptomatic granuloma. The organisms from the primary focus drain to the regional lymph gland, causing its enlargement, resulting in the *primary complex*. This is often asymptomatic and self-limited.

Bacilli from the regional lymph node also may enter through the thoracic duct into the blood, resulting in silent dissemination to various sites, including the renal cortex (see Fig. 52.3). Here the bacilli elicit an inflammatory response, resulting in granuloma formation that may heal and form a scar, remain dormant for many years, or rupture into the proximal tubule of the nephron. The bacilli in the nephron are trapped at the level of the loop of Henle, where they multiply. The relatively poor blood flow, hypertonicity, and high ammonia concentration in the renal medulla impair the immune response and favor the formation of medullary granulomas. These granulomas (tuberculomas), which contain macrophages, may undergo coagulative necrosis, forming cavities filled with cheese-like caseous material (Fig. 52.4) that occasionally rupture into the calyx.

The renal medulla is the most common site of involvement of clinical renal TB and is usually unilateral. When this caseous focus ruptures into the collecting system, cavities and ulcers are formed, and involvement of renal papillae may lead to sloughing and papillary necrosis. Healing in the kidney occurs by fibrosis and scarring, resulting in strictures and obstruction. Calcification commences intracellularly because of the accumulation of phosphate ions from the disintegration of nucleoproteins and entry of calcium ions from cell membrane damage. These dystrophic calcific lesions may harbor live or dormant mycobacteria, and such dystrophic lesions are considered active disease and not

signs of healing. Dystrophic calcification of damaged structures may result in a nonfunctioning kidney called *putty* or *cement* kidney. Spread of TB to contiguous structures may occur; ureteritis is common and may result in strictures and obstructive uropathy (Fig. 52.5).

The bladder may develop hyperemia near the ureteral orifice, followed by superficial ulcers and granulomatous changes involving all layers (pancystitis). Healing by fibrosis at the ureteral orifice results in a refluxing "golf-hole" ureter. Extensive fibrosis of the bladder wall results in a thick, small-capacity bladder called *thimble* bladder (Fig. 52.6). Bladder infection also may rarely result from instillation of bacillus Calmette-Guérin (BCG) in the bladder as part of treatment of superficial bladder carcinomas.

Involvement of the genital tract is also common. As many as 70% to 80% of men with TB of the urinary tract have epididymitis, prostatitis, seminal vesiculitis, orchitis, or cold abscesses (gradual pus accumulation with no signs of acute inflammation). In women, genital tract involvement is less common, but, if present, usually presents as salpingitis, often diagnosed during investigation for infertility.

TB can be transmitted from the donor to recipient through renal transplantation, and the risk can be minimized by thorough screening of the donor.[11]

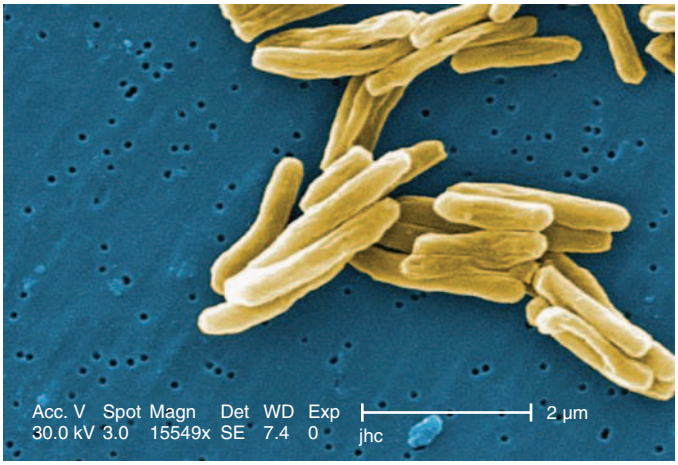

Fig. 52.1 Scanning electron microscopy of *Mycobacterium tuberculosis*. The bacillus is a straight or slightly curved rod about 2 to 4 µm long and 0.3 to 0.5 µm wide. (high magnification, 15,549×). (Courtesy Ray Butler MS, CDC. Division of Tuberculosis Elimination, National Center for HIV, STD, and TB Prevention. Atlanta, GA.)

CLINICAL MANIFESTATIONS

Urinary tract TB may be asymptomatic or may mimic other disorders. Patients may present with constitutional symptoms or symptoms related

TABLE 52.1 Cell Wall Characteristics Enabling Organisms to Survive Under Adverse Conditions

Composition of Cell Wall	Factors for Survival
Mycolic acid	Resist proteolysis and uptake into phagolysosomes
Lipoarabinomannan (LAM)	Detected by CD1 T cells
Muramyl dipeptide	Stimulate T cell response (granuloma formation)
Glycolipids	Inhibit macrophage function
Inert lipids and surface proteins	Dormant survival inside phagocytes

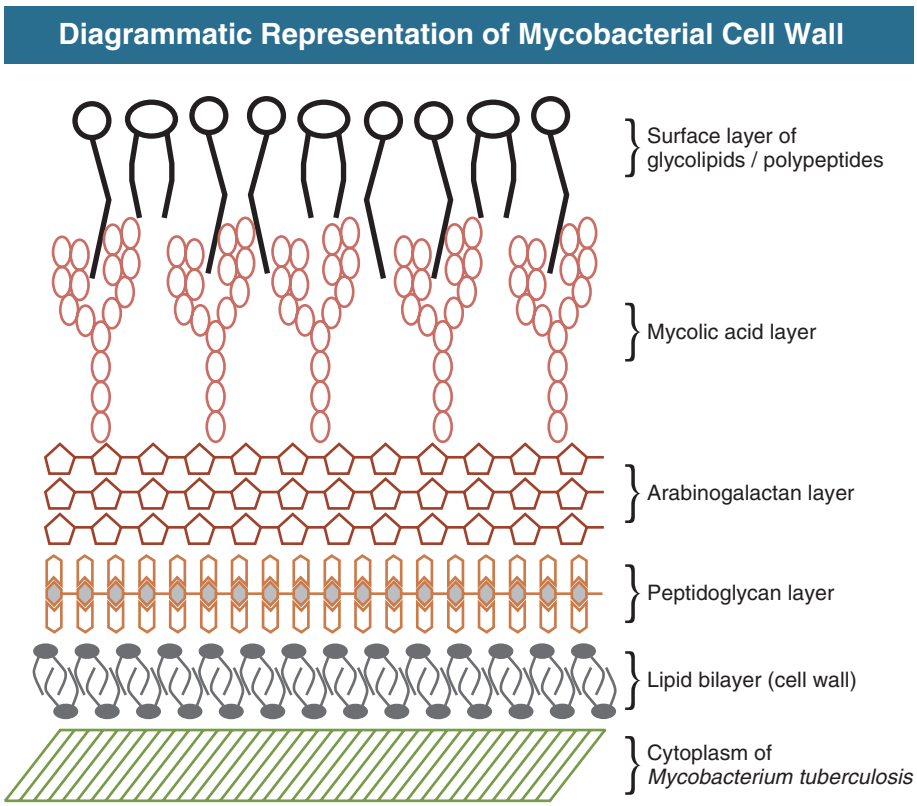

Fig. 52.2 Diagrammatic representation of mycobacterial cell wall.

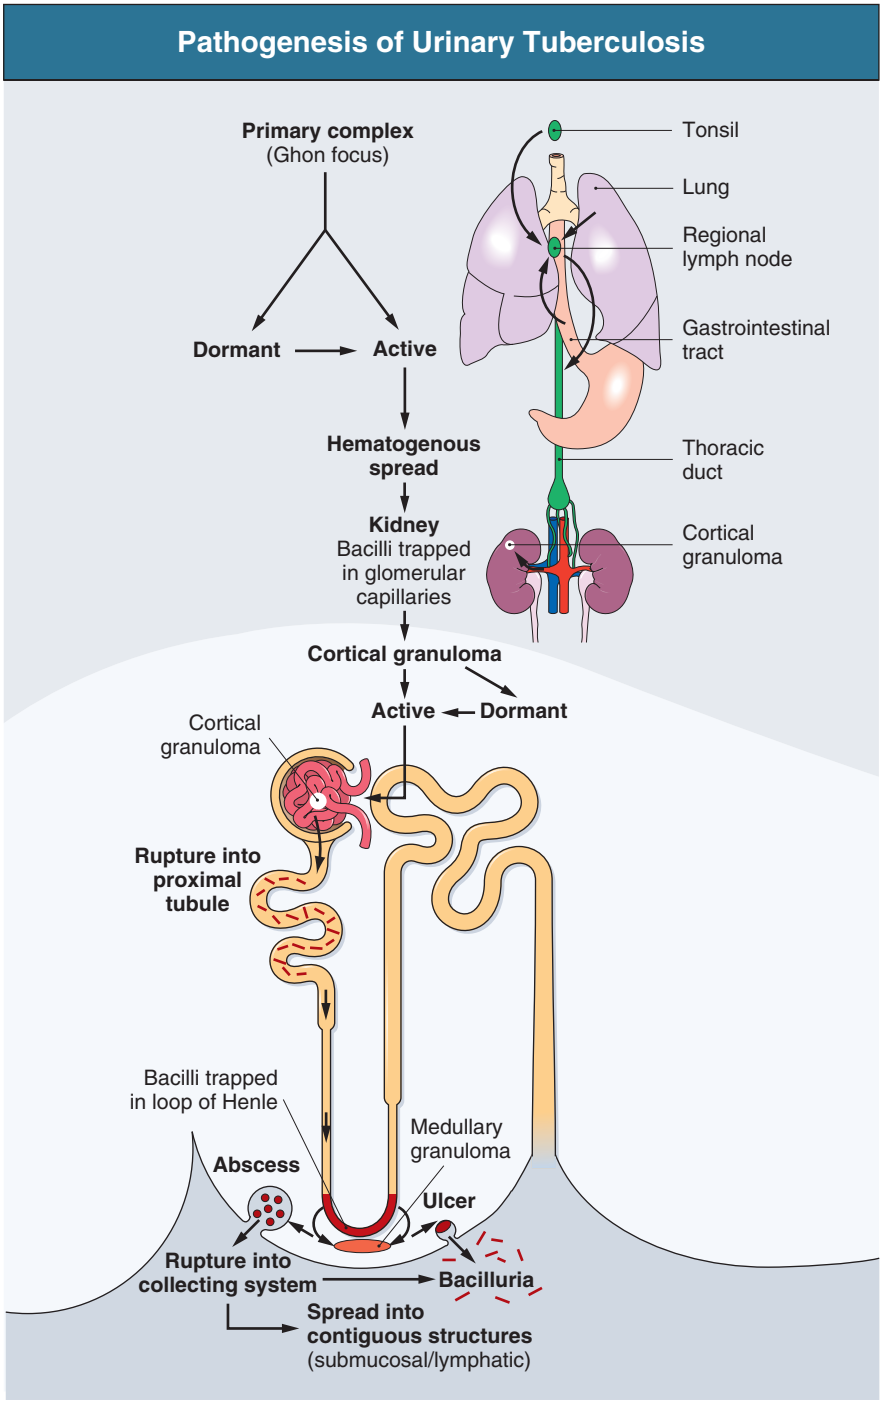

Fig. 52.3 Pathogenesis of urinary tuberculosis.

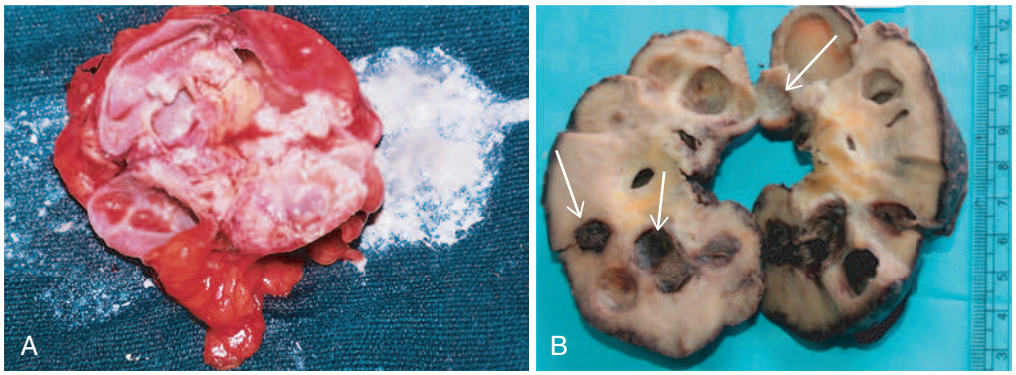

Fig. 52.4 Renal tuberculosis. (A) Cut section of kidney shows areas of cavitation and caseation necrosis (white chalky material). (B) Cavitating lesions *(arrows)* are caused by tuberculosis in cut section of kidney (autopsy). Fig. 52.5 Multiple ureteral strictures. Strictures *(arrows)* associated with dilated ureter, infundibular stenosis *(IS),* and caliectasis *(C)* are seen in this intravenous urogram. (Courtesy Professor K. Sasidharan, Kasturba Medical College, Manipal, India.)

Fig. 52.6 Thimble bladder. Cystogram shows small-capacity bladder.

to the lower urinary tract, abdomen, or genitalia (Table 52.2).[12] A high index of suspicion enables early diagnosis. Most patients are 20 to 40 years of age, with a male-to-female ratio of 2:1. Because active genitourinary TB manifests 5 to 15 years after primary infection, it is relatively rare in children. Risk factors for TB include close contact with sputum smear–positive individuals, social deprivation, neglect, immunosuppression, HIV infection, diabetes mellitus, CKD, vitamin D deficiency, and other debilitating illnesses.

Asymptomatic Presentations

Almost 25% of patients have no clinical or laboratory evidence of any abnormality, and the diagnosis of urinary TB is made on investigation for other diseases, during surgery, or at autopsy. Another 25% have asymptomatic urinary abnormalities, usually persistent asymptomatic pyuria or hematuria. In patients with persistent pyuria, conventional urine cultures do not yield any growth, and the urine is usually acidic (acid-sterile pyuria). Renal calcification may be asymptomatic and detected as an incidental finding on investigations.

Lower Urinary Tract Symptoms

Of the patients who are symptomatic, lower urinary tract symptoms, such as frequency, urgency, dysuria, nocturia, frank pyuria, or hematuria, occur in more than 75% of patients with TB. Increased urinary frequency is an early symptom and results from inflammation of the bladder. The defect in the urinary concentrating mechanism explains the nocturia. Recurrent bouts of painless gross macroscopic hematuria should alert the clinician to the possible diagnosis of urinary TB, although glomerular diseases such as immunoglobulin A (IgA) nephropathy also should be considered. Macroscopic hematuria in urinary TB is a result of bleeding from the ulcerating lesions, inflammation of the urothelium, or rupture of a blood vessel in the vicinity of a cavity. Episodes of frank pyuria also may be a manifestation of renal TB and indicate either secondary bacterial infection or drainage of a caseous focus into the collecting system. In advanced disease, frequency and urgency of micturition related to reduced bladder capacity, incomplete emptying, increased susceptibility to infection and secondary vesicoureteral reflux (VUR) may also occur.

TABLE 52.2 Clinical Features of Urinary Tuberculosis

Features	Frequency (%)	Symptoms
Asymptomatic	25	Detected during autopsy, surgery, or investigations for other diseases
Asymptomatic urinary abnormalities	25	Persistent pyuria, microscopic abnormalities, hematuria
Lower urinary tract symptoms (most common)	40	Frequency, urgency, dysuria, incontinence, nocturia, suprapubic pain, perineal pain
Male genital tract involvement	75	Epididymitis, hemospermia, infertility, reduced semen volume
Female genital tract involvement	<5	Amenorrhea, infertility, vaginal bleeding, pelvic pain
Constitutional symptoms	<20	Fever, reduced appetite, anorexia, weight loss, night sweats
Miscellaneous	—	Urolithiasis, hypertension, acute kidney injury, chronic kidney disease, abdominal colic, abdominal mass

Proteinuria and Nephrotic Syndrome

Long-standing renal TB may result in mild tubular proteinuria (<1 g/24 h) in about 50% or more than 1 g/24 h in 15% of patients. In rare instances when nephrotic proteinuria occurs, it could be due to mesangioproliferative glomerulonephritis or secondary amyloidosis resulting from accumulation of SAA protein.

Low Glomerular Filtration Rate

Some patients with urinary TB present with reduced glomerular filtration rate (GFR), pyuria, microscopic hematuria, and proteinuria, but the urine cultures for mycobacteria are repeatedly negative. These patients respond favorably to antituberculous chemotherapy combined with corticosteroids. The kidneys are of normal size and show noncaseating granulomas, diffuse interstitial nephritis, or caseating granulomas containing the bacilli in 75% of the biopsy samples.[13]

Pain

Colicky pain may occur as a presenting manifestation of urinary TB when it is associated with stone, blood clot, sloughed papilla, or other causes of acute obstruction. Obstruction of the upper tract may be associated with dull aching pain in the loin. Severe suprapubic pain with backache and dysuria suggests acute tuberculous cystitis. Patients with TB cystitis may show worsening of symptoms such as frequency and urgency after initiation of antituberculous treatment because of fibrosis and bladder wall contraction. This should not be mistaken for nonresponsiveness to therapy because it is part of the healing process.

Stone Formation

Nephrolithiasis may occur in 7% to 18% of patients. Secondary infection with *Escherichia coli* may be seen in 20% to 50% of patients.

Genital Involvement

In men, the most common genital involvement is epididymitis that manifests with scrotal discomfort, mass, cold abscess, or asymptomatic. When the cold abscess ruptures, a nonhealing posterior scrotal sinus discharging caseous material may form. Thickening of the vas deferens may result in a "beaded" texture. TB of the prostate may manifest with lower urinary tract symptoms and perineal pain. The prostate may be hard or boggy. Penile and urethral TB may manifest with strictures, fistulas, ulcers, or papulonecrotic skin lesions. Hemospermia, reduction of semen volume, and infertility are other manifestations of genital involvement. Direct spread of *M. tuberculosis* to a sexual partner is also possible.

Only 5% of women with renal TB also have genital TB. The major manifestation of genital involvement in women is infertility resulting from adherent salpingitis. Secondary amenorrhea, vaginal bleeding, and pelvic pain caused by inflammation may occur.

Other Manifestations

Anemia is seen in less than 20% of patients with nonmiliary disease, but the frequency is higher in those with CKD stages 3 to 5. A few patients may develop nephrogenic diabetes insipidus or renal tubular acidosis. Hyporeninemic hypoaldosteronism may result from the tubulointerstitial injury secondary to obstructive uropathy.[14,15] Renal function is usually normal, but CKD stages 3 to 5 may develop if both kidneys are extensively damaged.

Hypertension is unusual in renal TB, but intimal proliferation of vessels near inflamed areas may lead to segmental ischemia and renin release.[16] In patients with a nonfunctioning kidney, nephrectomy may help improve the hypertension. Relief of any obstruction also may help lower the blood pressure.

Constitutional symptoms, such as fever, weight loss, night sweats, fatigue, and anorexia, occur in less than 20% of patients and indicate active infection in other organs or secondary bacterial infection of the urinary tract. All patients who present with constitutional symptoms must be carefully examined to identify pulmonary, lymph node, or skeletal TB. The chest radiograph may show evidence of active or healed tuberculous lesions in more than half of cases. Rarely, hypercalcemia may be present because of increased synthesis of calcitriol in the granulomas.

PATHOLOGY

Urinary TB may present as a miliary or ulcerocavernous pathologic process. The miliary form of TB is rare and is seen particularly in immunosuppressed individuals. The gross appearance of the kidney is characteristic; the cortex is studded with yellowish white, hard, pinhead-sized nodules that on microscopy show several coalescent granulomas with central caseation.

In the more common ulcerocavernous form, the kidneys will initially appear normal or show yellow nodules on the outer surface. On cut section, granulomas and ulcers in the renal pyramid or medullary cavities may be seen. Larger cavities filled with caseous material communicating with the collecting system also may occur (see Fig. 52.4A and B). Other gross findings include multiple ulcers in the infundibular region of the calyces, calyceal stenosis with caliectasis, ulcers or strictures of the ureter with hydronephrosis, pyonephrosis, subcapsular collections, and perinephric abscesses. The bladder may show ulcers or be grossly fibrotic and contracted (thimble bladder) (see Fig. 52.6)

In early disease, neutrophilic infiltration with phagocytosis of the bacilli may be seen. Subsequent histologic features depend on the virulence of the organism and the cell-mediated immunity. With an effective cell-mediated response, granulomas are seen, characterized by the presence of macrophages with engulfed bacilli surrounded by epithelioid cells and Langhans giant cells (Fig. 52.7). There is often a cuff of lymphocytes and plasma cells surrounding the lesion. Healing occurs by fibrosis and scarring. In those with a less effective immune response, caseating necrosis is characterized by amorphous, cheese-like eosinophilic material replacing the normal tissue architecture. The presence of caseous necrosis generally implies that the lesion is active. Later, this may calcify. Dystrophic calcification suggests activity rather than healing.

Kidneys also may be enlarged from amyloidosis. In tuberculous interstitial nephritis, interstitial granuloma formation associated with normal-sized kidneys and negative urine cultures is seen.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

A high index of suspicion is necessary to diagnose genitourinary TB. Elderly patients, those recently exposed to infection,

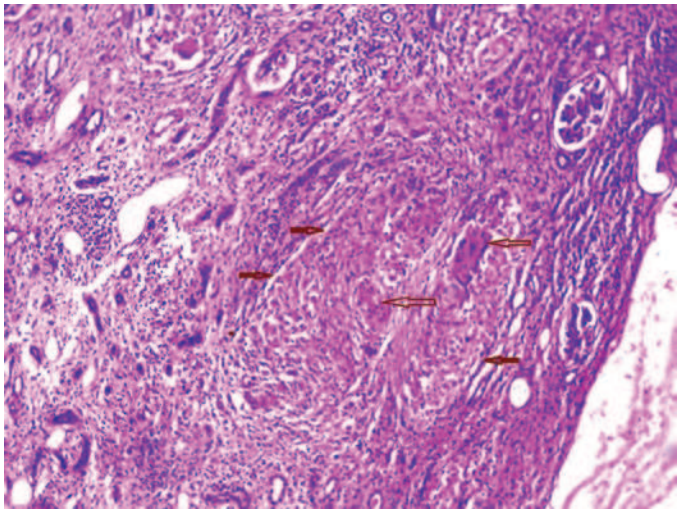

Fig. 52.7 Needle biopsy sample showing granuloma formation and Langhans giant cell in the kidney. Section from renal biopsy showing outline of evolving granuloma *(bold short arrows)* and multinucleated Langhans giant cell *(open arrows)* (Courtesy Department of Pathology, Government Medical college, Kottayam, India.)

immunocompromised individuals, and patients with TB elsewhere are at high risk. Suspicion also may occur if there is sterile pyuria, which is present in 50% of patients. The tuberculin test (Mantoux test) is useful for proving infection (or prior immunization with BCG), but not necessarily disease. A positive test response only suggests prior exposure to the antigen and does not indicate active infection. A negative test response in the absence of an immunosuppressed state helps rule out tuberculous infection in countries with high TB burden. Patients with stage 4 or 5 CKD, and after transplantation, particularly in the setting of malnutrition, may display anergy and have a false-negative result.[17] *M. tuberculosis*–specific enzyme-linked immunospot (ELISPOT) assay is useful for rapid confirmation of diagnosis.

Isolation of *M. tuberculosis* by urine culture is the definitive diagnostic test. Fully voided early-morning urine samples for 3 to 5 consecutive days are cultured on two standard solid mycobacterial culture media: egg-based Lowenstein-Jensen and agar-based Middlebrook 7H10. These transparent media enable earlier visualization of microcolonies, which grow by 6 to 12 weeks. Sensitivity tests are performed to choose the optimum chemotherapeutic agents. However, this may take an additional 6 to 12 weeks. Any tissue specimen submitted for mycobacterial culture should be macerated with sterile sand by a mortar and pestle before inoculation. Direct demonstration of acid-fast bacilli (AFB) in urine by Ziehl-Nielsen stain is not reliable for diagnosis because *Mycobacterium smegmatis,* a saprophyte, may be easily mistaken for *M. tuberculosis*.

Rapid methods for diagnosis of TB are increasingly available. With use of the radiometric broth method for AFB isolation, a positive growth can be obtained in about 9 days. Serologic tests with the soluble antigen fluorescent antibody test and polymerase chain reaction (PCR) can be used for early diagnosis of TB.[18] ELISPOT assays to monitor cellular immune response are used as in vitro diagnostic tests. They help accurately detect *M. tuberculosis* antigen–specific T cells and provide qualitative and quantitative information. The test results are unaffected by prior tuberculin testing or low CD4 counts.[19] Another reliable and simple test using whole blood is based on quantifying the interferon-γ (IFN-γ) released from the white blood cells that have been exposed to some of the mycobacterial antigens. Whole-blood IFN-γ release assays, available, for example, as the QuantiFERON test, have been approved by the U.S. Food and Drug Administration as an aid for diagnosing latent and active tuberculous infection replacing the conventional tuberculin skin testing[20] with greater than 95% sensitivity and 90% specificity. The availability of the result in 24 hours is the main advantage and has led to its widespread use.[21] Detection of LAM in urine using the lateral flow assay is a simple and rapid test for the detection of TB in patients with advanced HIV infection with a CD4 T lymphocyte count less than 200 cells/μl. The results are available in 30 minutes. A cartridge-based, rapid, and reliable automated test endorsed by the WHO to identify targeted nucleic acid sequences in the *M. tuberculosis* genome (Xpert MTB/RIF) is also available.[22] This test has a pooled sensitivity of 98% and specificity of 99%. In sputum AFB-positive cases, the sensitivity was 100%. This test detects the DNA sequences specific for *M. tuberculosis* and rifampin resistance by PCR, and results can be generated in 2 hours.[22] Ultrasound-guided fine-needle aspiration cytology is useful as a diagnostic tool in defining the granulomatous nature of the lesion in patients with positive urine culture. Histologic diagnosis is made by identifying the pathologic triad of caseating necrosis, loose aggregates of epithelioid histiocytes, and Langhans giant cells.

Plain radiographs of the chest and spine show active or healed tuberculous lesions in 60% to 70% patients with TB of urinary tract. Imaging the renal area may reveal extensive dystrophic calcification in advanced renal TB (Fig. 52.8). Sometimes, thick, wavy, puffy, cotton-like dense calcification resembling a cumulus cloud may be seen. Other abnormalities, such as minimal erosion of the tip of the calyx with spasticity, incomplete filling, distortion, infundibular stenosis, hydrocalicosis, multiple ureteral strictures, hydronephrosis, hydroureter, or nonvisualization of the kidney may be seen in the excretory urogram in 70% to 90%. The renal pelvis, which may be dilated initially, may eventually be obliterated, leading to a distorted appearance called *hiked-up pelvis* (Kerr kink sign). Irregularities or multiple strictures lead to a beaded or corkscrew appearance of the ureter or hydronephrosis. Later, thickening and straightening of the whole ureter may occur ("pipe-stem" ureter). The bladder may appear irregular and fibrosed, and VUR may occur. Antegrade or retrograde pyelography can identify the number, length, or site of ureteral strictures and assist in placement of a ureteric stent across the stenotic segment.

High-resolution ultrasound is useful to rule out obstruction and study the parenchyma closely. The earliest finding is mucosal thickening and calyceal irregularity followed by granulomas, small abscesses, or calcification[23] (Figs. 52.9 and 52.10).

Computed tomography (CT) is the most sensitive method for identifying renal parenchymal scarring, calcification, and cavitary lesions (Fig. 52.11). Cortical thinning is a common CT finding and may be either focal or global. These imaging modalities are helpful in follow-up of patients with cavities or mass lesions in the kidney. Cystoscopy under general anesthesia helps visualize the mucosal lesions, the golf-hole ureteral orifice, or the efflux of white toothpaste-like caseous material. Biopsy is avoided during the acute stage because of the risk for dissemination of TB.

Differential Diagnosis

TB mimics numerous diseases. Chronic nonspecific urinary tract infections may be confused with renal TB, especially because secondary bacterial infection may complicate 20% of cases of renal TB. Absence of response to usual antibiotics should raise suspicion of urinary TB. Conditions causing recurrent painless hematuria, such as IgA nephropathy (see Chapter 23) and schistosomiasis (see Chapter 54), are often misdiagnosed as TB in endemic areas. In interstitial cystitis, lower urinary

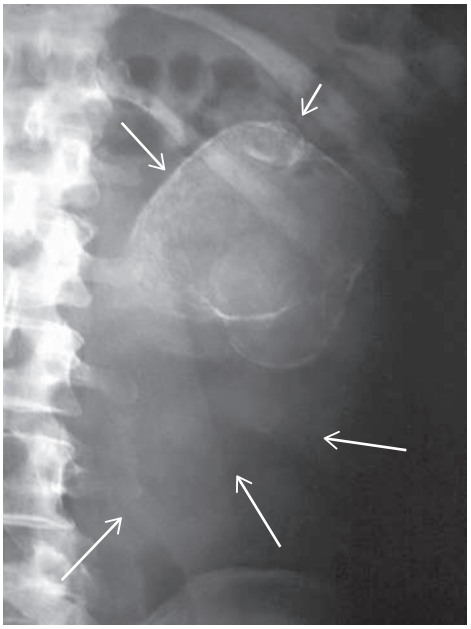

Fig. 52.8 Renal calcification. Plain radiograph shows calcification in the upper half of the left kidney. *Arrows* outline the kidney.

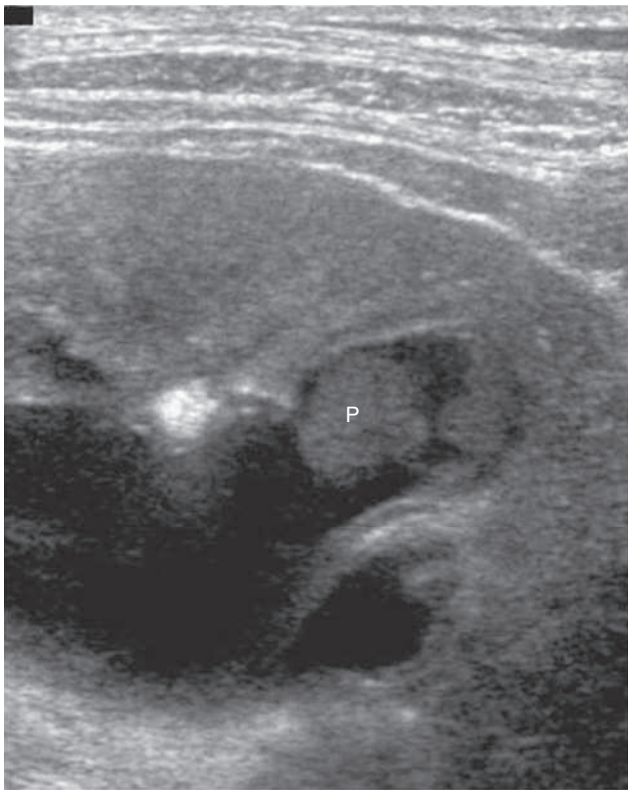

Fig. 52.9 Necrosed papilla. High-resolution ultrasound scan of the kidney shows a sloughed, necrosed papilla *(P)* in the calyx. (From reference 23, with permission of the American Institute of Ultrasound in Medicine.)

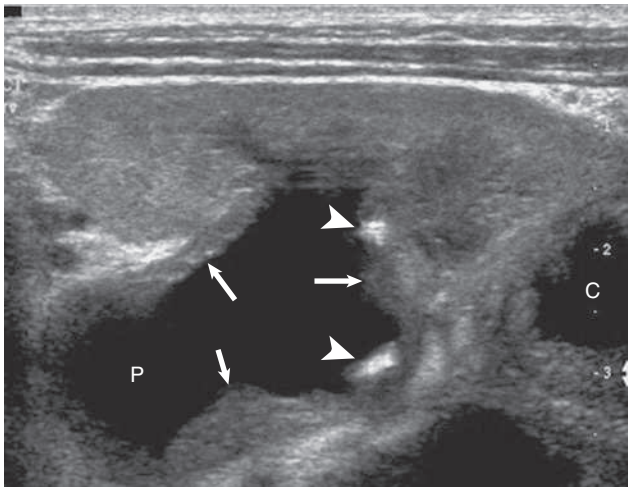

Fig. 52.10 Thickened mucosa and calcifications. High-resolution transverse ultrasound scan of kidney shows mucosal thickening *(arrows)* of calyces and the pelvis *(P)*. There are calcifications of the wall of the calyx and pelvis *(arrowheads)*. A parenchymal cavity *(C)* is also shown. (From reference 23, with permission of the American Institute of Ultrasound in Medicine.)

tract symptoms similar to tuberculous cystitis may occur, but the urinalysis does not show gross pyuria, and cultures for AFB are negative. On radiologic examination, chronic pyelonephritis, renal papillary necrosis, medullary sponge kidney, calyceal diverticulum, renal carcinoma, xanthogranulomatous pyelonephritis, and multiple small renal calculi need to be differentiated from TB. In a few reported cases

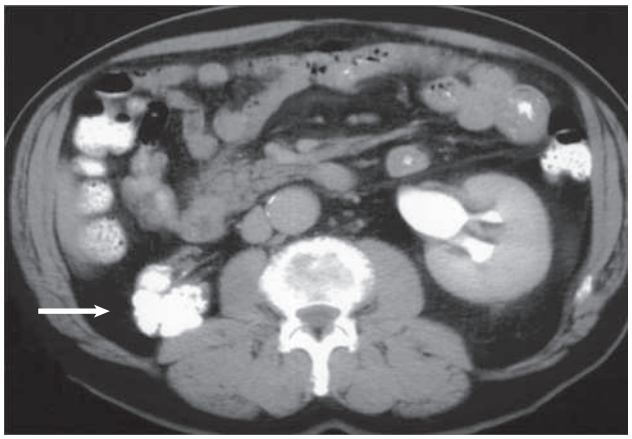

Fig. 52.11 Calcified kidney. Contrast-enhanced CT image shows contracted calcified right kidney *(arrow)* and normal opposite side.

of pseudotuberculous pyelonephritis, caseating granulomas resembling TB were observed in the renal parenchyma, but no mycobacteria or other microorganisms were detected in the renal tissue or urine culture.[24]

NATURAL HISTORY

The prognosis of genitourinary TB depends on host resistance and the load and virulence of the organism. In many cases, foci in the urinary tract remain dormant indefinitely. Progression occurs through formation of tuberculous granuloma, caseation, ulceration, and dystrophic calcification. Most manifestations result from complications of these processes, which can be prevented by timely chemotherapy and appropriate surgical intervention when indicated. The bacterial burden is lesser in genitourinary TB compared with pulmonary cavitary lesions, and hence treatment is easier. However, the problems with MDR and XDR TB remain challenges for the clinician. With the advent of effective chemotherapeutic measures, the frequency of long-term sequelae of TB has decreased significantly.

TREATMENT

Genitourinary TB is usually amenable to medical treatment. Many antituberculous drugs reach the kidneys, urinary tract, urine, and cavitating lesions in high concentration, and there are fewer organisms in the renal lesions compared with cavitating lung lesions. A wide variety of antituberculous agents are available (Table 52.3).

A short-course regimen is recommended.[25] Treatment is started with daily rifampin 600 mg, isoniazid 300 mg, and Pyrazinamide 25 mg/Kg body weight in the morning. Unless the culture sensitivity indicates otherwise, pyrazinamide is discontinued after 2 months and isoniazid and rifampin are continued for another 4 months. If the patient is very sick with irritative bladder symptoms, streptomycin in daily doses of 1 g may be added during the first 2 months. However, if the patient is older than 40 years, the daily dose of streptomycin is reduced to 0.5 to 0.75 g with periodic monitoring for ototoxicity and vestibular toxicity.

If the probability of drug resistance is high, ethambutol in daily doses of 800 to 1200 mg also may be used in the first 2 months. Longer courses of antituberculous treatment ranging from 9 months to 2 years are indicated under the following circumstances:

- Patients not tolerating pyrazinamide.
- Those responding slowly to a standard regimen.
- Miliary TB.
- Central nervous system disease.

TABLE 52.3 Antituberculous Drugs*

Dosage, Actions, and Side Effects

Drug	Dose Form	Dosage	Mode of Action	Dose Modification GFR (50-10 ml/min)
Isoniazid (INH)†	Tablet 100 mg, 300 mg	PO: 5 mg/kg/day (max: 300 mg/day)	Bactericidal for groups I and II Interferes with mycolic acid synthesis	Nil
Rifampin (rifampicin)†	Tablet/capsule 150 mg, 300 mg, 450 mg	PO: 10 mg/kg/day (max: 600 mg/day)	Bactericidal for groups I, II, and III Interferes with protein synthesis by inhibiting RNA polymerase	Nil
Pyrazinamide†	Tablet 400 mg, 500 mg	PO: 25 mg/kg/day (max: 2 g/day)	Bactericidal for semidormant *Mycoplasma tuberculosis*	Nil
Ethambutol	Tablet 100 mg, 400 mg	PO: 15-25 mg/kg (max: 2.5 g/day)	Bacteriostatic Bactericidal in high concentrations Inhibits cell wall synthesis	75%‡
Streptomycin	Injection 1 g, 0.75 g	IM: 15-25 mg/kg/day (max 1 g) Age >60 y: 75% dose	Bactericidal Inhibit protein synthesis	50%‡
Amikacin	IM/IV: Ampoules 500 mg, 1000 mg	15 mg/kg/day (max: 1 g/day)	Bactericidal Inhibit protein synthesis	50%‡
Levofloxacin	PO/IV: PO: Tablet— 250, 500, 750 mg IV: Ampoule—500-750 mg	750-1000 mg/day	Bactericidal Inhibit protein synthesis—DNA gyrase	50%‡ (500-750 mg q36h)
Moxifloxacin	PO/IV: PO—Tablet 400 mg IV— Infusion 400 mg in 100 ml	400 mg/day	Bactericidal	Nil
Capreomycin	IM/IV: 1-g vial	15 g/kg/day (max 1 g/day) On 5-7 days/wk	Strongly bactericidal Inhibits protein synthesis	75%
Ethionamide	PO	15-25 mg/kg/day (max 1 g/day in 2 divided doses)	Weakly bactericidal Blocks mycolic acid synthesis	Nil
Cycloserine	PO	15-25 mg/kg/day	Bacteriostatic	50%‡

*The main drugs are listed with dosage form, dosage, mode of action, side effects, and dose modifications in those with low glomerular filtration rate. *M. tuberculosis* exists as three subpopulations. Group I is extracellular, occurs mainly in cavitating lesions, and responds to streptomycin, isoniazid, and rifampin. Group II resides intracellularly in macrophages, replicates slowly, and responds to pyrazinamide, isoniazid, or rifampin. Group III organisms exist within closed caseous lesions, survive better in neutral pH, replicate slowly, and respond best to rifampin.
†Prescribed dose to be given after hemodialysis.
‡Dose reduction and / or increasing dosing intervals.
GFR, Glomerular filtration rate; *GI,* gastrointestinal; *HD,* hemodialysis; *IM,* intramuscular *IV,* intravenous, *MDR TB,* multidrug-resistant TB; *PO,* orally, *QTc,* corrected QT interval on electrocardiogram; *TB,* tuberculosis; *TDM,* therapeutic drug monitoring.

Dose Modification GFR (<10 ml/min)	Side Effects	Remarks
66%	Hypersensitivity Peripheral neuritis Hepatitis	Administer pyridoxine 50 mg/day.
Nil	Febrile reactions Acute interstitial nephritis Hepatitis	Dose adjustment when using calcineurin inhibitors or oral contraceptives. May be used in pregnancy and lactation.
50%‡	Hyperuricemia Hepatotoxicity Photosensitivity	Primary hepatic metabolism. Monitor liver functions and uric acid.
Avoid or 50%‡	Optic neuritis (monitor for color vision)	Primarily renal excretion. May be used during pregnancy and lactation.
25%‡	Ototoxicity Vestibulotoxicity Hypokalemia Hypomagnesemia	Therapeutic drug monitoring advised. Peak level for efficacy. Trough level for toxicity.
25%‡	Ototoxicity Vestibulotoxicity Hypokalemia Hypomagnesemia	Cleared by hemodialysis. Supplement dose after HD or give regular full dose after dialysis. Avoid coadministration of loop diuretics. TDM recommended.
25%‡ (250-500 mg q48h)	Severe upper GI symptoms Prolonged QTc Arthralgia Tendon rupture	Hepatic and renal elimination. Used in liver disease. More effective than ciprofloxacin and ofloxacin.
Nil	Severe upper GI symptoms Prolonged QTc Arthralgia Tendon rupture	Not removed by HD.
25%‡	Nephrotoxicity Ototoxicity Hypokalemia Hypomagnesemia Hepatotoxicity when combined with other anti TB drugs	Used only for MDR TB.
50%	Hepatotoxic Severe GI symptoms Hypothyroidism Gynecomastia	Not to be combined with cycloserine.
25%‡	Neurotoxicity, seizures, peripheral neuropathy	Maintain peak level <35 μg/ml. Cleared by dialysis. Avoid in pregnancy and lactation.

- Children with multisite involvement.
- Patients with HIV. The choice of drugs and duration of treatment for those with HIV/AIDS is essentially the same as for immunocompetent patients. In view of the drug interaction between antiretroviral drugs and rifampin, rifabutin may be used in place of rifampin. Another strategy is to delay initiation of antiretroviral therapy by 4 to 8 weeks after starting antituberculous therapy with a view to prevent immune reconstitution syndrome.

Fixed-dose combinations of anti-TB drugs incorporating two or more drugs in the same tablet may facilitate compliance and adequate dosing while minimizing the risk for medication errors and drug resistance.

During treatment, healing by fibrosis may lead to obstruction of one or both ureters, with hydroneprhrosis, parenchymal damage, and renal failure. Dehydration or salt depletion may occur from tubulointerstitial damage or adrenal involvement. Allergic interstitial nephritis may occur in patients receiving intermittent rifampin therapy. Nanoparticle-based drug delivery systems being developed may result in even more successful treatment of TB.[26]

Surgical Treatment

The role of surgical treatment in patients with urinary TB is limited. For ureteral strictures, timely introduction of stents across the narrow segment may avoid the need for major surgical procedures. Two broad types of surgical treatments are considered.

Reconstructive surgery involves the correction of obstruction to the ureter by pyeloplasty, ureteroureterostomy, correction of reflux by ureteral reimplantation, and increasing the bladder capacity by augmentation cystoplasty, which involves anastomosis of an isolated segment of bowel to the contracted bladder.

Ablative surgery involves removal of the diseased parts together with the infected material containing the dormant organisms. The need for removal of a unilateral nonfunctioning kidney is controversial. Because prolonged antituberculous treatment for 18 to 24 months effectively sterilizes caseous and calcified lesions in the tuberculous kidney, nephrectomy is advocated only in patients with secondary sepsis, pain, bleeding, uncontrollable hypertension, "putty kidney," or continued positive urinary cultures. Tuberculous abscesses can be aspirated under ultrasound or CT guidance and antituberculous drugs directly instilled into the cavity.

Treatment Regimens in Special Situations

Women During Pregnancy and Lactation

Most antituberculous drugs are safe for use during pregnancy. However, streptomycin is ototoxic to the fetus and must be avoided. If a four-drug schedule is indicated, streptomycin is replaced by ethambutol. There is no contraindication to the use of these drugs during breastfeeding, and it is not necessary to isolate the baby from the mother. The baby should receive BCG immunization and isoniazid prophylaxis. Because rifampin can reduce the efficacy of oral contraceptives, women taking these agents together should be advised to take a higher dose of estrogen or use alternative methods of contraception.

Patients With Liver Disease

The usual short-term (6-month) chemotherapy regimen can be used in patients with liver disorders if there is no evidence of chronic liver disease, hepatitis virus carrier state, history of acute hepatitis, or excessive alcohol consumption. In chronic liver disease, isoniazid and two of the nonhepatotoxic drugs (streptomycin and ethambutol) can be used for 8 to 12 months. If rifampin is used, liver function should be closely monitored. Pyrazinamide is contraindicated. In those with acute hepatitis unrelated to TB or its therapy, it would be safer to defer chemotherapy until the acute hepatitis has resolved. If immediate treatment of TB during acute hepatitis is mandatory, streptomycin plus ethambutol for 3 months followed by isoniazid and rifampin for 6 months is advised.

Patients With Chronic Kidney Disease

In patients with CKD, isoniazid, rifampin, and pyrazinamide, which are eliminated by the biliary route, can be given in normal dosages. Because streptomycin and ethambutol are excreted by the kidney, dosage modification of these drugs is necessary when GFR is reduced. Streptomycin 15 mg/kg is administered every 48 to 72 hours for a GFR of 10 to 50 ml/min and every 72 to 96 hours for a GFR of less than 10 ml/min to maintain a therapeutic peak level of 20 to 30 μg/ml. Patients taking streptomycin who have a sense of fullness of the ear, have tinnitus, or are older than 45 years should have an audiogram to detect ototoxicity early. For ethambutol, the dose is administered every 24 to 36 hours if GFR is 10 to 50 ml/min and every 48 hours if GFR is less than 10 ml/min. Monthly questioning for symptoms of visual dysfunction (alterations in visual fields, acuity, blue-green vision) with early referral for ophthalmic examination may identify ethambutol toxicity early, with potential reversibility.

Renal Allograft Recipients

A modified treatment regimen is recommended for patients with renal allograft, with adjusted doses of isoniazid and ethambutol for 18 months, combined with ofloxacin 200 mg twice daily for the first 9 months and pyrazinamide 750 mg twice daily for the first 3 months.[27] Rifampin should be avoided in patients receiving a calcineurin inhibitor (CNI) because enzyme induction will make it more difficult to maintain adequate CNI blood levels. If rifampin is used in those receiving a non–CNI-based immunosuppressive regimen, the maintenance dose of prednisolone should be doubled.

Acquired Immunodeficiency Syndrome

Short-term chemotherapy is sufficient for patients with AIDS. If the follow-up cultures are positive, prolonged therapy for up to 2 years may be needed based on antibiotic sensitivity.

Patients Who Fail Treatment

Failure to show clinical or radiologic improvement with treatment may signify poor compliance, inadequate regimen and dosage, incorrect diagnosis, MDR TB, XDR TB, delayed response, or the paradoxical reaction known as *immune reconstitution inflammatory syndrome*. This syndrome is characterized by unexpected worsening of symptoms or appearance of new lesions, including lymphadenopathy, serosal effusions, and pleural infiltrates. This syndrome is more common in those receiving antiretroviral treatment for coexisting HIV and TB infections.[28]

Patient Monitoring

After 2 months of intensive chemotherapy, urine is cultured for *M. tuberculosis* for 3 consecutive days. If cultures remain positive, sensitivity testing is done and treatment modified accordingly. After completion of treatment, all patients should provide three consecutive early-morning samples of urine for *M. tuberculosis* culture, and this is repeated after 3 months and 1 year. Intravenous urography or ultrasound is repeated at the end of 2 months and at the completion of treatment to detect any evidence of obstruction. In cases of renal calcification, the patient should be evaluated yearly by three early morning samples of urine for culture of mycobacteria and by plain radiography of the abdomen for up to 10 years, because calcification may harbor *M. tuberculosis* and may progress to destruction of the kidney.

Considerable progress has been made in the areas of TB diagnostics, antituberculous drugs, and vaccines during the last decade. New antituberculous agents and several vaccines are in various phases of clinical

trials. For example, nanoparticle-based drug delivery systems are being developed and have potential to improve TB treatment and control because of their superior solubility and bioavailability.[25] The "End TB" strategy of the WHO that is targeting global reductions in the number of new TB cases and TB deaths by 90% and 95%, respectively, between 2015 and 2035.

SELF-ASSESSMENT QUESTIONS

1. All of the following are features of immune reconstitution inflammatory syndrome (IRIS) *except*:
   - **A.** Development of new lesion
   - **B.** Worsening of symptoms
   - **C.** Severity inversely proportional to the load of organisms
   - **D.** Common in multidrug-resistant tuberculosis (MDR TB)
   - **E.** Common in patients with simultaneous treatment of coexisting HIV infection
2. The following antituberculous drugs act as bactericidal agents when used in therapeutic doses *except*:
   - **A.** Rifampicin
   - **B.** Isoniazid
   - **C.** Amikacin
   - **D.** Ethambutol
   - **E.** Pyrazinamide
3. The following symptoms point to suspicion of renal TB *except:*
   - **A.** Recurrent painless macroscopic hematuria
   - **B.** Acid, sterile pyuria
   - **C.** Sterility in women/epididymitis in men
   - **D.** Lack of constitutional symptoms
   - **E.** Icterus
4. Which of the following antituberculous drug combinations require dose modifications in patients with renal failure?
   - **A.** Isoniazid and rifampin
   - **B.** Streptomycin and ethambutol
   - **C.** Pyrazinamide and rifampin
   - **D.** Isoniazid and pyrazinamide
5. The drug uniformly effective against all three groups of *Mycobacterium tuberculosis*—group I (extracellular), group II (intracellular), and group III (closed caseous lesions) —is:
   - **A.** Isoniazid
   - **B.** Rifampicin
   - **C.** Pyrazinamide
   - **D.** Ethambutol
   - **E** Streptomycin

Fungal Infections of the Urinary Tract

Carol A. Kauffman

Funguria is a frequent finding in hospitalized patients. Almost always, the organisms found in urine are *Candida* spp., although several other yeasts and, less often, molds and endemic fungi, also can be found (Table 53.1). Candiduria is not a symptom, a sign, or a disease, but frequently it is a perplexing phenomenon for the physician to address. In reality, most patients with candiduria are asymptomatic and have colonization of the bladder or an indwelling urinary catheter. The most difficult diagnostic problem is determining when *infection,* rather than colonization, is present. Diagnostic tests to define whether candiduria is related to colonization or infection have not been standardized; similarly, diagnostic studies to localize the site of infection to either the bladder or the kidneys are not well established. In contrast to the situation with candiduria, growth in urine of organisms such as *Blastomyces dermatitidis, Aspergillus* spp., and *Cryptococcus neoformans* almost always reflects disseminated infection. This chapter outlines an approach to the diagnosis and treatment of candiduria and other, less common fungal urinary tract infections (UTIs).

CANDIDA

Epidemiology

Candida spp. are common inhabitants of the perineum but are not found in urine in appreciable numbers in healthy hosts. However, a variety of predisposing factors allow these commensals to grow in the urine and in some cases to invade the bladder or the upper urinary tract and cause infection. These factors are more frequently encountered in hospitalized patients, especially those in the intensive care unit (ICU).[1] In a cross-sectional survey of positive urine cultures obtained from hospitalized patients, *Candida* spp. were found in almost 10% of specimens and were the third most common microorganism isolated from urine.[2]

Risk factors for candiduria, but not specifically for *Candida* UTI, include increased age, female gender, antibiotic use, urinary drainage devices, prior surgical procedures, and diabetes mellitus[3-5] (Table 53.2). In the largest surveillance study, urinary drainage devices, mostly indwelling urethral catheters, were present in 83% of patients who had candiduria.[3] In a multicenter study of patients in an ICU setting, independent risk factors associated with candiduria were age over 65, female gender, diabetes mellitus, prior antibiotic use, mechanical ventilation, parenteral nutrition, and length of hospital stay before ICU admission.[4] A case-controlled study that compared candiduria caused by *Candida glabrata* with that from *Candida albicans* found that *C. glabrata* was more common in patients with diabetes and in those who had received prior treatment with fluconazole.[5] Most patients in these studies had colonization and not infection with *Candida*.

Prospective controlled studies assessing risk factors for well-documented *Candida* UTI have not been performed because firm diagnostic criteria have not been established. However, clinical experience suggests that UTI is more common in diabetic patients and those with urinary tract obstruction.

Pathogenesis

Candida can cause urinary tract disease by either the hematogenous or the ascending route. This contrasts with most bacterial UTIs, in which infection ascends from bladder to the collecting system of the kidney. The pathogenesis of hematogenous seeding of *Candida* to the kidney has been studied with animal models.[6] Multiple microabscesses develop throughout the cortex, with the yeasts penetrating through the glomeruli into the proximal tubules, where they are shed into the urine (Fig. 53.1). Healthy animals eventually clear the infection, but immunocompromised animals do not. Consistent with the experimental studies, renal microabscesses have been identified at autopsy in most patients with invasive candidiasis. For ascending infection with *Candida,* obstruction is an important factor in many patients. Virulence factors of *Candida,* such as those that control adherence and biofilm formation, are also likely relevant, but have not been studied in the context of *Candida* UTI.[6,7]

A unique syndrome seen early after kidney transplantation is graft site candidiasis, which appears to result from contamination of the donor kidney during the harvest procedure.[8] Arteritis with aneurysm formation and rupture can result from direct fungal invasion into the arterial wall. Most patients lose the graft, and mortality is high.

Microbiology

C. albicans accounts for 50% to 70% of all *Candida* urinary isolates, and *C. glabrata* for about 20% of isolates.[3] *Candida tropicalis* and *Candida parapsilosis* are less common, and other species are rarely isolated. Certain populations of patients have a predominance of *C. glabrata*. Older adults frequently have *C. glabrata* isolated from urine, but urine cultures from neonates rarely yield *C. glabrata*. In a prospective survey of candiduria in renal transplant recipients at one transplant center, *C. glabrata* represented 53% and *C. albicans* only 35% of isolates.[9]

For therapeutic reasons it is important to know the species causing candiduria. Resistance to fluconazole, the primary agent used for the treatment of *Candida* UTIs, is common among isolates of *C. glabrata* and in all isolates of *Candida krusei.* In contrast, almost all isolates of *C. albicans, C. tropicalis,* and *C. parapsilosis* are susceptible to fluconazole.

Clinical Manifestations

Most patients with candiduria are asymptomatic, and, indeed, most do not have infection. A large prospective surveillance study of patients

TABLE 53.1 Fungal Genitourinary Tract Infections

Fungal Infection	Prostate	Bladder	Kidney
Candidiasis	++	++++	++++
Cryptococcosis	++	+/–	+++
Blastomycosis	+++	+	++
Histoplasmosis	+	+/–	++
Coccidioidomycosis	+	+/–	++
Aspergillosis	+/–	+/–	++
Mucormycosis	+/–	+/–	++

Shown is the relative frequency of the site of infection for various fungal organisms.

TABLE 53.2 Risk Factors for Candiduria

Type	Risk Factors
Renal (hematogenous)	Neutropenia, recent surgery, central venous catheter, parenteral nutrition, antibiotics, dialysis
Lower urinary tract	Indwelling bladder catheter, older age, female, diabetes, obstruction, antibiotics, urinary tract instrumentation
Upper urinary tract	Older age, diabetes, antibiotics, obstruction, urinary tract instrumentation (e.g., nephrostomy tube, ureteral stent)

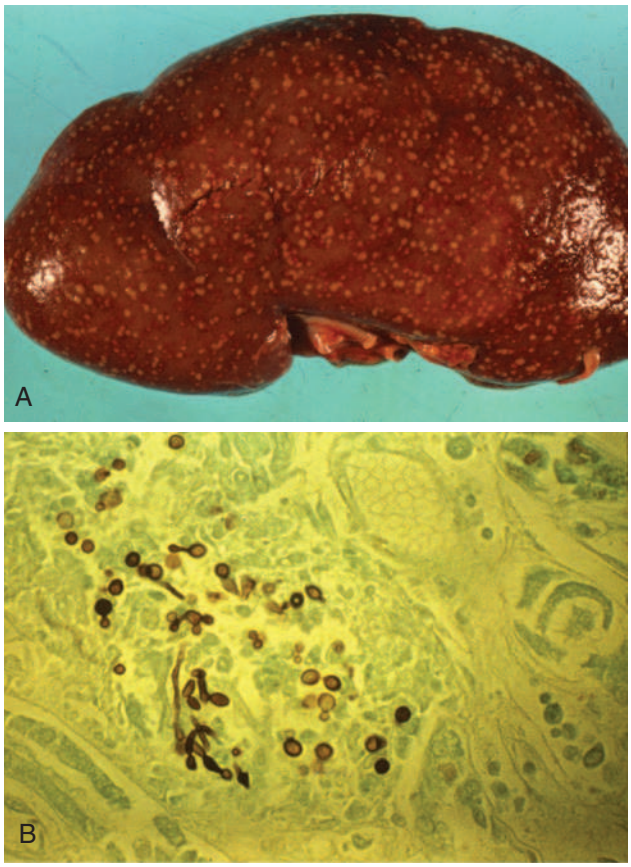

Fig. 53.1 Hematogenous renal candidiasis. (A) Multiple small abscesses are grossly obvious throughout the kidney. (B) Histopathologic demonstration of a microabscess caused by *Candida albicans* in the cortex of the kidney (methenamine silver stain; yeast shown in *gray-brown color*). Magnification 100x.

with candiduria noted that less than 5% of patients with candiduria had any symptoms suggesting UTI.[3] When patients have symptomatic cystitis or pyelonephritis, symptoms are indistinguishable from those noted with bacterial infections. Cystitis is manifested by dysuria, frequency, urgency, and suprapubic discomfort; patients with upper tract infection can manifest with fever, chills, and flank pain. Urinary tract obstruction occurs from formation of a bezoar or fungal ball in the bladder or the collecting system.

Patients who have had seeding of the renal parenchyma during an episode of candidemia manifest the symptoms and signs associated with invasive candidiasis and not UTI. Chills, fever, hypotension, and other manifestations of sepsis are often noted in patients who are candidemic.

Diagnosis

Major diagnostic difficulties are encountered in trying to differentiate contamination of a urine specimen from colonization of the bladder or an indwelling urethral catheter from invasive infection of the bladder or kidney.[10] Contamination is most easily differentiated by simply repeating the urine culture a day or two later to determine if candiduria persists. It may be necessary to obtain the second urine specimen by sterile bladder catheterization if the patient is unable to accomplish a clean-catch collection. In those patients who have an indwelling urethral catheter, the catheter should be replaced and a second urine specimen collected the next day. For either of these circumstances, if the repeated culture yields no yeasts, no further diagnostic studies or therapeutic interventions are needed.

Distinguishing colonization from infection is not straightforward. Compared with bacterial UTIs, in which the diagnosis is based on appropriate symptoms combined with the findings of pyuria and quantitative bacterial counts, no studies have established the importance of quantitative urine cultures or pyuria for the diagnosis of *Candida* UTI.[11]

The role of quantitative urine cultures to differentiate upper tract infection from bladder colonization was assessed by investigators in the 1970s and unfortunately showed broad ranges of colony counts for both colonization and infection.[11] In patients who did not have indwelling catheters, documented renal infection was found with colony counts as low as 10^4 yeast colony-forming units per milliliter (cfu/ml). For patients who had indwelling catheters, colony counts between 2×10^4 and 10^5 cfu/ml or more were noted and there was no correlation with biopsy-proven renal infection. A murine model of hematogenous renal candidiasis noted that renal involvement could be seen with any concentration of *Candida* in the urine.[12]

The techniques routinely used in most clinical laboratories for the detection of bacteria will also detect *Candida* in urine. However, *C. glabrata* grows more slowly than other species and more slowly than bacteria, and colonies may not appear for 48 hours, which is often after routine cultures of urine have been discarded. Laboratories should be notified if *C. glabrata* is a likely pathogen.

Pyuria is often not a helpful diagnostic criterion for infection in patients with candiduria. Concomitant bacteriuria is frequently noted in patients with candiduria and may be responsible for pyuria. In patients who have an indwelling bladder catheter, pyuria is routinely noted, regardless of whether infection is present. In patients who do not have an indwelling bladder catheter or bacteriuria, the presence of pyuria is helpful.

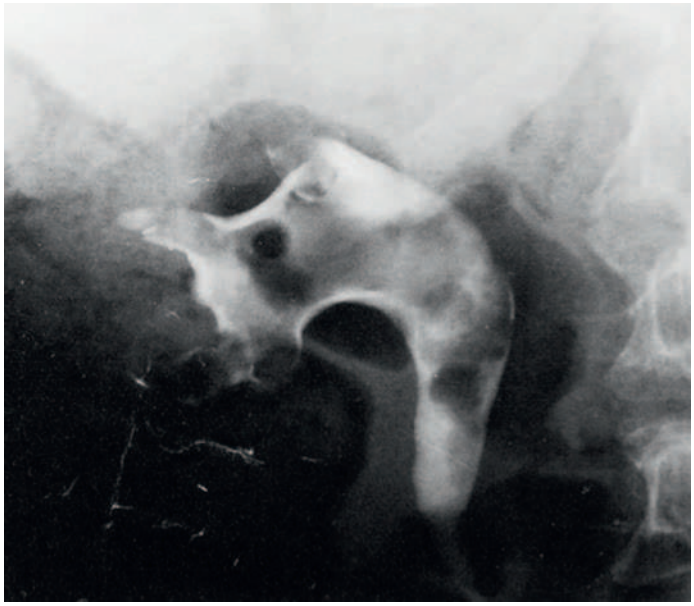

Fig. 53.2 Fungal hydronephrosis. Several fungus balls *(dark round "holes" in the contrast dye)* in the ureter and pelvis of the right kidney causing hydronephrosis.

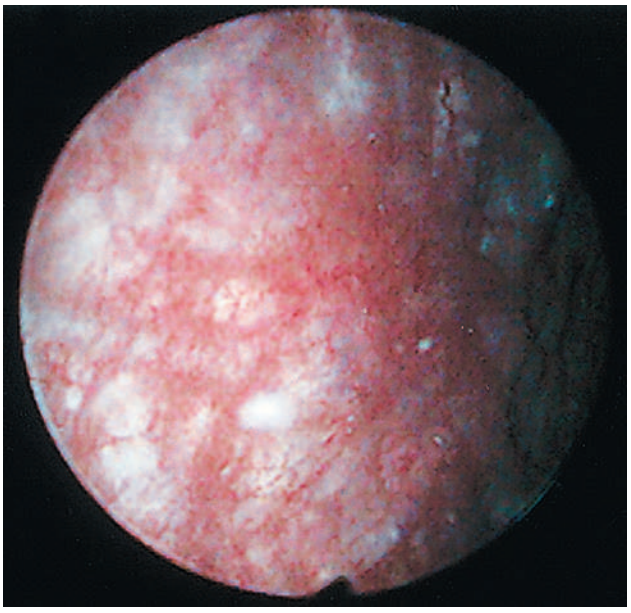

Fig. 53.3 *Candida* cystitis. Cystoscopic appearance of extensive cystitis caused by *Candida krusei.*

Imaging procedures, including abdominal ultrasound and computed tomography (CT), are essential to document obstruction at any level in the urinary tract and determine the presence of fungus balls in bladder or kidney (Fig. 53.2). In some patients, it is helpful to perform cystoscopy and biopsy of the bladder wall to determine whether inflammation is present and evaluate the extent of invasion (Fig. 53.3).

Treatment With Systemic Antifungal Agents

Most patients who have candiduria do not need treatment with an antifungal agent. For patients who are asymptomatic, treatment should be given only to those who are at high risk for development of candidemia or in whom the presence of candiduria, regardless of symptoms, is likely to represent disseminated infection.[13] The guidelines for the management of candidiasis published by the Infectious Diseases Society of America recommend treatment for patients about to undergo urologic procedures, infants with very low birth weight, and neutropenic patients[13] (Table 53.3). Patients who have candiduria and who are to undergo a urologic procedure are at increased risk for development of candidemia and should be treated with an antifungal agent a few days before and after the procedure. Candiduria in neutropenic patients and in infants with very low birth weight has a high probability of representing disseminated candidiasis; thus these groups also should be treated with an antifungal drug. Asymptomatic candiduria in the renal transplant patient does not warrant systemic antifungal treatment unless obstruction is present or symptoms suggestive of local or systemic infection develop.

In non–high-risk patients who have asymptomatic candiduria, removal of an indwelling urinary catheter will eradicate candiduria in many patients.[3] If catheterization cannot be discontinued, the existing catheter should be removed and a new one inserted. This will often eradicate candiduria transiently, but it is highly likely that the organisms will return within a short time. It is not known if a suprapubic catheter is less likely to be colonized than an indwelling urethral catheter. Relief of obstruction, whether it is present in the upper or lower urinary tract, is essential for the long-term eradication of *Candida* from the urinary tract.

Patients who have symptoms suggestive of cystitis or pyelonephritis, and in whom bacteria as well as *Candida* are found in the urine culture specimen, should be treated initially with an antibacterial agent. If no bacteria are present, treatment with an antifungal drug is appropriate. Eradication of the organism with antifungal therapy is more likely if the indwelling catheter is also removed.[14] Oral fluconazole, which is an azole antifungal agent and is excreted as active drug in the urine, is the agent of choice (see Table 53.3). A loading dose of 400 mg should be given, followed by 200 mg daily for 14 days.[13,15] Fluconazole does not effectively treat *C. krusei* infections, and many *C. glabrata* infections also do not respond to fluconazole.

The possibility of drug-drug interactions should be evaluated before fluconazole is prescribed. Phenytoin, warfarin, cyclosporine, tacrolimus, and sulfonylurea agents are a few of the drugs for which serum concentrations will increase and may reach toxic levels after the addition of fluconazole. Azoles should be used with caution in patients on drugs that prolong the QTc interval.

The other available azole agents, itraconazole, voriconazole, posaconazole, and isavuconazole are not excreted into the urine as active drug. Whether tissue concentrations might be high enough to treat invasive kidney or bladder infections is not known, but there is little clinical experience to suggest that they will be effective.[15]

Intravenous amphotericin B deoxycholate is effective in treating *Candida* UTIs but should be reserved for patients who have upper tract infection or for whom fluconazole therapy has failed, which will be predominantly those who have *C. glabrata* infection. Because of its inherent nephrotoxicity, intravenous amphotericin B must be used judiciously in patients who have renal dysfunction. The recommended dosage is 0.3 to 0.6 mg/kg/day for 1 to 7 days, although this may be extended to 2 weeks for those who have complicated upper tract infection.[13] The dose used depends on renal function and number of days infusions will be given; for example, some clinicians have had success with 0.3 mg/kg/day for 3 days, whereas others use a single dose of 0.6 mg/kg. Infusion-related side effects are seen in some patients, even when low dosages are used, and can include rigors, fever, nausea, vomiting, and headache.

Lipid formulations of amphotericin B are not recommended for treatment of fungal UTIs. The decreased nephrotoxicity that results

TABLE 53.3 Treatment Recommendations for Candiduria and *Candida* Urinary Tract Infections

Infection	Treatment	Other/Alternative Therapy
Asymptomatic candiduria	No treatment indicated except:	
	Urologic surgery	Treat a few days before and after the procedure with: Fluconazole 200-400 mg/day *or* Amphotericin B 0.3-0.6 mg/kg/day
	Low-birth-weight infant	Treat as for disseminated candidiasis/candidemia with fluconazole 12 mg/kg/day[13]
	Neutropenic patient	Treat as for disseminated candidiasis/candidemia with an echinocandin or fluconazole[13]
Cystitis	Preferred: PO fluconazole 200 mg/day × 14 days*	Alternatives include: Amphotericin B 0.3-0.6 mg/kg/day × 1-7 days Flucytosine 25 mg/kg q6h × 7-10 days†
Pyelonephritis	Preferred: PO fluconazole 200-400 mg/day × 14 days	Alternatives include: Amphotericin B 0.3-0.6 mg/kg/day × 1-7 days with or without flucytosine, 25 mg/kg q6h Flucytosine 25 mg/kg q6h × 14 days
Renal (hematogenous)	Treat as for disseminated candidiasis/candidemia with an echinocandin or fluconazole	—
Fungus balls	Surgical removal *plus* Fluconazole 200-400 mg/day until resolved	Alternatives include: Surgical removal *plus* Amphotericin B 0.3-0.6 mg/kg/day with or without flucytosine 25 mg/kg q6h Irrigation through nephrostomy tube with amphotericin B 25-50 mg in 200-500 ml sterile water
Prostatitis Epididymo-orchitis	Surgical drainage *plus* Fluconazole 400 mg/day until resolution noted on imaging studies	Alternatives include: Surgical drainage *plus* Amphotericin B 0.3-0.6 mg/kg/day

*Fluconazole dosage in renal failure: creatinine clearance (Cr Cl) 20-50 ml/min, reduce dose by 50%; CrCl <20 ml/min, reduce dose by 75%.
†Flucytosine dosage in renal failure: CrCl 20-40 ml/min, reduce dose to 25 mg/kg q12h; CrCl <20 ml/min, reduce dose to 25 mg/kg q24h.
PO, Orally; *q6h,* every 6 hours.

from the addition of the lipid component likely also precludes the drug's effectiveness by failing to achieve adequate levels in the urinary tract.[15]

One of the few uses of flucytosine is for the treatment of *Candida* UTIs. Flucytosine, which is excreted into the urine in high concentrations as active drug, should be used only when fluconazole is not tolerated or the organism is fluconazole resistant. The usual dosage of flucytosine in patients who have normal creatinine clearance is 25 mg/kg orally every 6 hours for 7 to 10 days.[15] Most species of *Candida,* with the exception of *C. krusei,* are susceptible to flucytosine, but resistance emerges quickly when this agent is used alone. Serious adverse effects of flucytosine include bone marrow suppression and hepatotoxicity. These effects are dose related, and the risk increases greatly with renal failure (see Table 53.3).

The echinocandins (caspofungin, micafungin, and anidulafungin) have minimal or no excretion into the urine as active drug. The tissue concentrations achieved with these agents may be adequate to treat invasive *Candida* infections of the bladder or kidney, but clinical data are limited.[16-18] Therefore echinocandins currently cannot be recommended for the treatment of *Candida* UTIs.

Local Antifungal Administration

Continuous bladder infusion of amphotericin B 50 mg in 1 liter of sterile water through a triple-lumen catheter is sometimes used to treat *Candida* bladder infection. Bladder irrigation clears candiduria more quickly than systemic antifungal agents.[19] However, the effect is brief, and recolonization occurs within 1 to 2 weeks. Amphotericin B bladder irrigation is rarely required as a strategy given the need for catheter placement and the availability of more convenient treatment options.[20] The one exception might be lower tract infection with azole-resistant *C. krusei* or *C. glabrata*.

In the patient with kidney obstruction caused by a fungus ball, irrigation through a percutaneous nephrostomy tube with amphotericin B is recommended, in addition to systemic antifungal therapy with fluconazole.[13] Absorption of amphotericin B does not occur, and direct infusion is not nephrotoxic. Surgical or endoscopic removal of the fungus ball is essential to eradicate the infection.

Localized *Candida* Infections

Prostatitis and prostatic abscess caused by *Candida* spp. manifest with symptoms that are similar to those of bacterial prostatic infection. The initial manifestation may be urinary retention; physical examination reveals a tender prostate, and imaging can show either discrete abscesses or diffuse inflammation. Treatment is drainage if an abscess is present, and fluconazole, which achieves excellent concentrations in the prostate for several months until the infection has resolved.[21] Epididymo-orchitis is less common and usually manifests as a tender scrotal mass. Surgical drainage or orchiectomy is required, along with fluconazole therapy until resolution has occurred.

OTHER YEASTS

C. neoformans infection in immunosuppressed hosts, especially patients with AIDS, is a systemic illness with involvement of many organs, including the genitourinary (GU) tract. In autopsy series, kidney involvement has been noted in 25% to 50% of patients who died of cryptococcosis,

but symptoms rarely are referable to the GU tract. The prostate is frequently infected and can be a reservoir for persistent *C. neoformans* infection. Isolated prostatitis and epididymo-orchitis have been reported in the absence of systemic cryptococcosis.[22] The diagnosis is usually made at the time of biopsy of a mass or nodule; granulomatous inflammation is typically seen. Treatment of localized GU tract cryptococcal infection is fluconazole 400 mg/day for 6 to 12 months.

Saccharomyces cerevisiae has been described rarely as a cause of UTI. The manifestation is the same as for *Candida* spp. In clinical microbiology laboratories that do not identify yeasts in urine to the species level, this organism will not be differentiated from *Candida*. *S. cerevisiae* is often resistant to fluconazole, and successful treatment may require amphotericin B.

ASPERGILLUS AND OTHER MOLDS

The urinary tract is an uncommon site of infection with molds. However, individual case reports have noted GU infections caused by a variety of molds, including the Mucorales (e.g., *Rhizopus, Mucor*), *Aspergillus, Penicillium*, and *Paecilomyces*.[23] The most common mold infection is aspergillosis. Hematogenous spread to the kidney with invasive disease in immunosuppressed patients results in numerous renal microabscesses and infarcts. This may be an incidental finding in light of massive dissemination at autopsy. Patients who have symptomatic UTI usually present with urinary tract obstruction from masses of fungal elements causing fungal balls, which can be visualized on CT scan or ultrasound. Treatment is surgical removal of the obstructing mass, often nephrectomy, and systemic antifungal therapy for the specific mold. Mortality is extremely high.

ENDEMIC FUNGI

All of the major endemic mycoses have been reported to infect the GU tract. For all of these organisms, infection is by hematogenous spread to the GU tract. For upper tract infection, treatment is the same as that for disseminated infection. The treatment of focal infection, which is more likely to involve the lower GU tract, often requires surgical removal of the infected tissue, as well as antifungal therapy.

B. dermatitidis has the greatest propensity to cause symptomatic infection. In patients with disseminated blastomycosis, involvement of the GU tract occurs in as many as a third of cases and usually manifests as prostate or epididymal infection.[24] In most patients, this involvement is discovered incidentally when urine cultures yield the organism or a biopsy is performed for a prostatic or epididymal mass.

Symptomatic GU tract involvement with histoplasmosis is uncommon. However, at autopsy, kidney lesions are often found in patients who have disseminated histoplasmosis.[25] Patients are usually asymptomatic in regard to urinary symptoms. Individual cases of testicular abscesses, epididymitis, and prostate nodules have been reported.

Coccidioidomycosis rarely causes symptomatic UTI. However, autopsy series of cases of disseminated coccidioidomycosis have noted kidney involvement in more than 50% of cases.[26] The finding of *Coccidioides* spp. in the urine in such patients is not uncommon. Localized infection, manifesting as abscesses or mass lesions of the epididymis or prostate, also occurs in patients with disseminated coccidioidomycosis.

SELF-ASSESSMENT QUESTIONS

1. Which of the following *Candida* spp. is isolated *most* often in patients with candiduria?
   - **A.** *C. glabrata*
   - **B.** *C. parapsilosis*
   - **C.** *C. albicans*
   - **D.** *C. krusei*
   - **E.** *C. tropicalis*
2. The presence of pyuria is a helpful diagnostic test for *Candida* UTI when there is:
   - **A.** An indwelling bladder catheter in a symptomatic patient
   - **B.** An indwelling bladder catheter in an asymptomatic patient
   - **C.** Concomitant bacteriuria and candiduria in an asymptomatic patient
   - **D.** Concomitant bacteriuria and candiduria in a symptomatic patient
   - **E.** No indwelling bladder catheter and no bacteriuria
3. The dose of which of the following antifungal agents used to treat fungal UTI should be reduced in patients who have a creatinine clearance below 40 to 50 ml/min?
   - **A.** Amphotericin B
   - **B.** Flucytosine
   - **C.** Caspofungin
   - **D.** Liposomal amphotericin B
   - **E.** Voriconazole

The Kidney in Schistosomiasis

Rashad S. Barsoum, Tarek S. Fayad

Schistosomiasis is a parasitic disease usually acquired by teenagers, often leading to complications that may extend into the fourth and fifth decades of life. It was known to the ancient Egyptians as "the bloody urine disease"[1] and is also known as *bilharziasis* in honor of its discoverer, Theodor Bilharz, the German physician who practiced in Egypt in the 1850s.

The life cycle of the parasite is shown in Fig. 54.1. Infection is acquired through contact with contaminated waters in ponds and slow-flowing canals. Cercariae enter through the skin or mucous membranes and migrate through the lymphatics and blood circulation into the portal or perivesical venous system, where they mature into sexually differentiated adult worms and live in almost continuous copulation. Females leave the males only to lay eggs, and, traveling against the blood flow, reach the rectal or bladder mucosa. The ova are driven out by visceral contraction during defecation or urination. Contact with fresh water within a couple of days allows the eggs to hatch, releasing miracidia, which infect specific snails. In this intermediate host, the organisms mature asexually into cercariae, which are eventually released, searching for their definitive host, usually humans and occasionally apes and cattle. The snail demography defines the endemicity and frequency of schistosomiasis in different geographic regions, and is largely influenced by climatic factors such as temperature and humidity.[2]

About 200 million inhabitants of 78 countries on five continents are infected, and an additional 600 million are at risk. Of the infected persons, 60% are symptomatic, 10% have serious sequelae, and 1% die of the disease each year, mainly in China, the Philippines, Egypt, Brazil, northern Senegal, and Uganda. These numbers reflect the outcome of a significant decline in prevalence during the second half of the past century, as a result of mass treatment with tartar emetic during the 1960s, the extensive use of praziquantel during the 1980s, and its use in a World Health Organization–sponsored global mass treatment program starting in the late 1990s. The latter had already captured 90% of the target population by 2016 and resulted in eradication of schistosomiasis from Japan and the Lesser Antilles islands; transmission was halted in Tunisia and significantly reduced in China, Egypt, Morocco, Saudi Arabia, Brazil, Venezuela, and Puerto Rico. However, certain schistosomal strains—up to 82% in Senegal—are resistant to praziquantel. Such strains are responsible for incremental prevalence in several countries, and even spread to adjacent geographical regions in East and West Africa.

Of seven species that affect humans, three are responsible for almost all major morbidity from the disease: *Schistosoma haematobium* throughout Africa and adjacent regions; *Schistosoma mansoni* in Africa, South America, and the Caribbean; and *Schistosoma japonicum* in the Far East (Fig. 54.2). The other four human-pathogenic schistosomal species (*Schistosoma intercalatum, Schistosoma mekongi, Schistosoma guineensis,* and *Schistosoma mattheei*) have a patchy distribution in certain geographical locations, hence their limited impact on the global epidemiology of schistosomiasis.

S. haematobium affects the urinary tract, whereas *S. mansoni* and *S. japonicum* affect the colon and rectum, ultimately reaching the liver and inducing periportal fibrosis. Sporadically, all three species cause metastatic lesions when ova are driven by the bloodstream to the lungs, brain, spinal cord, heart muscle, eyes, and other sites.[3] Overall morbidity is variable and depends on the virulence of the infective strains, host resistance, environmental factors, and standards of primary medical care. For example, chronic lower urinary tract disease among infected subjects is reported to vary from 2% in Nigeria in the west of Africa to 52% in Tanzania in the east.[4]

PATHOGENESIS

Schistosomes cause morbidity through two major mechanisms: (1) local reactions around the ova deposited in different tissues and (2) systemic effects attributed to the host's response to circulating antigens released from the worms or the ova (Fig. 54.3).[4,5]

The local reaction is a cell-mediated immune response to soluble egg antigens diffusing out of trapped ova through micropores in the eggshell. The initial response is innate, being driven by tissue macrophages, and involves natural killer cells, neutrophils, and complement. This response is followed by a specific immune response orchestrated by T helper (Th) lymphocytes.

The schistosomal granuloma is composed of mononuclear cells, eosinophils, neutrophils, basophils, and fibroblasts, which are recruited and activated by a variety of Th lymphokines as well as specific chemoattractants of parasitic origin (Fig. 54.4). These cells are involved in the elimination of the parasite by direct phagocytosis (monocytes), lymphocytotoxicity (T lymphocytes), antibody-dependent cytotoxicity (eosinophils), and antibody- and complement-dependent cytotoxicity (neutrophils). Later, the granuloma is modulated by gradual switching from Th1 to Th2 activation, largely mediated by a change in the monokine profile that favors release of interleukin (IL)-4, which is associated with a phenotypic change of the committed tissue macrophages. At this stage, the intensity of the inflammatory reaction is reduced, and progressive fibrosis is induced largely through the release of IL-4, IL-5, IL-10, somatostatin, and transforming growth factor β. Further on, tolerance to the parasite is achieved by an established population of regulatory T cells, which develop under the combined influence of host- and parasite-derived mediators. With the final extinction of the inflammatory reaction, granulomas in the bladder, lower ureters, and seminal vessels heal with dystrophic calcification.[6,7]

The systemic immune response is primarily a humoral reaction to circulating schistosomal antigens, which originate mainly from the

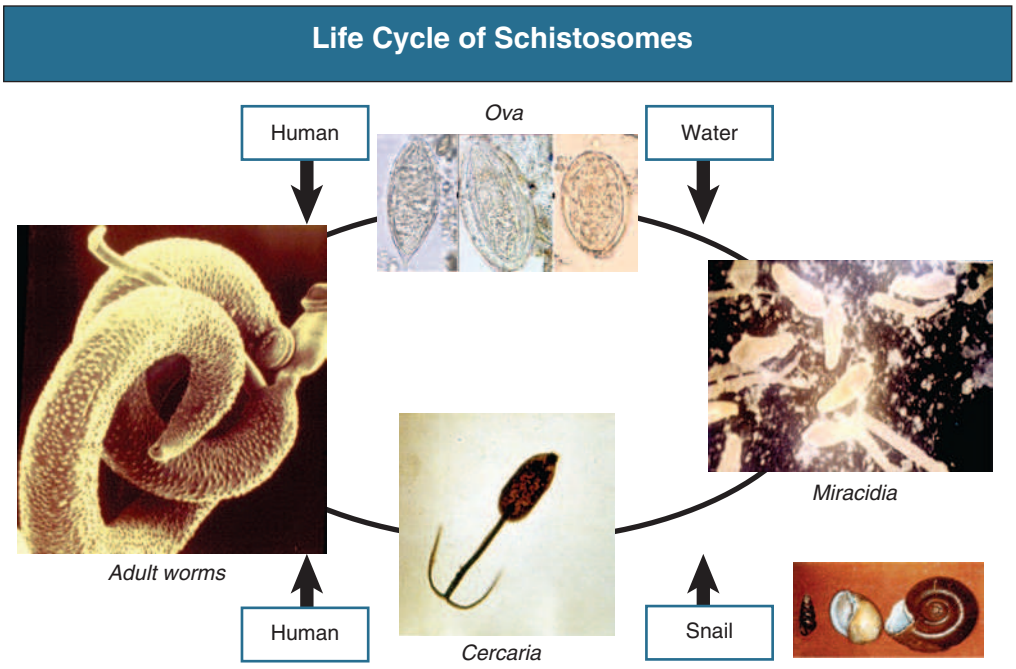

Fig. 54.1 Life cycle of schistosomes.

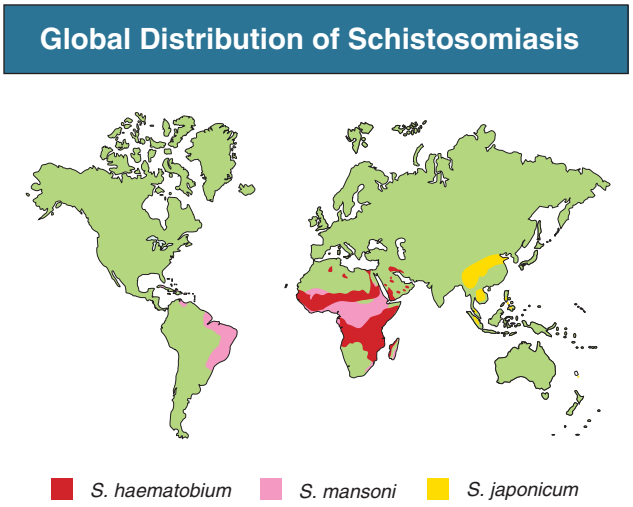

Fig. 54.2 World map showing the geographical distribution of the main pathogenic schistosomes.

worm's digestive enzymes (gut antigens), with a minor contribution from the tegument and ova. The gut antigens consist of a positively charged glycoprotein and a negatively charged proteoglycan (circulating cationic antigens and circulating anionic antigens, respectively). These antigens are present in most of the schistosomal immune complex–mediated lesions, particularly in glomeruli.[8] The antibody response is biphasic, reflecting the successive Th1 and Th2 stages of lymphocyte activation. In the Th1 stage, B cells tend to synthesize immunoglobulin M (IgM), IgG1, and IgG3 under the influence of IL-2. During the Th2 phase, IgG2, IgG4, and IgA predominate; these have a limited ability to fix complement and may even block its deposition, hence their importance in modulating the granulomas.[4,6]

CLINICAL MANIFESTATIONS

Schistosomal lesions in the urinary system mirror the two major pathogenetic mechanisms. On one hand, there are local lesions, mostly affecting the lower urinary tract, caused by the local granulomatous response to *S. haematobium* ova.[9] On the other hand are those lesions caused by immune complex deposition in the glomeruli, usually associated with hepato-intestinal *S. mansoni* and, less commonly, urogenital *S. haematobium* infections.[10] Although glomerular lesions can be readily induced by *S. japonicum* in experimental animals,[11] this species does not seem to cause significant kidney disease in humans.

Lower Urinary Tract Schistosomiasis

The lower urinary tract and adjacent genital structures are the primary sites of *S. haematobium* infection. Clinical disease starts by the coalescence of multiple granulomas that form small pseudotubercles in the bladder mucosa (Fig. 54.5). These may consolidate to form sessile, occasionally pedunculated masses or ulcerate, leading to painful terminal hematuria, the most typical presenting symptom. Hematuria may vary from microscopic (40% to 100% in different reports) to gross (0% to 97%).[12] Ulcers eventually heal by fibrosis, with calcified granulomas under the atrophic and dirty mucosa, leading to the characteristic cystoscopic appearance of sandy patches and also the radiologic appearance of linear bladder calcifications in 2% to 62% of cases.[12] Similar lesions may occur in the lower ureters, bladder neck, seminal vesicles, and other organs in the vicinity (Fig. 54.6).

The bladder lesions predispose to secondary bacterial infection, particularly with *Pseudomonas* or *Proteus* spp., usually after instrumentation. *Proteus* infection is notorious for favoring stone formation, which further complicates the scenario. The subsequent fibrotic process may involve the bladder neck, leading to outflow obstruction, or the vesicoureteral junction, leading to ureteral obstruction or vesicoureteral reflux. Involvement of the detrusor is a late event that may lead to an atonic or a hyperirritable bladder. Eventually, the bladder becomes a

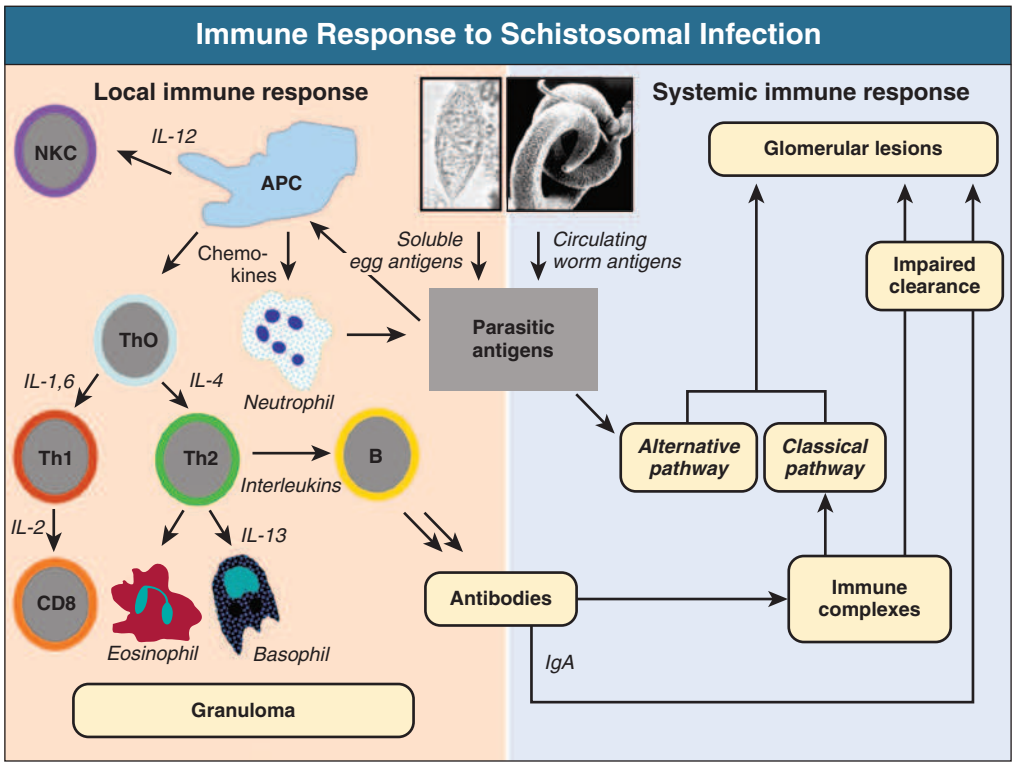

Fig. 54.3 Immune response to schistosomal infection. The local immune response to deposited ova leading to granuloma formation is shown on the *left;* all cells shown in the diagram, in conjunction with antibodies or complement, participate in eventual parasite elimination (see text). The systemic immune response is shown on the *right*; note the important role of impaired clearance of schistosomal antigens and IgA in the development of glomerular lesions. *APC,* Antigen-presenting cell; *IL,* interleukin; *NKC,* natural killer cell.

deformed, contracted, and calcified organ that accommodates a very small amount of urine that it can hardly void.

Bladder Cancer

Chronic bilharzial cystitis is precancerous. In a study of almost 10,000 Egyptian patients with bladder cancer, schistosomal association was confirmed in 55.3%. The predominant lesions were transitional cell carcinoma (65.8%) and squamous cell carcinoma (28.4%).[13] The tumor, particularly when of the squamous cell type, remains localized for a long time before spreading to the surrounding pelvic tissues or a distant site, thanks to the occlusion of lymphatics by the preceding fibrotic process.

Associated infection with high-risk human papillomavirus is encountered in about a third of cases,[14] which suggests an etiologic role in malignant transformation.[15] Specific *p53* gene mutations were detected in one third of cases.[16,17]

Development of malignancy is suspected when the symptoms of chronic cystitis exacerbate, along with recurrence of hematuria many years after the initial presentation and the passage of small pieces of necrotic tissue with urine (necroturia). A characteristic radiologic sign is the irregular "eating up" of the bladder calcification on a plain radiograph. Cystography shows the tumor mass as an irregular filling defect or bladder ulcer. Cystoscopy shows the tumor and provides the means for a histologic diagnosis (Fig. 54.7).

Upstream Consequences

Although ureteral strictures and calcifications are common, the hypertrophied upper ureteral musculature usually overcomes the lower obstruction, thereby limiting the upstream consequences. Nevertheless, hydronephrosis and progressive renal failure may develop when there is extensive ureteral scarring, in the presence of stones or secondary bacterial infection, or when the vesicoureteral junction is incompetent (Fig. 54.8). The frequency of upper urinary tract disease from *S. haematobium* is variably reported from different geographical regions—for example, from less than 10% in Niger to 48% in Cameroon.[10]

Interstitial Nephritis

Progressive renal scarring is the eventual outcome of complicated *S. haematobium* infection, resulting from obstruction, reflux, and bacterial infection. Granulomas have occasionally been seen in the renal interstitium but tend to be discrete and of no functional significance (Fig. 54.9). Immune-mediated tubulointerstitial nephritis has been described with *S. mansoni* in humans,[18] but the role of immune mechanisms remains questionable in *S. haematobium* pyelonephritis.

The typical pathologic picture is that of a deformed kidney with calyceal dilation, distortion, and atrophic parenchyma. Dense interstitial infiltration, fibrosis, and periglomerular scarring are present. The glomeruli may show ischemic collapse or other schistosomal lesions, such as proliferative glomerulonephritis (GN) or amyloidosis.

The clinical picture is that of chronic tubulointerstitial nephritis (see Chapter 62), often associated with residual manifestations of lower urinary tract involvement. Hypertension is a late feature, being checked by concomitant tubular salt wasting. Anemia and osteodystrophy may be disproportionately severe because of the associated secondary distal tubular acidosis and nutritional deficiency in endemic areas.

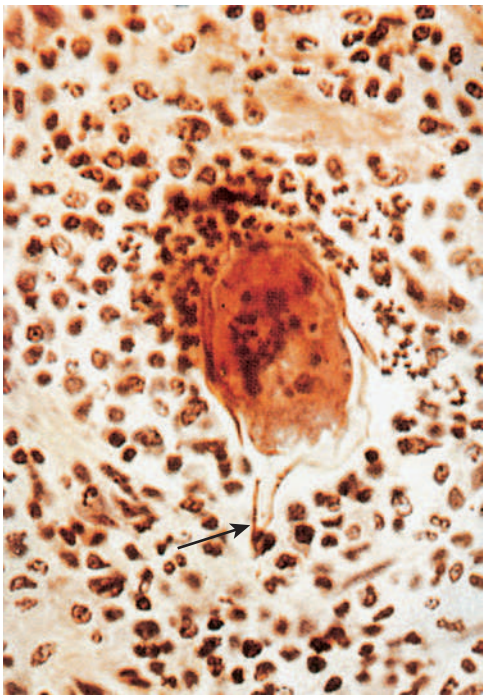

Fig. 54.4 ***Schistosoma haematobium*** **granuloma.** Note the egg's terminal spike *(arrow)*, which identifies *S. haematobium,* and the distortion of shell by proteases and oxidants released by the local neutrophil infiltration. (Hematoxylin-eosin stain, ×500.)

Glomerulonephritis

Immune complex–mediated GN has been described in experimental[11] and human[10] infection, mainly with *S. japonicum* and *S. mansoni*. The latter species accounts for most clinically significant disease in humans. *S. haematobium* GN is rare, transient, and usually subclinical.[19]

Schistosomal gut antigens are present in circulating immune complexes as well as in the immune deposits in mesangial, subendothelial, and intramembranous locations. The presence of liver fibrosis is critical because it results in impaired hepatic clearance of schistosomal antigens and immune complexes. These are mostly generated within the portal venous system, which accommodates the adult worms.

Most patients are 20- to 40-year-old men with evidence of hepatosplenic schistosomiasis. Renal involvement is asymptomatic in up to 40% of those, being identified by accidental or surveillance urinalysis, which may display various grades of proteinuria, or abnormal sediment. Some 15% of those with hepatosplenic schistosomiasis have overt GN, with proteinuria and microhematuria on presentation and with or without the nephrotic syndrome, hypertension, and impaired kidney function. Liver function test results are often normal. A polyclonal gammopathy is seen in most cases, whereas a monoclonal IgM response is seen in those with associated hepatitis C virus (HCV) infection and cryoglobulinemia. Rheumatoid factor activity and anti-DNA antibodies are detected in 5% to 10% of cases, particularly in association with *Salmonella* infection (see later discussion), but they do not correlate with clinical severity. Rheumatoid factor seropositivity is detected in much higher titers when HCV infection is associated.[20]

Six histologic classes of schistosomal GN are recognized (Table 54.1 and Fig. 54.10).[10,20] Class I (mesangial proliferative), class III (membranoproliferative), and class IV (focal segmental proliferative and sclerosing) result from the deposition of immune complexes representing different

stages in the evolution of pure schistosomal hepatosplenic disease. The main deposits in class I are schistosomal antigens, IgM, and C3; and in class III and class IV, IgG and IgA, usually without schistosomal antigens. The IgA deposits parallel the severity of proteinuria and mesangial proliferation. Impaired hepatic clearance and increased mucosal synthesis of IgA have been documented in those patients.[21] Whereas class I lesions are seen in most asymptomatic cases, class III and class IV are usually symptomatic and progressive, even with eradication of the parasitic infection.

Class II (diffuse proliferative and exudative) is associated with urinary or biliary coinfection with *Salmonella* strains, usually *Salmonella paratyphi* A in Africa and *Salmonella typhimurium* in Brazil, which are attached to specific receptors in the tissues of adult schistosomes. C3 and *Salmonella* antigens have been detected in the glomerular capillary walls and the mesangium. In these patients the clinical presentation is typical of acute postinfectious GN, associated with manifestations of *Salmonella*-related toxemia (fever, exanthema, and severe anemia).

Megaureter Resulting From Schistosomal Infection

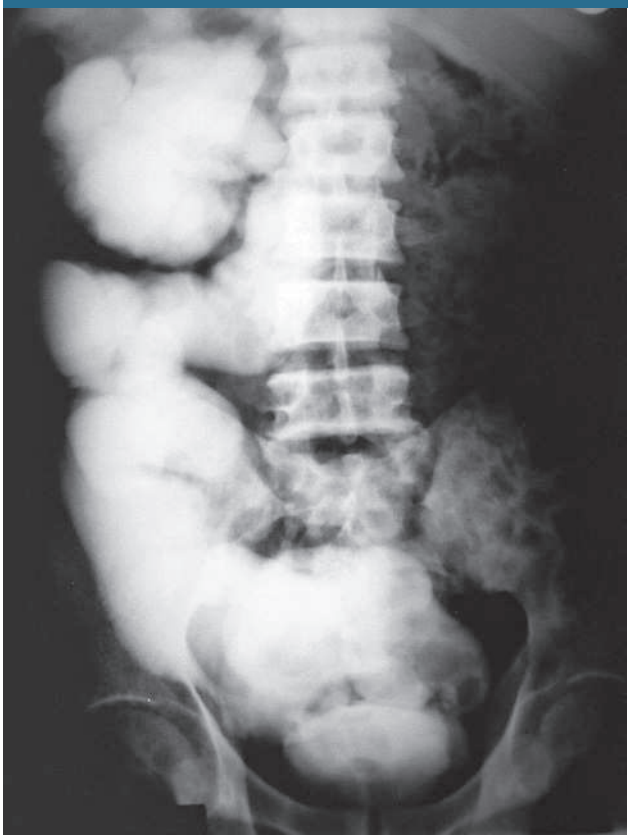

Fig. 54.8 Ascending cystogram showing right megaureter caused by vesicoureteral reflux.

Serum amyloid A protein deposits are detected by special stains or electron microscopy in up to 15% of biopsy samples from patients with class III and class IV, whereas AA-amyloidosis may be the predominant lesion (class V) in less than 5% of patients with clinically overt schistosomal GN. It occurs with heavy, often mixed infection regardless of

TABLE 54.1 Classification of Schistosomal Glomerulonephritis

Class	Histology	Immunofluorescence	Etiologic Agent	Prevalence	Clinical Findings	Treatment of Renal Disease
I	Mesangial proliferative GN	IgM, C3 Schistosomal gut antigens	*S. haematobium* *S. mansoni* *S. japonicum*	27%-60% of asymptomatic patients, 10%-40% of patients with renal disease	Microhematuria Proteinuria	May respond to antiparasitic treatment
II	Diffuse proliferative exudative GN	C3, *Salmonella* antigens	*S. haematobium* *S. mansoni* *plus Salmonella* spp.	*Salmonella* infections Reduced serum C3	Acute nephritic syndrome, toxemia	May respond to treatment of *Salmonella* and schistosomal infections
III	Membranoproliferative GN	IgG, IgA, C3, schistosomal antigens	*S. mansoni* (*S. haematobium*?)	7%-20% of asymptomatic patients and in 80% of patients with overt renal disease	Hepatosplenomegaly, nephrotic syndrome, hypertension, renal failure	No
IV	Focal segmental glomerulosclerosis	IgM, IgG (occasionally IgA)	*S. mansoni*	11%-38%	Hepatosplenomegaly, nephrotic syndrome, hypertension, renal failure	No
V	Amyloid	AA protein	*S. mansoni* *S. haematobium*	16%-39%	Hepatosplenomegaly, nephrotic syndrome, hypertension, renal failure	No
VI	Cryoglobulinemic GN	IgM, C3	*S. mansoni* + hepatitis C virus	Unknown	Hepatosplenomegaly, nephrotic syndrome, purpura, vasculitis, arthritis, hypertension, renal failure	Interferon plus ribavirin, corticosteroids, immunosuppression, plasma exchange

GN, Glomerulonephritis; *Ig,* immunoglobulin.

the anatomic site. Minimal amyloid deposits do not seem to alter the clinical presentation or prognosis, but typical class V lesions are grossly nephrotic and relentlessly progressive.

Class VI lesion was described in patients with hepatosplenic schistosomiasis and HCV infection.[20] This association is common, particularly in Egypt, where the virus may have been acquired decades earlier from intravenous injections used for mass treatment of schistosomiasis. The lesion consists of a mixture of mesangial proliferation, amyloid deposition, fibrinoid necrosis, and cryoglobulinemic thrombi in the glomerular capillaries with tubular casts. Patients have chronic hepatitis, cirrhosis, nephrotic syndrome, cryoglobulinemic skin vasculitis, polyarthritis, and rapidly progressive renal failure associated with severe protein-calorie malnutrition.

COINFECTION

Patients living in endemic areas may acquire one or more superimposed infections that can perturb schistosomal pathogenicity and modify its presentation. Mutually, schistosomiasis may modify the course of the confounding infection. The first reported coinfection is that of schistosomiasis and salmonellosis,[22] discussed earlier as class II schistosomal glomerulopathy. Likewise, class VI is attributed to coinfection with HCV. As mentioned earlier, superimposed papillomavirus infection is blamed in the pathogenesis of schistosoma-associated bladder cancer.

The list of other infections known to interact with schistosomiasis is expanding (Box 54.1). Some of the documented coinfections, namely those with plasmodium, filaria, mycobacterium tuberculosis, and staphylococci are clinically significant. However, they were not reported to modify the known renal lesions of schistosomiasis alone.

In addition to HCV, two viral infections—HIV and HBV infections—may modify the renal lesions in schistosomiasis.

Human Immunodeficiency Virus

Several recent studies have established an epidemiologic link between schistosomiasis and HIV infection. Women with lower urinary tract schistosomiasis are at significantly increased risk (odds ratio 2.9 in Zimbabwe[23] and 4.0 in Tanzania[24]) of acquiring and subsequently transmitting HIV to their sexual partners. Data on men with *S. hematobium*

infection or either gender with *S. mansoni* infection are inconsistent. There are no published data on *S. japonicum* and HIV coinfection

The immunologic perturbation induced by schistosomiasis seems to accelerate the progression and spread of HIV infection.[25] HIV coinfection leads to distortion of schistosomal granulomata, yet without known clinical sequelae. However, HIV-infected patients are more vulnerable to re-infection with schistosomes upon new exposure after successful eradication.[26]

There is some concern about the unexplained 3- to 16-fold increase of HIV viral load after treatment of schistosomiasis by praziquantel.[27] Fortunately, this effect is spontaneously reversible in a few weeks, and the benefit of eradicating the confounding parasitic infection on the clinical course and spread of HIV infection is unquestionable.[27]

Hepatitis B Virus

Vulnerability of patients with hepatosplenic schistosomiasis to coinfection with HBV is well documented in hospital-based,[28] but not in community-based,[29] studies, perhaps owing to the selection of complicated cases in the former. Such coinfection augments the liver injury induced by schistosomiasis,[30] leading to increased incidence of abnormal liver function (46.6%), jaundice (23.3%), hepatocellular carcinoma (17.8%), and liver-related mortality (23.3%).[31] It is unknown whether schistosoma and HBV coinfection influences the nature or severity of the renal lesions associated with either.

DIAGNOSIS

Schistosoma haematobium Urinary Tract Disease

The clinical diagnosis of lower urinary tract schistosomiasis is easily made, particularly in patients with the typical pattern of painful terminal hematuria after exposure to fresh river waters in an endemic area. Diagnosis is more difficult when the history of exposure is less convincing (e.g., swimming pools) or when the clinical presentation is atypical (e.g., bacterial pyelonephritis, typhoid, or amyloidosis).

The diagnosis is made by finding ova in a fresh urine sample, which is easy because of their abundance, large size, and typical appearance (see Fig. 54.4). Live ova, containing mobile miracidia, indicate active infection, whereas dead, calcified ova may continue to be shed from fibrotic lesions for many months or even years.

Serologic diagnosis is based on finding circulating schistosomal antigens or antibodies.[32] The circumoval precipitin test is most frequently used in clinical laboratories. Serologic diagnosis is useful for diagnosis in the absence of ova, which occurs with old infections when the worms are sterile but continue to release their antigens. Serologic tests are also useful in assessing the response to treatment because titers usually become negative within 3 to 6 months of complete eradication of infection.

A polymer chain reaction real-time assay is available for detection of the dra-1 *S. hematobium* antigen in the serum.[33] Owing to its high cost, its clinical use is limited to early detection of infection in expatriates visiting endemic areas.

The radiologic appearances of bladder and seminal vesicle calcification are so typical that no further confirmatory tests are needed in an endemic area. Cystoscopic findings are equally pathognomonic although seldom required. Early pseudotubercles are easily distinguished from mycobacterial infection by their size and the surrounding mucosal pathologic changes. The presence of sandy patches with associated masses, polyps, and even neoplasms makes the diagnosis. Tissue biopsy confirms the parasitic nature of the lesions. Different imaging techniques (e.g., ultrasound, intravenous urography, voiding cystography) are useful in the diagnosis of upstream complications, including obstruction and reflux (see Chapters 58 and 61).

The main differential diagnosis for urinary schistosomiasis is tuberculosis, which also causes hematuria, strictures, back pressure, and chronic kidney disease. This differential can be resolved with appropriate parasitologic and bacteriologic techniques (see Chapter 52).

SCHISTOSOMA MANSONI GLOMERULONEPHRITIS

Overt glomerular disease in patients with hepatosplenic schistosomiasis is suspected in those who develop hypertension, nephrotic or nephritic syndrome, or chronic kidney disease. Occult glomerular disease is indicated by the presence of abnormal urinary sediment or kidney function. Although renal biopsy is essential for diagnosis and classification, none of the lesions is pathognomonic unless schistosomal antigens are detected, which is unusual in clinically overt cases when sought with conventional immunofluorescence. Identification of *S. mansoni* eggs in the stools (Fig. 54.11) or submucosal rectal biopsy samples supports the diagnosis. Serologic tests for schistosomal gut antigens[34] and molecular tests for Sm1-7 antigens[35] are usually positive. However, it is important to remember that these tests only indicate schistosomal infection and do not necessarily implicate schistosomes as causing the kidney disease.

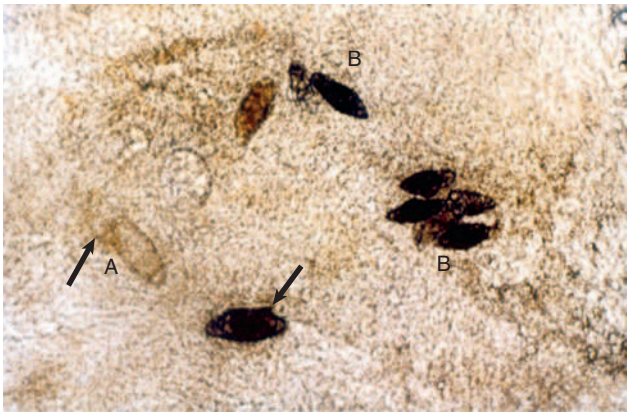

Fig. 54.11 Stool smears showing living *(A)* and dead *(B) Schistosoma mansoni* ova. Species are identified by the lateral spike *(arrows).*

Concomitant *Salmonella* or HCV infection can be detected by appropriate microbiologic tests. The various serologic abnormalities described are of limited diagnostic value, except the high rheumatoid factor, monoclonal IgM expansion, and low C4 that are typical of class VI.

Other glomerular disorders associated with hepatic fibrosis, such as secondary IgA nephropathy and hepatic glomerulosclerosis, should be considered in the differential diagnosis. However, in both these conditions the renal disease is rather mild, mainly with microhematuria at presentation but rarely with nephrotic-range proteinuria or impaired renal function. The glomerular deposits are mostly mesangial, in contrast to those seen in schistosomiasis, in which subendothelial and intramembranous deposits may also be present.

TREATMENT

Schistosoma haematobium Urinary Tract Disease

S. haematobium is susceptible to antimony compounds, organophosphates (metrifonate), and niridazole. The drug of choice is praziquantel, with a cure rate greater than 85% and the least toxicity. It is administered as a single oral dose of 40 mg/kg body weight, which may be repeated 2 weeks later if there is evidence of active disease. In infections resistant to praziquantel, the antimalarial *Artemisia annua* may be used as an alternative with equal effectiveness.[36] Antiparasitic treatment cures the early bladder disease, yet has no effect on sandy patches or other fibrotic lesions. Ureteral distension with radiologic evidence of hydronephrosis may be reversed in a few weeks after successful treatment.

Antibacterial therapy usually controls acute episodes of cystitis and pyelonephritis. However, it must be combined with simultaneous eradication of parasitic infection if still active, especially when the urinary bacterial infection is due to typhoid *(Salmonella typhi)*.

Chronic fibrotic lesions are difficult to treat. Surgery or the placement of stents may be necessary for the relief of an obstructive lesion. However, particular caution is required in dealing with the vesicoureteral junction to avoid induction of reflux. Several plastic procedures are available to restore the distorted ureteral, bladder, or urethral anatomy. Associated bacterial infections may require long-term low-dose antibiotics.

Chronic dialysis in such patients can be difficult owing to the negative effects of the associated schistosomal lesions in the liver, lungs, and other organs and the comorbid impact of undernutrition, viral infection, or malignant disease. The same factors can compromise outcomes of renal transplantation, with the additional risk for urinary leakage, which is many-fold higher than usual owing to the presence of fibrotic granulomas and anatomic distortion in the bladder wall. Reinfection with *S. haematobium* also has been described.[37]

Schistosoma mansoni Glomerulonephritis

S. mansoni is more resistant to treatment and may require higher doses of praziquantel (40 to 60 mg/kg body weight) or the use of oxamniquine (single dose of 15 mg/kg body weight in South America or 2 doses of 15 mg/kg body weight given 12 hours apart in Africa). Research is under way to overcome oxamniquine resistance, which is limiting its use in many geographical regions.[38] Nevertheless, eradication of the parasite can be curative only in classes I and II. In the latter, it must be combined with antibiotics for the control of *Salmonella* infection (usually quinolones, macrolides, or third-generation cephalosporins). Antischistosomal and immunosuppressive therapy are ineffective in all other classes of schistosomal GN.[10] No data are available on the course of class VI schistosomal glomerulopathy after treatment with anti-HCV direct-acting antiviral drugs.

Chronic dialysis may be complicated by the risk for bleeding from esophageal or gastric varices after anticoagulation. Endoscopy is essential before the start of regular hemodialysis, with prophylactic sclerotherapy

if necessary. Although peritoneal dialysis is viable for some, it is relatively contraindicated in those with significant ascites.

Renal transplantation is a viable option in those who develop end-stage renal disease, in the absence of major risk factors such as viral infection, undernutrition, or hepatic insufficiency. Uncomplicated residual hepatic fibrosis in the recipient does not seem to significantly modify the pharmacokinetics of immunosuppressive agents, but variations in cyclosporine blood levels can occur, perhaps secondary to altered gastrointestinal absorption.[37] Associated viral hepatitis may have a considerable impact on donor selection, choice of immunosuppression, and the eventual outcome (see Chapters 21, 55 and 102).

Recurrence of schistosomal GN after transplantation has been described in a few patients,[39] suggesting the persistent release of antigens from living worms. Although it is not an evidence-based practice, many authorities recommend the administration of a single dose of praziquantel to recipients known to have been previously infected with the parasite.

SELF-ASSESSMENT QUESTIONS

1. A 45-year-old male recent Egyptian immigrant to Canada presents with a 4-week history of pyrexia, abdominal discomfort, asthenia, and increasing generalized edema. His medical history includes two treatment courses for intestinal schistosomiasis. Examination shows significant pallor, facial puffiness, a faint macular itchy eruption on the forearms and abdominal wall, and bilateral soft pedal edema. Temperature is 38.7° C (101.7° F), and blood pressure is 100/70 mm Hg. The liver edge is felt 2 cm below the right costal margin, firm and moderately tender. The spleen is felt 5 cm below the left costal margin and acutely tender. Urinary protein is 14 g/g creatinine, and the sediment shows 20 to 25 white cells, 8 to 10 red cells, and a few blood casts per high-power field. Peripheral blood hemoglobin is 8.6 g/dl; leukocyte count is 14,300/μl, of which 85% are neutrophils with left shift. Rheumatoid factor is positive at 48 IU/l, C-reactive protein is 128 units, and C3 is 54 mg/dl. Aspartate aminotransferase (AST) is 75 IU/ml, alanine aminotransferase (ALT) is 62 IU/ml, and γ-glytamyl transferase (GGT) is 123 IU/ml. Serum albumin is 1.8 g/dl, serum creatinine is 2.1 mg/dl, and blood urea nitrogen (BUN) is 73 mg/dl. Which of the following is the *most* likely explanation for the patient's recent illness?
   A. Ascending pyelonephritis complicating neglected urinary schistosomiasis
   B. Schistosoma-associated *Salmonella* bacteremia
   C. Active hepatitis viral infection on top of hepato-intestinal schistosomiasis
   D. Schistosoma-associated secondary immunoglobulin A nephropathy
   E. Cryoglobulinemic vasculitis
2. A 50-year-old male Nigerian patient presents with severe burning during micturition, with passage of blood and necrotic tissue with urine for 2 weeks. He received treatment for urinary schistosomiasis 30 years previously and for recurrent urinary bacterial infection many times after that. Examination shows an ill man, with bilateral edema of the left lower limb. The left kidney is palpable and slightly tender. Rectal examination reveals a mass indenting the anterior rectal wall. Midstream urine examination shows a protein-to-creatinine ratio of 4 g/g, and uncountable red and pus cells. Serum creatinine is 4.3 mg/dl, and BUN is 103 mg/dl. The *most* likely cause of his edema is:
   A. Schistosomal glomerulonephritis
   B. Schistosoma-associated chronic pyelonephritis
   C. End-stage post-obstructive kidney disease
   D. Infiltrative bladder cancer
   E. Advanced prostatic cancer
3. A 38-year-old female Brazilian patient presents with painful swelling of the small joints of her hands, right knee, and left shoulder; bilateral soft lower limb swelling; and a raised brownish-purple macular skin eruption over the tibial shins. She has been under medical follow-up for compensated chronic hepatosplenic schistosomiasis. Urine examination shows a protein-to-creatinine ratio of 5.2 g/g, and the sediment shows many red cells, few leukocytes, and red cell and granular casts. Serum creatinine is 2.1 mg/dl; BUN is 26 mg/dl; serum albumin is 2.7 g/dl; serum C3 is 86 mg/dl, and C4 is 3.2 mg/dl. Rheumatoid factor is 256 IU/ml. ALT is 128 IU/l, AST is 9 IU/l, and GGT is 396 IU/l. Which of the following is the *most* likely diagnosis?
   A. Acute schistosomiasis
   B. Autoimmune hepatitis
   C. Schistosomal glomerulonephritis
   D. Concomitant virus-induced cryoglobulinemia
   E. Superimposed rheumatoid arthritis

Glomerular Diseases Associated With Infection

Cynthia C. Nast, Bernardo Rodríguez-Iturbe

More than 250 years ago, dark scanty urine was observed in the convalescent period of scarlatina. In the nineteenth century, Bright and others identified symptoms of nephritis in patients with scarlet fever. In the early 1900s, clinical observations by von Pirquet led him to propose that nephritis occurring after scarlet fever resulted from antibodies that were pathogenic, an insight that opened the field of immune-mediated renal disease. We now recognize that a wide variety of infectious organisms can induce a spectrum of glomerular lesions via differing pathogenetic mechanisms, including immune complex deposition, direct renal cell infection and injury, and sequelae of ongoing chronic inflammation (Table 55.1). Glomerular injury may occur as a consequence of resolved or ongoing infection; therefore the term *infection-related glomerulonephritis* (GN) is more accurate.[1] As demographics, access to health care, and public health conditions change, there are alterations in the epidemiology, clinical presentation, morphology, and therapeutic approaches to glomerular lesions associated with infectious organisms.[2] Table 55.2 shows microorganisms and their associated glomerular lesions.

BACTERIAL INFECTIONS

Poststreptococcal Glomerulonephritis

Etiology and Pathogenesis

Poststreptococcal GN (PSGN) is an immune complex–mediated lesion occurring after infection with a nephritogenic bacterial strain. There are three immunologic mechanisms likely involved in the glomerular injury associated with this infection; passive entrapment and deposition of circulating immune complexes, in situ immune complex formation associated with nephritogenic planted bacterial antigens or intrinsic antigens resulting from molecular mimicry, and deposition of nephritogenic bacterial antigens that activate plasmin resulting in local complement activation.[3-5] There are two known nephritogenic streptococcal antigens thought to be involved in PSGN immune complex formation. These include nephritis-associated plasmin receptor (NAPlr), characterized as glyceraldehyde-3-phosphate dehydrogenase, and streptococcal pyrogenic exotoxin B (SPEB) and its more immunogenic zymogen precursor (zSPEB).

Evidence for these mechanisms includes demonstration of NAPlr and SPEB in renal biopsy specimens of acute PSGN, and elevation of antibody titers to both antigens in most convalescent sera.[6] In a Japanese study, 92% of PSGN convalescent sera and 60% of sera from patients with uncomplicated streptococcal infections contained anti-NAPlr antibodies.[7] NAPLr has been localized to glomerular areas with plasmin-like activity but not with complement or immunoglobulin, suggesting the ability to bind plasmin locally producing glomerular inflammation and enhancing immune complex deposition.[4,7] SPEB also can bind plasmin, a possible common mechanism of action. However, unlike NAPlr, SPEB co-localizes with glomerular complement and IgG, suggesting participation in the immune-mediated glomerular damage.[5] SPEB is the only streptococcal nephritogenic antigen demonstrated in subepithelial "hump" electron-dense deposits characteristic of PSGN, possibly as a result of its cationic charge. Studies from Latin America and Central Europe demonstrated SPEB, but not NAPlr, in PSGN renal biopsy samples. In contrast, the group C *Streptococcus zooepidemicus* strain responsible for a Brazilian epidemic showed absence of the SPEB-related gene, suggesting that different streptococcal antigens induce PSGN in different ethnic groups.[8] Thus there likely are multiple nephritogenic antigens depending on the streptococcal species and genetic and other host factors.

PSGN is thought to occur when glomerular immune complexes or deposition of plasmin-activating nephritogenic bacterial antigens initiate an inflammatory cascade with local complement activation and recruitment of neutrophils and monocyte-macrophages. Subepithelial immune deposits (humps) develop associated with cationic antigens (e.g., SPEB) and result from dissociation of subendothelial immune complexes with transit and re-formation on the outer aspect of the glomerular basement membrane or in situ immune complex formation. Several issues remain unresolved. Immune complex disease generally results in classical complement pathway activation, yet C4 levels typically are normal and deposits have dominant C3. This may result from antigens, such as NAPlr, that activate the alternative pathway. C3Nef immunoglobulin G (IgG) antibodies, which activate the alternative complement pathway, have been demonstrated in sera of patients with PSGN. Bacterial antigen activation of the mannose-binding lectin complement pathway also has been postulated (see Chapter 16); however, individuals genetically unable to activate this pathway may still develop PSGN.

Autoimmune mechanisms may play a role in PSGN. Rheumatoid factors (especially IgG) and cryoglobulins have been found in 35% of patient sera in the first week of the disease. Rheumatoid factors similarly were demonstrated in PSGN renal tissue and kidney eluates from a fatal case. Loss of sialic acid from autologous IgG due to streptococcal neuraminidase or from binding of the IgG Fc fragment to type II Fc receptors in the streptococcal wall may induce anti-IgG reactivity.[6] This anti-IgG antibody may play a role in deposition of IgG-containing complexes. Additional manifestations of autoimmune reactivity include anti-C1q antibodies, particularly in severe cases, and rarely anti-DNA reactivity, antineutrophil cytoplasmic autoantibody (ANCA), and autoimmune hemolytic anemia.[6]

Epidemiology

PSGN is decreasing in incidence worldwide; however, it remains a problem in developing countries, with an incidence of 9.3 to as high as 28.5 in 100,000.[2,9] This likely is an underestimate, with the

TABLE 55.1 Pathogenetic Mechanisms of Infection-Related Glomerular Injury

Mechanism	Representative Microorganism	Supportive Evidence
Circulating immune complexes	*Streptococcus*	Circulating antibodies against SPEB and NAPlr antigens
In situ immune complex formation	*Streptococcus*	Identification of SPEB in subepithelial deposits in PSGN
Nephritogenic antigen deposition with complement activation	*Streptococcus*	Glomerular deposition of NAPlr with plasmin activity
Superantigen binding to APCs activates T cells and polyclonal B cells, inducing immunoglobulin production	*Staphylococcus*	Selective peripheral blood activation of TCR V_β repertoire
Direct renal cell infection	HIV, parvovirus	Virus identification in glomerular epithelial cells
Direct renal cell injury	Hepatitis B virus	HBV induces mesangial cell proliferation and type IV collagen production in vitro.
Cryoglobulin production	Hepatitis C virus (HCV)	IgM rheumatoid factor against the HCV E2 envelope protein

APCs, Antigen-presenting cells; *HIV,* human immunodeficiency virus; *NAPlr,* nephritis-associated plasmin receptor; *PSGN,* poststreptococcal glomerulonephritis; *SPEB,* streptococcal pyrogenic exotoxin B.

TABLE 55.2 Infectious Organisms Causing Glomerular Injury

Microorganism	Associated Glomerular Lesions*
Bacteria	
Gram Positive	
Streptococci	PIGN, MPGN, DDD, IgA-dominant IRGN
Staphylococci	IgA-dominant IRGN, ICMGN
Pneumococcus	DPGN, MPGN
Propionibacterium	MPGN, ICMGN (shunt nephritis)
Gram Negative	
Brucella	ICMGN
Campylobacter	DPGN, MesPGN
Escherichia coli	IgA-dominant IRGN
Hemophilus	IgAN
Klebsiella	DPGN, IgA-dominant IRGN
Legionella	Crescentic GN, PIGN, MesPGN
Meningococci	MesPGN, DPGN
Pseudomonas	MPGN, ICMGN (shunt nephritis)
Salmonella	MesPGN, IgAN
Serratia	MPGN, ICMGN (shunt nephritis)
Yersinia	IgAN, PIGN
Other	
Bartonella	Crescentic GN (endocarditis)
Coxiella	Crescentic GN (endocarditis)
Leptospira	Segmental glomerular necrosis
Mycobacteria	MPGN, ICMGN, DPGN, amyloidosis
Mycoplasma	ICMGN
Treponema	MN, MPGN, DPGN, MesPGN

Microorganism	Associated Glomerular Lesions*
Viruses	
Hepatitis A	MPGN, IgAN, MesPGN
Hepatitis B	MN, MPGN, MesPGN, IgAN, PIGN, FSGS, Amyloidosis
Hepatitis C	MPGN ± cryoglobulins, MN, fibrillary GN, immunotactoid GN, MesPGN, collapsing GP
HIV	Collapsing GP, FSGS, IgAN, ICMGN (including lupus-like), MCD
Parvovirus B19	Collapsing GP, ICMGN, IgAN, FSGS
Adenovirus	PIGN, MesPGN
Coxsackie B virus	Proliferative GN
Cytomegalovirus	MPGN, MesPGN, collapsing GP, MN, crescentic GN
Dengue	MesPGN
Epstein-Barr	Collapsing GP, MN, crescentic GN, MPGN, MesPGN
Hantavirus	MCD, MesPGN
Influenza	MesPGN, DPGN
Measles	DPGN
Mumps	MesPGN, DPGN
Rotavirus	MesPGN
Varicella	MesPGN, DPGN
Parasites and Protozoa (see Table 55.3 for more detail)	
Echinococcus	MN, MPGN
Filaria	MesPGN, MPGN, DPGN, MN, MCD, FSGS, amyloidosis
Malaria	MPGN, MesPGN, MN, IgAN, MCD
Leishmania	MesPGN, MPGN, amyloidosis
Schistosoma	MPGN, FSGS, MesPGN, MN, amyloidosis
With Salmonella	PIGN
Toxoplasma	MPGN, FSGS, MesPGN
Trichinella	MesPGN, MPGN
Trypanosoma	MesPGN, MPGN

*These are glomerular lesions described in humans. More infection-associated glomerulopathies have been identified in animal models. *Collapsing GP,* Collapsing glomerulopathy; *DDD,* dense deposit disease; *DPGN,* diffuse proliferative glomerulonephritis (may be exudative); *FSGS,* focal and segmental glomerulosclerosis; *ICMGN,* immune complex–mediated glomerulonephritis; *IgAN,* immunoglobulin A nephropathy; *IRGN,* infection-related glomerulonephritis; *MCD,* minimal change disease; *MN,* membranous nephropathy; *MesPGN,* mesangial proliferative glomerulonephritis; *MPGN,* membranoproliferative glomerulonephritis; *PIGN,* immune complex–mediated postinfectious glomerulonephritis.

actual incidence fourfold to fivefold higher because of subclinical cases. Over the past several decades, likely because of early antibiotic administration, the incidence of PSGN in children has decreased dramatically in developed countries, where it now is very infrequent; however, the incidence is increasing in older adults with comorbid conditions such as diabetes, alcoholism, and malignancy.[2,10] The higher incidence in developing countries and in alcoholics likely is associated with poor socioeconomic conditions, limited access to health care, delayed antibiotic administration, and a tropical climate.

PSGN is the most common finding in children with acute nephritis in developing countries and occurs sporadically or in epidemics. It typically affects those 2 to 14 years old, with a 2 : 1 male predominance, and represents a major problem in indigenous populations as in Australia, where more than 95% of the cases occur in aboriginal people residing in remote locations.[11] The risk for PSGN varies depending on the infection site and bacterial strain. The risk for developing PSGN ranges from 1% to 35%, averaging 15% after infection with a nephritogenic strain. Preceding skin infection confers a fivefold increased risk compared with that for throat infections, and risk reduction occurs with early antibiotic therapy. Epidemics have been associated with both sites of infection, as well as consumption of unpasteurized milk from cows infected with *S. zooepidemicus.* More cases of PSGN occur after impetigo caused by streptococci of M types 47, 49, 55, and 57 and with upper respiratory tract infections caused by types 1, 2, 4, and 12.[6] There also appears to be a genetic predisposition to developing PSGN, because of association with human leukocyte antigen (HLA)-DR4 and HLA-DR1, and siblings of sporadically affected patients have a 38% risk for developing clinical or subclinical glomerular disease.[10]

Clinical Manifestations

The presentation of PSGN differs in children and older debilitated adults. Children with symptomatic disease typically present with acute nephritis, including hematuria in virtually all patients, macroscopic hematuria in 30%, hypertension in 80%, edema in 80% to 90% (the chief complaint in 60%), and oliguria in 25% to 40%. Nephrotic syndrome occurs in only 2% and ascites is uncommon. In contrast, 20% of adults with PSGN have nephrotic syndrome, 83% have renal impairment, and 43% have congestive heart failure. Rapidly progressive renal failure with glomerular crescents occurs in less than 1% of children and adults. Asymptomatic subclinical cases have microscopic hematuria and transiently reduced complement levels. Serum CH50 is low and C3 levels are depressed in more than 90% of patients in the first week of disease; these normalize within 2 months of disease resolution. Levels of C1 and C4, indicating classical and lectin complement pathway activation, often are normal. Eighty percent have elevated IgG and IgM with normal IgA in contrast to rheumatic fever. Cryoglobulins, rheumatoid factor, and anti-C1q antibodies occur in up to one third of patients in the acute phase. Families may have various manifestations of PSGN; therefore inquiring about a family history of streptococcal infections and signs of glomerular disease is recommended.

Most patients give a history of a previous streptococcal infection, although it often has resolved at presentation. *Streptococcus* cultures are positive in 10% to 70% of cases during epidemics and in 20% to 25% of sporadic cases. Impetigo was more commonly associated with PSGN with a latent period of 2 to 4 weeks preceding glomerular symptoms. Pharyngitis now is the more frequently associated infection with a latent period of 7 to 10 days; however, skin infections predominate in group A streptococcal epidemics. Because cultures are often negative, antistreptococcal antibody levels are used to ascertain prior infection. The most widely used are antistreptolysin O (ASO) titers, which are increased in more than 65% of patients with PSGN after throat infections, and anti-DNAse B titers, which are elevated in 73% of postimpetigo cases. The more sensitive streptozyme panel measures anti-DNAse B, antihyaluronidase, antistreptolysin O, and antistreptokinase antibodies and is positive in more than 80% of patients. Antibody titers to NAPlr and SPEB/zymogen are more sensitive and specific, but currently are not clinically available.[6,9]

Pathology

Renal biopsy is not routinely indicated in PSGN but may be required to confirm the diagnosis when there are atypical clinical features such as nephrotic proteinuria, decreased C3 levels for more than a month (suggesting transformation to C3 GN or rarely to dense deposit disease), increasing renal dysfunction, or adult age. By light microscopy, renal biopsy typically shows diffuse proliferative GN characterized by endocapillary hypercellularity, including monocytes and often many neutrophils (exudative GN) with variable mesangial hypercellularity (Fig. 55.1). Less often or in the resolving phase, there may be a focal exudative pattern or mesangial proliferation; membranoproliferative GN (MPGN) is infrequent. Recent reports have identified NAPLr antigen in biopsy samples with MPGN features, raising the possibility of a more varied histologic presentation of PSGN than previously recognized. Small numbers of necrotizing and crescentic lesions are found in up to 50% of cases, whereas extensive involvement with crescents is unusual.[12]

Immunofluorescence is characterized by dominant C3 staining, and the pattern varies depending on the phase of the disease.[13] In acute and subacute disease the immune deposits are found in glomerular capillary walls and mesangial regions in a "starry sky" pattern, contain strong C3 with less frequent and intense IgG, and may have IgM in up to 50% of cases; IgA and C1q are not features of PSGN. The "garland" pattern is associated with numerous subepithelial hump deposits and heavy proteinuria, corresponding to active disease, although it has been described in later disease as well. As deposits are cleared in subacute to chronic injury, those in the mesangial regions remain the longest, resulting in a mesangial pattern with predominant C3 staining, loss of immunoglobulins and fewer infiltrating leukocytes (see Fig. 55.1). Although not part of routine renal biopsy assessment, properdin and the terminal membrane attack complex C5b-C9 have been identified in capillary wall and mesangial deposits.[14]

Electron microscopy (EM) demonstrates subepithelial individual hump deposits, which are typical, although not pathognomonic, of PSGN. These deposits may be infrequent or abundant and are preferentially sited where the capillary basement membrane reflects over the mesangium. GN resolves by clearing of the deposits and cell apoptosis. However, deposit fragments may remain for years with remote biopsy samples showing weak irregular granular glomerular staining for C3 with electron-lucent areas indicative of remote immune complex deposition.[15]

Differential Diagnosis

In a patient with typical symptoms and serologic findings, the diagnosis is straightforward. However, when there is oliguria lasting more than a week, azotemia lasting 2 weeks, hypocomplementemia lasting more than 1 month, or no clear history of preceding infection, renal biopsy is indicated to clarify the diagnosis. The renal biopsy differential diagnosis encompasses the spectrum of C3 dominant glomerulopathies and crescentic GN (see Chapter 22). C3 GN may appear morphologically indistinct from PSGN, including subepithelial humps, exudative GN, and weak immunoglobulin deposition. The rare case of dense deposit disease will demonstrate diagnostic electron-dense transformation of glomerular and tubular basement membranes. Correlating clinical findings and patient course with alternative complement factor and activity assessment may be required for a correct diagnosis. When there are glomerular crescents and a positive ANCA titer, the differential diagnosis

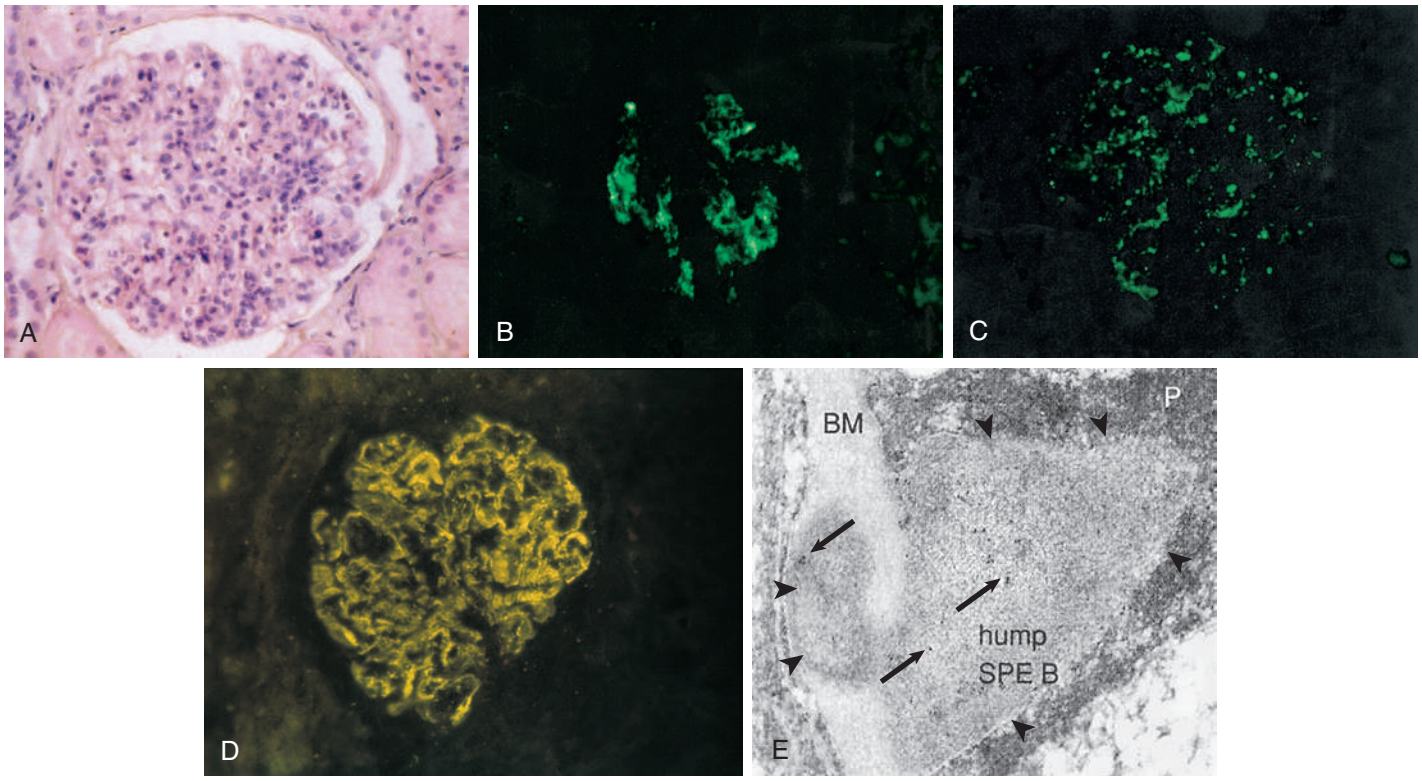

Fig. 55.1 Poststreptococcal glomerulonephritis (PSGN). (A) A diffuse proliferative and exudative GN can be seen with light microscopy. (B to D) Immunofluorescence showing the mesangial (B), starry sky (C), and garland (D) patterns. (E) Immune electron microscopy showing the characteristic subepithelial electron dense deposit (hump) with intramembranous extension (arrowheads), inside which streptococcal pyrogenic exotoxin B *(SPE B)* is demonstrated *(arrows)* (immunogold staining). *BM,* Basement membrane; *P,* podocyte. (Reprinted with permission from reference 5.)

is pauci-immune (ANCA-associated) crescentic GN; the diagnosis depends on identifying C3-containing electron-dense deposits in a pattern consistent with PSGN.

Natural History

Most children with PSGN recover with increased urine output by 1 week and resolution of clinical symptoms and serologic tests within 1 month. End-stage renal disease (ESRD) occurs in less than 1% of children observed for one to two decades after the acute attack.[9] After recovery, mild proteinuria (<500 mg/day) and microscopic hematuria may persist for up to 1 year without worsening the long-term prognosis. However, older patients with comorbidities have higher acute complication rates, including renal impairment, in 30% to 77%, with initially nephrotic patients at higher risk, congestive heart failure in 40%, nephrotic proteinuria in 20%, and mortality up to 30%.[9,16] Underlying alternative complement pathway dysregulation may represent a risk factor for progressive renal disease, leading to C3 GN, which is now thought to encompass most cases of atypical postinfectious GN. Certain epidemics also have reported a high incidence of chronicity, perhaps related to a predominance of affected adults, who tend to have worse outcomes.[17] A nephrotic presentation and persisting proteinuria also are associated with worse long-term prognosis. Studies in Australian aboriginal communities have shown that PSGN in infancy increases risk for subsequent albuminuria, hematuria, and chronic kidney disease (CKD).[16] The latter is attributed to a two-hit injury resulting from imposition of diabetes, metabolic syndrome, or low birth weight on early PSGN.

Treatment

Management includes culture and treatment of any persistent streptococcal infection. Early antibiotic treatment is likely to prevent PSGN, and prophylactic treatment of family members in high-risk communities or epidemic circumstances may be indicated. Treatment is with oral penicillin, intramuscular penicillin (a single intramuscular injection of 1.2 million units of benzathine penicillin in adults or half this dose in small children) erythromycin (in patients allergic to penicillin), or cephalosporins. Oral treatments should be given in doses every 6 hours for 7 to 10 days.[18] Treatment of acute nephritic syndrome includes fluid and sodium intake restriction and administration of loop diuretics for circulatory congestion. An oral long-acting calcium antagonist is usually sufficient to control hypertension. Intravenous medications may be indicated in exceptional cases with hypertensive emergency. Dialysis (hemodialysis or peritoneal dialysis) is required in 25% to 30% of adults but seldom in children. In those with acute tubular necrosis, supportive therapy should be provided; whereas those with PSGN complicated with crescents may benefit from pulse methylprednisolone. The prognosis of crescentic PSGN is significantly better than that for crescentic GN from other causes, but residual renal impairment occurs in more than half the cases.

IgA–Dominant Infection-Related Glomerulonephritis

Etiology and Pathogenesis

IgA-dominant infection-related GN (IRGN) is an immune complex–mediated lesion typically associated with *S. aureus* infections in

adult patients with underlying comorbidities.[19] Koyama and colleagues[20] suggested the pathogenesis involves staphylococcal enterotoxins functioning as superantigens that bind directly to the major histocompatibility complex (MHC) class II molecules on antigen-presenting cells. This enterotoxin–MHC class II complex engages the V_β T cell–receptor region, resulting in T cell activation and a cytokine burst, initiating a B cell polyclonal IgG and IgA response putatively against a *S. aureus* cell envelope antigen.[20] This antigen co-localizes with glomerular IgA deposits and induces mesangial deposits in an experimental model.

Epidemiology

IgA-dominant IRGN usually occurs in the setting of an ongoing (rather than a sequela of) infection in adults, with an average age of 58 and up to 41% over 65 years of age.[21,22] There is a male predominance, and most patients have comorbidities, including diabetes in up to 65% of patients, malignancy, heart disease, or alcohol or substance abuse.[10] The incidence is unknown, but IgA-dominant IRGN occurred in 1.6% of kidney biopsies in adults in one institution.[23] In developed countries, it has a 300% increased prevalence compared with that of PSGN, and many cases of IgA-dominant IRGN likely are asymptomatic and undiagnosed. Approximately 65% of patients are infected with methicillin-resistant *Staphylococcus aureus* (MRSA), and 25% have methicillin-sensitive *Staphylococcus aureus* (MSSA).[21] The most frequent sites of infection are the skin and viscera, including pneumonia, endocarditis, and osteomyelitis. Although less common, other pathogens such as *S. epidermidis, Streptococcus, Klebsiella,* and *Escherichia coli* have been associated with IgA-dominant IRGN.[10,19,22]

Clinical Manifestations and Pathology

Active disease often presents with acute or rapidly progressive renal failure, nephrotic range proteinuria in 50%, and universal hematuria with gross hematuria in 25%.[19] However, a mild clinical course is not uncommon, with subacute or chronic disease and delayed diagnosis due to underlying chronic disease in an elderly patient. Low C3 levels are found in 55% to 70% of patients, and serum IgA levels may be mildly increased.

Renal biopsy reveals endocapillary proliferative and exudative GN in 40% to 80% of cases, mesangial proliferative GN (MesPGN) in 20% to 60%, and crescentic GN in less than 5%.[20,24] Crescents are present in up to 35% and positive ANCA in 22%.[25,26] The deposits contain mild or intense IgA with co-dominant C3 staining in the same pattern and kappa light chain similar to or greater than lambda.[19,26] EM shows mesangial dense deposits in most cases, with up to 83% having variable numbers of subepithelial hump deposits and half with small and less frequent subendothelial deposits[2,25] (Fig. 55.2).

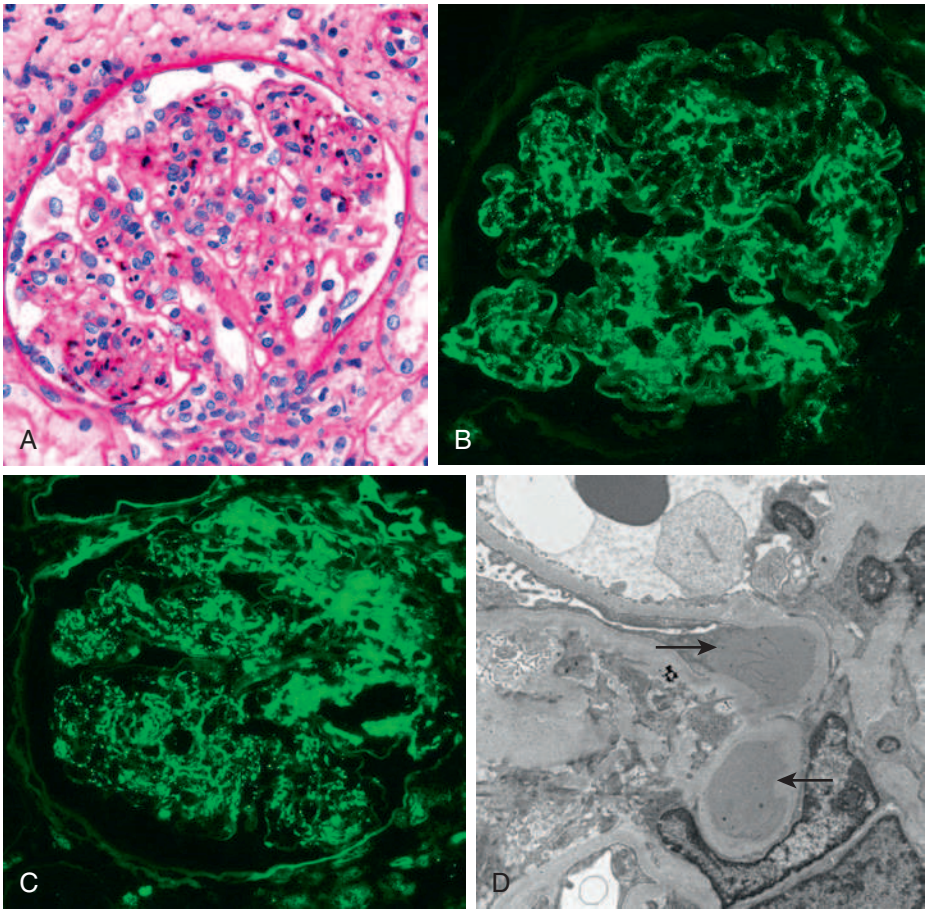

Fig. 55.2 IgA-dominant glomerulonephritis (GN) in a diabetic patient with methicillin-sensitive *Staphylococcus aureus* infection. (A) A diffuse exudative GN is present with neutrophil infiltration. (B) Immunofluorescence shows IgA irregular granular mesangial and capillary wall deposits. (C) Immunofluorescence shows C3 in a pattern similar to that of IgA. (D) Electron microscopy shows dome-shaped subepithelial deposit *(black arrow)* and mesangial deposit *(yellow arrow)*.

Differential Diagnosis, Natural History, and Treatment

Differentiation from IgA nephropathy is important for treatment and outcome. IgA-dominant IRGN is favored in the presence of associated staphylococcal infection, hypocomplementemia, severe proteinuria, and renal biopsy demonstrating deposits with strong C3 and IgA staining in the same pattern with kappa staining the same as or greater than lambda staining and subepithelial hump-shaped deposits. There is a worse outcome compared with IgA nephropathy, likely because of underlying comorbid conditions. There may be persistence of mesangial IgA deposits despite recovery from infection, possibly related to an underlying risk for IgA immune complex disease.

Active infection should be treated with appropriate antibiotics, and this may lead to renal functional recovery when there is ongoing infection. Corticosteroid treatment is contraindicated, at least during active infection, highlighting the importance of differentiation from IgA nephropathy, in which corticosteroids may be indicated in severe cases (see Chapter 23).

Endocarditis-Associated Glomerulonephritis

Etiology and Pathogenesis

Endocarditis may be an acute or subacute infection. The pathogenesis of endocarditis-associated GN involves the deposition of immune complexes containing bacterial antigens similar to that proposed for PSGN. It has been suggested that less virulent organisms with longer undiagnosed endocarditis predispose to immune complex formation and development of GN.[27] Polyclonal type III cryoglobulins are present in 50% of patients but rarely found in glomeruli. Some bacteria, classically MRSA, express superantigens that can activate T cells directly and lead to a polyclonal gammopathy and immune complex GN.

Epidemiology

The epidemiology of infective endocarditis (IE) has been changing over the last four decades. Historically, this disease affected young adults with rheumatic heart disease; however, it now occurs in older and at-risk patients, including drug users, prosthetic valve and implantable device recipients, and those with human immunodeficiency virus (HIV) and hepatitis C infection, diabetes, and health care–associated bacteremia.[27,28] *S. aureus* and *Staphylococcus epidermidis* are the most common pathogens in hospital-acquired IE, whereas *Streptococcus* infections are more frequent in community-acquired and native valve endocarditis, although the incidence of MRSA-associated community-acquired IE is increasing.[29] Gram-negative bacteria (*Enterococcus faecalis, E. coli, Brucella,* and *Proteus*) and HACEK microorganisms (*Haemophilus, Aggregatibacter, Cardiobacterium, Eikenella,* and *Kingella*) less frequently cause IE. Culture-negative IE is usually caused by *Coxiella burnetii, Bartonella* spp., and *Tropheryma whipplei* in untreated patients and by streptococcal spp. in those with prior antibiotic administration.[30] HACEK organisms require special laboratory procedures for isolation; if these are not used, infected patients will be culture negative. *Bartonella henselae* endocarditis is frequently associated with congenital valvular disease and exposure to cats. Polymicrobacterial infections are usually associated with drug abuse.

Clinical Manifestations

Patients often have fever, arthralgias, anemia, and purpura. Rarely, IE may manifest as primary renal disease without systemic symptoms. Classic findings such as Osler nodes, Janeway lesions, and splinter hemorrhages are seldom seen, and the diagnosis may be missed until autopsy in 38% of the patients.[27] Renal manifestations include reduction in kidney function, microhematuria, and mild proteinuria, with infrequent nephrotic syndrome or rapidly progressive GN. In recent studies, cardiac valvular disease occurred in only 30% of patients, involving the tricuspid valve in 43%.[28] Decreased C3 and C4 levels, elevated rheumatoid factor, circulating immune complexes, and type III cryoglobulins are identified in 50% of patients with IE. In patients who develop GN, there is more frequent hypocomplementemia, particularly C3, suggesting alternative complement pathway activation. However, complement levels may be normal in superantigen-mediated GN.[28]

Pathology

Studies examining autopsied kidneys from patients with IE demonstrated variable glomerular lesions in 7% to 17%, including crescentic GN, MPGN, and focal and diffuse PIGN patterns, although morphologic details are not uniformly provided.[27,31] Renal biopsy findings also are variable, with up to 45% of biopsies demonstrating GN, including 55% crescentic GN, approximately 35% diffuse or focal endocapillary proliferative GN or infrequently MPGN, and 10% MesPGN.[28,31] Immunofluorescence discloses C3 in all proliferative GN cases with IgG or IgA in mesangial regions in more than half and less frequently in capillary walls. Electron-dense deposits occur in 90% of all GNs, including mesangial in 85%, subepithelial hump-like in 49%, and subendothelial in 45%.[28,31]

Differential Diagnosis, Natural History, and Treatment

In crescentic GN with or without positive ANCA titers, hypocomplementemia should raise suspicion for underlying IE. Antibiotic treatment usually results in eradication of endocarditis and correction of serologic abnormalities. However, microhematuria, proteinuria, and renal functional impairment may persist for months after successful therapy. The overall mortality of IE is 20% and increases to 36% in patients who develop renal failure. Early diagnosis, risk stratification, and prompt antibiotic therapy are critical for an improved prognosis, with diminution of circulating immune complex levels correlating with better outcomes.[32] In patients with crescentic GN, pulse corticosteroid therapy and plasma exchange have been used in addition to effective antibiotic therapy, but the value of these treatments remains unconfirmed.

Shunt Nephritis

Etiology, Pathogenesis, and Epidemiology

Shunt nephritis is an immune complex GN. Ventriculoatrial shunts used to relieve increased intracranial pressure become infected in approximately 6% of adult patients. Ventriculoatrial shunts are used infrequently in children but have a similar rate of infection. GN develops in 0.7% to 2% of those with infected ventriculoatrial shunts 2 months to many years after insertion. The microorganisms are usually *S. epidermidis* and *S. aureus* and less frequently *Propionibacterium acnes,* diphtheroids, *Pseudomonas,* or *Serratia.* In contrast to atrioventricular shunts, ventriculoperitoneal shunts are rarely associated with GN.

Clinical Manifestations and Pathology

Children are most frequently affected, typically within 6 months of surgery, and have recurrent low-grade fever, arthralgias, weight loss, anemia, rash, hepatosplenomegaly, hypertension, and signs of increased intracranial pressure.[10] There also may be no signs of systemic infection. Microscopic hematuria is present in 90% of patients, often with nephrotic range proteinuria. Serologic findings include elevated rheumatoid factor, cryoglobulinemia, and decreased serum C3, less often with reduced C4, and occasionally positive PR3-ANCA titers. Cerebrospinal fluid may demonstrate eosinophils. Renal histology shows MPGN type I in nearly 60% of the cases and MesPGN in the remainder. IgM, IgG, and C3 with electron-dense deposits are present in subendothelial and mesangial regions.

Natural History and Treatment

Treatment requires antibiotic therapy and prompt removal of the infected ventriculoatrial shunt, which is usually replaced by a ventriculoperitoneal shunt. Delay in diagnosis and shunt removal worsens the renal prognosis. If dialysis is required, hemodialysis is preferred because peritonitis carries the risk for meningitis in patients with a ventriculoperitoneal shunt. Complete recovery occurs in more than half of the patients, 22% have persistent urinary abnormalities, and 6% develop ESRD.

Glomerulonephritis Associated With Other Bacterial Infections

Osteomyelitis and intra-abdominal, pelvic, pleural, and dental abscesses can be associated with GN, typically when infection has been present for several months. Renal disease varies from mild urinary abnormalities to rapidly progressive GN, with nephrotic syndrome the most frequent presentation. Unlike in other infection-associated GNs, complement levels are often normal. Renal histologic examination reveals MPGN, diffuse proliferative GN, MesPGN, or IgA-dominant IRGN, as discussed previously. Crescents may be present. Antibiotic treatment may result in recovery of renal function if it is started early.

Congenital, secondary, or early latent syphilis may be associated with GN. In congenital syphilis, nephrotic syndrome may be the primary clinical manifestation, with anasarca occurring 4 to 12 weeks after birth. Renal involvement is rare in acquired syphilis; when it ensues, the presentation is nephrotic syndrome or occasionally acute nephritis with positive serologic test results for syphilis. Membranous nephropathy (MN) is the most common glomerular finding, but diffuse proliferative GN with or without crescents, MPGN, and MesPGN have been observed. Treponemal antigens have been identified in the immune deposits. Syphilitic GN responds to antibiotic treatment, although remission may not occur for 4 to 18 months.

Acute typhoid fever from *Salmonella typhi* is characterized by fever, splenomegaly, and gastrointestinal symptoms. In severe cases, patients rarely may develop disseminated intravascular coagulation or thrombotic microangiopathy. Microhematuria and mild proteinuria are found in 25% of patients with MesPGN.[33]

Leprosy (*Mycobacterium leprae* infection) is calculated to affect 10 to 15 million patients worldwide, with up to 45% having glomerular diseases. GN is immune complex–mediated with frequent hypocomplementemia. Non-nephrotic to nephrotic range proteinuria occurs in 2% to 68% and renal dysfunction in 4% of patients.[34,35] Nephrotic syndrome is rare and usually associated with amyloidosis, often with erythema nodosum.[35] Prospective studies indicate that on follow-up, serum creatinine is elevated in 35% of patients at some time during their course and patients frequently have hypertension and nonsteroidal antiinflammatory drug use before beginning multidrug therapy. Renal biopsy samples show proliferative GN and MN with similar frequencies, whereas in autopsy studies, 4% to 31% have amyloidosis and 5% to 14% demonstrate MPGN or diffuse proliferative GN with IgG, C3, and less frequently IgM, IgA, and fibrin deposition.[33] The incidence of renal impairment decreases to 9% after 8 months of multidrug therapy

Pneumococcal pneumonia is rarely associated with microhematuria and proteinuria, seen with delayed treatment. Diffuse proliferative GN and MPGN have been reported, and pneumococcal antigen is present in the immune deposits. *Streptococcus pneumoniae* is rarely associated with hemolytic uremic syndrome because of unmasking of the glomerular and erythrocyte Thomsen-Friedenreich antigen by pneumococcal neuraminidase A, which allows preformed antibodies to bind and elicit an immune response.

Gastroenteritis caused by *Campylobacter jejuni* may be associated with MesPGN or diffuse proliferative GN. Other bacteria, including *E. coli, Yersinia,* meningococcus, and *Mycoplasma* pneumonia may induce GN in this setting (see Table 55.2).

VIRAL INFECTIONS

Glomerular injury can occur in a number of viral infections, primarily hepatitis B virus (HBV), hepatitis C virus (HCV), and HIV. These may occur with acute or chronic infection, depending on the virus and host response, including genetic risk factors such as *APOL1*. The advent of better antiviral therapeutic agents has modified associated glomerulopathies and improved prognoses for patients with virus-associated GN.

Hepatitis A–Associated Glomerulonephritis

Renal involvement is uncommon in patients infected with hepatitis A virus (HAV). IgA nephropathy has occurred temporally associated with HAV, with simultaneous resolution of the viral infection and GN suggesting a causal relationship. There are case reports of MesPGN and MPGN, including with dominant IgA. There is experimental evidence for HAV-associated mesangial proliferation and immune complex GN, further supporting causation in humans. Patients present with microscopic hematuria and non-nephrotic proteinuria or may be nephrotic, particularly in association with MPGN. Recovery from GN usually coincides with recovery from the viral infection.

Hepatitis B–Associated Glomerular Lesions

Etiology and Pathogenesis

HBV is a DNA virus of the Hepadnaviridae family and contains the hepatitis B surface antigen (HBsAg), hepatitis B core antigen (HBcAg), and hepatitis B e antigen (HBeAg), which is a splice variant of the core antigen. HBV causes immune complex–mediated glomerular injury predominantly through deposition of circulating immune complexes that have been identified in the serum of infected patients with GN. These immune complexes contain all three major hepatitis B antigens. Different antigens are associated with specific immune complex locations, likely related to their size and charge. HBeAg occurs in smaller cationic subepithelial immune complexes in MN. The larger HBcAg and HBsAg typically deposit in subendothelial and mesangial regions.[36] In situ immune complex formation may occur associated with locally expressed HBcAg, evidenced by identification of glomerular HBcAg and its corresponding RNA. There also is evidence of direct viral injury to glomerular cells, because HBV induces mesangial cell proliferation and increased expression of type IV collagen production in vitro. There likely are contributing host factors, including MHC class II risk alleles.

Epidemiology

Chronic HBV infection is defined as persistence of HBsAg-positive serology without IgM antibodies to HBcAg.[37,38] Persistent infection occurs in 0.1% to 15% of those with HBV infection and afflicts approximately 350 million people worldwide, who often are symptomatic. HBV infection becomes chronic in more than 90% of infants, 25% to 50% of children infected between 1 and 5 years of age, and 6% to 10% of older children and adults. Vertical transmission (maternal-infant) often occurs in endemic areas, such as China and Southeast Asia. Horizontal transmission follows blood contamination or direct mucous membrane contact. The prevalence of HBV infection is lower in Europe and the United States, with most carriers becoming infected as adolescents or adults by horizontal transmission because of drug abuse, blood transfusions, or sexual relations.

Clinical Manifestations and Pathology

Acute HBV infection may cause nausea, vomiting, fever, hepatomegaly, and a short-lived serum sickness–like syndrome with urticaria,

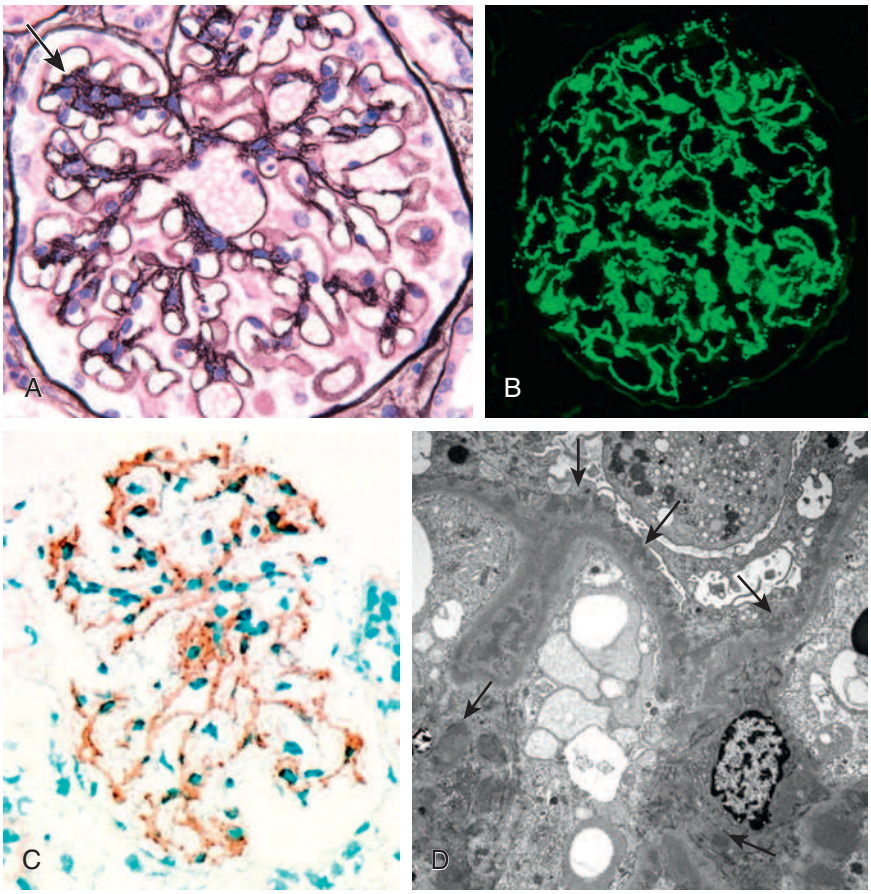

Fig. 55.3 Hepatitis B–associated membranous nephropathy (MN). (A) Capillary walls are irregular with small subepithelial spikes, and there is segmental mesangial hypercellularity *(yellow arrow)*. (B) Immunofluorescence shows granular IgG along capillary walls and segmentally in mesangial regions. (C) Immunohistochemistry is positive for HBsAg within glomerular deposits. (D) Electron microscopy shows subepithelial *(black arrows)* and mesangial (*yellow arrows)* deposits

maculopapular rash, neuropathy, arthralgias, arthritis, microscopic hematuria, and non-nephrotic proteinuria.[37] There are no published renal biopsy studies in acute infection, and renal symptoms resolve in 1 to 2 months in concert with recovery from the viral illness.

In chronic HBV infection, 3% to 5% of patients develop renal disease; additionally, 10% to 30% of patients with chronic HBV are coinfected with HCV and 5% to 10% with HIV.[36]

Hepatitis B Virus–Associated Membranous Nephropathy

MN is the most common glomerular disease in chronic HBV carriers. Children usually present between 6 and 12 years of age, show a strong male predominance, and often have asymptomatic proteinuria or nephrotic syndrome, microhematuria, normal renal function, and minimal liver disease.[37] The prognosis is usually good, and spontaneous remission is common associated with the appearance of circulating anti-HBeAg antibodies. Adults develop proteinuria or nephrotic syndrome, often with impaired kidney function and clinically apparent liver disease; approximately 30% will progress to CKD and 10% to ESRD. Hypocomplementemia occurs in less than half the patients.

Renal histologic examination shows MN, including subepithelial deposits in any stage of progression (Ehrenreich and Churg stage I to IV) depending on chronicity of the lesion. In contrast to primary MN, there often are mesangial hypercellularity and mesangial and/or subendothelial deposits indicative of secondary MN but not unique to HBV (Fig. 55.3). Endocapillary hypercellularity and endothelial cell tubuloreticular inclusions may be found. Circulating antiphospholipase A2 receptor (PLA2R) antibodies and PLA2R in subepithelial deposits typically are associated with primary MN and are not usual features of HBV-associated MN, although there are reports of PLA2R in HBV-associated MN, including co-localization with HBV antigens in glomerular deposits.[1] This appears to occur in HBV endemic areas in Asia, and the significance of this observation remains to be determined. Determination of IgG subclasses in glomerular deposits may be helpful because IgG1 usually predominates in secondary MN whereas IgG4 is dominant in primary MN. HBeAg and HBsAg may be identified in glomerular deposits and HBeAg in eluted proteins, but these are not standard procedures (see Fig. 55.3).

Hepatitis B Virus–Associated Membranoproliferative Glomerulonephritis

MPGN is the second most frequent HBV-associated glomerular lesion, more commonly found in adults. Patients present with nephrotic or less frequently non-nephrotic proteinuria and microhematuria; half are hypertensive and 20% have reduced renal function.[36] This pattern is associated with serum HBsAg and HBcAg and reduced serum C3 and C4 levels. Cryoglobulinemia, predominantly type III, occasionally occurs in HBV-infected patients but is more prevalent with concurrent HCV infection and found in 10% of the population worldwide.[1] Renal biopsy shows MPGN type I, or type III if there is concomitant MN.

HBsAg has been identified in eluted immune deposits from HBV-associated MPGN.

Other Hepatitis B Virus–Associated Glomerular Lesions

There are several reports of IgA nephropathy (IgAN) associated with HBV infection, including one in which a sustained remission of the clinical symptoms followed successful HBV treatment with pegylated interferon. However, other studies have shown no difference in outcome for patients with IgAN with and without HBV infection. This may be coincidental, because IgAN has a high prevalence in HBV endemic areas in Asia and mesangial IgA deposits occur in chronic liver disease secondary to impaired clearance of IgA circulating immune complexes (see Chapter 23). There is a recent report of PIGN in 10 patients with chronic HBV infection and all three HBV antigens in the serum.[39] Glomeruli demonstrated typical PIGN, although with fewer subepithelial humps compared with PSGN; HBsAg and HBV DNA were detected in glomeruli. AA amyloidosis is associated with chronic inflammatory diseases and has been identified in patients with chronic HBV infection, including children. The presentation is proteinuria or nephrotic syndrome, with amyloid infiltration of glomeruli, vessels, and less often the tubulointerstitium. There is one case report of collapsing focal segmental glomerulosclerosis (FSGS) associated with HBV infection and HBV DNA in shed urinary podocytes, suggesting direct infection with HBV. After entecavir therapy, HBV infection improved and the collapsing FSGS resolved.

Polyarteritis Nodosa

This vasculitis has been associated with HBV infection and is discussed in Chapter 25.

Treatment

Treatment should be considered when the HBV DNA level is greater than 2000 IU/ml, serum alanine aminotransferase (ALT) levels are elevated, and liver biopsy or other diagnostic tests show moderate to severe hepatitis and/or moderate fibrosis.[40,41] Newly diagnosed HBeAg-positive patients with normal liver function should be watched for 3 to 6 months to allow for spontaneous seroconversion. Treatment options include pegylated interferon, nucleotide analogues (lamivudine, entecavir, tenofovir, adefovir, telbivudine), or a combination of these agents. Dose adjustment is required with reduced renal function. Interferon should not be used in decompensated disease because of severe adverse effects. Standard interferon doses are 5 MU daily or 10 MU 3 times per week and pegylated interferon is given for 12 to 24 weeks in HBeAg-negative patients and 16 to 32 weeks in HBeAg-positive patients. Interferon treatment has resulted in improvement of HBV-associated MN; however, pegylated interferon-α2a may induce MN after several months of treatment.

Lamivudine 100 mg orally once daily for 52 weeks is frequently used as initial therapy and results in 75% to 80% resolution of MN in association with reduction of serum HBV DNA. However, there is a 20% annual rate of resistance, which may worsen renal disease. Dosing should be adjusted for renal function: creatinine clearance (CrCl) 30 to 49 ml/min: 100 mg first dose, then 50 mg/day; CrCl 15 to 29 ml/min: 100 mg first dose, then 25 mg/day; CrCl 5 to 14 ml/min: 35 mg first dose, then 15 mg/day; CrCl less than 5 ml/min or hemodialysis: 35 mg first dose, then 10 mg/day (after dialysis).[42]

Entecavir monotherapy is used in treatment-naïve patients and those refractory to lamivudine who cannot tolerate tenofovir. Entecavir confers less resistance, better seroconversion, and normalization of liver function and histology compared with lamuvidine or adefovir. Entecavir dosing is 0.5 mg/day and requires adjustment for reduced renal function: CrCl 30 to 50 ml/min: normal dose every 48 hours; CrCl 10 to 29 ml/min: normal dose every 72 hours; and CrCl less than 10 ml/min: normal dose every 7 days or after hemodialysis for patients on chronic dialysis.[42] Treatment should be maintained for 12 months after seroconversion and demonstration of undetectable HBV DNA, except in patients with cirrhosis in whom discontinuation carries the risk for fatal hepatitis. Tenofovir is used as initial therapy or in patients with resistance to other drugs. The main tenofovir adverse effects are reduced bone density and nephrotoxicity. Tenofovir 300 mg should be given once daily, or every 48 hours or every 72 to 96 hours if the CrCl is less than 50 ml/min or less than 30 ml/min, respectively. In patients on chronic dialysis, 300 mg should be given after dialysis once weekly.[42] Adefovir has been used in HBV resistant to lamivudine, but it has been replaced by tenofovir, which is more potent and effective.[42]

Drug combinations have been used with variable success. Lamivudine and interferon improved seroconversion and liver histology findings. Interferon and telbivudine should not be used together because of the risk for peripheral neuropathy. Kidney Disease: Improving Global Outcomes (KDIGO) guidelines recommend treatment with the previously mentioned agents for patients with HBV infection regardless of glomerular involvement. It has been argued that corticosteroid and immunosuppressive agents should not be used because they are ineffective and may delay or prevent seroconversion and accelerate the progression of liver disease. However, a meta-analysis of 12 clinical trials with 317 patients found that combined antiviral and immunosuppressive therapy can improve proteinuria in HBV-associated GN without altering HBV replication or damaging liver or renal function.[43]

Children with HBV-associated MN often have a benign course, with up to two thirds achieving spontaneous remission 4 years after disease onset. In contrast, approximately 30% of adults develop CKD. Therefore treatment generally is not required for children with HBV-associated MN. However, in controlled studies, clearance of HBV DNA and HBeAg was achieved in about half of the children, with more proteinuria resolution in the treated group. Because HBV-associated MN rarely progresses to ESRD in children, it is reasonable to treat when proteinuria is severe or kidney disease progresses. Treatment consists of a short course of corticosteroids (prednisone 1 mg/kg/day for 2 weeks) and plasma exchange (9 to 12 exchanges during 3 weeks) followed by interferon-α therapy or oral antiviral agents as indicated earlier.

Hepatitis C–Associated Glomerular Lesions

Etiology, Pathogenesis, and Epidemiology

HCV is an RNA virus of the Flaviviridae family and a common cause of chronic hepatitis, cirrhosis, and hepatoma. Up to 90% of infected patients have chronic infection, with HCV proteins inducing a polyclonal antibody response and development of immune complexes. HCV RNA has been detected in glomerular mesangial and endothelial cells and immune complexes, and Toll-like receptor 3 may play a pathogenic role in the development of GN.[44] In association with immune complex production, the HCV E2 envelope protein can induce an IgM rheumatoid factor response, with resulting cryoglobulins.[36] HCV thus induces a variety of glomerular lesions, most often MPGN with or without cryoglobulins (see Chapter 21). An estimated 170 million people in the world have chronic HCV infections, and renal disease is not common in this population, although the true incidence is unknown.

Clinical Manifestations and Pathology

Most patients with HCV-associated renal disease are asymptomatic. When symptoms occur, they include nephrotic syndrome in 20%, nonnephrotic proteinuria, nephritic syndrome in 25%, microscopic hematuria, and refractory hypertension in more than half. Low complement levels are common.[36] HCV infection may be associated with MPGN, MN, mixed cryoglobulinemia syndrome, and other lesions.

Hepatitis C Virus–Associated Membranoproliferative Glomerulonephritis

MPGN is the most frequent renal lesion associated with HCV infection, and most patients have cryoglobulins, although these may not be identified on renal biopsy. The presence of GN also may relate to host factors such as age and HLA polymorphisms. Renal biopsy discloses MPGN type I or type III if there is a MN component. When cryoglobulins are present, there are large protein thrombi occluding glomerular capillaries associated with marked endocapillary hypercellularity because of infiltrating monocytes (Fig. 55.4). Cryoglobulin deposits are in the subendothelium or form protein thrombi with a substructure consisting of 20- to 30-nm curvilinear microtubular, annular, fibrillar, or cylindrical forms, which also may be found in monocyte secondary lysosomes.

A limited number of patients with HCV infection develop mixed cryoglobulinemia, which is a systemic vasculitis associated with purpura, arthralgias, fever, neuropathy, and renal disease. Cryoglobulins are usually type II and occasionally type III, with HCV RNA and HCV antigen-antibody complexes present in the cryoprecipitate. C3, C1q, and particularly C4 are reduced. This is also discussed in Chapter 21.

Hepatitis C Virus–Associated Membranous Nephropathy

There is an association between MN and hepatitis G virus (HCV) infection and these likely are linked, although conflicting data exist regarding pathogenesis. Patients with MN are more commonly HCV RNA–positive compared with other GNs, except for MPGN, and MN appears more prevalent in HCV-positive transplant recipients, supporting this association.[44] MN has been found to have a similar incidence in HCV-infected and diabetic patients; however, MN also may be increased in the setting of diabetes. The clinical and renal morphologic findings are similar to those observed in idiopathic MN. Cryoglobulins, rheumatoid factor, and hypocomplementemia are absent.

Polyarteritis Nodosa

Polyarteritis nodosa may occur in patients with HCV infection with or without cryoglobulinemia (see Chapter 25).

Other Hepatitis C Virus–Associated Glomerular Lesions

Other reported associated glomerular lesions include fibrillary GN, immunotactoid GN, FSGS including the collapsing variant (especially in African Americans), and MesPGN.

Natural History and Treatment

In a large Italian study, 80% of patients had mild urinary or renal functional changes and 15% developed ESRD. Guidelines for HCV infection treatment have been published by the World Health Organization, the American Association for the Study of Liver Diseases, and the Infectious Diseases Society of America (www.hcvguidelines.org).[45] Interferon-free regimens are preferred because they have a 95% or higher virologic response (absent HBV RNA 3 months after treatment suspension) and minor side effects. Ledipasvir 90 mg and sofosbuvir 400 mg

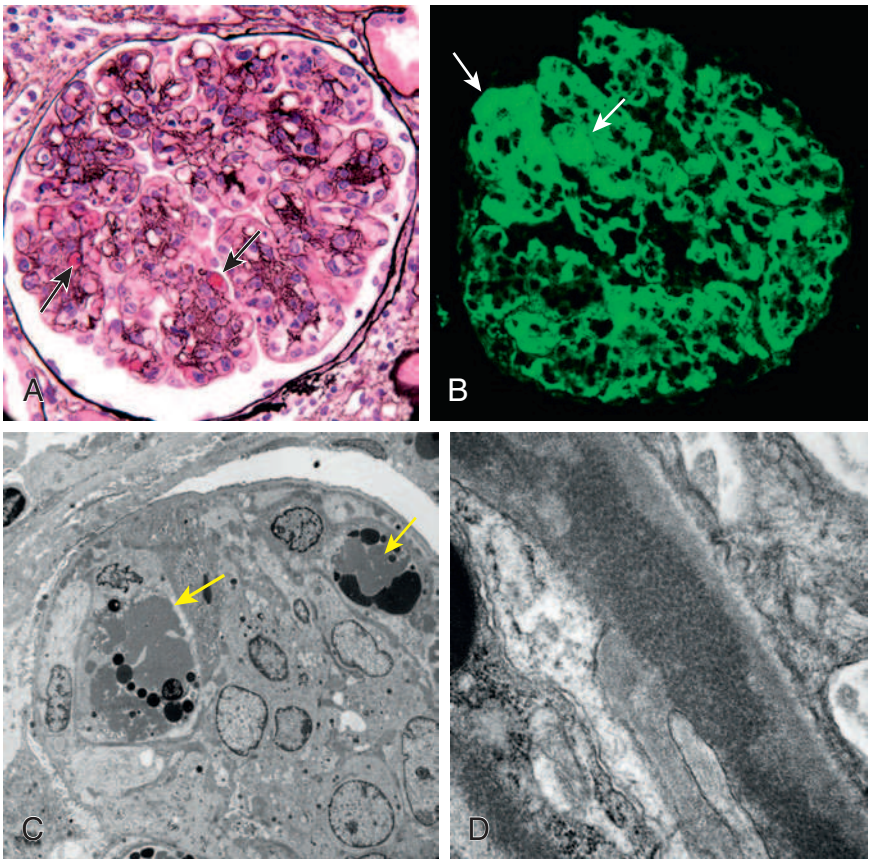

Fig. 55.4 Hepatitis C–associated membranoproliferative glomerulonephritis (MPGN) with cryoglobulins. (A) Lobular hypercellular glomerulus with capillary wall double contours and cryoglobulin thrombi *(yellow arrows)*. (B) Immunofluorescence for IgM demonstrates large intracapillary thrombi *(yellow arrows)* and segmental capillary wall deposition. (D) High magnification electron micrograph showing the annular microtubular substructure of cryoglobulin.

or sofosbuvir and velpatasvir 100 mg given daily in a combination tablet, with or without ribavirin 1000 mg/day if less than 75 kg or 1200 mg/day if 75 kg or greater are preferred treatments, given for 12 weeks in treatment-naïve and for 24 weeks in cirrhotic treatment-experienced patients. Ribavirin is teratogenic; therefore contraception is recommended during and for 6 months after ribavirin treatment.[45] When there is eradication of the HCV, diminished proteinuria, less progression to ESRD, and loss of cryoglobulins has been reported in up to half of treated patients.

Human Immunodeficiency Virus–Associated Renal Disease

HIV infection has been associated with a number of glomerular lesions, the most common of which used to be collapsing glomerulopathy in HIV-associated nephropathy (HIVAN). HIV-associated renal disorders are discussed in Chapter 56.

Other Virus-Associated Renal Disease

Cytomegalovirus (CMV) infection rarely has been reported to cause diffuse proliferative GN with immune deposits containing CMV antigens in native kidneys. CMV also has been linked to collapsing glomerulopathy and ESRD in patients without HIV infection. In renal allograft patients with CMV infection, antimetabolite immunosuppression is stopped. Depending on infection severity, oral valganciclovir 900 mg twice daily or ganciclovir 5 mg/kg intravenously every 12 hours is administered until clinical recovery and two blood samples negative for CMV by polymerase chain reaction are obtained, followed by oral valganciclovir 900 mg daily for 3 months.

Parvovirus B19 is a single-stranded DNA virus with marked tropism for erythroid precursor cells. In patients with sickle cell disease, parvovirus-induced aplastic crises are occasionally followed by nephritic or nephrotic syndrome, assumed to be the result of immune complex deposition. Diffuse proliferative GN and MPGN have been reported with C3 and IgG deposits in capillary walls and subendothelial regions. Collapsing FSGS similar to HIVAN has been attributed to parvovirus B19 infection, and some, but not all, studies have detected viral DNA in kidney biopsy samples. There is no specific treatment for parvovirus infection.

Dengue hemorrhagic fever, currently the most prevalent mosquito-borne urban viral infection worldwide, may be caused by four serotypes of the Flaviviridae virus family. The most common renal complication is acute kidney injury (AKI) (see Chapter 67). Acute endocapillary GN with IgG, IgM, and C3 deposits presenting with hematuria, proteinuria, and renal failure has been reported in infected patients.

Mild renal abnormalities occur in acute Epstein-Barr virus (EBV) infection, with microhematuria and proteinuria in 10% to 15% of cases. Diffuse proliferative GN and MPGN may occur, and there is an association with collapsing FSGS. Many viral infections, including varicella, mumps, adenovirus, coxsackievirus, and influenza, can be associated with transient microscopic hematuria, non-nephrotic proteinuria, and a mesangial or diffuse proliferative GN in which viral antigens can be identified in the mesangium. Measles may cause diffuse proliferative GN, but is better known for its unique ability to induce remission in patients with minimal change disease (MCD) and nephrotic syndrome, likely because of its ability to increase Treg cells as infection abates.

PARASITIC INFECTIONS

Kidney involvement is common in various parasitic infections and includes a range of renal lesions (Table 55.3). With the exception of malaria, leishmaniasis, filariasis, and schistosomiasis, glomerular involvement is usually mild and transient.[46]

Malaria

Etiology and Pathogenesis

There are four major species of *Plasmodium,* only two of which typically are associated with GNs in humans—*Plasmodium falciparum* and *Plasmodium malariae*.[47] Malarial antigens activate the immune system by interaction with monocytes, secretion of chemokines and cytokines, polyclonal B cell activation, and circulating immune complex formation. Malarial antigens have been identified in 25% of glomerular immune complexes and in the absence of immune complexes, suggesting in situ immune complex formation also may occur. Infected erythrocytes may participate in immune activation through preferential expression of surface antigens. Additionally, the alternative complement pathway may be directly activated.[33,47,48] Concomitant infection with other parasites (schistosomiasis) or viruses (EBV), or genetic factors such as *APOL1* risk alleles may participate in the pathogenesis of kidney injury and influence geographical disease variations.

Epidemiology, Clinical Manifestations, and Pathology

Malaria is a major world health problem, with 200 million cases predominantly occurring in Africa, India, Southeast Asia, and Latin America causing 600,000 deaths each year (Fig. 55.5). It can be acquired by the bite of infected *Anopheles* mosquitoes or infected vectors from aircraft, blood transfusion, or infected organs. *P. falciparum* invades erythrocytes of any age, and may cause AKI and multiple organ failure (see Chapter 67). Transient mild proteinuria and microhematuria are encountered in 25% to 50% of patients, and nephritic syndrome and impaired renal function are uncommon. Patients develop MesPGN with deposits of IgG, IgM, and C3; there are rare reports of IgAN (Fig. 55.6). In contrast, GN in patients infected with *P. malariae* (quartan malaria) infects aging erythrocytes and is less severe. Patients present with steroid-resistant nephrotic syndrome (tropical nephritis or nephrotic syndrome) primarily in children 4 to 8 years old. When adults develop GN, it often manifests with hypertension and renal impairment. Renal biopsy shows MPGN with granular IgG, IgM, and C3 deposition and subendothelial and mesangial electron-dense deposits[47,49] (Fig. 55.7). Infrequently, *P. malariae* induces MN or MCD. Despite treatment of the infection with or without corticosteroids, there is progression to ESRD, which is attributed to continuing autoimmune mechanisms. *Plasmodium vivax* causes AKI and rarely thrombotic microangiopathy (see Chapter 67), but GN has not been reported. Control of malaria and improvement of health care in general has resulted in a decline in renal disease in developing countries.

Filariasis

Filariae are nematodes, of which only eight of the hundreds of species affect humans and only three are associated with kidney disease. *Wuchereria bancrofti* is responsible for several clinical syndromes, including tropical eosinophilic pneumonia, elephantiasis, and chyluria, which induces proteinuria, hypoproteinemia, and hematuria in infected patients. The dominant glomerular lesion is MesPGN with less frequent MPGN and rare amyloidosis. Immune complex deposits containing worm antigens have been demonstrated in glomeruli.[47,50] Less often there is acute proliferative and exudative GN with eosinophilic predominance. Bancroftiasis is often associated with bacterial infection, usually staphylococci and certain streptococci; it is uncertain if this contributes to the development of GN. Even less understood is a potential role of the rickettsia-like bacteria *Wolbachia,* discovered within filarial nematodes and blamed for activation of innate immune pathways.

Onchocerca volvulus is less widely spread and causes scrotal lymph node obstruction ("hanging scrotum"). Onchocercosis is associated with several immune-mediated manifestations, including keratitis, anterior

TABLE 55.3 Renal Lesions in Parasitic Infections

Parasite	Glomerular Lesions	Tubulointerstitial Lesions	Amyloidosis	Tissue Reaction, Symptoms	Acute Kidney Injury	Post-Transplant Disease

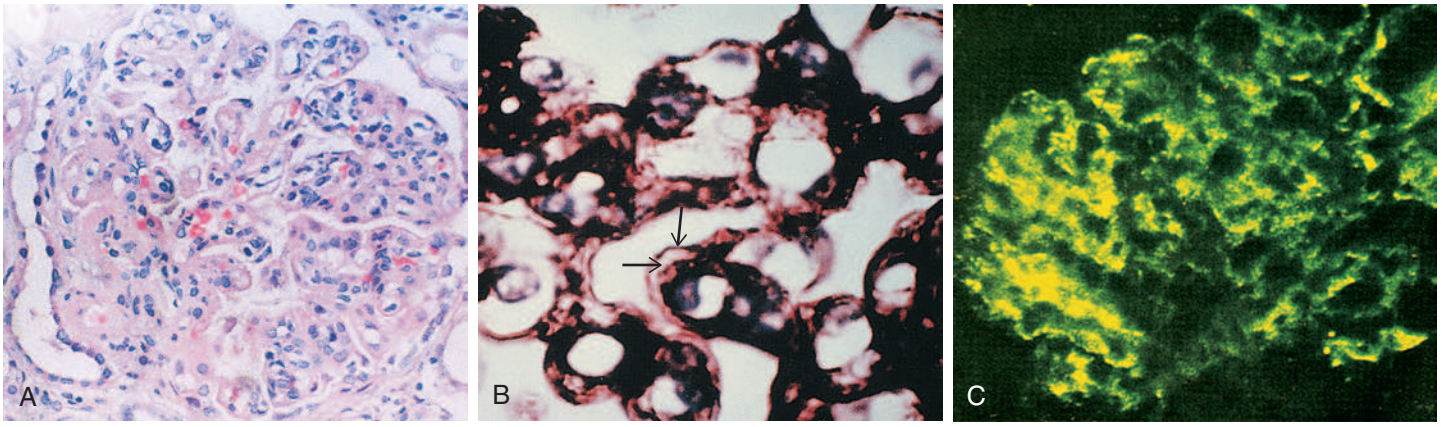

Fig. 55.7 Quartan malarial nephropathy. (A) Light microscopy shows sclerosing membranoproliferative glomerulonephritis. (B) Silver stain shows a double contour *(arrows)* of the basement membrane. (C) Malarial antigens are present on immunofluorescence. (From reference 49.)

uveitis, and optic atrophy leading to "river blindness." Infected patients with GN have proteinuria, including steroid-resistant nephrotic syndrome with progressive renal impairment.[47,50] Most common is MPGN with IgM, IgG, and C3 in subendothelial and mesangial deposits, with less frequent MCD and sclerosing glomerular lesions. Onchocercal antigens have been detected in the glomeruli, and onchocercal GN recurs in transplanted kidneys. When *W. bancrofti* or *O. volvulus* are treated, there may be worsening of the proteinuria and hematuria as a result of parasitic disintegration and increase in circulating immune complex formation. After successful eradication of the parasites, there is usually resolution of the renal symptoms.

Loa is the least prevalent of the nephritogenic filariae. Kidney disease associated with this infection includes MN and less commonly MPGN and FSGS.[47,51] Unlike the other forms of filariasis, treatment for *L. loa* generally is not effective in resolution of the GN. Infections with all three Filarioidea parasites often occur with hepatitis B and/or malaria coinfection, which independently can cause immune complex–mediated GN. It is unknown whether this affects the incidence or types of GN seen in patients with filariasis.

Leishmaniasis

Leishmaniae are obligatory intracellular protozoa that infect 12 million humans and many animals. Of 30 known leishmanial spp., only visceral leishmaniasis (kala-azar) induced by *Leishmania donovani* and by *Leishmania infantum* (*Leishmania chagasi*), which is closely related, involve the kidney. Sixty percent of those infected with *L. donovani* have mild proteinuria and microscopic hematuria. Reported glomerular lesions related to immune complex deposition include MesPGN and MPGN; the latter may occur with cryoglobulinemia.[52] Amyloidosis has been described, most frequently associated with coincident HIV infection.

Schistosomiasis

Schistosomiasis is a common cause worldwide of glomerular disease. This is discussed in Chapter 54.

SELF-ASSESSMENT QUESTIONS

1. At the present time, infection-related glomerulonephritis (GN) in developed countries is associated with debilitating conditions (neoplasia, diabetes, AIDS, alcoholism) and immunoglobulin A (IgA) deposits.
   A. True
   B. False
2. Patients with acute poststreptococcal GN usually have:
   A. Low serum CH50 and C3 levels
   B. Low serum C4 levels
   C. High serum C3 levels
   D. High serum CH50 and high serum C4 levels
3. Patients with infective endocarditis may have crescentic GN without immune deposits.
   A. True
   B. False
4. Combined antiviral therapy and immunosuppression (cyclophosphamide and steroids) is:
   A. Contraindicated in patients with HBV-associated GN
   B. Potentially useful in patients with HBV-associated GN

56

Human Immunodeficiency Virus Infection and the Kidney

Jeffrey B. Kopp, Saraladevi Naicker

The 2017 Joint United Nations Programme on HIV/AIDS (UNAIDS) report estimated that there are 36.7 million people worldwide with HIV virus infection (nearly 21 million on antiretroviral therapy [ART]). Since 2005, there has been a 48% decline in AIDS-related deaths each year, 1.5 million in 2010 to 1 million in 2016.[1]

HIV-1 infection is associated with glomerular and tubulointerstitial disease, and patients with HIV infection are at risk for nephrotoxicity from ART as well as from other medications such as blockers of the renin-angiotensin-aldosterone axis and prostaglandin inhibitors. The presence of kidney dysfunction in the setting of HIV infection acts as an independent predictor of poor outcome.

Acute kidney injury (AKI), interstitial nephritis from medication and opportunistic infection, and co-infection with hepatitis B virus (HBV) and hepatitis C virus (HCV) are all relatively common. With advances in treatment, patients with HIV are more likely to experience complications such as atherosclerosis, metabolic syndrome, type 2 diabetes, and end-stage renal disease (ESRD). In addition to HIV-1, HIV-2 can cause immunodeficiency but rarely causes kidney disease. In this chapter, we use HIV to refer to HIV-1.

EPIDEMIOLOGY OF HUMAN IMMUNODEFICIENCY VIRUS CHRONIC KIDNEY DISEASE

Developed World

In the European EUROSIDA observational study, only 3% of HIV-infected subjects had an estimated glomerular filtration rate (eGFR) less than 60 ml/min/1.73 m^2 and only 0.3% had an eGFR less than 30 ml/min/1.73 m^2.[2] In the United States, the incidence of ESRD attributed to HIV continues to decline.[3] The U.S. Renal Data System (USRDS) reported that for the period 2006 to 2010, there were 3834 cases of AIDS nephropathy, representing 0.7% of total ESRD. The USRDS 2017 data report states that for the period 2011 to 2015, there were 2356 cases of AIDS nephropathy (0.4% of total ESRD). Among these cases, 79% were Black, 13% European American and 8% Hispanic, who can be of any race.

The Developing World

Globally, an estimated 37 million individuals are infected with HIV, including an estimated 0.8% of those aged 15 to 49 years. Sub-Saharan Africa is home to 71% of the world HIV infections, with an overall HIV prevalence of 4.4%. Of HIV-positive individuals in sub-Saharan Africa, 48% have access to ART, but access to renal replacement therapy is frequently limited. The prevalence of chronic kidney disease (CKD) has been assessed by the presence of proteinuria or eGFR (based on serum creatinine measurements) and ranges widely from 6% to 48.5% in Africa. This wide variation may be partly ascribed to differences in study design, populations studied, and the definitions used for CKD. CKD prevalence in HIV-positive persons has been estimated at 1% to 6% in Brazil, 17% in India, 23% to 38% in Nigeria, and 35% among children in Zimbabwe.

In South Africa, HIVAN is the dominant HIV kidney disease and is present in up to 80% of kidney biopsy specimens of HIV-positive individuals, which is consistent with findings in the United States in the pre-ART era. As in developed countries, other renal causes are also observed, including HIV-immune complex kidney disease (HIVICK) from postinfectious and other causes, membranous nephropathy, and interstitial nephritis. Some renal biopsy samples show nonspecific changes (e.g., mesangial hyperplasia and chronic interstitial nephritis) that show regression on combination ART, which suggests that the diagnostic criteria for HIV-associated CKD may need to be revised.

GLOMERULAR DISORDERS

Human Immunodeficiency Virus–Associated Nephropathy

HIV infection is associated with various glomerular disorders (Table 56.1). The classic glomerulopathy of HIV infection is collapsing focal segmental glomerulosclerosis (FSGS) or HIVAN.

Etiology and Pathogenesis

HIVAN occurs with both acute infection and chronic infection; in the latter case, it is associated with higher viral RNA levels and lower CD4 T lymphocyte counts. Studies of human kidney biopsy samples have shown that HIV can infect glomerular and tubular cells, setting up a chronic and possibly latent infection.[4] HIV accessory proteins such as Vpr and Nef can damage renal cells independent of direct infection. In transgenic mice, the expression of HIV accessory proteins Vpr or Nef in podocytes is associated with progressive CKD, leading to ESRD, loss of podocyte differentiation markers, and collapsing FSGS.[5,6] Transgenic mouse experiments also suggest that HIV gene products are toxic to tubular epithelial cells, resulting in apoptosis and blocking cell proliferation.

Host factors also determine susceptibility to HIVAN, especially in individuals of African descent compared with those of European or Asian descent. Apolipoprotein L1, encoded by *APOL1* on chromosome 22, is a component of particular high-density lipoprotein particles termed *trypanosome lytic factors*.[7] *APOL1* variants have been identified as a major cause of the predilection for chronic glomerular disease that characterizes populations of sub-Saharan African descent.[8,9] The presence of two *APOL1* codon-changing variants confer an odds ratio of

TABLE 56.1 Kidney Diseases Associated With Human Immunodeficiency Virus Infection or Its Treatment

	Entity	Frequency	Associations
Glomerular	HIV-associated nephropathy (HIVAN)	Common	African descent; often advanced HIV disease
	HIV-associated immune complex kidney disease (HIVICK)	Common	All ethnic backgrounds
	Thrombotic microangiopathy	Uncommon	
	Membranoproliferative glomerulonephritis, with or without cryoglobulin-associated vasculitis	Rare	Hepatitis C; enfuvirtide
	Membranous nephropathy	Rare	Hepatitis B
	Fibrillary and immunotactoid glomerulopathies	Rare	
	Amyloid nephropathy (AA type)	Rare	
	Minimal change nephropathy	Rare	Nonsteroidal antiinflammatory medication
Tubular	Acute kidney injury	Moderately common	Aminoglycosides, cidofovir, foscarnet
	Proximal tubule injury (Fanconi syndrome)	Moderately common	Tenofovir disoproxil fumarate, adefovir, cidofovir, didanosine
	Diabetes insipidus	Uncommon	Amphotericin, tenofovir disoproxil fumarate, didanosine, abacavir
	Chronic tubular injury	Moderately common	Amphotericin, cidofovir, adefovir, tenofovir disoproxil fumarate
	Crystal nephropathy	Uncommon	Indinavir, atazanavir; sulfadiazine, ciprofloxacin, intravenous acyclovir
Interstitial	Interstitial nephritis	Uncommon	Allergy to β-lactam, sulfa, ciprofloxacin, rifampin, proton pump inhibitor, allopurinol, phenytoin; also causes of crystal nephropathy listed earlier, BK virus; generally advanced disease Immune reconstitution inflammatory syndrome; generally advanced disease; after initiation of antiretroviral therapy

29 in the United States and 89 in South Africa, a strikingly large effect for a complex disease.[10,11] Homozygosity or dual heterozygosity for two risk alleles (termed G1 and G2; G1 is actually a haplotype, but the term *allele* is used here for simplicity) are observed in 72% of African Americans and South Africans with HIVAN, compared with only 12% of African American controls and 3% of South African controls.[10,11] Among South Africans, a single copy of the *APOL1-G1* variant confers an odds ratio of 21 for HIVAN, an important finding with regard to mechanism because it demonstrates a dominant effect. These variants appear to protect individuals from African sleeping sickness caused by *Trypanosoma brucei rhodesiense,* and this may explain the rapid rise in allele frequency in Africa, particularly West African populations, that has occurred during the past 40,000 years. HIV-positive women with CKD with two *APOL1* risk alleles were shown to have greater proteinuria, more rapid decline in eGFR and 1.7- to 3.4-fold greater risk for incident CKD than those with low-risk genotypes.[12] Studies in cell culture suggest that *APOL1* variants may act by diverse mechanisms, including endolysosomal dysfunction, mitochondrial dysfunction, and altered transcellular cation flux leading to potassium depletion and activation of stress kinases. Transgenic mouse models have shown altered endolysosomal trafficking, FSGS,[13] and preeclampsia.[4]

Clinical Manifestations

Patients with HIVAN typically present with proteinuria and renal impairment. Some patients present with edema, although edema is less common than with other conditions associated with nephrotic range proteinuria, suggesting a defect in tubular sodium handing. Imaging studies may reveal increased kidney size despite reduced GFR and, in some cases, increased echogenicity; this unusual feature is shared with diabetic nephropathy and amyloid nephropathy. However, no radiologic features predict the renal histologic findings and renal biopsy is required for diagnosis.

Pathology

HIVAN is largely indistinguishable from idiopathic collapsing FSGS, with pathologic changes in glomeruli (proliferation and dysregulation of podocytes or podocyte stem cells, together with glomerular collapse), tubules (acute and chronic injury, sometimes with microcystic tubular changes), and interstitium (chronic inflammation, fibrosis) (Fig. 56.1). On electron microscopy, both HIVAN and idiopathic collapsing FSGS may manifest tubuloreticular inclusions within dilated endosomal compartments within glomerular endothelial cells, which are believed to be markers for interferon-mediated injury and may also indicate *APOL1*-mediated injury. Some patients with progressive loss of kidney function (e.g., from HIVICK or interstitial nephritis) may develop adaptive FSGS from the consequences of glomerular hyperperfusion and hyperfiltration.

Diagnosis and Differential Diagnosis

The evaluation of AKI or CKD in a patient with HIV infection resembles that performed in other settings: history, focused particularly on medication use and other infections; physical examination; examination of the urine sediment; serum and urine chemistries; and in many cases renal imaging studies, and in some cases kidney biopsy. Urine chemistries may include 24-hour timed or spot urine measurement of protein and albumin (for suspected glomerular disease), glucose, phosphate, and uric acid (for suspected proximal tubular disease). Indications for kidney biopsy include AKI without clear associated cause, especially with a nephritic sediment, nephrotic proteinuria, clinical evidence of thrombotic microangiopathy (TMA), and unexplained CKD. In the past, some clinicians argued that nephrotic proteinuria in an individual of African descent is likely to be HIVAN or idiopathic collapsing FSGS and that a biopsy is not necessary. The widespread use of ART in the current era makes this decision less tenable, and renal biopsy appears to be indicated to guide prognosis and therapy, particularly when substantial proteinuria is present.

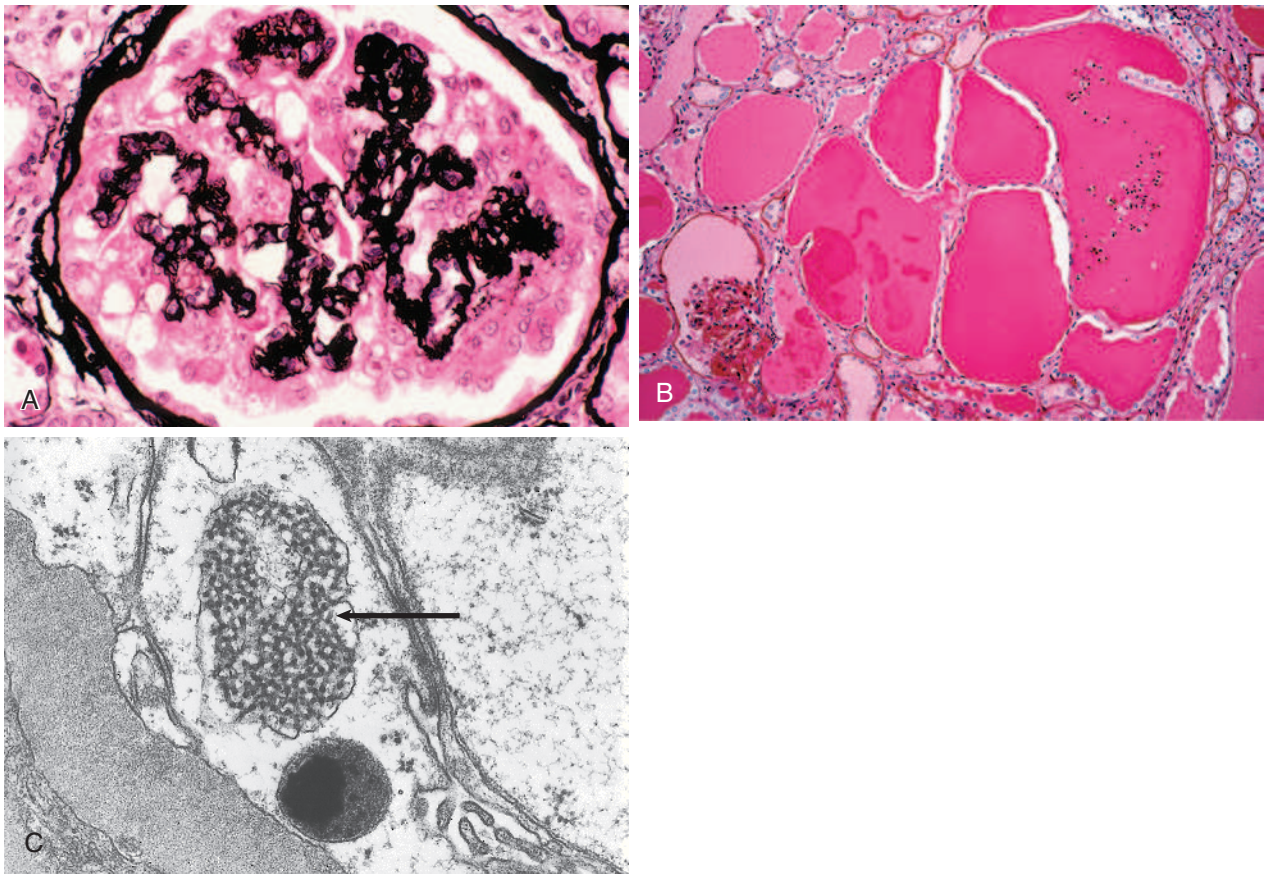

Fig. 56.1 HIV-associated nephropathy. (A) A globally collapsed glomerulus shows marked podocyte hypertrophy and hyperplasia. (Jones methenamine silver.) (B) At low power, the renal parenchyma contains abundant tubular microcysts with proteinaceous casts. The glomerulus is collapsed with dilated urinary space. (Periodic acid–Schiff.) (C) The glomerular endothelial cell pictured here contains a large intracytoplasmic tubuloreticular inclusion ("interferon footprint"; *arrow*) composed of inter-anastomosing tubular structures within a dilated cisterna of endoplasmic reticulum. (Electron micrograph.)

With the advent of ART, the range of common renal diagnoses has expanded from HIVAN in individuals of African descent and HIVICK among all ethnic backgrounds, to include diseases such as FSGS, diabetic nephropathy, and arterionephrosclerosis. In patients with HIV and hepatitis, membranoproliferative glomerulonephritis (MPGN) associated with HCV should be considered. Other diagnoses include membranous nephropathy (associated with HBV infection, or presumably idiopathic, but possibly related to the polyclonal B cell expansion typical of HIV disease) and amyloidosis. Chronic tubular injury, especially associated with tenofovir disoproxil fumarate (TDF) therapy but possibly associated with other ART, is not uncommon; but when early diagnosis leads to cessation of the offending medication, CKD is usually averted. Despite the plethora of diagnoses, HIVAN remains the leading cause of ESRD in patients with HIV disease in the United States.

The diagnosis of HIVAN is made by renal biopsy, although nephrotic proteinuria and low CD4 count in individuals of African descent is highly suggestive of HIVAN. Among individuals of African descent, other possible diagnoses include primary or adaptive FSGS (although a pathogenic role for HIV cannot be excluded in conferring susceptibility) and arterionephrosclerosis (see later discussion). In all individuals, diabetic nephropathy and HIVICK should be considered (see later discussion and Table 56.1).

Treatment

The HIV Medicine Association of the Infectious Diseases Society of America provides clinical practice guidelines for the management of adults and children with HIV.[2] All HIV-positive individuals should receive combination ART, beginning at the time of diagnosis. ART appears to prevent CKD. The presence of kidney disease does not affect this recommendation. In the era before ART was available, HIVAN progressed rapidly, with patients reaching ESRD in months to a few years. The marked decline in HIV-associated ESRD in the United States after the introduction of ART in 1995 suggests that effective control of viral replication with ART may prevent HIVAN. Retrospective studies also suggest that ART treatment of HIVAN may prolong renal survival. Rapid resolution or decrement in proteinuria within 6 months of commencing ART has been reported.[14]

The Development of Anti-Retroviral Therapy in Africa (DART) study, conducted in Uganda and Zimbabwe, demonstrated improvement of kidney function of 2 to 6 ml/min/1.73 m^2 after 4 to 5 years of ART.[2,15] Other studies suggest that ART is most effective when initiated before the onset of severe renal disease.[16] In a few cases, regression of histologic lesions with combined anti-retroviral therapy (cART) has been demonstrated.[17,18] A recent study of 221 HIV-positive patients in South Africa with renal histologic findings reported that both HIVAN and HIVICK respond to ART.[19]

There is some evidence that the pattern of renal disease has changed since the introduction of ART, with a relative decrease in HIVAN and emergence of classic FSGS as the most common cause of glomerular disease. In this study, HIVAN occurred more frequently in Black patients with severe immunodeficiency and severe renal failure; patients with FSGS were older, more likely to have received ART, more frequently had cardiovascular risk, and had more severe interstitial fibrosis on kidney biopsy.[20]

Treatment of HIV-associated renal disease also includes standard therapies for CKD, including control of blood pressure (BP) and the use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs), as well as ART if this has not been started. A prospective and controlled, but nonrandomized trial of HIVAN demonstrated improved renal survival with ACE inhibitor therapy. Glucocorticoids have shown benefit for HIVAN in a prospective study and several retrospective studies, as reviewed recently.[21] Nevertheless, although there is no consensus, these medications should be considered in HIVAN and HIVICK only when viral replication is suppressed with ART and proteinuria or progressive renal function decline continues.

BP targets should be similar to those for other patients with CKD. The Systolic blood PRessure INTervention (SPRINT) study suggests that BP targets should be lower than previously thought: less than 130 mm Hg in the general population over 50 years of age (excluding those with diabetes or prior stroke, who may not tolerate this lower target). Although HIV-positive subjects were not included in the SPRINT study, it would seem reasonable to treat them to this target if they lack the exclusions noted earlier.[22]

Natural History

Progression of CKD is more rapid in HIV-positive individuals of African descent, probably reflecting the effect of the *APOL1* variants. Patients with HIVAN may progress to ESRD despite ART. Predictors of progression are a high degree of chronic damage on histology, presence of large numbers of sclerotic glomeruli, severe renal dysfunction at baseline, and high-grade proteinuria.[23,24]

Human Immunodeficiency Virus Immune Complex Kidney Disease

In populations of European and Asian ancestry, the most common glomerular diseases associated with HIV disease are immune complex diseases.[25] HIVICK has been reported from both developed countries such as the United States,[26,27] the United Kingdom,[28] and France[20] and from developing countries (e.g., Thailand and India[29]). HIVICK is observed in populations of African descent, although much less frequently than HIVAN, and most lack two *APOL1* risk alleles. Compared with those with HIVAN, individuals with HIVICK tend to have lower HIV viral copy number and are more likely to have diabetes and hypertension.[30]

HIVICK can take various forms, including postinfectious glomerulonephritis, membranous nephropathy, and a lupus-like pattern. Patients with HCV coinfection may manifest MPGN (see Chapter 21). Some patients may have only mesangial immunoglobulin A (IgA) deposits (especially those with microhematuria and non-nephrotic proteinuria), resembling idiopathic IgA nephropathy. Hence, the diagnosis of HIVICK may be fraught with difficulties for the pathologist, who must exclude other immune complex disease.

HIVICK may be clinically indistinguishable from HIVAN, although hematuria may be more marked, and some patients present with lower levels of proteinuria. Renal biopsy findings may vary from mesangial proliferative glomerulonephritis (GN) to focal or diffuse proliferative GN with endocapillary proliferation (Fig. 56.2). In some cases, changes consistent with HIVAN also may be present, including tubuloreticular inclusions within glomerular capillary endothelial cells. Immune deposits may be in mesangial, subendothelial, or subepithelial locations and may include IgG and IgM or IgG, IgM, and IgA (so-called "full house deposits"), often with C3. These forms resemble lupus nephritis, although lupus serologic test results are typically negative.

The pathogenesis of HIVICK is not well understood and may involve heterogeneous mechanisms. It is not known whether complexes form locally within the glomeruli or are passively trapped as from the glomerular microcirculation. In some cases, immune complexes include HIV antigens. Other cases may represent generalized polyclonal B cell expansion that accompanies HIV disease.

HIVICK is often associated with progressive loss of kidney function. Foy and colleagues[30] in the United States found that at 2 years after diagnosis, 70% of HIVAN cases and 32% of HIVICK cases had reached ESRD. Further, the use of combination ART or the attainment of viral suppression was not associated with lower risk for ESRD in HIVICK (N = 83), whereas use of combination ART was associated with reduced likelihood of progression with HIVAN (N = 56.[30] In contrast, a U.K. study reported a slower rate of progression of HIVICK to ESRD, but these authors considered HIV-associated IgA nephropathy to be a

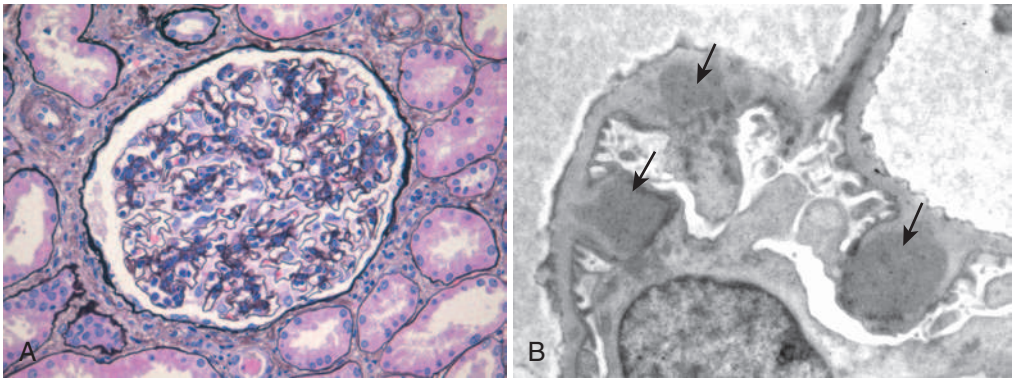

Fig. 56.2 HIV-associated glomerulonephritis. This HIV-positive patient presented with microhematuria and non-nephrotic proteinuria with normal renal function. Renal biopsy shows mild mesangial expansion (A), with mesangial and paramesangial deposits, together with varying numbers of subepithelial-based deposits *(arrows),* resulting in the "ball-and-cup" appearance (B). (Courtesy Professor Stewart Goetsch, University of the Witwatersrand, Johannesburg, South Africa.)

distinct entity and with likelihood of progression intermediate between HIVAN and HIVICK.[28]

OTHER GLOMERULAR DISORDERS

TMA may occur with HIV infection and is associated with lower CD4 cell counts, higher viral burden, and AIDS.[31] Fibrillary GN, immunotactoid GN, and amyloidosis also have been reported in HIV infection, but a causal role for HIV infection has not been firmly established.

SYSTEMIC INFLAMMATION AND ARTERIONEPHROSCLEROSIS

A paradigm shift has emerged over the past decade, with the recognition that long-term suppression of HIV replication dramatically improves survival but at the cost of chronic inflammation and premature aging.[32] Peripheral inflammatory markers correlate with Framingham risk scores and Veteran Aging Cohort Scores,[33] and hypertension is common.[34]

The causes of chronic inflammation in HIV disease are complex. Chronic immune activation is associated with lymphocyte depletion, manifesting as reduced numbers of $CD4^+$ and $CD8^+$ naïve T cells. Alterations in the intestinal microbiome and microbial translocation may contribute.[35] Inflammation leads to disease processes that resemble premature aging (including atherosclerosis) and manifests in the kidney as arterionephrosclerosis, comprised of arterial intimal thickening, medial hypertrophy, duplication of the internal elastic lamina, and global glomerulosclerosis. Arterionephrosclerosis is traditionally ascribed to hypertension, but increasing evidence suggests that afferent arteriolar lesions predispose to glomerulosclerosis and hypertension by altering renal autoregulation. Arterionephrosclerosis is associated with genetic mutations (e.g., *APOL1*), metabolic disorders (e.g., diabetes, obesity, hyperlipidemia, metabolic syndrome, and HIV infection), and chronic inflammation (smoking, oxidative stress, hemodynamic shear stress, and renin-angiotensin system activation).[36] A recent U.S. study of patients with HIV reported that isolated arteriosclerosis with glomerulosclerosis was the most common single pathologic condition,[37] and this is a trend that is likely to grow stronger.

TUBULAR DISORDERS

HIV infection is associated with tubular disorders, often resulting from medications (see Table 56.1), most commonly from TDF. AKI most commonly occurs in outpatient settings, with prerenal causes (extracellular volume contraction or reduced renal blood flow as a result of nonsteroidal antiinflammatory drugs [NSAIDS]) and postrenal causes (including obstruction as a result of prostate disease, kidney stone, or crystalluria). Renal causes of AKI, including tubular injury from medication, particularly TDF; interstitial nephritis resulting from NSAIDS or antibiotics; and, less commonly, acute presentations of glomerular disease. Risk factors for HIV-associated AKI include male sex, black race, low CD4 count, high viral load, diabetes, CKD, and hepatic disease.[38] Chronic proximal tubular injury manifests as various components of Fanconi syndrome: glycosuria, phosphaturia (sometimes associated with clinically significant hypophosphatemia), uricosuria, tubular proteinuria (predominantly low molecular weight proteins), and aminoaciduria. Nephrogenic diabetes insipidus also may be present, indicating that the distal nephron is also involved.

Current Antiretroviral Drug Regimens and Renal Toxicity

Current recommendations for first-line therapy for HIV in adults include a combination of three medications. These are TDF, a nucleotide reverse transcriptase inhibitor (NRTI); either lamivudine or emtricitabine (the latter a nucleoside reverse transcriptase inhibitor, also abbreviated NRTI); and efavirenz, a non-nucleoside reverse transcriptase inhibitor (NNRTI). The difference between a nucleotide and a nucleoside is that the latter must be phosphorylated to become active. To underscore its ubiquity, TDF is a component of four of the six regimens currently recommended for treatment of naïve patients and hence is widely used globally. TDF nephrotoxicity is discussed later. By contrast, NNRTIs have an excellent renal safety profile.

In addition to these two drug classes, there are four other classes of antiretroviral medications currently in clinical use (Table 56.2). These include protease inhibitors, fusion inhibitors (GP41 antagonist), entry inhibitors (CCR5 antagonist), integrase inhibitors, and pharmacokinetic enhancers. Of these, only protease inhibitors exhibit renal toxicity by forming crystals or stones. Indinavir was a formerly common cause of tubular injury but is rarely used at present. Currently, atazanavir is widely used. Case series show that in individuals taking ritonavir-boosted atazanavir, urinary crystals affect 10% of subjects[39] and renal stones occur at a rate of 2.4 cases per 100 patient-years.[40] Risk factors for nephrolithiasis include alkaline urine and renal impairment but not elevated serum atazanavir levels.[41] Atazanavir also has been associated with interstitial nephritis.[42]

TABLE 56.2 Renal Toxicity of Antiretroviral Therapy

Antiretroviral Class	Antiretroviral Therapy	Renal Effect	Clinical Recommendations
Protease inhibitors	Indinavir	Nephrolithiasis, crystalluria, dysuria, papillary necrosis, acute kidney injury, interstitial nephritis	Daily fluid intake of >2 l/day
		Ritonavir may increase toxicity of indinavir	
	Atazanavir	Crystalluria, stones, interstitial nephritis	
	Ritonavir	Increases levels of TDF	
Reverse transcriptase inhibitors	Tenofovir disoproxil fumarate (TDF)	Renal tubular damage: Proximal tubular dysfunction, Fanconi syndrome, nephrogenic diabetes insipidus, acute tubular necrosis, acute kidney injury	Patients taking TDF should be monitored for signs of tubular dysfunction (elevated serum creatinine, hypophosphatemia, low serum uric acid, acidosis, glycosuria, proteinuria)

TABLE 56.3 Adjustments in Drug Dosing for Antiretroviral Medications in Current Use

Medication Class	Medication	Adjustment for GFR	Dosing in Dialysis
NRTI (8)	Abacavir	No change	No change
	Didanosine (ddi)	Reduce for eGFR <60	No dose after dialysis
	Emtricitabine (FTC)	Reduce for eGFR <50	Dose after dialysis
	Lamivudine (3TC)	Reduce for eGFR <50	No dose after dialysis
	Stavudine (d4T)	Reduce for eGFR <50	Reduce dose
	Tenofovir disoproxil fumarate (TDF)	Reduce for eGFR <50	Dose after dialysis
	Tenofovir alafenamide	Not needed	Use not recommended
	Zidovudine (AZT)	Reduce for eGFR <15	Reduce dose
NNRTI (4)	Efavirenz	No change	No change
	Etravirine	No change	No change
	Nevirapine	No change >eGFR 20, not recommended eGFR <20	Dose after dialysis
	Rilpivirine	Not recommended for severe chronic kidney disease	Dose after dialysis probably not needed
Protease inhibitor (8)	Atazanavir	No change	Depends on status
	Darunavir	No change	No data
	Fosamprenavir	No data	No data
	Indinavir	No change	No change
	Nelfinavir	No data	No data
	Ritonavir	No change	No data
	Saquinavir	Not recommended for severe chronic kidney disease	No data
	Tipranavir	Probably no change	No data
Fusion inhibitor (CCR5)	Enfuvirtide	No change	No data
Entry inhibitor (gp41)	Maraviroc	Avoid for eGFR <30	Avoid
Integrase inhibitor (3)	Dolutegravir	Complex, suggest reviewing primary data	Avoid
	Elvitegravir	No change	No data
	Raltegravir	No change	Avoid administering before dialysis
Pharmacokinetic enhancer	Cobicistat	No change. For eGFR, avoid combination with TDF	No data

Shown are 26 antiretroviral drugs approved by the U.S. food and drug administration (FDA) as of 2018. Combination drugs, of which 14 are currently approved by the FDA, are not listed here.
eGFR, Estimated glomerular filtration rate; *TDF,* tenofovir disoproxil fumarate.

Tenofovir Disoproxil Fumarate and Tenofovir Alafenamide

TDF is the most common cause of tubular injury in HIV-positive individuals and manifests primarily as proximal tubular dysfunction with Fanconi syndrome. TDF is taken up by proximal tubular cells by one or more organic anion transporters, converted to the active drug, which inhibits DNA repair and replication in host cells as well as in HIV. TDF also causes mitochondrial enlargement, dysmorphic changes, and depletion of mitochondrial cristae.[43] A mild decrease in GFR also has been associated with TDF use, but usually it is not severe enough to require discontinuation of treatment. Nonetheless, recovery of renal dysfunction may take months to years after stopping TDF,[44] and in some cases recovery is partial and CKD ensues.[45] Risk factors for TDF-induced renal toxicity include low CD4 count, prior renal impairment, duration of therapy, and combined therapy with didanosine and protease inhibitors (lopinavir and ritonavir); the latter elevates TDF plasma levels, which in turn is associated with higher risk for nephrotoxicity.[46]

TDF is taken up into the renal tubular epithelial cell from basolateral space by the organic anion transporter (OAT) 1, and OAT3 and is secreted into the tubular lumen by the multidrug resistance protein (MRP) 4. Mutations in *ABCC4,* encoding MRP4, are associated with increased plasma TDF concentrations and nephrotoxicity risk,[47] and mutations in *ABCC10,* encoding MRP10, are associated with increased risk for phosphate wasting.[46,48] On the other hand, the use of MRP inhibitors such as NSAIDs, salicylates, and dipyridamole does not increase toxicity.[49]

TAF represents a potentially important advance.[50] Like TDF, TAF is a pro-drug, but unlike TDF, it is not a substrate for the OAT1 and OAT2 organic ion transporters, which transport solutes from plasma into the tubular epithelial cell. Current data suggest lower levels of renal toxicity than that with TDF.

ANTIRETROVIRAL THERAPY DOSING IN CHRONIC KIDNEY DISEASE

Many antiretroviral medications are partially or completely eliminated by the kidney and require dosage adjustment in CKD. Certain drug classes, such as the protease inhibitors and the NNRTIs, are extensively metabolized by the liver and do not require dosage adjustment. Most NRTIs are excreted unchanged in the urine and require dosage adjustment, except for abacavir, which has substantial extrarenal biotransformation that requires little if any dosage adjustment. In uremia, drug dosages may be affected by altered gastric pH and variable volumes of distribution. Factors that influence dialyzability of antiretroviral medications relate to the properties of the dialysis membrane and molecular

weight, degree of protein binding, molecular charge, and water solubility of the drug. Drugs that are substantially removed by hemodialysis (HD) should be taken after dialysis sessions. If the drug is removed in peritoneal dialysis (PD) effluent, the dose may have to be supplemented. Dosage recommendations (Table 56.3) in both HD and PD are limited; there is a recommendation for NRTI dosing in patients undergoing veno-venous hemofiltration.[51]

END-STAGE RENAL DISEASE

With the increasing survival of HIV-positive individuals with treatment and the declining cost of combination ART, the incidence of HIV-associated ESRD will likely increase worldwide, as it has in developed countries. Currently, survival among dialysis-dependent HIV-positive patients who are stable on combination ART is comparable to that among patients on dialysis without HIV infection, and choice of dialysis modality does not have an impact on survival.

Immunization schedules are the same as for non–HIV-negative patients on dialysis.[2] In both CKD and HIV infection, anemia is independently associated with shorter survival. The response to recombinant erythropoietin in HIV-positive patients with ESRD is similar to that seen in HIV-negative patients.[52] Measurements of iron indices are complicated in HIV-positive patients, because levels of ferritin (an acute phase reactant) are often elevated in patients with HIV infection. Elevated soluble transferrin receptor concentrations are more reliable than serum ferritin to distinguish iron deficiency in inflammatory disease states.[53,54]

Hemodialysis

Strict adherence to universal precautions is the best form of prevention of HIV transmission in dialysis units, and there is no reason for these patients to be isolated. Reprocessing of dialyzers from HIV-positive patients does not place staff members at increased risk for infection if necessary sterile precautions are undertaken. The risk for viral seroconversion after a needle-stick injury has been estimated as 6 in 1000 for HCV, 4 in 1000 for HBV, and 2 in 1000 for HIV.[55] ART may reduce the risk for transmission after a needle-stick injury, and postexposure prophylaxis for 28 days with a combination of two reverse transcriptase inhibitors and one protease inhibitor is recommended. Native arteriovenous fistulas are the preferred types of access for all patients with ESRD because of better patency rates once established and lower complication rates than other access options. A recent study from South Africa showed similar survival outcomes for HIV-positive and HIV-negative patients on HD, except for increased incidence of tuberculosis in the HIV-positive cohort.[14]

Peritoneal Dialysis

HIV has been shown to remain infectious at room temperature in PD exchange tubing for up to 48 hours and for up to 7 days in peritoneal effluent.[56] Dialysate should therefore be handled as a contaminated body fluid. Sodium hypochlorite (50% solution) and household bleach (10% solution), each further diluted 1:512, are effective at inactivating HIV in dialysate. Patients on PD should be instructed to pour dialysate into the home toilet, together with a cup of household bleach. Used dialysis bags and lines should be placed in plastic bags, exposed to household bleach, and disposed of in conventional home garbage or returned to the dialysis unit, according to instructions from the dialysis unit.

Kidney Transplantation

The past few years have seen a surge of interest in kidney transplantation for HIV-positive patients with ESRD. In a report of 150 kidney transplants from HIV-negative donors (both living and deceased) to HIV-positive recipients, acute rejection rates were higher than in other subjects but HIV replication remained controlled.[57] Similar outcomes were reported subsequently from other centers, including 27 HIV-positive recipients who received kidneys from HIV-positive deceased donors in South Africa[58] and 92 patients in the United States.[59] With longer term follow-up, compared with HIV-negative recipients, HIV-positive recipients had a marginally increased risk for graft loss and no increased risk for death.[60] Interestingly, Canaud and associates[61] reported that kidneys from HIV-negative donor kidney cells became infected after transplantation into HIV-positive recipients, with HIV RNA detected in podocytes and tubular. In 2013 the HIV Organ Policy Equity Act (HOPE Act) was passed by the U.S. Congress; this act legalized research involving HIV-positive living donors providing kidneys to HIV-positive recipients, and studies with this population are being developed.

EVALUATION FOR KIDNEY DISEASE

HIV-positive individuals should undergo regular evaluation for kidney disease: probably at least every 6 months and more frequently if renal disease is suspected (Fig. 56.3). Early identification of kidney injury disease offers the prospect of discovering kidney injury when it first appears, defining the nature of the process, removing provocative factors when possible (particularly medications), and initiating therapy to slow, halt, or possibly reverse the disease process.

Periodic testing should include a history of nephrotoxic medications and measurement of BP, serum creatinine, and blood urea nitrogen. Three studies in HIV-positive patients compared the CKD–Epidemiology Collaboration (CKD-EPI) equations against the gold standard iothalamate GFR; all three concluded that the CKD-EPI equation correlated well with measured GFR. When actual doses prescribed were compared with those recommended by the CKD-EPI eGFR, 6% to 19% of patients received an inappropriate dose; these subjects tended to be older and were more likely to have diabetes.

If serum creatinine is elevated or dipstick proteinuria is noted, a spot ratio of urine protein to creatinine (uPCR) should be measured. Most proteinuria in HIV-positive patients is tubular proteinuria. In a study from London, 10% of subjects had proteinuria (defined as uPCR >200 mg/g), most of which was not albumin; 17% had microalbuminuria, and 67% had increased excretion of the low molecular protein neutrophil gelatinase–associated lipocalin (NGAL).[62]

Moderately severe albuminuria (previously known as *microalbuminuria*) may indicate early glomerular disease (including in diabetic nephropathy, arterionephrosclerosis, HIV-associated glomerular disease), tubular disease, metabolic syndrome, or systemic inflammation. In six of seven South African patients with persistent modestly elevated albuminuria HIVAN was found on kidney biopsy, documenting that this disease may have an insidious presentation. Modestly elevated albuminuria may be persistent or intermittent and may reflect other processes, such as diabetes and hypertension. Indeed, in HIV-positive individuals, modestly elevated albuminuria is associated with Framingham risk score,[63] endothelial dysfunction,[64] and intimal medial thickness and with all-cause mortality.[65]

ACKNOWLEDGMENT

The authors appreciate the assistance of Alice Pau, Pharm D, NIH, with reviewing the information on medications. This work was supported by the Intramural Research Program, NIDDK, NIH, Bethesda, MD.

Management algorithm for screening HIV-positive individuals for acute and chronic kidney disease

All HIV-positive individuals should be offered anti-retroviral therapy at the time of HIV diagnosis and if they decline, should be offered at each clinic visit

↓

Assessment for kidney disease in all HIV-infected individuals
Risk factors for CKD: Sub-Saharan African descent, family history of CKD, use of nephrotoxic therapies includingtraditional medicines, hepatitis C, HIV viral load >400 copies/ml, CD4 cell count <200 cell^3/mm^3
Assessment: Urine dipstick and serum creatinine, then calculate eGFR (see Chapter 3)

↓

1. Urine dipstick for leukocytes
If negative, repeat annually
If positive, perform urine microscopy and culture for bacteria
UTI symptoms: Culture or treat empirically, adjust therapy when sensitivities are known
Sterile pyuria: Test for sexually transmitted infections, including syphilis, and tuberculosis
Repeat urine dipstick at follow-up visit

↓

2. Urine dipstick for proteinuria
If negative, measure urine albumin-to-creatinine ratio and repeat in 1 year
If positive, measure urine albumin/creatinine and urine protein/creatinine ratio

Microalbuminuria (albumin/creatinine ratio 20-200 mg/g). See Chapter 30
- Acute causes: Fever, pregnancy, uncontrolled hypertension, uncontrolled diabetes, congestive heart failure
- Chronic causes: Metabolic syndrome, diabetes

Macroalbuminuria (albumin/creatinine ratio >200 mg/g)
Acute causes: Fever, systemic infection, hypertensive emergency

Chronic causes:
Nephrotic or subnephrotic proteinuria: HIVAN, FSGS, arterionephrosclerosis, diabetes, hepatitis B, syphilis,
Nephritic syndrome: HIVICK, lupus, hepatitis C, postinfectious glomerulonephritis
Consider kidney biopsy

Tubular proteinuria (albumin/total protein <40%)
- Tenofovir toxicity
- Interstitial nephritis (NSAIDS, antibiotics, tenofovir)

↓

3. Serum creatinine and eGFR
Acute kidney injury: If eGFR has recently fallen by >25% (risk) or >50% (injury)
- Pre-renal conditions: Look for signs of extracellular volume contraction
- Renal conditions
  Review nephrotoxic medications including non-prescription medications (particularly NSAIDs), prescription medications (particular tenofovir disoproxil fumarate, atazanavir) and intravenous contrast
  Consider rhabdomyolysis if heme pigment is present without erythrocytes
- Post-renal conditions: Bladder retention (including prostatism), stone, cancer. Consider renal ultrasound

↓

Chronic kidney disease: If eGFR is stable or slowly declining and <60 ml/min/1.73 m^2
- Renal ultrasound for kidney size and echogenicity
- Review nephrotoxic medications
- Serologic testing for hepatitis B and C
- Evaluation for *Plasmodium malariae* in endemic areas
- Serum K <5 mmol/L: Start RAAS antagonist
- Manage blood pressure and CKD stage appropriately (Chapter 80)

Fig. 56.3 Management algorithm for screening of HIV-positive antiretroviral therapy–naïve patients for chronic kidney disease. Tuberculosis may be pulmonary or extrapulmonary. Antiproteinuric agents may be used in normotensive individuals with gradual up-titration of dose, depending on tolerance and severity of proteinuria. *CKD,* Chronic kidney disease; *eGFR,* estimated glomerular filtration rate; *FSGS,* focal segmental glomerulosclerosis; *HIVAN,* HIV-associated nephropathy; *HIVICK,* HIV-associated immune complex kidney disease; *NSAIDs,* nonsteroidal antiinflammatory drugs; *RAAS,* renin-angiotensin-aldosterone system; *UTI,* urinary tract infection.

SELF-ASSESSMENT QUESTIONS

1. In individuals of African descent with HIV infection, genetic variants in the *APOL1* gene are associated with which of the following renal biopsy diagnoses?
   - **A.** HIV-associated nephropathy (collapsing glomerulopathy) or focal segmental glomerulosclerosis (FSGS)
   - **B.** Membranous nephropathy
   - **C.** Immune complex glomerulonephritis
   - **D.** Immunoglobulin A (IgA) nephropathy
2. An HIV-positive individual is receiving antiviral therapy and has suppressed viral replication. At a routine clinic visit, reduced serum phosphate and uric acid along with glycosuria are noted. Which of the following is the *most* likely explanation for these abnormalities?
   - **A.** Efavirenz
   - **B.** Allopurinol
   - **C.** Tenofovir disoproxil fumarate
   - **D.** Ritonavir
3. The clinician of the patient in question 2 was not provided with the laboratory results, and no changes were made in the clinical management of the patient. On the next visit, 6 months later, the serum creatinine value has risen and a renal biopsy is performed. Which of the following findings would be *most* specific in clarifying the cause of the injury?
   - **A.** Arterionephrosclerosis
   - **B.** Focal global glomerulosclerosis
   - **C.** Tubular atrophy and interstitial nephritis
   - **D.** Giant mitochondria within the tubular cells

Nephrolithiasis and Nephrocalcinosis

Wei Chen, Rebeca D. Monk, David A. Bushinsky

NEPHROLITHIASIS

Epidemiology

Kidney stones are common in industrialized nations, with an annual incidence of over 1 in 1000 persons and a lifetime risk for forming stones of approximately 5% in women and 13% in men.[1-4] In the United States the prevalence of nephrolithiasis increased from 3.2% in the late 1970s to 5.2% in the 1990s and further to 8.8% in the first decade of the 2000s, in parallel with the rising incidence of obesity, insulin resistance, and type 2 diabetes mellitus.[5,6] Factors that determine renal stone prevalence include age, sex, race, and geographical distribution. Incidence peaks in the third and fourth decades, and prevalence increases with age until approximately 70 years in men and 60 years in women. Men are more prone to stone formation than women.[6] In the United States, Whites are more likely to develop renal stones than African Americans, Hispanics, or Asian Americans, but the prevalence is rising in non-Whites as well.[6] The tendency in the United States for the development of stones also depends on geographical location, with an increasing prevalence from north to south and, to a lesser degree, from west to east. The increase in nephrolithiasis rates from north to south may be due to increased environmental temperatures, and greater sunlight exposure leading to an increase in insensible losses through sweating and more concentrated urine.[4,7] The higher urine calcium excretion in a smaller urine volume will increase the risk for supersaturation for calcium-containing crystals, thereby promoting stone formation.

Stone type varies with worldwide geography and genetic predisposition. In the Mediterranean and Middle East, 75% of stones are composed of uric acid. In the United States, the majority of stones are calcium oxalate or calcium phosphate (>70%), with less than 10% being pure uric acid stones. Magnesium ammonium phosphate (struvite) stones account for 10% to 25% of stones formed (with a higher incidence in the United Kingdom), and cystine stones constitute 2% of all stones formed (Fig. 57.1).[8]

Outbreaks of kidney stones also can occur as a result of dietary supplements or medications. A large number of Chinese infants and toddlers developed kidney stones, and some children developed renal failure because of obstruction caused by stones. This outbreak was associated with melamine contamination in infant formulas and powdered milk as a means of raising the apparent concentration of protein in the products.[9]

Kidney stones are associated with systemic conditions including chronic kidney disease (CKD), cardiovascular disease, and bone disease. In a Canadian registry cohort of close to 2 million participants without end-stage renal disease (ESRD) at baseline,[10] having one or more episodes of kidney stones during follow-up was associated with increased risk for ESRD (adjusted hazard ratio [HR] 2.16, 95% confidence interval [CI] 1.79-2.62) and new CKD stage 3b-5 (HR 1.74, 95% CI 1.79-2.62) compared with those without kidney stones during follow-up. The risk for CKD development was greater in women than in men and in people younger than 50 years of age. However, the absolute increase in the rate of adverse renal outcomes associated with kidney stones was small; the unadjusted rate of ESRD was 2.48 and 0.52 per million person-days in people who developed kidney stones and in people without stones, respectively. In a prospective study of participants without a history of coronary heart disease, development of kidney stones was associated with increased risk for coronary heart disease in women but not in men.[11] In a retrospective, matched case-control study, calcium kidney stone formers had significantly higher degrees of aortic calcification and lower bone mineral density than age- and sex-matched non–stone formers.[12]

Pathogenesis

Stones occur in urine that is supersaturated with respect to the ionic constituents of the specific type of stone. Supersaturation depends on the product of the free ion activities of stone components rather than on their molar concentrations. The free ion activities of stone components can be affected by crystal component concentration, presence of inhibitors, and urine pH. An increasing concentration of crystal components increases their free ion activity. When calcium and oxalate are dissolved in pure water, the solution becomes saturated when the addition of any more calcium or oxalate does not result in further dissolution. However, urine, unlike pure water, contains numerous calcification inhibitors that can form soluble complexes with the ionic components of the stone. The interactions with these inhibitors (e.g., citrate) may result in a decrease in free ion activity that allows the stone constituents to increase in total concentration to levels that would normally cause stone formation in water. Urinary pH also influences free ion activity. The level of chemical free ion activity in which stones will neither grow nor dissolve is referred to as the *equilibrium solubility product,* or the upper limit of metastability. Above this level, the urine will be supersaturated and any stone present will grow in size.

When the solution becomes supersaturated with respect to a solid phase, ions can join together to form the more stable, solid phase, a process termed *nucleation.* Homogeneous nucleation refers to the joining of similar ions into crystals. The more common and thermodynamically favored heterogeneous nucleation results when crystals grow adjacent

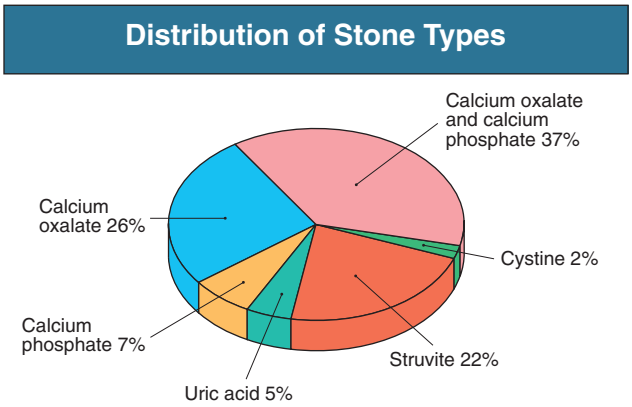

Fig. 57.1 Proportion of stone types in a typical U.S. population.

Fig. 57.2 Ureteral calculus. A 1-cm-wide calcium oxalate stone that provoked ureteral colic and required surgical removal.

to crystals or other substances in the urine, such as sloughed epithelial cells. Calcium oxalate crystals, for example, can nucleate with uric acid crystals. These small crystals may then aggregate to form larger stones, which would pass into the urine, causing crystalluria, if they did not anchor to the urothelium.

Calcium oxalate crystals anchor on areas of calcium phosphate deposits termed *Randall plaques* that are located in the renal papillae. Randall plaques appear to originate around the thin loop of Henle. In the outer medulla, the vascular bundles are surrounded by the thick ascending limb, which absorbs calcium independently of water. As the delivery of calcium to the thick ascending limb increases, the calcium concentration in the vascular bundles increases. This promotes supersaturation of crystals in the thin limb, which fosters plaque formation. This theoretical mechanism is referred to as *vas washdown* and has yet to be proven experimentally.[13] Calcium oxalate crystals attach to Randall plaques, allowing significant stone growth.[14] Clinically apparent stone disease occurs when the calcium oxalate crystals break off from the Randall plaques and cause injury or obstruction.

Several genetic polymorphisms have been implicated in the pathogenesis of calcium stones in genome-wide association studies. They include genes coding for proteins regulating tubular calcium and phosphate reabsorption (e.g., calcium-sensing receptor, vitamin D receptor, and claudins), genes coding for proteins preventing calcium salt precipitation (e.g., matrix gla protein), and genes coding for aquaporin in the proximal tubule.[2,15]

Clinical Manifestations

The two most characteristic symptoms of nephrolithiasis are pain and hematuria. Other presentations include urinary tract infections (UTIs) and acute kidney injury caused by obstructive uropathy if stones cause bilateral renal tract obstruction or unilateral obstruction in a single functioning kidney (Table 57.1).

Pain

The classic manifestation of pain in patients with nephrolithiasis is ureteral colic. Pain is of abrupt onset and intensifies over time into an excruciating, severe flank pain that resolves only with stone passage or removal. The pain may migrate anteriorly along the abdomen and inferiorly to the groin, testicles, or labia majora as the stone moves toward the ureterovesical junction. Gross hematuria, urinary urgency, frequency, nausea, and vomiting may occur. Stones smaller than 5 mm usually pass spontaneously with hydration, whereas larger stones often require urologic intervention (Fig. 57.2).[14] Ureteral colic may occur with the passage of clots from hematuria of any cause ("clot colic") or with papillary necrosis. Nephrolithiasis also may provoke less-specific loin pain that poorly localizes to the kidney and therefore has a wide differential diagnosis, particularly if not associated with other urinary symptoms. The finding of a stone on radiologic examination does not preclude a coincidental cause of pain from another source.

TABLE 57.1 Clinical Presentations of Nephrolithiasis

Presentation	Characteristics
Pain	Ureteral colic, loin pain, dysuria
Hematuria	—
Urinary tract infection	Recurrent, chronic infection, pyelonephritis
Asymptomatic urine abnormality	Microhematuria, proteinuria, sterile pyuria
Interruption of urinary stream	—
Calculus anuria	—

Hematuria

Stone disease is a common cause of hematuria. Macrohematuria occurs more commonly with large calculi and during UTI and colic. Although typically associated with loin pain or ureteral colic, the hematuria of nephrolithiasis also may be painless. The clinical differential diagnosis of hematuria is wide (Box 57.1). Painless microhematuria in children may occur with hypercalciuria in the absence of demonstrable stones.

Loin Pain–Hematuria Syndrome

Loin pain–hematuria syndrome is a poorly understood condition that must be considered in the differential diagnosis of nephrolithiasis. It is diagnosed by exclusion when patients (most typically young and middle-aged women) present with loin pain and persistent microhematuria or intermittent macrohematuria.[16] Careful evaluation is required to exclude small stones, tumor, UTI, and glomerular disease. Angiographic abnormalities implying intrarenal vasospasm or occlusion have been reported, as have renal biopsy abnormalities typified by deposition of complement C3 in arteriolar walls. However, these findings are not consistent, nor do they provide a coherent framework to explain the pathogenesis of this condition.

In one study, 43 consecutive patients with clinical manifestations of loin pain–hematuria syndrome were evaluated by renal biopsy after other causes of their symptoms had been excluded with at least two

BOX 57.1 Causes of Hematuria

- Nephrolithiasis
- Infection: Cystitis, prostatitis, urethritis, acute pyelonephritis, tuberculosis, schistosomiasis
- Malignancy: Renal cell carcinoma, transitional cell carcinoma, prostate cancer, Wilms tumor
- Trauma
- Glomerular disease
- Interstitial nephritis
- Polycystic kidney disease
- Papillary necrosis
- Medullary sponge kidney
- Miscellaneous: Loin pain–hematuria syndrome, arteriovenous malformation, chemical cystitis, caruncle, factitious

imaging studies.[16] Thirty-four patients were considered to have idiopathic loin pain–hematuria syndrome after nine with histologic evidence of immunoglobulin A nephropathy were excluded. Of these, 66% had glomerular basement membranes that were either unusually thick or thin on electron microscopy and 47% had a history of kidney stones, though none had obstructing stones at the time of imaging assessment. Evidence of glomerular hematuria was more common in biopsy samples of patients with loin pain–hematuria syndrome compared with those of healthy living kidney donors who also underwent renal biopsy. The investigators postulated that the structurally abnormal glomerular basement membranes in the majority of these patients may lead to rupture of the glomerular capillary walls, with consequent hemorrhage into the renal tubules. Tubular obstruction by red blood cells or potentially by microcrystals ensues. Local and global renal parenchymal edema follow, ultimately resulting in stretching of the renal capsule and in severe flank pain.

Loin pain–hematuria syndrome is a chronic condition requiring reassurance, careful management of analgesia, and ongoing psychological support. The condition usually remits after several years. Denervation of the kidney by autotransplantation is rarely successful. The extreme measure of nephrectomy has been used, but pain often recurs promptly in the contralateral kidney. Bilateral nephrectomy and renal replacement therapy has been reported as an approach of very last resort. Referral to a pain clinic can assist in providing psychiatric counseling, analgesia, and exclusion of other disorders. In one retrospective study, patients who eventually came to accept a nonsurgical approach along with pain-coping strategies that did not involve narcotic analgesics had the most successful outcomes.[17]

Asymptomatic Stone Disease

Even large staghorn calculi may be asymptomatic and discovered only during the investigation of unrelated abdominal or musculoskeletal symptoms. Obstructive uropathy caused by calculi also may be painless; therefore nephrolithiasis always should be considered in the differential diagnosis of unexplained renal failure.

In the outbreak of melamine-associated nephrolithiasis in Chinese infants, the majority of patients brought to a screening clinic had no symptoms or signs of stones, and the diagnosis of nephrolithiasis was made only by ultrasound in at-risk infants and toddlers.[9]

Clinical Evaluation of Stone Formers

All patients with recurrent nephrolithiasis merit metabolic evaluation to determine the cause of their kidney stones. Complete evaluation of patients who have formed only a single stone is controversial because of the undetermined cost-to-benefit ratio. A National Institutes of Health Consensus Development Conference on the Prevention and Treatment of Kidney Stones determined that all patients, even those with a single stone, should undergo a basic evaluation. Those with metabolically active stones (stones growing in size or number within 1 year), all children, non–calcium stone formers, and patients in demographic groups not typically prone to stone formation warrant a more complete evaluation, which includes a 24-hour urine collection made with the patient taking his or her typical diet.

BOX 57.2 The Basic Evaluation of Nephrolithiasis

- Stone history
  - Number of stones formed
  - Frequency of stone formation
  - Age at first onset
  - Size of stones passed or still present
  - Kidney involved (left, right, or both)
  - Stone type, if known
  - Need for urologic intervention such as ESWL or percutaneous nephrolithotomy
  - Response to surgical procedure
  - Association of stones with urinary tract infections
- Medical history
- Medications
- Family history
- Occupation and lifestyle
- Fluid intake and diet
- Physical examination
  - Evidence of systemic causes of stones (e.g., tophi)
- Laboratory data
  - Urinalysis
  - Urine culture
  - Stone analysis
- Blood chemistry
  - Sodium, potassium, chloride, bicarbonate
  - Creatinine, calcium, phosphorus, uric acid
  - Intact parathyroid hormone level if calcium elevated
- Radiologic evaluation
  - Abdominal radiograph (no contrast)
  - Noncontrast CT
  - Ultrasound

CT, Computed tomography; *ESWL,* extracorporeal shock wave lithotripsy; *IVU,* intravenous urography.

Basic Evaluation

The evaluation of stone formers includes a careful history and physical examination and requires specific data gathering on stone formation, diet, and specific laboratory studies, as shown in Box 57.2.

History. The history serves to uncover a systemic cause for nephrolithiasis. Any disease that can lead to hypercalcemia (including malignancy, hyperparathyroidism, and sarcoidosis) can result in hypercalciuria and increase the risk for calcium stone formation. A number of malabsorptive gastrointestinal disorders (including Crohn disease and sprue [celiac disease]) can result in calcium oxalate stone formation as a result of volume depletion and hyperoxaluria. Uric acid stones often occur in patients with a history of gout and, increasingly, in patients with insulin resistance.[8]

The stone history (see Box 57.2) includes the number and frequency of stones formed, patient age at incidence of first stone, size of stones, stone type (if known), and whether the patient required surgical removal of the calculi. This information indicates the severity of the stone disease and provides clues to the cause of the stone formation. For example, large staghorn calculi that do not pass spontaneously and recur despite frequent surgical intervention are more consistent with struvite than calcium oxalate stones. Stones that develop at a young age may be caused by cystinuria or primary hyperoxaluria. Stone response to intervention is also significant; cystine stones, for example, do not fragment well with lithotripsy. If stones recur frequently in a single kidney, a congenital abnormality in that kidney, such as megacalyx or medullary sponge kidney, should be explored.

Family history is important because a number of stone types have a genetic basis. Idiopathic hypercalciuria is most likely a polygenic disorder. Mutations in the claudins, which regulate calcium reabsorption in the thick ascending limb of the loop of Henle, cause familial hypercalciuria and nephrocalcinosis. A genome-wide association study in patients with kidney stones identified sequence variants in the gene encoding claudin 14 that were associated with hypercalciuria.

Cystinuria is usually autosomal recessive, and hyperuricosuria has been associated with rare inherited metabolic disorders. Nephrolithiasis and nephrocalcinosis can result from a variety of monogenic disorders, such as Dent disease (X-linked recessive nephrolithiasis), McCune-Albright syndrome, osteogenesis imperfecta type 1, and congenital lactate deficiency. The various genetic disorders can lead to hypercalciuria by increasing bone resorption, affecting intestinal absorption, by decreasing renal tubular reabsorption transport, or through other, as yet unknown, mechanisms.[4,14,18]

A number of medications are known to potentiate calcium stone formation (e.g., loop diuretics are calciuric) or may predispose to uric acid lithiasis (salicylates, probenecid) (Box 57.3). Certain drugs can precipitate into stones themselves, such as rapidly infused intravenous acyclovir, high-dose sulfadiazine, triamterene, and the antiretroviral agents indinavir and nelfinavir.[19] In addition, some medications, such as acetazolamide and topiramate (a medication used for seizures and migraine headaches), promote nephrolithiasis by inhibiting carbonic anhydrase activity. In this setting the metabolic acidosis that ensues, along with lower urine citrate, higher urine pH, and increased urinary calcium excretion, predisposes to calcium phosphate stone formation.

The social history should include details regarding occupation and lifestyle. Surgeons and real-estate agents, for example, may minimize fluid intake to avoid bathroom breaks during the workday. Those who engage in vigorous physical activities, such as running, may not rehydrate adequately to keep up with insensible losses, producing excessively concentrated urine and precipitation of stone crystals in those prone to nephrolithiasis.

A dietary history and review of fluid intake are essential in determining potential causes or contributors to stone formation. The patient should be asked about commonly consumed foods, with attention paid to sodium-containing foods, as well as quantities of calcium, animal protein, purine, and oxalate (Box 57.4). Dietary calcium intake should be reviewed, because many patients with nephrolithiasis are erroneously instructed to eliminate all calcium from their diet, a suggestion that can result not only in bone demineralization, particularly in women and children, but also in an increase in stone formation.[1-3,20] Sugar-sweetened soda appears to be associated with a greater risk for stone formation, whereas consumption of coffee, tea, beer, wine, and orange juice appears to be associated with a lower risk.[21] The exact mechanism of nephrolithiasis from soda is not known but is likely related to the high fructose content of soda, which may alter urinary composition and pH.

BOX 57.3 Medications Associated With Nephrolithiasis and Nephrocalcinosis

Calcium Stone Formation
- Loop diuretics
- Vitamin D
- Corticosteroids
- Calcium supplements
- Antacids (calcium and noncalcium antacids)
- Theophylline
- Acetazolamide*
- Amphotericin*
- Topiramate

Uric Acid Stone Formation
- Salicylates
- Probenecid
- Melamine (in contaminated infant formula and milk products)

Medications That May Precipitate Into Stones
- Triamterene
- Acyclovir (if infused rapidly intravenously)
- Indinavir
- Nelfinavir

*Associated with nephrocalcinosis.

BOX 57.4 Foods High in Oxalate and Purine

High-Oxalate Foods (Avoid in Setting of Hyperoxaluria)
- Green beans
- Beets
- Celery
- Green onions
- Leeks
- Leafy greens: Collard greens, dandelion greens, Swiss chard, spinach, escarole, mustard greens, sorrel, kale, rhubarb
- Cocoa
- Chocolate
- Black tea
- Berries: blackberries, blueberries, strawberries, raspberries, currants, gooseberries
- Orange peel
- Lemon peel
- Dried figs
- Summer squash
- Nuts, peanut butter
- Tofu (bean curd)

High-Purine Foods (Avoid in Setting of Hyperuricosuria)
- Organ meats: Sweetbreads, liver, kidney, brains, heart
- Shellfish
- Meat: Beef, pork, lamb, poultry
- Fish: Anchovies, sardines (canned), herring, mackerel, cod, halibut, tuna, carp
- Meat extracts: Bouillon, broth, consommé, stock
- Gravies
- Certain vegetables: Asparagus, cauliflower, peas, spinach, mushrooms, lima and kidney beans, lentils

Physical examination. Most patients with idiopathic hypercalciuria are healthy and have normal physical examination findings. Patients with hyperuricosuria and uric acid stone formation may display tophi. Central obesity is associated with a predisposition to metabolic syndrome and uric acid stones. Paraplegic patients with a chronic indwelling bladder catheter may be predisposed to chronic UTI and struvite stones.

Laboratory findings. Urine pH is generally high in patients with struvite and calcium phosphate stones but low in patients with uric acid and calcium oxalate stones. Bacteriuria with urine pH greater than 7.0 suggests struvite stones. Urine should be cultured, and because many bacteria produce urease even when urine bacterial colony counts are low, the microbiology laboratory should be instructed to type the organism even if there are fewer than 10^5 colony-forming units/ml. The specific gravity, if high, will confirm inadequate fluid intake in many patients. Hematuria may imply active stone disease with crystal or stone passage. Examination of the urine may reveal red blood cells along with characteristic crystals (Fig. 57.3).

Blood tests required in the basic evaluation are serum electrolytes (sodium, potassium, chloride, and bicarbonate), creatinine, calcium, phosphorus, and uric acid. If the serum calcium is elevated or at the upper limit of normal, especially if the serum phosphorus is low, a serum parathyroid hormone level should be measured. A low potassium or bicarbonate level may indicate a cause for hypocitraturia, such as distal renal tubular acidosis.

Stone analysis. Patients should be encouraged to retrieve any stone they excrete for chemical analysis, which may help define the underlying metabolic abnormality and guide therapy.

Imaging. Current imaging techniques used to evaluate stones include plain abdominal radiograph, unenhanced helical computed tomography (CT), and renal ultrasound.[22] Unenhanced CT is typically the diagnostic test of choice for acute ureteral colic, although a recent study suggested that renal ultrasound may be a better choice than CT.

Plain abdominal radiography performed with views of the kidneys, ureters, and bladder (KUB) may reveal opacifications in the areas of the kidneys and ureters that could be a result of calcium, cystine, or struvite stones (Fig. 57.4). Uric acid and xanthine calculi are radiolucent and will not be visible on plain films.

Unenhanced helical CT scanning, also known as spiral CT, or CT urography, has replaced contrast intravenous urography (IVU) as a

diagnostic test for acute ureteral colic because it has a higher sensitivity and specificity for detecting ureteral stones and ureteral obstruction and avoids the need for contrast (see Fig. 57.5A). It is rapid, with results being available in minutes rather than hours, and this is an advantage in the emergency room setting. There are several disadvantages of CT imaging: radiation dose from a CT urography is approximately three times that of a conventional IVU; CT urography is more expensive and is associated with a high rate of incidental findings that could lead to inappropriate referral and treatment. In addition, an experienced radiologist, required for optimal interpretation of the images, may not be available at all times in urgent care facilities. CT urography should be avoided or limited in patients at risk for radiation exposure, such as children and pregnant women.

Renal ultrasound also provides high specificity in the evaluation of stones, and a recent study indicated that it may be a better choice than CT, especially for those patients who must avoid radiation exposure (Fig. 57.5B). In a multicenter, comparative effectiveness trial, 2759 patients who presented to the emergency department (ED) with suspected nephrolithiasis were randomized to undergo either initial ultrasound or abdominal CT. Ultrasound was associated with lower cumulative radiation exposure than initial CT. There were no significant differences in high-risk diagnoses with complications (e.g., abdominal aortic aneurysm with rupture, pneumonia with sepsis), serious adverse events, pain scores, return ED visits or hospitalizations between the ultrasound (whether assigned to either point-of-care in ED or to radiology department) and CT.

Periodic monitoring, if deemed necessary, should be obtained with a KUB and/or ultrasound scan rather than CT, whenever possible, to minimize radiation exposure. The combination of ultrasound and KUB is more sensitive in detecting stones than either test alone, while minimizing radiation compared with CT. Many patients with stones have recurrent disease and may require repeated imaging. Children and young adults are at higher risk for consequences from radiation exposure, and studies in this population should be limited. Especially when caring for patients who may father or subsequently carry offspring, every effort

should be made to limit radiation exposure. In general, we do not order routine follow-up x-ray examinations and do not order x-ray examinations unless the results will alter subsequent care. If x-ray films are ordered, every effort should be made to limit radiation exposure, as the results of a noncontrast study alone are often sufficient to guide therapy.

Complete Evaluation

A complete evaluation should be undertaken in patients with multiple or metabolically active stones (i.e., stones that increase in size or number within a year), in all children, in patients from demographic groups not typically prone to stone formation, and in those with stones other than those containing calcium.

The complete evaluation should include a measure of urine volume and the quantity of calcium, oxalate, phosphorus, uric acid, sodium, citrate, and creatinine excreted in a 24-hour urine collection (Table 57.2). Urine creatinine is useful in assessing adequacy of the collection; men should excrete more than 15 mg/kg (132.6 μmol/kg), and women should excrete more than 10 mg/kg (88.4 μmol/kg) daily. Patients should be encouraged to perform the urine collection on a typical day while eating a typical diet, although many patients prefer to collect the urine on weekends when their diet and habits may differ from those during usual workdays. Specialized testing, such as urine collections during high- or low-dietary calcium intake is not recommended. Careful instructions should be given to avoid overcollection or undercollection. Patients should be instructed to discard the first morning urine at the start of the collection and collect all urine for the next 24 hours, including the first urine collection on the second morning.

A disadvantage of the standard 24-hour urine collection is that laboratories vary in the preservatives required to process the various constituents. Many require more than one collection to measure all the urinary constituents, reducing compliance and therefore the accuracy of the results.

TABLE 57.2 Optimal 24-Hour Urine Values in Recurrent Nephrolithiasis

24-Hour Urine Values	
Volume	>2-2.5 l
Calcium	<4 mg/kg (0.1 mmol/kg), ~300 mg (7.5 mmol) in men, ~250 mg (6.3 mmol) in women
Oxalate	<40 mg (0.36 mmol)
Uric acid	<750 mg (4.5 mmol) in women and <800 mg (4.7 mmol) in men (can be pH dependent)
Citrate	>320 mg (17 mmol)
Sodium	<2000 mg (<87 mmol)
Phosphorus	<1100 mg (35 mmol)
Creatinine	>10 mg/kg (88 μmol/kg) in women and >15 mg/kg (132 μmol/kg) in men, if specimen is a complete collection
Urine Supersaturation Values	
Calcium oxalate supersaturation	<5
Calcium phosphate supersaturation	0.5-2
Uric acid supersaturation	0-1

A better approach available in some laboratories is to undertake a 24-hour urine collection for quantification of supersaturation for the common solid phases of calcium oxalate, brushite (calcium phosphate), and uric acid (see Table 57.2). Urine for supersaturation analysis has been shown to correlate well with stone composition, and the risk for stone formation rises with increasing supersaturation. Determination of supersaturation is far more informative than evaluation of the individual urinary constituents.

Patients can bring their specimens to a local laboratory or may directly mail them to specialized laboratories that measure calcium, oxalate, citrate, uric acid, creatinine, sodium, potassium, magnesium, sulfate, phosphorus, chloride, urine urea nitrogen, and pH. Supersaturation is calculated with a computer program. Calculation of supersaturation from a 24-hour urine specimen will provide values lower than the peak postprandial supersaturation and peak nighttime supersaturation, either of which may initiate stone formation. Patients should stop taking any vitamin C or multivitamins containing more than 100 mg of vitamin C for at least 5 days before the urine collection because the antioxidants in the vitamin may interfere with the assay.

General Treatment

Intervention for stone removal may be required when pain, obstruction, and/or infection resulting from nephrolithiasis do not respond to conservative management. Surgical management of stones includes extracorporeal shock wave lithotripsy (ESWL) and both endoscopic and percutaneous surgical removal of stones, and is further discussed in Chapter 59. The risk for developing renal impairment varies with the type of stone, and this must be considered in planning management.

Medical Management

Patients who are seen by stone "specialists" often have a decrease in stone recurrence even without pharmacologic intervention.[23] This phenomenon, termed *the stone clinic effect*, is likely a result of modifications in diet and fluid intake. These nonpharmacologic measures include an increase in fluid intake, which increases urine volume; restriction of dietary sodium, which leads to a reduction of urine calcium excretion; restriction of animal protein, which also leads to a reduction of urine calcium excretion and an increase in excretion of the calcification inhibitor citrate; and ingestion of an age- and gender-appropriate amount of dietary calcium. Although dietary calcium restriction continues to be prescribed by many physicians, increasing evidence indicates that this is not beneficial and can actually increase the rate of stone formation (see later discussion of calcium stones).[3,20]

Fluid intake. An increase in urine volume to more than 2 to 2.5 liters daily has been proven to reduce the incidence of stones. Large urine volumes will reduce calcium oxalate supersaturation, as well as precipitation of other crystals. Increased fluid intake to augment urine volume is also a mainstay of therapy for patients with uric acid and cystine stones. The period of maximum risk for stone formation is at night, when urine concentration is physiologically increased. Patients should be encouraged to drink enough fluid in the evening to provoke nocturia and then drink further fluid before returning to bed.

Salt intake. Urine sodium excretion directly correlates with urine calcium excretion[1,2]; thus dietary salt restriction is associated with decreased urine calcium excretion. Patients should be instructed to limit daily sodium intake to 2 g (87 mmol sodium).

Dietary protein. Animal protein ingestion increases the frequency of renal stone formation by a number of mechanisms. Metabolism of certain amino acids leads to generation of sulfate ions, which render urinary calcium ions less soluble.[25,26] The metabolic acidosis that results from protein ingestion causes calcium release from bone and a consequent increase in the filtered load of calcium.[25,26] Acidosis also decreases

tubular calcium reabsorption, resulting in hypercalciuria. Urinary citrate excretion is also pH dependent, with acidosis leading to a decrease in citrate excretion. The result of increased animal protein intake is an increase in urinary calcium excretion that is rendered less soluble because of concomitant sulfate excretion and hypocitraturia. Low urine pH, coupled with increased uric acid excretion from the metabolism of animal protein, can result in uric acid lithiasis. Stone formers should be encouraged to consume a moderate protein intake. Dietary fructose may also increase uric acid lithiasis.

Dietary calcium. Despite conventional wisdom, several studies have demonstrated a decrease in stone incidence when people consume diets adequate in calcium.[23,24] This beneficial effect has been attributed to intestinal binding of ingested oxalate (which is highly lithogenic) by dietary calcium. Although women have reduced stone formation while ingesting an age-appropriate amount of dietary calcium, this benefit may not extend to those taking calcium in the form of calcium supplements.[27] The data are inconsistent as to whether calcium supplements increase the risk for nephrolithiasis. Some have postulated that any increased risk may be a result of timing the supplemental calcium ingestion apart from meals, which would enhance calcium absorption without reducing oxalate absorption. In addition, the calcium supplements may dissociate rapidly, leading to rapid absorption, increased filtered calcium load, and transitory hypercalciuria, leading to increased supersaturation. We advise patients that it is best to obtain calcium from dairy products rather than supplements.

Recent studies have demonstrated that women ingesting calcium supplements have a great risk for cardiovascular disease and death, perhaps by promoting vascular calcification.[28] In one long-term study of more than 60,000 Swedish women, those with a dietary calcium intake exceeding 1400 mg/day had an increased risk for cardiovascular mortality with a hazard ratio of 1.49 (95% CI 1.09-2.02). The risk for all-cause mortality rose to 2.57 (95% CI 1.19-5.55) when any calcium tablet supplements were added to this high dietary intake.[29] A review of cardiovascular mortality in over 15 studies involving calcium supplementation versus placebo showed increased risk for myocardial infarction in those randomized to calcium supplements with a hazard ratio of 1.31 (95% CI 1.02-1.67) that rose to 1.85 (95% CI 1.28-2.67) in patients already taking more than 805 mg of dietary calcium daily.[28] In a 10-year follow-up of 5448 adults free of clinically diagnosed cardiovascular disease calcium supplements increased the risk for incident coronary artery calcification (relative risk 1.22 (95% CI 1.07-1.39)).[30] The Institute of Medicine in the United States recently adjusted the recommended allowance of calcium to 1000 mg/day for adults older than 19 years and 1200 mg for women over age 50 years.[31] We recommend that women take the appropriate amount of calcium in the form of food with limited supplement intake, except in cases of severe osteoporosis with insufficient dietary intake.

Support for the use of an age- and gender-appropriate amount of dietary calcium was provided by a randomized prospective study comparing the rate of stone formation in men assigned a low-calcium diet with those assigned a normal-calcium, low-sodium, and low–animal protein diet.[20] The men assigned the low-calcium diet were twice as likely to have recurrent stones over 5 years compared with those on the normal-calcium, low-sodium, and low–animal protein diet. Urinary calcium oxalate supersaturation also diminished more rapidly in those on the higher calcium diet and remained lower than that of men on the low-calcium diet for most of the 5-year study. This reduction in supersaturation was the result of a greater fall in urinary oxalate in the men eating the normal-calcium, low-sodium, and low–animal protein diet.[20,32]

Patients prescribed a low-calcium diet can avoid excessive hyperoxaluria when adequately instructed to also consume a low-oxalate diet.[33] Some contend that this approach may benefit patients with excessive intestinal absorption of calcium associated with severe hypercalciuria by allowing calcium restriction without the risk for significant osteopenia. We recommend, however, an age- and gender-appropriate calcium intake, best derived from a diet containing an adequate amount of dairy products. Because stone formation can be reduced with normal calcium intake and there is a risk for bone demineralization with calcium restriction, we consider the low-calcium diet to be obsolete.[18,29] Dietary calcium intake exceeding the age and gender recommendations and calcium supplements should be avoided in patients with calcium nephrolithiasis.

Vitamin D. Given the great degree of vitamin D deficiency and insufficiency in Northern latitudes, vitamin D supplementation is very common.[34] There is concern that this might exacerbate nephrolithiasis, given the role of vitamin D in mineral metabolism. In fact, studies have shown no association between vitamin D supplementation or serum 25-hydroxyvitamin D levels and calcium excretion, nor an increased rate of stone formation in hypercalciuric patients on vitamin D supplementation. It is reasonable to treat vitamin D deficiency (25-hydroxyvitamin D levels below 20 ng/ml) with supplemental vitamin D (we prefer cholecalciferol to ergocalciferol because of more robust biological activity and greater half-life) with no fear of worsening hypercalciuria or increasing stone formation.[35]

SPECIFIC TYPES OF STONES

Calcium Stones

Calcium-containing kidney stones constitute approximately 70% of all stones formed. Most calcium stones are composed of calcium oxalate, either alone or in combination with calcium phosphate or uric acid. A small percentage of stones are composed entirely of calcium phosphate.[1] Most calcium stones do not exceed 1 to 2 cm in width. Surgical intervention is often required for stones greater than 5 mm.

Calcium-based stones most often develop as a result of hypercalciuria. Other causes of calcium stones are hyperoxaluria, hyperuricosuria, hypocitraturia, renal tubular acidosis, certain medications, and congenital abnormalities of the genitourinary tract (Fig. 57.6). Specific therapy for patients with calcium stones depends on the underlying metabolic abnormalities detected on evaluation. General therapy as outlined earlier always should be instituted; however, more definitive treatment is often required to significantly decrease the rate of recurrent stone formation.

Hypercalciuria

Etiology. Hypercalciuria for which a causative metabolic abnormality cannot be determined is called *idiopathic hypercalciuria.* Previously, hypercalciuric patients were divided into those with excessive renal calcium excretion (renal leak) and those who absorbed excessive amounts of calcium via the gastrointestinal tract (absorptive hypercalciuria). However, it is apparent that hypercalciuric patients generally do not have a transport defect limited to a single site; they appear to have a systemic dysregulation of calcium transport at the major calcium transporting sites, the intestine, kidney, and bone. In both hypercalciuric rats and in humans placed on a low-calcium diet, there is a continuous, wide spectrum of calcium excretion. Hypercalciuric patients may appear to have a renal leak on one examination and absorptive hypercalciuria on another.[1,2] Some patients excrete more calcium than they consume, indicating a negative total body calcium balance. This calcium must be derived from the mineral phases of bone, which contain by far the largest repository of calcium in the body. The cause of this systemic disorder in calcium transport has, in hypercalciuric stone–forming rats and perhaps in humans, been linked to an increased number of receptors for vitamin D in the major calcium transporting organs (intestine, kidneys, and

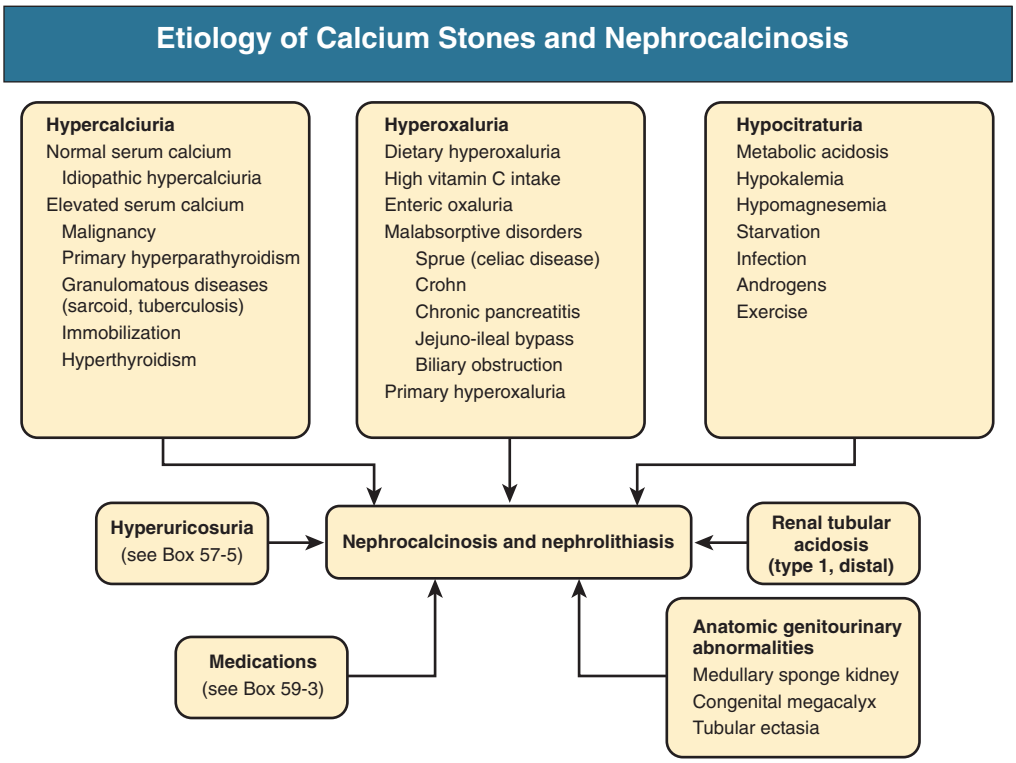

Fig. 57.6 Etiology of calcium stones and nephrocalcinosis.

bone).[36-38] Metabolic disorders leading to an elevation in serum calcium, parathyroid hormone, or 1,25$(OH)_2$D (1,25-dihydroxyvitamin D) also may result in hypercalciuria.

Treatment. For hypercalciuria the usual first-line therapy is a thiazide diuretic, which acts to reduce urinary calcium. In the United States, chlorthalidone 25 to 50 mg is the drug of choice because it requires only once-daily administration. Indapamide 1.25 to 2.5 mg/day does not tend to raise serum lipids as much as other thiazides and may be preferred for patients with cardiac risk factors or elevated serum lipids. On commencing these medications, patients should be instructed to increase their dietary potassium intake, and a serum potassium level should be checked 7 to 10 days later. If serum potassium is low, oral potassium supplementation should be initiated. Potassium citrate is generally preferred over potassium chloride. However, most patients find potassium citrate liquid preparations unpalatable. A wax matrix tablet of potassium citrate is well tolerated and is available in some countries. In general, patients are able to maintain a normal serum potassium level with potassium citrate 20 to 40 mmol/day. The serum potassium and bicarbonate levels should be rechecked 7 to 10 days later for further dosage adjustment. Because citrate is a base, potassium citrate may excessively raise the serum bicarbonate level and urinary pH, which could promote calcium phosphate stone formation. Urinary pH and supersaturation must be carefully monitored, and a change to potassium chloride may be required.

The 24-hour urine calcium, sodium, and citrate should be rechecked after several weeks. If the calcium excretion remains elevated, the thiazide dose should be increased. However, if the sodium excretion also remains high, patients should be encouraged to limit their sodium intake further because they will not have an adequate response to the diuretic on a high-sodium diet. If serum potassium remains low despite supplementation or the calcium excretion remains high despite increased thiazide dosing, addition of a potassium-sparing diuretic may be required to increase serum potassium. Amiloride with a starting dose 5 mg/day is the preferred treatment for thiazide-induced hypokalemia.[1,2] (Triamterene should not be used because it can precipitate into stones.)

Dietary recommendations. See the discussion of general treatment.

Hyperoxaluria

Etiology. Elevated urinary oxalate results from excessive dietary intake (dietary oxaluria), gastrointestinal disorders that can lead to malabsorption (enteric oxaluria), or an inherited enzyme deficiency that results in excessive metabolism of oxalate (primary hyperoxaluria) (see Fig. 57.6).[39]

Dietary excess of oxalate generally does not raise urinary oxalate above 60 mg/24 h (0.54 mmol/24 h). Enteric oxaluria may occur when malabsorption results in excessive colonic absorption of oxalate, as a result of sprue (celiac disease), Crohn disease, chronic pancreatitis, or short bowel syndrome or after bariatric surgery. The anion exchange transporter Slc26a6 appears responsible for intestinal oxalate secretion, and mice with targeted inactivation of this transporter have hyperoxaluria.[40] It is not yet known whether patients with enteric hyperoxaluria have mutations in Slc26a6. Urinary oxalate is generally more than 60 mg/24 h and can exceed 100 mg/24 h (0.54 and 0.9 mmol/24 h). In primary hyperoxaluria, the tremendous oxalate production results in widespread calcium oxalate deposition throughout the body at an early age. This infiltration of calcium oxalate into organs can result in cardiomyopathy, bone marrow suppression, and renal failure. Urinary oxalate values may range from 80 to 300 mg/24 h (0.72 to 2.70 mmol/24 h).

There are three types of primary hyperoxaluria with unique enzymatic defects in the liver glyoxylate pathway. In type 1, the defective enzyme is alanine–glyoxylate aminotransferase, encoded by the gene *AGXT* on chromosome 2; this accounts for approximately 80% of cases. Type 2 tends to be a milder disorder and is caused by mutations in the *GRHPR* gene on chromosome 9, which results in failure of glyoxylate reduction to glycolate; this accounts for approximately 10% of the cases. Type 3 is a result of mutations in the gene that encodes the

mitochondrial 4-hydroxy-2-oxoglutarate aldolase enzyme, which catalyzes the cleavage of 4-hydroxy-2-oxoglutarate to pyruvate and glyoxylate and accounts for about half of the remaining cases.[41]

Treatment of dietary and enteric hyperoxaluria. Treatment of dietary oxaluria consists of dietary oxalate restriction. Patients should be given a list of foods that have high oxalate content to avoid or eat in moderation (see Box 57.4). Calcium containing food may be included at each meal to bind intestinal oxalate and prevent its absorption.

Specific therapy for the malabsorptive disorder, such as a gluten-free diet for patients with sprue, is the first-line treatment for enteric hyperoxaluria. More generalized therapy for steatorrhea, such as a low-fat diet, cholestyramine, and administration of medium-chain triglycerides, may reduce fat malabsorption as well as oxalate absorption and subsequent excretion. The low-oxalate diet and mealtime calcium carbonate prescribed for patients with dietary oxaluria is also helpful for these patients. The diarrhea associated with these disorders may result in low urine volumes, hypokalemia, hypocitraturia, and hypomagnesuria. Patients should therefore be advised to increase their fluid intake and take potassium citrate (in this case, the liquid, although unpalatable, is better absorbed than the tablets), as well as a magnesium supplement. Magnesium also serves as a urinary stone inhibitor and can be given as magnesium gluconate 0.5 to 1 g once or twice a day or as magnesium oxide 400 mg every 12 hours.

Treatment of primary hyperoxaluria. Primary hyperoxaluria type 1 (PH1) is a severe disorder that can be cured only with liver transplantation to replace the defective hepatic enzyme. Pyridoxine (vitamin B_6) in doses ranging from 2.5 to 15 mg/kg/24 h may reduce oxalate production in patients with PH1. Efforts should be made to render the calcium and oxalate more soluble in the urine by raising the urinary pH (to at least 6.5) and giving supplemental citrate and magnesium. Orthophosphate is also an effective inhibitor of urinary calcium oxalate precipitation and can be safely administered in patients with a glomerular filtration rate (GFR) exceeding 50 ml/min. Because oxalate is poorly excreted in CKD and is not removed well by dialysis, renal transplantation serves not only to improve renal function, but also to improve oxalate excretion and diminish systemic oxalosis.[14]

Oxalobacter formigenes primarily uses oxalate for cellular metabolism.[42] Calcium oxalate stone formers who are colonized with *O. formigenes* have lower urine oxalate levels than those who are not colonized.[43] A small clinical trial involving administration of *O. formigenes* resulted in a modest decrease in urinary oxalate in some patients.[42] Further studies with larger numbers of patients and an end-point of reduction of recurrent stone formation will be necessary before this novel approach becomes accepted therapy.

Hypocitraturia

Citrate inhibits stone formation. A number of conditions reduce urinary citrate excretion, predisposing to stone formation. Excessive protein intake, hypokalemia, metabolic acidosis, exercise, hypomagnesemia, infections, androgens, starvation, and acetazolamide have all been implicated in decreased urinary citrate excretion. Therapy involves treatment of the underlying condition and potassium citrate supplementation. The potassium salt is preferred to sodium citrate because sodium promotes renal calcium excretion. Potassium citrate 15 to 25 mmol two to three times daily is required, and tablets are considered by most patients to be more palatable than the liquid preparation. In patients with renal impairment, serum potassium should be monitored carefully and dose reduction may be needed if hyperkalemia develops.[14]

Distal Renal Tubular Acidosis

Patients with distal (type 1) renal tubular acidosis have impaired distal tubular excretion of hydrogen ions with non–anion gap metabolic acidosis and alkaline urine. The acidosis causes calcium and phosphate to be released from bone with an ensuing increase in renal excretion of these ions. The acidosis also leads to an increase in citrate reabsorption by the proximal tubule. The end result is a high urinary pH, hypocitraturia (urinary citrate generally <100 mg/24 h [0.53 mmol/24 h]), and increased renal excretion of calcium and phosphate, all of which increase the propensity for calcium phosphate precipitation. Nephrocalcinosis in this setting is not uncommon because calcium precipitates with phosphorus in the alkaline tubular fluid. The metabolic acidosis and hypocitraturia should be treated with a combination of sodium citrate (or bicarbonate) and potassium citrate (or bicarbonate). Often large amounts, 1 to 2 mmol/kg/day in 2 or 3 divided doses, are required to neutralize the acidosis.[1] Citrate is generally preferred to bicarbonate by patients because it does not produce carbon dioxide on contact with stomach acid with resultant gastrointestinal bloating. However, citrate is usually more expensive than bicarbonate.

Hyperuricosuria

Calcium oxalate crystals often nucleate around other crystal types such as uric acid. Hyperuricosuria contributes to nephrolithiasis in 10% to 15% of calcium stones. Patients with hyperuricosuric calcium oxalate nephrolithiasis have hyperuricosuria with normal urinary calcium and oxalate, but often a higher urinary pH (>5.5) than patients with pure uric acid stones. Therapy for hyperuricosuria consists of increased fluid intake and reduced dietary purine intake. If uric acid excretion remains elevated, allopurinol should be initiated at 100 to 300 mg/day.[1]

Uric Acid Stones

Epidemiology

The prevalence of uric acid stones depends greatly on geographical location. In the United States, uric acid stones constitute 5% to 10% of all stones formed, whereas in Mediterranean and Middle Eastern countries uric acid stones may constitute up to 75% of stones. The stones are radiolucent and therefore poorly visible on plain radiographs. They are detectable on ultrasound and CT and as filling defects on IVU (Fig. 57.7).

Etiology and Pathogenesis

Causes of hyperuricosuria include excessive dietary purine or protein intake, disorders associated with cellular breakdown (tumor lysis syndrome, myeloproliferative disorders, hemolytic anemia), gout, uricosuric medications, certain inborn errors of metabolism, and possibly excessive fructose intake.

Three major factors influence uric acid stone formation: low urine pH, low urine volume, and elevated urinary uric acid levels (Box 57.5). Of the three, low urine pH is the principal metabolic disorder found in patients with uric acid nephrolithiasis. Uric acid is poorly soluble at pH below 5.5. Solubility increases with urine alkalinity such that at urine pH 6.5, urine can contain over six times the quantity of uric acid present at pH 5.3, without exceeding supersaturation. The rising incidence of obesity and insulin resistance in the United States led to a parallel increase in uric acid lithiasis. The urinary acidosis is likely a result of impaired ammoniagenesis, which results in excessive excretion of unbuffered acid and a very low urine pH.[8,44] The geographical and ethnic variations in the incidence of uric acid stones may be due to diet, caused by environmental factors, or the result of genetic susceptibility in some populations.[8]

Treatment

Treatment of uric acid stones involves increasing urine pH and volume as well as decreasing uric acid excretion. Alkaline urine not only can prevent uric acid stone formation, but also may result in stone

Radiolucent Urate Calculi

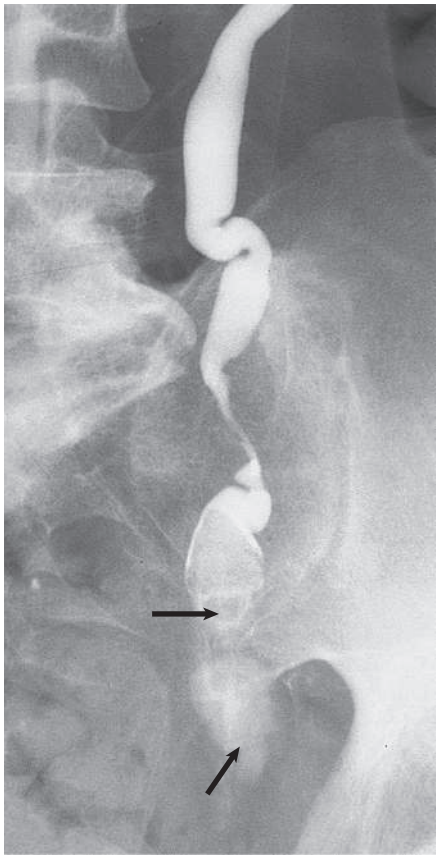

Fig. 57.7 Radiolucent urate calculi. Antegrade pyelogram showing multiple radiolucent uric acid stones *(arrows)* obstructing the lower ureter.

dissolution. To raise urine pH, potassium citrate is recommended. While sodium bicarbonate alkalinizes the urine and enhances uric acid solubility, the added sodium increases sodium urate formation, which serves as a nidus for calcium oxalate precipitation. Potassium citrate 40 to 50 mmol/day in divided doses is given, increasing the dose as necessary to achieve a urine pH of 6.5 to 7.0. Patients should monitor pH with urine dipsticks at various times of the day and adjust the dosage accordingly. If urine pH remains low despite potassium citrate exceeding 100 mmol/day, or if that dose results in hyperkalemia, acetazolamide may be added. This carbonic anhydrase inhibitor produces an alkaline urine similar to that seen in renal tubular acidosis. Patients should be cautioned not to exceed urine a pH of 7.0 because this may result in calcium phosphate precipitation.

A low-purine and low–animal protein diet is also useful in raising urinary pH and decreasing uric acid excretion (see Box 57.4). If uric acid excretion remains high despite dietary intervention, as in patients with disorders of cellular catabolism, allopurinol should be prescribed, 100 mg increasing to 300 mg/day as needed to keep urinary uric acid excretion below 750 mg/24 h (4.5 mmol/24 h). See Box 57.4 for high-purine foods to avoid.[45]

Struvite Stones

Struvite stones are also referred to as *infection stones* or *triple phosphate stones*. The stones grow rapidly to a large size, can reduce renal function in the affected kidney, and are difficult to eradicate. Because of the significant morbidity in patients with struvite stones, they also have been termed *stone cancer*. Most staghorn calculi, large stones that penetrate more than one renal calyx, are composed of struvite. Their formation requires the presence of urease-producing bacteria in the urine (Box 57.6).[46]

Etiology and Pathogenesis

Struvite stones are composed of magnesium ammonium phosphate and calcium carbonate apatite. They form when urease production by certain urinary bacteria breaks down urea to ammonium (NH_4^+) and a carboxyl (OH^-) group. The urine becomes quite alkaline; urinary phosphate becomes insoluble and forms a solid phase with magnesium, calcium, and the ammonium. Women are more prone to struvite nephrolithiasis than men because of an increased propensity for UTI. Others

BOX 57.5 Factors Associated With Uric Acid Stone Formation

Low Urine pH (≤5.5)
- High–animal protein diet
- Diarrhea
- Insulin resistance (high body mass index, metabolic syndrome, type 2 diabetes)

Low Urine Volume
- Inadequate fluid intake
- Excessive extrarenal fluid losses
  - Diarrhea
  - Insensible losses (e.g., perspiration)

Hyperuricosuria
- Excessive dietary purine intake
- Hyperuricemia
  - Gout
  - Intracellular-to-extracellular uric acid shift
  - Myeloproliferative disorders
  - Tumor lysis syndrome
- Inborn errors of metabolism
  - Lesch-Nyhan syndrome
  - Glucose-6-phosphatase deficiency

Medications
- See Box 57.3.

BOX 57.6 Factors Associated With Struvite Stone Formation*

- Urease-producing bacteria
  - *Proteus*
  - *Haemophilus*
  - *Yersinia* spp.
  - *Staphylococcus epidermidis*
  - *Pseudomonas*
  - *Klebsiella*
  - *Serratia*
  - *Citrobacter*
  - *Ureaplasma*
- Elevated urinary pH

**Escherichia coli* is not a urease producer.

predisposed to developing struvite stones through infections or urinary stasis include patients with indwelling urinary catheters, neurogenic bladders, genitourinary tract anomalies, and spinal cord lesions. An alkaline urine (pH 7.0), urine culture of urease-producing bacteria, and large stones suggest the diagnosis of struvite nephrolithiasis.[46]

A number of gram-negative and gram-positive bacteria have been implicated in urease production and consequent struvite formation, with the most common being *Proteus* spp. (see Box 57.6). *Escherichia coli,* which is frequently present in urine cultures, is not a urease producer. If there is a strong suspicion for struvite stones but no organism is detected in the urine, a specific culture request for *Ureaplasma urealyticum* should be considered, because it does not grow on routine culture media.

Treatment

Struvite stones require aggressive medical and surgical management. Antibiotic therapy is important to reduce further stone growth and for stone prevention. Bacteria will remain in the stone interstices, however, and stones will continue to grow unless chronic antibiotic suppression is maintained or the calculi are completely eradicated. Given the need for complete stone removal to effect a cure, early urologic intervention is advised. Stones smaller than 2 cm may respond well to ESWL; however, larger stones will likely require percutaneous nephrolithotomy, often in combination with ESWL (see Chapter 59). Any stone fragments retrieved should be cultured and culture-specific antibiotics continued. Once the urine is sterile, usually approximately 2 weeks after initiation of therapy, the dose is halved. Monthly urine cultures should be obtained, and if they remain sterile for 3 consecutive months, antibiotics may be discontinued, although surveillance urine cultures should continue monthly for a full year.[47]

Adjunct medical therapies include urease inhibitors and chemolysis. The most commonly used urease inhibitor is acetohydroxamic acid. By inhibiting urease, these agents retard stone growth and prevent new stone formation. Unfortunately, they have numerous side effects, including deep venous thrombosis and hemolytic anemia, that limit their use, although these resolve on discontinuation of the drug. In addition, they require adequate renal clearance to be effective and therefore are not useful in patients with CKD (estimated GFR <60 ml/min).[46] Chemolysis involves irrigation of the kidney via a nephrostomy tube or the ureter with a solution designed to dissolve the stones. The most common solution is 10% hemiacidrin, which contains carbonic acid, citric acid, D-gluconic acid, and magnesium at pH 3.9. Lavage chemolysis is controversial because it has previously been associated with a high mortality rate, but it is now considered safe with appropriate monitoring for UTI, assessment of obstruction to flow by intrapelvic pressure measurement, and monitoring of serum magnesium levels. Although not a treatment of choice for large stones, it may be useful when surgical techniques have been effective but have left residual stone fragments.

Cystine Stones

Cystinuria is an autosomal disorder in which there is a tubular defect in dibasic amino acid transport, resulting in increased cystine, ornithine, lysine, and arginine excretion. It is also discussed in Chapter 48. The pattern of inheritance may be autosomal recessive or autosomal dominant with incomplete penetrance. The stone disease is usually clinically manifested by the second and third decades of life. Because of the high sulfur content of the cystine molecule, the stones are apparent on plain radiographs (see Fig. 57.4A) and often will manifest as staghorn calculi or multiple bilateral stones.

Cystine is poorly soluble, only approximately 300 mg/l (1.25 mmol/l) at a neutral pH. Normal cystine excretion of approximately 30 to 50 mg (0.12 to 0.21 mmol) per day is readily soluble in the usual daily urine output of approximately 1 liter. However, homozygote cystinurics often excrete 250 to 1000 mg (1.04 to 4.20 mmol) of cystine per day, with heterozygotes excreting an intermediate amount. Treatment is directed at decreasing the urinary cystine concentration below the limits of solubility. Because the dietary precursor of cystine, methionine, is an essential amino acid, it is impractical to significantly reduce intake. Increasing urine volume so that cystine remains below the limits of solubility sometimes requires 4 liters of urine per day. A low-sodium diet has been reported to reduce urine cystine excretion, although the mechanism by which this occurs is not clear.[48] Increasing urine pH above 7.5 will increase cystine solubility, but this is difficult to achieve on a long-term basis. Tiopronin 800 mg/day in 3 divided doses or D-penicillamine with a starting dose 250 mg/day and maximum dose of 2 g/day will both bind cystine and reduce urinary supersaturation; however, side effects may limit their use. The angiotensin-converting enzyme inhibitor captopril may be effective by forming a thiol-cysteine disulfide bond that is more soluble than cystine.[49]

Stones Associated With Melamine Exposure

By late 2008, more than 50,000 Chinese children younger than 3 years had been reported to have kidney stones associated with contaminated milk products. Powdered milk and infant formulas were noted to contain melamine, a nitrogenous substance synthesized from urea that increases the apparent protein content of the product.[9] Risk factors for nephrolithiasis after melamine exposure may include volume depletion, small body size, uricosuria, and low urine pH.

Although affected children often presented with dysuria and hematuria, many children who were subsequently screened were asymptomatic despite kidney stones identified on ultrasound.[9] On urinalysis, some children exhibited fan-shaped crystals. The kidney stones formed were radiolucent and fragile. Many were composed of a combination of uric acid with melamine and were amenable to dissolution by hydration and alkalinization. In animal studies of melamine exposure, the distal tubular crystal deposition may lead to tubulointerstitial inflammation and fibrosis. Whether a similar process may occur in humans is unknown.

NEPHROCALCINOSIS

Nephrocalcinosis refers to augmented calcium content within the kidney.[50] This disorder may be symmetric or may involve only a single kidney.

Etiology and Pathogenesis

Medullary Nephrocalcinosis

Medullary nephrocalcinosis in which the calcification tends to occur in the area of the renal pyramids accounts for the majority of cases of nephrocalcinosis. It is typically associated with elevated urinary calcium, phosphate, and oxalate, or it can occur with alkaline urine (Box 57.7). Any disorder that can lead to hypercalcemia and/or hypercalciuria may be implicated. Instead of stone formation, smaller parenchymal calcifications deposit in the medulla, and they are usually bilateral and relatively symmetric (Fig. 57.8). Some metabolic disorders, particularly oxalosis caused by primary hyperoxaluria, can result in both medullary and cortical nephrocalcinosis[49] (Fig. 57.9).

In adults, the most common causes of medullary nephrocalcinosis are primary hyperparathyroidism, distal renal tubular acidosis, and medullary sponge kidney, as well as medications, including acetazolamide, amphotericin, and triamterene (see Box 57.3).

In children, a similar range of disorders can be seen, but the most common associations are with furosemide therapy and the hereditary disorders associated with hypercalciuria.[18] Furosemide, when used in premature neonates and older infants with congestive heart failure,

BOX 57.7 Causes of Nephrocalcinosis

Medullary

Disturbed Calcium Metabolism

- Hyperparathyroidism
- Sarcoidosis
- Milk-alkali syndrome
- Rapidly progressive osteoporosis
- Idiopathic hypercalciuria

Other Tubular Disease

- Distal (type 1) renal tubular acidosis
- Oxalosis*
- Dent disease (X-linked hypercalciuric nephrolithiasis)
- X-linked hypophosphatemic rickets
- Bartter syndrome
- Hypomagnesemia-hypercalciuria syndrome

Anatomic Disease

- Medullary sponge kidney
  - Papillary necrosis

Medications

- Acetazolamide
- Amphotericin
- Triamterene

Cortical

- Cortical necrosis
- Transplant rejection
- Chronic glomerulonephritis
- Trauma
- Tuberculosis
- Oxalosis*

*Oxalosis typically causes both cortical and medullary nephrocalcinosis.

Medullary Nephrocalcinosis

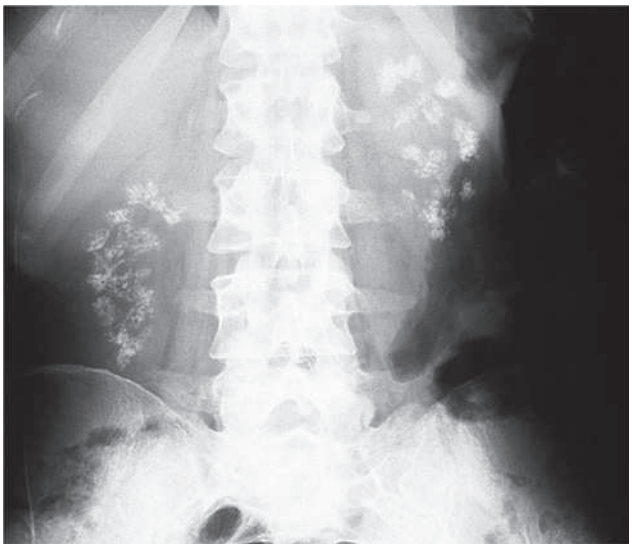

Fig. 57.8 Medullary nephrocalcinosis. Plain radiograph showing bilateral metastatic medullary nephrocalcinosis in a patient with distal renal tubular acidosis.

Nephrocalcinosis

Fig. 57.9 Nephrocalcinosis. Dense cortical and medullary calcification in the shrunken kidneys of a patient with oxalosis and long-standing renal failure.

can result in nephrocalcinosis with or without hypercalciuria. The lesions often resolve with discontinuation of therapy. A normal ratio of calcium to creatinine at the time of diagnosis of nephrocalcinosis (~0.40 [mg/mg] in premature infants) appears to be a good predictor of resolution.

There are many uncommon hereditary disorders associated with nephrocalcinosis, including Dent disease, X-linked hypophosphatemic rickets, hypomagnesemia-hypercalciuria syndrome, and Bartter syndrome.

Dent disease is an X-linked recessive disorder of proximal tubules characterized by low-molecular-weight proteinuria with hypercalciuria and nephrocalcinosis.[51] In most cases, it is due to mutations that inactivate a voltage-gated chloride transporter called *CLC-5*. A number of mutations affecting the *CLCN5* gene on the X chromosome have been identified that lead to inactivation of CLC-5. The result is a clinical syndrome typically affecting young boys and usually including hypercalciuria, nephrocalcinosis, nephrolithiasis, and hematuria, as well as low-molecular-weight proteinuria, glycosuria, aminoaciduria, hypophosphatemia, renal failure, and rickets. Dent disease is further discussed in Chapter 48.

In X-linked hypophosphatemic rickets, the recommended treatment, with phosphate repletion and vitamin D, may itself result in hypercalcemia, hypercalciuria, and nephrocalcinosis. Thus only enough phosphate and vitamin D should be prescribed to allow bone growth and prevent symptomatic hypophosphatemia.

Another cause of medullary nephrocalcinosis in children is primary hypomagnesemia-hypercalciuria syndrome.[2,11] This rare autosomal recessive condition results from defective production of the cellular tight-junction protein paracellin-1. This claudin family protein is necessary for adequate calcium and magnesium reabsorption in the thick ascending limb of the loop of Henle. Children typically present with symptoms of UTI (often with nephrolithiasis), polyuria, tetanic seizures (caused by hypomagnesemia), and muscle cramps and weakness. Hypercalciuria, hypermagnesuria, and a urinary concentrating defect also occur. Patients often have renal impairment and may require renal

Cortical Nephrocalcinosis

replacement therapy by the third decade of life. Sensorineural hearing disorders and ocular impairment may accompany the renal manifestations in a subset of patients.

Cortical Nephrocalcinosis

Cortical nephrocalcinosis is usually the result of dystrophic calcification, which follows parenchymal tissue destruction, rather than the precipitation of excessive urinary constituents. It is secondary to infarction, neoplasm, and infection. It is typically asymmetric and is usually localized to the renal cortex (Fig. 57.10). Causes of cortical nephrocalcinosis include transplant rejection, cortical necrosis, tuberculosis, ethylene glycol toxicity, and chronic glomerulonephritis.

Clinical Manifestations

Patients who do not have nephrolithiasis associated with nephrocalcinosis are often asymptomatic. Ultrasound and CT scanning are sensitive diagnostic tests for both cortical and medullary nephrocalcinosis, demonstrating the parenchymal calcifications before they can be visualized on plain radiographs. The extent of calcification correlates poorly with renal function.

Treatment

Similarly to nephrolithiasis, treatment of nephrocalcinosis relies on therapy for the underlying disease, as well as measures to reduce hypercalcemia, hyperphosphatemia, and oxalosis, if possible. The goal of treatment is usually to prevent further deposits, because therapy cannot eradicate existing calcium deposits.

SELF-ASSESSMENT QUESTIONS

1. A 49-year-old paraplegic man is referred for evaluation of nephrolithiasis. He has a suprapubic catheter and has had frequent urinary tract infections. He has reduced kidney function and is noted to have large staghorn calculi in both kidneys. On urinalysis he has many white blood cells and bacteria. Urine culture grows *Proteus.* All statements regarding this patient's kidney stones are true *except:*
   - **A.** His current stones can be treated with a course of antibiotics.
   - **B.** Stone formation is facilitated by the effects of urease-producing bacteria.
   - **C.** His stones are formed by a combination of phosphate with three cations.
   - **D.** Stone formation is potentiated by an elevated urine pH.
   - **E.** His current stones require surgical management.
2. A 35-year-old woman presents with her fourth kidney stone. Her father and brother have had stones as well. She was informed that her stones are composed of calcium. She tries to drink as much fluid as possible. Urine calcium excretion is elevated, but serum calcium is normal. All of the following dietary measures may be recommended for kidney stone prevention in this patient *except:*
   - **A.** Low-sodium diet
   - **B.** Reduction in animal protein intake
   - **C.** Reduction in dietary calcium intake
   - **D.** Low-oxalate diet
3. A 52-year-old obese man presents with flank pain and gross hematuria. Computed tomography (CT) reveals an obstructing left kidney stone and two other nonobstructing kidney stones in the right kidney measuring 0.5 mm. He passes the left kidney stone, which is found on analysis to be a uric acid stone. He was recently started on metformin for diabetes mellitus, his body mass index is 33, and he has normal kidney function; 24-hour urine reveals urine pH 5.3, volume 1.5 liter, and uric acid excretion of 500 mg. Which of the following is a *true* statement regarding this patient's kidney stones?
   - **A.** The patient's right kidney stones can be followed by serial abdominal x-ray examination of the kidneys.
   - **B.** The patient's insulin resistance may be contributing to his stone disease.
   - **C.** The patient should be treated with allopurinol.
   - **D.** Potassium citrate would not be beneficial.
   - **E.** The patient is drinking an adequate amount of fluid.

Urinary Tract Obstruction

Kevin M. Gallagher, Jeremy Hughes

DEFINITIONS

Obstructive uropathy refers to the structural or functional changes in the urinary tract that impede normal urine flow. *Obstructive nephropathy* refers to the renal disease caused by impaired flow of urine or tubular fluid. *Hydronephrosis* refers to dilation of the urinary tract. *Hydronephrosis* is not synonymous with *obstructive uropathy* because the former can occur without functional obstruction to the urinary tract and can be absent in established obstruction. Obstructive uropathy and nephropathy frequently coexist, and their management requires close collaboration between nephrologists and urologists. Some surgical aspects of obstruction to the urinary tract are discussed in Chapter 59.

Obstructive uropathy is classified according to the site, degree, and duration of the obstruction. Acute or chronic obstruction can occur anywhere in the urinary tract and includes intrarenal causes (casts, crystals) and extrarenal causes. Acute or chronic obstruction is further subdivided into upper urinary tract obstruction (usually unilateral obstruction occurring above the vesicoureteral junction) and lower urinary tract obstruction (usually bilateral obstruction located below the vesicoureteral junction). Complete obstruction of the urinary tract is termed *high grade,* whereas partial or incomplete obstruction is termed *low grade*.

Unilateral obstruction in a patient with two normal kidneys will not result in significant renal impairment because the contralateral kidney compensates. However, bilateral obstruction or the obstruction of a single functioning kidney will result in renal failure. In acute urinary tract obstruction, changes are mainly functional, whereas structural damage to the kidney results from more chronic obstruction. The kidney with acute functional changes may recover after effective release of the obstruction, but structural changes may be permanent and lead to chronic kidney disease (CKD). Urinary tract obstruction is a major cause of renal impairment worldwide in children and adults.

ETIOLOGY AND PATHOGENESIS

The causes of obstructive uropathy affecting the upper and lower urinary tracts are summarized in Boxes 58.1 and 58.2.

Congenital Urinary Tract Obstruction

Congenital urinary tract obstruction occurs most frequently in males, most commonly as a result of posterior urethral valves or pelviureteral junction (PUJ) obstruction. If obstruction occurs early during development, the kidney fails to develop and becomes dysplastic. If the obstruction is bilateral, there is a high mortality rate as a result of severe renal failure. If the obstruction occurs later in gestation and is low grade or unilateral, hydronephrosis and nephron loss will still occur, but renal function may be sufficient to allow survival, and such patients may not present until later in childhood. PUJ obstruction, if it is mild, may not manifest until adulthood and in some patients may be an incidental finding (Fig. 58.1). However, with increased use and improved sensitivity of antenatal scanning, congenital abnormalities of the urinary tract are now frequently identified early, allowing prompt postnatal (and in some cases antenatal) intervention to relieve the obstruction and hence preserve renal function. Congenital causes of obstruction are discussed further in Chapter 50.

Acquired Urinary Tract Obstruction

Acquired urinary tract obstruction may affect either the upper or lower urinary tract and can result from either intrinsic or extrinsic causes. Intrinsic causes of obstruction may be intraluminal or intramural.

Intrinsic Obstruction

Intraluminal obstruction. Intraluminal obstruction may result from tubular intrarenal obstruction, such as the deposition of uric acid crystals in the tubular lumen after treatment of hematologic malignancies (tumor lysis syndrome). It also may occur with the precipitation of Bence Jones protein in myeloma and with the precipitation or crystal formation of certain drugs, including sulfonamides, acyclovir, methotrexate, and indinavir. Uncommonly, patients with an underlying glomerulonephritis such as immunoglobulin A (IgA) nephropathy may develop severe glomerular hematuria with tubular obstruction from erythrocytes and acute kidney injury (AKI) that typically resolves with time.

Extrarenal intraluminal obstruction in young adults is most commonly caused by renal calculi (see Chapter 57). Calcium oxalate stones are the most common and typically cause intermittent acute unilateral urinary tract obstruction but rarely result in marked CKD. Less common causes of urinary lithiasis, such as struvite stones, uric acid stones, and cystinuria are often bilateral and hence more likely to cause long-term CKD. Renal calculi lodge more commonly in the calyx, PUJ, or vesicoureteral junction and at the level of the pelvic brim. Surgical management of stones is discussed in Chapter 59. Intraluminal obstruction also can result from a sloughed papilla after papillary necrosis or blood clots after macroscopic hematuria ("clot colic"). Papillary necrosis may occur in diabetes mellitus, sickle cell trait or disease, analgesic nephropathy, renal amyloidosis, and acute pyelonephritis. Clot colic can occur with bleeding from renal tumors or arteriovenous malformations, after renal trauma or surgery, and in patients with polycystic kidney disease.

Intramural obstruction. Intramural obstruction can result from either functional or anatomic changes. Functional disorders include adynamic ureteral segments (usually at the junction of the ureter with

BOX 58.1 Causes of Lower Urinary Tract Obstruction*

Urethral Anatomic Causes
- Urethral strictures: Trauma, *postinstrumentation,* infections such as gonococcal urethritis, nongonococcal urethritis, tuberculosis
- *Posterior Urethral Valves*
- Stones
- Blood clots
- Periurethral abscess
- Phimosis
- Paraphimosis
- Meatal stenosis

Urethral Functional Causes
- Anticholinergic drugs, antidepressants, levodopa

Prostate
- *Benign prostatic hypertrophy*
- *Prostatic carcinoma*

Bladder Anatomic Causes
- *Bladder cancer*
- *Schistosomiasis* (*Schistosoma haematobium* infection)
- Bladder calculi
- Bladder trauma, pelvic fracture

Bladder Functional Causes
- *Neurogenic bladder:* Spinal cord defects or trauma, diabetes, multiple sclerosis, Parkinson disease, cerebrovascular accidents

*The most common causes are in italics.

BOX 58.2 Causes of Upper Urinary Tract Obstruction*

Intrinsic Causes

Intraluminal
- Intratubular deposition of crystals (uric acid, drugs)
- *Stones*
- Papillary tissue
- Blood clots
- Fungal ball

Intramural
- Functional: Pelviureteral or vesicoureteral junction dysfunction
- Anatomic: Tumors (benign or malignant)
- Infections, granulomas, strictures

Extrinsic Causes

Reproductive System
- Cervix: *Carcinoma*
- Uterus: *Pregnancy, tumors,* prolapse, endometriosis, pelvic inflammatory disease
- Ovary: Tumor, cysts
- Prostate: *Carcinoma*

Vascular System
- Aneurysms: Aorta, iliac vessels
- Aberrant arteries: Pelviureteral junction
- Venous: Ovarian veins, retrocaval ureter

Gastrointestinal Tract
- Crohn's disease
- Pancreatitis
- Appendicitis
- Diverticulitis
- Tumors

Retroperitoneal Space
- Lymph nodes
- Fibrosis: Idiopathic, drugs, inflammatory or IgG4-related disease
- Tumors: Primary or metastatic

Surgical Disruption or Ureteral Ligation

*The most common causes are in italics.

the pelvis or bladder) and neurologic disorders. The latter may result in a contracted (hypertonic) bladder or a flaccid (atonic) bladder, depending on whether the lesion affects upper or lower motor neurons, and may lead to impaired bladder emptying with vesicoureteral reflux. Bladder dysfunction is very common in patients with multiple sclerosis and after spinal cord injury and is also seen in diabetes mellitus, in Parkinson disease, and after cerebrovascular accidents. Some drugs (anticholinergics, levodopa) can alter neuromuscular activity of the bladder and result in functional obstruction, especially if there is preexisting bladder outflow obstruction (e.g., prostatic hypertrophy).

Anatomic causes of intramural obstruction of the upper urinary tract include transitional cell carcinoma of the renal pelvis and ureter and ureteral strictures secondary to radiotherapy or retroperitoneal surgery. Rarely, obstruction may result from ureteral valve malfunction, polyps, or strictures after therapy for tuberculosis. Intramural obstruction of the lower urinary tract can result from urethral strictures, which are usually secondary to chronic instrumentation or previous urethritis, or malignant and benign tumors of the bladder. Infection with *Schistosoma haematobium* when the ova lodge in the distal ureter and bladder is a common cause of obstructive uropathy worldwide; up to 50% of chronically infected patients develop ureteral strictures and fibrosis, with calcifications and contraction of the bladder.

Extrinsic Obstruction

The most common cause of extrinsic compression in women is pressure from a gravid uterus on the pelvic rim; the right ureter is more commonly affected. It is usually asymptomatic, and the changes resolve rapidly after delivery. Rarely, bilateral obstruction and AKI may occur. Ureteral dilation frequently may be seen in pregnancy as a result of hormonal effects (especially progesterone) on smooth muscle, but this does not indicate functional obstruction (see Chapter 42, Fig. 42.1). Carcinoma of the cervix also may cause extrinsic obstruction secondary to direct extension of the tumor to involve the urinary tract. Other pelvic pathologic processes that can cause ureteral compression include benign and malignant uterine and ovarian masses, endometriosis, and pelvic inflammatory disease. Compression of the ureters outside the bladder also may occur with uterine prolapse. Rarely, inadvertent ureteral ligation may occur during surgical procedures, particularly those related to obstetrics and gynecology. Unilateral ligation may go undetected, but AKI will result from bilateral ligation.

In men, the most common cause of extrinsic obstruction of the lower urinary tract is benign prostatic hypertrophy. Carcinoma of the prostate can result in obstruction either from direct tumor extension to the bladder outlet or ureters or from metastatic spread.

Retroperitoneal pathology may result in extrinsic obstruction of the ureters, as can metastases or extension of tumors from the cervix,

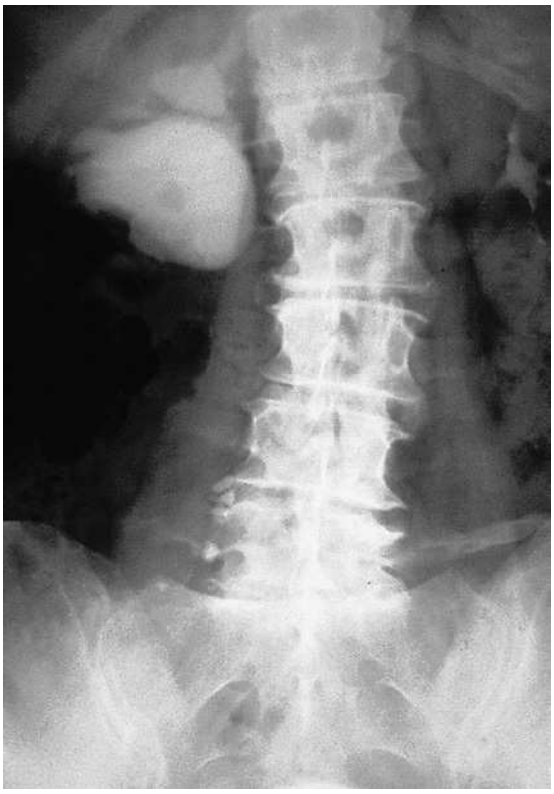

Fig. 58.1 Intravenous urogram demonstrating pelviureteral junction obstruction. The study was performed in a previously asymptomatic adult to investigate nonspecific right loin pain. There is unilateral dilation of the pelvicalyceal system. The ureter has not been visualized.

prostate, bladder, colon, ovary, and uterus. Primary tumors of the retroperitoneum, such as lymphomas and sarcomas, commonly cause obstruction. Obstruction also can result from inflammatory conditions affecting the retroperitoneum, such as Crohn's disease and large bowel diverticulitis. In Crohn's disease the obstruction is usually right sided as a result of ileocecal disease. Less common pathologic processes include retroperitoneal fibrosis, in which thick fibrous tissue extends out from the aorta to encase the ureters and draw them medially (Fig. 58.2). Retroperitoneal fibrosis may be idiopathic but can result from inflammatory aortic aneurysms, certain drugs (e.g., β-blockers, bromocriptine, and methysergide), previous irradiation, trauma or surgery, and granulomatous disease (e.g., tuberculosis, sarcoidosis). Retroperitoneal fibrosis is also associated with IgG4-related disease (see Chapter 62), which typically presents with autoimmune pancreatitis, and elevated serum IgG4 levels suggests this diagnosis.[1] IgG4-related disease may be diagnosed after retroperitoneal biopsy material with an IgG4-positive plasma cell infiltrate, fibrosis with a whorled cartwheel appearance, and an obliterative venous phlebitis evident.[2] Ureteral compression may be a result of vascular abnormalities, including aneurysmal dilation of the aorta or iliac vessels, aberrant vessels such as an aberrant anterior crossing accessory renal artery causing PUJ obstruction in adults, and anatomic variations in the location of the ureter (retrocaval ureter).

Pathophysiology

Obstruction of the renal tract causes profound functional and structural changes of the kidney. Initially, changes are predominantly functional and potentially reversible, but with time, chronic and irreversible structural changes occur. Our understanding of the consequences of urinary tract obstruction stems mainly from the study of animal models.[3] Although many studies have focused on the effects of complete ureteral obstruction in rodents, investigators have also examined models of chronic complete, partial, or reversible obstruction in adult and neonatal animals.[3] Available experimental data show little species-to-species variation in the response to acute obstruction, suggesting that similar changes are likely to occur in humans. The complex effects of urinary tract obstruction on the kidney affect both glomerular hemodynamics and tubular function.

Fig. 58.2 Retrograde pyelogram showing idiopathic retroperitoneal fibrosis. Dilation of the pelvicalyceal system is clearly demonstrated. The ureters, however, are not dilated, and the left ureter can be seen displaced medially as a result of being encased in thick fibrous tissue.

Changes in Glomerular Function

Glomerular filtration rate (GFR) declines progressively after the onset of complete ureteral obstruction. After complete ureteral obstruction, there is an initial rise in proximal tubular pressure. This is accompanied by afferent arteriolar dilation as a result of the generation of vasodilatory prostaglandins. Although this increases glomerular capillary hydraulic pressure, it does not offset the rise in tubular pressure, and there is a decrease in the hydraulic pressure gradient across glomerular capillaries, resulting in a dramatic decline in GFR. The relative changes in ureteral pressure, renal plasma flow, and GFR are summarized in Fig. 58.3. With ongoing obstruction, there is a progressive fall in renal blood flow secondary to the generation of angiotensin II (Ang II) and thromboxane A_2, the release of vasopressin (antidiuretic hormone), and decreased nitric oxide production. An interstitial leukocyte infiltrate develops, predominantly macrophages, and promotes the late structural changes that occur after obstruction as macrophage depletion limits experimental interstitial fibrosis.[4]

The extent to which glomerular function recovers after the release of ureteral obstruction depends on the duration of the obstruction. Whole-kidney GFR may return to normal after short-term obstruction (days), whereas recovery may be incomplete after prolonged obstruction.

Changes in Tubular Function

Abnormalities in tubular function are common in urinary tract obstruction and manifest as altered renal handling of electrolytes and changes in the regulation of water excretion. The degree and nature of the tubular defects after obstruction depend in part on whether the obstruction is bilateral or unilateral. These differences could result from the

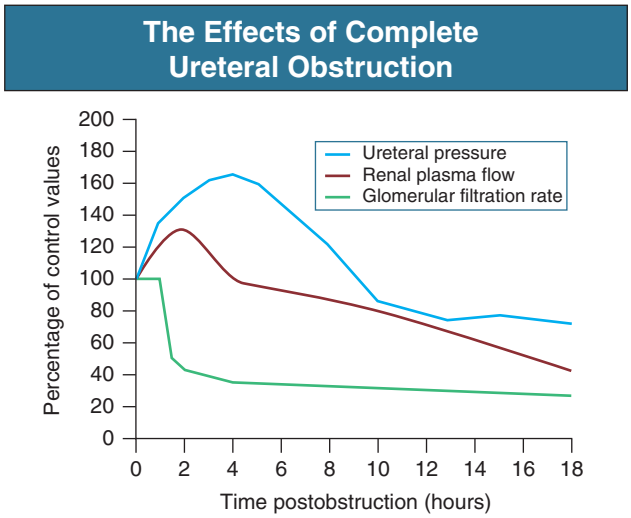

Fig. 58.3 The effects of complete ureteral obstruction. The relative changes in ureteral pressure, renal plasma flow, and glomerular filtration rate are shown using data from experimental studies of unilateral ureteral obstruction in rats.

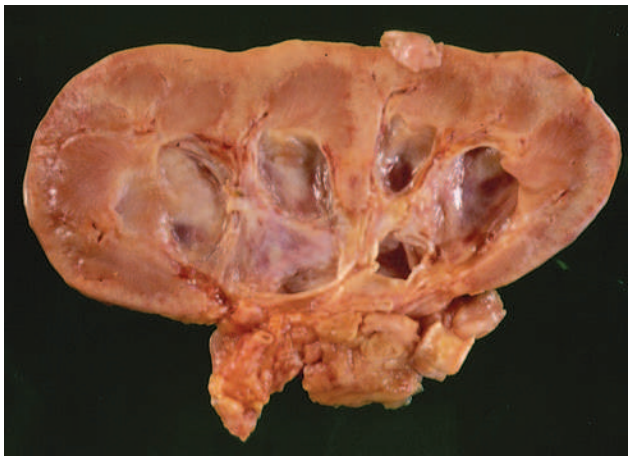

Fig. 58.4 Autopsy specimen of a kidney showing the early effects of ureteral obstruction. The kidney is enlarged and edematous with pelvicalyceal dilation. There is good preservation of the renal parenchyma.

Fig. 58.5 Chronic ureteral obstruction. Surgical specimen of a kidney showing gross dilation of the pelvicalyceal system and the reduction of the renal cortex to a thin fibrotic rim of tissue. There would have been no prospect for any significant functional recovery in this kidney after the relief of the obstruction.

dissimilar hemodynamic responses, different intrinsic changes within the nephron, or differences in extrinsic factors (e.g., volume expansion and accumulation of natriuretic substances in bilateral obstruction) between the two states.

After ureteral obstruction, the ability to concentrate the urine is markedly impaired, with maximum values of 350 to 400 mOsm/kg reported in the rat. Causative factors include a loss of medullary tonicity and reduced expression of sodium transporters. Also, the collecting duct is unresponsive to vasopressin because of reduced expression of renal aquaporins that results from both cyclooxygenase-2 activity and Ang II.

Rats exhibit reduced expression of multiple acid-base transporters after ureteral obstruction,[5] and patients with urinary tract obstruction often have urinary acidification defects. These defects may be detected only by exogenous acid loading, but hyperchloremic acidosis caused by impaired distal acid secretion, hyporeninemic hypoaldosteronism (type IV renal tubular acidosis), and a combination of these findings has been described. This acidifying defect results from a marked increase in bicarbonate excretion or from a distal acidification defect, possibly as a result of abnormalities of the H^+-ATPase activity of intercalated cells of the collecting duct after ureteral obstruction.

Obstruction also alters renal potassium handling. In the presence of a normal functioning contralateral kidney, potassium excretion is reduced after relief of obstruction, either in proportion to or perhaps even greater than the fall in GFR (i.e., fractional excretion of potassium is unaltered or slightly reduced). There is a defect in the distal potassium secretory mechanism after unilateral obstruction that may be secondary to reduced responsiveness of that nephron segment to aldosterone. By contrast, after release of bilateral ureteral obstruction, there is a marked increase in both net and fractional potassium excretion. The major mechanism by which potassium losses occur in this setting is an increased delivery of sodium to the distal tubule, resulting in increased sodium-potassium exchange.

Recovery of tubular function after release of obstruction is slow and may remain abnormal even after whole-kidney GFR has returned to normal. In rats, acidification and potassium-handling abnormalities persist for at least 14 days and urinary concentrating ability is abnormal for up to 60 days after the release of 24 hours of unilateral ureteral obstruction. These observations are consistent with persistent alterations in distal tubular and collecting duct function or a loss in functioning juxtaglomerular nephrons after the release of the obstruction.

HISTOPATHOLOGIC CHANGES

The morphologic alterations in renal architecture are similar irrespective of the cause of the obstruction. Initially, there is renal enlargement and edema with pelvicalyceal dilation (Fig. 58.4). Tubular dilation that predominantly affects the collecting duct and distal tubular segments is seen microscopically, although cellular flattening and atrophy of proximal tubular cells also can occur. Glomerular structures are usually preserved initially, although the Bowman space may be dilated and some periglomerular fibrosis may ultimately develop.

Inadequately treated urinary tract obstruction eventually causes irreversible structural changes to the renal tract. The renal pelvis becomes widely dilated, with the renal papillae either flattened or hollowed out. The cortex and medulla become grossly thinned, such that the kidney becomes a thin rim of renal tissue surrounding a large saccular pelvis (Fig. 58.5). Histologic examination demonstrates tubulointerstitial fibrosis and profound nephron loss. Tubular proliferation and apoptosis, interstitial myofibroblast accumulation, increased extracellular matrix

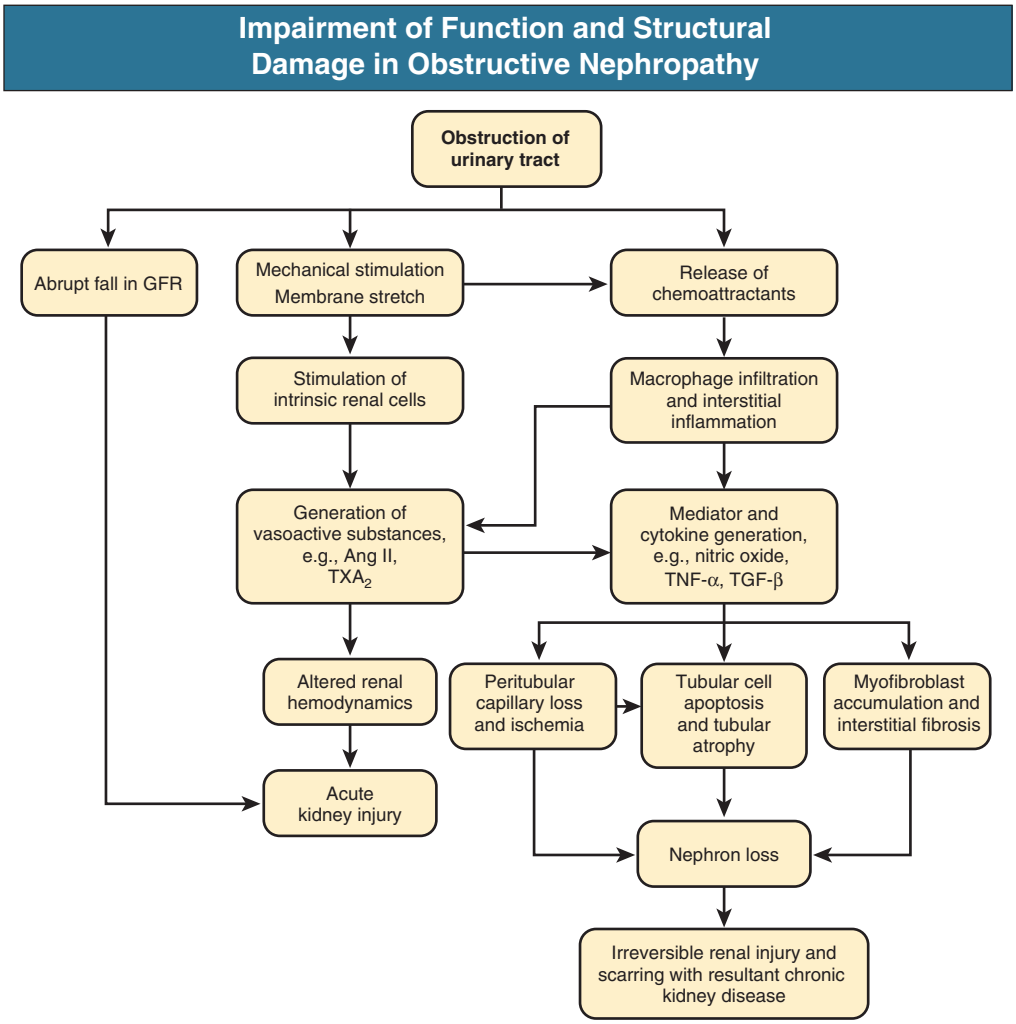

Fig. 58.6 Events leading to acute impairment of renal function and chronic structural damage in obstructive nephropathy. *Ang II,* Angiotensin II; *GFR,* glomerular filtration rate; *TGF-β,* transforming growth factor-β; *TNF-α,* tumor necrosis factor α; *TXA_2*, thromboxane A_2.

deposition, and tubular atrophy occur. Ischemia as a result of the decreased renal blood flow and the rarefaction of peritubular capillaries contributes to the parenchymal damage after obstruction. In both genetic and interventional studies, an important pathologic role for Ang II and transforming growth factor-β (TGF-β) has been established.[3]

Infiltrating macrophages release profibrogenic factors (e.g., TGF-β, galectin-3) and play a pivotal role in the chronic tissue injury and fibrosis that result from prolonged ureteral obstruction[4,6] (Fig. 58.6). Local Ang II generation also may stimulate tubular cell production of TGF-β. Treatments shown to ameliorate chronic interstitial damage in experimental obstructive uropathy include ARBs, pentoxifylline, simvastatin, and growth factors (such as bone morphogenetic protein 7, hepatocyte growth factor, and epidermal growth factor); beneficial effects include a reduction in tubulointerstitial inflammation, tubular cell apoptosis, and fibrosis.[3] However, it is pertinent that differences have been noted in the responses of adult and neonatal rodents to experimental therapeutic interventions and it is unclear whether such differences might occur in humans.

EPIDEMIOLOGY

Obstructive uropathy is a common entity and can occur at all ages, with the prevalence of hydronephrosis at autopsy being 3.5% to 3.8%, although this underestimates the true incidence because these figures exclude transient obstruction. The frequency and cause of obstruction vary in both sexes with age. Antenatal ultrasound has significantly increased the detection rate of lower urinary tract obstruction in the fetus.[7] In children younger than 10 years, obstruction is more common in boys; congenital urinary tract anomalies, such as urethral valves and pelviureteral obstruction, account for most cases. In North America, obstructive uropathy is a common cause of end-stage renal disease (ESRD) in children and accounts for 8.5% of cases.[8] In addition, congenital obstructive uropathy accounts for 0.7% of all patients (median age, 31 years) maintained with renal replacement therapy, demonstrating the continued impact of this disease into adult life.[9] In adults younger than 20 years, the frequency of urinary tract obstruction is similar in males and females. Beyond 20 years of age, obstruction becomes more common in females, mainly because of pregnancy and gynecologic malignancy. The peak incidence of renal calculi occurs in the second and third decades of life, with a threefold increased incidence in men. After the age of 60 years, obstructive uropathy occurs more frequently in men secondary to benign prostatic hypertrophy and prostatic carcinoma. About 30% of men older than 50 years have some symptoms of bladder outflow obstruction. In Europe, acquired urinary tract obstruction accounts for 3% to 5% of the cases of ESRD in patients older than 65 years, with most resulting from prostatic disease.[10] In the

United States, the number of patients receiving renal replacement therapy as a result of acquired obstruction continues to increase, accounting for 1.4% of prevalent patients, although the rise is not as rapid as with other causes of ESRD.[9]

CLINICAL MANIFESTATIONS

Obstruction of the urinary tract can present with a wide range of clinical symptoms, depending on the site, degree, and duration of obstruction. The clinical manifestations of upper and lower urinary tract obstruction differ. Symptoms can be caused by mechanical obstruction of the urinary tract (usually pain) or can result from the complex alterations in glomerular and tubular function that may occur in obstructive nephropathy. The latter commonly manifests as alterations in urine volume and as renal failure, which can be acute or chronic. For example, patients with complete obstruction present with anuria and AKI, whereas those with partial obstruction may present with polyuria and polydipsia secondary to acquired vasopressin resistance. Alternatively, there may be a fluctuating urine output, alternating from oliguria to polyuria. However, obstructive uropathy and hence obstructive nephropathy can occur without symptoms and with minimal clinical manifestations. Therefore obstruction of the urinary tract must be considered in the differential diagnosis of any patient with renal impairment.

Pain

Pain is a frequent complaint in patients with obstructive uropathy, particularly in those with ureteral calculi. The pain is believed to result from stretching of the collecting system or the renal capsule. The location of the pain may help determine the site of obstruction. With upper ureteral or pelvic obstruction, flank pain and tenderness typically occur, whereas lower ureteral obstruction causes pain that radiates to the groin, the ipsilateral testicle, or the labia. Acute high-grade ureteral obstruction may be accompanied by a steady and severe crescendo flank pain radiating to the labia, the testicles, or the groin (classic renal colic). The acute attack may last less than half an hour or as long as a day. By comparison, patients with chronic slowly progressive obstruction may have no pain or minimal pain; in such patients, any pain that does occur is rarely colicky. In PUJ obstruction, pain may occur only after fluid loading to promote a high urine flow rate.

Lower Urinary Tract Symptoms

Obstructive lesions of the urethra or bladder neck or bladder disease may cause a decrease in the force or caliber of the urine stream, intermittency, postmicturition dribbling, hesitancy, or nocturia. Urgency, frequency, and urinary incontinence can result from incomplete bladder emptying. Indeed, the development of nocturnal incontinence suggests chronic urinary retention that may be associated with painless renal failure. Such symptoms commonly result from prostatic hypertrophy and are frequently referred to as *prostatism*, but they are not pathognomonic of this condition.

Urinary Tract Infections

Urinary stasis resulting from obstruction predisposes to urinary tract infections (UTIs), and patients may develop cystitis with dysuria and frequency or pyelonephritis with loin pain and systemic symptoms. Infection occurs more often in patients with lower urinary tract obstruction than in those with upper urinary tract obstruction.

UTI in men or young children of either sex, recurrent or persistent infections in women, infections with unusual organisms such as *Pseudomonas* spp., and a single attack of acute pyelonephritis require further investigation to exclude obstruction. Also, the presence of obstruction makes effective eradication of the infection difficult. Infections of the urinary tract with a urease-producing organism such as *Proteus mirabilis* predispose to stone formation. These organisms generate ammonia, which results in urine alkalinization and favors the development of magnesium ammonium phosphate (struvite) stones. Struvite calculi can fill the entire renal pelvis to form a staghorn calculus that eventually leads to loss of the kidney if it is untreated. Thus stone formation and papillary necrosis also can be consequences of urinary tract obstruction as well as causes of obstruction.

Hematuria

Calculi may cause trauma to the urinary tract uroepithelium and result in either macrohematuria or microhematuria. Any neoplastic lesion that obstructs the urinary tract, especially uroepithelial malignancies, may bleed, resulting in macrohematuria. Urinary tract bleeding may result in obstruction, giving rise to clot colic when it is in the ureter or clot retention when it is in the bladder.

Changes in Urine Output

Complete bilateral obstruction or unilateral obstruction of a single functioning kidney such as a renal transplant will result in anuria. However, when the lesion results in partial obstruction, urine output may be normal or increased (polyuria). A pattern of alternating oliguria and polyuria or the presence of anuria strongly suggests obstructive uropathy.

Abnormal Physical Findings

Physical examination can be completely normal. Some patients with upper urinary tract obstruction may have flank tenderness. Long-standing obstructive uropathy may result in an enlarged palpable kidney in children. Lower urinary tract obstruction causes a distended, palpable, and occasionally painful bladder. A rectal examination and, in women, a pelvic examination should be performed because they may reveal a local malignancy or prostatic enlargement.

Acute or chronic hydronephrosis, either unilateral or bilateral, may cause hypertension secondary to impaired sodium excretion with expansion of extracellular fluid volume or from the abnormal release of renin. On occasion, in patients with partial urinary tract obstruction, polyuria, and volume depletion lead to hypotension.

Abnormal Laboratory Findings

Urinalysis may show hematuria, bacteriuria, pyuria, crystalluria, and low-grade proteinuria, depending on the cause of obstruction. However, urinalysis may be completely negative despite advanced obstructive nephropathy. In the acute phase of obstruction, urinary electrolyte values are similar to those seen in a prerenal state, with a low urinary sodium concentration (<20 mmol/l), a low fractional excretion of sodium (<1%), and a high urinary osmolality (>500 mOsm/kg). However, with more prolonged obstruction, a decreased ability to concentrate the urine and an inability to reabsorb sodium and other solutes occur. These changes are particularly marked after the release of chronic obstruction and give rise to the syndrome commonly referred to as postobstructive diuresis.

Increases in serum urea and creatinine are the most significant laboratory abnormalities in patients with obstructive uropathy. Electrolyte abnormalities may occur, including hyperchloremic hyperkalemic (type 4) metabolic acidosis or hypernatremia from acquired nephrogenic diabetes insipidus. The development of obstruction in patients with underlying CKD may accelerate the rate of progression. ESRD may occasionally be caused by chronic obstructive uropathy that had been asymptomatic.

Obstruction in Neonates or Infants

With the advent of routine antenatal scanning, the diagnosis of hydronephrosis and genitourinary abnormalities is now frequently made

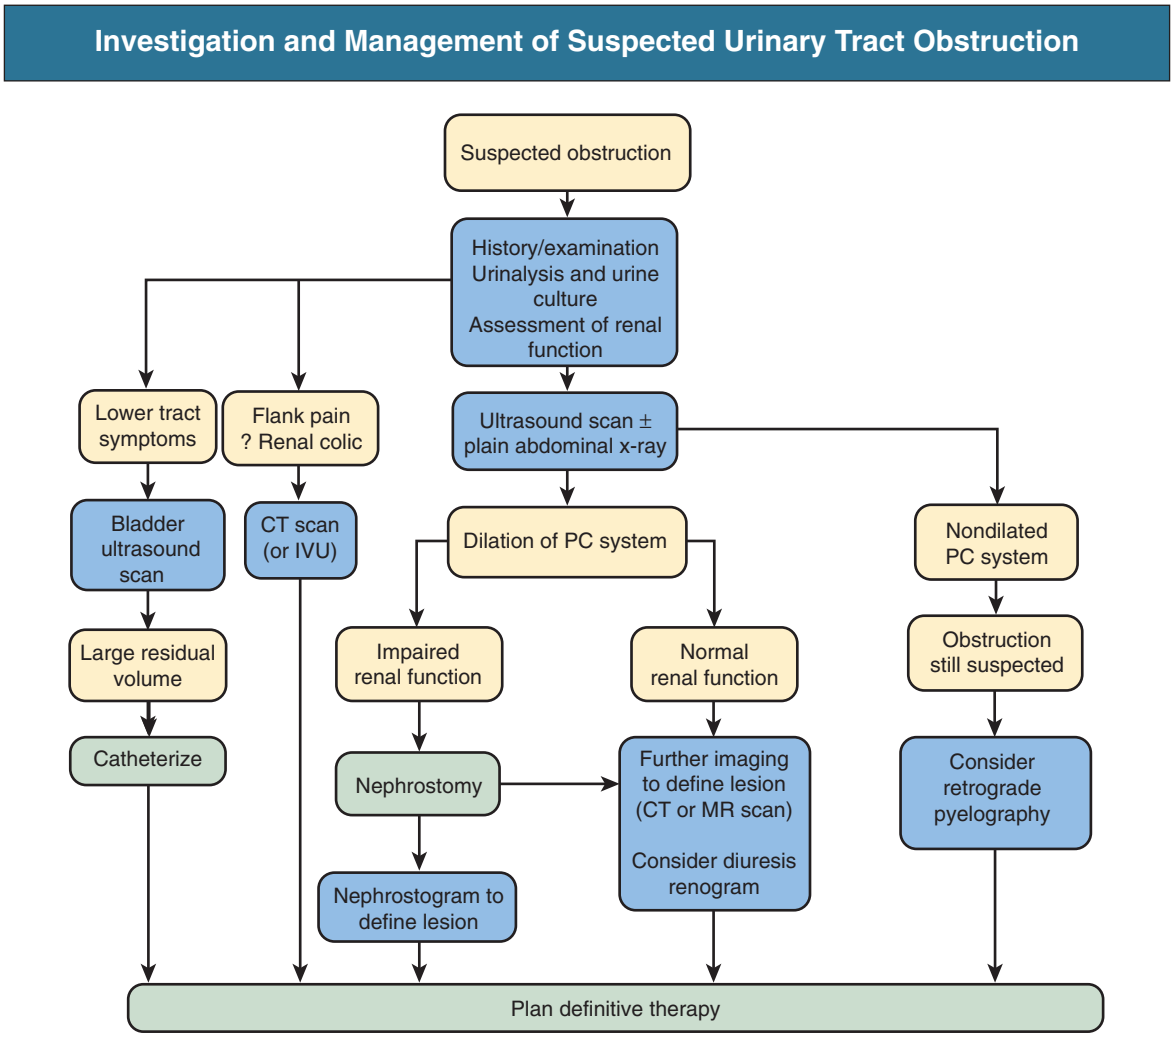

Fig. 58.7 Investigation and management of suspected urinary tract obstruction. A full history and examination should be performed, together with urinalysis, urine microscopy and culture, and measurement of renal function and serum electrolytes. Ultrasound is a useful first-line investigation for any patient with suspected urinary tract obstruction. Computed tomography *(CT)* is now the preferred imaging technique when renal calculi are suspected. Either CT or magnetic resonance *(MR)* urography can accurately diagnose both the site and cause of obstruction in most cases. If there is renal impairment, a nephrostomy or stenting allows the effective relief of the obstruction and time for renal function to recover while definitive therapy is planned. *IVU,* Intravenous urography; *PC,* pelvicalyceal.

antenatally; however, unsuspected obstructive uropathy may present in the postnatal period with failure to thrive, voiding difficulties, fever, hematuria, or symptoms of renal failure. Oligohydramnios at the time of delivery should raise the suspicion of obstructive uropathy, as should the presence of congenital anomalies of the external genitalia. Nonurologic anomalies such as ear deformities, a single umbilical artery, imperforate anus, or a rectourethral or rectovaginal fistula should prompt investigation for urinary tract obstruction. Any infant with neurologic abnormalities may have a neurogenic bladder with associated obstructive uropathy.

DIAGNOSIS

Prompt diagnosis of urinary tract obstruction is essential to allow timely treatment. Symptoms such as renal colic may suggest the diagnosis and prompt appropriate investigation. However, urinary tract obstruction should be considered in any patient with unexplained acute or chronic kidney impairment. The diagnostic approach must be tailored to the clinical presentation (Fig. 58.7), but a careful history and thorough physical examination are mandatory in all patients.

Urinalysis may provide valuable diagnostic information. Hematuria suggests that the obstructing lesion is a calculus, sloughed papilla, or tumor. Bacteriuria suggests urinary stasis, especially in men or pregnant women, but it also may be a complication of chronic obstruction. The presence of crystals in the urine sediment (cystine or uric acid) may be an indication of the type of stone causing the ureteral obstruction or the intrarenal obstruction resulting in AKI. Laboratory studies must include assessment of renal function and serum electrolytes.

Imaging

Because the sites, causes, and consequences of obstruction to the renal tract are so variable, no single imaging investigation can diagnose or exclude renal tract obstruction with certainty. Therefore if the clinical suspicion of obstruction is high, the patient may require investigation with multiple imaging techniques.

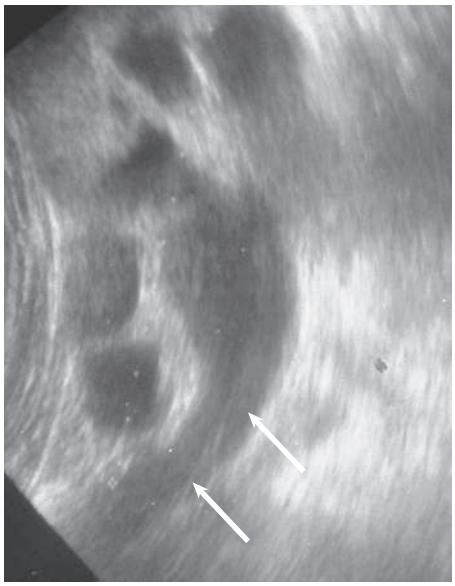

Fig. 58.8 Renal ultrasound scan of a patient with obstruction of the urinary tract causing hydronephrosis. The kidney is hydronephrotic with dilation of the pelvicalyceal system; dilation of the upper ureter is also clearly seen *(arrows)*.

Ultrasound is the most widely used imaging modality, but computed tomography (CT) scanning and magnetic resonance (MR) urography are increasingly used to accurately diagnose both the site and cause of obstruction. Although much less commonly used, older imaging techniques, such as intravenous urography (IVU), can be used to evaluate patients with obstructive uropathy. The role of imaging techniques is shown in Fig. 58.7 and discussed further in Chapter 5.

Ultrasound

Ultrasound can define renal size and demonstrate calyceal dilation[11] but depends on the expertise of the operator (Fig. 58.8). Although it is sensitive for detection of hydronephrosis, ultrasound often will not determine its cause. Pathologic change within the ureter is difficult to demonstrate, and tiny stones will not generate acoustic shadows. However, unilateral hydronephrosis suggests obstruction of the upper urinary tract by stones, blood clots, or tumors. Bilateral hydronephrosis is more likely to result from a pelvic problem obstructing both ureters or obstruction of the bladder outlet, in which case the bladder will also be enlarged. Ultrasound should be combined with radiographic examination of the kidneys, ureters, and bladder (KUB) to ensure that ureteral stones or small renal stones are not overlooked.

Ultrasound produces false-negative results in cases of nondilated obstructive uropathy.[11] Immediately after acute obstruction (within 24 hours), the relatively noncompliant collecting system may not have dilated, so ultrasound examination findings may be normal. Furthermore, if urine flow is low, as in severe dehydration or renal failure, there may be little dilation of the urinary tract. Dilation also may be absent in slowly progressive obstruction when the ureters are encased by fibrous tissue (as in retroperitoneal fibrosis) or by tumor, and in some renal transplants in which there is dense surrounding scar tissue. The acoustic shadow of a staghorn calculus also can mask dilation of the upper urinary tract. In view of this it is advisable to repeat the renal ultrasound if suspicion of obstruction is high. The sensitivity of ultrasound for diagnosis of obstruction can be improved by measuring the resistive index with color Doppler sonography. A resistive index above 0.7 reflects the increased vascular resistance present in obstruction and can assist discrimination between obstructed and nonobstructed kidneys,[11] though the resistive index can be increased in other conditions.[12] Such ultrasound techniques are particularly useful when it is especially important to minimize radiation exposure, for example, in pregnant women and children, and in the follow-up of patients requiring repeated imaging, such as after extracorporeal shock wave lithotripsy.

Even in experienced hands, ultrasound may have a significant false-positive rate, especially if minimal criteria are adopted to diagnose obstruction. In addition, the echogenicity produced by multiple renal cysts may be mistaken for hydronephrosis.

Ultrasound scanning can be used to assess bladder emptying and should be undertaken in patients with lower urinary tract symptoms, being performed at the bedside if necessary. The normal postmicturition residual volume is less than 50 ml (<100 ml is usually acceptable in patients older than 65 years), and a large postmicturition residual volume suggests bladder outflow obstruction, which should prompt further urologic investigation and treatment.

The investigation of neonates with hydronephrosis diagnosed antenatally depends on the grade of hydronephrosis identified. Neonates with grade 1 or 2 hydronephrosis (no calyceal dilation) undergo ultrasound scanning; neonates with grade 3 or 4 hydronephrosis (indicating increasingly severe pelvicalyceal dilation) require both ultrasound scanning and voiding cystourethrography.[13] This combination can distinguish megaureter resulting from obstruction or reflux and enable the diagnosis of posterior urethral valves and UPJ obstruction. Recent work suggests that using measurements of both calyceal dilation and the anteroposterior diameter of the renal pelvis at the first postnatal ultrasound may be able to distinguish those children who will require surgery, but this grading system will require further validation.[14]

Plain Abdominal Radiography

A plain abdominal radiograph (or KUB) allows an assessment of kidney size and contour and frequently demonstrates renal calculi because about 90% of calculi are radiopaque.

Intravenous Urography

IVU was formerly the first-choice investigation for suspected upper urinary tract obstruction. In patients with normal renal function, it can usually define both the site and the cause of the obstruction. However, the excretion of contrast material may be poor or delayed in patients with low GFR because of a decreased filtered load of the contrast agent, which is potentially nephrotoxic. IVU is no longer a first-line investigation to diagnose urinary tract obstruction, especially in patients with impaired renal function.

Computed Tomography

Non–contrast-enhanced spiral CT scanning is used increasingly as the primary imaging modality for the evaluation of patients with acute flank pain[15] and uses a low-dose protocol compared with conventional CT scanning of abdomen and pelvis.[16] Stones are easily detected because of their high density; CT can provide an accurate and rapid diagnosis of an obstructing ureteral calculus, with a stone being found more commonly in men.[17] In addition, it provides useful information about the site and nature of the obstructing lesion, especially when this is extrinsic to the urinary tract (Fig. 58.9; see also Chapter 59, Fig. 59.1), though a higher dose CT scan may be required for a full diagnostic study. CT demonstrates retroperitoneal disease, such as paraaortic and paracaval lymphadenopathy; retroperitoneal fibrosis is evident as increased attenuation within the retroperitoneal fat, with encasement of one or both ureters. Hematomas, primary ureteral tumors, and polyps are also detectable. The diagnostic potential of CT is enhanced by the administration of contrast material, but this may limit its use in patients

Fig. 58.9 Computed tomography scan of the abdomen showing a grossly hydronephrotic kidney on the left (*arrows* mark dilated renal pelvis). Dilated loops of small bowel are seen in the right hypochondrium. Sequential sections demonstrated that the ureter was dilated along its length and that there was a pelvic mass, which was responsible for both bowel and left ureteral obstruction. The mass was subsequently shown to be arising from a carcinoma of the colon.

Fig. 58.10 MR urography showing obstructive uropathy. T2-weighted MR image showing a proximal right-sided ureteric ureteral obstruction with an associated mild hydronephrosis. The obstruction was secondary to a ureteral calculus.

with renal impairment. In addition, it involves exposure to ionizing radiation, especially if patients require multiple CT scans over time.

Magnetic Resonance Urography

MR urography (combined with KUB) can enable the diagnosis of ureteral obstruction caused by renal calculi with accuracy similar to that of spiral CT scanning but without exposure to contrast medium or ionizing radiation. The technique has less observer variability and is more accurate than CT in detecting indirect evidence of obstruction,

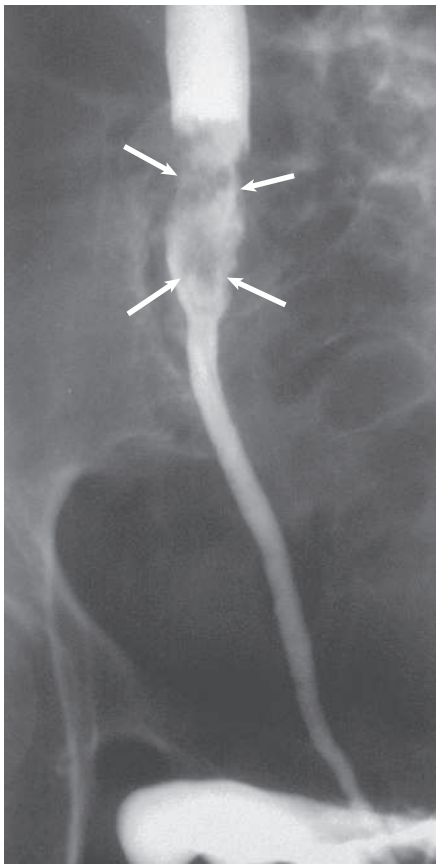

Fig. 58.11 Ureteral obstruction by a tumor. A retrograde pyelogram shows the tumor is within and obstructing the ureter *(arrows)*. Above the tumor, there is dilation of the ureter, but below it, the ureter is of a normal caliber.

such as perirenal fluid. MR urography can rapidly and accurately depict the morphologic features of dilated urinary tracts and provide information about the degree and level of obstruction[18] (Fig. 58.10). MR urography is a particularly attractive imaging modality for the evaluation of hydronephrosis in children because it provides both anatomic and functional data and can indicate whether the hydronephrosis is compensated (symmetric changes of signal intensity of the nephrogram) or decompensated.[19] Signs of decompensation (acute on chronic obstruction) include edema of the renal parenchyma, a delayed and increasingly dense nephrogram, a delayed calyceal transit time, and a more than 4% difference in the calculated differential renal function. MR urography is likely to be increasingly used in the future.

Retrograde Pyelography

Retrograde pyelography (Fig. 58.11; see also Fig. 58.2) usually requires a general anesthetic and cystoscopy but may be particularly useful to identify both the site and the cause of the obstruction because intervention (by stenting or dilatation) and biopsy of a suspected tumor (by ureteroscopy) are both possible. It is also helpful when nondilated urinary tract obstruction is suspected or when there is a history of allergic reactions to contrast material.

Diuresis Renography

A diuresis renogram using technetium-99m mercaptoacetyltriglycine (^{99m}Tc-MAG3), combined with intravenous furosemide administered 20 to 30 minutes after injection of the isotope (diuretic isotopic renography), can be used to distinguish between simple dilation of the

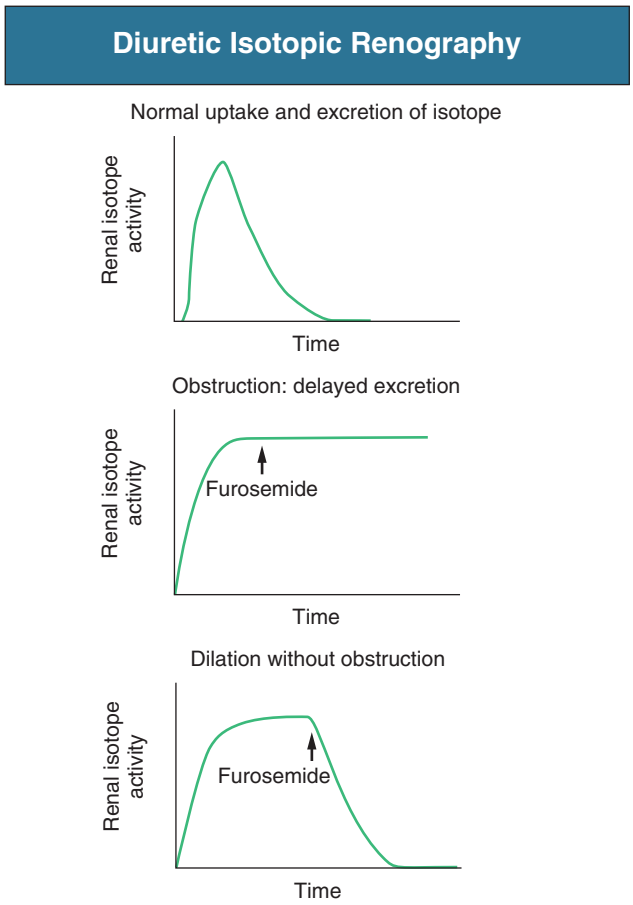

Fig. 58.12 Diuretic isotopic renography. Idealized tracings for normal, obstructed, and dilated kidneys without obstruction of the upper urinary tract. In obstruction, there is delayed excretion of ^{99m}Tc-MAG3 despite administration of furosemide. When there is dilation of the upper urinary tract without obstruction, the isotope is retained but is rapidly excreted after the administration of furosemide.

collecting system and true obstruction.[20] Normally, there is a rapid washout of the isotope from the kidney, and persistence of the isotope suggests a degree of obstruction (Fig. 58.12). Poor renal function significantly limits the usefulness of renography because the diuretic response to furosemide may be absent. Diuresis renography also may be used for follow-up of patients who have undergone surgical procedures to relieve obstruction, such as a pyeloplasty.

Pressure Flow Studies

A pressure flow study (Whitaker test) involves puncture of the collecting system with a fine-gauge needle to perfuse fluid (at 10 ml/min) with concurrent measurement of the differential pressure between the bladder and the collecting system; a pressure greater than 20 cm H_2O indicates obstruction. Although this test is rarely required, it may be informative in patients with potential upper tract obstruction when other, less invasive tests have generated equivocal results.[21]

Other Evaluations

Lower urinary tract obstruction may be evaluated by cystoscopy, which allows a visual inspection of the entire urethra and the bladder. Urodynamic studies (see Chapter 50, Fig. 50.14) can assess bladder outlet obstruction, measure the residual urine volume after voiding, and detect functional bladder abnormalities.

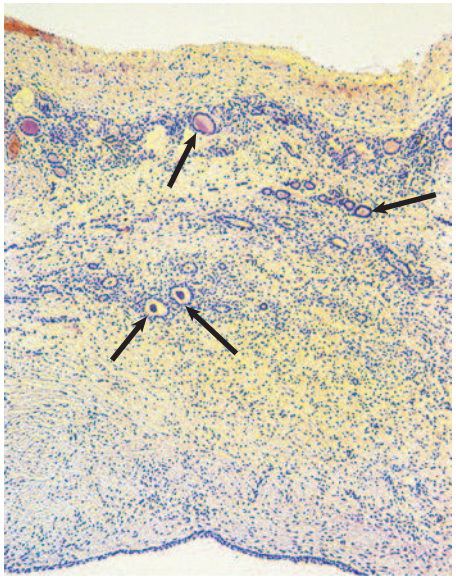

Fig. 58.13 Pathology of chronic ureteral obstruction. This is a section of the rim of renal tissue from the kidney shown in Fig. 58.7. The renal capsule is at the top, the urinary space at the bottom. The cortex is considerably thinned, and only a few atrophic tubules remain *(arrows)* within an interstitium comprising dense fibrous tissue and a mononuclear cell infiltrate *(blue staining nuclei)*. No glomeruli can be seen. This demonstrates why there would be no prospect for any significant functional recovery in this kidney even after the relief of the obstruction.

DIFFERENTIAL DIAGNOSIS

Diagnostic uncertainty arises with nonobstructive dilation of the upper urinary tract, which may be seen with vesicoureteral reflux, diuretic administration, diabetes insipidus, congenital megacalyces, chronic pyelonephritis, and postobstructive atrophy. Diuresis renography or retrograde pyelography may be required to exclude obstruction.

NATURAL HISTORY

Obstructive uropathy is potentially curable but will result in progressive irreversible loss of nephrons and renal scarring if it is left untreated (Fig. 58.13). ESRD will result if both kidneys are affected or if there is only a solitary kidney. Outcome data for obstructive uropathy are limited, but the exact prognosis will depend on the pathologic process responsible for the obstruction, duration of the obstruction, and presence or absence of urosepsis. Relief of short-term obstruction (<1 to 2 weeks) usually results in an adequate return of renal function. With chronic progressive obstruction (>12 weeks), there is often irreversible and severe renal damage, and renal functional recovery may be limited even after relief of the obstruction. A single-center study identified 104 patients who presented with obstructive nephropathy.[22] The mean GFR at presentation and at 3, 12, and 36 months was 9, 28, 29, and 30 ml/min, respectively (patients on dialysis excluded), demonstrating significant but nonprogressive renal impairment after relief of obstruction. It is likely that the prognosis for renal functional recovery is better the earlier the obstruction is diagnosed and relieved.

TREATMENT

General Considerations

Treatment is dictated by the location of the obstruction, the underlying cause, and the degree of any renal impairment. If renal impairment is

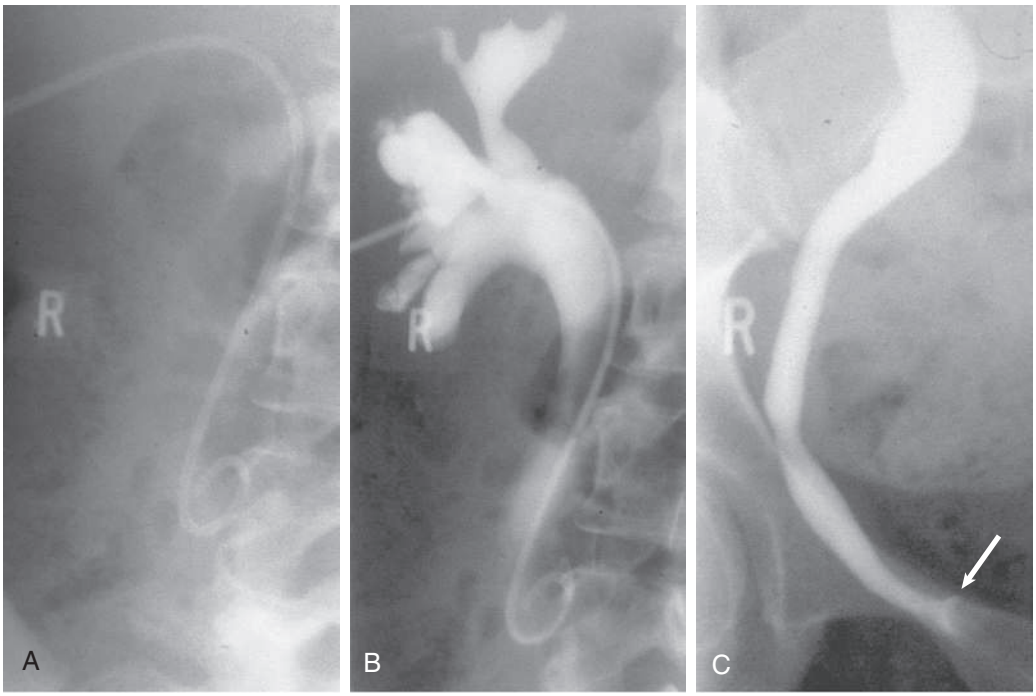

Fig. 58.14 Nephrostogram. A nephrostomy has been placed percutaneously into the dilated collecting system of the kidney under ultrasound control (A). After infusion of contrast material down the nephrostomy, the dilated pelvicalyceal system and upper ureter (B) and the lower ureter (C) are outlined. The ureter is dilated along its length but tapers abruptly at the vesicoureteral junction *(arrow)*. In this case, the obstruction was caused by a radiolucent stone.

present, the treatment of obstruction requires close collaboration between nephrologists and urologists to reduce the risks associated with the metabolic and electrolyte consequences of renal failure and to optimize the chances for long-term recovery of renal function. For example, complete bilateral ureteral obstruction manifesting as AKI is a medical emergency and requires rapid intervention to salvage renal function. Prompt intervention to relieve the obstruction should result in a rapid improvement in renal function. Dialysis rarely should be required in patients with AKI secondary to obstruction except to make the patient fit for intervention, for example, by improving life-threatening hyperkalemia or severe fluid overload. The rapid relief of obstruction will limit permanent renal damage but renal function may not recover immediately if acute tubular injury has resulted from obstruction or any accompanying sepsis.

Some surgical aspects of the management of obstructive uropathy are discussed in Chapter 59. The site of obstruction frequently determines the approach. If the obstruction is distal to the bladder, a urethral catheter or, if this cannot be passed, a suprapubic cystostomy, will effectively decompress the kidneys. Placement of nephrostomy tubes or cystoscopy and passage of a retrograde ureteral stent will relieve upper urinary tract obstruction. Percutaneous nephrostomy (PCN) is generally the appropriate emergency treatment for upper urinary tract obstruction, especially in the setting of AKI. PCN can be achieved with local anesthetic and should allow rapid recovery of renal function in most patients (>70%), avoiding the need for dialysis. After relief of the obstruction by a nephrostomy, the exact site and nature of the obstructing lesion can be determined by an antegrade study infusing radiographic contrast material into the nephrostomy tube (nephrostogram), and time can be taken to plan definitive therapy (Fig. 58.14). Major complications of nephrostomy insertion (abscess, infection, and hematoma) occur in less than 5% of patients. If both kidneys are obstructed, the nephrostomy should initially be placed in the kidney with the most preserved renal parenchyma, although bilateral nephrostomies may be required to maximize the potential for the recovery of renal function. If infection occurs above a ureteral obstruction (pyonephrosis), drainage of the kidney by PCN can play an important therapeutic role together with appropriate antibiotics.

A nephrostomy can be used to gauge the potential for functional recovery in patients with chronic obstruction. Failure of renal recovery after several weeks of nephrostomy drainage strongly suggests irreversible structural damage and thus no likely benefit from undertaking a more definitive surgical correction of the obstructing lesion. Long-term nephrostomy or stenting may be used as a definitive therapy for patients who are unsuitable for major surgical intervention and those with incurable malignant disease, though patient selection is important in the latter[23] (see Chapter 59 for further discussion). Various types of stent are now available, and there is some evidence that metallic stents may provide more durable functional decompression in patients with malignant ureteric obstruction.[24]

Ureteral obstruction requiring intervention occurs in up to 3% of renal transplant recipients.[25] It can be treated by nephrostomy and ureteral stenting, percutaneous incision or balloon dilation of the stricture, or open surgical repair (see Chapter 103).

Specific Therapies

Calculi are the most common cause of ureteral obstruction, and their treatment includes relief of pain, elimination of obstruction, and treatment of infection (see Chapters 57 and 59). Ureteral obstruction by papillary tissue, blood clots, or a fungus ball is treated by procedures similar to those used for calculi. When obstruction is caused by neoplastic, inflammatory, or neurologic disease, there is unlikely to be spontaneous remission of the obstruction, and some form of urinary diversion, such as an ileal conduit, or long-term intermittent ureteral stenting should be considered. Some obstructing neoplastic lesions,

such as lymphadenopathy from lymphoma, may respond to chemotherapy. Management of malignant urinary tract obstruction is discussed further in Chapter 59.

In idiopathic retroperitoneal fibrosis, ureterolysis (in which the ureters are surgically freed from their fibrous encasement) may be beneficial, especially if combined with corticosteroid therapy to prevent recurrence. A recent retrospective study demonstrated the effectiveness of ureteral stent insertion and corticosteroids in idiopathic retroperitoneal fibrosis[26]; retroperitoneal fibrosis complicating IgG4 disease may respond to corticosteroid treatment.[2] Although kidney obstruction per se results in renal inflammation involving multiple immune cells irrespective of the underlying cause, there are no published trials of therapies that target the immune system in this patient cohort. Although pharmacologic blockade of the renin-angiotensin system is not instituted in the acute setting, it is reasonable to employ angiotensin receptor blockers (ARBs) or angiotensin-converting enzyme inhibitors in patients with residual CKD.

Functionally significant PUJ obstruction should be corrected surgically; minimally invasive and robotic techniques have largely replaced the open (Anderson-Hynes) pyeloplasty. The laparoscopic approach results in significantly less morbidity and has good long-term outcomes that are comparable to those of the open procedure.[27] Balloon dilation of the abnormal segment of the ureter is also possible, but the recurrence rate is high. The severity of renal fibrosis and atrophy as assessed on intraoperative wedge renal biopsy in patients undergoing open PUJ surgery can be used to predict functional outcome.[28] There is increasing interest in the usefulness of urine proteomics to identify neonates with UPJ obstruction who require surgical intervention,[29] although a subsequent small study indicated that this approach was less specific and sensitive in older children.[30] Urinary biomarkers that show altered levels in children or adult patients with obstructive nephropathy include established well-studied AKI biomarkers (kidney injury molecule-1, neutrophil gelatinase–associated lipocalin, and liver-type fatty acid binding protein),[31] aquaporin-2, L1 cell adhesion molecule, and TGF-β,[32] as well as epidermal growth factor, monocyte chemotactic protein-1, and β_2-microglobulin.[33] Interestingly, a reduction in urinary epidermal growth factor is also seen in patients with CKD and is a predictor of CKD progression,[34] suggesting that urinary biomarkers may well facilitate the future stratification of patients with obstructive nephropathy and assist with predicting functional outcome after intervention.

Benign prostatic hypertrophy is the most common cause of lower urinary tract obstruction in men and may be mild and nonprogressive. A patient with minimal symptoms, no infection, and a normal upper urinary tract can continue with assessment until he and his physician agree that further treatment is desirable. Medical therapy with either α-adrenergic blockers (e.g., tamsulosin) or 5α-reductase inhibitors (e.g., finasteride) may be used in patients with moderate symptoms.[35] α-Blockers relax the smooth muscle of the bladder neck and prostate and decrease urethral pressure and outflow obstruction. 5α-Reductase inhibitors inhibit the conversion of testosterone to the active metabolite dihydrotestosterone and reduce prostatic hypertrophy. Combination therapy with these agents may be synergistic. Surgical intervention with transurethral resection of the prostate is generally required for failed medical treatment, debilitating symptoms, urinary retention, recurrent infection, or evidence of renal parenchymal damage. Holmium laser enucleation of the prostate is a less traumatic alternative to transurethral resection of the prostate with good short-term and long-term outcomes.[36]

Urethral strictures in men can be treated by dilation or direct-vision internal urethrotomy before definitive urethroplasty, although urethral stenting is evolving. The incidence of bladder neck and urethral obstruction in women is low and treatment rarely required. Suprapubic cystostomy may be necessary for bladder drainage in patients unable to void after injury to the urethra or in those who have an impassable urethral stricture.

When obstruction results from neuropathic bladder function, urodynamic studies are essential to guide therapy. The goals of therapy are to establish the bladder as a urine storage organ without causing renal parenchymal injury and provide a mechanism for bladder emptying acceptable to the patient. Patients may have either a flaccid atonic or an unstable hypertonic bladder. Ureteral reflux and parenchymal damage may develop in both cases, although it is more common in patients with a hypertonic bladder. Asking the patient to void at regular intervals may achieve satisfactory emptying of the bladder. Patients with an atonic bladder and significant residual urine retention associated with recurrent urosepsis need to undertake clean intermittent self-catheterization. The aim should be to catheterize four or five times per day to ensure the amount of urine drained from the bladder on each occasion is less than 400 ml. External sphincterotomy has been used in men with an atonic bladder and may relieve outlet obstruction and promote bladder emptying, but it may cause urinary incontinence and the need to wear an external collection device. In patients with a hypertonic bladder, improvement in the storage function of the bladder may be obtained with anticholinergic agents or intermittent detrusor injection with botulinum toxin. Occasionally, chronic clean intermittent self-catheterization is necessary.

Whenever possible, chronic indwelling catheters should be avoided in patients with a neurogenic bladder because they may lead to the formation of bladder stones, urosepsis, and urethral erosion, and they predispose to squamous cell carcinoma of the bladder. Patients who have chronic indwelling catheters for more than 5 years should have annual cystoscopic examinations. If deterioration in renal function occurs despite conservative measures or there is intractable incontinence or a small contracted bladder, an upper urinary tract diversion procedure such as an ileal conduit may be required.

Management of Postobstructive Diuresis

Marked polyuria (postobstructive diuresis) is frequently seen after the release of bilateral obstruction or obstruction of a single functioning kidney. Indeed, a diuresis of greater than 7 liters per day is associated with a good functional outcome.[37] Release of unilateral obstruction rarely results in a postobstructive diuresis despite the presence of tubular dysfunction and a concentrating defect. This is because of intrinsic differences in the tubular response to unilateral and bilateral obstruction and, more importantly, the salt and water retention and renal impairment that occurred in bilateral obstruction (not evident in unilateral obstruction because of the contralateral normal kidney). The resultant increase in natriuretic factors (including atrial natriuretic peptide) and substances able to promote an osmotic diuresis such as urea promote an appropriate postobstructive diuresis to excrete water and electrolytes that were retained during the period of obstruction. However, the postobstructive diuresis also may be inappropriate because of tubular dysfunction and, if not managed correctly, may result in severe volume depletion and electrolyte imbalance with continued renal dysfunction. Intravenous and oral fluid replacement is usually required, with careful and regular assessment of the fluid balance and serum electrolytes to tailor the fluid replacement regimen appropriately. Once the patient is deemed euvolemic, urine losses plus an allowance for insensible losses should be replaced. Urine volume should be measured regularly (hourly) to facilitate fluid administration, and serum electrolytes should be measured at least daily and as frequently as every 6 hours when there is a massive diuresis. Daily weighing of the patient is also helpful. Replacement fluid regimens should include sodium

chloride and a source of bicarbonate and potassium. Calcium, phosphate, and magnesium replacement also may be necessary.

If fluid administration is overzealous, the kidney will not recover its concentrating ability, and a continued "driven" diuresis will result. It may then be necessary to decrease fluid replacement to levels below those of the urine output and observe the patient carefully for signs of volume depletion.

Future Prospects

Understanding the pathophysiologic changes that follow ureteral obstruction has allowed the development of rational interventional therapies to hasten the recovery of renal function and limit permanent renal damage. Although the best treatment option in humans remains prompt and effective relief of the obstruction, development and implementation of improved imaging modalities that provide more sophisticated anatomic and functional information (including intrarenal oxygen content[38]) and future advances in urine proteomics will undoubtedly refine patient management and increase the data available for making key clinical decisions, such as whether and when surgical intervention is required.

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements are correct?
   - **A.** The presence of hydronephrosis does not always indicate significant obstruction.
   - **B.** Despite the effective relief of urinary tract obstruction, the majority of patients slowly progress to end-stage renal disease (ESRD).
   - **C.** Urinary tract obstruction is always associated with oliguria.
   - **D.** Patients with urinary tract obstruction typically exhibit microscopic hematuria on urinalysis.
   - **E.** Urinary tract obstruction is a risk factor for urinary infections.
2. Which of the following statements are correct?
   - **A.** The development of marked diuresis after relief of urinary tract obstruction is a poor prognostic indicator and is associated with the eventual development of end-stage renal disease.
   - **B.** Urinary tract obstruction may complicate neurologic disease.
   - **C.** Retroperitoneal disease may result in urinary tract obstruction.
   - **D.** Urinary tract obstruction leads to inflammation and scarring of the kidney.
   - **E.** Urinary tract obstruction may complicate immunoglobulin A (IgA) nephropathy.
3. Which of the following statements are correct?
   - **A.** Defective tubular function may persist after relief of urinary tract obstruction.
   - **B.** Urinary tract obstruction is associated with a reduction in the glomerular filtration rate but preservation of renal blood flow.
   - **C.** Non–contrast-enhanced spiral CT scanning is now established as the first-line imaging investigation in patients with suspected urinary tract obstruction.
   - **D.** A diuresis renogram accurately assesses kidney function but is unlikely to indicate the presence of obstruction.
   - **E.** Urinary tract obstruction may occur in the absence of hydronephrosis.

Urologic Issues for the Nephrologist

Raj P. Pal, James E. Dyer, J. Kilian Mellon

Close interaction between nephrologists and urologists is crucial to the optimal management of a number of common clinical problems. A proper understanding of urologic strategies helps the nephrologist ensure that patients with these problems are given clear information and are optimally managed. Areas in which such coordinated work is most important include the management of stone disease, the surgical approach to urinary tract obstruction, the investigation of hematuria, and the management of urinary tract malignant neoplasms.

ADVANCES IN MANAGEMENT OF KIDNEY STONES

The management of urinary tract stones has been transformed by the introduction of extracorporeal shock wave lithotripsy (ESWL), percutaneous nephrolithotomy (PCNL), and ureteroscopy. These advances mean that open stone surgery is now a final resort when other modalities have been exhausted or are contraindicated. Table 59.1 details the use of different treatment modalities over time since the introduction of newer techniques.[1] As familiarity with available techniques and technology develops, standardized treatment strategies will undoubtedly evolve, but the optimal treatment for certain patients with kidney stones remains controversial.

Improvements in Imaging

Unenhanced computed tomography (CT) scanning of the abdomen and pelvis has replaced intravenous urography (IVU) as the standard imaging modality for stone diagnosis (Fig. 59.1). CT is readily available, quicker to perform, offers increased sensitivity compared with IVU (99% vs. 70%), and avoids the need for intravenous contrast. An additional advantage is that CT can demonstrate radiolucent stones (mainly uric acid and xanthine stones) and detect concomitant lesions and/or alternative diagnoses. CT requires an increased radiation dose, but this is less of an issue with modern equipment and newer radiation protocols. Comparative doses are 2.5 mSv for IVU, 5 mSv for standard non–contrast-enhanced CT, and 2 mSv for low-dose non–contrast-enhanced CT.

Conservative (Nonsurgical) Management

Spontaneous stone passage can be expected in up to 80% of patients with stones smaller than 4 mm. Conversely, for stones with a diameter of more than 7 mm, the chance of spontaneous stone passage is very low. The location is also important; up to 70% of distal ureteral stones pass spontaneously, in contrast to only 45% of midureteral and 25% of proximal ureteral stones. Intervention is recommended when there is persistent pain (for more than 72 hours) despite adequate analgesia, persistent obstruction with risk for impaired renal function (e.g., with preexisting renal impairment or in a single kidney), bilateral obstruction, or associated urinary tract sepsis.

In the absence of an acute indication for surgical management, medical expulsive therapy (tamsulosin 400 μg once daily, nifedipine 30 mg once daily) had been thought to aid stone passage, particularly for distal ureteral stones. However, a recent large U.K. study demonstrated no significant benefit of this therapy, in contrast to earlier data from several systematic reviews of randomized trials.[2,3] Opinion is currently divided among urologists regarding medical expulsive therapy for ureteral stones.

Another conservative approach is chemolysis, because several stone types are in principle amenable to dissolution by oral medications or by direct instillation of chemical solutions. However, chemolysis is effective for only uric acid stones, which can be readily dissolved by alkalization of the urine, usually with oral potassium citrate, or with sodium bicarbonate solution instilled directly into the urinary tract via a percutaneous nephrostomy (PCN) tube.

Acute Surgical Intervention

The goals of acute surgical intervention are to relieve obstruction and, if feasible, remove the calculus. If the patient is well enough for general anesthesia, ureteroscopic stone destruction using laser lithotripsy can be attempted. Alternatively, a double-J stent (a ureteral stent with two coiled ends) can be inserted, which will relieve obstruction until definitive treatment is performed (Fig. 59.2). However, in the setting of uncontrolled urinary tract infection (UTI) resulting from an obstructing stone, PCN is the preferred option because it can be performed with local anesthesia and is less likely than endoscopic surgery to cause bacteremia (Fig. 59.3).

Elective Surgical Intervention

Extracorporeal Shock Wave Lithotripsy

During ESWL, acoustic shock wave energy is delivered to a stone under fluoroscopic or ultrasound guidance. Treatment sessions typically last about 30 minutes, during which 1500 to 2500 shock waves are delivered. Treatment is given to outpatients under analgesia or intravenous sedation and can be repeated at intervals of 10 to 14 days. Stones up to 20 mm in size can be treated effectively, and stone-free rates of 60% to 98% have been reported. However, ESWL is operator dependent, and outcome is influenced by the size, composition, and location of the stone and the type of lithotripter used. Cystine and calcium oxalate monohydrate stones are especially resistant. Targeting of the stone may be impossible in the presence of obesity and skeletal deformities

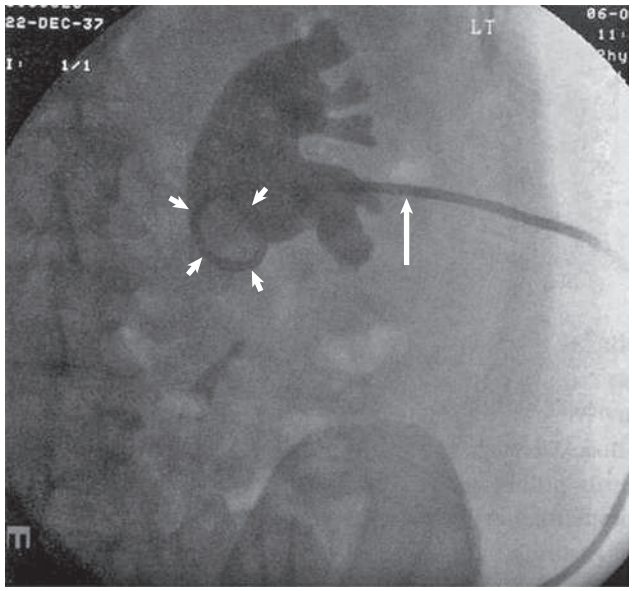

Fig. 59.3 Nephrostogram in ureteral obstruction caused by a stone. Contrast material is injected through a percutaneous nephrostomy tube placed in the lower pole calyx *(arrow).* The contrast material outlines a single large calculus *(arrowheads)* producing complete obstruction at the pelviureteral junction.

(increased skin-to-stone distance), and ESWL is contraindicated in patients with aortic or renal artery aneurysm, uncontrolled UTI, coagulation disorders, and pregnant women.

A double-J ureteral stent is sometimes placed endoscopically before ESWL treatment to prevent stone fragments from obstructing the distal ureter (*Steinstrasse,* literally "stone street"; Fig. 59.4). Other acute complications of ESWL include hemorrhage or hematoma, infection, and injury to adjacent organs. The risk for the later development of hypertension or renal impairment after ESWL remains controversial.

Percutaneous Nephrolithotomy

During PCNL, a tract through the renal parenchyma is created between the skin and the collecting system of the kidney. A metallic sheath within this tract is used as a working channel to remove stones. Preoperatively, CT imaging is used to localize calculi and neighboring organs (e.g., spleen, liver, large bowel, pleura, or lungs) and to plan access. The most frequently used access site is the dorsal calyx of the lower pole, and stone fragmentation is undertaken by ultrasound, pneumatic, or laser devices. With technologic advances, performing this procedure through smaller access sheaths (<18 Fr compared with standard 30-Fr sheaths) with fewer complications and equivalent stone clearance rates is becoming feasible.[5] The PCNL technique is modified for special circumstances, usually by altering the site of puncture (e.g., directly into a calyceal diverticulum) or, if there are ureteral stones, by using a higher placed puncture to permit antegrade ureteroscopy. The percutaneous puncture may be facilitated by the preliminary placement of a retrograde ureteral catheter to dilate and to opacify the collecting system, which is then punctured under fluoroscopy. After completion of PCNL, a self-retaining balloon nephrostomy tube is used to tamponade the tract and to provide further access if needed. Hemorrhage can complicate PCNL (from intrarenal or, rarely, intercostal arteries) and usually can be treated conservatively or by selective angiographic embolization. Other complications include sepsis; fluid overload (similar to transurethral resection syndrome); injury to spleen, pleura, or colon; and extravasation. PCNL usually results in minimal parenchymal injury, averaging only 0.15% of the total renal cortex.[6]

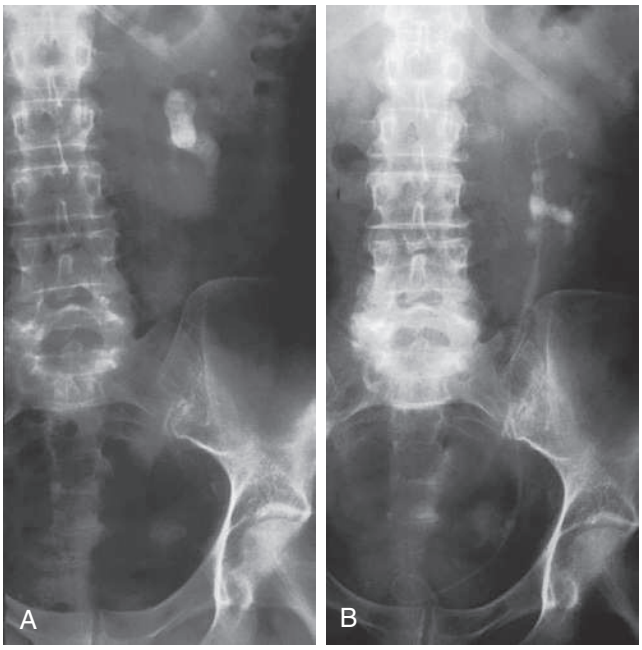

Fig. 59.4 Extracorporeal shock wave lithotripsy (ESWL) complicated by Steinstrasse. (A) Preoperative plain radiograph showing stones in the left renal pelvis. (B) After ESWL, note the disappearance of the pelvic stone, the string of stone fragments throughout the length of the ureter, and the double-J ureteral stent placed to facilitate their passage.

TABLE 59.2 Indications for Percutaneous Nephrolithotomy

Composition*	Struvite stones	Complete removal necessary to eliminate infection and minimize stone recurrence
	Calcium oxalate monohydrate stones	Difficult to pulverize by ESWL
	Cystine stones	Difficult to pulverize by ESWL
Stone position	Lower pole stones	Fragments less easily evacuated from dependent lower pole calyces, especially if collecting system dilated
Anatomic abnormalities	PUJ obstruction Calyceal diverticula	Prevent passage of fragments after ESWL
Patient characteristics	Morbid obesity Ureteral obstruction	Stone cannot be placed in focal point of ESWL machine

*Stone composition can be defined with certainty only by direct stone analysis, but advances in imaging may ultimately provide a means to accurately assess stone composition *in situ* before treatment, thus allowing the urologist to select the treatment most likely to be successful.
ESWL, Extracorporeal shock wave lithotripsy; *PCNL,* percutaneous nephrolithotomy; *PUJ,* pelviureteral junction.
ESWL is the first choice for stone intervention, except in those circumstances that may favor PCNL.

Indications for PCNL are shown in Table 59.2. These continue to evolve and are being challenged by developments in ureteroscopic techniques, which are allowing more upper ureteral and renal pelvic stones to be dealt with by a retrograde approach.

ESWL is the first-line treatment for more than 75% of stone patients. Table 59.2 shows circumstances in which ESWL is less effective and PCNL becomes the preferred approach or a combination of the two modalities is used. For lower pole stones in particular, ESWL may not provide optimal clearance because of problems with the drainage of residual fragments. A randomized controlled trial (RCT) has shown that for lower pole stones larger than 10 mm, PCNL has much better clearance rates than ESWL (92% vs. 23%).[4]

Open Stone Surgery

Open surgery still has a place in the treatment of stone disease. Approximately 2% of stone patients are now treated with open surgery, mainly when anatomic factors preclude the use of minimally invasive methods or when these techniques have failed. Other indications include complex stone burden and the presence of intrarenal anatomic abnormalities (e.g., pelviureteral junction [PUJ] obstruction). During surgery the renal pelvis as well as the parenchyma can be opened along avascular planes, and clamping of the renal vessels and hypothermia of the kidney may be needed. In selected patients a laparoscopic approach can be used for the treatment of stone disease.

Ureteroscopy

Continued advances in the design of endoscopes for ureteronephroscopy have rendered the entire urinary tract accessible to endoscopic examination and manipulation. Ureteroscopes may be semirigid or flexible, the latter allowing access to the renal pelvis and calyces. Stone fragmentation is achieved ideally by laser but also by ultrasound or pneumatic devices (lithoclast). Laser use is equally effective for all types of stones and has the additional advantages of a flexible fiber (allowing intrarenal stone fragmentation), low tissue penetration, and minimal stone displacement during use. Success rates for laser fragmentation of ureteral stones are approximately 80%. Fig. 59.5 highlights the increasing use of ureteroscopy in stone disease and also the increasing proportion of procedures in which a laser rather than ultrasound or a lithoclast is used to achieve stone fragmentation.

For lower pole renal stones, although flexible ureteroscopes can access the lower pole to facilitate treatment, the stone-free rate in comparative studies is similar to that of ESWL.[7,8] Furthermore, patients often prefer ESWL as the initial therapy compared with flexible ureteroscopy and lasertripsy. In the event of failed stone clearance after ureteroscopy, PCNL is commonly used next and is likely to remain an essential treatment for lower pole stones. Complications of ureteroscopy, particularly with use of graspers and baskets, include ureteral avulsion, perforation, extravasation, mucosal damage, hematuria, infection, and stricture. Advances in laser technology now enable stones to be reduced to dust-like particles, reducing the need for graspers and baskets and hence reducing complications.

Management of Staghorn Calculus

A staghorn calculus usually should be managed by intervention because reports of conservative therapy show a high rate of eventual nephrectomy (up to 50%) and an increase in associated morbidity (mainly renal failure) and mortality (up to 28%). Patient age and renal function heavily influence treatment decision making. The primary treatment option for staghorn calculi in a kidney with preserved renal function is PCNL. For a staghorn calculus in a nonfunctioning kidney, partial or total nephrectomy may be indicated. ESWL or ureteroscopic stone removal alone are rarely effective for large staghorn calculi, but can be used as an adjunct to PCNL to achieve total stone clearance. The advantage of a multimodal approach is the reduced need for additional renal

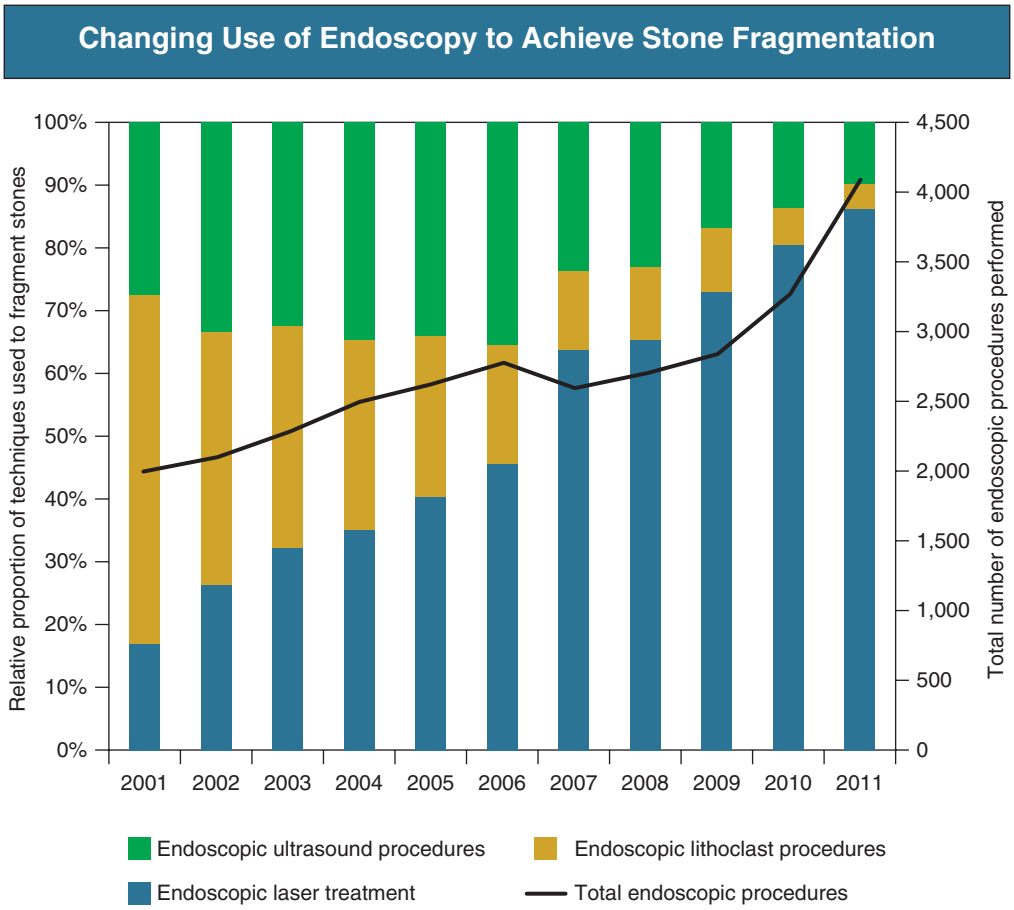

Fig. 59.5 Changing use of endoscopy to achieve stone fragmentation. Chart showing the increasing use of endoscopy in stone surgery in addition to the increasing proportion of cases using lasers to achieve stone fragmentation. (Data from UK Hospital Episode Statistics dataset. http://www.hscic.gov.uk/hes. Accessed June 9, 2012.)

access and secondary PCNL. Very rarely, open surgical removal of the stone may be indicated.

Stones in Transplanted Kidneys

The management of stone disease in a transplanted kidney is challenging because of the solitary kidney, the anatomic location within the pelvis, and the difficulty with retrograde access to the ureter and kidney. Early active intervention is indicated; prophylactic stenting, ureteroscopy, and PCNL are preferred to ESWL because stone targeting may not be possible. Open surgery may be needed in selected cases.

URINARY TRACT OBSTRUCTION

General Aspect

The causes of upper tract obstruction are listed in Chapter 58, Box 58.2, and a summary of the management of obstruction is given in Chapter 58, including Fig. 58.7. Upper tract obstruction caused by malignancy can be a result of direct tumor invasion or external compression by metastatic lymph node involvement or, rarely, true metastasis to the ureter. Some 70% of tumors causing ureteral obstruction are genitourinary (cervical, bladder, prostate) in origin; breast and gastrointestinal carcinomas and lymphoma constitute the majority of the remainder.[9] The presentation of a patient with obstruction may vary significantly, and hydronephrosis may develop progressively and insidiously and remain unrecognized until the patient develops anuria and uremia. Upper tract obstruction from malignancy rarely manifests with classic acute ureteral colic, which is typically seen with a benign cause such as a stone. Bladder outflow obstruction may be acute and dramatic or chronic with few or no symptoms. To aid in understanding of the immediate needs and longer term prognosis of these patients, the acute as well as the definitive management of the most common urologic diseases associated with obstruction and renal impairment are outlined.

Acute Management

Relief of obstruction is crucial to reverse renal impairment and preserve remaining renal function. In cases of bladder outflow obstruction, a urethral or suprapubic catheter is indicated; whereas in upper tract obstruction, a double-J ureteral stent is preferable, when possible. The most straightforward approach is endoscopic retrograde placement under fluoroscopy, with PCN reserved for patients in whom the procedure fails. Bilateral stents should be placed if technically possible. However, tumor infiltration can distort trigonal anatomy, making identification of ureteral orifices for double-J stent insertion impossible at the time of cystoscopy. Furthermore, it has been suggested that stents fail to relieve obstruction in 40% to 50% of cases of external ureteral compression. Thus these patients need to be closely monitored to ensure resolution of the obstruction. A new type of metallic, self-expanding stent, used alone or in conjunction with double-J stents, has had good results in maintaining ureteral patency and avoiding PCN in malignant ureteral obstruction.[10]

A stable patient with obstruction but without major signs of sepsis is a candidate for retrograde stent placement with use of general anesthesia. However, in a patient with sepsis, endoscopic manipulation can lead to bacteremia and septic shock. Furthermore, such patients may not be fit for general anesthesia, in which case the preferred initial approach is PCN, which can then be followed after an interval with antegrade ureteral stenting. The success rate of this combined approach is high (>90%).[11] In patients with bilateral ureteral obstruction, it is not always necessary to insert bilateral PCN tubes. Significant palliation and return to nearly normal renal function can be accomplished by drainage of the kidney with the better preserved parenchyma as determined by CT scan or ultrasound. Once they have been placed, PCN tubes or double-J stents need to be replaced every 3 to 6 months. If they are left for a longer period, they become increasingly brittle and encrusted and are liable to block or fracture under manipulation. Complications of ureteral stents include migration, obstruction with proteinaceous material, infection, fragmentation, and, rarely, erosion through the urinary tract.[12] As many as 70% of patients with stents report lower urinary tract symptoms, mainly urgency, frequency, and nocturia, as well as pain along the urinary tract.

Morbidity after stenting or PCN is similar.[13] The main problem with indwelling stents is the increased risk for recurrent obstruction (11% for stents vs. 1% for PCN). PCN may have an increased infection rate, and there may be psychological issues relating to the need for an external drainage bag.

Extraanatomic stents are an alternative for patients in whom conventional stent insertion has failed or for whom permanent nephrostomy drainage is unacceptable. An extraanatomic stent is placed by an initial percutaneous puncture and insertion of the upper end of a long (50-cm) double-J stent into the kidney. A subcutaneous tunnel is then created to bring the stent to the level of the iliac crest. Another tunnel is fashioned to bring the lower end of the stent out suprapubically, followed, finally, by suprapubic puncture of a full bladder and insertion of the lower end (Fig. 59.6).[14] Extraanatomic stents are usually changed at 6-month intervals, and preliminary experience confirms their value in maintaining ureteral patency and avoiding PCN. Because of the effectiveness of minimally invasive methods, open surgery today is rarely indicated in the acute setting.

Fig. 59.6 Extraanatomic stenting for malignant ureteral obstruction. Plain radiograph showing placement of an extraanatomic stent for malignant obstruction of the right ureter. The upper end of the double-J stent has been placed in the right renal pelvis *(arrow)*. The stent then runs through a subcutaneous tunnel before the lower end enters the bladder *(arrowhead)*.

SPECIFIC TYPES OF OBSTRUCTION

Pelviureteral Junction Obstruction

Surgical management of PUJ obstruction is aimed at obliterating the redundant (aperistaltic) portion of the ureter, allowing normalization of drainage from the affected kidney. The need for treatment is heralded by the onset of pain, infection, calculus formation, decline in renal function, or proven impaired excretion on mercaptoacetyltriglycine (MAG3) renography with impending decline in renal function. The gold standard treatment is now laparoscopic or robotic pyeloplasty, although traditional open techniques are still used. Endoscopic (endopyelotomy) treatments are also performed in some centers. However, in treatment-naïve patients, endopyelotomy has inferior outcomes compared with pyeloplasty.[15,16]

Retroperitoneal Fibrosis

Retroperitoneal fibrosis can be treated medically or surgically. A causative factor should be excluded (see Chapter 58). There are reports of favorable outcomes after immunosuppression with high doses of corticosteroids or azathioprine. Alternatively, surgery, consisting of ureterolysis (freeing the ureters from the fibrotic plaques) and omentoplasty (transposition of the ureters into the peritoneal cavity in omental wraps), can have good long-term results.

Malignant Obstruction

For upper tract transitional cell carcinoma, acute obstruction is best treated by internal stenting. PCN is avoided because of the risk for tumor seeding. Upper tract transitional cell carcinoma is an aggressive tumor and necessitates prompt extirpative surgery.

Bladder cancer can lead to hydronephrosis by invading the ureteral orifices and intramural ureter. In the absence of metastatic disease, radical cystectomy is indicated, although temporary ureteral decompression may normalize renal function if neoadjuvant chemotherapy is planned. In selected cases, bladder preservation strategies combining systemic chemotherapy and radiotherapy can offer long-term control of the disease.

Prostate cancer causes obstruction by occluding the urethra or invading the ureteral orifices. Hormonal treatment can shrink prostatic tissue and malignant deposits and offer long-term remission of symptoms. Limited resection of the prostate may sometimes be indicated.

The decision to offer ureteral decompression for upper tract obstruction caused by cancer is not straightforward and requires input not only from the urologist but also from colleagues in radiation and medical oncology and the palliative care team. There must also be careful discussion of the options with the patient and family.

Ureteral decompression is justified when radiotherapy and systemic chemotherapy remain therapeutic options after improvement in renal function but also may be justified for palliation of pain or ongoing renal tract sepsis.

A review of patients undergoing PCN for obstructive uropathy secondary to pelvic malignancy identified a subset with very poor survival in whom ureteral decompression is usually not justified (Table 59.3).[17] Patients with gastric or pancreatic cancer survive a median of only 1.4 months after ureteral decompression.[18] In another report, the average survival of patients with advanced malignant neoplasms undergoing endourologic diversion was only 5 months, half of which time was spent in the hospital.[19]

TABLE 59.3 Percutaneous Nephrostomy for Malignant Obstructive Uropathy

	Median Survival (wk)	5-yr Survival Rate (%)
Group I: Primary untreated malignancy	27	10
Group II: Recurrent malignancy with further treatment	20	20
Group III: Recurrent malignancy with no further treatment	6.5	None survived longer than 1 yr
Group IV: Benign disease as a result of previous treatment	Not stated	64
Overall	26	22

Outcome in 77 patients undergoing percutaneous nephrostomy for obstructive uropathy secondary to pelvic malignant disease.

Benign Ureteral Strictures

These can be secondary to stone disease, iatrogenic, or caused by various benign diseases. The treatment of choice is endoscopic balloon dilation or ureterotomy. Open surgical repair or major reconstructive surgery may be needed in cases of recurrent strictures.

Bladder Outflow Obstruction

Bladder outflow obstruction in men is most frequently caused by either benign or malignant prostatic enlargement. Common presentations of both conditions include the onset of lower urinary tract symptoms and acute (painful) or chronic (painless) retention of urine.

Chronic retention can be considered as the maintenance of voiding with incomplete bladder emptying. It is further classified into low- and high-pressure chronic retention. Low-pressure chronic retention occurs in the absence of upper tract compromise, whereas high-pressure chronic retention is associated with hydronephrosis and kidney injury.

In acute retention, low-pressure chronic retention, and lower urinary tract symptoms caused by bladder outflow obstruction, treatment with 5α-reductase inhibitors (finasteride, dutasteride) or α-adrenergic receptor blockers (tamsulosin, alfuzosin) is usually indicated before surgery is offered.[20] Given the risk for worsening renal failure if medical therapy fails, it is not a safe management option in high-pressure chronic retention. Surgical management is reserved for patients who either derive no benefit from or are not willing to pursue medical therapy, those with acute and low-pressure chronic retention, and those with high-pressure chronic retention. Before surgery, evaluation of likelihood of success is essential. Patients with very high postvoid residual volumes of urine (>1 liter) are less likely to benefit from surgery because of the chronicity of their symptoms and consequent detrusor muscle weakness. These patients are often treated best with intermittent clean self-catheterization or a permanent urethral or suprapubic catheter.

The number of surgical management options available for bladder outflow obstruction is continually increasing. Although transurethral resection of the prostate (TURP) has been the gold standard procedure for decades, the development of laser technology is challenging this. Holmium laser enucleation of the prostate (HoLEP) and vaporization of prostatic tissue (Green light laser) are being increasingly performed in specialist centers with superior results with respect to reduced patient stay, bleeding, and duration of postoperative catheterization. Unlike standard TURP, laser prostatectomy also can be routinely performed safely in patients with large gland size (>100 cc) and on anticoagulation therapy. A recently published 7-year follow-up study comparing TURP with HoLEP reported no significant difference in quality of life, maximum urinary flow, incontinence, or erectile dysfunction, with a reduced need for reoperation in the HoLEP arm of the study.[21]

Neurologic Diseases of the Lower Urinary Tract

Diseases of the central or peripheral nervous system can manifest with bladder underactivity or detrusor-sphincter dyssynergia and lead to bilateral hydroureternephrosis. Diabetes mellitus also can produce a flaccid denervated bladder through destruction of the peripheral nerves and can cause chronic retention and renal failure. Of diabetics who develop peripheral neuropathy, 75% to 100% will develop some neurogenic lower urinary tract dysfunction. The treatment of choice is generally intermittent clean self-catheterization, with a limited role for surgery.

INVESTIGATION OF HEMATURIA

Macroscopic hematuria is perhaps the most important symptom in urologic practice, and apart from being alarming to the patient, it can be the first presenting sign of an underlying malignant urologic condition (most often a transitional cell tumor of the bladder). Studies show that 15% to 22% of patients with visible hematuria have an underlying genitourinary tract malignant neoplasm.

Patients with visible hematuria must be distinguished from those who have been found to have microhematuria (microscopic or dipstick), in whom the risk for malignant change is significantly lower (2% to 11%).

The outcome of full evaluation of a large group of patients attending a hematuria clinic is shown in Table 59.4.[22] In addition to a small but important group of patients in whom malignant disease was identified, there was a significant pickup rate of parenchymal renal disease (~10%) presenting with both visible and nonvisible hematuria. It is also important to note the sizable proportion of patients in whom a definitive diagnosis could not be reached.

Evaluation of Visible Hematuria

All adults with a single episode of visible hematuria require full urologic evaluation, including renal imaging and cystoscopy. The only exception to this rule occurs when an adult younger than 40 years gives a history characteristic of glomerular hematuria, such as is typically seen in immunoglobulin A (IgA) nephropathy, in which dark brown hematuria lasting 24 to 48 hours coincides with intercurrent mucosal infection, usually of the upper respiratory tract. This hematuria may be painless, or there may be bilateral loin ache. These young adults should be referred first for nephrologic assessment.

Evaluation of Microhematuria

Perhaps the greatest degree of overlap in practice between urologists and nephrologists occurs in the initial assessment of patients with microhematuria. Concurrent UTI will cause microhematuria and should be treated before further evaluation. Furthermore, features such as menstruation, vigorous exercise, viral illness, and trauma can themselves account for microhematuria. In the presence of a transient or treatable underlying cause other than UTI, repeat urinalysis should be performed 2 days later. Further urinalysis should be deferred until 6 weeks after treatment of confirmed UTI. If microhematuria resolves, no further investigation is required.

In 2012 the American Urological Association, after extensive systematic review of the literature, produced their guidance on the assessment and management of asymptomatic microscopic (nonvisible) hematuria (AMH).

These guidelines defined AMH by the presence of three or more red blood cells (RBCs) per high-power field on microscopic examination of one properly collected, noncontaminated urine sample. In addition to the benign causes listed, pyuria and bacteriuria also should be excluded with either dipstick or microscopy.

The most notable departure from previous guidance is the recommendation of urologic investigation after one episode of AMH, rather than waiting for two of three positive samples as previously suggested. There are currently no direct comparative studies identifying diagnostic yields in patients with one or more than one episode of AMH. Indirect comparison, however, reveals a diagnostic yield of urinary tract malignancy of 1.8% and 3.6% in patients with one or more than one episode of AMH, respectively.[23] Dipstick-positive hematuria may still herald significant disease in the absence of RBCs on microscopy because RBCs may lyse in alkaline or hypotonic urine before reaching the laboratory for analysis.[24]

Complete evaluation of microhematuria includes a history and physical examination, laboratory analysis, and radiologic imaging of the upper urinary tract, followed by cystoscopy (Fig. 59.7). In women, urethral and vaginal examinations should be performed to exclude local causes of microhematuria. In uncircumcised men, the foreskin should be retracted to expose the glans penis, if possible. If phimosis is present, a catheter specimen of urine may be required. An assessment of renal function should be made (serum creatinine, estimated glomerular filtration rate [eGFR]) because intrinsic renal disease may have implications for consequent imaging and treatment. The remaining laboratory investigations are guided by specific findings of the history, physical examination, and urinalysis. Multiphase CT urography, which allows evaluation of renal parenchyma and also the collecting system, has been shown to have the highest sensitivity and specificity for imaging the upper tracts. If CT urography is unavailable, then IVU and ultrasound combined with plain abdominal radiography are alternative imaging strategies. Cystoscopy is now advocated in all patients with AMH who are older than 35 years and those under the age of 35 years with risk factors for urologic malignancy or clinical suspicion of malignancy (Box 59.1). The use of adjuncts to AMH workup such as urine cytologic examination and other urine biomarkers is no longer advocated.

BOX 59.1 Common Risk Factors for Urinary Tract Malignancy in Patients With Microhematuria

- Male gender
- Age (>35 years)
- Past or current smoking
- Occupational or other exposure to chemicals or dyes (benzenes or aromatic amines)
- Analgesic abuse
- History of visible hematuria
- History of urologic disorder or disease
- History of irritative voiding symptoms
- History of pelvic irradiation
- History of chronic urinary tract infection
- History of exposure to known carcinogenic agents or chemotherapy such as alkylating agents
- History of chronic indwelling foreign body

Significant proteinuria (>0.3 g/24 h), RBC casts, predominance of dysmorphic RBCs in the urine, or renal impairment should prompt referral to a nephrologist and evaluation for parenchymal renal disease. When present, RBC casts are virtually pathognomonic of glomerular bleeding, but they are often absent in low-grade glomerular disease. Accurate determination of RBC morphology requires inverted phase contrast microscopy. In general, glomerular bleeding is associated with more than 80% dysmorphic RBCs, and lower urinary tract bleeding is associated with more than 80% normal RBCs.[25] This assessment is operator dependent. (Urine microscopy is further discussed in Chapter 4). An alternative is to assess urinary RBC size by Coulter counter analysis because dysmorphic RBCs are smaller than normal RBCs, but this method is not useful when RBC numbers in the urine are small. Even in the absence of features of glomerular bleeding, many patients with isolated microhematuria have glomerular disease, most commonly IgA nephropathy or thin basement membrane nephropathy.[26] Because there is a low risk for progressive renal disease, renal biopsy in this setting is not usually recommended. Nevertheless, one study showed that microhematuria unexplained by urologic evaluation carries a twofold risk for eventual development of ESRD,[27] so these patients should be observed for the development of hypertension, renal impairment, or proteinuria.

Cyclophosphamide

Past treatment with cyclophosphamide increases the risk for bladder cancer up to ninefold, probably in a dose- and duration-dependent manner. Tumors have been reported 6 to 13 years after cyclophosphamide exposure and are often of high grade. Hematuria is also common after cyclophosphamide in the absence of cancer. If full evaluation does not identify a cause of hematuria, there is no agreed surveillance protocol; it is not clear whether routine follow-up by cystoscopy and urine cytology is valuable, although a high index of suspicion should be maintained.

INVESTIGATION AND MANAGEMENT OF A RENAL MASS

The incidence of renal cell carcinoma (RCC) has more than doubled in the last 30 years, now accounting for 3% of all cancers. It is the third

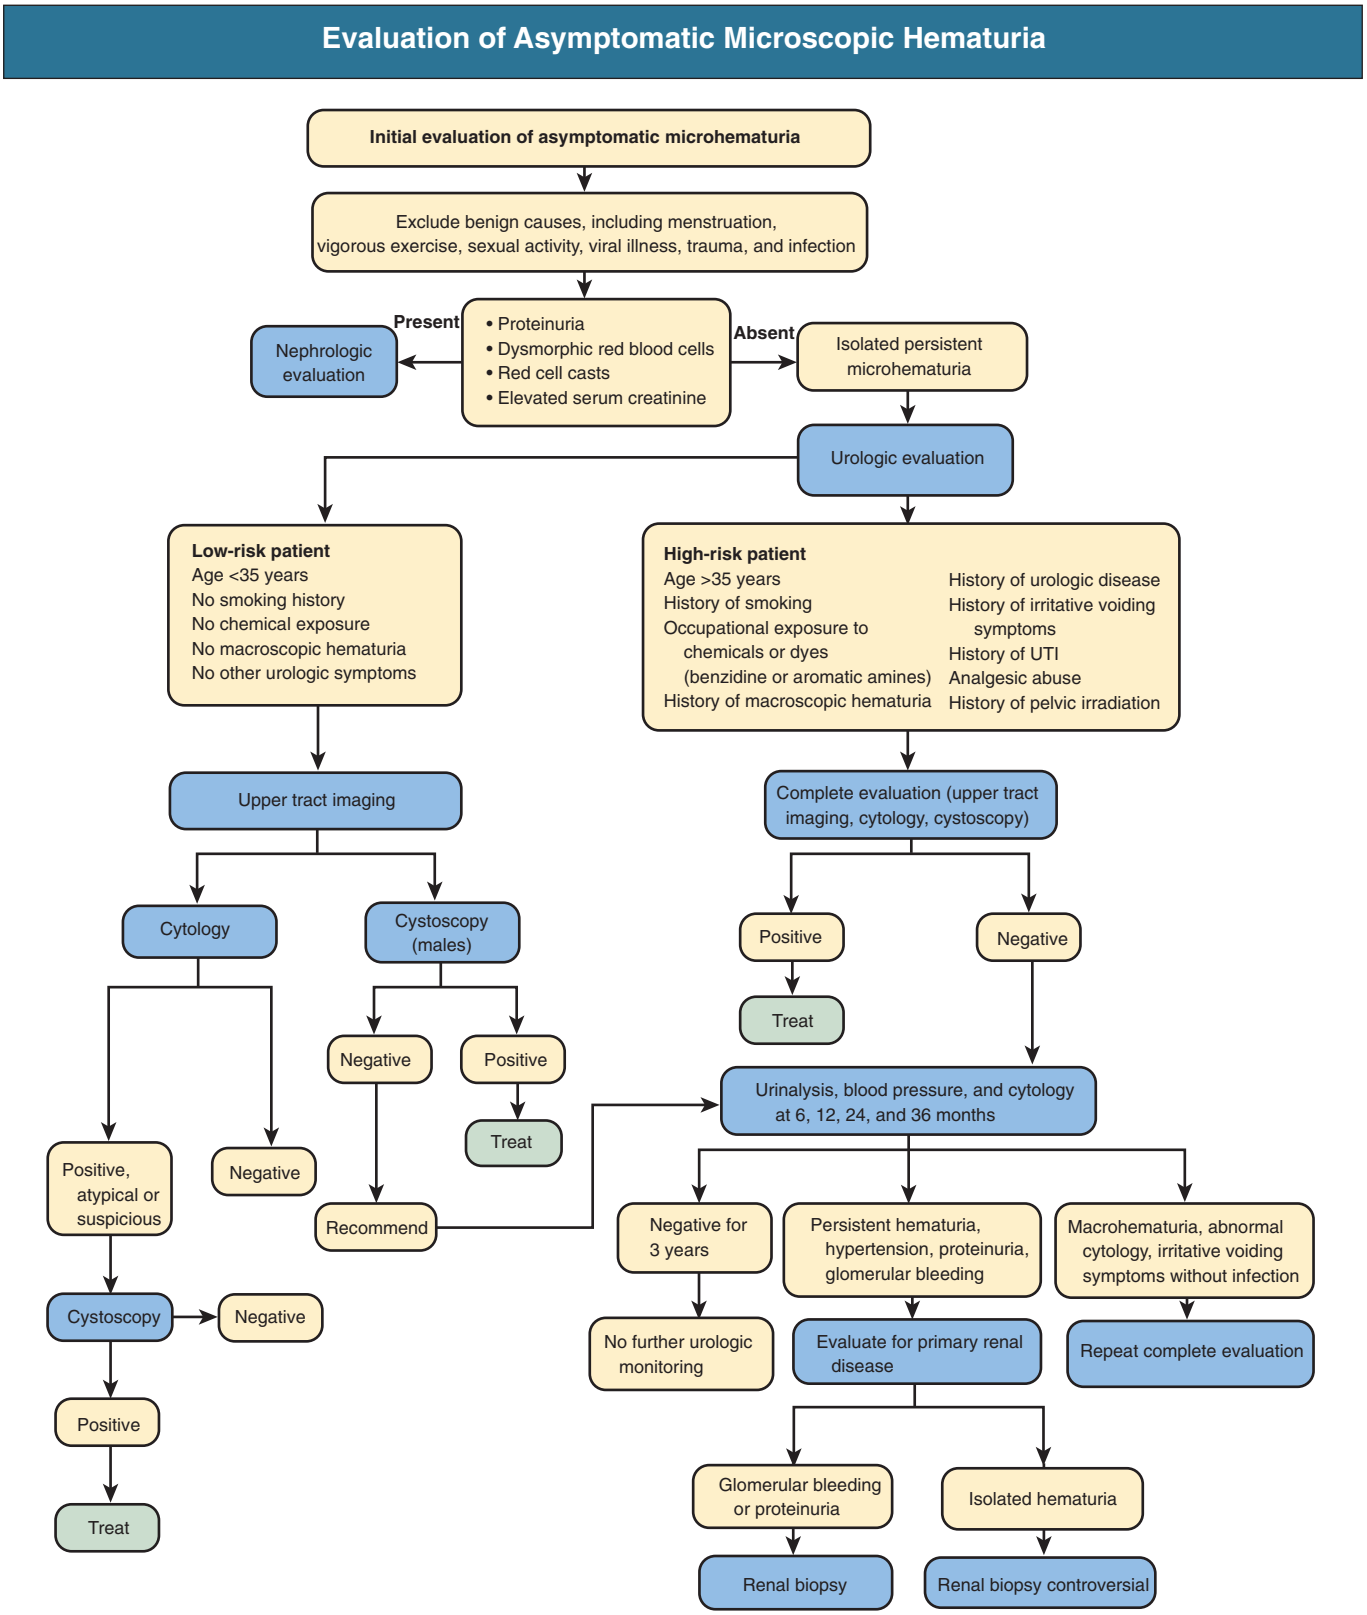

Fig. 59.7 Evaluation of asymptomatic microscopic hematuria. *UTI,* Urinary tract infection.

TABLE 59.5 Bosniak Classification and Management of Cystic Renal Masses*

Bosniak Class	Features on Imaging	Comment	Management
Class I: Simple benign cyst	Round or oval Uniform density <20 HU Unilocular No perceptible wall No contrast enhancement	Majority of asymptomatic cystic lesions	No further intervention required
Class II: Benign cyst	One or two nonenhancing septa Calcifications in the wall or septum Hyperdense lesions (50-90 HU, resulting from the presence of blood, protein, or colloid) <3 cm No contrast enhancement		No further intervention required
Class II F: Probable benign cyst	Multiple hairline septa "Perceived" enhancement Nodular calcification Hyperdense lesions >3 cm	"Perceived" enhancement resulting from contrast within capillaries of septa	Surveillance with CT scans every 6-12 months
Class III: Indeterminate cystic lesions	One or more of the following: Thick, irregular borders Irregular calcifications Thickened or enhancing septa Multilocular form Uniform wall thickening Small nonenhancing nodules	About 40% are neoplastic Magnetic resonance imaging may improve characterization	Surgical exploration
Class IV: Presumed malignant cystic masses	Appear malignant Heterogeneous cysts Shaggy, thickened walls or enhancing nodules	Appearances result from necrosis and liquefaction of a solid tumor or a tumor growing in the wall	Surgical exploration

Data from reference 25.
Approach to renal mass found incidentally by ultrasound or CT scanning.
*All patients with symptomatic renal masses should be referred for urologic assessment.
HU, Hounsfield units.

most common tumor of the urinary tract but the most lethal. The apparent increased incidence is partly attributed to the widespread use of cross-sectional and ultrasound imaging; more than 50% of new cases are incidental findings on CT, magnetic resonance imaging (MRI), or ultrasound.

The primary goal in investigating a renal mass is to diagnose or exclude malignancy. Ultrasound has been reported to be 79% sensitive for the detection of renal parenchymal masses but does not detect lesions smaller than 5 mm. Contrast enhancement with ultrasound also can identify malignancy and improve sensitivity. However, CT scanning before and after contrast administration is the most common modality used to characterize renal masses. MRI, especially with T2-weighted images and diffusion weight imaging, may be superior to CT in the correct characterization of benign lesions,[28] but distinguishing an RCC from a benign lesion (i.e., oncocytoma, fat-free angiomyolipoma) is occasionally not feasible radiologically. Choice of imaging techniques and their interpretation are discussed further in Chapter 5.

Because of the limitations of radiologic evaluation, percutaneous biopsy of a renal mass is increasingly used to obtain a histologic diagnosis before treatment. Up to 30% of small renal masses (<3 cm) are nonmalignant. Traditional fears regarding tumor seeding after percutaneous biopsy are not supported by recent studies. Biopsy of a renal mass is now recommended for diagnostic uncertainty, despite imaging, before systemic therapy for metastatic RCC and in renal tumors managed with surveillance or ablative modalities.[29] Many clinicians also perform biopsy before embarking on surgery in high-risk or elderly surgical candidates, those who will require technically challenging surgery, and patients with small renal masses. In a recent systematic review evaluating 57 studies investigating over 5000 patients, percutaneous biopsy was shown to have a high diagnostic yield, sensitivity (>98%), and specificity (>98%) for renal cancers, with a low associated complication rate.[30]

The management of mixed cystic and solid masses is more problematic. Table 59.5 shows the Bosniak classification of cystic renal masses.[31] This classification, based on CT appearances, provides the basis for management according to risk for malignancy. The evaluation of multiple cystic lesions in the kidney is discussed further in Chapter 45.

Tumor size is important; in a large retrospective study of 2935 patients with surgically treated solid renal tumors, 46% of lesions smaller than 1 cm were benign compared with 22% and 10% of tumors 1 to 2 cm and 4 to 5 cm, respectively. Furthermore, only 2.3% of cancers smaller than 1 cm were of high grade, whereas for tumors larger than 7 cm, the percentage was 58%.[32] Surveillance studies of small renal tumors have shown a median growth rate of 0.28 cm per year; about 30% of these lesions will not increase in size.

Traditionally, radical nephrectomy was the gold standard treatment for localized renal cancers. However, nephron-sparing surgery (NSS) is now recommended in all tumors smaller than 7 cm where technically feasible.[29] Comparison of these two approaches for T1a (<4 cm) and T1b (4 to 7 cm) lesions has shown equivalent tumor clearance and a reduction in long-term renal complications with partial nephrectomy.[33] Radical nephrectomy therefore should be reserved for larger renal cancers (≥T2), those technically not amenable to partial nephrectomy and in patients unlikely to benefit from NSS.[29]

The last two decades have also seen a shift from open to minimally invasive surgery. Laparoscopic radical nephrectomy and robotic assisted partial nephrectomy (particularly for small exophytic tumors) have

TABLE 59.6 Evidence-Based Recommendations for Targeted Therapy in Metastatic Renal Cell Carcinoma

now superseded open approaches for these techniques in most large centers. Minimally invasive treatment modalities give equivalent long-term cancer control, while reducing perioperative blood loss, postoperative analgesic requirement, and hospitalization.

Cryosurgery and radiofrequency ablation via laparoscopic or percutaneous approaches have emerged as treatment options for small localized renal cancers. There is currently no consensus on the maximum size of lesions amenable to these techniques, but they are usually reserved for tumors smaller than 4 cm. Such treatments offer the advantages of NSS, especially in patients with high surgical risk. Case series evaluating these modalities individually have reported promising results. However, there are no data from RCTs on either modality and nonrandomized studies have not shown any significant oncologic or survival benefit when comparing these modalities to partial nephrectomy, although several studies have reported reduced efficacy in terms of local recurrence, metastatic progression, and survival.[34-36] Further disadvantages of both techniques include absence of histologic confirmation of complete tissue destruction and potential for more difficult salvage surgery for local recurrence.

Adjunctive Therapy for Renal Cancer

The 5-year survival for patients diagnosed with localized RCC is approximately 80% to 90%. However, in the United States up to 20% of patients with RCC present with metastasis. The 5-year survival falls to 60% and 10% in the presence of regional and distant metastasis, respectively. Metastatic RCC is resistant to commonly used chemotherapeutic agents, and cytokine therapy with either interleukin (IL)-2 or interferon-α (IFN-α) was standard treatment for metastatic RCC in the United States and Europe until 2005. Although more effective than traditional chemotherapy, it produced only modest response rates with significant toxicity.[37] Identification of the molecular pathways implicated in the etiology of RCC has led to the development of targeted tyrosine kinase inhibitors and monoclonal antibodies directed against the vascular endothelial growth factor (VEGF) pathway (sorafenib, sunitinib, bevacizumab, pazopanib, axitinib, cabozantinib) and mammalian target of rapamycin (mTOR) (temsirolimus, everolimus). In randomized studies, many of these agents, when compared with standard existing therapy, have improved both progression-free and overall survival when used as first- or second-line therapy.[38-43] The European Association of Urology has made recommendations on the sequence in which these agents should be used (Table 59.6).[29] Nephrologic aspects of cancer therapy are further discussed in Chapter 65.

Natural History of Renal Impairment After Surgical Treatment of Renal Cancer

Normal renal function is usually preserved in the long term after donor transplant nephrectomy. Donors are highly selected to minimize comorbidities and generally are younger than patients treated for renal tumors. However, emerging long-term evidence suggests those undergoing donor nephrectomy do have increased long-term cardiovascular complications and reduced survival.[44] Similarly, after surgery for renal cancer, when the residual functioning renal tissue is reduced, there is significant risk for late sequelae, including proteinuria, glomerulosclerosis, and progressive renal failure resulting in increased cardiovascular complications and reduced survival. These risks are thought to be greater when radical rather than partial nephrectomy is performed. A recent systematic review of 21 nonrandomized comparative studies (11,204 patients) evaluating partial nephrectomy versus radical nephrectomy demonstrated superiority for NSS.[45] Partial nephrectomy was associated with greater perioperative blood loss and postoperative complications, affirming that it is a more challenging procedure. However, NSS was associated with a lower long-term decline in eGFR and reduced risk for chronic kidney disease. NSS also provided a more favorable cancer-specific survival. The one RCT to compare partial nephrectomy versus radical nephrectomy also has demonstrated that fewer patients undergoing NSS develop chronic kidney disease (eGFR <60), but overall survival and cancer outcomes are similar with either modality.[33]

Renal Cell Carcinoma in von Hippel–Lindau Disease

von Hippel–Lindau disease (VHL) is a rare autosomal dominant condition with a predisposition to the development of RCC. The genetics, clinical manifestations, and general management of VHL are discussed further in Chapter 45. The incidence of RCC in patients with VHL is about 45%. On histologic examination, the tumors are of the clear cell

type, often multifocal and bilateral, and can be solid or cystic. The mean age at diagnosis is 39 years, and there is a 30% to 35% risk for tumor progression, metastasis, and death.

Longitudinal imaging studies have described the natural history of VHL renal lesions. In one study multifocal lesions were frequent[46] (on average, eight per patient), of which 74% were classified as simple cysts, 8% as complex cysts with solid components, and 18% as solid masses. The solid components of VHL lesions almost always contain RCC. During a mean 2.4-year follow-up, most cysts remained the same size (71%) or enlarged (20%), and 9% became smaller. On the contrary, 95% of solid masses increased in size. Although it is generally thought that the cysts are premalignant, the transformation of a simple cyst to a solid lesion was observed in only two patients. Patients with VHL require multidisciplinary management. Surgical intervention is not used for tumors smaller than 3 cm because metastasis is rare below this threshold. In addition, bilateral nephrectomy should be avoided, if possible, because of the substantial morbidity associated with renal replacement therapy. The standard of care for these patients is partial nephrectomy, and a 10-year survival rate of 81% has been reported.

The results of NSS for VHL appear less satisfactory than for sporadic RCC because of a high risk for local tumor recurrence. Repeated surgery may be needed for new or growing lesions, and for this reason the use of minimally invasive methods is being investigated. Repeated ablation of tumors with radiofrequency and cryotherapy is possible with minimal morbidity; however, the long-term effectiveness of these methods has not yet been established.

SELF-ASSESSMENT QUESTIONS

1. A 50-year-old man presents with right-sided ureteral colic and on subsequent investigation is found to have a 4-mm distal ureteral calculus with no hydronephrosis. He has a normal estimated glomerular filtration rate (eGFR). In the absence of ongoing pain or sepsis, what is the most appropriate management option?
   A. Acute endoscopic lasertripsy
   B. Decompression with ureteric stenting
   C. Trial of medical expulsive therapy
   D. Discharge from care of urologist
   E. Percutaneous nephrostomy
2. A 70-year-old man is seen in an outpatient clinic with a 2-month history of intermittent hematuria. He takes warfarin for atrial fibrillation but is otherwise healthy. His eGFR is in the normal range. What urologic investigations does he require?
   A. Clotting screen to exclude overanticoagulation as the sole cause of his hematuria
   B. Clotting screen; proceed to urologic workup only if international normalized ratio (INR) is within therapeutic range
   C. Clotting screen, flexible cystoscopy, and computed tomography (CT) urogram
   D. Clotting screen, renal function tests, flexible cystoscopy, and CT urogram
3. A 60-year-old man with diabetic nephropathy is referred with a 3-cm lower pole renal lesion suspicious for malignancy on routine ultrasound scan. These findings are confirmed on CT scan. Despite his comorbidity he is deemed fit for surgery. What is the most appropriate procedure to consider?
   A. Open radical nephrectomy to achieve maximum oncologic benefit
   B. Laparoscopic cryosurgery
   C. Laparoscopic partial nephrectomy
   D. Laparoscopic radiofrequency ablation

Acute Interstitial Nephritis

Jérôme A. Rossert, Evelyne A. Fischer

DEFINITION

Acute interstitial nephritis (AIN) is an acute, often reversible disease characterized by inflammatory infiltrates within the interstitium. AIN is a relatively rare cause of acute kidney injury (AKI), but it should not be overlooked because it usually requires specific therapeutic interventions.

PATHOGENESIS

Most studies suggest that AIN is an immunologically induced hypersensitivity reaction to an antigen that is classically a drug or an infectious agent. Evidence for a hypersensitivity reaction in drug-induced AIN includes the following: it occurs only in a small percentage of individuals; it is not dose dependent; it is often associated with extrarenal manifestations of hypersensitivity; it recurs after accidental reexposure to the same drug or to a closely related one; and it is sometimes associated with evidence of delayed-type hypersensitivity reaction (renal granulomas). Similarly, AIN secondary to infections can be differentiated from pyelonephritis by the relative absence of neutrophils in the interstitial infiltrates and the failure to isolate the infective agent from the renal parenchyma, again suggesting an immunologic basis to the disease.

Experimental models of AIN have identified three major types of antigens that induce AIN.[1] Antigens may be tubular basement membrane (TBM) components (e.g., the glycoproteins 3M-1 and TIN-Ag/TIN1), secreted tubular proteins (e.g., uromodulin), or nonrenal proteins (e.g., from immune complexes).

Although human AIN may be secondary to an immune reaction directed against a renal antigen, most cases of AIN are probably induced by extrarenal antigens, being produced in particular by drugs or infectious agents. These antigens may induce AIN by a variety of mechanisms, including binding to kidney structures ("planted antigen"); acting as haptens that modify the immunogenicity of native renal proteins; mimicking renal antigens, resulting in a cross-reactive immune reaction; and precipitating within the interstitium as circulating immune complexes.

Experimental models have identified both cell-mediated immunity and antibody-mediated immunity in the pathogenesis of AIN (Fig. 60.1). In humans, most forms of AIN are not associated with antibody deposition, which suggests that cell-mediated immunity plays a major role. This hypothesis is reinforced by the fact that interstitial infiltrates usually contain numerous T cells and these infiltrates sometimes form granulomas. Nevertheless, deposition of anti-TBM antibodies or of immune complexes can be observed occasionally in renal biopsy specimens, and antibody-mediated immunity may play a role in the pathogenesis of the disease in these cases.

Formation of immune complexes within the interstitium, or interstitial infiltration with T cells, will result in an inflammatory reaction. This reaction is triggered by many events, including activation of the complement cascade by antibodies and release of inflammatory cytokines by T lymphocytes and phagocytes (see Fig. 60.1). Although the interstitial inflammatory reaction may resolve without sequelae, it sometimes induces interstitial fibroblast proliferation and extracellular matrix synthesis, leading to interstitial fibrosis and chronic kidney disease (CKD). Cytokines such as transforming growth factor-β appear to play a key role in the latter process.

EPIDEMIOLOGY

AIN is a relatively uncommon cause of AKI, although its incidence may be increasing.[2] It accounts for 2% to 3% of all renal biopsies, 10% to 15% or biopsies performed for unexplained AKI, and up to 25% of those performed for drug-induced AKI.[2] Of kidney biopsies done in children with AKI, 3% to 7% show AIN.[3]

Before antibiotics were available, AIN was most commonly associated with infections such as scarlet fever and diphtheria. Drug-induced AIN now appears to account for about 70% to 90% of all cases.

DRUG-INDUCED ACUTE INTERSTITIAL NEPHRITIS

Clinical Manifestations

In the 1960s and 1970s, most cases of drug-induced AIN were caused by methicillin, and the clinical manifestations of methicillin-induced AIN were considered the prototypical presentation of AIN. Since then, many other drugs have been implicated in the induction of AIN (Box 60.1), of which antimicrobial agents (in particular, β-lactam antibiotics, sulfonamides, fluoroquinolones, and rifampin), nonsteroidal antiinflammatory drugs (NSAIDs) (especially fenoprofen), and proton pump inhibitors (PPIs) have been most commonly involved.[4,5] In a large case series of biopsy-proven AIN, drug-induced AIN was due to antibiotics in 49% of cases, NSAIDs in 11%, and PPIs in 14%.[4] Other antiulcer agents, diuretics, phenindione, phenytoin, allopurinol, highly active antiretroviral therapy (HAART), and anticancer agents such as tyrosine kinase inhibitors, pemetrexed, and ifosfamide also have been reported

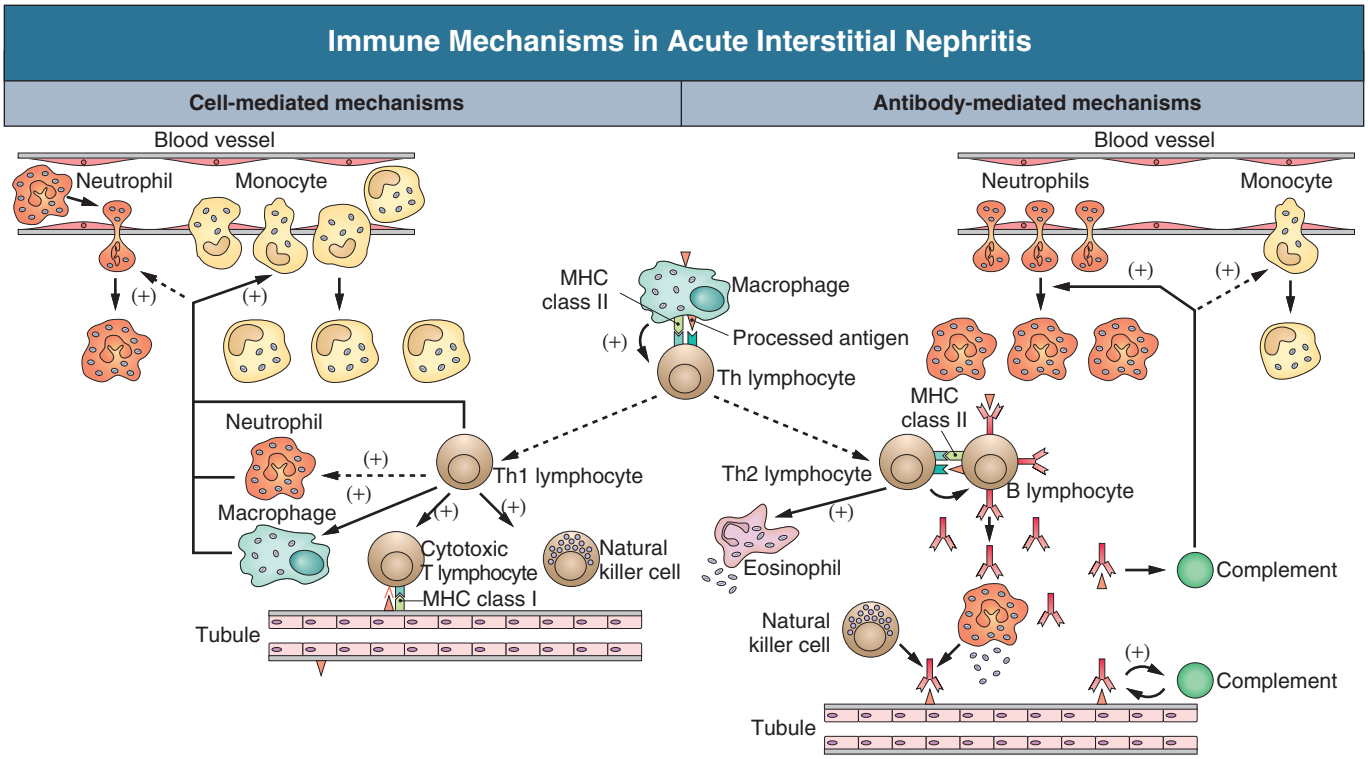

Fig. 60.1 Immune mechanisms that can be involved in acute interstitial nephritis. Both cell-mediated and antibody-mediated mechanisms occur. The cell-mediated mechanism is primarily associated with macrophages and T cells. The antibody-mediated mechanism is frequently associated with neutrophil or eosinophil infiltration as well as with local complement activation. *MHC,* Major histocompatibility complex.

to cause AIN.[6,7] In addition, AIN is one of the immune-related adverse events that can be caused by immune checkpoint inhibitors (e.g., PD-1, PD-L1, and CTLA-4 inhibitors), and more than 20 cases have been published.[8,9] Most other drugs only rarely have been linked with AIN (see Box 60.1). AIN also has been reported after snake or wasp envenomation, and the pathogenic mechanism is likely to be similar to that in drug-induced AIN.

The clinical characteristics of drug-induced AIN are now recognized as much more varied and nonspecific than the spectrum seen in classic methicillin-induced AIN (Fig. 60.2).[2,10,11]

Renal Manifestations

Symptoms of AIN usually develop a few days to a few weeks after the inciting drug is started, although cases have occurred months after initial exposure to the drug. In particular, AIN induced by NSAIDs or PPIs is often diagnosed several months after treatment initiation, and a similar delay has been reported with immune checkpoint inhibitors. The typical presentation is sudden impairment in renal function, associated with mild proteinuria (<1 g/day) and abnormal urinalysis, in a patient with flank pain, normal blood pressure, and no edema. However, the clinical presentation is often incomplete (see Fig. 60.2), and AIN should be considered in any patient with unexplained AKI.[2,10,11] Renal dysfunction may be mild or severe, and dialysis is required in about one third of patients. Hematuria and pyuria are present in a little more than half of the patients, and although leukocyte casts are common, hematuria is almost never associated with red blood cell casts. Flank pain (reflecting distention of the renal capsule) is observed in about one third of the patients and can be the main complaint on hospital admission. Some patients have low fractional sodium excretion.

Standard imaging procedures show kidneys normal in size or slightly enlarged. Ultrasound usually discloses an increased cortical echogenicity (comparable to or higher than that of the liver).

Extrarenal Manifestations

Extrarenal symptoms consistent with a hypersensitivity reaction are occasionally observed, including low-grade fever, maculopapular rash (Fig. 60.3), mild arthralgias, and eosinophilia. However, each of these symptoms is typically present in fewer than half of the patients (see Fig. 60.2), and these symptoms are all present together in less than 10% of patients.[2,10,11] With some drugs, other manifestations of hypersensitivity, such as hemolysis or hepatitis, can be present. Serum immunoglobulin E (IgE) levels also may be elevated.

The association of AKI with clinical signs suggestive of hypersensitivity or eosinophilia should lead to consideration of AIN. However, signs of hypersensitivity can be observed in patients with AKI not related to AIN, including patients with drug-induced acute tubular necrosis.

Specific Drug Associations

The clinical and biological manifestations of AIN may have some specificity, depending on the drug involved.

As outlined earlier, methicillin-induced AIN was characterized by a high frequency of abnormal urinalysis and extrarenal symptoms and by well-preserved renal function. Renal failure has been reported in only about 50% of patients (see Fig. 60.2).[10]

More than 200 cases of rifampin-induced AKI have been reported.[12] Prior exposure is common; most cases have been observed either after readministration of rifampin or several months after intermittent administration of the drug has begun. Renal failure is usually associated

BOX 60.1 Drugs Responsible for Acute Interstitial Nephritis

Antimicrobial Agents

Penicillins

Amoxicillin
Ampicillin*
Aztreonam
Carbenicillin
Cloxacillin
Flucloxacillin
Methicillin*
Mezlocillin
Nafcillin
Oxacillin*
Benzylpenicillin*
Piperacillin

Cephalosporins

Cefaclor
Cefazolin
Cefotaxime
Cefotetan
Cefoxitin
Ceftriaxone
Cephalexin
Cephaloridine
Cephalothin
Cephradine

Quinolones

Ciprofloxacin*
Levofloxacin*
Moxifloxacin
Norfloxacin

Others

Acyclovir
Azithromycin
Clarithromycin
Colistin
Cotrimoxazole*
Erythromycin*
Ethambutol
Flurithromycin
Foscarnet
Gentamicin
Indinavir
Interferon
Isoniazid
Lincomycin
Linezolid
Minocycline
Nitrofurantoin*
Piromidic acid
Polymyxin B*
Quinine
Rifampin* (rifampicin*)
Spiramycin*
Sulfonamides*
Teicoplanin
Telithromycin
Tetracycline
Vancomycin*

NSAIDs Including Salicylates

Salicylates and Derivatives

Aspirin (acetyl salicylic acid)
Diflunisal*

Propionic Acid Derivatives

Benoxaprofen
Fenbufen
Fenoprofen*
Flurbiprofen
Ibuprofen*
Ketoprofen
Naproxen

Acetic Acid Derivatives

Indometacin* (indomethacin*)
Alclofenac
Diclofenac
Fenclofenac
Sulindac
Zomepirac

Enolic Acid Derivatives

Meloxicam
Piroxicam*

Fenamic Acid Derivatives

Mefenamic acid

Coxibs

Celecoxib
Rofecoxib

Others

Azapropazone
Mesalamine (mesalazine, 5-ASA)
Phenazone
Phenylbutazone
Sulfasalazine
Tolmetin

Antalgics

Aminopyrine
Antipyrine

Anticonvulsants

Carbamazepine*
Diazepam
Lamotrigine*
Levetiracetam
Phenobarbital (phenobarbitone)
Phenytoin*
Valproic acid (valproate sodium)

Diuretics

Chlorthalidone
Etacrynic acid (ethacrynic acid)
Furosemide* (frusemide*)
Hydrochlorothiazide*
Indapamide
Triamterene*

Antiulcer Agents

Histamine-2 Receptor Antagonists

Cimetidine*
Famotidine
Ranitidine

Proton Pump Inhibitors

Esomeprazole
Lansoprazole
Omeprazole
Pantoprazole
Rabeprazole

Immune Checkpoint Inhibitors

Ipilimumab*
Nivolumab
Pembrolizumab

Other Anticancer Agents

Adriamycin
Bevacizumab
Bortezomib
Carboplatin
Cytosine arabinoside
Gemcitabine
Ifosfamide
Interleukin-2
Lenalidomide
Methotrexate
Pemetrexed
Sorafenib
Sunitinib

Others

Allopurinol*
α-Methyl dopa
Amlodipine
Azathioprine
Betanidine (bethanidine)*
Bismuth salts
Captopril*
Carbimazole
Cetirizine
Chlorpropamide*
Clofibrate
Clozapine
Cyclosporine
Deferasirox
Diltiazem
D-Penicillamine
Etanercept
Exenatide
Fenofibrate*
Fluindione
Gold salts
Griseofulvin
Interferon
Isotretinoid
Liraglutide
Nifedipine*
Phenindione*
Phenothiazine
Phenylpropanolamine
Probenecid
Propranolol
Propylthiouracil
Sirolimus
Streptokinase
Sulfinpyrazone
Warfarin
Zopiclone
Nonsteroidal antiinflammatory drugs.

*Drugs that can cause granulomatous AIN.
Drugs most commonly involved are in bold.

with the sudden onset of fever, gastrointestinal symptoms (nausea, vomiting, diarrhea, abdominal pain), and myalgias. It also may be associated with hemolysis, thrombocytopenia, and, less frequently, hepatitis. Renal biopsy typically discloses tubular injury in addition to interstitial inflammatory infiltrates. Although circulating antirifampin antibodies are usually found in these patients, immunofluorescence staining of renal biopsy specimens for immunoglobulin and complement has been negative in most cases, suggesting that cell-mediated immunity plays a key role in the induction of the nephritis. In a few cases, AIN developed after continuous treatment with rifampin for 1 to 10 weeks. It

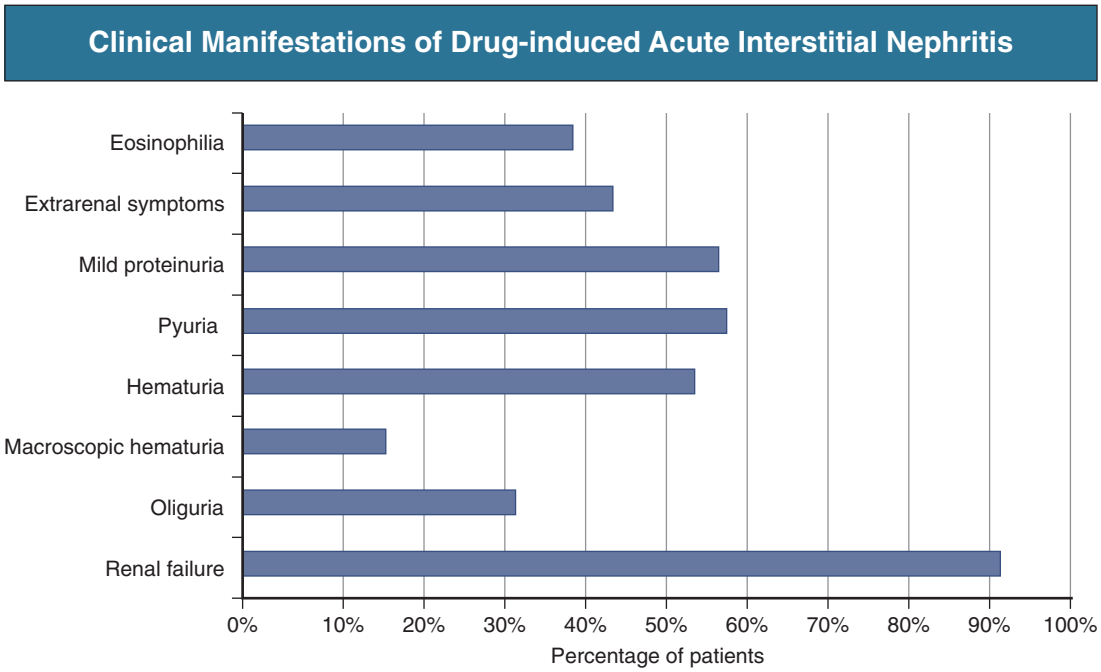

Fig. 60.2 Clinical manifestations of drug-induced acute interstitial nephritis (AIN). Data were pooled from different case reports, including more than 200 patients with drug-induced AIN. Patients with AIN associated with methicillin therapy or with a nephrotic syndrome are not included.

Fig. 60.3 Maculopapular rash in a patient with drug-induced acute interstitial nephritis (AIN). Such cutaneous lesions occur in about 40% of patients with drug-induced AIN, but they can also be seen in patients with drug-induced acute tubular necrosis.

was almost never associated with extrarenal symptoms or antirifampin antibodies, and renal biopsy specimens showed severe interstitial infiltrates but few tubular lesions.

Phenindione-induced AIN is generally associated with the development of hepatitis, which can be fatal.

Allopurinol-induced AIN appears to occur more often in patients with CKD and is usually seen in association with rash and liver dysfunction and sometimes with full manifestations of Stevens-Johnson syndrome.[13] This severe allergic reaction is primarily observed in patients with the human leukocyte antigen B58 genotype.

AIN caused by NSAIDs is associated with nephrotic syndrome in about three fourths of cases. This usually occurs in patients older than 50 years, and although it has been observed with all NSAIDs, including COX-2–selective inhibitors, half of the cases have been reported with fenoprofen. Most occurrences develop after the patient has taken NSAIDs for some months (6 months on average), but AIN can occur within days or after more than a year. With the exception of the heavy proteinuria and associated edema, the presentation of these patients is similar to that of patients with other forms of drug-induced AIN (Fig. 60.4). The main difference is that extrarenal symptoms are present in only about 10% of patients. Renal disease caused by NSAIDs must be differentiated from other NSAID-induced nephropathies, including hemodynamically mediated AKI, papillary necrosis, and NSAID-induced membranous nephropathy. Drugs other than NSAIDs can rarely induce AIN associated with the nephrotic syndrome; a few cases have been reported after administration of ampicillin, rifampin, lithium, interferon, phenytoin, pamidronate, and D-penicillamine.

PPIs, such as omeprazole or pantoprazole, are increasingly recognized as a cause of AIN, with over 100 cases reported. Symptoms are often nonspecific, although approximately 10 percent of subjects present with fever, chills, and anorexia. Consistent with the fact that drug-induced AIN can lead to permanent kidney damage, large observational studies have shown that the use of PPIs is associated with an increased risk for development or progression of CKD, and development of AIN is viewed as being the likely underlying mechanism.[18]

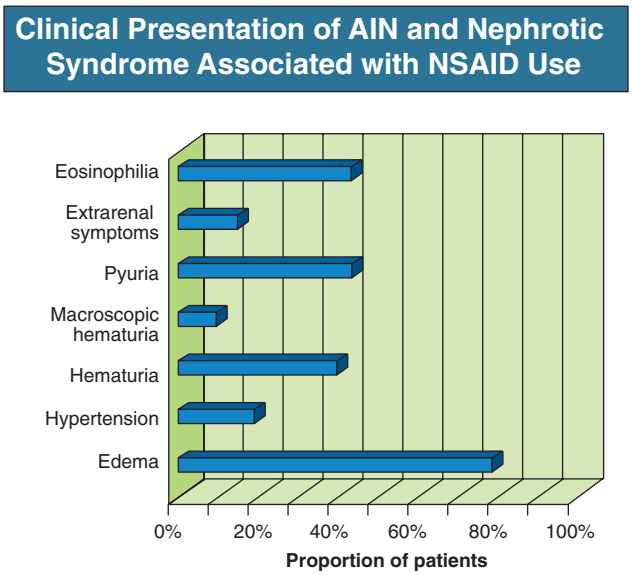

Fig. 60.4 Clinical presentation of acute interstitial nephritis (AIN) and nephrotic syndrome associated with nonsteroidal antiinflammatory drug (NSAID) use. Data were pooled from different case reports including more than 60 patients.

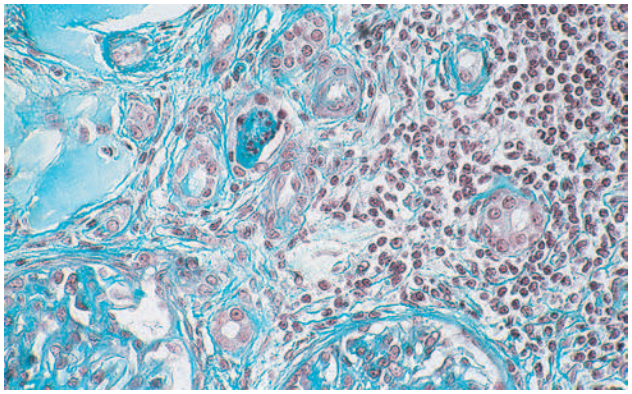

Fig. 60.5 Drug-induced acute interstitial nephritis. On light microscopy, the characteristic feature is interstitial infiltration with mononuclear cells, with normal glomeruli. It is usually associated with interstitial edema and tubular lesions. (Courtesy Dr. B. Mougenot, Paris VI University, Paris.)

Pathology

The hallmark of AIN is the presence of inflammatory infiltrates within the interstitium (Fig. 60.5). These infiltrative lesions are often patchy, predominating in the deep cortex and outer medulla, but they can be diffuse in severe cases. They are composed mostly of T cells and monocytes-macrophages, but plasma cells, eosinophils, and a few neutrophilic granulocytes also may be present. The relative number of $CD4^+$ T cells and $CD8^+$ T cells is variable from one patient to another. In some cases, T lymphocytes infiltrate across the TBM and between tubular cells, mainly in distal tubules, and the resulting lesion is referred to as *tubulitis*.

In some cases of drug-induced AIN, renal biopsy shows interstitial granulomas (Fig. 60.6). These granulomas are usually sparse and nonnecrotic, with few giant cells, and are associated with nongranulomatous interstitial infiltrates. Granulomas are also found in AIN related to infection (Table 60.1), sarcoidosis, Sjögren syndrome, and Wegener granulomatosis.

Interstitial infiltrates are always associated with an interstitial edema, which is responsible for separating the tubules (see Fig. 60.5). They can

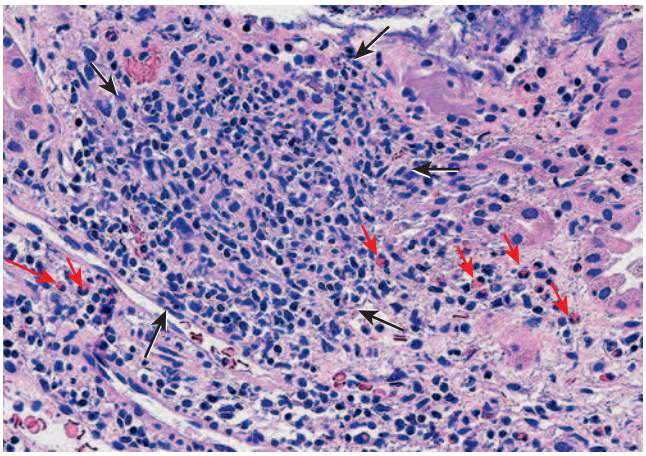

Fig. 60.6 Drug-induced granulomatous acute interstitial nephritis (AIN). The patient was taking omeprazole over the counter and presented with fever, chills, malaise, and cough. Workup showed a serum creatinine of 4.5 mg/dl (400 µmol/L) and 15.5-cm enlarged kidneys that were pushing up on the diaphragm, causing the cough. Biopsy shows AIN with eosinophils *(red arrows)*, lymphocytes, and early granuloma formation (demarcated by *black arrows*). (Courtesy R. J. Johnson, University of Colorado, Denver, Colo.)

also be associated with focal tubular lesions, which range from mild cellular alterations to extensive necrosis of epithelial cells, and are sometimes associated with a disruption of the TBM. These tubular lesions usually predominate where the inflammatory infiltrates are most extensive.

Tubulointerstitial lesions are not associated with vascular or glomerular lesions. Even in AIN associated with a nephrotic syndrome, glomeruli appear normal on light microscopy; glomerular lesions are similar to those seen in minimal change disease (see Chapter 17).

In most patients with AIN, renal biopsy specimens do not show immune deposits, and both immunofluorescence and electron microscopy are negative. Nevertheless, staining of the tubular or capsular basement membrane for IgG or complement may occasionally be seen by immunofluorescence; the staining pattern is either granular or linear (Fig. 60.7). Linear fixation of IgG along the TBM indicates the presence of antibodies directed against membrane antigens or against drug metabolites bound to the TBM, and circulating anti-TBM antibodies have been detected in some cases. These linear deposits are seen mostly in patients taking NSAIDs, phenytoin, or allopurinol.

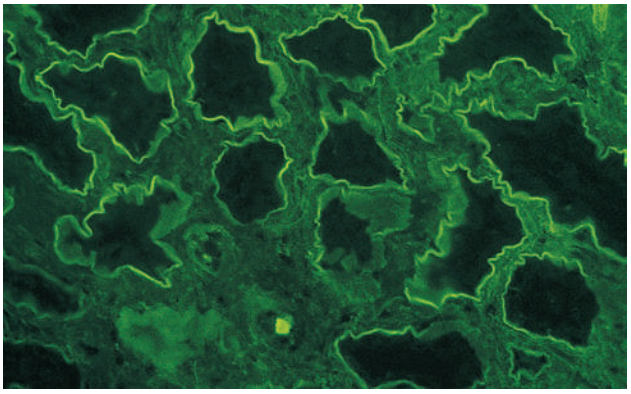

Fig. 60.7 Linear deposits of IgG in drug-induced acute interstitial nephritis. Deposits along the tubular basement membrane (TBM) are shown on immunofluorescence microscopy. These antibodies recognize either a component of the TBM or a drug metabolite bound to the TBM. (Courtesy Dr. B. Mougenot, Paris VI University, Paris.)

Diagnosis

The most accurate way to diagnose AIN is by renal biopsy. However, both eosinophiluria and gallium scanning have been suggested as helpful in making the diagnosis.

Eosinophils can be detected in urine and, although eosinophiluria is frequently used to corroborate the diagnosis of drug-induced AIN, review of published series shows that this test has rather poor sensitivity and a low positive predictive value, even when only patients with AKI are considered. In the largest and most recent series, only 36% (26 of 73) of patients with drug-induced AIN had eosinophiluria, and 28% (20 of 69) of patients with acute tubular necrosis also had eosinophiluria (Fig. 60.8).[14] In addition, eosinophiluria has been reported in patients with diseases such as proliferative or crescentic glomerulonephritis (GN), atheroembolic renal disease, urinary tract infection, urinary schistosomiasis, and even prerenal AKI.[15] Thus eosinophiluria as a screening test for AIN should be abandoned. Firm diagnosis requires renal biopsy and/or a clinical response on withdrawal of the drug of concern.

An increased renal uptake of gallium-67 (^{67}Ga) has been reported in AIN.[16] Analysis of available series shows that in 53 patients with AIN, 83% had an abnormal renal scan (maximum after 48 hours), whereas it was normal in 17 of 18 patients with acute tubular necrosis. However, these studies were small and retrospective, and ^{67}Ga renal scanning is not specific for AIN and may be abnormal in patients with pyelonephritis, cancer, or glomerular diseases. Therefore we do not recommend use of gallium scanning as a diagnostic tool.

Because the clinical presentation of AIN may be polymorphic and because noninvasive diagnostic procedures have important limitations, renal biopsy is often essential for the diagnosis of AIN. Several studies have shown that prebiopsy diagnosis may be incorrect in a substantial number of patients.

Identification of the Causative Drug

Identification of the causative drug is relatively easy when AIN occurs in a patient taking only one drug. However, patients are often taking more than one drug capable of inducing AIN. Two biological tests have been used, primarily in research laboratories, to help identify the

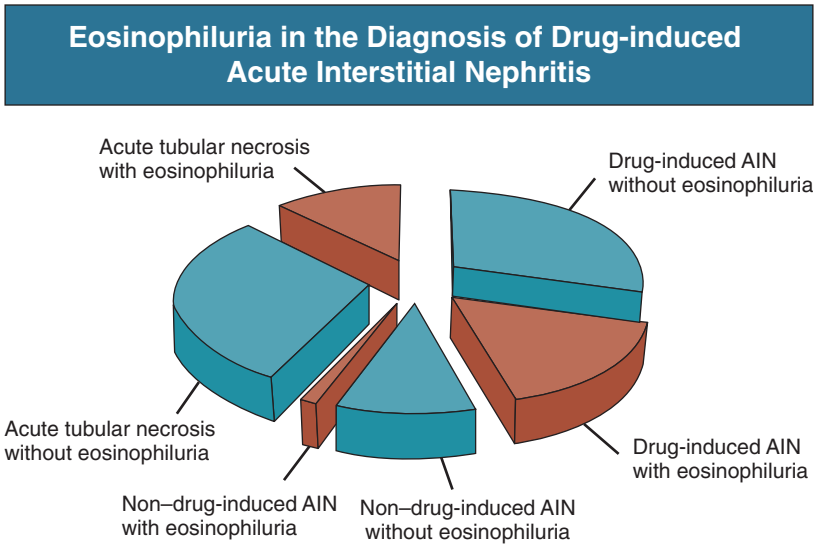

Fig. 60.8 Eosinophiluria in the diagnosis of drug-induced acute interstitial nephritis (AIN). Data from a recent and large retrospective series confirm that eosinophiluria (defined by the presence of 1% or more eosinophils in urine) lacks sensitivity and specificity for the diagnosis of drug-induced AIN in patients with AKI. (From reference 14.)

causative drug: the lymphocyte stimulation test and the identification of circulating antidrug antibodies.

Identification of circulating antidrug antibodies has been used mostly for patients thought to have AIN induced by rifampin. Antirifampin antibodies are present in most patients with rifampin-induced AIN, but, unfortunately, they have also been detected in patients taking rifampin and having no adverse reaction to the drug, so this test has limited diagnostic value.

The lymphocyte stimulation test has been used since the 1960s to identify a sensitizing drug. It is based on the measurement of lymphocyte proliferation in the presence of different drugs; a high proliferative index reflects a sensitization of T lymphocytes against the drug. However, this test lacks specificity and we do not recommend using it.

Natural History

Drug-induced AIN was long considered benign, with complete recovery of renal function if the inciting agent was removed. However, recent studies show that the course of AIN is not always benign and serum creatinine does not return to baseline in about 40% to 50% of patients.[4,10,17] Even in those with renal recovery, an increase in serum creatinine can persist for several weeks. Unfortunately, there are few known prognostic predictors. The severity of renal failure does not appear to be linked with the prognosis.[4,10] It has been suggested that the presence on renal biopsy of diffuse neutrophil- or macrophage-rich infiltrates, interstitial granulomas, or tubular atrophy is associated with a poor prognosis, but this has not been consistently found in all series. The best prognostic predictors may actually be the duration of AKI and the severity of interstitial fibrosis.

Treatment

In addition to removal of the inciting agent, which is essential and should be done as soon as possible, corticosteroids have been used to treat AIN. Most commonly, patients received high-dose oral corticosteroids sometimes associated with pulses of intravenous methylprednisolone. Analysis of series comparing patients who did or did not receive corticosteroids does not allow firm conclusions about the effect of corticosteroid therapy on long-term renal function because all the series were small, uncontrolled, and retrospective. However, some authors advocate an early and systematic use of a short course of corticosteroids[11,17] because of the possibility that this will hasten the recovery of renal function. In different series, corticosteroids rapidly induced a reduction in serum creatinine in patients whose renal function did not improve within about 1 week after discontinuation of the inciting agent. It is interesting to note that in patients with NSAID-induced AIN, corticosteroids do not seem to modify the course of the nephrotic syndrome.

On the basis of anecdotal case reports, some authors have advocated use of mycophenolate mofetil in patients resistant to corticosteroids.[19]

We recommend administration of a short course of prednis(ol)one in patients who are dialysis dependent or whose renal function fails to improve within 1 week after discontinuation of the inciting drug and rapidly return to baseline values, provided the diagnosis of AIN has been confirmed by renal biopsy. We initiate the treatment with a dose of prednisone of 1 mg/kg/day and not higher than 60 mg/day, and after 1 to 2 weeks, we progressively taper the dose so that the total duration of treatment is 4 to 6 weeks.

ACUTE INTERSTITIAL NEPHRITIS SECONDARY TO INFECTIOUS DISEASES

Infections were once the most common cause of AIN, but the frequency of AIN induced by an infection has dramatically decreased with the widespread use of antibiotics. Nevertheless, the diagnosis of infectious AIN should not be overlooked, and AIN occurring in patients treated with antibiotics should not always be attributed to the drug.

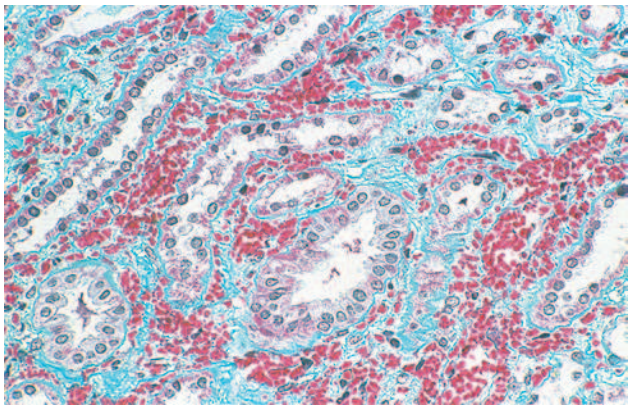

Fig. 60.9 Acute interstitial nephritis secondary to Hantavirus infection. Vascular congestion and foci of medullary hemorrhage are suggestive of the diagnosis. (Courtesy Dr. B. Mougenot, Paris VI University, Paris.)

Infectious agents can cause renal parenchymal inflammation by direct infection, resulting in acute pyelonephritis (see Chapter 51). However, many infectious agents may induce an immunologically mediated AIN in the absence of direct invasion (see Table 60.1). In this case, the clinical presentation depends mostly on the underlying infection. On histologic examination, lesions are identical to those described for drug-induced AIN, and they also can occasionally result in granulomas (see Table 60.1). Infection-associated AIN usually resolves with the treatment of the underlying infection, and corticosteroid therapy is not recommended.

An important cause of infection-associated AIN is hantavirus.[20] Hantavirus infections occur worldwide and are responsible for a disease that has been known as *hemorrhagic fever with renal syndrome*, epidemic hemorrhagic fever, and nephropathia epidemica. Rodents are the main reservoir of the virus, and humans are most probably infected by the airborne route. Besides fever, fatigue, and muscle aches, which are observed in all patients, extrarenal symptoms often include headache, lightheadedness, abdominal pain, nausea and vomiting, and thrombocytopenia; the last can be responsible for hemorrhagic complications. AKI is almost always associated with proteinuria, sometimes in the nephrotic range, and with hematuria. When a kidney biopsy is performed, it discloses not only interstitial inflammatory infiltrates, which predominate in the medulla, but also vascular congestion and interstitial bleeding (Fig. 60.9). In about 50% of patients, immunofluorescence studies show granular immune deposits along the TBM and within glomeruli. Serum creatinine concentration usually starts to decrease after a few days, and a complete recovery of renal function is the rule. Nevertheless, in the more severe cases, recovery can be complicated by the occurrence of hemorrhagic complications or severe shock. The diagnosis is based on serologic test results, which become positive early (within weeks) in the course of the disease.

Tubulointerstitial lesions are common in HIV-positive patients who undergo a renal biopsy for AKI. Interstitial infiltrates are often associated with glomerular lesions, but they can be isolated. These forms of AIN have been observed in both White and Black patients, and they might be related not only to drugs and opportunistic infections but also to the HIV infection itself.[21,22]

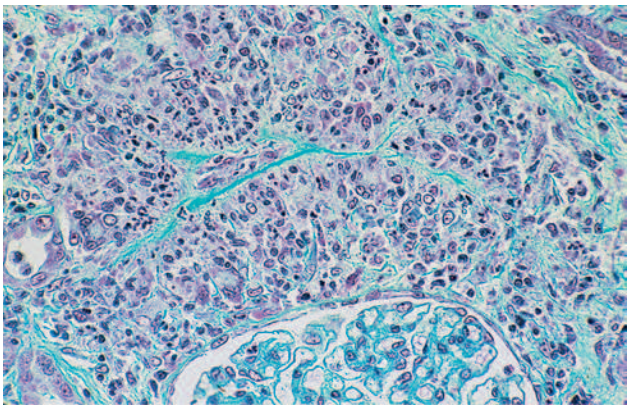

Fig. 60.10 Granulomatous acute interstitial nephritis in a patient with sarcoidosis. (Courtesy Dr. B. Mougenot, Paris VI University, Paris.)

ACUTE INTERSTITIAL NEPHRITIS ASSOCIATED WITH SYSTEMIC DISEASES

Sarcoidosis

In sarcoidosis, renal impairment usually occurs as a complication of hypercalciuria and hypercalcemia, but granulomatous AIN associated with sarcoidosis also has been reported (Fig. 60.10).[23,24] The presentation is usually that of AKI, which can be isolated or associated with mild proteinuria and sterile leukocyturia. It is associated with extrarenal symptoms of sarcoidosis in about 90% of patients, most frequently with lymphadenopathy and lung, eye, or liver involvement. Nevertheless, only slightly more than half of the patients have hilar lymphadenopathy or pulmonary interstitial fibrosis at the time of diagnosis.[24] Treatment with high-dose corticosteroids quickly improves renal function, but most patients do not recover completely. The starting dose should be prednis(ol)one 1 mg/kg/day and not higher than 60 mg/day, and corticosteroid therapy should be tapered slowly and not withdrawn before at least 1 year to prevent relapses. Whereas some authors advocate long-term maintenance therapy with low-dose corticosteroids, we usually stop corticosteroids after 2 to 3 years. Because of the risk for late relapse, these patients should be observed for a prolonged time.

Sjögren Syndrome

Clinically significant interstitial nephritis is rare in Sjögren syndrome and usually results in chronic tubular dysfunction.[25,26] Some patients may present with severe symptomatic hypokalemia with distal renal tubular acidosis. Rarely, Sjögren syndrome presents with AKI due to AIN, which is often responsive to treatment with high-dose corticosteroids.

Systemic Lupus Erythematosus

About two thirds of renal biopsy samples in patients with systemic lupus show some tubulointerstitial involvement, but significant tubulointerstitial injury in the setting of minimal glomerular abnormalities is rare, with only about 10 cases reported in the literature.[27] In these cases, renal biopsy shows typical features of AIN on light microscopy and immunofluorescence staining always discloses immune deposits along the TBM, usually with a granular pattern. Renal function improves after high-dose corticosteroids, and additional immunosuppressive drugs are not usually required. However, azathioprine has been used as a corticosteroid-sparing agent.

Immunoglobulin G4–Related Disease

IgG4-related disease is a newly recognized systemic autoimmune disease that predominantly affects males older than 50 years of age (see Chapter 62). In the kidney, it is most commonly responsible for AIN characterized by the presence of interstitial infiltrates rich in IgG4-positive plasma cells and immune deposits along the TBM.[28,29] This interstitial nephritis can be associated with membranous nephropathy, with renal inflammatory masses visible on imaging or with ureteral obstruction. It usually responds very rapidly to treatment with corticosteroids.

Other Systemic Diseases

Among patients with cryoglobulinemia and AKI, a few exhibit significant interstitial inflammatory infiltrates associated with granular immune deposits in the interstitium and along the TBM. This AIN is usually associated with characteristic glomerular lesions and, rarely, lesions of the arterioles, and treatment is the same as for cryoglobulinemia-induced GN (see Chapter 21).

Most renal lesions associated with small-vessel vasculitis consist of both extracapillary GN and tubulointerstitial nephritis (see Chapter 25). Nevertheless, a few patients with AIN and minimal glomerular lesions have been described.

ACUTE INTERSTITIAL NEPHRITIS ASSOCIATED WITH MALIGNANT NEOPLASMS

Infiltration of renal parenchyma by malignant cells is common in patients with leukemia or lymphoma. Most of the time, this infiltration is clinically silent (or causes enlarged kidneys), but a few patients with AKI have been described.[30] Chemotherapy or radiotherapy may rapidly improve renal function in these patients, but before these treatments are started, it is important to exclude more common causes of AKI associated with neoplastic diseases (see Chapter 65).

IDIOPATHIC ACUTE INTERSTITIAL NEPHRITIS

More than 50 cases of idiopathic AIN with anterior uveitis have been reported (TINU syndrome).[31] This syndrome is found most commonly in girls of pubertal age but also can occur in pubertal boys and in adults. Initial symptoms may be ocular, with ocular pain and visual impairment, or pseudoviral, with fever, myalgia, and asthenia. AIN is responsible for AKI, ranging from mild to severe, that may be associated with abnormal urinalysis. Renal biopsy shows diffuse interstitial inflammatory infiltrates, almost always without granulomas and without immune deposits. In children, renal prognosis is excellent, and serum creatinine usually returns to baseline values within a few weeks, with or without corticosteroid therapy. In adults the renal prognosis seems to be less favorable, and corticosteroid therapy might be useful in preventing evolution to chronic renal impairment. Uveitis, which can occur at any time in respect to AIN, is usually responsive to topical corticosteroids, but it may relapse without any recurrence of AIN.

Cases of idiopathic AIN without uveitis have been reported. Immunofluorescence studies of renal biopsy specimens can show linear deposits of IgG along the TBM, granular deposits of IgG along the TBM, or no immune deposits, suggesting this entity is heterogeneous. The treatment of patients with idiopathic AIN is still controversial. Patients who receive corticosteroids usually show a dramatic improvement of renal function, but others have recovered normal renal function without any treatment.

ACUTE INTERSTITIAL NEPHRITIS IN RENAL TRANSPLANTS

Acute rejection is by far the most common cause of AIN in renal allograft recipients (see Chapter 104). Nevertheless, AIN can be induced by drugs or infections. Cases of drug-induced AIN have been reported even in the first weeks after transplantation, when immunosuppression is

maximal.[32] Among patients with infectious AIN, the frequency of polyomavirus (BK)-induced AIN appears to be increasing, and it should be suspected in patients with acute deterioration of renal function and so-called decoy cells in urine (see Chapter 105).[33]
